FOREWORD

As its primary source of fresh water, North American rivers are the continent's most important natural resource. They are the nerve system of its ecology and define the geology, biology, culture, and civilization of its watersheds. It's no accident that the earliest civilizations evolved beside major river systems, such as the Tigris and Euphrates and the Nile. Rivers irrigated their crops and regularly replenished their fields. They provided food for their tables and water for drinking, bathing, and waste removal. They were an efficient means of transportation, communication, and trade. They were places for baptism, playgrounds for recreation, and sources for artistic inspiration. Later, as humans learned to harness the power of rivers, they became the foundation of the industrial revolution and the staggering economic development that came in its wake.

Yet, despite our dependence on rivers for so many aspects of our lives, we have diverted, drained, dammed, and degraded them to the point where we have killed, in some instances, every living thing in their waters. Meanwhile, we are learning more and more about how important rivers really are. For example, healthy rivers support an enormous diversity of plant and animal life; this intricate web, scientists have discovered, forms more than an interdependent food chain. It also enables the river to process nutrients and pollutants and in doing so, restore itself and combat, within limits, the mess we have all too often made of it.

Now, more than ever, rivers need our help. With waters that flow in a continuum from the source to the sea, rivers are by their very nature a shared resource, a public asset that cannot readily be reduced to private property. The flip side of that, unfortunately, is that rivers have suffered from the "tragedy of the commons"—a resource that is owned by everyone, cared for by no one, and a tempting target for polluters who can profit by privatizing the commons. The Waterkeeper Alliance, which I head, was established to counteract this occurrence. Our primary goal is to motivate millions of people across thousands of watersheds to take ownership of their streams and rivers and to defend them from those

determined to steal them from the public and exploit them for private gain. The return of the commons to their rightful owners is a perpetual battle; our success often depends on empowering our volunteers with good information about their common property.

Until now, there has never been a comprehensive effort to detail the state of America's rivers. Arthur Benke and Colbert Cushing have made that effort. *Rivers of North America* is the first complete reference book on the subject—a detailed encyclopedia of information about the physical, biological, hydrological, and ecological characteristics of more than 200 rivers from southern Mexico to the Arctic. This book is much more than a compendium of facts and figures. The authors of each chapter have published extensively on river science, are leading figures in the region about which they write, and are well-known experts in the field. Together these contributors have woven a tapestry of information that is as accessible to lay people as it is to scientists, and that captures the wonderful diversity of our continent's rivers in photographs, color topographic maps, and data summaries.

Rivers of North America is a useful starting point for understanding both the overall pressures on our rivers and the particular attributes of North America's great waterways. In its pages you will find the few remaining pristine rivers that deserve conservation as benchmark systems. And you will also find those that have major problems and for which radical and immediate CPR is required. This volume is a must for river scientists, conservationists, paddlers, river recreationists, sports fishermen—for anyone and everyone concerned about the future of the continent's most valuable natural resource. It should be the standard reference on North American rivers for a long time to come. And for those, such as the Waterkeepers, who work to defend our waters, *Rivers of North America* gives us a new and critical weapon. Our defense is now stronger because we know better what we are defending.

Robert F. Kennedy Jr.
President, Waterkeeper Alliance

PREFACE

For many river scientists, nature-lovers, canoeists, and photographers, rivers are the most fascinating natural features on earth. As the primary source of fresh water, however, they also happen to be the earth's most *important* natural resource—nothing less than our long-term survival depends on them. Thus, we hope this book will not only be informative, but also will be used to promote the stewardship of these vital resources.

Rivers of North America is first and foremost a reference volume for the researcher and river enthusiast alike and is devoted to presenting a compendium of comparable physical, biological, and ecological information about many rivers. Its genesis can be traced to the suggestions of Donna James of Academic Press in early discussions with Art Benke. Although her original vision of a book covering North American rivers was slanted more toward a pictorial or coffee-table book, subsequent deliberations pushed it toward the detailed reference volume that you now hold.

This book was written by scientists, not only for other scientists, but also for students, river conservationists, and lay persons. As a reference volume, this book contains an enormous amount of information that cannot be found in any other single source about many of the major rivers in North America, the result of considerable research and synthesis by the chapter authors. The book can be used by those seeking specific information about rivers of a particular region, those wishing to compare rivers among regions, or those who are simply curious about rivers. As a reference book, it contains information about river animals and plants, ecology, hydrology, geology, geography, river management, river conservation, and the human history of river basins. This book also describes the severe degradation of many rivers that have been heavily exploited for far too long without regard for the natural benefits they bring to mankind—their ecological services, their biodiversity, their incredible beauty, and their opportunities for recreation and fishing. Few people besides river biologists realize, for example, that many unaltered river systems can support several hundred species of

invertebrate animals and plants. Few realize that many contain more than 100 species of fishes, even though fishes have been an essential food source for humans in North America for millennia.

We have attempted to make this book as user-friendly as possible, particularly for the non-scientist. For example, there is a color topographic map for every river and color photographs of most rivers that will give a feel for these natural systems that words and statistics alone cannot convey. We also have used common names rather than scientific names for all species for which common names exist (plants, vertebrate animals, and some invertebrate animals). For those who wish to verify the identity of species names, an appendix of common and scientific names is provided. Chapter 1 presents considerable background information for various scientific concepts and terms used in every chapter. A glossary of common scientific terms is also provided for easy reference.

A unique feature of this book is its basin maps. They were created by the Cartography Laboratory in the Department of Geography at the University of Alabama using the United States Geological Survey's web-based National Atlas for the United States, GeoGratis (Natural Resources of Canada) for Canada, and the HydroLk Elevation Derivative Database for Mexico. Black and white regional maps of river basins and color topographic maps for each river are provided for each chapter. The color maps are simplified to include only basin boundaries, topographic features, major tributaries, major dams, major cities, and delineation of physiographic provinces. Only dams on main-stem rivers and only major dams on tributaries are shown; otherwise important features of many basins would be obscured by a mass of yellow dots (dams). Similarly, only selected cities are shown as reference points.

Almost 190 color photographs illustrating the diversity of North American rivers are included in the book, making it reminiscent of the coffee-table book originally envisioned by the publishers. In many cases, the authors, their colleagues, or the editors provided the photographs. However, the noted

author and photographer Tim Palmer contributed more than one-quarter of the photographs in this book. Tim has written eloquently about the flowing waters of the United States and the importance of their conservation. His words and photographs from *America by Rivers*; *Lifelines: The Case for River Conservation*, *Endangered Rivers and the Conservation Movement*; *The Wild and Scenic Rivers of America*; *The Snake River: Window to the West*, and several others, have inspired river conservationists and scientists alike. His contributions to *Rivers of North America* have not only contributed to the total number of photographs and added to the attractiveness of the book, but they have filled some very important gaps.

A major dilemma we faced in planning this book was how to include a large number of rivers in a single volume and still be reasonably detailed in describing individual rivers. To include a large number of rivers, we decided that all rivers would have a one-page summary of major physical and biological features, including the individual color maps. We borrowed the one-page concept from the excellent compendium of rivers in *Watersheds of the World: Ecological Value and Vulnerability* by Carmen Revenga and others, but we used a substantially different format. In addition to the one-page summaries, up to five rivers per chapter have received more detailed coverage in the text. One-page summaries were placed at the end of each chapter so that comparisons among rivers can be made more easily. This format means that while reading the text, the reader will need to refer to maps and some graphs in the one-page summary at the end of the chapter.

The authors of each chapter have conducted research on many of the rivers in the regions about which they write. Most of them are river ecologists/biologists with a natural orientation toward freshwater fauna and flora. Such scientists usually use interdisciplinary approaches, viewing rivers as complex ecosystems. They thus recognize the essential interactions of the river's biota with the physical environment that includes hydrology, geology, and water chemistry. They also have an acute appreciation of the importance of the conservation of natural ecosystems. Thus, the focus of this book is to describe rivers as natural ecosystems, rather than treating them as resources for exploitation.

After reading about many rivers in this book, one will realize that humans have already exploited many of the rivers in North America to the point where they are seriously degraded as natural ecosystems. One might therefore wonder if it is too late to do anything about the massive construction projects and pollution that have devastated rivers for decades, such as on the Colorado, Columbia, Rio Grande, Missouri, Nelson, and many others. As the editors of this book, we believe that it is not too late. Ecologists and other scientists have shown that rivers can be rehabilitated, but only if governments have the political will, recognize the economic benefits of free-flowing clean rivers, and have an appreciation of their natural features. Scientists and conservation groups (American Rivers, Waterkeeper Alliance, and many others) must educate the public, and the public must apply pressure to politicians so natural rivers will be protected. We sincerely hope that this book will serve as a new source of knowledge for river conservation, and that it will encourage the scientist, conservationist, river manager, lay person, and politician to want to learn more about their unique characteristics.

Arthur C. Benke and Colbert E. Cushing

ACKNOWLEDGMENTS

First and foremost, we want to acknowledge the contributions of chapter authors. Clearly, this book would not have been possible without their first-hand knowledge of these complex river ecosystems. We sincerely thank them for their considerable efforts and patience with the editors in adhering to the strict format that makes the information between chapters comparable.

We are especially grateful to Kelly Sonnack of Academic Press/Elsevier, who was associated with the coordination of book preparation for over two years and played a major role in seeing the book through several phases. We gratefully acknowledge Donna James for her proposal of a book on rivers of North America. Special thanks also go to Chuck Crumly, formerly of Academic Press/Elsevier, for twisting Art Benke's arm to do the book in the first place, and guiding us through the first three years of planning and execution. Thanks also to Keith Roberts, the production editor, particularly for his attention to details in such a complex and atypical format.

We especially want to thank those associated with the creation of the color topographic maps of all river basins used throughout the book. Craig Remington, Director of the University of Alabama Cartography Laboratory (Department of Geography), supervised the maps project. Angela Brink, a geography graduate student, spent many hours creating the maps, and Jennifer White, another graduate student, was instrumental in making many subsequent revisions after Angela graduated.

We thank the many individuals who contributed photographs that greatly enhanced the beauty and appeal of this volume. We are especially grateful to the professional photographer Tim Palmer for his generosity in sharing so many beautiful photos from

his collection. We also want to thank Beth Maynor Young, another professional photographer, who contributed several striking photographs for Chapter 4. Thanks also to the many other individuals (besides chapter authors and editors), agencies, and organizations that contributed one or more photographs: E. Benenati, D. Bicknell, C. Bourgeois, J. Boynton, C. S. Brehme, C. Burton, T. Carter, M. Chapman, D. J. Cooper, D. D. Dauble, W. E. Doolittle, K. Ekelund, J. M. Farrell, S. Fend, M. Gautreau, W. Gibbons, Great Valley Museum, G. Harris, T. Harris, D. M. Merritt, NASA, North Dakota Game and Fish Department, M. O'Malley, B. Oswald, R. Overman, S. Parker, G. Pitchford, Raritan Riverkeeper, J. Rathert, M. Rautio, J. Robinson, K. Schiefer, D. Schnoebelen, J. Schwindt, A. H. Siemens, M. C. T. Smith, C. Spence, Tourism Saskatchewan, Virginia Institute of Marine Science, S. Wade, C. White, A. P. Wiens, K. Wilhelm, and G. Winkler.

Art Benke gratefully acknowledges the support of the University of Alabama and its Department of Biological Sciences (Martha Powell, chairperson) for providing the time, library services, and other support to work on this book for an extended period of time. Both editors also wish to thank the many colleagues, chapter authors, and students who provided encouragement and feedback over the past few years.

Most importantly, we wish to express gratitude and appreciation to our wives, Susan Benke and Jackie Cushing, for their patience, encouragement, sacrifices, proofreading, and support. They had to endure our many hours away from home or stuck in front of our computers over the more than four-year span that was necessary for completing this volume.

CHAPTER CONTENTS AND BACKGROUND

CONCLUDING COMMENTS

LITERATURE CITED

INTRODUCTION

Rivers are one of the most dramatic features of a continent. They are the inevitable result of precipitation falling across the land, coalescing into streams, and uniting into ever larger streams and rivers. Over millions of years, these networks of flowing waters have delivered sediments and nutrients to downstream areas, sometimes eroding valleys and at other times depositing sediments, before eventually reaching the sea or an inland lake. This movement of water and material has helped shape terrain, created a diversity of freshwater environments, and allowed the evolution of thousand of species of plants, animals, and microbes. Together, these flowing water environments, with their uniquely adapted species, form the river ecosystems that we see today.

The North American continent contains a tremendous diversity of river sizes and types. Rivers range from the frigid and often frozen Arctic rivers of northern Canada and Alaska to the warm tropi-

cal rivers of southern Mexico. They range from the high-gradient turbulent rivers draining the western mountains to the low-gradient, placid rivers flowing across the southeastern Coastal Plain. River size ranges from the tiny Dunk River of Prince Edward Island to the enormous Mississippi, the 2nd longest river in the world and the 9th largest by discharge (Leopold 1994). Such variations in latitude, topography, and size contribute to the great variation in biodiversity and ecological characteristics that we see among the continent's rivers (e.g., Abell et al. 2000).

Total annual discharge from North American rivers is approximately $8200 \text{ km}^3/\text{yr}$ or about 17% of the world total (Shiklomanov 1993). The Mississippi is by far the largest river, yet its mean discharge is only 7% of total continental discharge ($580 \text{ km}^3/\text{yr}$ or $18,400 \text{ m}^3/\text{s}$) (Shiklomanov 1993, Karr et al. 2000). Among the top 25 rivers by discharge, more than a dozen have annual discharge greater than $2000 \text{ m}^3/\text{s}$, with the other largest being the St. Lawrence, Mackenzie, Ohio, Columbia, and Yukon (Table 1.1). Of these six largest rivers, all flow to the sea except the Ohio, which contributes almost half the flow of the Mississippi River. The Nelson and Missouri rivers are among the top five in drainage area, but only rank

► **FIGURE 1.1** Grand Canyon of the Yellowstone River, downstream of Yellowstone Lake in Yellowstone National Park, Wyoming. The Yellowstone River is the longest free-flowing river in the coterminous states, eventually joining the Missouri River (see Chapter 10) in western North Dakota (PHOTO BY A. C. BENKE).

TABLE 1.1 Largest rivers of North America ranked by virgin discharge. All rivers may be found in this book except the Koksoak and La Grande.

	River name	Discharge (m ³ /s)	Basin area (km ²)
1	Mississippi	18,400	3,270,000
2	St. Lawrence	12,600	1,600,000
3	Mackenzie	9,020	1,743,058

11th and 15th, respectively, in discharge because their basins receive only moderate precipitation. Three rivers with exceptionally large drainage basins, but not among the top 25 by discharge, are the Colorado, Rio Grande, and Arkansas (see bottom of Table 1.1). The Colorado River and Rio Grande (Bravo) each drain >600,000 km² (among the top ten by basin area) but are located in arid regions and have substantially lower discharge than many rivers draining much smaller basins. In addition to these extremely large rivers and river basins, there are many rivers of moderate to large size (100 to >1000 m³/s) that each flow for several hundred kilometers to the sea or are tributaries of larger rivers.

Although humans have been attracted to rivers throughout North America for more than 12,000 years, it has not been until the past 100 years that industrialization has caused a radical transformation of most rivers. They have been dammed for flood control, hydropower, and navigation; dewatered for human and agricultural consumption; contaminated with waste products; and invaded by many nonnative species. Such activities have seriously degraded water quality, habitat diversity, biological diversity, and ecosystem integrity of rivers throughout most of the continent. In spite of such extensive alterations, rivers have displayed a remarkable degree of resilience, capable of returning to at least seminatural conditions when human impacts are reduced. Fortunately, there are still some rivers that have escaped major human alterations (Benke 1990, Dynesius and Nilsson 1994), particularly those in the Arctic and Northern Pacific (Chapters 16, 17, and 20). Such pristine or lightly altered rivers retain much of the natural physical and biological properties they have had for millennia, and can serve as benchmarks by which to evaluate impacts and restoration success of altered rivers.

As editors of this volume, we recognize that modern societies inevitably must exploit rivers for necessary human needs and not all rivers can retain pristine features. However, any objective evaluation of North American rivers would reveal that we have gone well past a balance between human needs and the need for natural riverine ecosystems (e.g., Palmer 1986, 1993, 1996; National Research Council 1992; Karr et al. 2000; Postel and Richter 2003). Fortunately, the past 35 years have seen a major shift in society's attitudes toward rivers and the need to conserve these valuable natural resources (Boon, Calow, and Petts 1992, Boon, Davies, and Petts 2000). In spite of progress in our treatment of rivers, however, there have been no efforts in North America to comprehensively evaluate the state of its rivers (but see Stanford and Ward 1979, Benke 1990, Palmer 1996, and the U.S. National Park Service Web site for its Nationwide Rivers Inventory [www.nps.gov/ncrc/programs/rtca/nri]) that is comparable to wetlands evaluations (e.g., Cowardin et al. 1979, National Research Council 1992, Dahl 2000, and the U.S. Fish and Wildlife Service Web site for the National Wetlands Inventory [<http://wetlands.fws.gov>]). Hopefully, the better understanding of North American rivers revealed in this book will help lead to wiser management, sustainability, and restoration of these essential resources.

FIGURE 1.2 Major river basins and regions used in organization of chapters.

BASIC APPROACH

Our basic goal in planning this book was to provide as much information about as many rivers as possible in a single volume. Therefore, working with chapter authors, we have selected a total of 218 rivers throughout the continent. River descriptions are

organized into 22 chapters, some of which are represented by a single major river and its tributaries, such as the Missouri River, and others by region, such as the Atlantic Coast rivers of the northeastern United States (Fig. 1.2). Chapter authors were asked to include a range of rivers representing differences in size, physical diversity, biological diversity, ecosys-

tem function, and degree of human influence. This selection strategy enabled us to include most of the major rivers and much of the diversity of rivers present in North America. Selection of rivers in some regions, particularly in the Arctic, was limited by the amount of information available.

Each chapter follows the same format, enabling readers to make comparisons among various physical and biological characteristics. All chapters include the following:

- A regional map highlighting rivers to be described and indicating major political boundaries.
- One-page summaries of up to 12 rivers, including abbreviated descriptions of physical and biological features; graphs of monthly temperature, precipitation, and runoff; and a color topographic map showing major tributaries, cities, dams, and boundaries of physiographic provinces.
- Expanded text for up to five “focus” rivers per region, or a total of 100 for the book.

CHAPTER CONTENTS AND BACKGROUND

This overview provides some background and rationale for the types of information found in each chapter. Each focus river includes several pages of additional description beyond the one-page summaries. This information is organized into the following categories: (1) an introduction, with some early human history; (2) physiography, climate, and land use; (3) geomorphology, hydrology, and chemistry; (4) river biodiversity and ecology; and (5) human impacts and special features.

Physiography, Climate, and Land Use

The character of a river is primarily determined by features of its *drainage basin*, the land area within which it and its tributaries flow.¹ A drainage basin, usually with well-defined boundaries, can be part of or encompass various other types of land designations that may be less precise in their boundaries, but are useful in characterizing a river. One or more drainage basins may be found within a broad *landscape* that is initially characterized by physical features such as geology and topography. Climate,

¹Drainage basin is also called *watershed* (primarily in North America) and *catchment* (primarily in Europe). All these terms are used synonymously in this book.

including temperature and precipitation patterns, further characterizes the landscape and is itself influenced greatly by latitude, global air circulation patterns, ocean currents, the shape of the continent, and mountain ranges. A landscape’s physical features and climate together determine its terrestrial *ecosystems* and their biological *communities*. Thus, *landscape*, as used in the general ecological sense, refers to a large area of land composed of many clusters of interacting ecosystems. As we will see, there are various ways of describing the landscape, such as with physiographic provinces and ecoregions, and these can be useful in describing the drainage basin. The important point is that the drainage basin, however its physical and biological features are described, plays a major role in determining the characteristics of the river itself. As the pioneering running-water ecologist H. B. N. Hynes succinctly stated, “the valley rules the stream” (Hynes 1975). Thus, any description of a river is incomplete without characterizing the landscape through which it flows. On the other hand, it should be acknowledged that large drainage basins often intersect multiple landscape categories.

Physiography and Landscape

Each chapter attempts to characterize the landscape through which its rivers flow by describing the physiography, biome, and terrestrial ecoregions of the basin. Physiography is an early physical classification in which the land is divided into *physiographic provinces*: broad-scale subdivisions of the continent based on topographic features, rock type, and geological structure and history. Fenneman (1931) originally described a three-tier hierarchical structure of division, province, and section, and Hunt (1974) provided an updated version and maps of physiographic provinces for the United States and Canada. A physiographic map of the United States that is consistent with Hunt, but also includes sections, can be found on the U.S. Geological Survey (USGS) *Tapestry* Web site (<http://tapestry.usgs.gov/physiogr/physio.html>). We have prepared a complete physiographic map of North America showing only the *provinces* (Fig. 1.3), primarily based on Hunt and the USGS map, but using Arbingast et al. (1975) for Mexico. The boundaries of these physiographic provinces are also seen on the individual color topographic maps for every river basin in this book, with province names indicated by an acronym (e.g., CP = Coastal Plain).

An early biological classification of the landscape was identification of *biomes*. Biomes are broad global subdivisions of the earth based on terrestrial plant communities (Whittaker 1975) and are described in

FIGURE 1.3 Physiographic provinces of North America. Provinces for Canada and the United States are based on Hunt (1974) and the USGS Tapestry Web site. Provinces for Mexico are based on Arbingast et al. (1975).

most biology texts. Biome categories and boundaries can vary greatly according to author and degree of subdivision, however. One of the most recent and detailed maps was constructed by G. J. Schmidt and is available on the University of Tennessee botany Web site (<http://botany1.bio.utk.edu/botany120lect/Biomes/biomemap.htm>). We follow this map in defining the major biome categories of North America: *Desert*, *Chaparral*, *Temperate Deciduous Forest*, *Boreal Forest (Taiga)*, *Tundra*, *Temperate Grassland*, *Temperate Mountain Forest* (Rocky Mountain and Pacific Coast evergreen forest), *Tropical Rain Forest*, and *Mexican Montane Forest*. Biomes through which each river flows are indicated on the one-page summary for each river.

A more recent and detailed biological approach to landscape classification is characterization by *ecoregions*. Terrestrial ecoregions are relatively large landscape divisions, but much smaller than biomes, that contain a geographically distinct assemblage of natural communities. However, there are different versions of terrestrial ecoregion classification (e.g., Bailey et al. 1994, Omernik 1995, Ricketts et al. 1999). The version used in this book was developed by the World Wildlife Fund (WWF) and provides a detailed classification within the context of a continentwide conservation assessment (Ricketts et al. 1999). As with physiographic provinces and biomes, we also list the major terrestrial ecoregions (including dominant terrestrial vegetation) through which the rivers flow.

Climate

Climate varies greatly over North America and has a major influence on biomes and ecoregions and their associated rivers. Mean annual air temperatures range from 26.5°C in the Lower Usumacinta basin of tropical Mexico to -12.6°C in Barrow, Alaska. Where temperatures consistently fall well below freezing for extended periods, streams and rivers may freeze, particularly in the Tundra and Boreal Forest biomes. In the southern United States and Mexico, with mean daily air temperatures usually above zero, water temperatures in major rivers rarely fall below 10°C. Precipitation in North America can range from <10 cm/yr in the western deserts to >300 cm/yr in the mountains of British Columbia and southern Mexico. However, rivers in arid regions are often sustained by precipitation falling at higher elevations. Precipitation ranges from 20 to 70 cm/yr in the mid-continental grasslands and is usually >100 cm/yr in the eastern part of the United States and Canada. Precipitation declines to <40 cm/yr in northern Canada

and Alaska. The seasonal distribution of precipitation is very significant as well. It can occur relatively evenly throughout the year, as in much of the U.S. east coast, or it can be very seasonal, as on the U.S. west coast (mostly winter precipitation) and throughout Mexico (mostly summer precipitation). To help understand how climate affects rivers and their basins, all river summaries include graphs showing mean monthly values of air temperature and precipitation. Such information can be obtained from many sources, but one which includes over 16,000 cities throughout the world is www.weatherbase.com.

Land Use

Land use can have a major influence on the quality of rivers. It has been known for many decades that “changes in the valley wrought by man may have large effects” on the stream (Hynes 1975). Human activities modify the landscape within drainage basins, and much of this activity results in river degradation through erosion of sediments, transport of pollutants, destruction of river banks, or acceleration of runoff. The major land use categories that degrade rivers are agriculture, commercial forests, and urbanization. All chapter authors have attempted to provide statistical information on land use in river basins. The greatest land use alteration is agriculture, which approaches or exceeds 90% for many sub-basins in the Upper Mississippi (Chapter 8) and Missouri (Chapter 10) basins. Revenga et al. (1998) provided information on land use, area of river basins modified, and percent of basin protected for the major “Watersheds of the World,” including 32 of the largest basins in North America (also see <http://www.waterandnature.org>). The amount of drainage basin areas protected from harmful land-use practices ranges from zero for many (e.g., Mobile River basin) to 29% in the Yukon basin. Protection in most basins is <10%. Protection of the land in most basins is by designation as national or state/provincial parks or wilderness areas. Separate protection of river corridors is usually through their designation by federal (U.S. National Wild and Scenic Rivers, Canadian Heritage Rivers), or state/provincial governments.

River Geomorphology, Hydrology, and Chemistry

This subsection describes the physical and chemical properties of the river itself. River geomorphology involves the physical structure of the river channel

and its floodplain. Hydrology describes the pattern and magnitude of river discharge through time and combines with geomorphology to create the physical habitats to which organisms have adapted. Water chemistry is important from at least two perspectives. Natural variation in chemical variables often determines the types of organisms that can survive in a river, but pollutants can alter water chemistry to the point that few, if any, organisms can survive.

River Geomorphology

The geomorphology of river channels can be characterized in many ways (e.g., Leopold 1994, Rosgen 1994). It can be defined in part by slope or gradient (meters of vertical drop per kilometer of river length), shape of river cross section, and composition of bed substrate. Channel shape and behavior today can be a product of millions of years of physical history, including geological uplift, rise and fall of the sea, ancient floods, volcanic activity, and activity of glaciers. A river's medium-term physical history (hundreds to thousands of years) includes deposition (aggradation) of alluvial sediments onto the valley floor, and subsequent erosion (degradation) of alluvial fill, formation of floodplains, creation of river meanders, braiding, and other channel characteristics (Leopold 1994). A river's geomorphology can be altered in a geological instant, however, by major engineering projects, such as dams, levees, and diversions.

The gradient of a river is primarily dependent on the relief of the landscape through which it flows. Although gradients of smaller streams can be >4% (Rosgen 1994), most major rivers have gradients well below 1% (10 m/km). For example, the gradient of the Madison, a Rocky Mountain river, is about 0.35% (3.5 m/km). Gradients in the southeastern Coastal Plain are usually <0.04% (<40 cm/km), and can be as low as 0.002% (2 cm/km) for the St. Johns River in Florida. Substrate composition of the river bed is often associated with river gradient. Substrate composition is a major habitat feature and is also affected by current velocity, rock type, and geological history. Mineral substrates can be solid bedrock or can range in size of bed materials from boulder to cobble, gravel, sand, and fine clays. An organic substrate that is influenced by gradient and in turn influences hydrology and habitats is wood (Gregory et al. 2003).

Rosgen (1994) developed a channel classification scheme using width-to-depth ratio, slope, size of bed substrate, and ratio of floodplain width to bankfull width (also see Leopold 1994). Channel patterns typically fall into one of three types: meandering, straight, and braided (Leopold 1994). The predomi-

nant type is meandering channels that twist and turn, often in a sinuous fashion, eroding on the outside of bends and depositing sediments on inside bends (point bars). Braided channels contain multiple streams separated by bars or islands.

River size can be represented in several ways: basin area, mean annual discharge, river length, and stream order. Stream order is a gross means of assessing river size and complexity based on the number of tributaries and how they are linked (Strahler 1957, Leopold et al. 1964, Allan 1995). The smallest permanent stream (based on a USGS topographic map) is a 1st order stream. If two 1st order streams join, they form a 2nd order stream. If two 2nd order streams join, they create a 3rd order stream, and so forth. If a smaller order stream (e.g., 1st) enters a larger stream (e.g., 2nd), it does not change the order of the larger stream. This approach is not easily applied to some regions, particularly in arid parts of the continent. Rivers that might normally be considered as 4th or 5th order may sometimes go dry (or underground) and are really temporary streams, not even designated as 1st order in other regions. Regardless of this and other problems, stream order designations are still widely used today, and were used in development of the River Continuum Concept (RCC), which will be described more fully later in this chapter. Authors of individual chapters usually have provided estimates of order for their rivers, but different approaches have been necessary. Some designations are from published information, some were determined directly from topographic maps, and some were determined indirectly from regressions of order and basin area. Thus, whereas stream order across chapters is not entirely consistent, it does provide some measure of river size within a region.

Hydrology and the Fate of Water

Probably the most fundamental physical feature of a river is its hydrology: the pattern and magnitude of river flow, or discharge, through time. It is now widely accepted that the biodiversity and ecological integrity of rivers are directly dependent on their natural flow regime (Poff et al. 1997). A river's hydrology is part of the water budget of the basin that concerns the balance of water inflows to the basin with outflows from the basin. When precipitation strikes the ground it has three obvious fates: surface runoff, infiltration into the ground, and evaporation. The average annual precipitation over North America is 67 cm, of which only 29 cm (43%) actually runs off or infiltrates the ground and eventually contributes to the flow of rivers (Hornberger et al.

1998). The remaining 38 cm are returned to the atmosphere by evaporation and transpiration by plants. Because it is difficult to separate evaporation from transpiration, together they are called *evapotranspiration*. Storage and discharge from groundwater sustain streams and rivers at “base flow” during periods when no rain occurs. Some streams may even go underground as they dry out on the surface. Because of large differences in climate, hydrological budgets vary greatly across the continent; the fraction of precipitation running off the landscape can be extremely low (<5%) or extremely high (>70%).

Discharge is the actual measurement of flow, usually presented as cubic meters per second (m^3/s) or cubic feet per second (cfs). An enormous amount of information about river discharge is available for rivers throughout North America. A large network of river gauges has been established by the USGS, beginning in 1895 (Leopold 1994). The USGS has collected streamflow data at about 19,000 sites, of which about 7000 have gauges that are currently operational. Real time and historical data (many with >50 years of data) are available through the USGS Web site (<http://water.usgs.gov>). Extensive data on river discharge also are available through Water Survey of Canada (WSC), a branch of Environment Canada. Data collection began in 1908 and since 1991 has been available on the national HYDAT CD-ROM. HYDAT contains data from more than 2900 active gauging stations, but many additional or WSC-abandoned gauges are maintained by provincial governments and water management agencies (e.g., hydro companies), which report their data to WSC for inclusion in HYDAT. A limited amount of discharge information (British Columbia and the Yukon) is now available on the Environment Canada Web site. In addition, the University of Wisconsin’s Center for Sustainability and the Global Environment and the International Hydrological Programme of UNESCO (I. A. Shiklomanov) have developed useful Web sites that provide historical monthly discharge values for many rivers throughout the world (www.sage.wisc.edu/riverdata, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>).

Runoff is a measure of the height of water (centimeters) that drains from a basin over a unit of time (day, month, year). It is calculated by dividing discharge (m^3/s) by basin surface area (km^2) and multiplying by the appropriate conversion of time units. For many rivers throughout the world, runoff can be obtained directly from the International

Hydrological Programme Web site. Such information has sometimes been presented as annual unit area discharge or water yield (km^3 of water/ km^2 of land, or m^3 of water/hectare of land). However, runoff, presented simply as cm/mo, is especially useful when compared to precipitation (cm/mo) throughout the year (e.g., Benke et al. 2000). Doing so provides a rough approximation of the water budget for a particular basin (i.e., fraction of precipitation that discharges to the mouth). On average, the difference between annual precipitation and annual runoff should be roughly equal to evapotranspiration losses, assuming no major movements of water among basins from groundwater exchanges. When considered on a daily or monthly basis, however, the difference between precipitation (PPT) and runoff (RO) is not only due to evapotranspiration (ET), but also to groundwater storage or loss (GW) and snow storage or loss (SN). Human storage in reservoirs or transfers between basins (HU) may affect the balance as well. Thus, the short-term fate of precipitation can be represented by the following equation:

$$PPT = RO + ET + GW + SN + HU$$

Seasonal variation in runoff is largely explained by the difference between PPT and RO:

$$(PPT - RO) = ET + GW + SN + HU$$

Seasonal influences on runoff are often apparent by plotting monthly runoff with monthly precipitation, and these plots are provided on the one-page summaries for all rivers. In most cases the major seasonal influences on runoff appear to be seasonal differences in ET and SN. A positive SN for any given month represents snow storage (accumulation on the land), and negative SN represents snow melt. Similarly, a positive GW represents groundwater storage during seasons of high precipitation, such as during the fall and winter on the west coast, and negative GW represents groundwater losses to runoff during the dry season. For some basins, human extraction can be great on an annual basis (>50%), and several examples are described throughout the book and in Chapter 24.

All rivers described in this book contain a figure showing long-term monthly precipitation and runoff. The default interpretation is that the difference between precipitation and runoff is an approximation of evapotranspiration (annual basis). However, this is based on the assumption that there are reliable

long-term estimates of runoff and mean basinwide precipitation. This assumption is usually valid for most rivers that have an excellent long-term record of discharge. On the other hand, it is not always possible to obtain good estimates of basinwide precipitation. This is particularly true when there is only a single climate station within a basin containing a spatially heterogeneous pattern of precipitation, such as in mountainous areas. Clearly, if the precipitation estimates available do not reflect basinwide values, then the difference between precipitation and runoff will not provide a good estimate of evapotranspiration. Similarly, long-term losses or gains of water from the basin through groundwater can affect such approximations of evapotranspiration, but such losses are usually unknown. To summarize, plots of monthly precipitation and runoff often can be very useful in interpreting factors affecting seasonal runoff, but they must sometimes be viewed with extreme caution.

Several examples of rivers from across the continent illustrate the factors affecting seasonal runoff (Fig. 1.4). Alaska's Porcupine River (Chapter 17) has very low annual precipitation, but because evapotranspiration is very low, most of the water reaches the mouth of the river (see Fig. 1.4a). As would be expected in an Arctic environment, most of the Porcupine's frozen precipitation that falls during the winter does not flow until snowmelt in late spring. The Moisie River, Quebec (Chapter 21), has much higher annual precipitation but also experiences a strong seasonal runoff pattern due to snow storage in the winter and snowmelt in the spring (see Fig. 1.4b). In contrast, the Umpqua River, Oregon (Chapter 12), has a strong seasonal runoff pattern, primarily responding to a strong seasonal precipitation pattern (see Fig. 1.4c). The Ogeechee River, Georgia (Chapter 3), on the other hand, receives fairly uniform precipitation throughout the year, yet experiences its highest runoff during winter and spring because evapotranspiration is lower than during warm months (see Fig. 1.4d). The combination of low precipitation and high evapotranspiration in the Virgin River basin, Utah (Chapter 11), results in extremely low runoff, often accompanied by increased flow during spring snowmelt from the mountains (see Fig. 1.4e). Damming and water extraction in many rivers of the southwestern United States and northern Mexico reduce flows to zero for much of the year. Damming and flow regulation in eastern rivers can be more subtle but can have significant effects on seasonal runoff patterns. For example, regulation of the Savannah River,

Georgia–South Carolina (Chapter 3), results in considerably less seasonal variation than the adjacent Ogeechee River (compare Fig. 1.4f to Fig. 1.4d).

Water Chemistry

Information on river water chemistry is provided for each river to the extent possible. The availability and quality of river water chemistry data varies widely among rivers of North America. However, because water chemistry is extremely sensitive to human influences, we have asked authors to provide information that can help readers understand both natural water chemistry and chemical changes resulting from human impacts. Among the measures often reported are alkalinity and nutrients. Alkalinity is a measure of the buffering capacity of water and is commonly presented as milligrams of calcium carbonate per liter (mg/L as CaCO_3).² Natural alkalinity values can fall below 5 mg/L as CaCO_3 in low-pH blackwater rivers such as the Satilla River in the Coastal Plain of Georgia (Chapter 3). Alkalinity values are more commonly greater than 20 mg/L as CaCO_3 , and in regions draining carbonate rocks, values can easily exceed 100 mg/L as CaCO_3 .

The most common nutrients reported for rivers are phosphorus and nitrogen, either of which may be important in limiting production of algae and plants. Dissolved inorganic phosphorus (commonly presented as soluble reactive phosphorus [SRP], orthophosphate, or phosphate-phosphorus [$\text{PO}_4\text{-P}$]) averages about 10 micrograms of phosphorus per liter ($\mu\text{g P/L}$) among unpolluted rivers throughout the world (Meybeck 1982, Allan 1995, Wetzel 2001). Total dissolved phosphorus (inorganic + organic) averages about 25 $\mu\text{g/L}$. A recent study of streams and rivers in the United States, however, described natural background concentrations of total phosphorus as varying from 6 $\mu\text{g/L}$ in the xeric west to more than 80 $\mu\text{g/L}$ in the Great Plains (Smith et al. 2003). Waters polluted by agricultural runoff or municipal sewage commonly increase phosphorus levels to at least twice as high as natural background.

Nitrogen concentrations may be presented as total dissolved inorganic nitrogen (DIN), nitrate nitrogen ($\text{NO}_3\text{-N}$), nitrite nitrogen ($\text{NO}_2\text{-N}$), and ammonia nitrogen ($\text{NH}_4\text{-N}$). Nitrate-nitrogen values are commonly measured in rivers and average about 100 $\mu\text{g/L}$ (Wetzel 2001). Median natural background

²Alkalinity has commonly been presented in units of mg/L as CaCO_3 , and these are the units provided in this book. However, alkalinity is increasingly being expressed as milliequivalents per liter (1 meq/L = 50 mg/L as CaCO_3) (see Wetzel 2001).

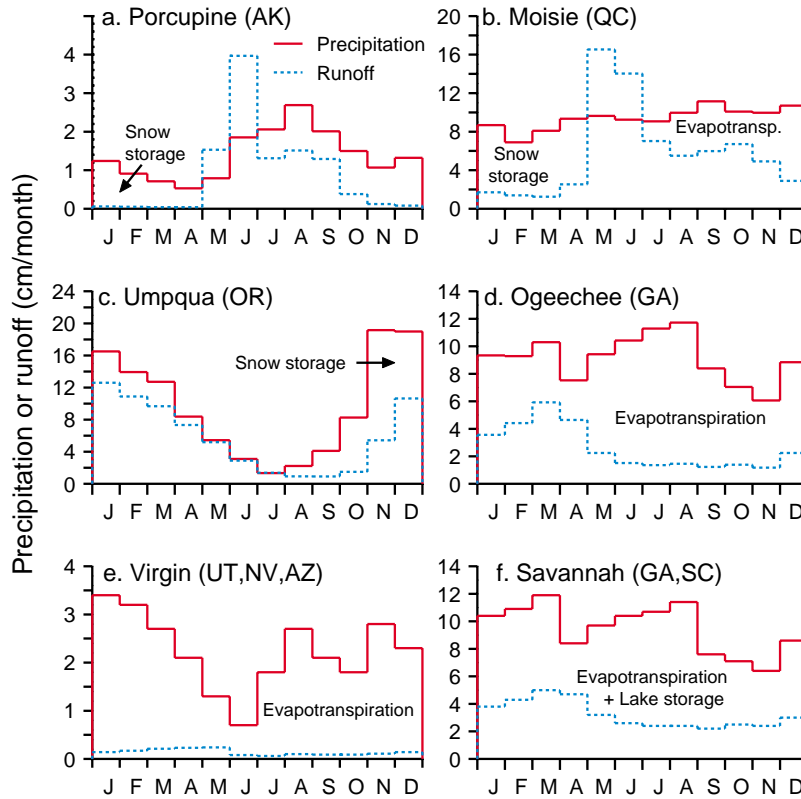

FIGURE 1.4 Patterns of precipitation and runoff for rivers from a diversity of regions in North America. a. Porcupine River (Alaska) showing snowmelt peak of runoff during low precipitation. b. Moisie River (Quebec) showing snowmelt peak of runoff. c. Umpqua River (Oregon) showing runoff peak following seasonal precipitation. d. Ogeechee River (Georgia) showing runoff pattern caused by seasonal changes in evapotranspiration. e. Virgin River (Utah, Nevada, Arizona) showing very low runoff due to low precipitation and high evapotranspiration. f. Savannah River (Georgia, South Carolina) showing flattened runoff pattern due to regulation (compare to Ogeechee).

levels for total nitrogen are about $140\mu\text{g/L}$ in the United States but range from less than $20\mu\text{g/L}$ in the xeric west to more than $500\mu\text{g/L}$ in the Great Plains (Smith et al. 2003). In contrast to the twofold increase in stream phosphorus, actual nitrogen concentrations currently exceed natural background levels by more than sixfold due to both terrestrial (e.g., agriculture) and atmospheric inputs (Smith et al. 2003).

River Biodiversity and Ecology

This subsection attempts to characterize each river as a living system, highlighting the major species of plants and animals and describing ecosystem processes to the extent possible. For more detailed treatments of these subjects, see Allan (1995) and Cushing and Allan (2001). Early descriptions of the biological communities in rivers recognized that

organisms are typically found on or within substrate of the river bed (benthic habitat) or found in the water column. It was soon recognized that river habitats are much more complex than this simplistic picture. The bed substrate can vary greatly in sediment particle size and the water column can vary greatly in current velocity, creating a diversity of physical habitat features that strongly influence the presence of various species. In more recent years the importance of submerged wood (snags), the hyporheic zone, and adjoining floodplain wetlands have all become widely recognized. Wood is introduced to the channel typically by the undercutting of banks lined with trees. The hyporheic zone occurs where porous substrate extends below the bed surface, and through which there is an exchange of water, nutrients, organic matter, and organisms. Floodplain wetlands become directly connected with river channels for short or extended periods as rivers

flood and overflow their banks, increasing the width of the river as much as 100-fold. Each of these habitats provides substrate and food for different types of organisms and can make important contributions to ecological processes. The relative occurrence of such habitats varies widely among rivers across the continent.

The great diversity of river types and habitats across North America has resulted in the evolution of a tremendous diversity of biological species that have become adapted to the particular habitats and environmental conditions in which they are found. We provide a brief description of the biodiversity within the major groups of organisms that compose the food chains so vital to the functioning of rivers as living biological systems: (1) algae, (2) plants, (3) invertebrate animals, and (4) vertebrate animals. Common names, rather than scientific names, are used throughout the text for all plants and vertebrates, and for some invertebrates (particularly mollusks). Scientific names of these species may be found in the Appendix.

Other groups of great importance in decomposition of organic matter, in nutrient regeneration, and as food sources for invertebrate animals are the bacteria, protists, and fungi; however, less is known about these groups and they will not be treated further.

We know much more about the continental and regional diversity of some groups than others. For certain groups of animals, their biodiversity, number of extinctions, and risk of extinction are well documented. Of particular concern are freshwater animals, which are highly sensitive to oxygen concentrations, habitat and flow conditions, pollutants, and thermal regimes. The World Wildlife Fund has classified regions of North America into freshwater ecoregions (as they did for terrestrial ecoregions), based primarily on native fish distributions (Abell et al. 2000). All chapters use this classification scheme. At the end of this subsection we will describe the major concepts of rivers ecosystems that address ecological processes.

Algae

Algae and plants are organisms in rivers that produce their own organic matter by photosynthesis; hence, they are *autotrophic* and are frequently referred to as *primary producers*. Algae are often single-celled organisms, but some riverine species occur as multinucleate filamentous forms, visible to the unaided eye as long, green filaments attached to solid substrates. The most abundant algae in streams and rivers are the diatoms, many of which are firmly

attached to solid substrates such as rocks, wood, and plant stems. Diatoms and green algae are important components of the *biofilm* (or *periphyton*) that coats these surfaces. Biofilm also includes bacteria, fungi, protists, microinvertebrates, detritus, and other organic matter. In larger rivers (plus lakes and wetlands connected to rivers), algae suspended in the water column (*phytoplankton*) can also be important as a basal energy source for food chains.

Plants

The aquatic plants consist of mosses and flowering plants. The mosses are small, leafy, nonvascular plants that are attached to solid substrates. They form dense, matlike growth forms on stones and wood and may themselves be important habitat for small animals. The vascular flowering plants are primarily found where the current slows and the substrate is conducive to the growth of rooted plants, collectively called *macrophytes*. Huge beds of these plants can be found in certain locations, such as backwaters, pools, and floodplains where conditions are suitable. The macrophytes, much like the mosses, are important as habitat and after they die may be valuable food resources to aquatic animals. This dead organic matter is called *detritus* and forms the base of the detrital food web. In addition to the aquatic macrophytes, a terrestrial plant community often grows along the edges of rivers and streams and is dominated by trees such as willows, alders, cottonwoods, and red maple. This *riparian* vegetation can contribute substantial quantities of dead leaves and wood (detritus) to rivers, which serve as habitat and food sources for many animals. In rivers with broad floodplains, however, extensive macrophytes or floodplain forests can extend for kilometers from the edge of the river channel, and the “riparian” vegetation becomes greatly extended.

Invertebrates

Invertebrates are by far the most abundant and diverse group of animals found in rivers. The term *macroinvertebrate* usually applies to *benthic* (bottom-dwelling) invertebrates that will not pass through a 0.5 mm sieve. Among these are herbivores, which feed directly on primary producers; detritivores, which feed on dead organic matter (detritus); and carnivores, which feed on other animals. Aquatic insects are the most diverse and abundant group of invertebrates in flowing waters. Four orders generally compose the majority of numbers and biomass of insects in most rivers and streams. These are the Diptera (true flies), Ephemeroptera (mayflies), Ple-

coptera (stoneflies), and Trichoptera (caddisflies). Other important but less abundant insect species are from the orders Coleoptera (aquatic beetles), Hemiptera (true bugs), Odonata (dragonflies and damselflies), and Megaloptera (hellgrammites).

In addition to insects, other common macroinvertebrates in streams and rivers include aquatic crustaceans, mollusks, and oligochaetes (worms). The crustaceans include crayfishes, amphipods, and isopods. The mollusks include bivalves (primarily mussels) and snails. In addition to these macroinvertebrates, there are many smaller but abundant benthic groups that are commonly called *meiofauna*. These nematodes, microcrustaceans, rotifers, and other smaller groups are often the only invertebrates that can live deeper within the interstitial waters of the streambed (hyporheic zone). In addition to the benthic and hyporheic invertebrates, the *zooplankton* of the water column can be important components of the food web. The zooplankton community feeds upon the phytoplankton and typically includes microcrustaceans such as copepods and cladocerans, as well as rotifers.

Biodiversity of invertebrates is best known among the larger animals. There are 338 crayfish species in the United States and Canada, as well as 297 freshwater mussels and 342 freshwater snails (Williams et al. 1992, Lydeard and Mayden 1995, Taylor et al. 1996, Karr et al. 2000, Abell et al. 2000). There are probably in the vicinity of 10,000 aquatic insect species in North America (e.g., see Merritt and Cummins 1996), but we are unaware of separate estimates of stream and rivers species from those found in ponds, lakes, and wetlands. Intensive studies have revealed that there can be several hundred species in a single stream.

Vertebrates

The most widely recognized and important vertebrates occurring in rivers are fishes, simply because they live entirely in the water and are thus more intimately associated with riverine food webs. Fishes have long been an important source of food for native North Americans, and sport and commercial fisheries have been a major industry for over a century. Like the invertebrates, fishes function as herbivores, detritivores, and carnivores. Although representatives of many families of fishes are found in rivers and streams, the Salmonidae (salmon and trout), Cyprinidae (minnows), Catostomidae (suckers), Ictaluridae (bullheads and catfishes), Centrarchidae (sunfishes and bass), Percidae (particularly darters), and Cottidae (sculpins) are certainly among the most common and

important. Depending on the river, however, amphibians, reptiles, birds, and mammals can also be important. Amphibians (salamanders and frogs) and aquatic reptiles (turtles, snakes, and alligators) occur primarily along the edges of streams and rivers, including floodplains. Many birds (e.g., wading birds) and mammals (e.g., beavers, river otters), depend heavily on the riverine and floodplain environment for habitat and food. Totally aquatic mammals such as beluga whales and porpoises can swim well up into the freshwater portions of large rivers.

Fish diversity is the best known of any aquatic group, with more than 1000 species of native freshwater fishes throughout North America (Abell et al. 2000, Nelson et al. 2004). This diversity varies greatly across the continent, with a particularly high concentration of species occurring in the southeastern United States (see Fig. 1.3 for Canada and the United States in Karr et al. 2000). Many rivers of only moderate size (<100,000 km² basin) have well over 100 native species (Gido and Brown 1999). A large number of fish species are at risk of extinction in the southeastern United States, where native diversity is high, but a much higher proportion of species are endangered in southwestern states, where native diversity is low (Abell et al. 2000, Karr et al. 2000).

Ecosystem Processes

The foundation for all life and food webs in rivers, as in any ecosystem, is the production of organic matter. Organic matter is produced in rivers and streams by two main processes: *primary production* and *secondary production*. Primary production is the formation of autotrophic biomass (algae and plants) by the process of photosynthesis. Secondary production is the formation of heterotrophic biomass by growth of animals, although the term may also be applied to production of heterotrophic microbes. Secondary producers may obtain their food directly from primary producers (herbivores), after primary producers have died (detritivores), or from feeding on other animals (carnivores).

Two general sources of energy from primary production are often distinguished for running water ecosystems: *autochthonous* (in-stream production) and *allochthonous* (organic matter produced in the terrestrial environment outside the river boundary). Probably the two most important autochthonous energy sources are the diatoms, a major component of periphyton, and the phytoplankton of large rivers. The remaining autochthonous energy sources, filamentous green algae, mosses, and macrophytes,

perform important functions (e.g., oxygen production and as habitat), but they are often less important in the overall energy flow of streams and rivers. On the other hand, when macrophytes occur in abundance, particularly in backwaters and floodplain wetlands, they can decompose and become a major autochthonous detrital food source.

Allochthonous sources include any organic matter originating in the terrestrial environment that is transported to the aquatic system via wind, gravity, surface runoff, or some other way. Included here are the more obvious contributions of detritus from riparian or floodplain plants, such as leaves, twigs, and tree trunks (also called *coarse particulate organic matter* [CPOM]). CPOM (>1 mm diameter) is usually considered the major allochthonous source in small forested streams, but it is also of major importance in floodplain wetlands. CPOM undergoes decomposition by microbes (particularly fungi) and fragmentation by invertebrates, producing fine particulate organic matter (FPOM). FPOM (<1 mm diameter) processed in the low-order tributaries or flushed from floodplains often becomes a dominant form of organic matter and food source in large rivers. FPOM carried by the current is often called *seston*. Dissolved organic matter (DOM) is another component of organic matter that is becoming well recognized as a sizable portion of total organic matter in transport (Webster and Meyer 1997). DOM (<0.5 μm diameter) originates from both in-stream processing (autochthonous), from adjoining floodplain wetlands, and from more distant sources in terrestrial areas (allochthonous). It can be an important energy source for heterotrophic microbes and higher food webs, but much of it is *refractory* and passes through river systems unaltered. Finally, allochthonous *animal* sources of food may include fish carcasses (fishes that die after upstream migration) and terrestrial insect feces (frass), but the latter are less well documented inputs from terrestrial vegetation.

A variety of animals, particularly invertebrates, have evolved a great diversity of feeding strategies to make use of primary and secondary producers in rivers. Animals may be classified into the classic trophic groups: herbivores, carnivores, omnivores, and detritivores. However, many stream and river ecologists have found it more useful to classify benthic invertebrates into *functional feeding groups*: how they obtain their food rather than what they eat (Cummins 1973, Wallace and Webster 1996). The major functional feeding groups are *shredders*, *scrapers* (also called *grazers*), *filtering collectors*, *gathering collectors*, and *predators* (carnivores).

Shredders (including many species of stoneflies, caddisflies, true flies, and crustaceans) obtain their nutrition by consuming microbially conditioned CPOM, producing FPOM in the form of smaller particles and fecal pellets. Scrapers (including many caddisflies, mayflies, and snails), as the name implies, feed by scraping diatoms and periphyton from the surface of solid substrata. Filtering collectors (including some mayflies and many caddisflies, true flies, and mussels) feed on FPOM (seston) from the water column using a variety of nets, leg hairs, modified mouthparts, and other structures to strain the food. In large rivers, filter-feeding zooplankton can be an important part of the food web. Gathering collectors are mainly free-living organisms that feed on FPOM where it has settled on the river bed, and include representatives of all major insect orders. Predators, particularly odonates (dragonflies and damselflies), hellgrammites, true bugs, and several stoneflies, kill and feed on other animals. Other predaceous species can be found in most insect orders.

A common measurement made in streams and rivers to determine the relative dependence on autochthonous or allochthonous energy is the *P/R ratio*. This is defined as the ratio of primary production (which produces oxygen) to community respiration (which consumes oxygen) over a 24-hour period. A value of unity or above denotes an *autotrophic* section of river, where the system is producing sufficient oxygen to meet its needs. A value of <1 denotes a significant *heterotrophic* influence, in which the system is using more oxygen than it produces and dissolved oxygen must be replenished from the atmosphere. Hence, a heterotrophic section of river receives a food subsidy from the terrestrial environment (originally as allochthonous primary production) in the form of CPOM, FPOM, and DOM.

In order to make sense of the variation among streams and rivers in terms of geomorphology, hydrology, habitats, productivity, feeding strategies, and the fate of organic matter produced in rivers basins, various authors have proposed conceptual models. The best known model in use today that describes rivers in a holistic construct is known as the River Continuum Concept (Vannote et al. 1980, Minshall, Petersen et al. 1983, Minshall, Cummins et al. 1985). The basic model, often illustrated as in Fig. 1.5, describes headwater reaches (orders 1 to 3) as heterotrophic, with P/R ratios <1 and an invertebrate community dominated by shredders and collectors. Of more relevance to this book, however, are higher-order rivers. In middle reaches of the continuum, small to medium rivers (typically 4th to 6th order) are

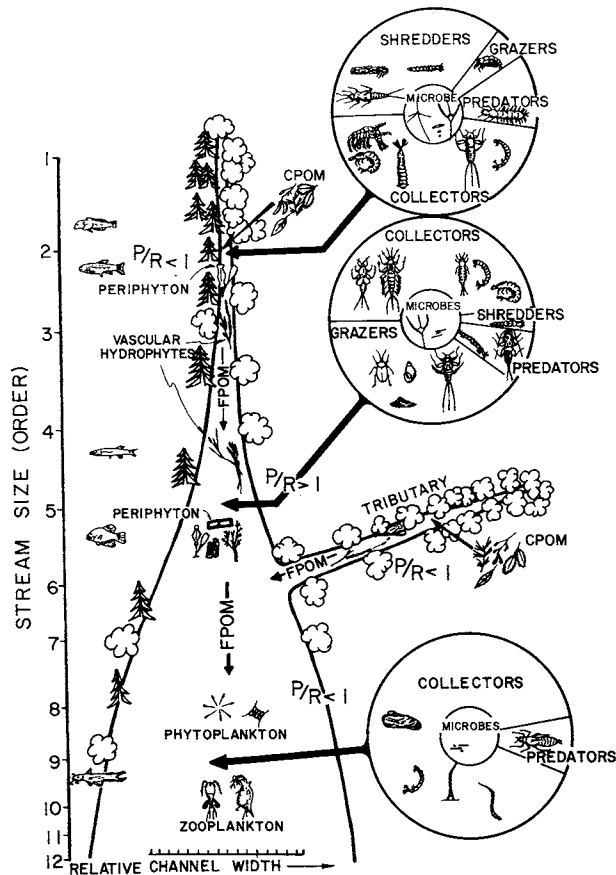

FIGURE 1.5 The River Continuum Concept, showing predicted changes in P/R ratio and functional feeding groups with stream order (from Vannote et al. 1980, with permission).

usually shallow, open to direct sunlight, and have a P/R ratio >1 due to enhanced autochthonous (algal and macrophyte) production. Scrapers are expected to be codominant with filtering and gathering collectors. In the large rivers (7th to 10th order), the channel would widen and deepen and the primary energy source would be excess FPOM produced from the midreaches plus a viable assemblage of phytoplankton. The net result would be P/R ratios <1 and functional feeding groups being dominated by bottom-dwelling filtering and gathering collectors, such as mollusks, oligochaetes, and dipteran larvae, and zooplankton in the water column. Thus, the RCC postulated that the entire river continuum, from headwaters to mouth, is linked in a predictable series of energy changes and functional feeding group adjustments along its course.

Several significant concepts in river ecology have been developed since the RCC, the most important

of which is the linkage of the river with its floodplain. This linkage was described most comprehensively as the “flood pulse concept” by Junk et al. (1989), in which river communities depend on the annual inundation of broad floodplains and the subsequent recession of water levels to the main channel. Junk and colleagues’ major deviation from the RCC was to suggest that the lateral exchange of materials with the floodplain will have a much greater influence on the biota and ecosystem function than the organic matter transported from upstream sources. Whereas the authors of the flood pulse concept focused on extremely large rivers such as the Amazon and Mississippi, more recent work has emphasized that the flood pulse can be very important in middle-order rivers as well (e.g., Benke et al. 2000, Tockner et al. 2000). This can be particularly important in the low-gradient rivers of North America, such as in the southeastern Coastal Plain (Benke et al. 2000). The importance of the flood pulse in North American rivers has probably not been as widely recognized because the flows of so many of these rivers are highly regulated by dams.

In addition to the RCC and flood pulse concept, Thorp and Delong (1994) have suggested that a substantial portion of the organic matter consumed by animals in large rivers is either of autochthonous origin (phytoplankton, periphyton, macrophytes) or is produced by the riparian forest, rather than being transported longitudinally from upstream tributaries or laterally from interactions with the floodplain. Furthermore, submerged wood (snags) originating from streamside forests has been of considerable historical importance to many rivers throughout North America, can have a major influence on hydrology and geomorphology (Gregory et al. 2003), and can be of great importance in creating habitat and cover for many animals (Benke et al. 1984, Benke and Wallace 2003). Removal of wood from many rivers in North America for over 100 years has undoubtedly caused a significant shift in their habitat structure, biodiversity, and functional group structure compared to their pristine condition (e.g., Sedell and Froggatt 1984).

In summary, it is difficult to generalize about organic matter budgets and energy sources for food webs in North American rivers. Too few studies have been done that address such questions in rivers having a discharge $>25 \text{ m}^3/\text{s}$ (e.g., see Webster and Meyer 1997), and many authors in this book could only speculate about ecosystem processing. Furthermore, it is difficult to find such a river for study because most rivers are highly regulated. The source

of organic matter for a river food web (longitudinal, lateral, or autochthonous derivations) probably depends largely on geographical, geomorphological, and physiographic differences, even in their unaltered state. Human alterations to rivers undoubtedly affect their relative contributions as well. An earlier approach to such questions was examined in Cushing et al. (1995), where authors attempted to put the streams occurring in various broad regions of the world into the context of the RCC.

Human Impacts and Special Features

At the end of each chapter, authors highlight what is special about the river and summarize its major impacts by humans. Special features of each river include such things as the existence of dramatic falls, large floodplain swamps, unique species, or special protection status (e.g., U.S. National Wild and Scenic Rivers, Canadian Heritage Rivers). Impacts to rivers have often been grouped into three major categories: *pollution*, *flow regulation*, and *water extraction*. A fourth significant impact has come from both intentional and accidental introduction of *nonnative species*. In spite of human alterations, each river is or was unique.

Pollution of rivers in North America has probably been a problem since the 1700s, when the early Europeans developed industrial cities that polluted east-coast rivers. This early pollution was undoubtedly from domestic sewage, a source that remains the second most common pollutant (Karr et al. 2000). Throughout the 1800s and 1900s, the types and amounts of point-source pollution released into rivers created stretches of rivers where little aquatic life could survive for many kilometers downstream of an outfall. In many rivers, persistent toxic chemicals such as mercury, polychlorinated biphenyls (PCBs), and pesticides have accumulated in sediments and magnified through food chains to the point where fishes are unsafe for human consumption (Karr et al. 2000).

Nonpoint sources of pollution also became major problems during the last two centuries, particularly from land use associated with deforestation, agriculture, and urbanization. Deforestation reduces energy inputs that normally are transported to rivers in the form of allochthonous leaf litter and its breakdown products. Urbanization typically accelerates surface runoff patterns and introduces large amounts of both point and nonpoint pollutants. Similarly, agriculture greatly increases silt and nutrient loads to rivers and is the leading pollutant source in the United States

(Karr et al. 2000). Federal laws to reduce pollution in North American rivers have had varied success. Although enforcement of water quality laws in the United States has resulted in significant reductions in point-source pollutants, nonpoint pollution goes largely unchecked (Smith et al. 1987, Karr et al. 2000).

The construction of dams, levees, and channels for flow regulation has been especially devastating to the natural biodiversity and ecology of rivers (Ward and Stanford 1979, National Research Council 1992, World Commission on Dams 2000). Dams have been constructed to control floods, generate electricity, enhance navigation, create recreational areas, and provide water for domestic and industrial use. Unfortunately, the ecological costs associated with dam building have been largely ignored by dam-building agencies and politicians. Dams destroy essential habitats and eliminate river corridors for the passage of materials and migration of biota. Some dams regulate flow to such an extent that downstream reaches may become totally dry or at least prevented from their natural flooding patterns. Hydropower dams required to maintain a minimum flow typically have highly unnatural surges of flow on a daily or weekly basis, creating an enormous stress on biota. Often the water released is devoid of natural sediment loads (left behind in the reservoir), is low in oxygen, and is much colder than natural river temperatures, eliminating many native species for many kilometers below the dam. Dams also may alter seasonal discharge and natural flooding patterns.

The widespread impact of dams on rivers in North America cannot be overstated. The U.S. Army Corps of Engineers (USACE) has built the majority of major dams on rivers of the United States, beginning in the late 1800s. The USACE maintains an inventory of dams that now totals about 76,000 (<http://crunch.tec.army.mil/nid/webpages/nid.cfm>). This incredible number of dams alone is a strong indication of the major influence that dam-building has had on North American rivers. Benke (1990) estimated that out of over 5.2 million km of rivers in the 48 coterminous United States, there were only 42 relatively small rivers that were reasonably natural and unregulated for at least 200 km of length. Stanford and Ward (1979) reached a similar conclusion in an earlier study. Dynesius and Nilsson (1994) conducted an analysis of large rivers in the northern third of the world, quantifying channel fragmentation and flow regulation. They found that the vast majority of large river systems in the United States and central/eastern Canada were strongly fragmented by dams. Only in

Alaska, British Columbia, and rivers flowing into the Arctic are there many rivers unaffected by dams. Revenga et al. (1998) list the number of large dams (>15 m in height) for many rivers of the world, including 2091 for the Mississippi, 265 for the Colorado, and 184 for the Columbia. Among all the river basins of the world, there are nine with more than five major (>150 m in height) dams, four of which are in North America: Columbia (13), Colorado (12), Mississippi (9), and Nelson (7).

Associated with dam building, and a major reason for the dewatering of major rivers, is water extraction and interbasin transfers. Approximately 8% of freshwater runoff in North America is withdrawn for human use (WRI 2000). In the United States and Canada, the greatest amounts of water are withdrawn for industry (65% and 80%, respectively) (WRI 2000). About 27% of withdrawals are used for agriculture in the United States, but 78% of withdrawals are used for agriculture in Mexico. The greatest problems with extractions are in arid regions. The most noteworthy examples are the Colorado and Rio Grande rivers, where so much water is withdrawn that flow to the sea ceases for much of the year.

The introduction of nonnative species to North American rivers has had a more subtle impact than pollution, flow regulation, and water extraction.³ Although their effects are difficult to document, nonnative species are believed to have caused the extinction of native species and have resulted in significant changes in the function of river ecosystems (Gido and Brown 1999, Heinz Center 2002). For example, fish management practices have resulted in the widespread introduction of rainbow trout outside of their native habitat. Accidental introductions include the Asiatic clam, which is now distributed throughout much of the United States, and the zebra mussel, which has made its way from the Great Lakes down the major waterways to Louisiana. Sixty percent of 350 watersheds in the coterminous 48 states have 1 to 10 nonnative fish species, 22% have 11 to 20 nonnative species, and 2 watersheds have >40 nonnative species (Heinz Center 2002).

³We use the term *nonnative species* to indicate species that have intentionally or accidentally been introduced to a river system where they did not previously exist without the influence of humans. Synonyms for nonnative species are *introduced*, *exotic*, *alien*, *nonindigenous*, and *invasive*.

CONCLUDING COMMENTS

The editors and chapter authors of this book have come to realize that our understanding of natural biodiversity and ecology in North America rivers is fair at best. We are well aware of the major factors that threaten river biodiversity and ecosystem integrity such as habitat loss, pollution, and the spread of nonnative species (e.g., Allan and Flecker 1993). However, the biological and ecological data for many rivers are superficial, and sometimes nonexistent, as will become apparent throughout the book. It is difficult to assess the natural ecological characteristics of most rivers now that they are highly modified or polluted. On the other hand, most of the remaining untouched rivers are at such remote locations (e.g., the Arctic) that little research has been conducted in them. There is a great need for major new research initiatives that can lead to better scientific understanding, wider appreciation of their importance, and wiser management. In spite of this large gap in scientific knowledge of rivers, it is imperative that our current knowledge, particularly the extensive information on hydrology, be put to good use in conservation and management if the natural features and biodiversity of rivers are to be retained. Some of the major challenges we face in applying this knowledge to river conservation and management are described in Chapter 24.

INTRODUCTION

The Atlantic slope region of the northeastern United States stretches from the Penobscot River in northern Maine (46°N) to the Rappahannock River on the lower Chesapeake Bay (37.5°N). The larger rivers in this region flow south or southeast between the Appalachian Mountains and the Atlantic Ocean (Fig. 2.2). The relatively short distance between the mountains (or other basin divides) and the coast limits both basin area and river length in the region, but the region's abundant precipitation and high runoff result in high average discharge relative to basin area.

The river basins of the northeast have long histories of human occupation, with archaeological evidence at some locations dating back at least 11,000 to 12,000 years. In more recent times, the rivers played important roles in the European colonization of North America and the establishment of the United States. The basins were dominant features

in 10 of the original 13 English colonies, and they contributed vast quantities of lumber, minerals, fish, agricultural products, and power for both local consumption and export. The rivers themselves served as economic, transportation, and communication conduits, and early settlers established such cities as Boston, New York, Philadelphia, and Baltimore on sites where there were natural ports and river access. Although urban, suburban, and industrial development have had major impacts on the streams and rivers in the northeast, agriculture, silviculture, mining, dams and diversions, and nonnative species have also significantly affected the quality and quantity of these freshwater systems.

There are six large river basins (>20,000 km²) in the Atlantic U.S.–Northeast region: Penobscot, Connecticut, Hudson, Delaware, Susquehanna, and Potomac. Several smaller river basins (7000 to 15,000 km²) also occur (e.g., Kennebec, Merrimack, Androscoggin, and Rappahannock), as well as numerous coastal and bay streams and rivers

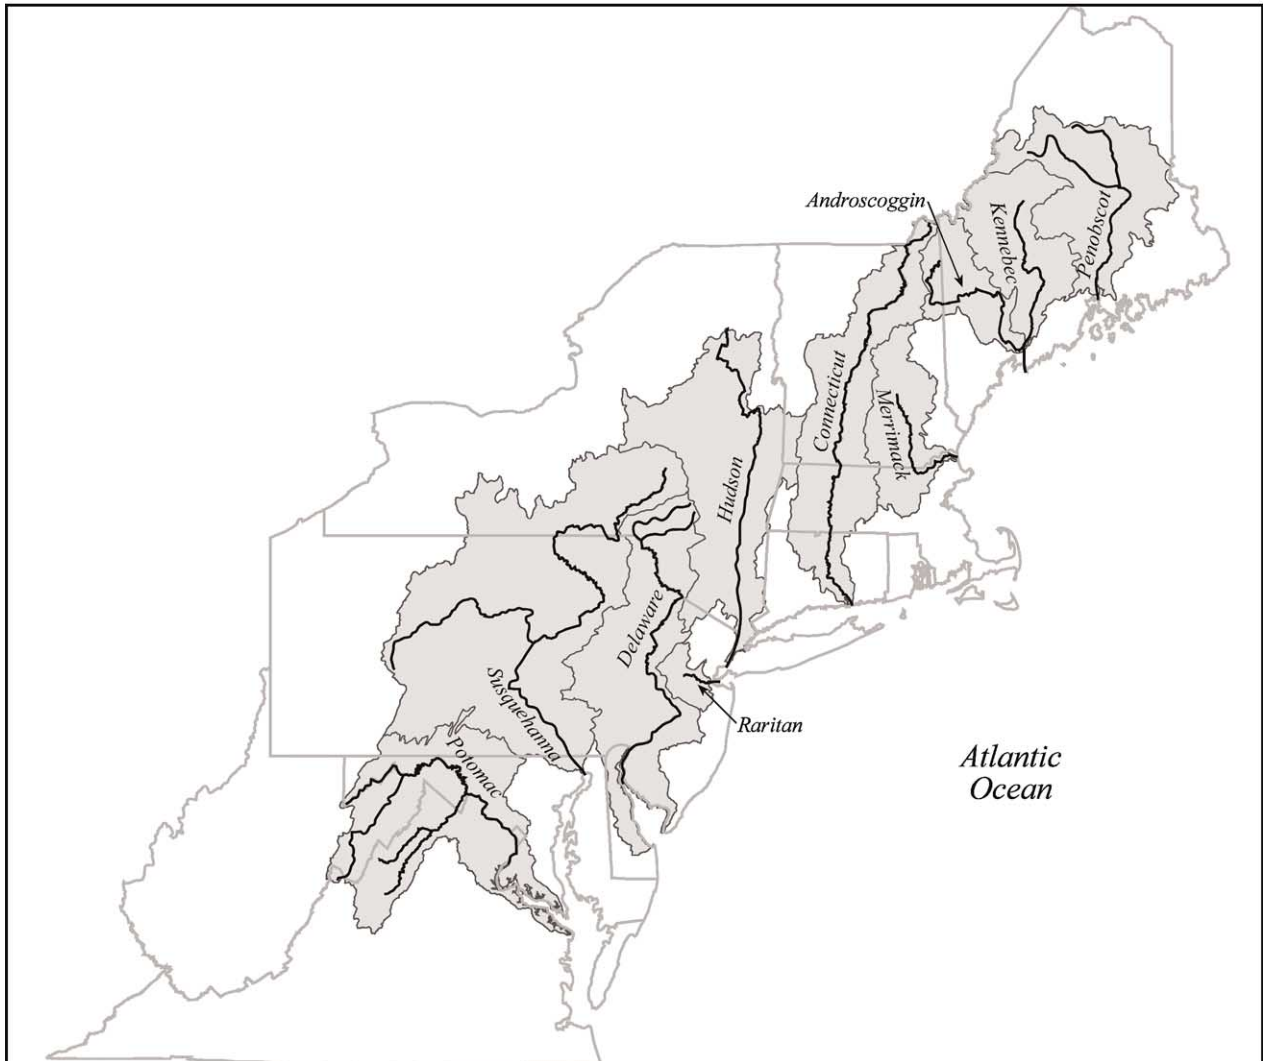

FIGURE 2.2 Atlantic coast rivers of the northeastern United States that are covered in this chapter.

(<5000 km²) (e.g., Saco, St. Croix, Housatonic, Raritan, Mullica, Choptank, and Patuxent). The largest river in the region is the Susquehanna, which is the 22nd largest river in North America that flows to the sea and the 3rd largest in North America that flows into the Atlantic Ocean (after the St. Lawrence and Churchill [Labrador]; Leopold 1994). The Hudson River is one of the most intensively studied rivers in North America, making it one of the best examples to illustrate the physical, chemical, and biological complexity characteristic of large river basins. This chapter addresses in detail five large river basins: the Penobscot, Connecticut, Hudson, Delaware, and Susquehanna. It also provides brief summaries of the physical and biological characteristics of the

Kennebec, Androscoggin, Merrimack, Raritan, and Potomac rivers.

Physiography and Climate

The Atlantic drainage of the northeastern United States is physiographically and climatically diverse. The Appalachian Mountains form the western border of the region and include such well-known ranges as the White Mountains in New Hampshire, the Green Mountains in Vermont, the Catskill Mountains in New York, and the Allegheny Mountains in Pennsylvania and West Virginia. Elevations in the mountains and uplands are frequently 600 to

800 m asl, with peaks reaching 1100 to >1600 m asl. Conditions in the northern mountain ranges of Maine, New Hampshire, and Vermont contrast markedly with those in the flat coastal plain that lies near sea level in Virginia, Maryland, and Delaware. The northern topography is the result of repeated cycles of uplifting and erosion as continental glaciers eroded soils and bedrock and then redeposited them as thin mantles and valley fill. The southern portion did not experience such “smoothing” processes.

The region has seven physiographic provinces (Hunt 1974, Olcott 1995, Trapp and Horn 1997). Three (Appalachian Plateau, New England, and Adirondack) predominate in the northern portion, although limited portions of the Valley and Ridge, Piedmont Plateau, and Coastal Plain also extend up from the south. Four physiographic provinces (Appalachian Plateau, Valley and Ridge, Piedmont, Coastal Plain) dominate the southern portion, although limited portions of the Blue Ridge from the south and the New England province from the north are also found. The northernmost basins originate in the mountains and highlands of the New England province and reach the ocean without entering another physiographic province. In contrast, the southernmost basins originate in the mountains and highlands of the Appalachian Plateau and Valley and Ridge, cross the Piedmont, and end in the Coastal Plain.

The soils and underlying rocks vary greatly across the region (Cuff et al. 1989, Olcott 1995, Trapp and Horn 1997). Sedimentary rocks (e.g., sandstone, shale, carbonate rocks, and in some areas coal) are widespread, especially in the southern portion of the region, whereas metamorphic and igneous rocks (e.g., granite, gneiss, mica schist, slate) are common in the northern portion of the region. There are four common soil orders in the region. Spodosols are mature, acidic soils that are important in the northern basins. Ultisols and alfisols are also mature soils that are often characteristic of the Valley and Ridge, Piedmont Plateau, and Coastal Plain in the southern portion of the region (e.g., Delaware, Susquehanna, and Potomac rivers). Ultisols are thoroughly leached of bases and have low fertility, whereas alfisols have moderate to high levels of bases and are more fertile than spodosols or alfisols. Inceptisols are immature soils (erosion or glaciation have inhibited soil maturation) that do not show horizons and are common in upper portions of the Delaware, Susquehanna, and Potomac rivers.

Mean annual precipitation is generally 100 to 125 cm but can range from 90 to >180 cm (Cuff

et al. 1989, Olcott 1995, Trapp and Horn 1997). Although precipitation is abundant throughout the year, its peaks are historically in July to September and are generally associated with tropical storms. Total precipitation tends to be greatest at higher elevations and near the coast. Snowfall occurs throughout the region, but it is far more common in the north and at higher elevations.

This region typically has cold winters and warm summers. Mean annual temperature ranges from 3°C to 13°C. Temperature is colder at higher elevations and further north, and warmer in coastal areas and further south. Coastal areas also tend to experience less variation in temperature than areas further inland.

Basin Landscape and Land Use

There are 10 terrestrial ecoregions in the Atlantic U.S.–Northeast region (Ricketts et al. 1999). The predominant ecoregions are New England/Acadian Forests in the New England province, Northeastern Coastal Forests in the New England province and Piedmont Plateau, Eastern Forest/Boreal Transition in the Adirondack province, Allegheny Highlands Forests in the Appalachian Plateau, and Appalachian/Blue Ridge Forests in the Valley and Ridge. Additional ecoregions include the Eastern Great Lakes Lowland Forests and Appalachian Mixed Mesophytic Forests in the Appalachian Plateau, Southeastern Mixed Forests in the Piedmont Plateau and Coastal Plain, and Atlantic Coastal Pine Barrens and Midatlantic Coastal Forests in the Coastal Plain. Although most of these ecoregions are in the Temperate Deciduous Forest biome, the Eastern Forest/Boreal Transition ecoregion in the Adirondacks and the New England/Acadian Forests ecoregion are partially in the Boreal Forest biome.

Forests were the predominant precolonial land cover in the Atlantic U.S.–Northeast region, although there is evidence that open areas were maintained by fires set by Native Americans and by periodic blow-downs. Forest types vary with latitude and elevation (Braun 1950, Cuff et al. 1989, Ricketts et al. 1999). Appalachian oak forests predominate in the south, northern hardwood forests in the north. Appalachian oak forests commonly contain several oak species, sugar maple, sweet birch, American beech, tulip poplar, and pines. American chestnut, which was common before the blight in the early twentieth century, has since been replaced by hickory. The relative abundance of these species varies among ecoregions.

The transition from Appalachian oak forest to northern hardwood forest occurs in northern Pennsylvania and southern New York (and further north along the coast), and it corresponds in part with the southern limits of glaciation. Characteristic northern hardwood forests include sugar maple, yellow birch, American beech, and eastern hemlock, as well as eastern white pine and red pine. Red spruce and balsam fir become more abundant further north and at higher elevations. White pine and hemlock, which were harvested intensively in the 1800s and early 1900s, were often replaced by hardwood species during reforestation.

The primary forests in the region were harvested 100 to 300 years ago, except in small isolated locations. Some areas have undergone complex evolutions: from forest to farmland or population center, later abandoned and reforested, and finally deforested once again for suburban development. Forests currently represent about 60% of the land cover in most basins in the region, although they are rarely evenly distributed within the basins. For example, forests are often more abundant in areas with steep slopes, whereas agricultural uses and population centers dominate lower gradient areas. Agriculture remains an important feature in the region. Farms tend to be small (0.4 to 0.8 km²) and have a wide range of products compared with farms in other parts of the United States. Dairy, meat, and poultry production and forage crops that support these industries are common, as are vegetable (beans and peas, bell peppers, squash, and tomatoes) and fruit (apples, grapes, peaches, and pears) crops. Whereas forests and agriculture are the predominant land use in the northeastern river basins, industrial, urban, and suburban development continues to expand into agricultural and forested areas. This has connected many of the old colonial cities to form the “northeastern megalopolis,” a giant urban zone that extends from Washington, D.C., to Boston and includes 43 million people.

The Rivers

Rivers in the Atlantic U.S.–Northeast region are in either the Chesapeake Bay freshwater ecoregion (which also includes some rivers in the Atlantic U.S.–Southeast region) or the North Atlantic freshwater ecoregion (Abell et al. 2000). The Chesapeake drainages include the Potomac and Susquehanna rivers and numerous smaller drainages on the eastern and western shores of the Chesapeake Bay. The aquatic fauna of the Chesapeake Bay freshwater

ecoregion is classified as Continentally Outstanding, with 95 native fish species (two endemic), 14 crayfish species, and 22 unionid mussel species (four endemic). The North Atlantic freshwater ecoregion consists of the drainages from the Delaware Bay north to the Penobscot River in Maine. Its aquatic fauna is classified as Nationally Important, with 98 native fish species (two endemic), 9 crayfish species, and 12 unionid mussel species. Neither of these regions has the degree of biological distinctiveness that characterizes the South Atlantic and Florida ecoregions. This difference probably reflects a number of factors, including extinction associated with glaciation in the northern basins. Although land and marine barriers now separate the coastal basins, millennia of stream migration and capture as well as interbasin connections and dispersal from common refugia during glaciation have contributed to similarities among faunas.

Physicochemical characteristics vary greatly among the rivers. Some are soft, circumneutral, and nutrient poor, and others are hard, alkaline, and nutrient rich. Some are warmwater fisheries, whereas others contain elements of both coldwater and warmwater fisheries. It appears that evapotranspiration is the major factor responsible for the seasonal pattern in runoff. Snowmelt contributes to seasonal variation in discharge in some rivers, whereas others show little or no effect from snowmelt. Variation, reflecting such factors as differences in elevation, river gradient, physiography and geology among branches and tributaries, and proximity to the coast, can also be observed within a basin. Daily tides influence significant portions of the lower reaches of most of these rivers, coming as far as 174 km up the Potomac, 248 km up the Hudson, and 110 km up the Delaware. Much of the tidal portion of the Susquehanna River, however, is “officially” part of the Chesapeake Bay (which is 320 km long), and only 11 km of the Susquehanna is considered tidal. The tidal areas are primarily freshwater, and tidal flows shape channel morphology and determine local flow and related physicochemical conditions. Open access to the sea allows marine animals to enter the rivers, which affects biodiversity and ecosystem function.

Great migratory fish runs, on a par with the better known migrations along the Pacific coast of North America, were once a distinguishing characteristic of the region’s rivers. Many millions of anadromous American shad, hickory shad, alewife, blueback herring, striped bass, and Atlantic salmon returned each year to spawn in the rivers and their estuaries. Conversely, catadromous American eels migrated

FIGURE 2.3 Total catch of American shad for the U.S. Atlantic coast (i.e., Florida to Maine). Totals should be considered minima. Years with zero catch either had no data or missing data from several states (Atlantic States Marine Fisheries Commission 1985).

from the coastal streams and rivers to spawn in the Sargasso Sea. These large fish migrations were important to the economies of both Native Americans and European settlers. As late as the 1890s, after changes in these basins had presumably begun to affect fish migrations, annual harvests of American shad along the U.S. Atlantic coast were still 12 to 23 million kg or 6 to 13 million fish (Fig. 2.3), and harvests of alewife and blueback herring were similar (13 to 28 million kg or 72 to 148 million fish per year). Unfortunately, dams, pollution, and overfishing decimated most of these annual fish runs long before scientific studies could evaluate their ecological significance, and it has been many years since migratory fish have played a major role in the economy and ecology of this region. With both the public and the rivers themselves disconnected from the once magnificent fish runs, efforts are now being made throughout the region to restore the fisheries and reestablish the connection.

The rivers and their basins in the Atlantic U.S.–Northeast region have been modified significantly over their long histories. Trees have been cut; coal and other minerals mined; land tilled and fertilized; fish harvested; river channels dammed, diverted, and dredged; and waterways polluted with waste from industries, farms, and people. In addition, a wide variety of terrestrial species (e.g., chestnut blight, Dutch elm disease, gypsy moth) and aquatic species (plants, mollusks, and fish) have been introduced to the region. Although the direct and indirect effects of introducing these species are generally unproven, their presence is obvious: Chestnut trees are absent from all basins, nonnative species dominate the region’s sport fisheries, and pestiferous zebra mussels have visibly modified the Hudson River.

None of these river basins is considered even close to pristine, but their water quality has improved significantly in the last 50 to 100 years. If current local and national efforts continue this trend, the rivers should be able to provide appropriate water resources for recreation, drinking, fishing, agriculture, manufacturing, and shipping far into the future.

PENOBSCOT RIVER

The Penobscot River arises in western Maine at latitude 46°N (Fig. 2.20). Its drainage (22,253 km²) covers more than a quarter of the state and contains 11,470 stream and river km, 1604 streams (including 188 named streams), and 1224 lakes and ponds (Houtman 1993, PNWRP 2001). Along its southeasterly path, from the border of Quebec to the Gulf of Maine, the Penobscot River cascades through rugged gorges and meanders through tranquil chains of lakes. The western mountains of Maine provide spectacular scenery for this river basin, particularly in the region of the Katahdin massif.

The Penobscot River is the ancestral home of the Penobscot Indian Nation, a tribe once dependent on the river for sustenance and cultural identity (PNWRP 2001). They are Eastern Abenaki—members of the Eastern Algonquian language group (Snow 1978). European exploration of the lower Penobscot River began early in the seventeenth century. Nevertheless, the basin was still largely unpopulated by Europeans as late as 1800. At this time a rapid increase in demand for timber resulted in significant colonization of the Maine forests by Anglo-Americans. By 1840 most of the river valley

had a population density of 4 to 19 people/km² (Judd et al. 1995), which is comparable to today.

Physiography, Climate, and Land Use

The Penobscot River basin is in the New England (NE) physiographic province (see Fig. 2.20). The upper basin is mountainous with peaks rising above 1500m asl. The topography of the lower basin is subtler, being covered by a layer of glacial till that is shaped into ribbed moraines, terraces, and spectacular eskers. Glaciomarine clay covers areas lower than 90m asl. This results in a poorly drained landscape supporting an exceptional richness of wetlands (PNWRP 2001). The topography of the basin began to take shape as glaciers receded from the coast about 13,000 years ago. Since this time the Penobscot River has down cut through till and glaciomarine deposits to produce a channel characterized by extensive bedrock-based waterfalls and rapids that are locally known as “ledge” (Penobscot River Study Team 1972).

The average precipitation for the river basin is 107 cm/yr, including snowfall (240 cm/yr). The maximum monthly precipitation (10 cm) occurs in June and the minimum (6 cm) occurs in February (see Fig. 2.21). Precipitation is greatest in the lower basin. The highest values (~125 cm/yr) have been measured near the Penobscot Bay, whereas the western interior of the basin receives the lowest precipitation (~90 cm/yr; Barrows and Babb 1912). Average air temperature in the lower basin is 9.5°C. The maximum mean temperature (19.6°C) occurs in July and the minimum (-10.1°C) occurs in January.

Despite two centuries of intensive logging (Houtman 1993), the Penobscot River basin remains heavily forested (95% forest and wetland). The upper catchment (New England/Acadian Forests ecoregion) is mantled with spruce–fir (primarily red spruce, white spruce, eastern hemlock, balsam fir). The lower catchment (Northeastern Coastal Forests ecoregion; Ricketts et al. 1999) is a mosaic of spruce–fir, pine (red pine, eastern white pine), and maple–beech–birch stands (silver maple, red maple, American beech, paper birch, gray birch). Acidic bogs and peatlands and mineral-rich swamps and marshes cover almost a third of the basin (Barrows and Babb 1912, Houtman 1993). A small proportion of land cover (5%) consists of farms (hay, potatoes), wood lots, and small urban centers (Houtman 1993). Human density of the basin is sparse, averaging about 8 people/km². Bangor, the largest urban center within the drainage, has a population of 33,000.

River Geomorphology, Hydrology, and Chemistry

The Penobscot River is about 320 km long and begins its flow to the Penobscot Bay at about 500m asl. Its main channel can be divided into four geomorphic segments: mountainous upland, island/bar, rapids/terrace, and estuary (PNWRP 2001). The mountainous upland segment contains the East and West Branches. Their headwaters are separated from the St. John and Kennebec river drainages by extremely low divides. This has resulted in major diversions of flow to and from the Penobscot drainage in both prehistoric and historic times. Moosehead Lake, which now empties into the Kennebec River drainage, emptied into the West Branch of the Penobscot more than 8000 years ago. Its waters were diverted into the Kennebec River due to a slight tilting of the landscape that resulted from isostatic adjustment following deglaciation. The Telos Canal, constructed around 1840 to facilitate the transportation of timber, diverted water from the St. John drainage into the East Branch and increased the effective Penobscot River basin by 3% (~700 km²; Barrows and Babb 1912).

The main stem of the river is formed by the confluence of the West and East Branches and flows for about 158 km. This portion of the river channel contains the island/bar, rapids/terrace, and estuary segments. The island/bar segment is the most extensive, occupying about 80 km of channel (Fig. 2.4). There are more than 119 islands (0.4 ha or more in size), representing a combined area of 1791 ha (Baum 1983). Between the island/bar segment and the estuary is a short (13 km) rapids/terrace segment that is characterized by numerous bedrock-based rapids. The word *Penobscot* translates to “at the place of the descending rocks” and refers specifically to this reach of the river (PNWRP 2001). The rapids/terrace unit terminates near Bangor, where the river becomes tidally influenced. At this point the main channel is greater than 300m wide. A classic salt-wedge estuary occupies the final 50 km of the main stem before it empties into the Penobscot Bay (Baum 1983, Moore and Platt 1996).

The average annual discharge of the Penobscot River near the point of tidal influence is 402 m³/s. The greatest discharge on record (4502 m³/s) was measured in April 1987; the lowest (79 m³/s) was measured the following September (Houtman 1993). Although precipitation is distributed relatively uniformly over the year, the pattern of discharge is strongly seasonal (see Fig. 2.21) due to winter snow

FIGURE 2.4 Penobscot River at Five Islands Rapids, below Mattawamkeag, Maine (PHOTO BY TIM PALMER).

and ice accumulation and high rates of evapotranspiration during summer (Barrows and Babb 1912). The Penobscot River is usually ice covered from late December to March. Average runoff is about 5 cm/mo (63 cm/yr) (59% of annual precipitation); about 44 cm/yr is lost through evapotranspiration. The highest monthly discharge typically occurs in April, whereas the lowest occurs in September (see Fig. 2.21).

There are currently 116 licensed dams in the Penobscot River basin. These are used for power generation and water-level control (PNWRP 2001). An analysis of discharge records at West Enfield (93 km upstream of the Penobscot Bay) indicates that the natural runoff during April to June and November to December has been reduced by 21% to 27% due to storage. The runoff for January to March and July to October has been increased by 26% to 33% by release of stored water (Penobscot River Study Team 1972).

The Penobscot River is slightly acidic (average pH = 6.6), moderately buffered (mean hardness = 12 mg/L as CaCO₃ equivalents), and relatively oligotrophic. Total dissolved nitrogen ranges from 0.15

to 2.60 mg N/L (average = 0.45 mg N/L), total dissolved phosphorus ranges from 0.01 to 0.16 mg P/L (average = 0.03 mg P/L), and total organic carbon ranges from 5.2 to 16.0 mg C/L (average = 9.5 mg C/L). The water temperature ranges from about 0°C in February to 22°C in July, with an annual mean of 9.3°C (<http://water.usgs.gov>).

River Biodiversity and Ecology

The Penobscot River is in the North Atlantic freshwater ecoregion. Much is known about macroinvertebrate assemblages because of their use in biomonitoring (Davies et al. 1999, PNWRP 2001) and recent concern about the conservation of freshwater mussels (e.g., Nedeau et al. 2000). There is also much known about fisheries biology due to efforts to manage populations of diadromous fishes (Cutting 1963, Baum 1983).

Plants

Red maple, silver maple, and black ash are major trees species, and tussock sedge is a major grass

species of seasonally flooded bottomlands. Other common riparian trees are chokecherry, paper birch, gray birch, quaking aspen, tamarack, northern white cedar, and balsam fir. Although American elm is in serious decline, saplings can be numerous. In shallow river reaches with soft sediment, floating-leaf pondweed and bur-reed are important habitat for black fly larvae. The pond-lily and broadleaf arrowhead are abundant in backwaters. Riverweed, listed as threatened in Maine, occurs in a few rocky shoals and rapids.

Invertebrates

Rabeni and Gibbs (1980) conducted the first comprehensive study of benthic invertebrate assemblages of the Penobscot River. They used artificial samplers (rock baskets) and SCUBA to quantify macroinvertebrates from 33 locations along 100 km of the river and two of its major tributaries. Habitats with stony substrata and current velocities >11 cm/s had communities represented by caddisflies (*Brachycentrus*, *Cheumatopsyche*, *Chimarra*, *Helicopsyche*, *Hydropsyche*, *Ithytrichia*, *Macrostemum*, *Neureclipsis*, *Oecetis*), stoneflies (*Agneta*), mayflies (*Eurylophella*, *Serratella*, *Stenonema*, *Isonychia*, *Baetidae*), and dragonflies (*Neurocordulia*). Macroinvertebrate richness in other habitats was lower. Dragonflies (*Boyeria*) and stoneflies (*Acroneturia*) characterized habitats with stony substrata and current velocities <5 cm/s. Habitats with moderate levels of silt and current velocities of 5–11 cm/s were inhabited by mayflies (*Drunella*, *Stenonema*, *Tricorythodes*), riffle beetles (*Stenelmis*), hydrobiid snails (*Amnicola*), and turbellarians. Habitats with silt substrata and current velocities <5 cm/s were characterized by mayflies (*Eurylophella*, *Stenonema*, *Leptophlebia*, *Paraleptophlebia*), caddisflies (*Nyctiophylax*, *Polycentropus*), aquatic earthworms (Tubificidae), fingernail clams (*Musculium*), leeches (*Helobdella*), isopods (*Asellus*), and amphipods (*Hyallela*). Macroinvertebrate assemblages in highly polluted reaches below pulp mills had high proportions of aquatic earthworms and chironomid midges.

Ten species of freshwater mussels are known in Maine (Nedeau et al. 2000). All occur in the Penobscot River. The most widespread are the eastern elliptio, triangle floater, eastern floater, and eastern lampmussel. These have been recorded from ten or more locations. The creeper, brook floater, and yellow lampmussel occur at six or more locations. The latter three species are of particular conservation concern in Maine and throughout New England (Nedeau et al. 2000).

Vertebrates

Forty-five species of freshwater and 39 species of marine fishes have been recorded from the Penobscot River basin (Baum 1983). Thirty-one freshwater species are permanent residents. Eighteen are either obligatorily or facultatively diadromous, and thus use marine habitats for some part of their life cycle. The assemblage of permanent residents inhabiting the main stem of the river is relatively small and is composed of a handful of warmwater species.

The top predators are the smallmouth bass, a warmwater predator in both riverine and lacustrine habitats, and the chain pickerel, restricted to large pools and impoundments. Other abundant piscivores are the white perch, which is facultatively anadromous, and yellow perch. Abundant invertivores include the creek chub, fallfish, and redbreast and pumpkinseed sunfishes. Omnivores include the brown bullhead, white sucker, and common shiner (FERC 1997). Coldwater species include the piscivorous burbot, restricted to deep pools and impoundments, and the salmonids. Nonmigratory salmonids are scarce in the main stem, however, and resident populations are apparently not sustainable. Brook trout are numerous in smaller tributaries and only occasionally enter the main stem.

The American eel is the only catadromous fish species in the Penobscot River. They are abundant in impoundments and backwaters. Eels are able to travel more than 200 km upstream of the Penobscot Bay. To achieve this they must pass through 11 major hydroelectric projects (FERC 1997). Of 17 anadromous fish species, alewife, American shad, and Atlantic salmon are perhaps best known. Prior to European occupation, millions of alewife migrated as far as 320 km upriver each year (Baum 1983). The current run, however, has been reduced by three orders of magnitude (FERC 1997). American shad were also historically abundant, with 2 million adults running more than 270 km up the river prior to 1800 (Moore and Platt 1996). The current population is probably less than several thousand individuals (PNWRP 2001). Returning Atlantic salmon once penetrated 230 km up the Penobscot River (Moore and Platt 1996). Early in the nineteenth century, 40,000 to 75,000 fish returned each year (Baum 1983). As settlement and development of the basin intensified, populations declined catastrophically. By 1960 Atlantic salmon were extirpated, presumably due to a decline in water quality as the Penobscot basin was industrialized (Cutting 1963, Baum 1983; Fig. 2.5). Atlantic salmon have since been reestab-

FIGURE 2.5 Atlantic salmon harvest by angling below the Veazie Dam (~43 km upstream of the Penobscot Bay) from 1893 through 1963 (Cutting 1963).

lished (Baum 1983, PNWRP 2001). Since 1990, annual returns of 2000 to 4000 adult fish have occurred regularly, and natural spawning occurs as far as 100 km upstream (Moore and Platt 1996; PNWRP 2001). Nevertheless, 6000 to 10,000 spawning salmon are required for a sustainable population. The survival of this Atlantic salmon population thus depends on a hatchery program (Baum 1983, Moore and Platt 1996).

A diverse assemblage of aquatic and riparian reptiles, birds, and mammals are associated with the Penobscot River. The snapping turtle and the eastern painted turtle are both common. Wood ducks, goldeneyes, and black ducks nest along the main stem. Black ducks, greater scaup, and goldeneyes overwinter in the lower river, and common eiders and surf scoters overwinter in the estuary. Canada geese are common during spring migration (Penobscot Study Group 1972). Bald eagles forage along the main stem during winter and nest in the riparian zone during spring and summer (FERC 1997). Muskrat, beaver, mink, and river otter are common throughout the central and lower drainage. Harbor seals frequent the estuary and pilot whales have appeared as far as 20 km upstream of the Penobscot Bay.

Ecosystem Processes

Like most large rivers, little is known about ecosystem processes in the Penobscot River. Nevertheless, several generalizations can be made. First, the enormous area of wetland moderates fluctuations in river discharge. This results in a highly predictable annual flood pulse. Although numerous dams punctuate the river, its flow is only moderately regulated because these dams tend to be “run-of-the-river.” The natural flow regime of the main stem of the

Penobscot River is thus at least nominally intact and the spring flood pulse maintains numerous riparian swamps and wetlands. Second, the acidic, peat-laden soils of the wetlands result in river water that is poor in nutrients but rich in dissolved organic matter. Low nutrient concentrations and low light penetration due to highly stained water indicate that primary production should be low. Production by microbial and animal communities in this river system is thus probably based upon terrestrial carbon. Nevertheless, primary production is probably significant in the shallow rapids and shoals that have not yet been affected by dams.

Special Features and Human Impacts

Baxter State Park protects >800 km² of the upper Penobscot River basin and contains Mt. Katahdin, an important alpine habitat in New England. Henry David Thoreau popularized the Baxter area in *The Maine Woods* (Thoreau 1864). Sunkhaze National Wildlife Refuge, in the lower basin, encloses one of the largest peat bogs in Maine and protects a further 40 km² of land. The Penobscot Indian reservation includes all the islands of the 80 km island/bar segment of the Penobscot River. The Penobscot Indian Nation has continuously occupied these islands for thousands of years.

Following 1800, perhaps the most obvious human impact on the Penobscot River ecosystem is the near extirpation of what were once enormous runs of anadromous fish. This is attributed to dams that obstruct movements of fish, the introduction and establishment of warmwater fish species, and a long legacy of habitat destruction and pollution associated primarily with timber extraction and processing.

The first major dam was constructed near Old Town (~56 km from the Penobscot Bay) during the 1820s; the last was constructed at Mattawamkeag Town (~134 km from the Penobscot Bay) in 1939 (Cutting 1963, Baum 1983). There are currently five dams that span the main stem of the river. Although all of these have functional fishways, this was not always the case. The first fishways were constructed around 1879, almost half a century after the first dam effectively stopped upstream migration of fish 50 to 60 km upstream of the Penobscot Bay. A complex of 21 major dams on the West Branch of the Penobscot, which arguably comprise the largest privately owned hydroelectric development in the United States (Moore and Platt 1996), is notable in that there currently are no fishways. These dams have stopped

movement of anadromous fishes into a major portion of the drainage (PNWRP 2001).

The Penobscot River has a rich history of introductions of both salmonids and warmwater gamefish. Some of these were successful, most were not. The first was the chain pickerel, introduced in 1819. The smallmouth bass was introduced in 1869. Both are now abundant and important predators of and competitors with Atlantic salmon. The emerald shiner, a warmwater forage fish, was introduced more recently (Baum 1983), apparently as “bucket bait.” From 1874 through 1950, coho salmon, steelhead and rainbow trout, pink salmon, brown trout, and grayling were introduced on one or more occasions. With the exception of the brown trout, which remains as a small population in streams entering the estuary, all introductions of salmonids have failed (Baum 1983).

The Penobscot River was the center of what was arguably the largest basin-specific timber industry in North America. Significant logging had begun by 1815 (Cutting 1963). By 1851 Bangor held the world's record for lumber exports (Cutting 1963). Old-growth timber was virtually exhausted by about 1880, and the timber industry focused on pulp production (Cutting 1963). When the log drives ended in the mid 1960s, over two trillion board feet of lumber (4.8 billion m³) had been floated down the river (Cayford and Scott 1964). Between 10% and 15% of all logs driven downriver sank (“sinkers”) and remain buried in the sediments of impoundments and low gradient river segments. In addition, a century of intensive sawmill operation contributed a layer of bark and sawdust that exceeds 60cm in places over the bottom of the estuary. This deposit is apparently trapped by the circulating flow of the estuary (Moore and Platt 1996).

Prior to 1960 wastewater from pulp and paper mills, municipalities, and miscellaneous industries resulted in poor water quality throughout most of the main stem. The decomposition of these wastes resulted in extremely low concentrations of dissolved oxygen, and much of this material was contaminated with dioxin and PCBs (Davies et al. 1999). Although severely polluted throughout much of the twentieth century, the water quality of the Penobscot River has shown astonishing improvement since 1975 (Rabeni et al. 1985, Davies et al. 1999). Nevertheless, water-quality issues remain. Major sources of continuing pollution include wastewater from five pulp and paper mills and ten municipal water treatment plants, fish hatcheries, miscellaneous industrial waste discharges, combined sewer overflows, a contaminated

woolen mill, and a host of nonpoint sources dominated by timber harvesting and agriculture (Davies et al. 1999). Tissues from fish sampled during 1999 from locations below pulp and paper mills had dioxin and PCB levels exceeding statutory limits for human consumption (PNWRP 2001).

Perhaps the best integrative measure of the legacy of human impact on the Penobscot River ecosystem is the change in its carrying capacity for Atlantic salmon from first European settlement to the present. The Penobscot River and its tributaries currently provide good water quality and excellent salmonid spawning and nursery habitat (Baum 1983, Davies et al. 1999). Although the total area of this habitat is substantive, when compared with other New England rivers, conservative estimates of the present carrying capacity for Atlantic salmon is only about 6000 to 9000 returning adults (Baum 1983). This is a large decrease compared with estimates of 40,000 to 75,000 returning adults prior to European colonization (Baum 1983). Although these statistics require many assumptions, the apparent order of magnitude decrease in carrying capacity from 1780 to the present indicates the magnitude of structural and functional changes to the Penobscot River ecosystem that have occurred since colonial times. Perhaps the most significant and obvious of these changes was the introduction of warmwater game fish, which act as competitors and predators of Atlantic salmon, and the loss of about 30% of excellent salmon habitat due to channel obstruction and impoundment (Baum 1983).

CONNECTICUT RIVER

The Connecticut River drains the largest watershed in New England and, at 660 km, is its longest river (see Fig. 2.2). Originating as a group of ponds (First to Fourth Connecticut Lakes) in the northern highlands of New Hampshire and Quebec, the river flows southerly through a valley bordered by the two major mountain ranges of New England, the Green and White mountains (Fig. 2.22). Further south, it traverses central Massachusetts and through the coastal plain of Connecticut into Long Island Sound. The drainage encompasses 29,160 km². Beginning at an elevation of 568 m asl at Third Connecticut Lake, the river descends rapidly in its first 150 km to an elevation of about 210 m asl at Fifteen Mile Falls near Lancaster, New Hampshire. Thereafter, the descent is more gradual and the natural channel begins to meander (Fig. 2.6). The final 90 km upstream of Long

FIGURE 2.6 Connecticut River near White River Junction, Vermont. White River at upper right (PHOTO BY TIM PALMER).

Island Sound is a tidal estuary that gave the Connecticut its Native American name, “Quinni-tukqut” or “Quoneh-ta-cut,” meaning “long tidal river” (Bacon 1906).

There is evidence that the Connecticut River valley was first colonized by Native Americans about 9000 years ago following the retreat of the last glacier. These peoples hunted the megafauna (e.g., mastodon, giant beaver, dire wolf) that inhabited the valley. As those animals disappeared, greater focus was given to the fish and wetland vegetation provided by the river as a food source. The Pequot tribe occupied the lower tidal area of the river, whereas the Mohegan tribe occupied the upper watershed. These peoples also introduced the first agriculture, growing corn, beans, squash, sunflowers, and tobacco (Hauptman and Wherry 1993). In 1614, the Dutch explorer Adriaen Block was the first European to discover the river. Settlement along the river began in 1633 by members of the Plymouth Colony. The rich farmland along the river, coupled with a convenient transportation corridor afforded by the river, led to rapid settlement in the valley. Waterpower provided

by the river allowed early industrialization and by the late 1800s towns along the river had attained prominence in the manufacturing of a variety of goods (Hard 1947).

Physiography, Climate, and Land Use

The Connecticut Valley basin is located within the New England (NE) physiographic province. The basin developed as part of a rift system during the formation of the Atlantic Ocean. The Eastern Border Fault defines the eastern edge of the basin south from Keene, New Hampshire. Beginning over 200 million years ago, rivers deposited gravel to form alluvial fans along the west face of this fault system, and lakes formed repeatedly in the valley as the basin expanded. By the end of the Mesozoic era, erosion and sediment deposition created a large flat plain (Olsen et al. 1989).

Two prominent events in the Cenozoic era shaped the Connecticut Valley: uplift and glaciation. The former plain was uplifted, resulting in extensive erosion and valley development. Continental glaciers

further eroded the valley by excavating bedrock to depths below the present land surface. In low-lying areas, glacial-fluvial, glacial-lacustrine, or glacial-marine sediments were deposited after ice recession. During the Pleistocene, the Connecticut valley was occupied by glacial lakes. The last glacier reached its maximum extent about 20,000 years ago. When the face of the glacier receded to the area of Rocky Hill, Connecticut, deposits blocked the valley, forming a dam that collected meltwater to form a great glacial lake, Lake Hitchcock. At its maximum extent, Glacial Lake Hitchcock extended to an area near St. Johnsbury, Vermont, approximately 320 km. The lake drained about 14,000 years ago. The Connecticut River returned to its valley and began to erode the Hitchcock sediments. The river has left abandoned channels (oxbow lakes) in many areas, floodplains, and where the land was resistant to erosion, narrow valley segments formed with waterfalls and rapids. The lacustrine deposits of Lake Hitchcock created the fertile agricultural soils that later attracted human settlement of the valley.

The river originates in the New England/Acadian Forests ecoregion (Ricketts et al. 1999), a transition area of boreal forest biome in the north to temperate deciduous forest biome in the south, with considerable vertical zonation. The river drains south into the Northeastern Coastal Forests ecoregion. This ecoregion is characterized by a flat gradient. Forests are predominantly hardwood, with red and white oak, sugar maple, beech, and eastern hemlock.

The climate of the Connecticut River watershed is temperate and humid. The mean annual precipitation of about 109 cm is distributed relatively uniformly throughout the year (Fig. 2.23) but ranges from 107 cm at the northern end of the valley to 204 cm in adjacent mountain areas (Garabedian et al. 1998). Mean annual air temperature ranges from 3°C to 10°C in the upper watershed area, with tropical air masses influencing summer weather and polar air masses influencing winter weather. Frozen conditions may persist for four to five months and snow accumulation exceeds 250 cm (Bailey 1980). In the lower watershed, mean annual temperature ranges from 5°C to 13°C, with more humid conditions and oceanic influence. Mean monthly temperatures range from 23.1°C in July to -2.0°C in January (see Fig. 2.23).

Land use varies considerably, from the heavily forested headwaters to highly urbanized areas. Approximately 80% of the watershed is forested and 11% is in agriculture. The rural headwaters support a wood products and tourist-based economy. The

watershed of southern Vermont and New Hampshire and northern Massachusetts is agriculture based, especially dairy, vegetables, and tobacco. The urban/suburban corridor of the Holyoke–Springfield area of Massachusetts to Hartford, Connecticut, supports about 85% of the estimated 2 million people living within the watershed. The lower estuary is characterized by a more rural landscape of small towns. The population of the lower watershed of the river continues to grow as the river traverses the urban corridor connecting Boston and New York City.

River Geomorphology, Hydrology, and Chemistry

The morphology of the river is remarkably symmetric and dendritic in shape, with no singularly large branches or tributaries. The five largest tributaries (Chicopee, Deerfield, Farmington, Westfield, White) are only from 1295 to 1865 km² in area, each being less than 7% of total watershed area. After flowing out of First Connecticut Lake, the river flows into the first of many impoundments, Lake Francis. It flows freely for about 150 km until it reaches the next impoundment at Moore Reservoir. Bottom substrate is characterized by coarse eroded material of gravel, cobble, and boulder. Thereupon, the river starts to encounter a series of impoundments formed by the many hydroelectric dams on the river. The contour of the river is a series of steps as water passes from one impoundment to another with short sections of flowing rapids below each dam. Each impoundment provides a gradation of substrate types, from coarser gravel and cobble near the head to predominantly sand and finer organic material in the deeper tail segment. The river reaches a final set of free-flowing rapids at Enfield, Connecticut, above the head of tide.

Average discharge at the river mouth is about 445 m³/s. Peak discharge occurs in late winter and early spring despite relatively uniform precipitation throughout the year (see Fig. 2.23). Such a strongly seasonal runoff pattern is apparently caused by seasonal variation in evapotranspiration and snow/ice storage. These peak flows (averaging 690 m³/s) are dampened by storage behind the estimated 125 dams in the drainage. Many of the larger dams are used for power generation and 16 are flood control structures (Merriman and Thorpe 1976, Garabedian et al. 1998). A large portion of the flow of the Chicopee River tributary in Massachusetts is retained in Quabbin Reservoir and diverted as a water supply

for the Boston area, approximately 80 km to the east. The Connecticut River contributes about 70% of the total freshwater inflow of Long Island Sound.

The Connecticut is a soft-water river, low in total ion concentration, and circumneutral. Measurements of water chemistry in the lower river, above tidal influence, have a mean specific conductivity of 116 $\mu\text{S}/\text{cm}$, mean calcium and magnesium concentrations of 11.0 mg/L and 1.7 mg/L, respectively, and mean pH of 7.0. The presence of elevated chloride concentrations indicates the chemistry of the lower river may be substantially altered by human activities (Trench 1996). Patrick (1996) notes an N/P ratio for the lower river indicative of organic pollution that may increase the growth of pollution-tolerant algae species.

River Biodiversity and Ecology

The Connecticut River watershed is placed within the North Atlantic Freshwater ecoregion, Long Island Sound subregion (Abell et al. 2000). With the exception of the work of Merriman and Thorpe (1976) in the lower Connecticut River, there have been no comprehensive studies of the river ecosystem. Merriman and Thorpe provide a detailed analysis of the Connecticut River estuary before and after the start-up of the Connecticut Yankee atomic power facility, including analysis of the composition, movement and migration, recruitment, and mortality of the zooplankton, benthic fauna, and fish populations.

Plants

The lower Connecticut River, beginning near its mouth and continuing upstream for a distance of approximately 58 km, contains one of the least disturbed large-river tidal marsh systems in the United States. From a regional standpoint, there are no other areas in the Northeast that support such extensive, high-quality fresh and brackish tidal wetland systems as the Connecticut River estuary. These tidal river waters and marshes provide essential habitat for a variety of fish and an important nursery. Shallow soft bottom areas of the river are populated with wild celery, with fringing populations of broadleaf arrowhead, water plantain, cattail, and pickerel-weed in the fresh intertidal areas and cord grass in the saline intertidal area (Massengill 1976). The river above the estuary does not provide extensive habitat for the development of macrophyte vegetation with the exception of the oxbows and shallow portions of the many impoundments. A number of nonnative species occur that alter the community composition. These

include common reed, purple loosestrife, Eurasian watermilfoil, water chestnut, and flowering rush (Hellquist 2001).

Invertebrates

The upper river above the impounded portions has not been well studied. This flowing habitat will support communities typified by stoneflies (*Acroneuria*), mayflies (*Eurylophella*, *Serratella*, *Stenonema*), caddisflies (especially filter-feeding forms such as *Brachycentrus*, *Chimarra*, *Hydropsyche*, *Neureclipsis*), and riffle beetles (*Stenelmis*, *Psephenus*). The impounded segments support a community typical of lentic habitats. In the impoundment above Holyoke Dam in the 1970s, Patrick (1996) reports from collections made in the 1970s a community dominated by worms (Tubificidae), caddisflies (*Oecetis*), and chironomid midges (*Chironomus*, *Polypedilum*, *Microtendipes*, *Glyptotendipes*, *Tanytarsus*). Patrick describes a benthic fauna of the river below Holyoke Dam dominated by worms (Tubificidae), snails, pill clams (Pisidiidae), and chironomids. These communities changed following wastewater treatment improvements; however, current data do not exist for this part of the river.

The largest remaining population of the federally listed dwarf wedge mussel in New England is thought to be in the Connecticut River. The Connecticut River has been invaded by the Asiatic clam, but has not been invaded by zebra mussel and may be too soft to support a significant population.

Vertebrates

The most extensive fishery surveys of the river have been made in the lower estuary. Marcy (1976) collected 44 species from 21 families and reported the occurrence of an additional 6 species known to inhabit this area of the river. Ten species were marine and restricted to the brackish portion of the estuary. Ten diadromous species utilize the river for passage, spawning, or nursery habitat. Immature fishes of 28 species were found, indicating the importance of the estuary to fish production.

It is estimated that the nontidal waters of the river support about 64 species (Whitworth 1996, Hartel et al. 2002). Twenty-three species have been introduced, four from outside North America. Like many North American waters, biological composition has been substantially altered by numerous introductions in the watershed. Many fish species that presently dominate the river have been introduced, including brown trout, rainbow trout, common carp, northern pike, bowfin, channel catfish, rock bass, smallmouth bass,

FIGURE 2.7 Number of Atlantic salmon and American shad reported at the Holyoke Dam (Massachusetts) fish lift on the Connecticut River from 1955 through 2001 (Massachusetts Department of Fisheries and Wildlife).

largemouth bass, bluegill, white crappie, black crappie, and walleye. Most of these species are more suited to the altered habitat provided by the slower, deeper impounded waters of the river than many native species. A number of native species adaptable to the altered habitat and increased competition persist, including white sucker; yellow perch; American eel; fallfish; common, golden, and spottail shiners; banded killifish; redbreast and pumpkinseed sunfishes; and brown bullhead. In the upper watershed, a more lotic assemblage of species, including salmonids (native brook trout and introduced brown and rainbow trout), smallmouth bass, and white sucker, occur in greater relative abundance and provide evidence of the shift in species composition that has occurred.

The federally listed shortnose sturgeon is known to occur in the estuary and in several upriver impoundments of the Connecticut River. The shortnose sturgeon occurred in tidal rivers from North Carolina to New Brunswick, but numbers have been decimated in many rivers by dams that have prevented access to spawning areas, pollution, and over-exploitation. The eastern silvery minnow is listed as a species of concern in Massachusetts, occurring only in the Connecticut River.

Once abundant, anadromous fish were seriously reduced, predominantly by the construction of dams and, to a lesser extent, water pollution. Atlantic salmon were extirpated over a century ago by dams on the main stem and tributaries that cut off access to spawning habitat. A salmon restoration effort involving hatchery production and stocking and provisions for fish passage at dams has produced a

limited run of fish (Fig. 2.7). A more remarkable restoration occurred for American shad and river herring beginning in the 1950s. The Enfield Dam in Connecticut was breached, and a fish lift was provided at the Holyoke Dam in Massachusetts and at dams further upriver, providing access for these species to a greater extent of the watershed (see Fig. 2.7). Other diadromous species that have benefited from improved passage and water quality include striped bass, sea lamprey, American eel, alewife, and gizzard shad.

Ecosystem Processes

In its natural state the Connecticut River would be a good model of the River Continuum Concept (Vannote et al. 1980). Arising from a number of small tributaries with steep gradients, the river continually grows in relation to the size of the drainage area, becoming slower and more meandering in the lowland reaches until it reaches a large estuary. Carbon sources of the upper river are linked to its forested watershed. Processing of coarse particulate organic matter in the tributaries contributes smaller fractions to downstream communities. About 300 km of the river have been largely altered by a series of impoundments that change the character and transfer of organic matter. The impoundments are a sink for large particulates, contributing to a larger detritivore population. The impoundments also become the source of a larger fraction of phytoplankton, utilized by planktivores in the impoundments and by filter-feeding organisms in the runs below each dam. Fish populations are dominated by lentic species, better suited to the slow, deep habitats. Primary

production in the lower river and estuary is increased by the addition of nutrients that occurs in the lower river from human sources (Patrick 1996).

Human Impacts and Special Features

The Connecticut River was the first large river of the Americas to be significantly modified and controlled for transportation and power. The first dam and canal at Hadley Falls, Massachusetts, was constructed in 1795. Six canals constructed between 1795 and 1829 provided access to the upper reaches of the watershed, and presumably afforded passage for many aquatic species, especially introduced species, to extend their colonization of the river along with the early settlers. The first large power dam was constructed at Holyoke, Massachusetts, in 1848, and completely obstructed passage for upstream migrating fish. It is estimated that upward of 900 dams have been constructed on the river and its tributaries for various purposes to control and store the water, for log-driving in the nineteenth century, and later to generate power and reduce flooding. The Connecticut is one of the most developed rivers in the Northeast, with 16 operating power dams that impound over 300km of the river, affecting water quality, flow, fisheries, and other river aspects. Federal operating licenses for these dams must be renewed; thus, water management can be expected to change in coming years to accommodate other uses and its natural values.

As a consequence of its long history of human settlement, agriculture, industrialization, and urbanization, the Connecticut River contains a substantial burden of contaminants that affect the river ecosystem and become a significant source of contamination for Long Island Sound. Toxic and nutrient contaminant loads are significant, particularly affecting that portion of the river in Massachusetts and Connecticut. Surveys conducted from 1992 to 1995 found contamination of sediments and tissue with trace metals—chromium, copper, lead, mercury, nickel, and zinc—and organic compounds—chlor-dane, DDT, PCBs, and various polycyclic aromatic hydrocarbons (PAHs) (Garabedian et al. 1998). Massachusetts and Connecticut have issued consumption advisories for fish and shellfish taken from the river because of high levels of PCBs. In addition, these states have issued consumption advisories for all their freshwaters due to mercury contamination, presumably from atmospheric deposition (MADEP 1998).

The Connecticut River, certain tributaries, the estuary, and Long Island Sound have all been

adversely affected by increased nutrient loading, primarily associated with wastewater treatment facilities. Other sources include urban storm water, agriculture, and atmospheric deposition. Overall water quality has improved in recent decades. Trench (1996) and Garabedian et al. (1998) report a decline of total phosphorus since 1980 for the lower Connecticut. This is presumed to be due to improved wastewater treatment and reduction of the use of phosphates in detergents. A similar trend was not found for nitrogen compounds. Further reductions in nutrients are planned for wastewater facilities in the watershed to reduce their effects on Long Island Sound, where algal blooms have caused low oxygen levels.

In recent years, the Connecticut River has earned a number of designations. The rich natural diversity and special qualities of the Connecticut and its watershed have gained both national and international recognition. The tidal wetlands in the lower 58 km of the estuary were designated “wetlands of international importance especially for wildlife” under the Ramsar Convention in 1994. This international treaty identifies wetlands of critical value for wildlife habitat. In 1993, The Nature Conservancy similarly recognized the tidal wetlands of the lower Connecticut River as an area of global ecological importance by naming it among their “Last Great Places” and a target for land conservation and ecological research. In 1991, the entire Connecticut River watershed was designated a National Fish and Wildlife Refuge (NFWR). This unique designation recognizes the national significance of the watershed and the diversity of life that it supports. The Silvio O. Conte NFWR is a model of resource conservation based on a partnership between the U.S. Fish and Wildlife Service, state and local agencies, nonprofit organizations, and landowners. In 1998, the Connecticut River was designated as an American Heritage River. The designation is the result of a valleywide effort led by the Connecticut River Watershed Council and communities and institutions in the four watershed states. As an American Heritage River, the Connecticut receives special attention from government agencies working in partnership with local sponsors to protect the environmental, cultural, and economic values of the river.

HUDSON RIVER

The Hudson is one of North America’s most important, best-studied, and fiercely protected rivers. It

begins in the Adirondack Mountains and flows south, draining most of eastern New York State (Fig. 2.24). It has been a vital transportation route since the seventeenth century, is part of the Erie Canal system, and is used today for commercial shipping. The Hudson Valley was a center of Native American and early European settlement, and the site of key battles in the Revolutionary War. Its beauty inspired painters of the Hudson River school and helped to motivate the modern environmental movement in the United States. The Hudson's stocks of anadromous fishes have supported commercial fisheries for centuries and still are among the largest remaining populations of striped bass, American shad, and shortnose sturgeon. Today, despite changed land use, altered hydrology, a reshaped channel, invasions of nonnative species, and episodes of serious pollution, including an unresolved problem with PCBs, the Hudson supports diverse biological communities and is used for recreation, drinking water, commercial shipping, and commercial fishing.

The Hudson was an important source of fish and shellfish for the Native Americans of the Algonquin and Iroquois groups who lived in the Hudson Valley before European settlement. Dutch and English settlers drove most of these people from the Hudson basin in the seventeenth and eighteenth centuries, leaving behind Native American names for many places in the basin (e.g., Manhattan, Esopus, Schodack). Despite a long history of European exploration and trade in the Hudson Valley in the seventeenth and eighteenth centuries, the land was not heavily settled or widely cleared for agriculture until after the American Revolution.

Physiography, Climate, and Land Use

The Hudson basin includes parts of several physiographic provinces and ecoregions (Hunt 1974, Isachsen et al. 1991, Ricketts et al. 1999; Fig. 2.24). The northern parts of the basin are in the Adirondack Mountains (AM) province in the Eastern Forest/Boreal Transition ecoregion. The bedrock here is highly metamorphosed plutonic rock, including granitic gneiss, metanorthosite, and olivine metagabbro, and soils are acidic. Much of the central part of the basin is in the Valley and Ridge (VR) province (specifically the Hudson-Mohawk Lowlands and the Taconic Mountains), which includes two ecoregions, the Eastern Great Lakes Lowland Forests to the north and the Northeastern Coastal Forests to the south. This part of the basin is underlain by sedimentary rocks (shale, limestone, sandstone) of Cambrian to Sil-

urian age, which have been metamorphosed in the eastern part of the basin. The Catskill Mountains, part of the Appalachian Plateau (AP) province, form the western edge of the basin. They are composed mainly of shale and sandstone. Finally, the New England (NE) province (Hudson Highlands and Manhattan Prong) and the Piedmont Plateau (PP) province (Newark Lowlands) cover the extreme southern part of the Hudson basin. This area is a complex mix of sedimentary, metamorphic, and igneous rocks.

The entire present-day basin was covered by glaciers, although adjacent parts of the continental shelf were exposed by the low sea levels during full glacial times and were ice-free. Freshwater biota has recolonized the Hudson basin in the 18,000 years since glacial retreat. The Hudson basin has been connected to the Great Lakes and Lake Champlain basins by natural and manmade waterways, allowing many aquatic species to move between these basins.

Climate varies widely across the Hudson basin. Most of the basin is mesic (92 cm annual precipitation at Troy, near the center of the basin; Fig. 2.25), with cold winters and warm summers (mean annual temperature at Troy = 8.9°C). Precipitation, much of which falls as snow, is distributed evenly over the year. The Adirondacks are colder and wetter than Troy, with a mean annual temperature and precipitation of 4.2°C and 99 cm at Indian Lake. The climate at the southern end of the basin is mild and maritime, with a mean annual temperature and precipitation of 12.6°C and 120 cm at New York City.

Before 1700, most of the Hudson basin was covered by mixed hardwood or hardwood-coniferous forests (Braun 1950). Dominant species include eastern hemlock, white pine, sugar maple, red maple, American beech, several species of oak, and formerly American chestnut. Most of the basin was deforested in the late eighteenth and nineteenth centuries, although large tracts of the Adirondacks are uncut. Today, 62% of the basin is forested, 25% is used for agriculture, 8% is urban, and 5% is in other land uses (Wall et al. 1998). Land use varies across the basin (Swaney et al. 1996). Forests cover >95% of the upper basin, agricultural lands cover 30% to 50% of the middle basin, and urban and suburban areas near New York City cover much of the southern part of the basin.

River Geomorphology, Hydrology, and Chemistry

The Hudson can be divided into four sections on the basis of physiography, water chemistry, and human

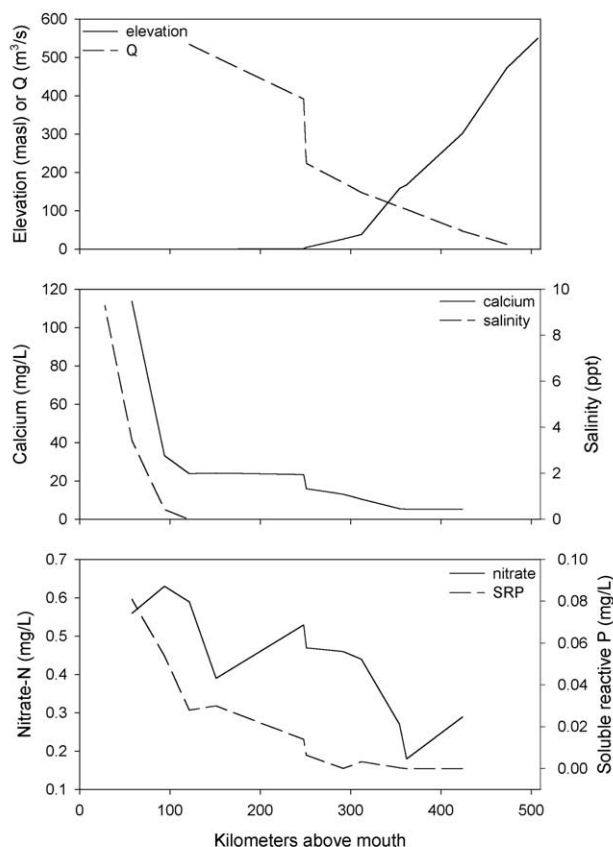

FIGURE 2.8 Longitudinal variation in selected physical and chemical characteristics of the Hudson River (USGS 2002, Lampman et al. 1999).

impacts. From its headwaters at Rkm 507 to the village of Corinth (Rkm 354), the “upper Hudson” flows through the forested Adirondack Mountains. The upper Hudson is a wild high-gradient (2.6 m/km) river largely unaffected by gross human impacts. Much of the river bottom is coarse (gravel, cobbles, boulders, and bedrock), and parts of the river run through dramatic gorges. The water is clear, soft, and low in dissolved phosphorus (Fig. 2.8). Although the flow of the upper Hudson is moderated by many lakes and wetlands in the region, the natural flow is highly variable, with high peaks from snowmelt in March to May. The flow of the upper Hudson is regulated strongly by the outflow from Indian Lake (a reservoir) at Rkm 454 and to a lesser extent by outflows from other lakes.

The “middle Hudson” (Rkm 354 to 248) is a broad, low-gradient, warmwater river flowing through a pastoral landscape. It is distinguished from the upper Hudson by its lower gradient, harder water, and greater human impacts. As the Hudson

enters the Hudson-Mohawk Lowlands near Glens Falls (Rkm 323), its gradient drops to ~ 0.5 m/km and its calcium content rises (see Fig. 2.8). The sediments are predominantly mud and sand, and beds of rooted aquatic plants are common (Moore 1933, Feldman 2001). Historically, the first serious water pollution entered the Hudson in this region, from industries at Corinth, Glens Falls, Hudson Falls, and Fort Edward. The heavily regulated Sacandaga River enters the Hudson just above Corinth, so the flow of the middle Hudson is significantly moderated. Finally, the Hudson is part of the Champlain Canal between Rkm 248 and Rkm 312, and its channel has been modified by navigational dredging and a series of dams.

Runoff in the middle Hudson shows a strong seasonal pattern (see Fig. 2.25). Although precipitation is lowest from December through March, the melting of accumulated snow and ice result in peak discharge from March through May. The low runoff from July through September is a result of high evapotranspiration during this active growing period.

The “freshwater tidal Hudson” extends 149 km from the last dam at Troy (Rkm 248) to Newburgh (Rkm 99). It is distinguished from the middle Hudson by the entry at Troy of the Hudson’s largest tributary, the nutrient-rich Mohawk River, by the dominance of tidal flows in shaping the channel and determining local flow conditions, and by the open passage to the sea, which allows free access to many aquatic animals. The channel of the freshwater tidal Hudson averages 8 m deep and 0.9 km wide, and the gradient is scarcely measurable (~ 1 cm/km). Most of the bottom is sand or mud, but patches of cobbles and exposed bedrock occur throughout the reach. Large beds of rooted plants are common. Mean discharge at the mouth of the Hudson is almost 600 m³/s. However, the entire freshwater tidal Hudson has tides of 0.8 to 1.6 m, which reverse the direction of water flow every six hours and prevent stratification. Tidal flows are much larger than net freshwater flows. Summer water temperatures often exceed 26°C (Ashizawa and Cole 1994), and much of the freshwater tidal Hudson is ice covered in cold winters. The water in the freshwater tidal Hudson is hard, rich in nutrients, and usually free from oceanic salinity (see Fig. 2.8).

The “brackish Hudson” extends 99 km from Newburgh to New York City (Fig. 2.9). This section of the river physically resembles the freshwater tidal Hudson, with a large channel, beautiful scenery, no measurable slope, soft sediments, and strong tidal flows, but typically contains significant sea salt

FIGURE 2.9 Hudson River above West Point, New York (PHOTO BY TIM PALMER).

during at least part of the year (see Fig. 2.8). The brackish Hudson includes both narrow, deep reaches (up to 66m deep between Rkm 70 and 90) and broad, shallow bays like Haverstraw Bay, which is 5 km wide. The water in the brackish Hudson is hard and nutrient rich; its composition varies spatially and seasonally according to the balance between freshwater flow and inputs from the sea (the latter carrying effluent from New York City upriver).

River Biodiversity and Ecology

As many of the rivers in this chapter, the Hudson is found within the North Atlantic Freshwater ecoregion. Unlike most of these rivers, however, it has been one of the most intensively studied large rivers in North America.

Algae, Cyanobacteria, and Protists

The phytoplankton of the upper and middle Hudson River has not been described, although the middle Hudson presumably contains a rich

community during low flow. The freshwater tidal Hudson supports a rich phytoplankton community. Large diatoms strongly dominate the community, but cyanobacteria and other forms were abundant before the zebra mussel invasion (Smith et al. 1998). In the brackish Hudson, diatoms, green algae, dinoflagellates, and cyanobacteria are abundant (Weinstein 1977). Little is known about attached algae anywhere in the Hudson, although they probably are an important part of the food web.

Plants

Aquatic macrophytes are rare in most of the upper Hudson (Moore 1933), probably as a result of unstable flows, coarse sediments, and shading by streamside vegetation. Aquatic plants are important elsewhere in the Hudson. The middle Hudson contains large beds of aquatic plants (wild celery, pickerel-weed, water star-grass, water chestnut, slender water nymph, waterweed, water bulrush, various pondweed, needle-rush) (Moore 1933, Feldman 2001). Nearly pure beds of wild celery and the nonnative water chestnut cover ~10% and 5%,

respectively, of the freshwater tidal Hudson (Findlay et al. 2005). Mixed emergent vegetation (cattail, common reed, yellow water lily, bulrush, pickerelweed, southern wild rice, broadleaf arrowhead, arrow-arum) lives in marshes along the shore. Beds of submersed plants are rare further downriver, and are dominated by wild celery, the nonnative curly-leaved pondweed, slender water nymph, Eurasian watermilfoil, and water star-grass. Marshes in the brackish Hudson contain common reed, cord grass, cattail, spike grass, arrow-arum, swamp rose-mallow, and pickerelweed (Weinstein 1977).

Invertebrates

The upper Hudson supports a diverse community of “clean-water” insects, including the beetle *Stenelmis concinna*, the mayflies *Isonychia bicolor*, *Pseudocloeon* sp., *Epeorus* sp., and *Leucocuta* sp., the caddisflies *Helicopsyche borealis*, *Hydropsyche sparna*, *Brachycentrus appalachia*, and *Chimarra* spp., and the chironomid midge *Micropsectra* sp. (Boyle 1979; Bode et al. 1993, 1996). Stoneflies, hellgrammites, and black flies also are common.

The middle Hudson River presumably supports zooplankton, at least during low water, but it has not been studied. Scattered studies of the zoobenthos (Simpson et al. 1972; Feldman 2001; Bode et al. 1993, 1996) have shown that chironomid midges (including *Rheotanytarsus*, *Polypedilum*, *Orthocladus*), caddisflies (*Neureclipsis*, *Chimarra*, *Hydropsyche*, *Cheumatopsyche*), the mayfly *Stenonema modestum*, and oligochaetes are common in the sediments. Plant beds are inhabited by a rich fauna of invertebrates, including chironomids, nematodes, sphaeriid clams, oligochaetes, the amphipod *Hyaella azteca*, the isopod *Caecidotea*, the mayfly *Caenis*, several gastropods (*Ferrissia*, *Amnicola*, *Gyraulus*), several caddisflies, and several odonates.

More than 200 species of invertebrates inhabit the freshwater tidal Hudson (Strayer and Smith 2001, Pace and Lonsdale 2003). The zooplankton is dominated by protozoans and rotifers, the cladocerans *Bosmina freyi* and *Leptodora kindtii*, and the copepods *Diacyclops thomasi* and *Eurytemora affinis*. The zooplankton is small-bodied and sparse compared to that of lakes, presumably because of constant washout downriver (Pace et al. 1992). The zoobenthos is dominated by tubificid oligochaetes (chiefly *Limnodrilus hoffmeisteri*), bivalves (unionids, sphaeriids, and the zebra mussel), the amphipod *Gammarus tigrinus*, and chironomids. Since 1992, the zebra mussel has dominated the zoobenthos of the freshwater tidal Hudson and has greatly reduced

populations of native planktivores (unionid mussels, sphaeriid clams, and *Chaoborus*).

The zooplankton of the brackish Hudson is dominated by the copepods *Eurytemora affinis*, *Acartia tonsa*, and *Acartia hudsonica*. Other copepods, protozoans, ctenophores, rotifers, cladocerans, mysids, and larvae of benthic animals can also be abundant (Pace and Lonsdale 2005). The zoobenthos is dominated by polychaete (*Marenzelleria viridis*, *Streblospio benedicti*, *Eteone heteropoda*, *Nereis succinea*, *Polydora* spp.) and oligochaete worms, amphipods (*Leptocheirus plumulosus*, *Monoculodes edwardsi*), and bivalves (Atlantic rangia, Baltic macoma, soft-shell clam). Zoobenthic densities are low (<5000/m²) in the transition zone between fresh and brackish water (Rkm 30 to 100), but high (>10,000/m²) in the lower Hudson (Rkm 0 to 30) (Strayer 2005).

Vertebrates

The Hudson contains a rich, ecologically important, and economically valuable fish community. More than 200 species of fishes have been recorded from the Hudson basin (Smith and Lake 1990). About 95 of these are marine and essentially restricted to the brackish Hudson. Of the remaining species, 10 are diadromous and occur regularly above Rkm 99, 70 are native freshwater species, and 33 are nonnative freshwater species.

The fish community changes dramatically from the headwaters of the Hudson to its mouth. The cold waters of the upper Hudson are inhabited by just a few species, including brook trout, white sucker, blacknose and longnose dace, cutlips minnow, creek chub, and common shiner (Moore 1933, Smith 1985). Parts of the upper Hudson basin, isolated by waterfalls, probably contained no fish before post-Columbian stocking. The middle Hudson contains a rich community of warmwater fish, including white sucker, common carp and other minnow species, brown bullhead, chain pickerel, American eel, trout-perch, walleye, yellow perch, tessellated darter, and several sunfishes, including smallmouth and largemouth bass. Below the Troy dam, the mixed warmwater fish community is supplemented by large populations of diadromous and estuarine species, including shortnose sturgeon, American shad, blueback herring, alewife, American eel, white catfish, fourspine stickleback, striped bass, and white perch. Marine or brackish-water fish like the menhaden, bay anchovy, Atlantic tomcod, bluefish, weakfish, and flounder are increasingly abundant toward the sea (Smith 1985, Smith and Lake 1990).

The shortnose sturgeon, the only species in the river that is protected as rare or endangered, is listed as “endangered” by the U.S. Fish and Wildlife Service and the New York State Department of Environmental Conservation. Shortnose sturgeon live their entire lives within the Hudson estuary, spawning in the upper estuary (Rkm 200 to 248), and migrating throughout the rest of the estuary to feed and overwinter (Dovel et al. 1992). The Hudson’s population, at 10^4 to 10^5 fish, is thought to be one of the largest remaining populations of this species (National Marine Fisheries Service 1998).

Dozens of species of other vertebrates live in and along the Hudson and are sometimes important in its ecology. Especially notable are waterfowl, including the nonnative mute swan, which is now common on the freshwater tidal and brackish Hudson, and the bald eagle, which breeds and overwinters along the tidal Hudson. Beavers are abundant in the upper Hudson and in tributaries throughout the basin and are important because of their key role as habitat modifiers. Marine mammals (harbor seals, harbor porpoises, dolphins, and even whales) are seen occasionally in the tidal Hudson River as far north as Troy (Rkm 248).

Ecosystem Processes

Ecosystem processes are best known in the freshwater tidal section of the Hudson. The organic carbon budget of the freshwater tidal Hudson is strongly dominated by allochthonous inputs, advective losses, and respiration by bacteria and zebra mussels (Table 2.1). Autochthonous production is limited by light rather than nutrients (Cole and Caraco 2005). Outputs of nitrogen are much less than inputs, suggesting that burial and denitrification may be important (Lampman et al. 1999). Even though allochthonous inputs dominate organic matter inputs and probably support much of microbial respiration (Findlay et al. 1998, Cole and Caraco 2001), autochthonous production appears to provide crucial support to the upper food web. At the least, populations of zooplankton, zoobenthos, and fish changed radically following the loss of phytoplankton and increase in macrophyte production that accompanied the zebra mussel invasion.

Five interacting factors control the ecosystem in the freshwater tidal Hudson. First, land use in the basin controls the delivery of silt, organic matter, and other materials into the river. Because primary production is light-limited and inputs of silt help to determine water clarity, phytoplankton could be much more productive if silt inputs were cut (Caraco

TABLE 2.1 Organic carbon budget ($\text{g C m}^{-2}\text{yr}^{-1}$) for the freshwater tidal Hudson River, before and after the zebra mussel invasion.

	Preinvasion	Postinvasion
Inputs		
Allochthonous	650	650
Phytoplankton GPP	330	80
Macrophyte GPP	41	44
Total	1000	780
Outputs		
Phytoplankton R	280	70
Macrophyte R	37	37
Bacterioplankton R	116	116
Zooplankton R	8	2
Zebra mussel R	0	83
Other zoobenthic R	9	5
Advection	636	482
Total	1086	795

Modified from Cole and Caraco (2005), who summarized data from several sources.

Many data are approximate. Benthic algal activity and benthic bacterial respiration are omitted because they have not been well studied in the Hudson. GPP = gross primary production, R = respiration.

et al. 1997). Land use in the watershed also controls the amount and kind of organic matter that is brought into the river (Howarth et al. 1996, Swaney et al. 1996). Second, inputs of fresh water set the residence time of water in the river. Residence time must be long enough during the growing season for plankton to develop. In wet years, residence time is short and plankton is sparse (Fig. 2.10). Other parts of the ecosystem depend on plankton, so the effects of hydrology probably extend to processes like organic matter processing, nutrient cycling, and fish recruitment (see Fig. 2.10). Third, the morphology of the river critically determines where primary production by phytoplankton and benthic plants can occur. Fourth, primary production by phytoplankton and benthic plants are negatively correlated because phytoplankton populations decrease water clarity and so can modulate production by benthic plants. This interaction is important because it can stabilize the primary production of the entire ecosystem: When phytoplankton populations decline, benthic primary production can increase, and when phytoplankton populations increase, benthic primary production will decrease. This interaction probably reduced the impact of the zebra mussel invasion on the Hudson’s ecosystem. Fifth, the waxing and waning of biologi-

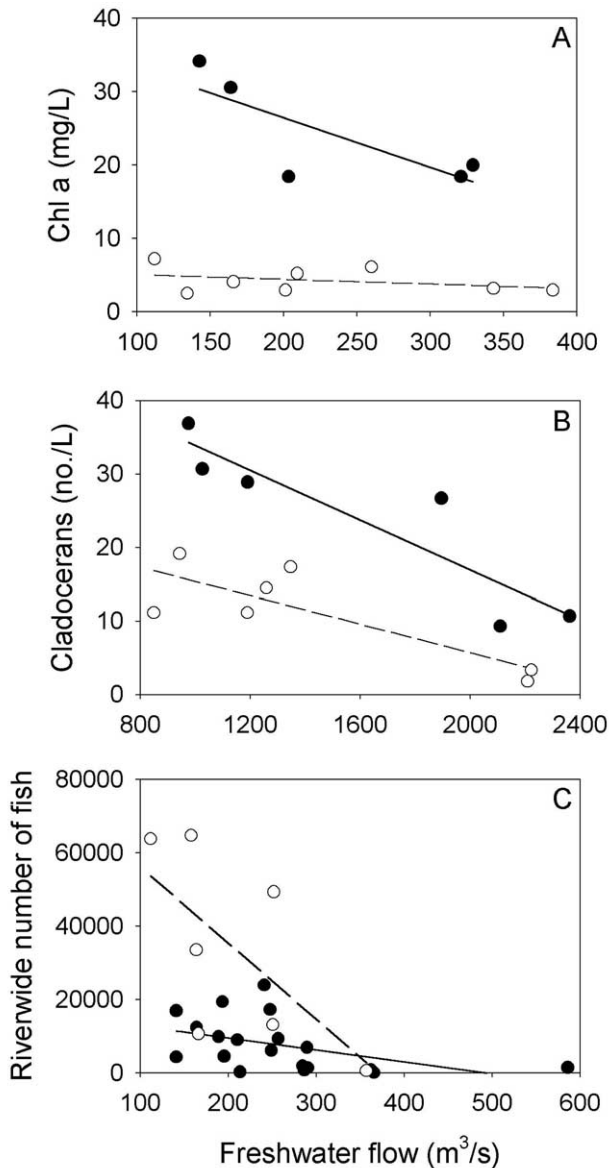

FIGURE 2.10 Sensitivity of populations at different trophic levels in the freshwater tidal Hudson River to freshwater flow, before (black dots) and after (white dots) the zebra mussel invasion. A. Phytoplankton and flow, 15 May to 1 October (Cole and Caraco 2005); B. Planktonic cladocerans and flow, annual means (Pace and Lonsdale 2005); C. Number of young-of-year redbreast sunfish, August to September. Note the interaction between flow and grazing by the zebra mussel (Cole and Caraco 2005, Pace and Lonsdale 2005, Strayer et al. 2005).

cal populations can affect ecosystem function. The best example is the recent invasion of the Hudson by zebra mussels, which changed water clarity, concentrations of dissolved nutrients and oxygen, phytoplankton biomass and composition, bacterio-

plankton, zooplankton, zoobenthos, and fish (Caraco, Cole, Raymond et al. 1997; Caraco, Cole, Findlay et al. 2000; Strayer, Caraco et al. 1999; Strayer, Hattala, and Kahnle 2004; Strayer and Smith 2001). Other species may likewise control ecosystem processes, but have not been well studied in the Hudson. The nonnative aquatic plant water chestnut affects dynamics of dissolved oxygen and probably nutrients (Caraco and Cole 2002), and the large populations of juvenile anadromous fish probably have far-reaching impacts.

Four of these five key factors are strongly affected by humans. Humans control land use in the watershed and thereby alter inputs of silt and organic matter. Humans also changed the hydrology of the Hudson, reducing spring flows and increasing summer flows, possibly reducing plankton populations. The morphology of the Hudson has been vastly altered by attempts to better suit the river to navigation. In particular, large shallow-water areas in Rkm 180 to 248 have been filled or deepened, making this part of the river less hospitable to phytoplankton and benthic plants. Finally, humans have changed biological populations in the river through the introduction of alien species and the exploitation of fish and shellfish.

Human Impacts and Special Features

Although the Hudson is a beautiful river with a rich biota, it is far from being a natural river. Humans have physically altered the river channel, regulated the river's flow, polluted its water, harvested its inhabitants, and introduced nonnative species of plants and animals. The channel alteration that began in the early nineteenth century to make the river more suitable for navigation, afford access to rail lines along both shores, make the shoreline more hospitable to human use, and eliminate "waste" wetlands vastly transformed the tidal river by 1900. Particularly in the upper freshwater tidal Hudson, the channel was deepened and narrowed by dredging, bulkheading, and filling of wetlands and backwaters with dredge spoils (Fig. 2.11). Rail lines between the main channel and coves created new wetlands and restricted access between these marginal shallows and the main channel, and everywhere shorelines were straightened and hardened with riprap, bulkheads, and concrete (Ellsworth 1986). The middle Hudson River was transformed into a series of slowing-moving pools by low-head dams and locks.

The Hudson and its tributaries have been extensively dammed for power production, flood control,

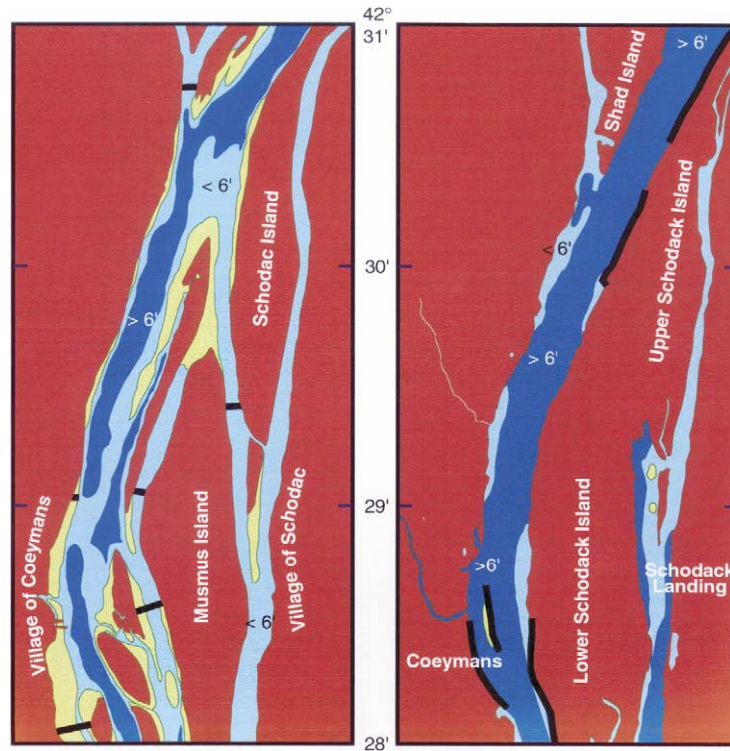

FIGURE 2.11 Modification of the channel of a 5 km stretch of the freshwater tidal Hudson River between 1820 (left) and 1970 (right) showing loss of channel complexity and shallow-water habitats. Key: red = dry land, yellow = intertidal zone, light blue = shallow water (<1.8 m deep), dark blue = deep water (>1.8 m deep), heavy black lines = dikes or bulkheads to constrain the channel (John W. T. Ladd unpublished).

and water supply, but the Hudson has been less altered than many American rivers. The main-stem Hudson is blocked by 14 dams, but they extend over a limited geographic area (Rkm 248 to 354) and do not alter the flow regime greatly. Most significantly, the lower 248 km of the Hudson are undammed, allowing diadromous fish access to a long reach of river (although many tributaries are now inaccessible because of dams near their mouths). Two dams on tributaries (Indian River and Sacandaga River in the Adirondacks) significantly alter the Hudson's flow. Both were built for flood control, and moderate flood peaks and summer low flows. Although the operation of these dams has had devastating ecological impacts on the Indian and Sacandaga rivers, it probably has not had a major impact on the Hudson proper.

Pollution has affected large reaches of the Hudson. Much of the wood cut in the southeastern Adirondacks was processed in the towns along the middle Hudson for pulp, paper, or timber. Consequently, the Hudson between Corinth (Rkm 354) and Hudson Falls (Rkm 312) was badly polluted by pulp

and paper wastes, sawdust, dyes, and sewage for much of the late nineteenth and twentieth centuries. As late as 1972, Simpson et al. (see also Boyle 1979) described "large clumps of paper waste floating on [the water] surface," a bottom of "grayish muck," widespread sewage bacteria (*Sphaerotilus natans*), and low dissolved oxygen in the middle Hudson. This pollution has been largely controlled, and water quality in the middle Hudson has vastly improved (Bode et al. 1993, 1996). Other significant sources of pollution in the middle Hudson are General Electric plants in Fort Edward and Hudson Falls, which released 90,000 to 600,000 kg of PCBs into the Hudson in the mid-twentieth century (Baker et al. 2001). PCBs now contaminate the entire Hudson and its biota downriver from Fort Edward, and have resulted in closures and severe restrictions on commercial and sport fisheries throughout much of the Hudson. Because PCBs are long-lived, the ecosystem will remain contaminated unless action is taken to address "hot spots" of PCB contamination in the middle Hudson. Before the 1970s, many cities released raw or partially treated sewage into the

Hudson. These releases were large enough in the middle Hudson (see previous discussion), the Albany–Troy area, and around New York City to seriously deplete dissolved oxygen and make large parts of the river unsuitable for aquatic life and human recreation. Improvements in water treatment after the Clean Water Act of 1972 greatly reduced sewage pollution in the Hudson. Finally, industrial discharges have contaminated parts of the Hudson with toxins. The most severe example probably is Foundry Cove (Rkm 86), which was contaminated with cadmium and nickel from a battery factory. An estimated 22 tons of cadmium were released into the cove, and cove sediments contained up to 22% cadmium (Wallace et al. 1998). Foundry Cove was designated as a federal Superfund site and remediated in the mid-1990s.

The Hudson has supported commercial fisheries for fishes, blue crabs, and eastern oysters. American shad are by far the most important species (and the only fish now caught commercially), but Atlantic sturgeon, striped bass, American eel, white perch, and other species also were taken. Catches of shad have been highly variable, but exceeded 10^6 kg in some years (Fig. 2.12). The striped bass fishery, closed in 1976 because of PCB contamination, was much smaller but historically important (see Fig. 2.12). The Hudson River contributed to the millions of kilograms of Atlantic sturgeon caught every year along the East Coast in the late nineteenth century, but by the time the fishery was closed in the mid-1990s because of dwindling stocks the commercial catch had fallen to <100,000 kg rangewide, 3700 kg of which came from the Hudson (NYSDEC 1994).

Blue crabs occur as far north as Troy and are caught commercially well into the freshwater tidal Hudson; recent landings in the Hudson have averaged $\sim 40,000$ kg/yr (NYSDEC 1993). Although eastern oysters were taken commercially in the brackish Hudson in the nineteenth century (Stanne et al. 1996) and still occur in the river, there is currently no commercial fishery for eastern oysters in the Hudson. These fisheries have provided important economic benefits to the local economy but also have almost certainly affected fish stocks in the river. Despite recent closures and restrictions from PCB contamination, sport fisheries on the Hudson are worth millions of dollars every year (Connelly and Brown 1991).

Finally, humans have introduced hundreds of nonnative species into the Hudson and its tributaries. Mills et al. (1996) catalogued 113 species of macroscopic plants and animals from the freshwater parts of the basin, and microscopic and brackish-water species would surely add >100 species to this total. Many of these aliens are among the most familiar and ecologically important species in the river: The zebra mussel, largemouth and smallmouth basses, common carp, brown trout, purple loosestrife, water chestnut, and Atlantic rangia all are nonnative species that are common in the Hudson. Nearly all aquatic habitats in the basin contain at least one dominant nonnative species. New species of aliens appear to be entering the freshwater parts of the basin at a rate of ~ 6 species/decade (Mills et al. 1996); including the brackish parts of the river would substantially increase this estimate.

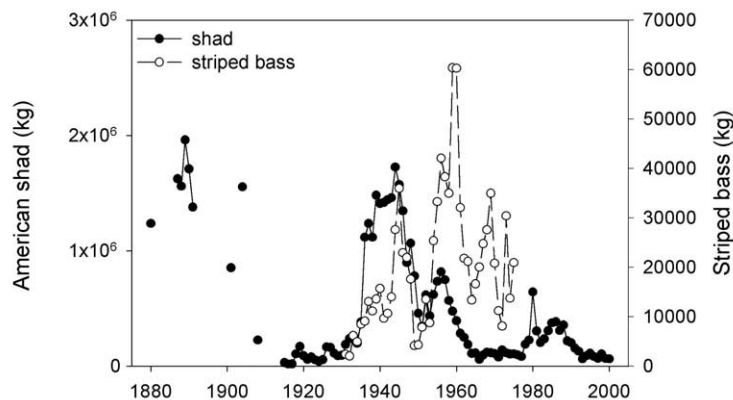

FIGURE 2.12 Reported commercial landings of American shad and striped bass from the Hudson River (shad data compiled by Kathryn Hattala [personal communication] from various sources; striped bass data from McLaren et al. 1988).

DELAWARE RIVER

The Delaware River flows south and forms part of the boundary between New York, Pennsylvania, New Jersey, and Delaware (Fig. 2.26). About 50.3% of the basin lies in Pennsylvania, with the rest in New Jersey (23.3%), New York (18.5%), and Delaware (7.9%). The Delaware basin lies between latitudes 39° 52' and 42° 27' N and comprises <0.4% of the land area of the United States (~33,041 km²). It ranks only 42nd in North America in terms of mean annual flow (422 m³/s at Fort Mifflin, Pennsylvania; Leopold 1994). However, it contains the nation's largest freshwater port (Philadelphia) and provides water to about 10% of the nation's people, including 7.3 million living in the basin and another 10 million living outside (including New York City). More than 2411 billion liters of water were withdrawn from the Delaware River basin in 1996. There are over 1250 permitted waste-water discharges in the basin, including 360 municipal sewage plants. This activity makes the Delaware one of the most intensively used rivers in the United States (Majumdar et al. 1988, www.state.nj.us/drbc/thedrb.html 2002).

Even though its watershed had been occupied by humans for about 12,000 years, and Algonkin natives greeted him on his arrival, the Delaware River was “discovered” by Henry Hudson in 1609 while pursuing a northwest passage to China (Custer 1996). In 1620 Captain Samuel Argall named the river for Lord de la Warr, who was then governor of Virginia (Majumdar et al. 1988). Sweden established the first European settlement in 1630 at what is now Wilmington, Delaware, as a home for deported convicts. William Penn founded the basin's largest city, Philadelphia, in 1682. As evidenced by the name Pennsylvania (or “Penn's Woods”), the Delaware watershed encountered by the early Europeans was dominated by forests (Majumdar et al. 1988). Yet by 1700, colonists of Dutch, British, and German ancestry had cleared the forests, transformed the lower Delaware basin into the “granary of America,” and begun harvesting its seemingly limitless stands of trees in the upper basin. The river and its tributaries soon became the main arteries for shipping grain, flour, and timber products to other colonies, the West Indies, and elsewhere (Majumdar et al. 1988). Thus, it is not surprising that the crossing of the Delaware River and capture of the Trenton, New Jersey, portion of the watershed by General George Washington on Christmas Eve 1776 proved to be the pivotal victory for the continental army during the American Revolution.

Physiography, Climate, and Land Use

Situated in the Temperate Deciduous Forest biome, the Delaware River passes through three terrestrial ecoregions and, for a medium-size river, an unusually large number (5) of major physiographic provinces (Ricketts et al. 1999; see Fig. 2.26). The sequence from headwaters to the mouth includes (1) Allegheny Highland Forests ecoregion, including the Appalachian Plateau (AP) province underlain by the Catskill formation (sandstone with shale and conglomerates); (2) the Appalachian/Blue Ridge Forests ecoregion, including the mountainous Valley and Ridge (VR) province (sandstone, shale, and limestone); and (3) the Northeastern Coastal Forests (NCF) ecoregion. The NCF ecoregion is large and includes the highly weathered Great Valley province (quartzite), the Piedmont Plateau (PP) province (a mix of igneous and metamorphic rocks [granite and gneiss], metamorphosed sedimentary rocks [schist, phyllite, and quartzite], and slightly metamorphosed limestone and dolomites), the Triassic Lowlands province (arkosic sandstone, shale, siltstone, and conglomerates), and the Coastal Plain (CP) province (sands, clays, and gravels; Majumdar et al. 1988). Topographic relief in the watershed ranges from 698 m asl in the Appalachian Plateau at High Knob, New York, to sea level at the Delaware Bay (Majumdar et al. 1988).

The Delaware basin has a humid continental climate. Average annual air temperature varies from about 8.8°C (upper basin) to about 12.2°C (lower basin), with annual monthly temperatures for the northern/southern end of the watershed ranging from a mean of -5.0/1.6°C in January to 18.3/25°C in July (Fig. 2.27). Annual extreme temperatures at the southern and northern end of the basin are about -36°C to -23.8°C and 34.4°C to 40.5°C, respectively. Relative humidity averages about 65% to 72% for the region (*Climate and Man* 1941, cited in Majumdar et al. 1988).

Mean annual precipitation is fairly uniform throughout the basin (see Fig. 2.27), averaging about 105.1 cm/yr near Philadelphia and 107.9 cm/yr for the entire basin. February and July to August are usually the driest and wettest periods, respectively (www.state.nj.us/drbc/thedrb.html 2002). Extreme precipitation (15 to 20 cm per storm) occurs as hurricanes about once a decade (Majumdar et al. 1988).

Vegetation, past and present, reflects the watershed's topographic, geologic, and climatic features. Pollen analysis shows that the basin was historically dominated by forest, with the following temporal sequence: pine-spruce-fir (13,000 to 10,000 years

ago), pine–spruce–oak forest (8500 to 10,000 years ago), hemlock–oak–pine forest (5000 to 8500 years ago), oak–pine–hickory (2500 to 5000 years ago), mixed oak–chestnut (2500 years ago to present; Custer 1996). The present forest falls into two categories: Appalachian oak forest—a deciduous forest in the south/central part of the basin dominated by oak trees (white and northern red)—and, to the north, the Northern Hardwood Forest—a deciduous forest with sugar maple, yellow birch, and American beech predominating in addition to some evergreen trees (pines, hemlock) (Cuff et al. 1989).

Today, the basin has about 7.3 million people (or about 214/km²; www.state.nj.us/drbc/thedrb.html 2002) and is about 60% forest, 24% agriculture, 9% urban, and 7% surface water and miscellaneous land cover (<http://nj.usgs.gov/delr/factsheet.html> 2002). However, land cover can vary greatly from region to region (e.g., the adjacent West Branch, East Branch, and Neversink subbasins vary as follows, respectively: row-crop agriculture, 1.5%, 0.4%, 0%; grass-pasture lands, 28%, 12%, 0.8%; forest, 56%, 81%, 98%; and impervious surface, 0.7%, 0.1%, 0.1%; Stroud Water Research Center 2001). The basin also contains about 2270 km² of freshwater wetlands, mostly nontidal and palustrine marshes located in New Jersey (43%), New York (27%), Pennsylvania (19%), and Delaware (11%).

River Geomorphology, Hydrology, and Chemistry

The Delaware is a 7th order river (estimated based on basin area) fed by 216 tributaries (www.state.nj.us/drbc/thedrb.html 2002). It begins as the East and West branches in the Catskill Mountains of New York. The branches join in Hancock, New York, and the river then flows southeast for 530 km to the sea. Although dammed in its headwaters region, the middle and lower sections comprise the longest free-flowing reach of river east of the Mississippi River (www.state.nj.us/drbc/thedrb.html 2002). The upstream middle portion near Narrowsburg, New York, is narrow and deep (maximum depth of 34.4 m) and a relatively steep gradient of 1.4 m/km produces Class I and Class II rapids downstream until Port Jervis, New York, where it widens again. From Port Jervis to Easton, Pennsylvania, the river gradient is half as steep at 0.7 m/km, but this reach also contains several sets of Class I and Class II rapids (Fig. 2.13). The river then flattens slightly to 0.5 m/km as it flows from Easton to the Fall Line at Trenton, New Jersey. The navigable portion of the

river begins at Trenton with a gradient of 3.5 cm/km to Marcus Hook (near Philadelphia). The Delaware contains many islands, with more than 20 in the Port Jervis to Stroudsburg, Pennsylvania, reach alone.

Annual discharge of the Delaware River (1913 to 2000) at Trenton averages 333 m³/s, with mean monthly discharge ranging from 163 m³/s (September) to 630 m³/s (April; see Fig. 2.27). Mean annual runoff ranges from 45.7 to 71.1 cm for the basin. Runoff varies throughout the basin due to the many lakes, ponds, and wetlands formed during Pleistocene glaciation, as well as factors such as geology, topography, land use, vegetative cover, and size of the watershed (Page and Shaw 1977, cited in Majumdar et al. 1988). The annual pattern of runoff relative to precipitation seems to reflect a strong seasonal influence of evapotranspiration and, to a lesser degree, snow storage (see Fig. 2.27). The highest flow on record at Trenton was 9316 m³/s on August 20, 1955, during Hurricane Diane. The lowest historic flow was 35 m³/s on July 10, 1965 (<http://water.usgs.gov/nj/nwis/monthly/site.html> 2002).

The natural flow pattern of the Delaware has been altered by reservoirs constructed between 1926 (Toronto Reservoir) and 1979 (Blue Marsh Reservoir). For example, river flow at Trenton for March (a period of peak reservoir storage) averaged about 28.5% higher for the prereservoir period of 1913 to 1922 (716 m³/s) than for the postreservoir period of 1980 to 2000 (511 m³/s). This is especially noteworthy because the 1980 to 2000 March period was actually slightly wetter than the years 1913 to 1922 (avg: 113.2 versus 104.7 cm/yr and 9.24 versus 8.63 cm/March). Three large reservoirs (Cannonville, Pepacton, and Neversink) owned by New York City contribute significantly to the modified flow. The volume and timing of water releases from these reservoirs has been controversial. A 1983 agreement stipulates that conservation releases from all three reservoirs be used to augment flows in the Delaware, especially during the summer (Majumdar et al. 1988).

The chemistry of the Delaware River at Trenton reflects local geology and anthropogenic enrichment and varies seasonally, ranging in 2001 as follows: pH (7.1 to 9.0), dissolved oxygen (8.9 to 15.6 mg/L), turbidity (<2 to 200 NTU), hardness (25 to 80 mg/L), alkalinity (19 to 55 mg/L as CaCO₃), Cl (9.2 to 30.3 mg/L), SO₄ (8.8 to 21.3 mg/L), NH₄-N (<0.03 to 0.07 mg/L), NO₂-N + NO₃-N (0.56 to 1.38 mg/L), PO₄-P (<0.018 to 0.067 mg/L), total P (0.031 to 0.266 mg/L), and dissolved organic carbon (0.4 to 12.0 mg/L).

River Biodiversity and Ecology

The Delaware is the southernmost river of the North Atlantic freshwater ecoregion, which extends up the East Coast into southern Nova Scotia and southern New Brunswick (Abell et al. 2000). The biology of both the upper and lower Delaware is relatively well studied, with several surveys of algae, invertebrates, and fishes.

Algae, Cyanobacteria, and Protists

A recent quantitative study of algae, primarily diatoms, on the middle reaches of the Delaware near Belvidere, New Jersey, revealed an average of 41 species per sample (ANSP 2000). The five most common species were (in rank order) *Cocconeis placentula* (36.1%), *Navicula minima*, *Navicula pusilla*, *Nitzschia amphibia*, and *Amphora veneta* (3.9%). Patrick (1994) provides qualitative data on the historical (1957 to 1959) composition of algae for the 11 km of tidal freshwater river. She reported 99 species of diatoms and 25 species of green algae and cyanobacteria upstream from Philadelphia but only

about 29 species of diatoms and 22 species of green algae and cyanobacteria downstream of Philadelphia. Phytoplankton estimates for the 1977 to 1988 period in the freshwater tidal Delaware River were quite variable, with median chlorophyll concentrations and phytoplankton production values for the period of 8.1 $\mu\text{g/L}$ and 14.6 $\text{mmol C m}^{-3} \text{d}^{-1}$, respectively, and peak values occurring in the summer (Frithsen et al. 1991). The summer peak was confirmed by Marshall (1992), who also showed that mean monthly phytoplankton concentrations in the tidal river near Trenton (5.7 to 10^5 cells/L) were only about half the level observed downstream near Philadelphia (10.4 to 10^5 cells/L) or Marcus Hook, Pennsylvania (9.8 to 10^5 cells/L).

Plants

Twelve species of macrophytes have been collected from the tidal river since 1970. Common species are wild celery, Eurasian watermilfoil, ditchmoss, slender water nymph, horned poolmat, curly-leaved pondweed, sago pondweed, common hornwort, and water-starwort. Another 14 species, that were ob-

served earlier have not been collected since 1970 (e.g., white water-crowfoot, common bladderwort, floating-leaf pondweed, water star-grass, common water nymph; Majumdar et al. 1988).

Invertebrates

The headwater and upper main-stem reaches of the Delaware contain a fairly abundant and diverse macroinvertebrate community. In 1983, riffle areas of the East Branch below Pepacton Reservoir averaged about 13,545 macroinvertebrates/m², with chironomid (midge) insects comprising 47% of the community (Stroud Water Research Center, unpublished data). More recently, riffle areas of the river at Belvidere, New Jersey (see Fig. 2.13), averaged about 19,270 macroinvertebrates/m² (range 8,800 to 54,400; ANSP 2000) and contained about 68 taxa. The dominant genera and families of the headwater and upper main-stem reaches of the river are alderflies (*Sialis*), amphipods (*Gammarus*), beetles (*Optioservus*, *Oulimnius*, *Psephenus*, *Promesia*, *Stenelmis*), caddisflies (*Apatania*, *Brachycentrus*, *Ceraclea*, *Cheumatopsyche*, *Chimarra*, *Glossosoma*, *Helicopsyche*, *Hydropsyche*, *Lepidostoma*, *Macrostemum*, *Nectopsyche*, *Neophylax*, *Neuroclipsis*, *Oecetis*, *Rhyacophila*), clams (*Corbicula*), true flies (*Antocha*, *Chironominae*, *Hemerodromia*), dragonflies (*Argia*, *Gomphidae*), mayflies (*Acentrella*, *Baetis*, *Epeorus*, *Eurylophella*, *Isonychia*, *Leucrocuta*, *Serratella*, *Stenonema*, *Tricorythodes*), leeches, mites (*Hydracarina*), moths (*Petrophila*), snails (*Ferissia*, *Hydrobiidae*, *Physidae*), stoneflies (*Acronuria*), and worms (*Oligochaeta*).

In the lower tidal Delaware, surveys during 1957 to 1959 revealed 38 insect and 23 noninsect macroinvertebrate taxa for the reach upstream of Philadelphia, but only 6 insect and 20 noninsect macroinvertebrate species for the reach immediately below Philadelphia (Patrick 1994). ECS (1993) reported that mean densities (and biomass) of macroinvertebrates during 1992 and 1993 varied from 2951/m² (35.5 g dry mass/m²; 34.4 g/m² were Asiatic clams) near Trenton to 3901/m² (3.4 g/m²) near Philadelphia to 2621/m² (2.9 g/m²) at the downstream freshwater limit near Chester, Pennsylvania. Although their survey revealed 129 taxa representing nine phyla, the benthic community was dominated by oligochaete worms (range 52 to 75%) and chironomid insects (range 14 to 24%).

Vertebrates

There are currently about 105 species of fish representing 33 families inhabiting the Delaware River

basin (Schmidt 1986). The main stem alone has 53 species (15 families). Many species (39) in the basin are nonnative. Recent surveys for the reach near Belvidere, New Jersey, revealed 32 species (10 families) of fish (ANSP 1995, 2000), with the 10 most abundant (in rank order) being margined madtom (11.5% of total catch), shield darter (9.6%), swallowtail shiner (9.1%), American eel (9.0%), red-breast sunfish (8.5%), tessellated darter (8.2%), satinfish shiner (7.9%), spottail shiner (6.1%), fallfish (5.8%), and white sucker (4.2%).

For the lower Delaware, Patrick (1994) lists 27 fish species in the reach between Yardley and Bristol, Pennsylvania, in her surveys from 1957 to 1959. The most common species were golden shiner, spottail shiner, satinfish shiner, pumpkinseed, black crappie, banded killifish, blueback herring, and the Mississippi silvery minnow. The same survey found only 17 species in the freshwater tidal reach below Philadelphia, with only the blueback herring and the mummichog being common. More recent surveys (see Horwitz 1986 for review) indicate that as many as 95 species of fish inhabit the lower Delaware River, including the endangered shortnose sturgeon and threespine stickleback. According to Horwitz's (1986) review, 78 of the 95 species (82%) are native freshwater or estuarine species.

Although scientific details of the seventeenth-century condition of fisheries in the Delaware River are lacking, William Penn complained that the shortnose sturgeon were a danger to small boat safety as they jumped into the air by the dozens near Philadelphia (Wildes 1940, cited in Majumdar et al. 1988). However, pollution brought a swift decline to the Delaware River fishery. The American shad industry is a case in point. Early records near Gloucester, New Jersey, show an average annual catch of 131,229 fish for the years 1818 to 1822, with a subsequent decline to 43,915 for the period from 1870 to 1873, at which point the fishery was declared economically nonviable (Howell and Slack 1871, cited in Majumdar et al. 1988). Near Lambertville, New Jersey, the annual shad catch declined throughout the first half of the twentieth century, reaching zero by 1953 (Majumdar et al. 1988). Apparently, dissolved oxygen levels of <2 mg/L along a 48 km section of river near Philadelphia blocked shad migration during the period (Majumdar et al. 1988). Pollution abatement measures have now restored shad migration and data for juvenile shad indicate a fairly steady population since about 1981 (New Jersey Department of Fish, Game, and Wildlife, personal communication).

Besides fishes, other important vertebrates associated with the main river include the northern water snake, snapping turtle, eastern mud turtle, eastern painted turtle, spotted turtle, red bellied turtle, Kemp's ridley turtle, beaver, and river otter. In addition, some vertebrate species in the basin are on the federal list of endangered species, including the short-nose sturgeon, Kemp's ridley turtle, bald eagle, and peregrine falcon.

Ecosystem Processes

To date, the various ecological data have not been integrated into a comprehensive model describing the dynamics of either the upper or lower main stem of the Delaware River. Regardless, some general patterns are apparent. The headwaters of the ecosystem were highly disturbed in the 1970s following construction of large reservoirs on the East and West branches of the Delaware River. Much of this disturbance has been mitigated by adoption of a minimum flow program, but the seasonal temperature regime in the headwaters remains altered by the bottom-release reservoirs. Nevertheless, the presence of a coldwater fishery and a diverse and abundant (10,000 to 20,000 individuals/m²) macroinvertebrate community in both the headwaters and free-flowing middle main stem of the Delaware River suggest that the ecosystem has a diverse and abundant food base (both allochthonous and autochthonous organic inputs) that is being processed extensively. In contrast, although the tidal freshwater portion of the Delaware River ecosystem is much healthier than it was 50 years ago, the structure and abundance of its aquatic plant and animal communities remain compromised.

Human Impacts and Special Features

Water quality in the lower Delaware declined steadily following European colonization of the basin in the mid-1600s (see extensive review by Patrick et al. 1992). Water-quality surveys in 1799 indicated significant pollution around Philadelphia. A 1915 sanitary survey reported a mean dissolved oxygen level of 2.9 mg/L near Philadelphia, and 50 years later readings were only 0.2 mg/L in the lower Delaware (Majumdar et al. 1988). Contamination reached its peak during World War II, when the river's odor nauseated dock workers, its water blackened the hulls and decks of vessels, and pollution caused frequent fish kills near Philadelphia. The Interstate Commission on the Delaware River Basin (INCDEL), founded in 1936, established the first water-quality

standards for the river. By summer 1985, dissolved oxygen levels had improved to 4 mg/L (Majumdar et al. 1988). Unfortunately, toxic substances have also impacted the river. A nationwide survey (1975 to 1979) ranked the Delaware River at Trenton eighth—and its largest tributary, the Schuylkill, first—in the number of detections of organochlorine pesticides in stream bed sediments (Gilliom et al. 1985, cited in Majumdar et al. 1988).

Unfortunately, water quality in the upper Delaware has also been impacted by humans. The demand for wood and wood products by Philadelphia and New York led to almost complete deforestation of the basin by the end of the nineteenth century. Philadelphia's enormous economic growth in the early 1800s triggered the need for a transportation network to penetrate into portions of the basin far from the river's main stem. The historic construction of canals provided this penetration and contributed greatly to rapid development of the basin by humans. In 1824, the Schuylkill Navigation Company established one of the nation's first canals. No other river in the nation has more canals serving one river valley as the Delaware (Majumdar et al. 1988). These canals facilitated the large-scale development of coal mining activities and agriculture in the basin, which has left a legacy of acid pollution and stress related to sediment and chemical laden runoff.

Permitted waste-water discharges to the river are presently a big threat to the basin. The West Branch in New York currently receives effluent (hence, nutrients) from nine permitted discharges (about 10,456 m³/d of effluent) and the East Branch from five (895 m³/d). In addition, the cold, bottom-water discharge from New York reservoirs greatly modifies the natural temperature pattern of the river for a distance of >50 km (Sweeney et al. 1986).

Water quantity or river flow also became an issue in the 1920s when New York City added the Delaware River basin to its water supply system. In 1931, litigation involving the U.S. Supreme Court (later modified in 1954) granted New York access to the water but required a minimum flow downstream of any reservoirs constructed. Today, the 1954 modified ruling still assures that discharge from the New York reservoirs meets the river's downstream flow requirements.

Despite the historical challenges, the river today is much improved from the river of the 1950s. In fact, it was among the first rivers to be authorized for inclusion in the National Wild and Scenic River System, with 241 of the 454 km main river included in the system (Majumdar et al. 1988). A 64 km reach

of this Wild and Scenic River, from Milford, Pennsylvania, to the Delaware Water Gap, is further protected as the Delaware Water Gap National Recreation Area. Ironically, this stretch of river was originally purchased by the federal government to build a large main-stem dam just upstream from the Water Gap at Tocks Island Dam. The plan was eventually abandoned due to public pressure and environmental impact studies. In addition to the main stem, significant portions of tributaries have been designated wild and scenic, including White Clay Creek, which is the last Pennsylvania tributary to the Delaware and the first entire watershed to be added to the National Wild and Scenic River System.

SUSQUEHANNA RIVER

The Susquehanna River is a major landscape feature in Pennsylvania, New York, and Maryland, as well as the principal tributary of the Chesapeake Bay, the largest freshwater estuary in North America, and the second largest estuary in the world (Fig. 2.28). The river begins at Lake Otsego in Cooperstown, New York (43.0°N), and flows 721 km to Havre de Grace, Maryland, on the Chesapeake Bay (39.5°N). Along the way, it crosses high plateaus, rugged mountains and ridges, and fertile valleys. The drainage of the Susquehanna River covers 71,432 km² and includes almost 50% of Pennsylvania and 13% of New York. Within the basin are 50,190 km of named streams and 2293 lakes, reservoirs, and ponds (Stranahan 1993, Edwards 1996). The Susquehanna River is the 22nd largest river in North America that flows to the sea and the 3rd largest (after the St. Lawrence and Churchill [of Labrador]) that flows into the Atlantic Ocean (Leopold 1994). Because the river channel is relatively wide, the Susquehanna has been described as “a mile wide and a foot deep” and has earned the distinction of being the longest commercially nonnavigable river in North America.

The north–south orientation of the Susquehanna River made it an important economic, transportation, and communication artery connecting the Mid-Atlantic region (including the Chesapeake Bay) with the interior of upstate New York. The river and its valley also provided valuable resources to both Native Americans (primarily the Susquehannocks in the 1600s, after whom the river was named) and European colonists. Evidence of human occupation and use of basin resources dates back at least 9600 years, and Native American occupation in the valley is thought to have been continuous from 11,000

years ago through the American Revolution (Custer 1996). Native Americans were few in number and were concentrated in the southern portion of the basin at the time of the American Revolution. Following European colonization, the basin has yielded vast quantities of lumber, coal, fish, agricultural products, and power, and in the process has been modified significantly relative to its prehistoric conditions.

Physiography, Climate, and Land Use

The Susquehanna River basin includes four physiographic provinces: the Appalachian Plateau (AP) in the north, the Valley and Ridge (VR) in the middle, a small portion of the Blue Ridge (BL) and the Piedmont Plateau (PP) in the south (see Fig. 2.28). Most of the basin lies in the Appalachian Plateau and Valley and Ridge. The Appalachian Plateau is relatively flat with deep, steep valleys, for much of the region was glaciated during the Wisconsin and earlier glacial episodes (Sevon and Fleeger 1999). Some valleys have deep deposits of glacial fill, and outwash sediments from the glaciers extend downstream as far as Conestoga Creek on the main stem. The glacial fill and outwash form terraces up to 10 m high and 1 km wide immediately adjacent to the river. Folded and faulted rocks in the Valley and Ridge form steep mountains and ridges separated by valleys. The upland soils (primarily inceptisols) in the Appalachian Plateau and Valley and Ridge tend to be poorly developed and infertile, whereas valley soils range from poor to excellent (Cuff et al. 1989). The Piedmont’s rolling hills and fertile soils (alfisols and ultisols) contain some of the most productive farmland in eastern North America. The quality of the soils reflects their maturity and parent material, with mature soils over metamorphic rock or limestone the most fertile and immature soils in glaciated or steep, mountainous areas the least fertile in the basin. Bituminous coal fields underlie the westernmost portions of the Appalachian Plateau, and distinct beds of anthracite coal are found in the eastern Appalachian Plateau and Valley and Ridge.

There are three predominant terrestrial ecoregions in the Susquehanna River basin: the Allegheny Highlands Forests in the Appalachian Plateau, the Appalachian/Blue Ridge Forests in the Valley and Ridge, and the Northeastern Coastal Forests in the Piedmont Plateau (Ricketts et al. 1999). The Allegheny Highlands Forests are part of the northern hardwood forests that commonly include American beech, sugar maple, eastern hemlock, and yellow and sweet birch, as well as eastern white pine, red pine,

white ash, and black cherry. The Appalachian/Blue Ridge and Northeastern Coastal forests are predominantly Appalachian oak forests that contain several oak and hickory species, sugar maple, sweet birch, American beech, tulip popular, and pines.

The climate in this region is humid continental. Average annual temperature is 9.7°C, with warmest conditions in June to August and coldest conditions in January to February (Fig. 2.29). Total precipitation ranges from 79 cm/yr (e.g., near Corning, New York) to 129 cm/yr (along the basin boundary east of Sunbury, Pennsylvania), and averages 98 cm/yr (6 to 10 cm/mo) across the basin. Precipitation is greatest in May to July (9 to 10 cm/mo) and least in January to February (6 to 7 cm/mo) (see Fig. 2.29).

Land use in the Susquehanna River basin ranges from state forests and game lands to modern urban centers (Cuff et al. 1989). Forests cover 63% of the basin, agriculture 26% (19% cropland, 7% pasture), and urban development 9%. Land use patterns vary between the upper and lower basins (i.e., above and below Sunbury). For example, forests are most common in the upper basin, especially in the areas with steep terrain (Edwards 1996). Most of these forests have regrown after intensive timber harvests between 1850 and 1900 had removed most of the trees (Stranahan 1993). Agricultural activities, which are primarily dairy and livestock related, are concentrated in the flat river valleys and plateaus, especially in the lower basin. The lower basin is also the location of the major hydropower facilities, as well as more than half of the basin's 3.97 million people (56 people/km²).

River Geomorphology, Hydrology, and Chemistry

The upper Susquehanna River basin's two major branches originate in the Appalachian Plateau and converge in the Valley and Ridge near Sunbury, Pennsylvania (see Fig. 2.28). The North Branch begins as the outflow from Lake Otsego in New York and drains 29,275 km² as it flows 521 km to its confluence with the West Branch. The West Branch begins about 20 km west of Altoona, Pennsylvania, and drains 18,109 km² (Stranahan 1993, Edwards 1996). The lower Susquehanna includes one major tributary (the Juniata River) and crosses both the Valley and Ridge and Piedmont before ending at Chesapeake Bay (Fig. 2.14).

Very little of the Susquehanna has tidal influences, and the tidal/estuarine characteristics it does have are

actually attributes of the Chesapeake Bay rather than the river itself. Because the Susquehanna River is relatively wide and shallow, distinct riffle pool sequences are visible during low and moderate flow levels. Prominent features in the river channel throughout the basin are islands, the most famous of which is Three Mile Island with its nuclear power facility.

Average discharge is 438 m³/s for the North Branch (at Danville, Pennsylvania), 309 m³/s for the West Branch (at Lewisburg, Pennsylvania), and 1153 m³/s at the Conowingo Dam, Maryland (16 km from the mouth). The Susquehanna River contributes almost 60% of all freshwater inputs into Chesapeake Bay (Porse 2000). Because the four major water retention/hydroelectric dams are all within 100 km of the river's mouth, the seasonal flow regime is relatively unmodified throughout most of the basin. Discharge exhibits a strong seasonal pattern, with discharge in March and April several times greater than that in August and September (see Fig. 2.29). Rainfall exceeds evapotranspiration in all months except May to August (Cuff et al. 1989), whereas runoff slightly in excess of precipitation in March and April is presumably due to snowmelt. It appears that evapotranspiration is the major factor responsible for the seasonal pattern in runoff.

The Susquehanna River is renowned for its frequent floods, and major floods have occurred every 14 to 20 years (Stranahan 1993, Porse 2000). Maximum discharge recorded at the Conowingo Dam was 32,002 m³/s following Hurricane Agnes in June 1972. Minimum discharge was 43 m³/s in September 1964 (Porse 2000). Flows in excess of 11,328 m³/s (about 10 times mean annual flow) occur an average of twice per year (Porse 2000). A combination of conditions—intense precipitation from tropical storms, a river topography that produces ice dams, less pervious soils, and even possibly land use such as the deforestation of the late nineteenth century—contribute to this pattern (Stranahan 1993, Porse 2000). The economic and social impact of these floods has been particularly great in areas where the wide terraces adjacent to the river have attracted agricultural and urban development.

Water chemistry varies greatly within the basin in response to natural variations in underlying soils as well as anthropogenic activities. Some streams naturally have high alkalinity and pH and abundant nutrients (e.g., in the Valley and Ridge, with mature soils derived from carbonate bedrock), whereas other streams may have low alkalinity and pH and be nutrient poor (e.g., in glaciated portions of the

FIGURE 2.14 Susquehanna River above Harrisburg, Pennsylvania (PHOTO BY TIM PALMER).

Appalachian Plateau, with shallow, immature soils). In the main stem, pH is 6.9 to 9.0, alkalinity is 40 to 110 mg/L as CaCO_3 , $\text{NO}_3\text{-N}$ is 0.29 to 1.49 mg/L, and $\text{PO}_4\text{-P}$ is <0.02 to 0.1 mg/L (Rowles and Sitlinger 2000). pH and alkalinity are lowest in areas affected by acid mine drainage, whereas nitrate and phosphate are highest in areas where agriculture is most intense.

River Biodiversity and Ecology

The Susquehanna River is in the Chesapeake Bay freshwater ecoregion (Abell et al. 2000) and was connected to other Chesapeake tributaries and nearby Atlantic drainages when sea levels dropped during past glacial periods (Hocutt et al. 1986). Ecological studies of the Susquehanna River have generally been limited to qualitative and quantitative collections associated with environmental monitoring, taxonomic surveys, or fisheries management. These collections occur most often during low summer flow, when more of the river can be waded.

The taxa collected give some indication of organic matter processes and ecosystem function, which otherwise remain unexamined.

Algae, Cyanobacteria, and Protists

The wide, shallow riverbed of the Susquehanna River supports a variety of algae at relatively high densities. Collections by the Academy of Natural Sciences of Philadelphia on the North Branch near Meshoppen Creek found over 100 species, most of which were diatoms (Bacillariophyceae), especially *Cyclotella atomus*, *Cocconeis placentula* var. *lineata*, and *Nitzschia palea*. Common green algae (Chlorophyceae) in these collections were *Cladophora glomerata*, *Hydrodictyon reticulatum*, *Rhizoclonium hieroglyphicum*, *Oedogonium*, and *Spirogyra*, whereas *Schizothrix calcicola* was the common cyanobacteria. Algal biomass during low flow can average 30 to 90 mg chlorophyll a/m^2 in the riffles at these sites (Jackson and Sweeney, unpublished data), with greater accumulations associated with mats of filamentous green algae (e.g., *C. glomerata*, *R. hieroglyphicum*). Reduced light from fine particle

transport and accumulation appears to limit algal biomass in pools and some depositional areas.

Plants

Although macrophytes are not common at most sites, they do occur and can be abundant at some sites (e.g., water star-grass, jewel weed, water willow, lizard tail). As with most rivers in the region, several nonnative plants (e.g., watercress, Eurasian water-milfoil, purple loosestrife, curly-leaved pondweed) are now common in some locations.

Invertebrates

Macroinvertebrates are both abundant and diverse, with densities in riffles often averaging 10,000 to 30,000/m² (e.g., Jackson, Sweeney et al. 1994; Jackson, Horwitz, and Sweeney 2002). Although the exact number of aquatic invertebrate species in the basin is not known, it is well over 100. For example, 120 aquatic insect species alone (including 27 mayflies, 20 beetles, 17 caddisflies, and 30 dipterans) were recently collected from a North Branch site downstream of Meshoppen Creek (Jackson and Sweeney, unpublished data). In riffles, common macroinvertebrates include those that feed on attached algae (e.g., baetid [*Baetis*, *Pseudocloeon*, *Centroptilum*] and heptageniid [*Stenonema*, *Leucrocuta*] mayflies, numerous chironomid midges), fine particles suspended in the water (e.g., hydropsyhid caddisflies [*Hydropsyche*, *Cheumatopsyche*], isonychiid mayflies, and the chironomid *Rheotanytarsus*), and fine particles on the surface or in sediments (e.g., anthopotamid [*Anthopotamus*] mayflies and many chironomids). In contrast, common macroinvertebrates in depositional areas are predominately those that feed on fine particles on the surface or in sediments (e.g., oligochaete worms, several chironomids [*Tanytarsus*, *Polypedilum*], elmid [*Stenelmis*, *Optioservus*, *Dubiraphia*] beetles, and anthopotamid [*Anthopotamus*] mayflies). There are two crayfish species native to the main stem and branches of the Susquehanna River (Ted Nuttall, personal communication). The spiny-cheek crayfish is found in slower areas, whereas *Orconectes obscurus* is found in faster areas, especially in the north. In addition, the Appalachian brook crayfish may be found entering from smaller tributaries in mountainous sections, and the nonnative rusty crayfish can be common in the lower basin.

Although mollusks have been well inventoried in the Susquehanna basin (Strayer and Fetterman 1999, A. E. Bogan, personal communication), their ecological role is not well studied. The most abundant mollusks are small bivalves (Sphaeriidae), limpids

(Ancylidae), and snails (e.g., Physidae, Viviparidae) (e.g., Jackson et al. 1994). There are a total of 13 unionid species in the basin, five of which are widespread and sometimes common: eastern elliptio, triangle floater, elktoe, creeper, and yellow lampmussel. Strayer and Fetterman (1999) found little evidence of large changes in mussel communities in the New York portion of the North Branch between 1955 to 1965 and 1996 to 1997. However, the brook floater clearly declined in range, which may be due to hybridization with the elktoe. Asiatic clams are established in the lower Susquehanna River. Adult zebra mussels were only recently collected in Eaton Brook Reservoir (2000) and Canadarago Lake (2002), and appear established.

Vertebrates

At least 103 fish species are found in the Susquehanna River basin (Hocutt et al. 1986, Argent et al. 1998), and densities can be as high as 6/m² (e.g., Jackson et al. 2002). The native fish fauna is similar to nearby Atlantic drainages but includes some species also found in the northern Mississippi basin (Hocutt et al. 1986). Only the Maryland darter is endemic; 14 species spend some portion of their life in marine or brackish waters (Hocutt et al. 1986) and at least 29 species are not native to the basin (Argent et al. 1998). Reductions in species distribution have occurred for 29 species in the last 100 years, including the loss of 4 to 7 species from several watersheds (Argent et al. 1998). The impact of nonnative species, which are now the dominant insectivorous and piscivorous fishes at many locations in the basin (e.g., Jackson et al. 2002), on native fishes and other components of the ecosystem is unknown.

Fishes, especially the migratory American shad, alewife, blueback herring, and American eel, played an important role in the lives of the native Susquehannocks and early European settlers in the Susquehanna basin (Custer 1996). All were abundant, but shad were considered especially valuable. Accounts from the 1800s and early 1900s are largely anecdotal, but the shad harvests clearly included hundreds of thousands and even millions of fish (Anonymous 2000). Harvests plummeted by the early twentieth century in response to changes in the basin. The Susquehanna River still supports an active warmwater sport fishery that is focused primarily on several nonnative fishes, especially smallmouth bass, but also channel catfish, rock bass, walleye, and muskellunge. Popular native species include striped bass and white perch, both of which are most abundant below the Conowingo dam. A variety of native

and nonnative sunfishes are also frequently caught in the river, even though they are generally thought of as pond species.

The Susquehanna River basin supports a wide variety of additional aquatic vertebrates, such as beaver, muskrat, turtles, snakes, blue heron, bald eagle, and various ducks and geese.

Ecosystem Processes

Although intensive ecosystem studies have not been conducted on the Susquehanna, observations of the flora and fauna give some indication of the structure and function of the river. First, benthic algae and fine particles (benthic and suspended) are abundant and the major food resources for invertebrate consumers in the river. Second, benthic algae may be a more important primary food resource than in rivers of similar size because light reaches the river bottom in the shallow riffles. Third, abundant food, high macroinvertebrate densities, and warm water temperatures suggest that invertebrate production is relatively high. Finally, high invertebrate production contributes to the high densities of insectivorous and piscivorous fishes. The impact of fish introductions and losses has not been studied to date.

Human Impacts and Special Features

The Susquehanna River basin is known for the broad river channel with shallow, rocky reaches and numerous islands. It is also known for its abundance of natural resources. Although human activities in the basin over the last 300 years have been well chronicled, their impact has not. One reason for this is that residents of the basin have relied on groundwater and tributaries for drinking water, rather than the Susquehanna River, and with the exception of shad fisheries, human activities were generally not dependent on the environmental quality of the river. The three activities that have had the greatest effect on the river are logging in the middle to late 1800s, coal mining from the late 1890s to the middle 1900s, and dams/diversions in the early 1800s and then again in the early 1900s. Portions of the river still appear to be responding to those activities.

Forests (white pine, hemlock, oak, chestnut) were vital in the development of this region, and the Susquehanna River played a key role in transporting and processing cut timber. By 1850 the best stands were exhausted in northern and eastern areas. However, lumbering on the West Branch continued into the early twentieth century. Some cleared lands quickly became productive croplands and pastures,

whereas others were abandoned immediately or after agricultural efforts failed. Today hardwood and mixed-hardwood forests cover 63% of the basin, including those areas that were primarily pine and hemlock. Croplands and pastures now account for 26% of land use in the basin. There is little documentation of the impact of forest removal on the river, but it presumably affected flow regime and water quality. Sediment transport between 1890 and 1940 was at least nine times greater than it had been 200 years earlier (Reed 2000). Two-thirds of the increase was due to soil erosion, primarily from forestry and agriculture, and the remaining third was caused by coal mining. Sediment transport has declined significantly, but remains a great concern (along with nutrients) for the Chesapeake Bay.

Coal is plentiful throughout much of the Susquehanna basin, with some of the world's largest deposits of anthracite in the north and east and vast bituminous coal fields in the west. Over the last 200 years almost 30 billion tons of coal has been mined in Pennsylvania, and much of it came from the Susquehanna basin. Coal waste and acid mine drainage decimated great lengths of the river and its tributary streams. Coal silt was so abundant that it spawned the Susquehanna's Hard Coal Navy, a fleet of over 200 vessels that dredged the dust from the river bottom (Stranahan 1993). From 1920 to 1950, 3 million tons of coal were recovered from behind the Holtwood Dam, and from 1951 to 1973, about 10 million tons of coal dust were recovered from behind the Safe Harbor Dam (O'Donel 2000). The coal industry is now relatively small, but its environmental impact (primarily from acid mine drainage) continues in the basin (Edwards 1996).

Dams and Susquehanna River fisheries (especially for American shad) have long been entwined, as residents in the 1700s recognized that even low-head dams blocked fish migrations in tributaries (Anonymous 2000). Shad fisheries flourished until the 1830s, when main-stem dams were constructed to supply water to the 950 km canal system associated with the river. In addition to the role played by the dams, excessive harvests and poor water quality associated with timber and coal development and industrial and municipal effluents may have contributed to the shad harvest decline. Shad migrating up the Chesapeake Bay had access to very little of the Susquehanna River following the completion of the York Haven hydroelectric dam at Rkm 90 (1905), the Holtwood hydroelectric dam at Rkm 40 (1910), and finally the Conowingo Dam at Rkm 16 (1928). Remnants of the fisheries that remained in the lower

FIGURE 2.15 Number of adult American shad returning to the Susquehanna River and captured at the fish lift on the Conowingo Dam, Maryland. No fish passed the dam between 1928 and 1972.

river and upper Chesapeake Bay declined in the 1970s, and shad fishing has been prohibited in these areas since 1980 (Anonymous 2000).

Although economic development and population growth have produced some grim periods in the environmental history of the Susquehanna Basin, significant improvement has occurred (e.g., Reed 2000, Rowles and Sitlinger 2000) and the future appears bright. River biota have responded positively to improved water and habitat quality. For example, the number of aquatic insects collected at a North Branch site near Mehoopany Creek has almost doubled since 1974 (Jackson and Sweeney, unpublished data). Only 11% of the 28,038 km of streams and rivers recently assessed did not support their designated use (Edwards 1996). Acid mine drainage continues to be the major cause of degradation at these sites, followed by agricultural effluents. Finally, the fishery remains productive, and migratory fish are responding positively to stocking programs and modern fishways (Fig. 2.15).

ADDITIONAL RIVERS

The adjacent Kennebec and Androscoggin river basins are located entirely within the New England physiographic province (Figs. 2.30 and 2.32). Their forested headwaters arise in the rugged mountains of western Maine (Fig. 2.16), and after leaving the mountains, the rivers flow across the gently rolling agricultural landscape of the lower basin (Fig. 2.17). The two rivers join downstream of Lewiston and Augusta, just before flowing into the Atlantic Ocean.

FIGURE 2.16 Androscoggin River near Wilsons Mills, Maine (PHOTO BY TIM PALMER).

There are numerous lakes and wetlands throughout their catchments, which act to dampen changes in flow. The peat-laden soils of these wetlands result in river water that is poor in nutrients but rich in dissolved organic matter. Consequently, aquatic productivity is low to moderate. A few of the lakes—Moosehead Lake (Kennebec River) in particular—are exceptionally large. Like most rivers of New England, they have been dammed for centuries. Their flow is only moderately regulated, however, because most of the dams are “run-of-the-river.” The Edwards Dam on the Kennebec River at Augusta was the first major dam on a major river that was ordered to be removed by the federal government. It was breached in 1999.

The Merrimack River is recovering from a history of intensive industrial use. Rising in the largely forested White Mountains of New Hampshire, the Merrimack flows swiftly south and east into the urban and suburban landscape of southern New

FIGURE 2.17 Kennebec River at Solon, Maine (PHOTO BY TIM PALMER).

Hampshire and Massachusetts (Fig. 2.34). The Hubbard Brook Experimental Forest, a site of intensive long-term ecological research, is in the headwaters of the Merrimack. The Merrimack's water is clear and soft. The Merrimack was so heavily impounded (there are more than 500 dams in its basin) that it was called "America's hardest working river." These dams and pollution from paper mills and other industries led to the disappearance of important migratory fish species in the nineteenth century. Dramatic improvements in water quality and installation of fish passages are helping to restore American shad and Atlantic salmon to the Merrimack (Fig. 2.1).

The Raritan River is the longest river found entirely in New Jersey, and it is an excellent example of the urban/suburban conditions that characterize portions of many rivers and streams in this region. The Raritan begins in the highlands of the New England province and crosses the Piedmont Plateau and Coastal Plain before emptying into the Raritan Bay near the mouth of the Hudson River (Fig. 2.36). The basin is highly fragmented; over 250 dams (most are <8m high) slow and divert river flow and

block fish migrations and extensive agriculture and urban/suburban development (19% and 36% of current land cover, respectively) have resulted in small, isolated forest areas. Impervious cover is presently 11% across the basin, and is between 10% and 25% in most watersheds. A majority of mainstem and tributary sites show evidence of moderate or severe impairment; only 38% were classified as unimpaired. Even so, the Raritan supports a diverse flora and fauna and represents an important aquatic resource in the region. Efforts to maintain or improve water quality and quantity are underway, but they face resistance from continued urban development (Fig. 2.18).

The Potomac River begins its 616km journey to the Chesapeake Bay in the Allegheny Mountains of West Virginia (Fig. 2.38). Along that route it crosses five physiographic provinces and five terrestrial ecoregions. Although best known as a scenic backdrop for the U.S. capital and Arlington and Alexandria, Virginia, most of the Potomac basin is still undeveloped forests and open agricultural fields and the river is relatively free flowing (Fig. 2.19). Most (80%) Potomac basin residents live in the

FIGURE 2.18 Raritan River at Route 1 bridge between New Brunswick and Edison, New Jersey (PHOTO BY RARITAN RIVERKEEPER).

FIGURE 2.19 Potomac River near Harper's Ferry, West Virginia (PHOTO BY A. C. BENKE).

Washington metropolitan area. Biological diversity and productivity are similar to the James, Susquehanna, Delaware, and Hudson Rivers. Likewise, the Potomac River has many of the same environmental problems associated with more than 250 years of intensive use. The most common sources of stream impairment are excessive nutrients and sediments; urban, industrial, and agricultural toxins; and acid mine drainage. Efforts over the last 50 years have significantly improved water and habitat quality in the river.

ACKNOWLEDGMENTS

The staff of the Old Town office of the U.S. Fish and Wildlife Service and Dr. John Moring of the Cooperative Fish and Wildlife Research Unit at the University of Maine provided references and publications regarding the Penobscot River. Vivian Butz Huryn and Michael Chadwick provided helpful comments on an early draft for the Penobscot River. Bob Bode, Kathy Hattala, and colleagues at the Institute of Ecosystem Studies provided helpful advice and data for the Hudson, and John Ladd allowed us to use his beautiful Figure 2.11. The Delaware River Basin Commission, Susquehanna River Basin Commission, and Interstate Commission on the Potomac River Basin provided access to their publications and libraries. Michael Hendricks provided recent shad data for the Susquehanna River, and Richard St. Pierre helped us access historical shad data for the Atlantic region. This is a contribution to the program of the Institute of Ecosystem Studies, and contribution number 2003001 for the Stroud Water Research Center.

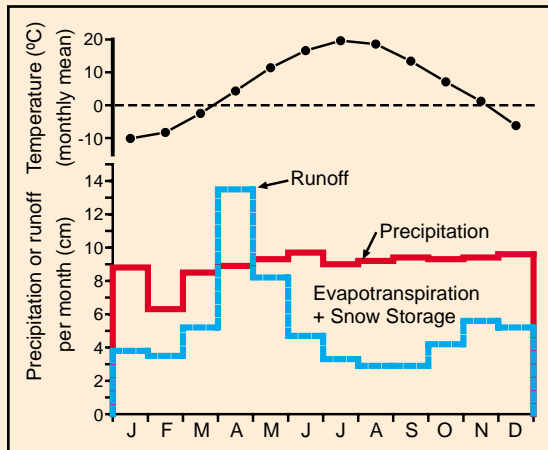

FIGURE 2.21 Mean monthly air temperature, precipitation, and runoff for the Penobscot River basin.

PENOBSCOT RIVER

Relief: 1607 m

Basin area: 22,253 km²

Mean discharge: 402 m³/s

River order: 6 (approximated)

Mean annual precipitation: 107 cm

Mean air temperature: 9.5°C

Mean water temperature: 9.3°C

Physiographic province: New England (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: New England/Acadian Forests, Northeastern Coastal Forests

Number of fish species: 45

Number of endangered species: 1 fish

Major fishes: alewife, American eel, American shad, Atlantic salmon, brown bullhead, burbot, chain pickerel, common shiner, creek chub, fallfish, pumpkinseed, redbreast sunfish, smallmouth bass, white sucker, white perch, yellow perch

Major other aquatic vertebrates: eastern painted turtle, snapping turtle, muskrat, beaver, mink, river otter

Major benthic invertebrates: mayflies (*Centroptilum*, *Ephemerella*, *Eurylophella*, *Heptagenia*, *Stenonema*), stoneflies (*Acronuria*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Macrostemum*, *Neureclipsis*, *Polycentropus*), hellgrammites (*Corydalus*), mollusks (*Ammicola*, *Elliptio*, *Musculium*), beetles (*Stenelmis*), odonates (*Calopteryx*, *Hagenius*), crayfish (*Cambarus*, *Orconectes*)

Nonnative species: chain pickerel, smallmouth bass, brown trout

Major riparian plants: balsam fir, red maple, silver maple, paper birch, black ash, quaking aspen, chokecherry, northern white cedar, American elm (declining)

Special features: River islands north of Old Town comprise Penobscot Indian reservation; Baxter State Park and Mt. Katahdin; Sunkhaze National Wildlife Refuge

Fragmentation: 5 major dams span main stem; 111 additional licensed dams (many hydroelectric) on tributaries.

Water quality: 4 pulp and paper mills, 9 major municipal discharges. Major pollutants are dioxin, PCBs, mercury, organic waste. Total nitrogen = 0.45 mg N/L, total dissolved phosphorous = 0.03 mg P/L, total organic carbon = 9.5 mg/L, hardness = 12.0 mg/L as CaCO₃, pH = 6.6, specific conductance = 61.3 μS/cm

Land use: 95% forest and wetland, 5% agriculture and urban

Population density: 8 people/km²

Major information sources: Barrows and Babb 1912, Cutting 1963, Rabeni and Gibbs 1980, Baum 1983, Davies et al. 1999, PNWRP 2001

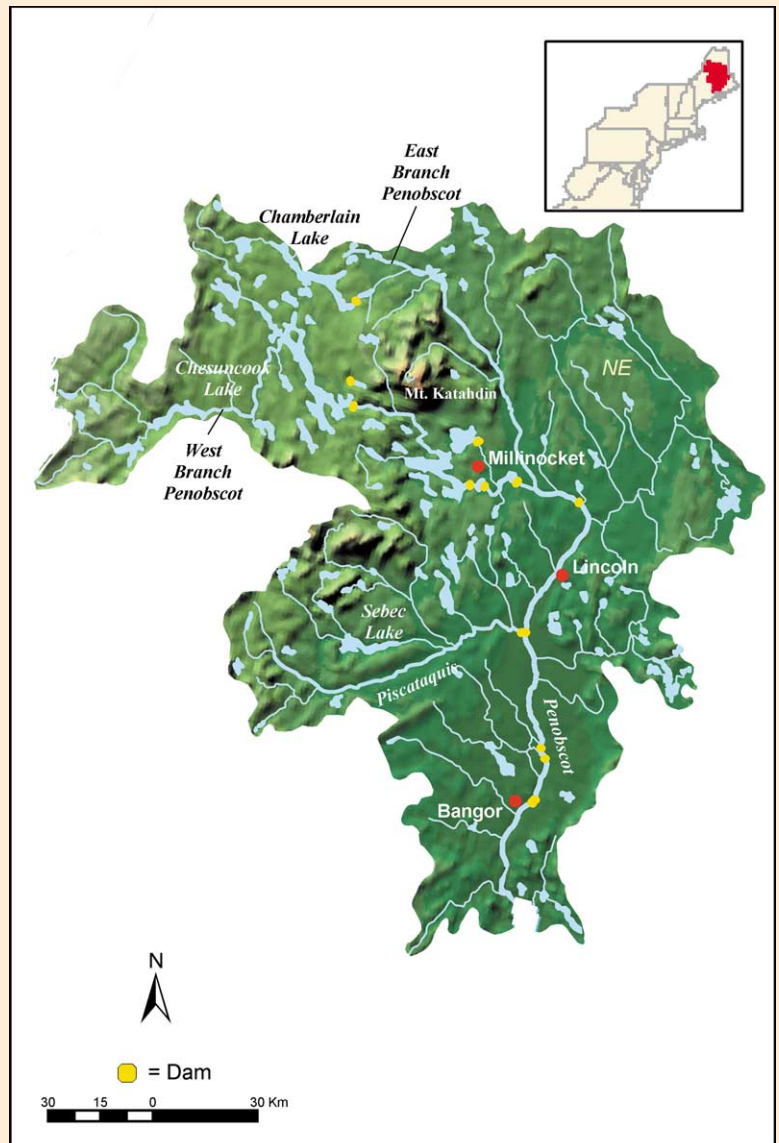

FIGURE 2.20 Map of the Penobscot River basin.

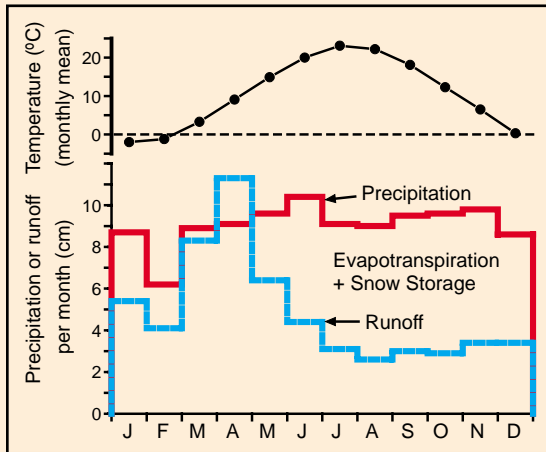

FIGURE 2.23 Mean monthly air temperature, precipitation, and runoff for the Connecticut River basin.

CONNECTICUT RIVER

Relief: 1917 m

Basin area: 29,160 km²

Mean discharge: 445 m³/s

River order: 7 (approximated)

Mean annual precipitation: 109 cm

Mean air temperature: 10.5°C

Mean water temperature: NA

Physiographic province: New England (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: New England/Acadian Forests, Northeastern Coastal Forests

Number of fish species: 64 freshwater, 44 estuarine

Number of endangered species: 1 fish, 1 mussel

Major fishes: anadromous: American shad, blueback herring, sea lamprey, striped bass; freshwater: brook trout, American eel, white sucker, yellow perch, fallfish, common shiner, golden shiner, spottail shiner, banded killifish, redbreast sunfish, pumpkinseed, brown bullhead

Other aquatic vertebrates: beaver, river otter, northern water snake, snapping turtle, bald eagle, bank swallow, common loon, common merganser, belted kingfisher, great blue heron

Major benthic invertebrates: stoneflies (*Acronuria*), mayflies (*Eurylophella*, *Serratella*, *Stenonema*), caddisflies (*Brachycentrus*, *Chimarra*, *Hydropsyche*, *Neureclipsis*, *Oecetis*), beetles (*Stenelmis*, *Psephenus*), chironomid midges (*Chironomus*, *Polypedilum*, *Microtendipes*, *Glyptotendipes*, *Tanytarsus*), mollusks (Pisidiidae), worms (Tubificidae)

Nonnative species: 20 fish species (brown trout, smallmouth bass, largemouth bass, black crappie, white crappie, northern pike, common carp, rainbow trout, bowfin, bluegill), Asiatic clam

Major riparian plants: Estuary: cord grass. Freshwater: wild celery, broadleaf arrowhead, cattail, pickerelweed, purple loosestrife, common reed

Special features: Watershed, including tidal wetlands, has received national and international recognition of its ecological uniqueness and value.

Fragmentation: 16 large hydroelectric dams

Water quality: pH = 6.5 to 7.5, alkalinity = 20 to 47 mg/L as CaCO₃, specific conductance = 116 μS/cm, NO₃-N + NO₂-N = 0.19 to 0.61 mg/L, total phosphorus P = 0.04 to 0.16 mg/L

Land use: 80% forest, 11% agriculture, 9% other

Population density: 69 people/km²

Major information sources: Merriman and Thorpe 1976, Patrick 1996, Garabedian et al. 1998

FIGURE 2.22 Map of the Connecticut River basin.

FIGURE 2.25 Mean monthly air temperature, precipitation, and runoff for the Hudson River basin.

HUDSON RIVER

Relief: 1629 m

Basin area: 34,615 km²

Mean discharge: 592 m³/s

River order: 7 (approximated)

Mean annual precipitation: 92 cm

Mean air temperature: 8.9°C

Mean water temperature: 12.4°C

Physiographic provinces: Adirondack Mountains (AD), Valley and Ridge (VR), Appalachian Plateau (AP), New England (NE), Piedmont Plateau (PP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: Eastern Forest/Boreal Transition, Eastern Great Lakes Lowland Forests, Northeastern Coastal Forests

Number of fish species: >200 (70 native freshwater, 95 brackish)

Number of endangered species: 1 fish

Major fishes: American eel, American shad, blueback herring, alewife, white catfish, white sucker, common carp, cutlips minnow, blacknose dace, creek chub, fallfish, common shiner, spottail shiner, brook trout, Atlantic tomcod, banded killifish, striped bass, white perch, smallmouth bass, largemouth bass, tessellated darter

Major other aquatic vertebrates: snapping turtle, mute swan, Canada goose, beaver

Major benthic invertebrates: mollusks (zebra mussel, eastern elliptio, *Ferrissia*, *Ammicola*, *Gyraulus*), worms (*Limnodrilus hoffmeisteri*), crustaceans (*Gammarus tigrinus*, *Hyalella*, *Caecidotea*), mayflies (*Stenonema*, *Caenis*), caddisflies (*Neureclipsis*, *Chimarra*, *Hydropsyche*, *Cheumatopsyche*)

Nonnative species: curly-leaved pondweed, water-chestnut, Eurasian watermilfoil, purple loosestrife, mud bithynia, zebra mussel, dark falsemussel, Atlantic rangia, common carp, brown trout, northern pike, rock bass, smallmouth bass, largemouth bass, black crappie, mute swan

Major riparian plants (freshwater tidal Hudson): silver maple, red maple, cottonwood, sycamore, willows, common reed, narrowleaf cattail

Special features: Drains much of Adirondack Mountains; long (248 km) intertidal zone; important anadromous fishery

Fragmentation: 14 dams in middle section; no dams on lower 248 km or in upper river

Water quality: highly variable: soft (<25 mg/L as CaCO₃) and nutrient-poor (soluble reactive phosphorus <10 µg/L) in headwaters; moderately hard (~50 mg/L as CaCO₃) and nutrient-rich (SRP ~20 mg/L) in middle section; brackish (>2 psu) and nutrient-rich (SRP >25 µg/L) in lower section

Land use: 62% forest, 25% agriculture, 8% urban, 5% other

Population density: 135 people/km² (approximated); 0/km² in headwaters to >10,000/km² in Manhattan

Major information sources: Weinstein 1977, Boyle 1979, Limburg et al. 1986, Stanne et al. 1996, Levinton and Waldman 2005

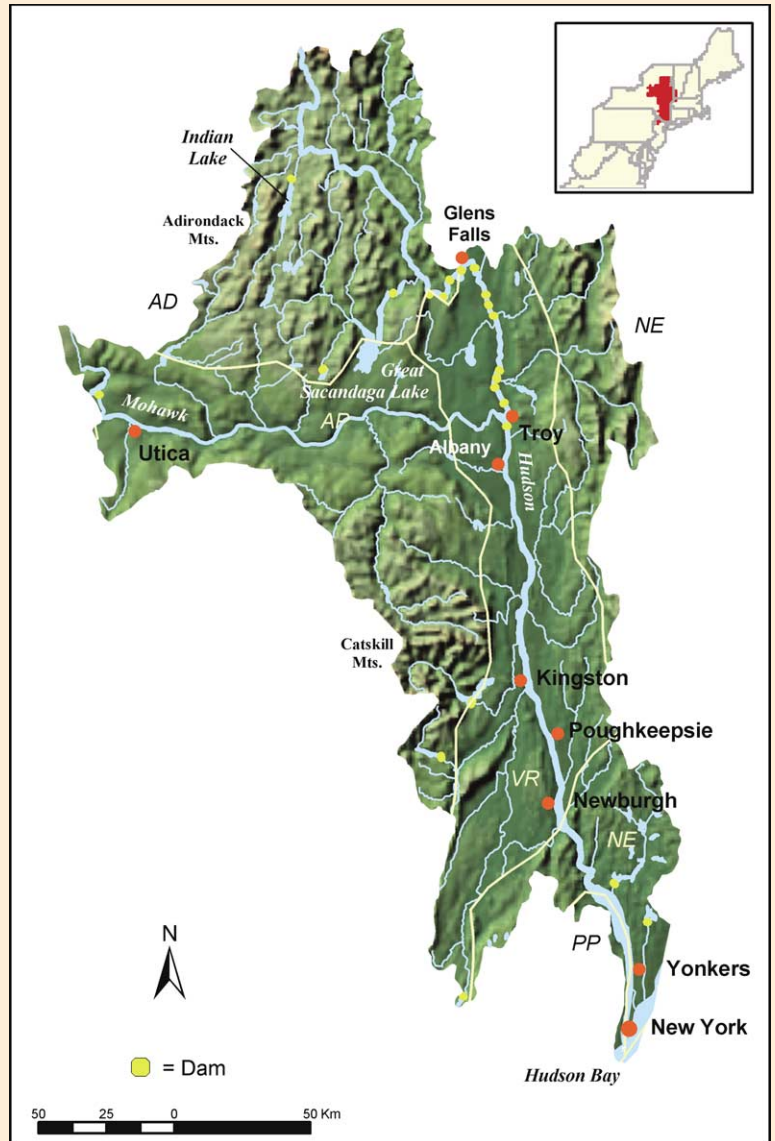

FIGURE 2.24 Map of the Hudson River basin. Physiographic provinces are separated by yellow lines.

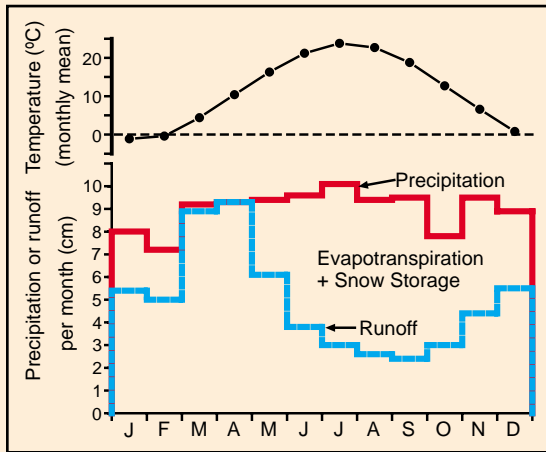

FIGURE 2.27 Mean monthly air temperature, precipitation, and runoff for the Delaware River basin.

DELAWARE RIVER

Relief: 698 m

Basin area: 33,041 km²

Mean discharge: 422 m³/s

River order: 7 (approximated)

Mean annual precipitation: 108 cm

Mean air temperature: 11.8°C

Mean water temperature: 13.8°C

Physiographic provinces: Appalachian Plateau (AP), Valley and Ridge (VR), New England (NE), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: Northeastern Coastal Forests, Allegheny Highlands Forests, Appalachian/Blue Ridge Forests

Number of fish species: 105

Major fishes: American eel, American shad, black crappie, bluegill, blue catfish, brown bullhead, brown trout, carp, channel catfish, fallfish, largemouth bass, river chub, river herring, rainbow trout, redbreast sunfish, rock bass, smallmouth bass, striped bass, walleye, white perch, yellow perch

Endangered species: 1 mussel, 1 fish, 1 turtle, 2 birds

Major other aquatic vertebrates: northern water snake, snapping turtle, eastern mud turtle, painted turtle, spotted turtle, red bellied turtle, beaver, river otter

Major benthic invertebrates: alderflies (*Sialis*), crustaceans (*Gammarus*, *Cyathura*), beetles (*Optioservus*, *Psephenus*, *Stenelmis*), caddisflies (*Brachycentrus*, *Cheumatopsyche*, *Chimarra*, *Hydropsyche*, *Lepidostoma*, *Rhyacophila*), mayflies (*Acentrella*, *Baetis*, *Epeorus*, *Eurylophella*, *Isonychia*, *Stenonema*, *Tricorythodes*), stoneflies (*Acronuria*), mollusks (*Ferissia*)

Nonnative species: Brazilian waterweed, brittle naiad, Carolina fanwort, dotted duckweed, Eurasian watermilfoil, European water clover, hydrilla, parrot feather, pond water starwort, purple loosestrife, sacred lotus, watercress, water lettuce, Asiatic clam, bluegill, brown trout, carp, channel catfish, largemouth bass, smallmouth bass, rock bass, walleye

Major riparian tree species: American beech, American chestnut, American hornbeam, bitternut hickory, sweet birch, black cherry, black locust, black walnut, butternut, eastern hemlock, catalpa, chestnut oak, hackberry, pignut hickory, red elm, red maple, northern red oak, shagbark hickory, silver maple, sour gum, sugar maple, tulip poplar, white ash, white oak

Special features: Longest undammed main-stem river (530 km) in eastern United States; several km of main stem and tributaries designated National Wild and Scenic Rivers; Delaware Water Gap

Fragmentation: 16 major dams on tributaries

Water quality: Port Jervis, New York: pH = 7.40, alkalinity = 11.36 mg/L as CaCO₃, NO₃-N = 0.23 mg/L, PO₄-P = 0.012 mg/L; Trenton, New Jersey: pH = 7.96, alkalinity = 43.54 mg/L as CaCO₃, NO₃-N = 0.87 mg/L, PO₄-P = 0.047 mg/L

Land cover: 60% forest, 24% agriculture, 9% urban, and 7% surface water or other

Population density: 214 people/km²

Major information sources: Schmidt 1986, Majumdar et al. 1988, Cuff et al. 1989, Patrick et al. 1992, Patrick 1994, DRBC 2002

FIGURE 2.26 Map of the Delaware River basin. Physiographic provinces are separated by yellow lines.

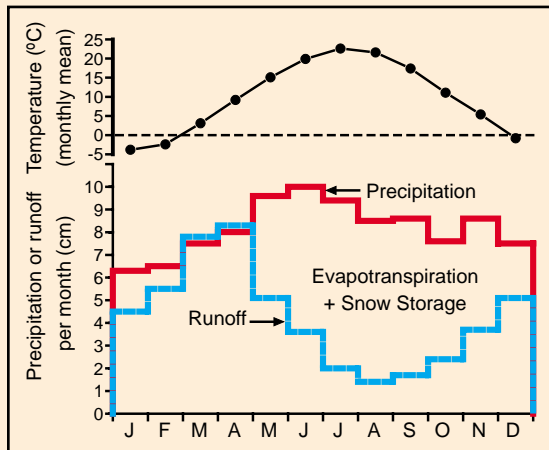

FIGURE 2.29 Mean monthly air temperature, precipitation, and runoff for the Susquehanna River basin.

SUSQUEHANNA RIVER

Relief: 959 m

Basin area: 71,432 km²

Mean discharge: 1153 m³/s

River order: 7 (approximated)

Mean annual precipitation: 98 cm

Mean air temperature: 9.7°C

Mean water temperature: 14°C

Physiographic provinces: Appalachian Plateau (AP), Valley and Ridge (VR), Piedmont Plateau (PP), Blue Ridge (BL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Chesapeake Bay

Terrestrial ecoregions: Allegheny Highlands Forests, Appalachian/Blue Ridge Forests, Northeastern Coastal Forests, Appalachian Mixed Mesophytic Forests

Number of fish species: 103

Number of endangered species: 2 birds

Major fishes: American eel, American shad, blueback herring, alewife, rock bass, smallmouth bass, channel catfish, walleye, muskellunge, striped bass, spotfin shiner, banded darter, bluntnose minnow, margined madtom, bluegill

Major other aquatic vertebrates: beaver, muskrat, common map turtle, eastern painted turtle, snapping turtle, wood turtle, northern water snake, great blue heron, bald eagle, peregrine falcon, mallard duck, wood duck, Canada goose

Major benthic invertebrates: mayflies (*Baetis*, *Pseudocloeon*, *Centroptilum*, *Stenonema*, *Leucocuta*, *Isonychia*, *Serratella*, *Anthopotamus*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*), crustaceans (spinycheek crayfish), mollusks (eastern elliptio, yellow lampmussel), stoneflies (*Agnatina*), beetles (*Stenelmis*, *Optioservus*, *Dubiraphia*), chironomid midges (*Rheotanytarsus*, *Polypedilum*, *Tvetenia*, *Chironomus*, *Dicrotendipes*)

Nonnative species: 27 fishes (smallmouth bass, channel catfish), Asiatic clam, zebra mussel, rainbow mussel, rusty crayfish, watercress, Eurasian watermilfoil, purple loosestrife, curly pondweed, Japanese knotweed, mile-a-minute weed

Major riparian plants: sycamore, tulip poplar, red maple, silver maple, river birch, black willow, black cherry, American beech, American elm, black locust

Special features: Broad river channel, numerous islands, largest commercially non-navigable river in U.S., short tidal/estuarine section for a coastal river.

Fragmentation: >100 dams, first major dam 16 km from mouth

Water quality: pH = 6.9 to 9.0, alkalinity = 40 to 110 mg/L as CaCO₃, NO₃-N = 0.29 to 1.49 mg/L, PO₄-P = <0.02 to 0.1 mg/L; pollution from acid mine drainage and agricultural runoff

Land use: 63% forest, 20% cropland, 9% urban, 7% pasture

Population density: 56 people/km²

Major information sources: Hocutt et al. 1986, Stranahan 1993, Edwards 1996, Rowles and Sitlinger 2000, Susquehanna River Basin Commission

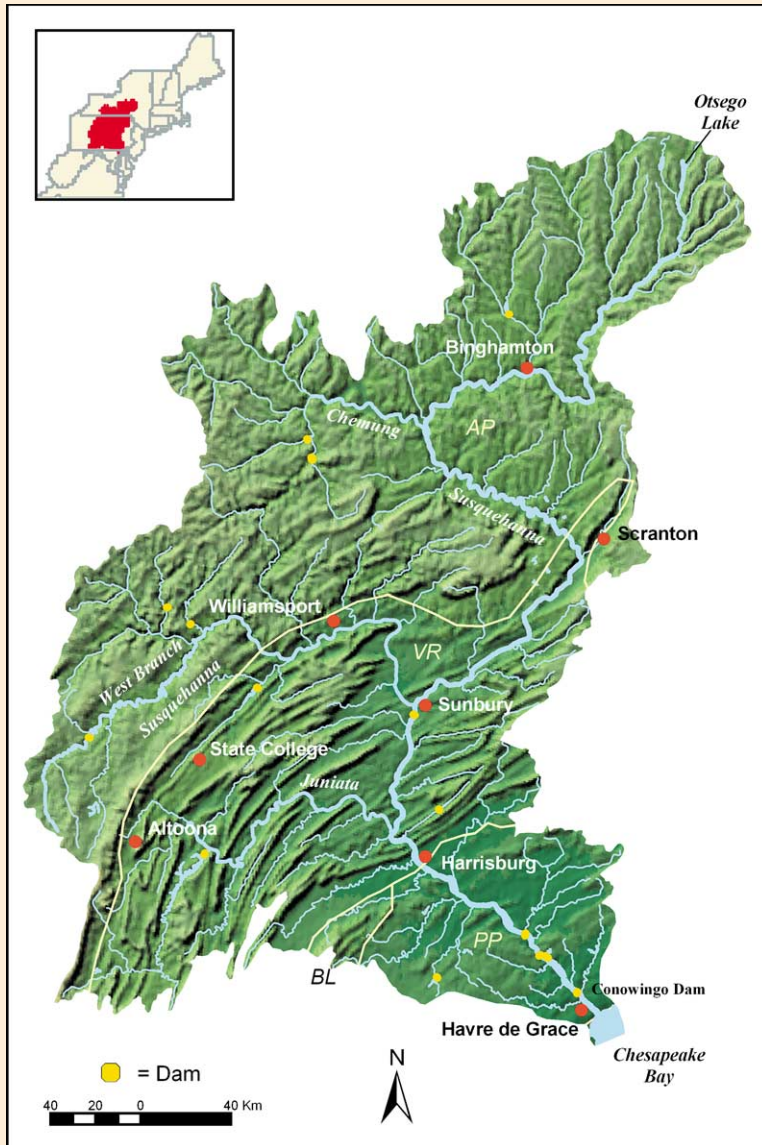

FIGURE 2.28 Map of the Susquehanna River basin. Physiographic provinces are separated by yellow lines.

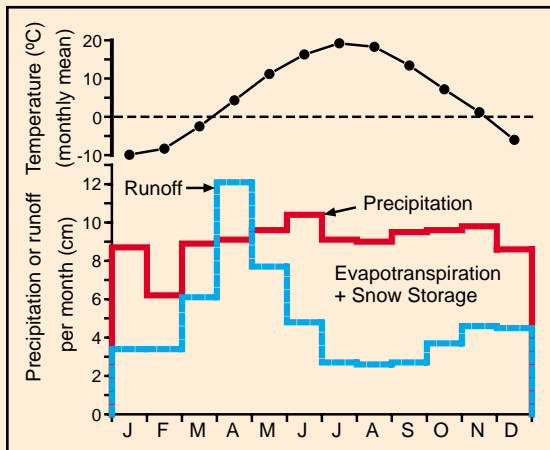

FIGURE 2.31 Mean monthly air temperature, precipitation, and runoff for the Kennebec River basin.

KENNEBEC RIVER

Relief: 1234 m

Basin area: 13,944 km²

Mean discharge: 257 m³/s

River order: 6 (approximated)

Mean annual precipitation: 108 cm

Mean air temperature: 11.9°C

Mean water temperature: 10.2°C

Physiographic province: New England (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: New England/Acadian Forests, Northeastern Coastal Forests

Number of fish species: 48

Number of endangered species: 1 fish

Major fishes: alewife, blueback herring, Atlantic salmon (including migratory and landlocked populations), American shad, striped bass, rainbow smelt, smallmouth bass, brook trout, brown trout, rainbow trout, white perch, yellow perch, white sucker, fallfish

Major other aquatic vertebrates: eastern painted turtle, snapping turtle, beaver, muskrat, river otter

Major benthic invertebrates: mayflies (*Ameletus Caenis*, *Epeorus*, *Ephemerella*, *Eurylophella*, *Heptagenia*, *Stenacron*, *Stenonema*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Macrostemum*, *Mystacides*, *Neureclipsis*, *Polycentropus*), hellgrammites (*Corydalus*), beetles (*Macronychus*), odonates (*Calopteryx*), crustaceans (*Asellus*, *Cambarus*, *Hyalloa*, *Orconectes*), mollusks (*Alasmidonta*, *Amnicola*, *Anodonta*, *Campeloma*, *Elliptio*, *Lampsilis*)

Nonnative species: purple loosestrife, rusty crayfish, common carp, white catfish, gizzard shad, brown trout, rainbow trout, smallmouth bass, largemouth bass, black crappie, northern pike, European rudd

Major riparian plants: balsam fir, red maple, paper birch, eastern white pine, chokecherry, northern red oak, eastern hemlock

Special features: First major dam (Edwards Dam) on major river breached by U.S. government (1999); Moosehead Lake (311 km²); Merrymeeting Bay—large freshwater tidal estuary

Fragmentation: 8 hydroelectric dams

Land use: 82% forest, 6% agriculture, 2% urban, 10% surface water; upper basin largely forested; lower basin with significant agriculture

Water Quality: total nitrogen = 1.4 mg/L, total phosphorous = 0.03 mg/L, total organic carbon = 7.0 mg/L, hardness = 17.9 mg/L as CaCO₃, pH = 7.1, specific conductance = 66.9 μS/cm. Pollution source from two pulp and paper mills

Population density: 15 people/km²

Major information sources: Patrick 1996, Davies et al. 1999

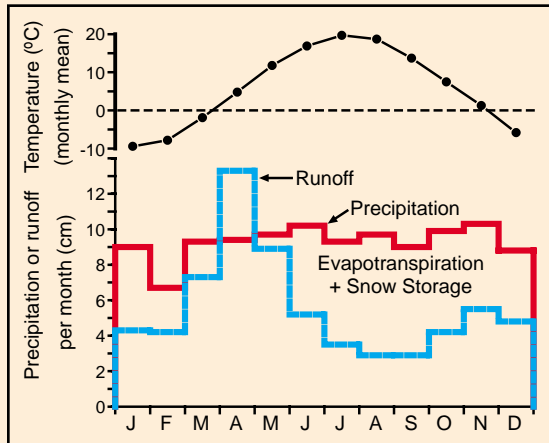

FIGURE 2.33 Mean monthly air temperature, precipitation, and runoff for the Androscoggin River basin.

ANDROSCOGGIN RIVER

Relief: 1234 m

Basin area: 8451 km²

Mean discharge: 175 m³/s

River order: 6 (approximated)

Mean annual precipitation: 111 cm

Mean air temperature: 10.9°C

Mean water temperature: 9.7°C

Physiographic province: New England (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: New England/Acadian Forests, Northeastern Coastal Forests

Number of fish species: 33 (27 native), 7 estuarine

Number of endangered species: 1 fish

Major fishes: brown trout, rainbow trout, smallmouth bass, white perch, yellow perch, white sucker, fallfish

Major other aquatic vertebrates: beaver, muskrat, river otter

Major benthic invertebrates: mayflies (*Ameletus*, *Caenis*, *Ephemerella*, *Eurylophella*, *Heptagenia*, *Stenacron*, *Stenonema*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Macrostemum*, *Mystacides*, *Neureclipsis*, *Polycentropus*), hellgrammites (*Corydalus*), beetles (*Macronychus*), crustaceans (*Asellus*, *Hyalolela*, *Orconectes*), mollusks (*Alasmidonta*, *Ammicola*, *Anodonta*, *Campeloma*, *Elliptio*, *Strophitus*, *Lampsilis*, *Margaritifera*)

Nonnative species: purple loosestrife, rusty crayfish, calico crayfish, brown trout, rainbow trout, smallmouth bass, largemouth bass, northern pike, spottail shiner, common carp, white catfish

Major riparian plants: balsam fir, red maple, paper birch, American witch hazel, eastern white pine, chokecherry, northern red oak, eastern hemlock

Special features: Lake Umbagog National Wildlife Refuge

Fragmentation: 14 hydroelectric dams from source at Umbagog Lake to tidewater

Land use: 86% forest, 5% agriculture, 2% urban, 7% surface water; upper basin largely forested; lower basin with significant agriculture

Water quality: Total nitrogen = 0.77 mg/L, total phosphorous = 0.06 mg/L, total organic carbon = 7.5 mg/L, hardness = 19.1 mg/L as CaCO₃, pH = 6.7, specific conductance = 101.8 μS/cm. Pollution source from three large pulp and paper mills

Population density: 25 people/km²

Major information sources: Davies et al. 1999

MERRIMACK RIVER

Relief: 1563 m

Basin area: 12,986 km²

Mean discharge: 235 m³/s

River order: 6 (approximated)

Mean annual precipitation: 92 cm

Mean air temperature: 7.3°C

Physiographic province: New England (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: New England/Acadian Forests, Northeastern Coastal Forests

Number of fish species: 50

Number of endangered species: 1 fish

Major fishes: American eel, alewife, brook trout, brown trout, rainbow trout, chain pickerel, fallfish, common shiner, white sucker, white perch, smallmouth bass, largemouth bass, black crappie, bluegill

Major benthic invertebrates: caddisflies (Hydropsychidae, Philopotamidae, Leptoceridae), chironomid midges, crustaceans (Gammaridae), snails, worms

Nonnative species: common carp, brown trout, smallmouth bass, largemouth bass, black crappie

Major riparian plants: NA

Fragmentation: high (>500 dams in basin, several on main stem)

Water quality: formerly very poor, now improved: pH = 6 to 7; alkalinity = 8 to 10 mg/L as CaCO₃; NO₃-N = 0.1 to 0.4 mg/L; PO₄-P = <0.01 to 0.05 mg/L

Land use: 75% forest, 13% urban, 6% agriculture, 5% surface water, 1% other

Population density: 156 people/km² (approximated)

Major information sources: Hoover 1938, Scarola 1973, Flanagan et al. 1999

RARITAN RIVER

Relief: 430 m

Basin area: 2862 km²

Mean discharge: 34 m³/s

River order: 5 (approximated)

Mean precipitation: 118 cm

Mean air temperature: 10.9°C

Mean water temperature: 13.6°C

Physiographic provinces: New England (NE), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregions: Northeastern Coastal Forests

Number of fish species: 88 (including 23 estuarine)

Number of endangered species: 1 mussel, 1 turtle

Major fishes: white sucker, blacknose dace, American eel,

tessellated darter, longnose dace, redbreast sunfish, spottail shiner, common shiner, banded killfish, rock bass, bluegill, brown trout, brook trout, smallmouth bass, largemouth bass, American shad, alewife

Major other aquatic vertebrates: beaver, muskrat, river otter, eastern painted turtle, common snapping turtle, northern water snake, Canada goose, mallard duck, wood duck, great blue heron, osprey

Major benthic invertebrates: mayflies (*Anthopotamus*, *Baetis*, *Centroptilum*, *Leucocuta Pseudocloeon*, *Stenonema*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), chironomid midges (*Rheotanytarsus*, *Tanytarsus*, *Polypedilum*)

Nonnative species: 25 fishes (smallmouth bass, largemouth bass, channel catfish), Asiatic clam, Eurasian watermilfoil, purple loosestrife, phragmites

Special features: Longest river entirely in New Jersey; heavily urbanized/suburbanized

Fragmentation: High (>250 dams in basin; 57 for flood control; only 5 are >15 m high)

Water quality: pH = 7.3 to 7.9, alkalinity = 36 to 53 mg/L as CaCO₃, total N = 0.67 to 2.50 mg/L, PO₄-P = 0.08 to 0.25 mg/L, conductivity = 234 to 762 μS/cm

Land use: 27% forest, 36% developed, 19% agriculture, 15% wetland, 2% water, 1% barren

Population density: 419 people/km²

Major information sources: Kennen 1999; NJWSA 2000, 2002a, 2002b

POTOMAC RIVER

Relief: 1481 m

Basin area: 37,995 km²

Mean discharge: 320 m³/s

River order: 7 (approximated)

Mean annual precipitation: 99 cm

Mean air temperature: 12.3°C

Mean water temperature: 14.0°C

Physiographic provinces: Appalachian Plateau (AP), Valley and Ridge (VR), Piedmont Plateau (PP), Blue Ridge (BL), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Chesapeake Bay

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Appalachian Mixed Mesophytic Forests, Middle Atlantic Coastal Forests, Northeastern Coastal Forests

Number of fish species: 95 species (65 native)

Number of endangered species: 1 fish, 1 mussel

Major fishes: smallmouth bass, channel catfish, spottail shiner, spotfin shiner, bluntnose minnow, redhorse sucker, redbreast sunfish, bluegill, tessellated darter

Major other aquatic vertebrates: beaver, muskrat, common snapping turtle, eastern painted turtle, great blue heron, bald eagle, osprey, Canada goose, mallard duck

Major benthic invertebrates: mayflies (*Anthopotamus*, *Caenis*, *Ephoron*, *Serratella*, *Stenonema*, *Tricorythodes*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Potamyia*, *Macrostemum*), chironomid midges (*Thienemannimyia*, *Tanytarsus*, *Cricotopus*, *Polypedilum*, *Cryptochironomus*, *Synorthocladus*), beetles (*Stenelmis*)

Nonnative species: smallmouth bass, channel catfish, common carp, several sunfishes, northern pike, muskellunge, Asiatic clam, hydrilla, Eurasian watermilfoil, common hornwort, purple loosestrife, phragmites

Special features: second-largest tributary to Chesapeake Bay, 174 km tidal/estuarine section, no native piscivores originally above Great Falls

Fragmentation: High, but only three impoundments >4 km²; >60 blockages in the Anacostia basin being removed or altered for fish passage.

Water quality: pH = 7.3 to 8.0, alkalinity = 36 to 86 mg/L as CaCO₃, NO₃-N = 0.58 to 1.48 mg/L, PO₄-P = <0.01 to 0.3 mg/L, conductivity = 194 to 491 μS/cm

Land use: 58% forest, 5% developed, 32% agriculture, 4% water, 1% wetland, 1% barren

Population density: 138 people/km²

INTRODUCTION

The Atlantic slope region of the southeastern United States encompasses a broad geographic area from 38°N to 26°N latitude, ranging from central Virginia to eastern Florida (Fig. 3.2). The northern part of the region includes the Southern Appalachian Mountains along its western boundary to the flat coastal areas along the Atlantic Ocean. Below 31°N latitude in southern Georgia and Florida, however, there is only Coastal Plain. The region has abundant rainfall, moderate to warm temperatures, historically dense forests, and a landscape mosaic of forests, wetlands, agriculture, and urbanized areas. A series of rivers drain the region, most flowing in a primarily southeasterly direction to the Atlantic coast (Garman and Nielsen 1992, Smock and Gilinsky 1992, Patrick 1996). The diverse geology, physiography, and climate of the region have produced rivers that have variable geomorphic, hydrologic, and biological characteristics. Many of the larger rivers have their

headwaters in the rugged Appalachian Mountains, whereas others originate among rolling Piedmont hills or on the flat Coastal Plain.

Flowing here are some of the most historic rivers on the continent. They had a profound influence on Native American civilizations that occupied these basins for over 11,000 years until well into the eighteenth century. The first Europeans to occupy this region were the Spanish missionaries who settled along the coast in the early 1500s and remained for more than a century. The establishment of Jamestown in 1607, along the James River in Virginia, marked the British arrival in North America that would eventually push Native Americans out of the southeastern Atlantic region. British colonists established towns at the mouths of major rivers that would eventually become major cities. They used the rivers as corridors for inland incursions that would help develop the agricultural and commercial strength of the United States.

Sixteen major rivers are found along the southeastern Atlantic slope, from the York River on the

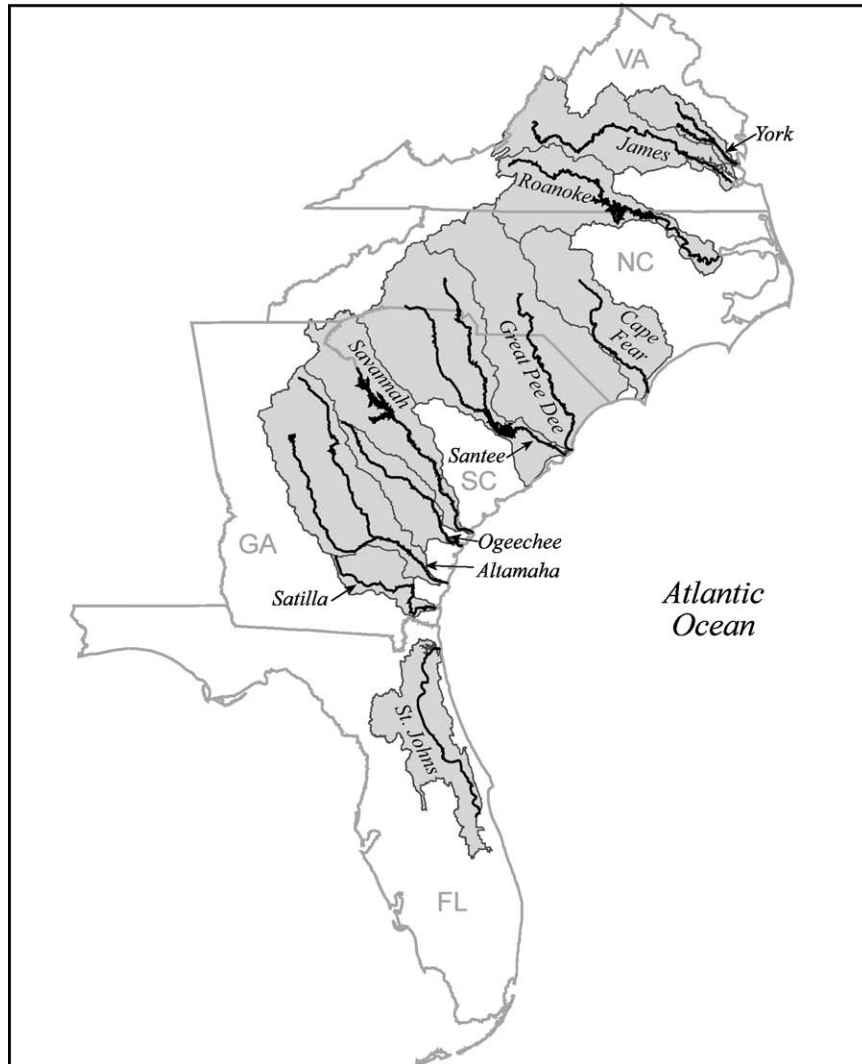

FIGURE 3.2 Atlantic coast rivers of the southeastern United States that are covered in this chapter.

northernmost border to rivers on the eastern coast of Florida. The mouths of major rivers occur about every 100km along the coast (see Fig. 3.2). We will discuss five major rivers that together cover a considerable range in natural diversity and human impacts: James, Cape Fear, Savannah, Ogeechee, and St. Johns. Abbreviated descriptions of physical and biological information are provided for six additional rivers: York, Roanoke, Great Pee Dee, Santee, Altamaha, and Satilla.

Physiography and Climate

The southeastern Atlantic slope region is an area of varied physiography that includes four physiographic provinces. Along its western edge the region encom-

passes the unglaciated topography of the eastern slopes of the Southern Appalachian Mountains, comprised of the Valley and Ridge and Blue Ridge provinces. The Blue Ridge province tapers into the rolling hills of the Piedmont Plateau, and the Piedmont abruptly drops down to the broad, flat Coastal Plain. Geologically old and highly weathered rock and soil characterize the area.

The Valley and Ridge, Blue Ridge, and Piedmont are areas of heavily dissected and primarily highly metamorphosed rock of Paleozoic age, with occasional areas of igneous and sedimentary rock. The Valley and Ridge consists of parallel valleys and ridges that extend south through Georgia and into Alabama at an elevation typically 300 to 900m asl. The underlying rock is varied, with bands of lime-

stone, dolomite, shale, sandstone, cherts, and marble. Numerous springs and caves are scattered throughout the area. The Blue Ridge, terminating to the south in northern Georgia, is the easternmost ridge of the Appalachian Highlands, rising to peaks of more than 1700m asl. It varies from narrow ridges to plateaus and broad mountains formed from primarily metamorphic rock. The Blue Ridge has some of the highest floral and faunal biodiversity in the eastern United States.

The Piedmont Plateau is a transition zone between the mountains to the west and the flat coastal areas to the east. Cutting through the central portions of Virginia, the Carolinas, and north-central Georgia, these rolling uplands of largely metamorphic rock with igneous intrusions generally range in altitude from 150 to 600m asl, the higher altitudes occurring to the south. At its eastern boundary, the metamorphic rock of the Piedmont dips below the sedimentary deposits of the Coastal Plain. This boundary is termed the Fall Line, where a steep drop in elevation causes rivers to quickly descend through a series of rapids before leveling off in the Coastal Plain.

The Coastal Plain, a former sea bottom, is up to 200km wide along the southeastern Atlantic and contains Cretaceous, Tertiary, and Quaternary sediments that drop gently from the Piedmont to the Atlantic Ocean. Its topography is that of a broad plain, with low relief and numerous wetlands and only a few inland ridges paralleling the coast. Elevation is usually <150m asl, and much of it is <30m asl.

Soils of the region are old and highly weathered, with ultisols predominating over much of the area. These are light-colored, acidic soils with a low cation-exchange capacity and a sandy or loamy surface horizon and a loamy to clay subsurface. Spodosols, with a high organic content and a high water-retention capacity, are common along the Florida coast.

The climate of the region ranges from humid continental in the north to humid subtropical in the south. Temperate summers and cool winters prevail in the north and at higher altitudes, grading to hot wet summers and mild winters in the subtropical southern region. Mean monthly air temperature across the region ranges from highs of 24°C to 28°C to lows of 2°C to 11°C. Precipitation is ample and fairly evenly distributed over the year, autumn being the driest period. Nearly all precipitation occurs as rainfall. The range in mean annual precipitation over the region is about 100 to 140 cm, being highest to the south and along the coast. Tropical storms and

hurricanes cause short periods of high precipitation primarily during late summer and autumn.

Basin Landscape and Land Use

The southeastern Atlantic river basins all occur in the Temperate Deciduous Forest biome, which is further divided into four terrestrial ecoregions (Ricketts et al. 1999). These ecoregions generally lie along a north-east to southwest axis. The mountainous Valley and Ridge and Blue Ridge physiographic provinces roughly correspond to the Appalachian/Blue Ridge Forests ecoregion, which originally contained dense oak and American chestnut communities. The Piedmont roughly corresponds to the Southeastern Mixed Forests ecoregion, consisting of oak, hickory, and pine forests. The Coastal Plain is divided into the Middle Atlantic Coastal Forests (Virginia and the Carolinas) and the Southeastern Conifer Forests (Georgia and Florida) ecoregions. These Coastal Plain ecoregions supported extensive pine forests where fire suppressed the growth of oak, gum, beech, southern magnolia, and other deciduous trees. Winding through the coastal uplands are broad floodplain forests, intimately associated with both major and minor river systems. They range up to several kilometers in width along the major rivers and support highly productive bottomland hardwood forests, typically dominated by bald cypress, swamp black gum, and water tupelo, which exist as a broad ecotone between upland areas and river channels.

Although the region originally was covered by deciduous and pine forests, today the landscape is highly fragmented. The region was among the first in North America to be colonized and impacted by European settlers. Widespread forest clearing began in earnest during the eighteenth century and peaked during the nineteenth and early twentieth centuries, resulting in heavy soil erosion and input of sediment to streams and rivers. Today, the landscape includes a mosaic of second-growth forests, farmland, old fields, and timbered and urbanized areas. The Valley and Ridge, Blue Ridge, and Piedmont were highly cultivated, although large portions of those regions have reverted to pine and hardwood forests. Extensive areas of the Coastal Plain presently support regrowth forests, although much of that land consists of managed monoculture pine forests. The southeastern pine forests are one of the two principal lumber-producing regions of the United States. Cropland covers from 15% to nearly 50% of the Coastal Plain sections of the river basins, with higher crop

cover occurring to the north, where soils are better drained, than to the south. The major cities in the region are often the oldest cities, which either developed along the coast (Norfolk, Wilmington, Charleston, Savannah, Jacksonville) or near the Fall Line (Richmond, Raleigh, Columbia, Augusta), where rivers could be most easily crossed without bridges. These growing urban areas have put continuous pressures on their rivers over the past two to three centuries.

The recent revegetation of much land originally under cultivation has resulted in a decrease in soil erosion, although all rivers of the region continue to receive significant inputs of soils and nutrients as nonpoint-source pollutants. The ongoing inputs of soil, along with the existing bed load in tributaries accumulated from decades to centuries of soil erosion, continue to provide a high input of sediment to most rivers of the region. As such, suspended and bed load solids are the most widespread and prevalent water pollution problem throughout the region. Most of the rivers also show local effects from municipal and industrial point-source discharges, and most are significantly impacted by impoundments. All of the rivers support heavy recreational use by boaters and fisherman.

The Rivers

There are three freshwater ecoregions within the southeastern Atlantic slope region, divided primarily as a function of latitude and drainage basin, according to the classification of Abell et al. (2000). These include the southern portion of the Chesapeake Bay ecoregion, the South Atlantic ecoregion (southern Virginia to eastern Georgia), and the Florida ecoregion (southern Georgia and Florida).

The rivers covered in this chapter are quite varied in their geomorphology, hydrology, chemistry, and biology. Some of these differences, such as in mean annual temperature, are largely due to the region extending over 10 degrees of latitude. Other differences are caused by the variation in geology, dominant vegetation, and land use within the river basins. Although there are many differences among the rivers, Garman and Nielsen (1992) provide a useful scheme that classifies the rivers into four groups based on similarities in their physicochemical and ecological characteristics. The groups cluster roughly according to latitude and mostly overlap the freshwater ecoregion classification scheme of Abell et al. (2000).

The first group includes the York, James, and Roanoke rivers, the northernmost rivers with the coolest water and widest fluctuations in water temperature (see Fig. 3.2). They originate in the Virginia mountains and Piedmont, have a higher gradient than the other rivers, and have a generally rocky substratum of gravel, cobble, and bedrock until reaching their coastal areas. Their water is relatively clear and slightly alkaline. The York and James are included in the Chesapeake Bay freshwater ecoregion and the Roanoke is in the South Atlantic freshwater ecoregion. The Roanoke, however, has many characteristics similar to the more northern basins, and other characteristics, such as its fish assemblage, that are transitional to the rivers to the south.

The largest group of rivers occurs immediately south of the Roanoke and encompasses most of the major rivers of the Carolinas and parts of Georgia, corresponding to the South Atlantic freshwater ecoregion (see Fig. 3.2). Included in this group are the Tar, Neuse, and Cape Fear of North Carolina, the Great Pee Dee and Santee-Cooper systems flowing across the Carolinas, the Savannah River along the South Carolina–Georgia border, and the Ogeechee and Altamaha rivers of Georgia. These rivers have their headwaters primarily in the mountains or Piedmont, but are of lower gradient than rivers of the first group. Their sediment is mainly sand and silt, with some rocky areas primarily upriver. The rivers are high in suspended solids, especially in their Piedmont section, and have neutral to slightly acidic waters that are stained in their Coastal Plain sections because of high dissolved organic carbon (DOC) concentrations.

The watersheds of the third group of rivers lie entirely within the Coastal Plain and are found within both the South Atlantic and Florida freshwater ecoregions. They include the Edisto of South Carolina, the Satilla of Georgia, and the St. Marys along the Georgia–Florida border. These are low-gradient rivers with sediment of fine sand and silt and no rocky areas. They are acidic, low alkalinity, black-water systems, and their DOC concentrations often range up to 50 mg/L.

The St. Johns River typifies a fourth type of river that occurs exclusively in the Florida freshwater ecoregion and has characteristics very different from the other rivers covered in this chapter. They are wide and shallow systems with very low gradients. Although all of the rivers covered in this chapter are tidal, with estuaries at their mouths, the Florida rivers have extensive salt and fresh tidal areas extending far upriver. Their highly alkaline water chemistry,

fringing salt marshes, and mix of freshwater and estuarine biota reflect their close connection with the ocean. An exception among Florida rivers is the extensively channelized Kissimmee River, which flows in a southerly direction before emptying into Lake Okeechobee.

The large rivers originating in the mountains offer the greatest change in aquatic biota because they each begin as high-gradient systems and end as low-gradient systems, during which time they traverse substantially different geological formations and substrata. At higher elevations their flow is typically turbulent, but once they enter the Coastal Plain their flow becomes laminar as they meander through broad floodplain forests that have their own unique plant communities. In those rivers found entirely within the Coastal Plain, there is only laminar flow within the wide floodplains.

Although precipitation is relatively uniform throughout the region, natural discharge regimes are strongly seasonal. Highest mean discharge occurs during the winter and spring, driven largely by seasonal changes in evapotranspiration. Under the natural regime of low evapotranspiration and high discharge in winter and spring, floodplain forest swamps are inundated for weeks to months, an important factor in the ecology of both the floodplains and main river channels (Benke et al. 2000). Hurricanes also are an integral aspect of the hydrology and ecology of rivers in the southeast, occasionally causing extensive flooding. Though these rivers can go decades without a significant impact from a hurricane, they can just as quickly be struck by a series of hurricanes that can have devastating effects both on the river and the people in the basin.

For most of the southeastern Atlantic slope rivers, natural flooding has been substantially reduced or altered by dams in upstream reaches and by channelization for navigation in the lower reaches. Although a few rivers in the region have no major dams (e.g., the Ogeechee and Satilla), others such as the Roanoke, Santee, and Savannah are highly fragmented by impoundments. The impoundments were constructed for a variety of intended uses, in particular hydroelectric power generation and flood control, but also drinking and industrial water supply, low-flow augmentation, recreation, and fish and wildlife. Besides altering hydrographs, with associated effects on river and floodplain ecology, the dams have affected water chemistry, the downstream transport of sediment, and the structure and functioning of the biological communities of the rivers. The decrease in migratory fish runs resulting from damming the

rivers, for example, has had important effects on the nutrient dynamics and food webs of many rivers of the region (Garman and Macko 1998).

An important natural feature of most Coastal Plain rivers is the occurrence of wood (snags) that is deposited when trees are undercut along the banks. Snags provide an important habitat, particularly for invertebrates, fishes, and reptiles, and thus likely enhance overall biodiversity and faunal productivity (Benke, van Arsdall et al. 1984, Benke, Henry et al. 1985). Unfortunately, wood has been removed from many of these rivers by snagboats for over a century because of the hazard it creates for recreational and commercial navigation.

Rivers of the southeastern Atlantic slope have a high degree of biological distinctiveness. The South Atlantic and Florida ecoregions are considered to be globally outstanding, and the Chesapeake Bay ecoregion is considered continentally outstanding (Abell et al. 2000). The South Atlantic ecoregion is the richest, supporting many endemics among at least 177 species of fishes, 39 species of unionid mussels, and 56 species of crayfishes, although not all of these are riverine species. Unfortunately, the conservation status of both the South Atlantic and Florida ecoregions is currently endangered and anticipated to become critical within the next 20 years (Benz and Collins 1997, Abell et al. 2000). At least 47 species of fishes and mussels are at risk of extinction in the South Atlantic (Master et al. 1998).

The primary perturbations to the rivers of this region include dams, nonpoint-source runoff, point-source discharges, channelization, and snag removal. Nearly all of the rivers have been impounded at or above the Fall Line, altering their geomorphology, hydrology, and ecology. The proliferation of non-native species also is affecting the ecology of many of the rivers. The Asiatic clam is widespread and common throughout the region, although limited by low Ca concentrations in some rivers, such as the Satilla. Many species of nonnative fishes now are widespread and abundant, have substantially altered riverine food webs, and are having considerable negative impact on other species of fishes.

JAMES RIVER

Arising in the western mountains of Virginia at the confluence of the Jackson and Cowpasture Rivers, the James River flows eastward for about 540 km to the southern portion of the Chesapeake Bay (Fig. 3.13). It drains a large portion of central Virginia

FIGURE 3.3 James River at Blue Ridge Parkway, northwest of Lynchburg, Virginia (PHOTO BY TIM PALMER).

(basin area = 26,164 km²), including extensive areas of mountains, rolling Piedmont hills, and flat Coastal Plain. Along its path to the bay the main-stem James changes from a rushing, cool 5th order river to a broad, meandering tidal 7th order river. Much of the river is very scenic, and water quality is generally quite high (Fig. 3.3). Although a number of low-head dams occur along the river, the James has been spared the large impoundments that occur on many of the other major rivers of the southeastern Atlantic slope. Fishing is excellent and includes one of the premier smallmouth bass recreational fisheries on the continent.

The James is one of the most historic rivers in North America. Paleo-Indians using Clovis points were in the basin about 12,000 years ago, and bands using pre-Clovis points may have been present 6000 years earlier. A number of Native American tribes developed throughout the basin, including the Powhatans in coastal areas and the Monacans in the Piedmont. The river was the focal point for many of their activities as well as those of the earliest English colonial settlements, beginning with Jamestown and

Captain John Smith's explorations of the lower river in 1607. The shores of the lower river became lined with historic tobacco plantations, producing the crop that fueled the early economy of the area. The river served both the North and South throughout much of the Civil War, being a key pathway for invasion into the Confederacy during several Northern campaigns. Some of the nation's first ironworks and flour and paper mills were built along the river, helping to make the river a major artery for commerce then as it is now.

Physiography, Climate, and Land Use

The James River basin flows primarily along an east–west axis at 37°N latitude and crosses the Valley and Ridge (VR), Blue Ridge (BR), Piedmont (PP), and Coastal Plain (CP) physiographic provinces (see Fig. 3.13). This area corresponds to the Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, and Middle Atlantic Coastal Forests terrestrial ecoregions (Ricketts et al. 1999). The predominant trees throughout the basin include a variety of oaks,

hickories, sweetgum, tuliptree, and loblolly pine. Soils are generally highly weathered ultisols, their characteristics varying across the physiographic provinces.

Annual mean air temperature is about 14°C, with monthly mean temperatures typically ranging from 2°C in January to 26°C in July (see Fig. 3.14). Annual precipitation averages 108 cm, falling primarily as rainfall and being relatively evenly distributed over the year.

The landscape, once dominated by the extensive Temperate Deciduous Forest biome, is still largely rural but is greatly influenced by agriculture and silviculture. About 71% of the basin is forested, 23% is in agriculture, and 6% is urbanized (http://www.dcr.state.va.us/waterways/the_problem/watersheds_and_you/p_james_river_watershed.htm). Three major urban areas occur along the river: Lynchburg in the upper Piedmont, Richmond at the Fall Line, and Norfolk and other cities at the river's mouth. Population density, at a mean of 96 people/km², varies considerably across the basin, from the highly urbanized areas to large rural expanses.

River Geomorphology, Hydrology, and Chemistry

The river can be separated into five sections, each defined in terms of its physical, hydrological, and chemical characteristics and constituting an area of the river of relatively similar habitat and biotic characteristics (adapted from Garman and Smock 1999). Though the headwaters arise high in the mountains, the main-stem James River arises at an elevation of 328 m asl in its Valley and Ridge section. This part of the river, with a channel gradient of 90 cm/km and a mean width of 75 m, is distinguished by well-developed riffles, runs, and pools. A diversity of depth and velocity regimes exist, providing a wide variety of habitats for riverine biota. The river's sediment here consists primarily of boulders, cobble, and gravel that is well sorted with little embedding. The highest concentrations of benthic organic matter in the river occur here, both as large woody debris and finer particles. The water chemistry of this section also is distinct from downstream areas, with the mean conductivity (271 μS/cm), pH (8.3), alkalinity (81 mg/L as CaCO₃), and hardness (111 mg/L as CaCO₃) of the water all higher than downstream, reflecting inputs from tributaries that flow through areas of limestone.

The river's physical and biological characteristics change substantially as it flows into an impounded

section above the city of Lynchburg, where a series of three dams regulate flow through shallow impoundments. The habitat produced by these dams is intermediate between a free-flowing river and that of the more typical deep and broad reservoirs of the southeast. Although the habitat here is less diverse and conducive to riverine biota than elsewhere along the river, the impoundments do increase overall habitat and biotic diversity when viewed on the scale of the entire river.

The James then winds its way eastward for 220 km across the Piedmont. This is a long stretch where the river widens to a mean of 170 m and the channel gradient, at 45 cm/km, is half that in the Valley and Ridge section. A riffle-run-pool geomorphology is evident, but the riffles are not nearly as well developed or extensive as upriver. A variety of sediment particle sizes occurs, including some extensive areas of bedrock, and many of the riffles and especially the runs are highly embedded with gravel and sand. The water chemistry of this section of the river shows the influence of inputs from tributaries that drain areas with predominately crystalline rock, resulting in lower conductivity (183 μS/cm), pH (7.7), alkalinity (61 mg/L as CaCO₃), and hardness (71 mg/L as CaCO₃) than upriver.

At Richmond the river begins its descent through the Fall Line to the Coastal Plain. The Fall Line along the James is about 15 km in length, dropping about 2 m/km. Fast-flowing water, extensive outcroppings of bedrock, and riffles of well-sorted boulders and cobble characterize this section of the river, famous for its Class IV white-water rapids. Intermixed among these riffles are extensive depositional areas of shifting sand that embed boulders and overlay bedrock. A number of old low-head dams span the channel, all recently having been breached or having fish passages installed to provide for the upstream migration of anadromous fishes.

The character of the river changes dramatically below the Fall Line. The channel quickly widens as it meanders for about 170 km through the Coastal Plain with a gradient of about 20 cm/km. The river here is tidal, with freshwater tides predominating for about 70 km down to the city of Hopewell. Although numerous oxbows and islands occur in the lower James, the river's channel, with sediment of sand and silt, has been substantially straightened and deepened by dredging to accommodate deepwater shipping up to Richmond's port facilities.

Annual mean discharge at Richmond, just above where the river becomes tidal, is 213 m³/s, or about four times greater than at the river's origin. The

James River has highest discharge during late winter and spring and lowest flows in late summer and autumn (see Fig. 3.14). With highest precipitation in July and August, it appears that the river's hydrology is primarily influenced by seasonal changes in evapotranspiration. Tropical storms from midsummer through autumn occasionally result in much flooding along the river's length. Flow in the river is stabilized only slightly by the series of low dams at and above Lynchburg. The daily tidal amplitude just below the Fall Line is about 1.1 m.

River Biodiversity and Ecology

Given the river's ecological and economic importance to the region, there have been surprisingly few comprehensive studies of the ecology of the James River, which lies within the Chesapeake Bay freshwater ecoregion (Abell et al. 2000). The studies that have been conducted have focused on documenting the biodiversity of the flora and fauna of the river. Almost no attention has been given to examining the structure and function of the aquatic communities, their ecological interactions, or aspects of ecosystem dynamics.

Algae, Cyanobacteria, and Protists

Patrick (1996) summarized the findings of previous studies on the algae and cyanobacteria of the river, noting that diatoms such as *Navicula*, *Cymbella*, *Fragilaria*, *Nitzschia*, and *Melosira* were consistently among the dominant periphyton in the river. Higher richness of algal taxa was found along the channel margins associated with silt and detritus than on rocks in midchannel, but highest densities of periphytic algae occurred on midchannel rocks.

Plants

Submerged macrophytes are uncommon in the swift-flowing upper section of the James River but become common to abundant during the summer and autumn throughout the Piedmont. About one-third of the river bottom in the Piedmont section was covered with submerged macrophytes during midsummer (Sprenkle et al. 2004). By far the most abundant species is grassleaf mudplaintain; other common species are sago pondweed, Illinois pondweed, American eelgrass, southern water nymph, and waterweed. American water willow occurs as an emergent species along the banks of much of the river. Macrophytes also occur in the tidal James River, but submerged species there probably have been reduced by low light penetration because of turbid waters.

A narrow corridor of dense riparian vegetation, primarily of sycamore, swamp black gum, river birch, American elm, red maple, and ash-leaf maple, shades channel margins along much of the nontidal river, providing a buffer between the river and the surrounding agricultural landscape. The riparian areas and floodplain forests along the lower James are composed primarily of sycamore, swamp black gum, red maple, river birch, and stands of bald cypress.

Invertebrates

A mosaic of habitats are available to invertebrates along the length of the James River. On a river-basin scale, these habitats range from the fast-flowing, erosional riffles in the upper reaches of the river to slow-flowing depositional areas in the lower section and impounded areas. Large woody debris and extensive macrophyte beds provide other important habitats, and the tidal fresh- and saltwater sections of the river add an additional environment for invertebrates. These and other aspects of the river's physical and chemical features result in a heterogeneous riverine environment that supports a high biodiversity of invertebrates (Smock and Mitchell 1991, Patrick 1996).

Significant differences in invertebrate species composition and abundance occur among the primary habitats in the river. Densities are highest in riffles, whereas high numbers of large species, including clams, mussels, snails, and crayfish, cause standing crop biomass to be highest in the slower flowing reaches and among macrophytes (Smock and Mitchell 1991). The Valley and Ridge section supports the highest species richness and most distinctive invertebrate community in the river. Stoneflies, baetid and heptageniid mayflies, and riffle beetles typify the fauna of this section, with many species occurring only there or in far lower numbers downriver. The invertebrate fauna of the Piedmont and Fall Line sections also is varied, resulting from the mix of erosional and depositional areas and the abundant macrophyte beds. Overall abundance of invertebrates, however, is higher in the Valley and Ridge section. The predominant species in the Piedmont and Fall Line sections include the nonnative Asiatic clam *Corbicula*, the pea clam *Pisidium* spp., the snails *Elimia* and *Somatogyryus*, the mayflies *Tricorythodes* and *Stenonema*, and the caddisflies *Hydropsyche*, *Cheumatopsyche*, and *Polycentropus*.

The invertebrate community changes considerably as the river drops into the Coastal Plain, with species richness there about half that of the Piedmont

section (Garman and Nielsen 1992). Species of oligochaete worms, chironomid midges, and clams predominate in the sediments of the main channel; the mayfly *Caenis* occurs frequently in backwater areas. Many of these same taxa also are typical of the upstream impounded section of river. In addition, a variety of estuarine species appear in the tidal area.

Filter feeders and scrapers dominate the trophic structure of the river's invertebrate community (Garman and Smock 1999). Filter feeders are abundant throughout the river, suggesting high concentrations of seston in the water column. Among the dominant filter feeders are *Corbicula* and *Pisidium*, occurring primarily in fine sediments. The net-spinning caddisflies *Hydropsyche* and *Cheumatopsyche* are common in riffles, whereas the long trumpet nets of *Neureclipsis* caddisflies are frequently encountered on large rocks in the reaches. The filter-feeding chironomid *Rheotanytarsus* and species of black flies are common throughout the river, especially on macrophytes in fast-flowing areas.

The abundance of periphyton covering the sediments and other substrata along much of the river through the Fall Line results in scrapers also being an important component of the invertebrate community. The snails *Elimia* and *Somatogyrus* are common throughout the river. Several species of mayflies, such as *Stenonema*, *Baetis*, and *Heptagenia*, and elmids also are among the more common scrapers.

A wide variety of predaceous invertebrates occur in the river, the most conspicuous being the hellgrammite *Corydalus cornutus*. Common in riffles with well-sorted cobble sediment, this species in turn is important prey for several species of fishes. Crayfish feed heavily on the abundant snails and macrophytes in the river, though their numbers are limited by the availability of nonembedded cobble substrata that provide a refuge from heavy predation pressure from smallmouth bass (Mitchell and Smock 1991).

Although the James River has not garnered the attention that some other Virginia rivers have in terms of its freshwater mussel populations, numerous species do occur in the river and several are included on lists of protected species. Johnson (1970) reported that 12 species of Unionidae mussels occur in the nontidal portion of the drainage basin. By far the most common mussel in the river is the eastern elliptio, found throughout the drainage basin. The yellow lance, listed as "rare" to "very rare" both in the state and globally, is rare but of regular occurrence in the river. Other mussels, including the brook floater, Atlantic pigtoe, green floater, eastern pondmussel, and James spinymussel, all appearing on federal or

state lists of threatened and endangered species, have been reported in the James River (e.g., Johnson 1970, Garman and Smock 1999). All of these species, however, were found in isolated locations at best, and their current distribution and abundance are unknown.

Vertebrates

The fish community of the river is quite diverse, with at least 13 families and 75 species occurring in the nontidal portion of the river (G. C. Garman, personal communication). These species represent three-fourths of all freshwater species occurring throughout the entire James River basin (Jenkins and Burkhead 1994). In addition, many estuarine species occur in the lower tidal river.

The families Cyprinidae, Centrarchidae, Catostomidae, and Percidae comprise over 70% of the species in the nontidal river (Garman and Smock 1999). The Cyprinidae dominate fish diversity. Among the most common cyprinids are the bull chub, satinfish shiner, rosefin shiner, and spottail shiner. The James River ichthyofauna, dominated by cyprinids, more closely resembles fish communities of Atlantic slope rivers to its north than to the south, where sunfishes and suckers typically are most common (Garman and Nielsen 1992).

The majority of fishes in the river are trophic generalists. The numerically dominant cyprinids and centrarchids feed heavily on immature mayflies, caddisflies, and terrestrial arthropods during the summer, the latter suggesting a strong trophic link between riparian areas and the river channel. An increasing prevalence of planktivores such as gizzard and threadfin shad and white mullet at and below the Fall Line suggest a decreasing reliance on benthic and terrestrial food sources as the river descends into the Coastal Plain. Various piscivores, in particular largemouth bass and the nonnative smallmouth bass and flathead catfish, are the primary apex predators in freshwater areas.

The most abundant species in the Valley and Ridge section include two cyprinids, the bull chub and the rosefin shiner, and several sunfishes. In the Piedmont, most of these species continue to be quite common, along with the satinfish shiner, the margined madtom, and the American eel. The common carp, catostomids, including the golden and shorthead redhorse, and several sunfishes are among the dominant species in the impounded areas of the river.

The fishes at the Fall Line and in the Coastal Plain sections are markedly different from those upriver. High numbers of gizzard shad occur along with

various minnows, sunfishes, and bullheads. Substantial numbers of anadromous shads and herrings also are present seasonally. In addition, estuarine species such as Atlantic needlefish, hogchokers, summer flounder, and white mullet can be found as far upriver as the Fall Line during the late summer and autumn (Garman and Smock 1999).

Three species of fishes are endemic to the James River basin, but all occur in small tributaries and are not regular inhabitants of the main stem (Jenkins and Burkhead 1994). The James has few endemic species compared to more southern rivers, being more typical of mid-Atlantic rivers to the north.

The lower James provides critical habitat for one of the largest populations of bald eagles along the Atlantic coast. Many other species of birds, including a wide array of piscivorous species, occur along the river. The James and its floodplain also support a variety of amphibians and reptiles, including disjunct populations of cottonmouth at the northern edge of its range. The lower river and some of its larger tributaries have populations of the glossy crayfish snake and the greater siren, both included as very rare or extremely rare on Virginia's Rare Animal List.

Ecosystem Processes

The lack of information on ecosystem-level processes for a river of the size and ecological importance of the James is striking. No quantitative studies have been conducted to determine levels of primary or secondary production throughout the freshwater section of the river, and almost no data except for anecdotal information exist on food web structure and dynamics. Epilithic algae no doubt are an important part of primary production in the river above the Fall Line. The deeper, more turbid water in the Coastal Plain likely limits periphyton production, but phytoplankton production may be locally high in the slower flow and extensive backwaters of the lower river. The abundance of macrophytes in the middle section of the river suggests that they may be an important component of primary production there and that they provide much detritus during their senescence. Inputs of allochthonous detritus occur primarily from tributaries rather than from riparian areas. Many of the fringing wetlands that historically occurred along the lower river have disappeared, removing what may have been important inputs of dissolved and particulate organic matter directly to the river.

The river's food web above the Fall Line likely is based primarily on periphyton production and macrophyte-derived detritus, whereas inputs of

allochthonous detritus and phytoplankton production probably are of secondary importance. Much of the material passes to filter feeders and scrapers, which compose the most abundant primary consumers in the river. Their production must be substantial in order to support the high numbers and biomass of both invertebrate and vertebrate secondary consumers throughout the river.

Human Impacts and Special Features

In spite of three centuries of human exploitation, the James River remains highly scenic and supports a diverse and productive biota. Alteration of the river's hydrology by dams also has been minimal, unlike many of the major rivers to the south that are highly fragmented by large impoundments. Although the river receives inputs of both point and nonpoint pollutants along its entire length, water quality in much of the river down to the Fall Line is quite good, as evidenced by both physicochemical and biological indicators.

Trends from water-quality monitoring programs show that water quality has generally increased over the past decade (e.g., Sprague et al. 2000). Several urbanized areas and industries in the upper river cause local water-quality problems, but the most significant problems occur in the lower James. Fecal coliform concentrations increase greatly at the Fall Line, primarily due to the antiquated combined sewer outfalls in Richmond that discharge directly to the river during storms. A high incidence of free-living pathogenic amoebae, including *Acanthamoeba* and *Naegleria*, have been found associated with lesions on a variety of fish species in the lower James River (Webb et al. 2002). Their distribution and abundance may be associated with degraded water quality.

Much of the emphasis on reducing inputs of nutrients and sediment to the river is driven by programs to improve water quality in the Chesapeake Bay. About 38% of the nitrogen and 28% of the phosphorus entering the river originate from point sources (Virginia Department of Conservation and Recreation Web site for the James River Watershed: http://www.dcr.state.va.us/waterways/the_problem/watersheds_and_you/p_james_river_watershed.htm), with the remainder coming from nonpoint sources. The input of sediment from land erosion, however, is the primary pollution problem for much of the upper river. The heavy load of sediment and resulting embedding of benthic habitats has caused substantial loss of critical habitat for periphyton, invertebrates, and fishes.

The lower James River was the site of one of the nation's most publicized incidents of river pollution. A manufacturing plant discharged the chlorinated insecticide Kepone from 1966 to 1975 to the lower river (Cutshall et al. 1981). The widespread contamination of sediments and biota and accumulation of Kepone up the food chain raised concerns of carcinogenic effects for humans through consumption of fishes and shellfish. A ban on commercial fishing in the lower James decimated a flourishing industry (Diaz 1989). Though the ban was lifted in 1989, much Kepone remains buried in the sediments and continues to be monitored today because of fears of its resuspension during storms or dredging operations.

Nonnative fishes have had a major impact on the ecology of the James River. Over one-third of the fish species in the nontidal James River have been introduced over the past 150 years (Garman and Smock 1999). Possibly the most successful is the smallmouth bass. Brought from the Ohio River drainage around 1870 (Snyder et al. 1996), its population has turned the James River into one of the premier smallmouth rivers in North America. Other introduced species, such as the channel and blue catfish, muskellunge, and several species of sunfishes, also have become local favorites of anglers. The historical fish community, however, was dominated numerically by small insectivorous minnows and sunfishes as well as anadromous species. The establishment of thriving populations of large nonnative piscivorous species likely has had a significant effect on the river's trophic structure, given that some of the species feed at least one trophic level higher than do the native piscivores (Garman and Smock 1999).

Another anthropogenic disturbance that has had a major impact on the ecology of the river was the construction of the low- and medium-head dams in the Richmond and Lynchburg areas in the 1800s. These dams became barriers to migratory fishes, halting previously large runs of clupeids, including American and hickory shad, blueback herring, and alewife. Along with water-quality and habitat degradation in the lower river and its tributaries, the dams caused these species to steadily decline to near complete collapse in the late 1970s. Recent stocking programs, breaching of dams, and construction of fish passages have focused on revitalizing stocks and restoring access to the river above the Fall Line. Efforts such as these and the generally successful programs focused on improving water quality are helping to restore migratory fish runs and other aspects of the biological integrity of this river.

CAPE FEAR RIVER

The Cape Fear River basin, located entirely within North Carolina, is the largest basin within the state (basin area = 24,150 km²). The river's headwaters lie in the Piedmont hills of the north-central part of the state, whereas the main-stem Cape Fear River flows primarily through the Coastal Plain (Fig. 3.15). Two large blackwater tributaries, the Black (called "South River" upstream) and Northeast Cape Fear rivers, join the Cape Fear near its mouth at Wilmington. The basin is highly populated and developed but also supports many rare species and includes some of the ecologically most significant riverine and wetland habitats in the state. Among these are blackwater rivers, broad floodplain swamps, Carolina Bay lakes, and an extensive estuarine system.

The river basin was historically inhabited by various Native American tribes, primarily hunter-gatherers whose subsistence included the bountiful game and fishes of the Cape Fear River and its tributaries and floodplain. Giovanni da Verrazano, sailing under a French flag, was the first European explorer to the region, briefly visiting the mouth of the Cape Fear in 1524. Two years later, a Spanish colony was established, but disease and starvation soon led to failure of the colony. The first permanent English settlers arrived in the 1660s, their numbers steadily increasing through the late 1600s and early 1700s. Encroachment on Native American land led to a series of Indian wars that ended in the early 1700s, followed by rapid expansion by the settlers upriver.

The initial settlers, who first established rice plantations near the mouth of the river, undertook explorations upriver. Accounts from that time attest to the beauty and condition of the river and surrounding area. "The whole Country consists of stately Woods, Groves, Marshes and Meadows; it abounds with variety of as brave Okes as Eye can behold, great Bodies tall and streight from 60 to 80 foot, before there be any Boughs. . . . Here are as brave Rivers as any in the World." (*A Brief Description* . . . 1944). Although the river was deep, the ability to navigate it and its primary tributaries was greatly impeded by the abundance of snags in the channel: "Small Craft [could go far upriver] were it not for a multitude of Logs that have fallen into the Rivers, which are so heavy and solid that they lie at the bottom, and many of them show but little Appearance of Decay. . . . In some Places we saw whole Heaps jambed together, almost from Side to Side, and so firm that they are immovable, being sound, heavy, fast and deep in

the Sand, other-wise this would be a fine river.” (Meredith 1731).

Even with its abundance of snags, however, the Cape Fear was heavily used by settlers, employing boats made from cypress logs to transport tobacco, timber, produce, and furs. River “improvement projects,” begun in 1815 to remove the snags, led to the river becoming easily navigable by larger ships far upriver, with the first steamboats plying its waters in 1818. With the opening of the river came a rapid expansion of settlements upriver; today the Cape Fear River basin is the most densely populated basin in North Carolina.

Physiography, Climate, and Land Use

The Cape Fear River flows in a southeasterly direction between 36°N to 34°N latitude. The basin lies within two physiographic provinces, about one-third of the basin being in the Piedmont (PP) and two-thirds in the Coastal Plain (CP) (see Fig. 3.15). The geology of the Piedmont, where the majority of the river’s headwaters flow, is dominated by old crystalline rock with areas of sedimentary rock. The red and yellow soils of the Piedmont are predominately highly weathered ultisols with a sandy-clay or silty-clay texture. The Coastal Plain consists of flat terraces of sand, silt, clay, and limestone, with extensive areas of wetlands, including pocosins and riverine floodplains. The soils of this area are primarily sand and clay, with upland areas having well-drained soils, whereas those of the lowlands are poorly drained. The river basin lies within the Temperate Deciduous Forest biome, historically covered by dense hardwood forests of oak, hickory, and sweetgum, and pine forests of loblolly, slash, and shortleaf pine. The basin’s Piedmont section roughly corresponds to the southeastern Mixed Forests ecoregion, whereas the Coastal Plain section generally corresponds to the Middle Atlantic Coastal Forests ecoregion (Ricketts et al. 1999).

The climate over the basin is one of warm, humid summers and mild winters. Annual mean air temperature over the basin is 16°C, with monthly mean temperatures typically ranging from 4°C in January to 26°C in July and August (Fig. 3.16). Annual precipitation averages 119cm, nearly all of which is rainfall. Precipitation is distributed fairly evenly over the year, with the driest period from October through December and the wettest period during July and August. Precipitation during the summer and autumn is greatly influenced by tropical storms and hurricanes.

The Cape Fear River basin is the most industrialized and populated basin in the state, with significant changes in land cover from historical times. As of 1992, about 56% of the basin was forested, 24% in agriculture, 9% urbanized, and 11% in other land uses, including open water (NCDENR 2000). Urban land cover increased 43% from 1982 to 1992, whereas uncultivated cropland increased by 18% during that time. Cotton and tobacco are the primary crops, and extensive swine, poultry, and timber operations occur within the basin.

The basin supports 27% of the state’s population at a density of 69 people/km², with the highest density occurring in the basin’s Piedmont headwaters. The major urban and industrial areas are the Greensboro–Burlington–High Point area at the head of the basin, Durham–Chapel Hill in the eastern Piedmont, Fayetteville at midbasin, and Wilmington near the mouth of the river.

River Geomorphology, Hydrology, and Chemistry

The main stem of the Cape Fear River arises near the Fall Line at the confluence of the Haw and Deep rivers at an elevation of about 83m asl, just to the southwest of Raleigh (see Fig. 3.15). Immediately above the confluence is the B. Everett Jordan Reservoir, created in 1981 on the Haw and New Hope rivers. At 5642 ha, it is the largest impoundment in the basin, operated by the U.S. Army Corps of Engineers for flood control, water supply, recreation, fish and wildlife, and augmentation of low flows.

The main-stem Cape Fear flows as a 6th order river for 518km, first dropping down across the Fall Line at a rate of about 1m/km and then flattening out as it winds across the Coastal Plain (Fig. 3.4). The river’s gradient from its origin to its mouth is about 6cm/km. Water depth in the channel typically is 1 to 2m, flowing over a bed primarily of sand with patches of silt along the banks (Patrick 1996). The few riffles that occur are along the Fall Line. The channel often is incised into steep clay banks. Snags occur frequently throughout the river, primarily near the banks, although the number and sizes of snags must be nowhere near what they were historically.

The river’s hydrology is affected to some degree by the many impoundments throughout the basin, including the Jordan Reservoir on the river’s primary tributary. The Cape Fear main stem, however, is generally free flowing, having only three low-head locks and dams, built in the early 1900s, along its course.

FIGURE 3.4 Cape Fear River near Erwin, North Carolina (PHOTO BY TIM PALMER).

Annual mean discharge is about $217\text{ m}^3/\text{s}$. Flow is highest during winter and spring and lowest during autumn, driven by evapotranspiration but also occasionally greatly impacted by hurricanes (Fig. 3.16). The majority of flow along much of the river is from its Piedmont tributaries, as its two primary Coastal Plain tributaries, the Black (or South) River and the Northeast Cape Fear River, enter near the upper estuary. The final 55 km of river from above Wilmington to the ocean is a tidal, estuarine basin.

Because most of the flow in the Cape Fear originates from its Piedmont tributaries, the river's chemistry primarily reflects the characteristics of those waters and is far less influenced by the smaller inputs of Coastal Plain blackwater tributaries than are most other southeastern Atlantic slope rivers. The Cape Fear is a slightly acidic, soft-water river, with conductivity typically around 80 to $110\ \mu\text{S}/\text{cm}$. Water temperature averages 17°C , rarely falling below 5°C or going above 30°C . The river is highly turbid, even during low flow but especially during rain events, as a result of erosion from the large proportion of developed land in the Piedmont portion of the basin. The

river acquires more of the characteristics of a black-water river system as it flows deeper into the Coastal Plain, receiving water with high color caused by dissolved organic compounds from tributaries and its extensive floodplain. Color in the river is highest in the spring and early summer when the channel is most closely connected with its floodplain.

River Biodiversity and Ecology

The Cape Fear, lying within the South Atlantic Freshwater ecoregion (Abell et al. 2000), has ecological characteristics similar to those of the Coastal Plain sections of other southeastern rivers. It is characterized by a meandering channel, slow current, and primarily sandy sediment. Snags are the only stable substratum in the river except for some rocky shoals along the Fall Line. The river has a close connection with its often broad, seasonally inundated floodplain. These characteristics establish the template that determines the composition and structure of the river's flora and fauna and the ecosystem dynamics of the river.

Even with its high population and extensive industrialization and agricultural activities, the Cape Fear basin supports several areas of outstanding ecological importance. The U.S. Fish and Wildlife Service has designated areas of the Deep, Rocky, and Haw rivers, all major Piedmont tributaries to the Cape Fear, as critical habitat for rare aquatic fishes, mussels, and insects. The South-Black river system is named an "Outstanding Resource Waters" and is one of the best examples of Coastal Plain blackwater rivers. The river supports many rare fishes and mussels and an ancient cypress-gum swamp with trees dating to over 1600 years ago. The Sandhills, occurring in an area with deep sandy soils, longleaf pine forests, stream-head pocosins, and mixed hardwood and Atlantic white cedar swamps, has streams with clean sand sediments and many rare species. The Cape Fear's extensive and highly productive estuary has four areas designated as "Outstanding Resource Waters."

Algae, Cyanobacteria, and Protists

Patrick (1996) summarizes studies by the Academy of Natural Sciences of Philadelphia on the river's algae and cyanobacteria, of which about 200 taxa have been found in the river. An additional 160 taxa of protists also have been identified from the river (Patrick 1996). The periphyton in the channel is dominated by cyanobacteria and diatoms, among the more common genera being *Oscillatoria*, *Melosira*, *Eunotia*, *Gomphonema*, *Navicula*, and *Cyclotella*. Green algae are most commonly encountered along the banks on silty sediment, debris, and snags in slow flowing areas. Phytoplankton occur in the upper river, primarily as a result of their being washed out of Jordan Reservoir, and in the lower river during periods of low flow.

Plants

Macrophytes are not common along much of the channel except in backwater areas. The river's riparian zone and floodplains are largely forested. Sycamore and ash are common along the riparian zone of the upper river and in elevated, drier areas downriver. The broad floodplains support bald cypress, water tupelo, swamp black gum, red maple, sweetgum, oaks, and other hardwoods. Far downriver the hardwood swamps give way to estuarine marshes where cordgrass and rush are the dominant species.

Invertebrates

The species composition and structure of the invertebrate community of the Cape Fear is similar

to that of other large Coastal Plain rivers (Patrick 1996, Mallin et al. 2000). Patrick (1996) lists about 150 taxa of macroinvertebrates found in the upper river. Collector-gatherers are numerically dominant in the sediment and collector-filterers are dominant on snags. Oligochaete worms, chironomid midges, sphaeriid clams (*Sphaerium*, *Pisidium*), and the non-native Asiatic clam are among the most abundant taxa in the sediment. These taxa and the mayfly *Tricorythodes*, freshwater grass shrimp (*Paleomonetes*), dragonflies (*Gomphus*, *Neurocordulia*), damselflies (*Argia*, *Enallagma*), chironomids, and crayfishes are common along the banks and among debris accumulations in the channel.

The most diverse assemblage of macroinvertebrates in the river occurs on snags, where the most frequently encountered taxa are mayflies (*Baetis*, *Stenonema*, *Tricorythodes*), elmid beetles (*Ancyronyx*, *Macronychus*), black flies (*Simulium*), chironomids (*Rheotanytarsus*), dragonflies (*Boyeria*), damselflies (*Calopteryx*), and hydroptychid caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Chimarra*). The caddisflies seemingly are not as abundant in the Cape Fear River as in other rivers along the southeastern Coastal Plain, possibly because the high silt load in the river decreases the efficiency of their filter-feeding activity.

Unionid mussels once were diverse and abundant in the river (Patrick 1996), but the number of species present and their densities have declined over the years, probably in response to decreasing water quality and competition from the Asiatic clam. The North Carolina Nongame and Endangered Wildlife Fund lists 15 species of mussels within the Cape Fear River basin as endangered, threatened, or of special concern.

Vertebrates

At least 95 species of fishes live in the Cape Fear River (NCDENR 2000). Studies from the 1960s show that bluegill, pumpkinseed, longnose gar, spotted sucker, whitefin shiner, largemouth bass, snail bullhead, white catfish, and channel catfish were among the more abundant species (Patrick 1996). More recent studies, however, have shown a change in the relative abundance of fishes in the river linked to the introduction of several nonnative species (Moser and Roberts 1999, Mallin et al. 2000). The nonnative blue catfish now is one of the more abundant species in the river. Flathead catfish were introduced in 1966 and now are abundant and the dominant predator in the river. They have caused the near extirpation of native catfishes and the channel

catfish, the latter having been introduced in the early 1900s (Moser and Roberts 1999, Mallin et al. 2000). Among other nonnative species, common carp are ubiquitous and grass carp are becoming more common. White bass and white perch were introduced into Jordan Reservoir, the latter species being highly successful in the reservoir and both species having dispersed downriver. Overall, from about 50% to 100% of the fishes captured in gill nets in a recent study in the lower river were nonnative species (Mallin et al. 2000).

Seven species of migratory fishes are reported from the river. American shad, hickory shad, and blueback herring are important commercial and recreational species, although their numbers are declining. Atlantic and shortnose sturgeon, once plentiful in the river, are federally listed as endangered. The last shortnose sturgeon was captured in the river in 1993 (NCDENR 2000). The striped bass population is far below historical numbers. A moratorium on the taking of stripers in North Carolina was put into effect from 1985 to 1990. Although populations rebounded in most other rivers with a moratorium, stripers have not fared as well in the Cape Fear. Predation by nonnative catfishes and reproductive competition from hybrid striped bass may be hindering their recovery (NCDENR 2000).

A wide variety of vertebrates other than fishes occur in the Cape Fear. Water snakes are abundant and cottonmouths are occasionally encountered along the river. Turtles such as sliders and river cooters are frequently observed along the banks and on snags projecting above the water's surface. Snapping turtles and mud turtles also are common. The federally endangered West Indian manatee is an infrequent visitor to the lower river.

Ecosystem Processes

Information on ecosystem-level processes such as energy flow and nutrient cycling is generally lacking for the Cape Fear. The river no doubt functions much like other large Coastal Plain rivers. Primary production likely is low, dominated by periphyton on snags and other structures in the channel. Periphyton growth overall, however, is limited by low light caused by the high turbidity of the water (Mulholland and Lenat 1992, Mallin et al. 2000). Phytoplankton production is highest below the Jordan Reservoir from algae washing out of the impoundment, and also in backwaters and near the river's mouth, where flushing rates are low. Macrophyte production is low because of the lack of extensive plant beds throughout much of the river. The river likely is a highly

heterotrophic system, the primary source of energy being allochthonous organic matter washed in from tributaries and from the fringing floodplain. The latter is a source primarily during the winter–spring period, when the broad floodplain is inundated and water exchanges directly with the channel.

Levels of primary and secondary consumer production are unknown. As in other Coastal Plain rivers, invertebrate production likely is predominately on snags and in backwaters, where organisms can complete their life cycles without being disturbed by shifting sand during high-flow events. Many fishes in the river no doubt are dependent on invertebrate production from snags for food (e.g., Benke et al. 1985).

Human Impacts and Special Features

The Cape Fear River basin supports a variety of ecologically and economically important riverine habitats. The river system is known for its broad floodplains and scenic beauty and the many rare species of flora and fauna that occur within the basin. Ever rising demands are being placed on the river, however, because of increasing population and industrial, commercial, and agricultural development in the basin. The river provides water for businesses, residential users, and irrigation. It serves as a commercial transportation route and receives heavy recreational use for boating and fishing as well as supporting some commercial fisheries in the lower river. Its waters and floodplain provide important habitat for fishes and other wildlife. Even with these many existing demands on the water resources of the basin, it is estimated that water use throughout the basin will increase 95% from the early 1990s to 2020 (NCDENR 2000).

At the same time that there are increasing demands on the river to provide a safe and reliable source of water, it also is heavily used for waste assimilation. There presently are about 280 permitted wastewater discharges in the basin, the majority of them to tributaries in the Piedmont section of the basin (NCDENR 2000). Nonpoint-source inputs to the river and its tributaries also are widespread and significant. Large quantities of nutrients and sediment enter the river from land deforested primarily for agricultural, timbering, and urban land uses. These many point discharges and nonpoint-source inputs have resulted in over 20% of the monitored waters in the basin being rated as impaired.

The river showed a general trend of decreasing water quality into the 1980s, with conductivity, nutrient concentrations, and sediment load increas-

ing as pH and dissolved oxygen concentrations decreased. Improvements in both industrial and municipal wastewater treatment, as well as better land management, have slowed or reversed that trend. The many textile mills that once were a major source of a variety of pollutants to the Haw River, including organic compounds and trace metals, have now largely been abandoned. The result has been an improvement in water quality in the Cape Fear's primary tributary.

The Cape Fear has been spared major impoundments along its main stem. The Jordan Reservoir, however, located just above where the main stem originates, does have major impacts on the hydrology and ecology of the river. In addition, there have been long-standing concerns about nutrient trapping and eutrophication in the impoundment given the significant inputs of municipal wastewater to its tributaries and the low flushing rate of most of the reservoir (Moreau and Challa 1985).

The Cape Fear basin has a long history of being impacted by hurricanes, but the late 1990s brought a succession of unusually severe storms. Although hurricanes are natural events to which these river systems are adapted, human development in the basin, especially in the Cape Fear's floodplain, greatly increased their negative impact on water quality and the biota of the river. A primary problem was the flooding of numerous industrial hog and poultry operations located in and near the floodplain, causing the release of large quantities of at best partially treated animal wastes to the river (Mallin, Posey, Moser et al. 1999, Mallin, Posey, Shank et al. 1999, Mallin 2000). In addition, numerous municipal wastewater treatment facilities were flooded, releasing untreated human waste to the river. Severe dissolved oxygen depletion occurred along with high inputs of sediments, nutrients, and fecal coliform bacteria. The benthic invertebrate community was negatively impacted and fish kills were numerous (Mallin, Posey, Moser et al. 1999, Mallin, Posey, Shank et al. 1999). The fish community now may be experiencing the cumulative impacts of the succession of hurricanes during this period, with both species richness and abundance showing a declining trend (Mallin, Posey, Moser et al. 1999).

SAVANNAH RIVER

The Savannah River is among the most hydrologically, ecologically, and historically important rivers of the southeastern United States, forming the border

between South Carolina and Georgia along its entire 476 km length (Fig. 3.17). Its headwaters, arising in the cool, swift-flowing streams of the Blue Ridge Mountains, coalesce in the upper Piedmont to form the main stem of this large warmwater river (basin area = 27,414 km²). At its point of origin and along much of its route among the rolling hills of the Piedmont, the river is mainly a series of large hydroelectric impoundments (Fig. 3.5). Below the Fall Line, however, the Savannah is a long, free-flowing river, meandering through the Coastal Plain and bordered by broad riverine swamps.

From the tenth to the fifteenth centuries, well before the arrival of Europeans, the Savannah River basin was occupied by prehistoric chiefdoms of the Mississippian culture. For unknown reasons, the Mississippians disappeared from the Savannah basin between about 1450 and 1600, eventually being replaced during the seventeenth century by the Creek Confederacy in the lower river basin and tribes of the Cherokee Nation in the upper basin. Spanish influence came to the region during the early 1500s, notably when the explorer Hernando de Soto crossed the upper basin in 1540 searching for gold, and Jesuit and Franciscan missions became established along the coast, remaining for more than 100 years. It was not until the arrival of the English, led by James Oglethorpe in 1733, that European settlement spread out from the coast. These settlers slowly pushed upriver through the mid 1700s until after the Revolutionary War, when they rapidly spread to the headwaters of the river. From 1777 until 1796, the Georgia state capital alternated between Savannah, located about 35 km above the river's mouth, and Augusta, located at the Fall Line on the river.

Agriculture in the Savannah basin flourished into the mid-nineteenth century, with much of the primary cash crops of cotton, rice, and tobacco being grown on plantations supported by slave labor. During the Civil War, the North maintained a blockade of the river, limiting its use as a supply line for the South. Savannah fell to General Sherman in late 1864 during his "march to the sea." With the end of the Civil War the area fell into an agricultural depression as the plantation-based economy disintegrated. It was not until the early 1900s that an economy based on forestry, shipping, and a restructured agricultural system revitalized the area.

Physiography, Climate, and Land Use

The Savannah River flows in a southeasterly direction between 34°N to 32°N latitude. About 55% of

FIGURE 3.5 Savannah River below Thurmond Dam, upstream of Augusta, Georgia (PHOTO BY A. C. BENKE).

the basin is in Georgia, 43% in South Carolina, and 2% in North Carolina. The basin lies within three physiographic provinces, 10% in the Blue Ridge (BL), 56% in the Piedmont (PP), and 34% in the Coastal Plain (CP) (see Fig. 3.17). The red soils of the Piedmont are predominately highly weathered ultisols with a sandy-clay or silty-clay texture. Soils of the Coastal Plain are well-drained sands in the uplands and poorly drained sands and clays in the lowlands. The basin lies within the Temperate Deciduous Forest biome and encompasses four terrestrial ecoregions (Ricketts et al. 1999): Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests, and the Southeastern Conifer Forests. The predominant upland pine forests range from white pines in the mountains to loblolly and shortleaf pine in the Piedmont and longleaf and slash pine in the Coastal Plain. Hardwoods are more common at higher elevations and include oaks, hickory, poplar, and maple.

The climate over much of the basin is subtropical, with hot, humid summers and mild winters. Annual mean air temperature is 18°C, with monthly mean temperatures typically ranging from 7°C in

January to 27°C in July and August (Fig. 3.18). Annual precipitation averages 114cm, nearly all of which is rainfall. Precipitation is distributed fairly evenly over the year, with the driest months from September to November.

Though historically covered by deciduous and pine trees, today the landscape is a mix of land uses. About 65% of the basin is forested, 22% in crop or pasture, 4% urbanized, and 9% in other land uses. Forest products are a major component of the region's economy. Agriculture is based on a mix of animal operations and crops, especially cotton, peanuts, tobacco, and grain. The major urban and industrial areas are Savannah, with a deep-draft harbor; Augusta, with an inland port at the Fall Line; and Anderson, South Carolina, located near the origination of the river's main stem.

River Geomorphology, Hydrology, and Chemistry

The Savannah arises from the merging of the Seneca and Tugaloo rivers in the upper Piedmont at an elevation of about 190m asl. It arises not as a

free-flowing river but rather as an impoundment (see Fig. 3.17). Hartwell Lake, a 22,663 ha reservoir completed in 1963, forms the head of the main stem. Just 48 km below Hartwell Dam is the Richard B. Russell Lake, a 10,785 ha reservoir completed in 1985. Farther downstream is the J. Strom Thurmond Lake, completed in 1954 and at 28,329 ha is the largest of the river's impoundments (see Fig. 3.5). All three impoundments are operated for hydroelectric power generation, flood control, recreation, and fish and wildlife.

The three impoundments create a chain of reservoirs along most of the approximately 160 km length of the Piedmont section of the Savannah. In the few stretches that are not impounded, especially from the lower lake down to the Fall Line at Augusta, the river is about 110 m wide and has a series of well-developed riffles. River banks typically are 1 to 3 m high, consist of sand-clay, and are mostly lined with trees (Sehlinger and Otey 1980).

The river is impounded again for a short distance at Augusta by several low-head locks and dams, but otherwise drops quickly through a series of riffles into the Coastal Plain. Thereafter the channel broadens from 75 to 100 m wide to nearly 200 m near Savannah (Sehlinger and Otey 1980). Channel gradient across the Coastal Plain is about 20 cm/km, compared to 50 cm/km across the Piedmont. The river's gradient from headwaters to mouth is 3.5 m/km. Dredging in the lower river maintains depth at about 3 m. The Coastal Plain section is free flowing and meanders through floodplain forests that occasionally reach 3 to 4 km in width. Oxbow lakes are common in the floodplain, with 24% of the channel length in oxbows (Schmitt and Hornsby 1985). The sediment consists primarily of sand with some silty areas (Patrick et al. 1967). Snags are common, especially along the banks. Above Savannah, the floodplain swamps give way to tidal marshes, including the Savannah National Wildlife Refuge, where numerous side branches of the river wind through the marshes before the river passes the city and empties into the Atlantic Ocean.

Annual mean discharge 98 km above the river's mouth is 319 m³/s. The river is tidal over its lower 70 km. Flow in the river, especially in the Piedmont, is highly regulated by the dams, dampening the natural seasonal changes of highest discharge in winter and spring and lowest in late summer and autumn (see Fig. 3.18). Prior to construction of the dams, high levels of evapotranspiration would reduce the dependable minimum flow in the river to 32 m³/s (U.S. Army Corps of Engineers 1981), or a runoff

of only 0.30 cm/mo. The J. Strom Thurmond Dam, however, now provides a minimum flow of 164 m³/s, or a runoff of about 1.55 cm/mo.

The Savannah is a neutral to slightly acidic, soft-water river, the majority of its flow being derived from the crystalline geology of the Piedmont. Alkalinity averages about 20 mg/L as CaCO₃. Water temperature can exceed 30°C and rarely falls below 8°C. The river carries a high sediment load during storms, although turbidity is ameliorated some by the settling of solids in the impoundments. Within the Coastal Plain, the river becomes a blackwater system, highly stained by dissolved organic compounds derived primarily from the floodplain. Color in the lower river typically is 30 to 80 Pt units, highest in the spring and early summer and lowest in the autumn when connectivity between the channel and floodplain is at its lowest (Patrick 1996). Dissolved organic carbon concentrations in the lower river typically are 4 to 8 mg/L and constitute the majority of the total organic carbon transported by the river (Patrick 1996). Water salinity is about 15 ppt near Savannah and the salt wedge travels 30 km above the city.

River Biodiversity and Ecology

The Savannah River, within the South Atlantic freshwater ecoregion (Abell et al. 2000), provides a variety of habitats that support a diverse flora and fauna. Much is known of the organisms inhabiting the river because of long-term, ongoing studies begun in 1951 about 40 km below the Fall Line. Led by Dr. Ruth Patrick, scientists from the Academy of Natural Sciences of Philadelphia have been studying the river at the U.S. Department of Energy's Savannah River Plant (SRP). They and researchers associated with the SRP and the Savannah River Ecology Laboratory of the University of Georgia have produced a considerable body of information on the physicochemical characteristics, flora and fauna, and ecology of the river, its tributaries, and floodplain.

Algae, Cyanobacteria, and Protists

Over 800 species of algae, cyanobacteria, and protists have been identified in the river (see Patrick 1996 for species lists). Diatoms dominate, in particular *Melosira*, *Gomphonema*, *Fragilaria*, *Navicula*, *Eunotia*, and *Achnanthes*. Green algae also are common, including *Chaetophora*, *Closterium*, *Stigeoclonium*, *Oedogonium*, and *Spirogyra*. Less common are cyanobacteria, such as *Calothrix*, *Oscillatoria*, *Microcoleus*, and *Phormidium*, and the red algae *Compsopogon* and *Batrachospermum*. Lentic

species of phytoplankton prevail in the impoundments. Periphyton peak during the summer, biomass on artificial substrates being 2.6 to 5.5 g/m², and chlorophyll *a* ranging up to 95 mg/m² from May to August (Specht et al. 1984). The highest densities of phytoplankton in the lower river also occur during the summer (Patrick 1996). Thick algal mats often occur in the sloughs and backwaters.

Plants

Among the most abundant macrophytes in the river are alligatorweed, coon's tail, and waterweed. The moss *Leskea obscura*, and to a lesser extent the liverwort *Porella pinnata*, are common on snags (Cudney and Wallace 1980). Nonnative hydrilla has been established in the J. Strom Thurmond Lake since 1995 and has become a serious problem. Cordgrass and rush are the predominant species in the estuarine marshes along the lower 45 km of the river (Schmitt and Hornsby 1985). The river's riparian zone and floodplains are predominately forested. Among the most common species of trees in the floodplain are bald cypress, water tupelo, swamp black gum, red maple, water ash, water oak, and sweetgum.

Invertebrates

Numerous studies have reported on the over 300 taxa of macroinvertebrates in the Savannah and on their associations with different habitats within the river (summarized by Patrick 1996). Collector-gatherers and collector-filterers together comprise about 75% of the invertebrate biomass in the free-flowing river (Specht et al. 1984). Most of that biomass is filter-feeders, which are abundant on snags throughout the river (Cudney and Wallace 1980) and also on rocks downstream of the impoundments, the discharges from which provide filter-feeders an abundant and nutritious supply of sestonic algae and zooplankton. Predaceous species comprise about 19% of the biomass, shredders 4%, and scrapers 2% (Specht et al. 1984).

The invertebrate fauna of the impoundments is typical of that of large southeastern reservoirs, with many species of zooplankton and benthic invertebrates occurring in the profundal and littoral areas. The benthic invertebrates are numerically dominated by chironomid midges and oligochaete worms. High numbers of phantom midge larvae (*Chaoborus*) also are found in the impoundments, their third and fourth instars occurring in the profundal sediments during the day and migrating into the water column to feed on zooplankton at night.

The riffles in the upper river support a diverse array of species. Among the more common insects are mayflies (*Baetis*, *Stenonema*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Macrostemum*, *Brachycentrus*, *Chimarra*), hellgrammites (*Corydalus cornutus*), black flies (*Simulium*), and a variety of chironomids, especially *Rheotanytarsus*. The sand sediment of the lower river supports many chironomids and oligochaetes as well as lesser numbers of other taxa such as beetles, dragonflies, and damselflies. The nonnative Asiatic clam is the most abundant bivalve mollusk and *Physella heterostropha* the most common snail in the river.

Within the Coastal Plain section of the river, snags and backwater areas support the most diverse and productive assemblage of invertebrates. As in other sand-bottomed rivers of the southeast, snags provide the only stable habitat for invertebrates in the main channel and hence are heavily colonized. Among the more frequently encountered taxa on snags are mayflies (*Baetis*, *Heptagenia*, *Stenonema*), dragonflies (*Boyeria*), damselflies (*Calopteryx*), elmid beetles (*Ancyronyx*, *Macronychus*), hellgrammites (*Corydalus*), black flies (*Simulium*), and chironomids (*Rheotanytarsus*). Also abundant on snags are filter-feeding caddisflies of the genera *Hydropsyche*, *Cheumatopsyche*, *Macrostemum*, *Chimarra*, and *Neureclipsis*.

Macroinvertebrates of the bank and backwater areas also are diverse and presumably productive. Many species of benthic copepods are abundant, as are oligochaetes, chironomids, beetles, and sphaeriid clams (*Musculium*, *Pisidium*). Decapods are more abundant in the floodplains than in the main channel (Hobbs et al. 1976). The mayfly *Tortopus* occurs primarily along the upper river, where their burrows are found in the vertical walls of the silt-clay banks.

About 20 species of unionid mussels are reported in the Savannah River basin, with the eastern elliptio and the variable spike being the most common (Johnson 1970, Britton and Fuller 1979, Chris Skelton, Georgia Department of Natural Resources [GDNR], personal communication). Overall abundance of unionids in the river has declined since the 1950s, possibly as an effect of the invasion of Asiatic clams or human alteration of the river's environment (Patrick 1996). The Atlantic pigtoe mussel is federally listed as endangered; seven other mussels designated as being of special concern on South Carolina's list of protected species occur in the river basin, primarily in the river's tributaries. Several species of crayfish in the basin also are on state protected species lists.

Vertebrates

The Savannah River basin supports at least 21 families and 106 species of freshwater fishes (Chris Skelton, GDNR, personal communication). The most species-rich families are the Cyprinidae (28 species), Centrarchidae (20), Catostomidae (12), Percidae (12), and Ictaluridae (10). Among the most abundant species in the main stem along the Upper Coastal Plain are the eastern silvery minnow, spottail shiner, redbreast sunfish, and spotted sucker (McFarlane et al. 1979). Fish biomass, however, is dominated by spotted sucker, silver redhorse, common carp, bowfin, gizzard shad, and channel catfish (McFarlane et al. 1979, Schmitt and Hornsby 1985). Striped mullet are abundant in the Savannah estuary and the lower part of the river.

Among the more important migratory species in the river are the anadromous American shad and blueback herring and the catadromous American eel. Striped bass, normally a migratory species, likely are not migratory in the Savannah. Stocks of this species have been decreasing since the mid 1980s with the loss of their primary spawning grounds near Savannah due to salt water encroachment caused by harbor improvement projects (GDNR 2001b).

The Savannah River supports a thriving sport fishery in both the impoundments and lower river. The primary focus of sport fishermen is on largemouth bass, black crappie, channel catfish, striped bass, American shad, bluegill, redear sunfish, redbreast sunfish, and yellow perch (GDNR 2001b). The river supports only a small commercial fishery, primarily for ictalurids (Schmitt and Hornsby 1985).

Seven species of fishes in the basin are on Georgia or South Carolina lists of protected species. Among these is the federally endangered shortnose sturgeon. The robust redhorse, once thought extinct in the river, was found in 1997 in the shoals below the J. Strom Thurmond Dam down to Augusta (GDNR 2001b). A program stocking this species in the Broad River, a major tributary to the Savannah, is now underway.

The Savannah River supports a high diversity of vertebrates besides fishes. At least 9 species of frogs, 17 salamanders, 9 snakes, 11 turtles, and 1 crocodylian occur in the river or its floodplain (John Jensen, GDNR, personal communication). Water snakes, cottonmouths, snapping turtles, sliders, and river cooters are common in the river, and the American alligator is occasionally seen. The river and its floodplain also are important avian habitats, with the Savannah National Wildlife Refuge near the mouth

of the river an important migratory and wintering ground for waterfowl.

Ecosystem Processes

Little information exists on ecosystem-level processes in the river. High phytoplankton cell counts, high periphyton biomass, and locally abundant macrophytes combined with warm water temperatures suggest that the Savannah is a productive system. However, the impoundments along the upper river no doubt have substantially altered the river's energy flow and metabolism. The river's energy base historically would have depended largely on inputs of allochthonous organic matter from tributaries, riparian areas, and the extensive floodplain along the lower river. The impoundments, however, provide a habitat for high phytoplankton production, some portion of which passes to downstream food webs. Thus, the river likely is far more autotrophic now than historically, though it probably still is a heterotrophically based system in the Coastal Plain.

Primary and secondary consumer production likely is high based on the abundance of invertebrates and fishes throughout the river. Invertebrate production is predominately of zooplankton in the impoundments and on snags and in backwaters in the Coastal Plain. Annual production of net-spinning caddisflies on snags was estimated at 12 to 36g ash-free dry mass/m² of snag surface area (Cudney and Wallace 1980); total consumer production on snags probably is considerably higher than this. Fish production, higher in the river's backwaters than in the main channel, must be substantial given estimates of their standing stock biomass (e.g., Patrick 1996).

Human Impacts and Special Features

The Savannah River serves a multitude of uses. Foremost are withdrawals for drinking and industrial use, power generation, navigation, and sport fishing and other recreational activities. Nearly 14 million people use Hartwell Lake annually for recreational purposes, making it one of the three most visited Army Corps of Engineers impoundments in the nation. Another 7 million people use the J. Strom Thurmond Lake and 10 million use the Richard B. Russell Lake (GDNR 2001b). Even with the heavy use of the Savannah, however, water quality in the river overall is quite good and has been improving over the past few decades. The designated use of the river down to the Thurmond Dam is for recreation, and from there to Augusta it is for drinking water. Portions of the lower part of the river are designated for fishing and

drinking water (GDNR 2001b). The Savannah has been identified as one of 26 rivers in North America with a mean annual virgin discharge $>350\text{ m}^3/\text{s}$ that are highly fragmented by dams (Dynesius and Nilsson 1994).

Although water quality is generally good, ecologically the Savannah is a highly modified system. The impoundments alter the daily and seasonal hydrograph, reduce downstream sediment load, and negatively impact water quality through hypolimnetic releases of cold, oxygen-depleted water during the late summer and autumn. The seasonal impact of the dams on the river's hydrograph can be seen by comparing runoff in the Savannah with that in the neighboring Ogeechee River, which is unregulated and likely represents the natural flow regime for rivers in the region (compare Figs. 3.18 and 3.20). The relative differences in runoff between dry and wet periods over the year are far smaller in the Savannah than in the Ogeechee. Summer and autumn runoff in the Savannah is augmented by releases from the dams, maintaining higher than natural flow during this time, whereas winter and spring runoff is decreased by the impoundments, in particular affecting the extent of inundation of downstream floodplains.

The river below the Fall Line also is impacted by dredging and channelization, performed to maintain a shipping channel and for flood control. Channelization has reduced the length of the river by 13% (Schmitt and Hornsby 1985). Flow regulation and channelization together have reduced the frequency and magnitude of downstream flooding, allowing development in the floodplain as well as causing a decrease in the size, inundation period, and probably the productivity of the floodplain.

The river is impacted by various industrial and municipal discharges, especially in the vicinity of Augusta and Savannah, as well as by nonpoint sources from timbering, agricultural, and urban land uses that result in the input of considerable quantities of sediment and nutrients. In addition, habitat alteration in the floodplain, heavy recreational fishing pressure, the introduction of nonnative sport fishes, the blocking of anadromous fish runs by dams, and removal of the historically abundant snags from the channel to aid navigation all have altered the ecology of this once prime example of a southeastern river.

OGEECHEE RIVER

The Ogeechee River is a medium-size river (basin area = $13,500\text{ km}^2$) in eastern Georgia that arises

from spring-fed streams in the Piedmont physiographic province but flows most of its 400 km length through the Coastal Plain (Fig. 3.19). During most of its length the Ogeechee is a scenic, low-gradient blackwater river meandering within a broad forested swamp, then through vast marshes, before emptying into Ossabaw Sound about 24 km south of Savannah. The Ogeechee is one of the few rivers along the southeastern Atlantic slope that flows its entire length without any major dams, including its largest tributary, the 137 km Canoochee River. Water quality is generally good along most of the river, fishing is popular among local residents, and paddle trips are common (Sehlinger and Otey 1980).

Like many eastern rivers, the Ogeechee has an interesting history of human influence dating to the arrival of the Paleo-Indians 11,500 years ago. For several hundred years before the arrival of Europeans, the Ogeechee basin and much of the Georgia Coastal Plain were occupied by prehistoric Indian chiefdoms of the Mississippian culture. European influence began with the establishment of Spanish missions along the coast from the mid 1500s to late 1800s. By this time, the chiefdoms had disappeared and their descendents across much of middle Georgia became known as the Creeks. In the early eighteenth century, the British took control of the Georgia coast, as James Oglethorpe founded Savannah in 1733. Oglethorpe's treaties with the Creek Indians began the cession of land in the Ogeechee and surrounding basins to Georgia that would continue after the Revolutionary War. By 1790, seven years after the war ended, the entire Ogeechee basin became the central portion of the new state of Georgia as the remainder of the Native Americans was expelled. In 1796, the town of Louisville was established in the upper Ogeechee basin as the third of five state capitals. Little more than 50 years later, Civil War General Sherman's "march to the sea" crossed the basin to capture Fort McAllister, built on the southern shore of the Ogeechee to protect Savannah's southern flank.

Physiography, Climate, and Land use

The Ogeechee flows in a southeasterly direction between 34°N to 32°N latitude (see Fig. 3.19). The upper 5% of the basin is in the Piedmont (PP) physiographic province, but the river soon crosses the Fall Line, where it flows over shallow rocky shoals. The Ogeechee then flows through the somewhat hilly upper Coastal Plain (CP) (57%), and then through the nearly flat lower Coastal Plain (38%). Soils of the

Coastal Plain consist of sedimentary deposits that are sandy, porous, and vary from zero to 150 m in depth. These sediments overlay the extensive Upper Floridan aquifer, containing water from limestone and dolomite rocks. The basin encompasses three terrestrial ecoregions on its way to the coast: Southeastern Mixed Forests, Middle Atlantic Coastal Forests, and Southeastern Conifer Forests (Ricketts et al. 1999). The predominant upland trees are slash, longleaf, and loblolly pines, with hardwoods such as oak, hickory, sweetgum, and poplar scattered throughout the basin.

The Ogeechee basin has a subtropical climate, characterized by hot summers and mild winters. Annual mean air temperature is 18°C, ranging from a monthly mean of 8°C in January to 26°C in July (see Fig. 3.20). However, daily nighttime temperatures commonly fall below 0°C in winter and daytime temperatures exceed 38°C in summer. Annual precipitation is relatively high and uniform over the basin, with averages ranging from 100 to 130 cm. Precipitation falls mostly as rain and is distributed fairly evenly through the year, as illustrated by a high of 12 cm in August and a low of 6 cm in November at Millen, Georgia, in the upper Coastal Plain.

Human population density in the basin is 30 people/km², which is deceptively high because Statesboro (population = 21,000) is the largest city wholly within the basin. Near the coast, however, intensive development around Savannah has occurred, increasing the basinwide average density. In spite of a relatively low density throughout most of the basin, very little of the Ogeechee basin forests remain in a natural state due to agricultural conversion during the late 1700s and early 1800s, particularly with cotton and tobacco in the uplands and rice along the tidal portions of the river where marshes were drained. During the twentieth century, agriculture became more diversified (soybeans, tobacco, cotton, peanuts, corn, cattle, poultry), particularly after World War I, when the boll weevil devastated cotton production. Furthermore, extensive pine forests were planted over former croplands, particularly in the lower Coastal Plain, where pulpwood production became extensive. Currently, about 54% of the Ogeechee basin is covered with forests (mostly managed), 18% with crops or pasture, 1% urban, 17% forested wetlands, and most of the remaining 11% as nonforested wetland (GDNR 2001a). Floodplain (wetland) forests with native species remain intact throughout most of the basin in spite of having been extensively logged in the past; rice plantations near the coast have reverted back to marshlands. The

lower section of the Canoochee River passes through the Fort Stewart Military Reservation, which occupies about 1130 km², mostly in managed forest.

River Geomorphology, Hydrology, and Chemistry

The Ogeechee basin begins at an elevation of about 200 m asl on the edge of the Piedmont Plateau, and the average gradient over its entire length is about 50 cm/km (Meyer 1992). Below the Fall Line, its gradient is eventually reduced to only 20 cm/km, with laminar flow. Channel width of the Ogeechee increases from 10 to 15 m just below the Fall Line, to about 60 m when it is joined by the Canoochee River, to >100 m just before emptying into Ossabaw Sound. Once in the Coastal Plain, the major substrate of the river bed is shifting sand, but backwaters along the many bends of the river have substantial organic deposits. Sandbars are commonly observed at low water during summer months. Extensive snags that originate from undercut riparian trees are a major feature of the channel along most of its length. In contrast to many rivers throughout North America in which wood has been removed by snagging operations, particularly during the nineteenth and twentieth centuries, the Ogeechee retains a substantial amount. Such wood has important influences on the geomorphology of the river, but more obviously it provides stable habitat for many aquatic animals, given the unstable nature of the riverbed. Unfortunately, the same wood habitat that perpetuates biological diversity and productivity is not always appreciated by the public because of the boating hazards it creates.

Much of the Ogeechee meanders within heavily forested swamps that can be 1 to 2 km in width, with many horseshoe bends and backwaters (Fig. 3.6). However, scenic sand and clay bluffs also occur intermittently among its length. The Ogeechee's broad forested swamp diminishes just below its confluence with the Canoochee as the floodplain is transformed into a vast marsh. The floodplain provides a highly variable environment with diverse habitat for both aquatic and terrestrial species. Aquatic life abounds during the flooded periods in winter, but when most of the waters recede during the warmer months, terrestrial species use the forest floor. Even during dry periods when the river is no longer flooding, floodplain pools and oxbows persist in many portions of the swamp, replenished by groundwater and rainfall.

Mean discharge for the Ogeechee River at its mouth is about 115 m³/s, but there is usually a strong

FIGURE 3.6 Ogeechee River, upstream of I-16 (PHOTO BY A. C. BENKE).

seasonal pattern that typically varies from only 10 to 20 m³/s in summer to over 400 m³/s in winter and spring. Rainfall is relatively uniform throughout the year, suggesting that the pattern of runoff is due to seasonal variation in evapotranspiration, as illustrated by a site near Interstate Highway 16, about 63 km from the mouth (Benke et al. 2000; see Fig. 3.20). As discharge increases during winter and spring, ever-increasing areas of floodplain become inundated and substantial flooding can continue for weeks or months. Thus, virtually every year floodplain inundation effectively increases the width of the river near I-16 from about 33 m to more than a kilometer. Because the Ogeechee is a free-flowing system with no regulation, the seasonal pattern of flooding can serve as a benchmark for the type of hydrological pattern that should be expected (and sought) in attempts to restore the hydrological regimes of similar rivers that are now regulated for power generation and flood control. The Ogeechee experiences a tidal influence just upstream of the confluence with the Canoochee, approximately 50 km from its

mouth. The saltwater wedge also extends nearly this far upstream.

The Ogeechee is a blackwater river, often tea-colored as a result of dissolved organic carbon consisting mostly of fulvic acids that are leached from the terrestrial environment (Meyer 1992, Smock and Gilinsky 1992). DOC ranges from 4 to 34 mg/L, with a mean of 13 mg/L, and color ranges from 35 to 92 Pt units (Meyer 1992). The Ogeechee does not have the low pH and low alkalinity typical of many blackwater rivers because it receives discharge of carbonate-rich waters from the Upper Floridan aquifer, particularly from Magnolia Springs near Millen. Alkalinity ranges from about 10 to 40 mg/L as CaCO₃ (mean = 23 mg/L), and pH ranges from 6.6 to 7.2 (mean = 7.0). In spite of extensive agriculture in the basin, NO₃-N concentrations typically are <0.3 mg/L and total phosphorus is usually <1 mg/L. Dissolved oxygen concentrations are usually above 6 mg/L but can fall below 4 mg/L during droughts due to high amounts of organic matter (as will be discussed later). Water temperatures in the main channel

at the I-16 study site typically range from a daily low of about 10°C to a daily high of 30°C, with an annual mean of about 19°C.

River Biodiversity and Ecology

The Ogeechee River lies wholly within the South Atlantic freshwater ecoregion (Abell et al. 2000). The ecological characteristics of the Coastal Plain portion of the Ogeechee are well known based on studies conducted during the 1980s at a site near I-16 (e.g., Meyer 1990, 1992; Benke 2001). Most of these studies focused on ecological processes, such as primary and secondary production, organic matter processing, ecosystem metabolism, and the role of microbes in food webs. Only the invertebrate taxa were intensively inventoried, but information was also obtained for protists. However, relatively complete information is available from the GDNR and other publications for fishes, amphibians, reptiles, crayfish, and mussels.

Algae, Cyanobacteria, and Protists

Water-column protists of the Ogeechee River have been studied to understand their taxonomic composition and their role in the microbial food web (Carlough 1989, Carlough and Meyer 1989). Protist densities were very high (typically >2 to 10⁶/L). They included small flagellates such as choanoflagellates and *Spermatozopsis*, as well as large flagellates such as cryptomonads (*Cryptomonas*, *Chroomonas*, *Chilomonas*), the dinoflagellate *Glenodinium*, and various euglenoids (*Euglena*, *Distigma*, *Phacus*). Colonies of *Volvox*, *Eudorina*, and *Dinobryon* were also present. Some limited collections from the water column (A. C. Benke, unpublished data) also included diatoms (*Achnanthes*, *Melosira*, naviculoids), green algae (*Scenedesmus*, *Ankistrodesmus*), and Cyanobacteria (*Lyngbya* and *Oscillatoria*). Algae were also found as components of the biofilm on snags (including the filamentous alga *Tribonema*, as well as *Microspora* and *Melosira*) (Couch and Meyer 1992). The complete algal assemblage is probably similar to that found in the adjacent Savannah River (Patrick 1996).

Plants

The dominant plants along the Ogeechee River are those found in the swamp forest, an integral feature of this river-floodplain system. Among the most common tree species in the floodplain near the I-16 field site are bald cypress, swamp black gum, red maple, water oak, and sweetgum, with willows found

along sandbars (Meyer 1992). The floodplain forest subsidizes the food webs of the river with its high production of leaves, which partially decompose on the forest floor and a large portion of which are ultimately flushed into the main channel (e.g., Meyer 1990). Aquatic macrophytes are not a common feature of the main channel, except for those found within quiet backwater and floodplain pools, such as the yellow pond-lily. Mosses and liverworts commonly are found growing on snags and tree trunks at the river's edge and in the floodplain forest. As the river enters the tidewater region, the floodplain forests give way to vast marshes of rush and cordgrass.

Invertebrates

Over 270 species of freshwater invertebrates have been collected within the channel and floodplain habitats at the I-16 field site (A. C. Benke, unpublished data). This includes 208 species of aquatic insects, with 31 mayflies, 18 caddisflies, 34 beetles, 13 stoneflies, 59 dipterans, 37 dragonflies and damselflies, and 10 mollusks.

Snags are the most stable habitat in the main channel and are heavily colonized by a high diversity (>108 species) of aquatic invertebrates with a mean density of >97,000/m² of wood surface (e.g., Benke 2001, Benke et al. 2001). Snag invertebrates primarily consist of species that feed by filtering particles from the water or gathering food from the wood substrate. Among the more abundant filter-feeders are hydropsychid caddisflies (*Hydropsyche*, *Cheumatopsyche*), Tanytarsini midges (*Rheotanytarsus*), black flies (*Simulium*), and the mayfly *Isonychia*. Among the more abundant gatherers are over 20 mayfly species (*Stenonema*, *Baetis*, *Tricorythodes*, *Ephemerella*), as well as several elmids beetles (*Stenelmis*, *Macronychus glabratus*) and many chironomid midges (*Polypedilum*, *Rheocricotopus*, *Stenochironomus*). There is also a diverse assemblage of predaceous insects, including hellgrammites (*Corydalus cornutus*), perlid stoneflies (*Paragnetina kansensis*, *Perlesta placida*, *Neoperla clymene*), and dragonflies (*Neurocordulia molesta*, *Boyeria vinosa*).

Invertebrates of the sandy bed include oligochaete worms (enchytraeids and tubificids) and a diverse assemblage of chironomids (*Rheosmittia*, *Cricotopus*, *Cladotanytarsus*, *Polypedilum*, *Cryptochironomus*, and *Robackia*) (Stites 1986). Trails of the burrowing dragonfly larvae *Progomphus obscurus* commonly are observed along the edges of sandbars at low water. By far the most common mollusk at the I-16 site is the nonnative Asiatic clam. Other mollusk

taxa include the sphaeriids *Sphaerium* and *Musculium* and the gastropods *Amnicola*, *Gyraulus*, *Menetus*, *Physella*, and *Viviparus* (Stites 1986). At least 12 species of unionid mussels have been reported from the Ogeechee River (Johnson 1970; Chris Skelton, GDNR, personal communication), but these were not apparent at the I-16 site. The Atlantic pigtoe mussel is the most endangered mollusk. At least 16 crayfish species, most in the genera *Cambarus* and *Procambarus*, occur in the Ogeechee, none of which are considered to be endangered (Chris Skelton, GDNR, personal communication).

The inundated floodplain forest also supports an extensive assemblage of aquatic invertebrates (Benke et al. 2001), consisting primarily of oligochaete worms, small mollusks, dipterans, and crustaceans. Although the densities and production of floodplain invertebrates are not nearly as high as that found on snags, the large floodplain area results in the greatest overall total abundance and biomass of invertebrates in the river system. At least 34 species of microcrustaceans (zooplankton and bottom dwellers) have been found in the inundated floodplain swamp, including cladocerans (*Alona*, *Camptocercus*, and *Chydorus*), copepods (*Acanthocyclops*, *Diacyclops*, and *Mesocyclops*), and ostracods (*Candona parvula*, *Cypria turneri*) (Anderson 1995).

Vertebrates

The fish assemblage of the Ogeechee is quite diverse, particularly for a river that is primarily in the Coastal Plain. Various sources suggest at least 80 species, including marine species sometimes found in freshwater (Swift et al. 1986, Schmitt 1988, Warren et al. 2000; Chris Skelton, GDNR, personal communication). There are at least 15 species of Cyprinidae (carps and minnows) and 13 species of Centrarchidae (sunfishes). Most of the Centrarchidae and many small species (Cyprinidae and others) are insectivores. Several species of the Centrarchidae are snag-feeding insectivores, particularly redbreast sunfish, warmouth, spotted sunfish, and redbreast sunfish (Meyer 1990, 1992). Bottom-feeding fishes include spotted sucker and at least six species of Ictaluridae. Among the most abundant piscivorous species are largemouth bass, longnose gar, bowfin, and chain pickerel. These piscivores feed primarily on the smaller forage fishes such as shiners, minnows, and darters. Several species are floodplain spawners, as in other Coastal Plain rivers, including the anadromous American shad (Meyer 1990).

The GDNR (<http://georgiawildlife.dnr.state.ga.us>) describes the Ogeechee as excellent for redbreast

sunfish fishing, with bluegill, redbreast, black crappie, and spotted sunfish as other popular species. Largemouth bass are plentiful but represent only 3% of the harvest. The most common catfish in the river is the snail bullhead; the white catfish is found in the lower reaches. The Ogeechee is surprisingly free of nonnative fish species; it is unclear whether the channel catfish is native (Warren et al. 2000). Fisheries managers are much more concerned about the flathead catfish, which has not yet invaded the river. Only the shortnose sturgeon, a diadromous species, and the robust redhorse sucker are considered rare or endangered in the Ogeechee (Warren et al. 2000). The robust redhorse, once thought extinct, has been introduced to the Ogeechee. Although native to adjacent basins (Savannah and Altamaha), it is uncertain whether it is native to the Ogeechee. The abundance of the anadromous American shad decreased dramatically over the latter half of the twentieth century, apparently due to commercial fishing (Schmitt 1988).

The amphibians and reptiles directly associated with the Ogeechee River also are diverse. Seven species of frogs, 13 salamanders, 9 snakes, 12 turtles, and 1 crocodylian are found either in the main stem of the river or in the floodplain much of the year (John Jensen, GDNR, personal communication). Considerable overlap occurs with species found in the much larger Savannah and Altamaha Rivers, which only have a few additional species. Among the more charismatic amphibians are the large salamanders: the two-toed amphiuma, the greater siren, the lesser siren, and the dwarf waterdog. Only a few amphibians are on Georgia's protected list or are of special concern: the dwarf waterdog, Brimley's chorus frog, and the many-lined salamander. Water snakes are very common in the Ogeechee and are often mistaken for the only poisonous aquatic snake, the cottonmouth. Among the more common turtles is the river cooter, often seen basking on snags projecting from the water. The snapping turtle, two species of softshell turtles, and the American alligator are among the more fascinating but elusive species. The rainbow snake and the spotted turtle are the only species of special concern.

Ecosystem Processes

There is extensive literature on ecosystem processes in the Ogeechee River, only a portion of which will be described here. Plant production in river swamps is typically higher than in upland areas and supports a high plant diversity in contrast to much of the upland that has been transformed into pine forest monoculture. Much of the litter fall

partially decomposes on the swamp floor (Cuffney and Wallace 1987) and, along with its bacterial assemblage, it ultimately is flushed as dissolved or fine particulate organic matter to the river. The runoff containing this bacteria-rich organic matter becomes even further enriched with protists, algae, and drifting animals as it flows in the river channel. This seston becomes the major food source on which many species of filtering and gathering invertebrates depend (Meyer 1990, 1992). With the high inputs of organic matter to the river, community respiration rates of the main channel water column are relatively high, with an annual average of $6.7 \text{ g O}_2 \text{ m}^{-2} \text{ day}^{-1}$ at the I-16 field site (Meyer 1992). In contrast, gross primary production in the water column is only moderate, with an annual average of $2.2 \text{ g O}_2 \text{ m}^{-2} \text{ day}^{-1}$. Thus, the Ogeechee River is heterotrophic, with allochthonous organic matter from the floodplain swamp contributing to an annual Production/Respiration (P/R) value of only 0.25. A more complete description of the organic matter dynamics of the Ogeechee can be found in Meyer et al. (1997).

The nutritious seston provides an unlimited food supply for the snag inhabitants that are able to gather this material as it is intercepted by the wood itself or filtered from the water by the silken nets and specialized appendages of many species. This food subsidy from the flowing waters results in high invertebrate production on snags ($>100 \text{ g dry mass m}^{-2} \text{ yr}^{-1}$ of snag surface; Benke et al. 2001). Chironomids, caddisflies, and mayflies are especially productive, and they in turn are preyed upon by hellgrammites, dragonflies, and stoneflies. Invertebrate production and diversity are much higher on the snag habitat (a biodiversity hot spot) than in the shifting sand bed of the main channel, a habitat of low stability. The importance of the snag habitat is further shown by high densities of invertebrate drift ($>20 \text{ animals/m}^3$ of water), most of which originate from snags, and the heavy use of snag prey as food by many species of fishes (Benke et al. 1985).

Human Impacts and Special Features

The Ogeechee River is one of only 42 reasonably natural rivers of at least 200 km in length that is free flowing in the coterminous United States (Benke 1990). Thus, with no major dams, channelization, or water diversions on the Ogeechee, discharge and inundation patterns are unaltered (Benke et al. 2000). Although the floodplain swamp forest has been exploited for over a century, it remains relatively intact along most of the river (i.e., most areas have

not been drained). Virtually all of the floodplain forest is second growth, and enormous stumps of previously harvested cypress trees are still visible in the swamp. During the 1980s, the Ogeechee was under consideration for the Federal Wild and Scenic River system.

Water quality is very good in the Ogeechee River and has been well summarized by Meyer (1992) and GDNR (2001a). Although nitrate and phosphate are not especially high (see previous text), the combined inputs from municipal wastewater treatment plants and agricultural runoff sometimes cause phytoplankton blooms during low summer discharge. Higher concentrations in the spring at the time of cropland fertilization implicate agriculture. There is relatively little sewage pollution in the Ogeechee, with five-day biochemical oxygen demands low, and reports of high fecal coliform counts are infrequent. Although dissolved oxygen is periodically low, it is what might be expected in an unpolluted blackwater Coastal Plain river rather than being caused by cultural waste inputs. Approximately 3% of the total flow of the Ogeechee River is withdrawn from both groundwater and surface water sources. Attempts to release pollutants into the river and develop landfills in floodplains are strongly opposed by local conservation groups such as the Ogeechee River Valley Association as well as statewide organizations.

The only nonnative aquatic animal in the Ogeechee River that may have caused ecological problems is the Asiatic clam. It apparently arrived in the mid 1970s as it did in many rivers of the southeastern Atlantic slope, with the exception of low-pH rivers such as the Satilla. Although the clam is relatively abundant, its production is not very high and there are often die-offs, suggesting that the low-to-moderate alkalinity in the Ogeechee may be near the clam's tolerance limits. Although other bivalves are not abundant in the vicinity of the I-16 study site, we are unaware of any evidence showing the Asiatic clam having a negative effect on native species or significantly altering the natural ecosystem functioning of such systems.

In spite of extensive agricultural and forestry development in the uplands, the Ogeechee River remains one of the more natural free-flowing rivers in the eastern United States and can serve as a benchmark for restoration of other rivers of the region. The absence of large cities, industries, and dams, and the presence of a wide forested floodplain swamp, are major factors that have allowed the Ogeechee to remain in a relatively natural state. Vigilant conservation groups will probably play a major role in

FIGURE 3.7 St. Johns River, north end of Lake George, Florida (PHOTO BY M. O'MALLEY/ST. JOHNS RIVER WATER MANAGEMENT DISTRICT).

preserving the Ogeechee and its floodplain as development pressures increase. Increased growth in the Savannah metropolitan area, which lies on the edge of the lowest part of the Ogeechee basin, has placed heavy water demands on the Upper Floridan aquifer near the coast. Potential use of the Ogeechee River as a supplementary water source could have severe impacts on the ecological conditions of the lower river reaches.

ST. JOHNS RIVER

The Native Americans of the Timucua tribe called it Welaka, roughly translating as “the Chain of Lakes,” for that is how the St. Johns River appears. The longest river in Florida is more a series of interconnected lakes than a swift-flowing river (see Fig. 3.21). It is a broad, shallow, blackwater system that widens into a number of lakes as it drains much of northeast Florida on its way to the Atlantic Ocean (Fig. 3.7). It is a tidal river with an extended estuary,

in which tides influence its hydrology and ecology far upriver into broad freshwater marshes. As such, its geomorphology and hydrology are quite different from the other Atlantic slope rivers described in this chapter.

The earliest Native Americans probably moved into the area around 12,000 years ago, living off the river and bountiful plants and game throughout the basin. The French Huguenots founded the first colony in 1564 along the river near present-day Jacksonville. A Spanish force drove the French from the region the following year, beginning 250 years of Spanish influence in the area. American settlers moved into the river basin in earnest beginning around 1819 when Spain ceded Florida to the United States. Clashes between Native Americans and Europeans began almost with the earliest settlements and became more frequent as more and more of the former’s land was lost to plantations. Hostilities finally stopped at the end of the Seminole Wars in 1842. Since that time, agricultural and then commercial development in the basin has been an

important component of the growth and vitality of the region.

Physiography, Climate, and Land Use

The St. Johns River basin lies completely within the Coastal Plain (CP) physiographic province at latitude 28°N to 30°N, draining a watershed of rolling hills and lowlands set within the Southeastern Conifer Forests and Florida Sand Pine Scrub ecoregions (Ricketts et al. 1999). Its watershed is located in an area of Pleistocene barrier islands, coastal dunes and ridges, and estuarine marshes and lagoons (Cooke 1945). The basin began to take shape with the formation of barrier islands 16 to 25 km off the Florida peninsula. Those islands and the coastal dunes and ridges on the mainland eventually enclosed a long shallow bay running parallel to the coastline. As ocean levels dropped, the bay turned from an estuarine to a freshwater system. The Oklawaha River, now the largest tributary to the St. Johns, originally drained directly into the bay but then was captured by the newly forming St. Johns. The north-south coastal axis of the basin gives the St. Johns the distinction of being one of the few rivers on the North American continent that flows in a northerly direction.

The river basin today lies on the flat Pamlico terrace, with the highest elevation in the basin at 107 m asl. Rich spodosol and histosol soils occur throughout the region, with vegetation characterized by oaks, maples, magnolias, bays, and palmettos. Lowland areas are poorly drained, resulting in numerous lakes and extensive wetlands throughout the basin, with the marshes underlain by fibrous peat deposits. Portions of the basin occur in a karst topography of limestone and dolomite, particularly along the basin's western boundary, where the watershed sits on Ocala limestone and the Floridan aquifer (Cooke 1945).

The climate of the river basin is humid subtropical. Summer months are warm, with mean air temperature from June through August of 27°C (see Fig. 3.22). Winter months are mild, with a mean temperature of 12°C. The annual mean temperature is 20°C. Air temperatures occasionally drop to freezing during many winters, but most frequently only in the northern portion of the basin. Over half of the basin's annual rainfall occurs from June through September, primarily as thunderstorms. The mean annual rainfall for the basin is about 131 cm.

Land use throughout the river basin is mixed, significant portions of the basin remaining in wetlands

and open water (24%) and upland forested areas (45%), but much of the land is converted to crop and livestock agriculture (25%) and urbanized areas (6%). The primary urban areas in the basin include Orlando, Deland, Ocala, and Jacksonville. Population density in the basin is quite high at 78 people/km².

River Geomorphology, Hydrology, and Chemistry

The river arises in a broad marsh located north of Lake Okeechobee at 8 m asl. From there it flows 460 km north to Jacksonville, where it takes an abrupt turn to the east and travels an additional 40 km to its mouth at the Atlantic Ocean. The river's overall gradient is only 2 cm/km, making it one of the flattest major rivers in North America. Along its slow meandering route the channel passes through eight broad lakes and has an immediate connection to at least five additional lakes. The river has three relatively distinct sections, based on differences in channel shape, sediment, hydrology, and ecology (Burgess and Franz 1978). All are encompassed by the St. Johns River Water Management District, a state agency charged with preserving and managing the ground and surface water resources throughout the river's basin.

The upper section, which includes the initial 121 km, begins as indistinct channels in dense headwater marshes. Distinct but shallow multiple channels gradually develop and then pass through a series of lakes, some formed from remnant coastal lagoons. The lakes are all small and shallow, with maximum depths typically of 1 to 3 m. They support a dense growth of emergent, floating, and submerged macrophytes, with occasional sections of channel through the lakes free of macrophytes. Sediment in the channel and lakes is a thick peat with some areas of sand. The floodplain historically was quite broad but has been much reduced, largely by the many canals built to drain land for agricultural purposes. Partway through this section the river develops distinct banks and has a firm sand substrate, but then again broadens into a valley of braided channels, palmetto hammocks, and marshes. Just above Lake Harney the river receives inputs from salt springs that raise surface water salinities to 11 ppt (DeMort 1991).

The middle section of river runs from Lake Harney to the confluence with the Oklawaha River, a distance of 161 km, much of which is in the Ocala National Forest. The channel through this section alternates between having elevated, well-defined banks to flowing through broad shallow lakes,

including Lake George, the largest of the lakes along the river at over 20 km wide. Sediments are typically sand with areas of peat. Below where the Wekiva River enters the St. Johns north of Orlando, the channel deepens to 3 m and broadens to a mean width of 100 m. Dredging and channelization are employed to maintain a navigation channel throughout this middle section and down to the river's mouth.

The lower section includes that portion of river from just below Lake George, where the Oklawaha enters, to the river's mouth, a distance of about 200 km. Much of the river basin here is mixed forest and urban land. Down to Jacksonville the river widens from 1.5 km to 5 km, but with a depth still generally no greater than 3 m. At Jacksonville, where the river is heavily used for the city's thriving industrial port, the channel deepens to about 9 m, with some scoured and dredged areas that are 18 m deep (DeMort 1991). The river through this section is tidal, with freshwater marshes grading into salt marshes.

The primary sources of water to the river are from rainfall draining from marshes at the head of the basin and from groundwater from karst aquifers, especially the Floridan Aquifer. Several of the main tributaries, such as the Wekiva and Econlochhatchee rivers, have extensive inputs of water from karst formations and shallow aquifers, providing flow even during prolonged dry periods (DeMort 1991). Mean annual discharge in the river at Jacksonville is 222 m³/s. Mean monthly discharge is remarkably uniform throughout the year in spite of substantially higher rainfall from June through September than during the rest of the year (see Fig. 3.22). The ability of the basin's wetlands to store water during the wettest months, higher evapotranspiration in the summer, and the substantial and relatively constant groundwater inputs to the river system all contribute to maintaining the uniform discharge over the year.

Tides have a major impact on the hydrology and chemistry of much of the river. A salinity wedge regularly reaches 42 km upriver and occasionally 90 km or more (Mason 1998). The lower river near Jacksonville is mesohaline at 15 to 18 ppt, increasing to 32 to 35 ppt at its mouth. Freshwater tides typically occur up to Lake George 160 km inland and occasionally farther upriver, affecting nearly half of the river's length. Tidal amplitude at the river's mouth is about 1.5 m. The low gradient and tidal action of the river make it very sluggish, with the direction of flow often determined by the prevailing winds and tides (Kautz 1981).

The mean annual water temperature of the river is about 22°C, typically ranging from 9°C to 30°C,

but occasionally reaching up to 38°C. High concentrations of dissolved organic carbon leaching from wetland vegetation result in the highly stained, blackwater appearance of the river, with its color often >200 Pt units (Aldridge et al. 1998). The river is neutral to slightly basic and highly buffered (Garman and Nielsen 1992). Conductivity and total dissolved solids are higher, and turbidity lower, than in other northern Florida rivers (Kautz 1981). Upwellings from salt springs cause pockets of higher salinity (>5 ppt) in otherwise freshwater portions of the river. The river's hydrology results in a high retention time for its water and dissolved and suspended constituents. Retention times in the lower river of 3 to 4 months greatly affect the river's water quality and ecology. Water quality is highly variable among the upper, middle, and lower sections of the river.

River Biodiversity and Ecology

The St. Johns River is located entirely within the Florida freshwater ecoregion (Abell et al. 2000). It supports a diverse flora and fauna. Plant and animal diversity is high in the river system because of the variety of aquatic habitats along the river, including riverine, lake, and wetland areas, as well as the strong estuarine influence far upriver.

Algae and Cyanobacteria

Little information exists on the periphyton in the river and its wetland. Phytoplankton species richness is high; DeMort (1991) noted that at least 343 species had been identified from the river. Cyanobacteria typically dominate in the upper river and diatoms in the lower river. Among the more common phytoplankton are *Cylindrospermopsis raciborskii*, *Microcystis incerta*, *Lyngbya contorta*, *Melosira italica*, *Skeletonema costatum*, *Anabaena circinalis*, *Pediastrum simplex*, and *P. duplex* (D. Dobberfuhl, personal communication; DeMort 1991). The marine benthic green algae *Ulva latuca* and *Enteromorpha intestinalis* are common in the estuarine section of the river. Chlorophyll *a* concentrations generally range from 4 to 20 µg/L in the upper sections of the river, but considerably higher concentrations frequently occur in the middle and lower sections. For example, the lower section can reach 174 µg Chl/L and averages around 22 µg Chl/L (D. Dobberfuhl, personal communication).

Plants

A diverse array of species of macrophytes occurs throughout the river system, with over 300 species

recorded from the river and its floodplain. American eelgrass is the most abundant species in the channel, and waving beds of this species occur throughout much of the freshwater portion of the river. Other common submerged species in the channel and lakes include coon's tail, pondweed, widgeon grass, and southern waterhyacinth.

The extensive marshes in the headwaters, fringing wetlands, and near-bank areas of the river's channel and lakes are characterized by a variety of emergent and floating-leaved species, with the species assemblage depending primarily on elevation and salinity. Typical species in freshwater areas include maidencane, pickerelweed, arrowhead, swamp sawgrass, cattail, yellow pond-lily, and American white waterlily. Bald cypress occurs along sections of the lower river and its tributaries. Halophytes occur in the extensive estuarine marshes and also in patches in otherwise freshwater areas where salt springs emerge. Needlegrass rush and smooth cordgrass dominate in high and low salt marshes, respectively; sand cordgrass and other halophytes dominate in inland areas with increased salinity. A variety of non-native macrophytes have been introduced to the river, with common water hyacinth and hydrilla the most abundant.

Invertebrates

The slow flow of the river and its many lakes allows far higher numbers of zooplankton to occur in the St. Johns River than in most other rivers. Zooplankton assemblages in the freshwater section of the river are composed predominately of cyclopoid copepods and rotifers. Estuarine species predominant in the lower river, with calanoid copepods and barnacle nauplii, in particular, increasing in number downriver but often occurring far upriver depending on river hydrology and time of year.

The benthic invertebrate assemblage also is a mix of freshwater and estuarine species. Studies suggest high species richness, in part because of the mix of freshwater and estuarine species and also because of the heterogeneous environment provided by the abundant submerged aquatic vegetation. Mason (1998) refers to studies that document the occurrence of nearly 300 macrobenthic taxa in the lower river. Several species of endemic crayfish and at least 14 species of endemic gastropods occur in the drainage basin (Garman and Nielsen 1992). A diverse, though probably declining, unionid mollusk fauna also occurs in the basin (Johnson 1970).

Chironomid midges and tubificid (oligochaete) worms are the most common species in the silt and

organic sediments, where low oxygen concentrations, especially in the lakes during the summer and autumn, affect species composition and abundance. Abundance of invertebrates is higher in these sediments than in sand sediment (Mason 1998), where the clams *Corbicula fluminea*, *Rangia cuneata*, and various sphaeriids are among the more obvious species. *Rangia* is the most abundant bivalve in the lower section of the river (DeMort 1991).

Macrobenthic biodiversity is highest in beds of aquatic vegetation. The baetid mayfly *Callibaetis floridanus* is ubiquitous and often abundant in freshwater littoral zones and fringing wetlands. Many hydroptilid caddisflies also are common among the vegetation, including species of *Hydroptila*, *Orthotrichia*, and *Oxythira*. A variety of species of other mayflies, caddisflies, odonates, coleopterans, and hemipterans, as well as many species of dipterans, also occur among the vegetation. Amphipods, including *Hyaella azteca* and various gammarid species, as well as mysid and grass shrimp, pulmonate snails (e.g., *Physella*), and many species of tubificid and naidid worms are the most common noninsects in macrophyte beds.

Freshwater and estuarine species coexist throughout much of the lower river, although the number of freshwater species is low in the last 60 km of the river. Crustaceans replace insects as the dominant taxa as salinity increases downriver. It is not unusual to find high numbers of chironomids and tubificids in mud and peat beds, barnacles and mussels encrusted on nearby submerged objects, and mayflies, caddisflies, and estuarine crabs together inhabiting fringing macrophyte beds. The Harris (or white-fingered) mud crab is widespread, occurring from the river's mouth to far upriver (DeMort 1991). Economically important white shrimp occur over 200 km upriver, and blue crab often are abundant upriver to Lake George and occur over 300 km upriver (DeMort 1991). Salt springs allow the establishment of patches of estuarine species within an otherwise freshwater landscape far upriver.

Vertebrates

The St. Johns River is one of the more species-rich rivers in terms of fishes along the southeastern Atlantic slope, supporting a diverse warmwater and euryhaline fish assemblage. At least 75 freshwater species occur in the drainage basin, representing 23 families (Garman and Nielsen 1992). Of those, 55 species occur regularly in the main stem. Tagatz (1967) noted an additional 115 euryhaline species occurring in the river, often far upriver because of the

influence of tides and the salt springs. Numerous estuarine and marine species are found in the lower river. The freshwater assemblage is dominated by invertivores. Of the freshwater species, centrarchids are the most abundant and diverse group, with 15 species occurring in the river. Centrarchids compose the majority of fishes in the lower river, with bluegill and redbreast sunfish alone composing 60% of the individuals (Bass 1991). Other species-rich families in the river include the Cyprinodontidae, Gobiidae, and Clupeidae.

The river serves as an important nursery for many marine species and also supports an important commercial fishery focused on American eel, channel catfish, and white catfish. Freshwater sport fishing concentrates on largemouth bass, black crappie, and bluegill (DeMort 1991). Six anadromous species occur in the river, with American shad the most abundant and economically important. A thriving striped bass population likely is nonmigratory (Garman and Nielsen 1992). Several nonnative species have been introduced, and three endemic subspecies are reported from the river, including the Lake Eustis minnow, Florida largemouth bass, and a subspecies of the pugnose minnow (Tagatz 1967, Burgess and Franz 1978).

The river, its tributaries, and its basin harbor many species of reptiles, amphibians, birds, and mammals. Reptiles and amphibians are abundant throughout the basin, including alligators, turtles, snakes, and frogs. Many aquatic birds, including anhingas, herons, egrets, ibises, limpkins, pelicans, and ducks, flourish along the river and in its marshes and lakes. The river basin harbors a population of the endangered Everglades snail kite that has been making a comeback since the early 1990s. Brown pelicans were listed as endangered in 1970 but were removed from the list in 1985 due to population recovery. Continual loss of habitat through the drainage of wetlands is the likely cause of the decline of the endangered wood stork. Bobcat and river otter occur in the floodplains, as do dwindling numbers of the endangered Florida panther. The federally endangered West Indian manatee is frequently found at many locations along the river.

Ecosystem Processes

The trophic basis of the river's food web is a mix of algae, including periphyton and phytoplankton, particulate detritus from senescing vascular plants both from within the channel and from the fringing wetlands, and DOC, which supports microbial communities, primarily from emergent plants throughout

the wetlands. Primary production in the river system appears to be quite high and dominated by vascular plants. The contribution of phytoplankton to primary production can be substantial in the channel and fringing lakes and also increases downriver as the channel deepens, aided by the low flushing rate of the river. Phytoplankton production likely is light limited, both through shading by the abundant macrophytes and by the high concentrations of DOC that cause high light attenuation in the water column. High turbidity, especially in the lower river, and phosphorus limitation because of high Fe concentrations also may affect phytoplankton production in the river. Although phytoplankton production is high today, it is likely that prior to intensive development the river was dominated by allochthonous detrital-based production (D. Dobberfuhl, personal communication). With development and ensuing eutrophication, the system has made a relatively dramatic shift to autochthonous algal production.

Production of primary consumers in the river and its floodplain likely is very high. The year-round high water temperature and high availability of food, particularly periphyton, but also decaying macrophyte tissue, no doubt provide considerable food resources to the abundant invertebrate consumers in the river system. Production of several species of chironomids must be very high, as they occasionally reach nuisance status. The exuviae of the chironomids *Chironomus plumosus*, *C. decorus*, and *Glyptotendipes lobiferus* form sufficiently dense mats that they clog channels in the floodplains (Mason 1998). Secondary consumer production also must be high given the abundance of fishes and other vertebrates in the river system.

Human Impacts and Special Features

The St. Johns River is unique among the major rivers along the Atlantic slope. Its river-lake geomorphology, extremely flat gradient, and extensive estuarine influence greatly affect the biota and ecosystem functioning of the river. The river is strongly coupled to its broad floodplain marshes and swamps in terms of hydrology, geochemistry, and food web dynamics. The variety of aquatic habitats supports a diverse flora and fauna, made even more interesting by the coexistence far inland of both freshwater and marine species. In addition, the St. Johns is one of the few free-flowing large rivers in the southeastern United States, the low gradient of the system having precluded the construction of major impoundments along the river.

The St. Johns river basin, however, has a long history of use by humans that has resulted in a highly modified landscape. The basin continues to absorb a rapid increase in population. Jacksonville is a major maritime business center, and the ever-increasing shipping that moves through its port affects the lower St. Johns through dredging operations and water-quality issues. The river supports a high degree of agricultural, industrial, and recreational uses. The hydrology of the system, and especially inflow to the river, has been greatly changed over the past century. Draining of fringing marshlands began in earnest in the early 1900s. Flow patterns have been altered by canals and levees as well as by diversion of water from the upper drainage basin into neighboring river systems. These modifications have resulted in a floodplain much reduced in size and function from its natural state. Along the upper St. Johns River, for example, over 80% of the floodplain has been highly modified. Water withdrawal from the river and its tributaries occurs for irrigation as well as for drinking water and industrial use. The result of the many hydromodification projects has been an altered hydroperiod and reduced discharge in the river.

Water quality in the river is affected by point discharges and especially by nonpoint runoff from agricultural land. The impact of these inputs is exacerbated by the high retention time of water, and thus pollutants, because of the low flushing rate of the river. Increasing rates of sedimentation and eutrophication result as decreasing discharge in the river causes even longer retention rates. Pesticide concentrations are elevated from agricultural runoff. Metal concentrations are elevated in urbanized areas, especially in the lower river near Jacksonville, where the highest industrial inputs occur.

The introduction of nonnative plants and animals, including both invertebrates and vertebrates, is a problem in the river basin as it is throughout much of Florida. Two species that have had considerable impact are the macrophytes water hyacinth and hydrilla. Hyacinth, introduced in the late 1800s, forms dense floating mats that can cover extensive areas of the river and lakes. Hydrilla, probably introduced in the 1970s, also has proliferated, especially in the lakes. Both are nuisance species, decreasing biodiversity, reducing fish stocks, increasing organic deposits, and impeding navigation. Extensive hyacinth and hydrilla control programs using herbicides are ongoing in the lower river to control these species and maintain an open navigation channel.

Several restoration and management projects are underway to address the many issues facing the St.

Johns. An effort to restore wetlands and a more natural hydroperiod in the upper basin is being undertaken by the St. Johns River Water Management District and the Army Corps of Engineers. Ecosystem management efforts in the middle basin are directed toward restoring water quality in the riverine lakes, especially Lake George. Programs focused on water-quality issues, including both point and nonpoint inputs, as well as restoration of degraded aquatic habitat, are ongoing in the lower river basin.

ADDITIONAL RIVERS

The York River, located in the Piedmont and Coastal Plain of Virginia, is part of the Chesapeake Bay watershed (see Fig. 3.23). The main-stem river, formed below the Fall Line at the confluence of the Pamunkey and Mattaponi Rivers, is tidal over its entire length (Fig. 3.8). Over two-thirds of the basin is forested, including extensive floodplain forests, resulting in relatively high water quality throughout much of the basin. The largely intact marshes along the upper reaches of the York are included in the Chesapeake Bay Natural Estuarine Research Reserve System. The York and its tributaries are largely free flowing, the only major impoundment being Lake Anna in the upper watershed of the North Anna River, allowing strong runs of anadromous clupeid fishes. Recreational fishing is excellent, with abundant largemouth bass, pickerel, and white perch. Rapidly increasing urban sprawl and timbering, however, threaten the water quality and scenic beauty of this river.

The Roanoke River arises in the Blue Ridge Mountains of Virginia and flows in a southeasterly direction through the Piedmont and Coastal Plain before emptying into Albemarle Sound in North Carolina (see Figs. 3.9, 3.25). Forest predominates across much of the basin. The river is highly fragmented by large impoundments along much of its length. Despite this hydrological regulation, the lower Roanoke River floodplain contains some of the largest intact and least-disturbed bottomland forest floodplains along the Atlantic coast. The ancient bald cypress and water tupelo forests in the lowest section of the basin are up to 8km wide. The river is an important habitat for anadromous fishes and other wildlife. It harbors a diverse biota, including a variety of endemic species as well as many state and federally listed threatened, rare, and endangered species.

FIGURE 3.8 Mattaponi River, one of two major branches of the York River, just before it joins the York near West Point, Virginia (PHOTO FROM VIRGINIA INSTITUTE OF MARINE SCIENCE).

The Great Pee Dee River has its headwaters in the Blue Ridge Mountains in western North Carolina (see Fig. 3.27). The river drains large portions of the Piedmont and Coastal Plain of the Carolinas (Fig. 3.10). Much of the basin is in agriculture or has been urbanized, with only about half of the landscape forested, resulting in the river carrying a heavy silt load. A series of impoundments occur along the upper half of the river (in the Piedmont), regulating the river's hydrology. The wide river channel winds through broad water tupelo and bald cypress bottomland forests along its Coastal Plain section. The river and its floodplain support a diverse fauna, including various endemic species in its tributaries. A

primary blackwater tributary to the river, the Lumber River, is a National Wild and Scenic River.

Tributaries of the Santee River originate in the Blue Ridge Mountains, but the major drainage occurs in the Piedmont of the Carolinas (see Fig. 3.29). After entering the Coastal Plain, the Congaree and Wateree rivers join to form the Santee as the primary waterway of central South Carolina. Although the Santee flows only within the Coastal Plain, its basin extends across a large portion of the western Carolinas, making it the second largest river basin along the U.S. Atlantic coast. The river's hydrology is highly regulated by dams along its tributaries and main stem. Lake Marion, on the main stem, is a broad

FIGURE 3.9 Roanoke River below Altavista, Virginia (PHOTO BY TIM PALMER).

FIGURE 3.11 Congaree River, one of two major branches of Santee River, downstream of Congaree National Park, South Carolina (PHOTO BY A. C. BENKE).

impoundment behind an 8-mile-long dam. In addition, the flows of the Santee and the Cooper rivers, the latter originally a short tidal river, have been connected by water-diversion projects. The river basin is well known for its recreational fishing. One of the most significant tracts of virgin bottomland forest in the eastern United States exists in the Congaree National Park, near the point of origin of the Santee (Fig. 3.11).

The Altamaha River lies entirely within Georgia and is one of the largest river basins in the eastern United States (see Fig. 3.31). It begins with the Ocmulgee and Oconee rivers, which originate in the Piedmont province. The Ocmulgee and Oconee cross the Fall Line and eventually form the Altamaha, which meanders within broad forested swamps of the Coastal Plain (Fig. 3.1). As one of the most biologically rich rivers draining into the Atlantic, the Altamaha has been designated a Bioserve by The Nature Conservancy and is on their list of “last great places” in the world. The river is known for its outstanding largemouth bass and sunfish fishery. The recent illegal introduction of the flathead catfish has

resulted in a significant decline of redbreast sunfish, and the flathead catfish itself has become a primary game species. Although there are major dams on the Oconee and Ocmulgee, their lower reaches and the main-stem Altamaha are free flowing. The river faces major threats from development around Atlanta in the upper basin, particularly by newly proposed dams that threaten to alter natural hydrological regimes.

The Satilla River basin is located entirely in the lower Coastal Plain of Georgia, within a forested and agricultural landscape (see Fig. 3.33). It is a true blackwater river, with highly stained water and a pH that typically fluctuates between 4 (at high water) and 6 (low water). The Satilla’s almost-white sand bars, blackwater, and broad floodplain swamps are striking (Fig. 3.12). Like the Ogeechee, the Satilla is one of the few relatively natural rivers >200km in length in the coterminous states that is unimpounded from headwaters to mouth. Its biological diversity and productivity depend heavily on snags in the main channel for habitat and on its floodplain swamps. However, the Satilla’s diversity is not as high

FIGURE 3.12 Satilla River, about 16 km downstream of Atkinson, Georgia (PHOTO BY A. C. BENKE).

as the more alkaline rivers that drain the Piedmont and mountains farther inland. Although the basin is mostly forested, it faces threats from timber harvesting within its floodplain swamps.

ACKNOWLEDGMENTS

We thank Chris Skelton and John Jensen, both of the Georgia Department of Natural Resources, for the considerable information they provided on the occurrence of crayfishes, amphibians, reptiles, and fishes in the Georgia rivers included in this chapter. Greg Garman, Steve McIninch, and Charles Blem, all of Virginia Commonwealth University, provided information on the distribution, status, and ecology of amphibians, reptiles, and fishes in the Virginia rivers. Dean Dobberfuhl provided information on the St. Johns River. Thanks to R. Overman and M. O'Malley for photos of the Altamaha and St. Johns, respectively.

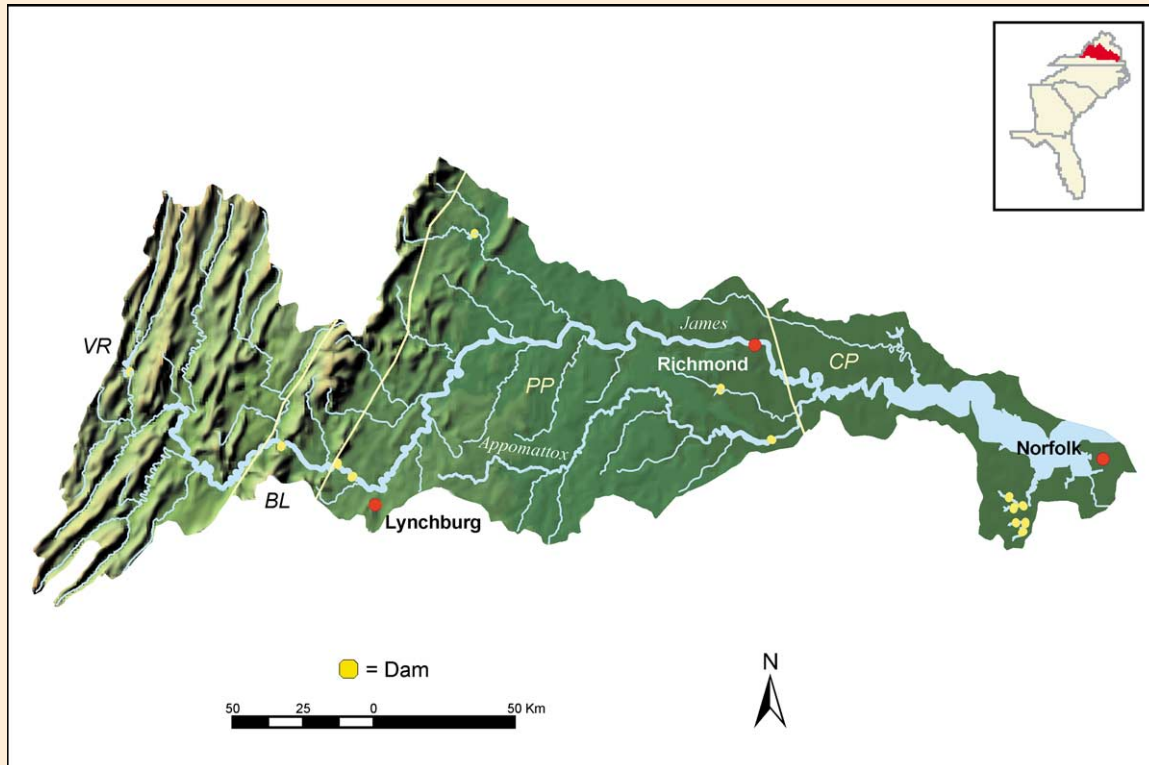

FIGURE 3.13 Map of the James River basin. Physiographic provinces are separated by yellow lines.

JAMES RIVER

Relief: 1250 m

Basin area: 26,164 km²

Mean discharge: 227 m³/s

River order: 7

Mean annual precipitation: 108 cm

Mean air temperature: 14°C

Mean water temperature: 16°C

Physiographic provinces: Valley and Ridge (VR), Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Chesapeake Bay

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 109

Number of endangered species: 3 fishes, 1 amphibian, 1 reptile, 6 mussels

Major fishes: American eel, American shad, hickory shad, blueback

herring, alewife, gizzard shad, common carp, bull chub, quillback sucker, satinfish shiner, spottail shiner, flathead catfish, blue catfish, white perch, striped bass, redbreast sunfish, bluegill, smallmouth bass, largemouth bass

Major other aquatic vertebrates: cottonmouth, water snakes, painted turtle, musk turtle, river cooter, red-bellied turtle, snapping turtle, muskrat, beaver

Major benthic invertebrates: mayflies (*Tricorythodes*, *Stenonema*, *Baetis*, *Caenis*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Polycentropus*), hellgrammites (*Corydalus*), beetles (*Macronychus*), midges (*Rheotanytarsus*), crustaceans (*Orconectes*), bivalves (*Elliptio*, *Corbicula*, *Pisidium*), snails (*Elimia*, *Somatogyrus*)

Nonnative species: Asiatic clam, smallmouth bass, largemouth bass, rock bass, bluegill, flathead catfish, blue catfish, channel catfish, muskellunge, walleye, threadfin shad

Major riparian plants: sycamore, swamp black gum, river birch, American elm, red maple, ash-leaf maple, bald cypress

Special features: drains from four physiographic provinces, no large impoundments, class IV white-water rapids at Fall Line

Fragmentation: 12 low-head dams, some partially breached, that regulate flow in about 10% of nontidal river

Water quality: major pollutants are sediment, combined sewer-stormwater runoff, Kepone; pH = 7.4, alkalinity = 52 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.02 mg/L

Land use: 71% forest, 23% agriculture, 6% urban

Population density: 96 people/km²

Major information sources: Jenkins and Burkhead 1994, Garman and Nielsen 1992, Patrick 1996, G. C. Garman personal communication, www.dcr.state.va.us/waterways/the_problem/watersheds_and_you/p_james_river_watershed.htm

FIGURE 3.14 Mean monthly air temperature, precipitation, and runoff for the James River basin.

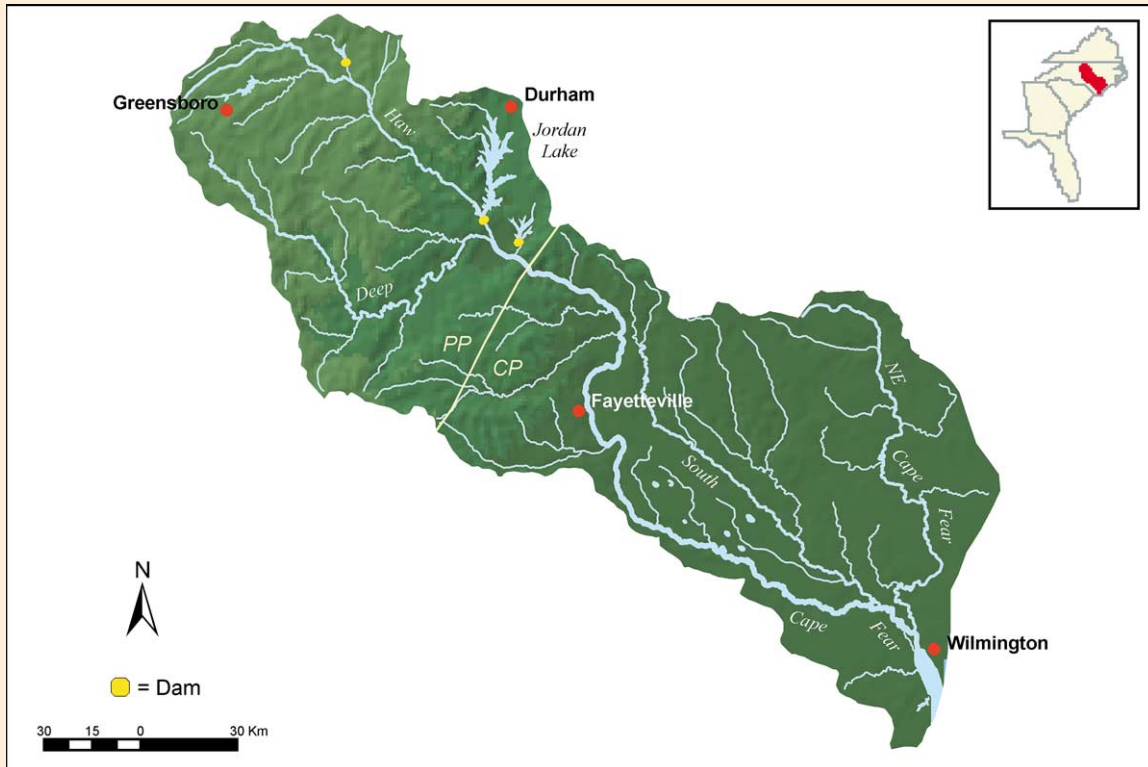

FIGURE 3.15 Map of the Cape Fear River basin. Physiographic provinces are separated by yellow line.

CAPE FEAR RIVER

Relief: 305 m

Basin area: 24,150 km²

Mean discharge: 217 m³/s

River order: 6

Mean annual precipitation: 119 cm

Mean air temperature: 16°C

Mean water temperature: 17°C

Physiographic provinces: Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: South Atlantic

Terrestrial ecoregions: Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 95

Number of endangered species: 8 fishes, 1 mammal, 15 mussels

Major fishes: American eel, American shad, hickory shad, blueback herring, gizzard shad, common carp, spotted sucker, shiners, darters, channel catfish, bluegill, pumpkinseed, largemouth bass, striped bass

Major other aquatic vertebrates: cottonmouth, water snakes, painted turtle, musk turtle, river cooter, slider, mud turtle, snapping turtle, muskrat, bull frog, river otter, beaver

Major benthic invertebrates: mayflies (*Tricorythodes*, *Caenis*, *Stenonema*, *Baetis*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), damselflies (*Argia*), hellgrammites (*Corydalus*), beetles (*Stenelmis*, *Macronychus*), bivalves (*Elliptio*, *Corbicula*, *Sphaerium*, *Pisidium*), crustaceans (*Palaemonetes*)

Nonnative species: Asiatic clam, smallmouth bass, white crappie, flathead catfish, channel catfish

Major riparian plants: sycamore, sweetgum, swamp black gum, red maple, bald cypress, water tupelo, ashes, oaks

Special features: lower tributaries (Black River, Northeast Cape Fear River) are classic southeastern blackwater rivers with broad hardwood floodplains; Carolina Bay lakes in basin

Fragmentation: 3 locks and dams on main stem; large impoundment on primary tributary (Haw River)

Water quality: pH = 6.9, alkalinity = 29 mg/L as CaCO₃, NO₃-N = 0.83 mg/L, PO₄-P = 0.07 mg/L

Land use: 56% forest, 24% agriculture, 9% urban, 11% other

Population density: 69 people/km²

Major information sources: Hocutt et al. 1986, Garman and Nielsen 1992, Patrick 1996, NCDENR 2000

FIGURE 3.16 Mean monthly air temperature, precipitation, and runoff for the Cape Fear River basin.

FIGURE 3.17 Map of the Savannah River basin. Physiographic provinces are separated by yellow lines.

SAVANNAH RIVER

Relief: 1743 m
Basin area: 27,414 km²
Mean discharge: 319 m³/s
River order: 7
Mean annual precipitation: 114 cm
Mean air temperature: 18°C
Mean water temperature: 17°C
Physiographic provinces: Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)
Biome: Temperate Deciduous Forest
Freshwater ecoregion: South Atlantic
Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests, Southeastern Conifer Forests
Number of fish species: 106
Number of endangered species: 7 fishes, 4 amphibians, 2 reptiles, 8 mussels, 3 crayfishes
Major fishes: bowfin, American eel, American shad, blueback herring, common carp, eastern silvery minnow, shiners, silver redhorse, spotted sucker, channel catfish, striped bass, black crappie, redbreast sunfish, bluegill, largemouth bass
Major other aquatic vertebrates: American alligator, cottonmouth, water snakes, snapping turtle, musk turtle, river cooter, slider, river frog, muskrat, river otter, beaver
Major benthic invertebrates: mayflies (*Baetis*, *Caenis*, *Isonychia*, *Stenonema*, *Tricorythodes*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Hydropsyche*, *Macrostemum*, *Neureclipsis*, *Oecetis*), beetles (*Ancyronyx*, *Macronychus*, *Stenelmis*), midges (*Rheotanytarsus*), black flies (*Simulium*), crustaceans (*Hyaella*), bivalves (*Elliptio*, *Corbicula*, *Pisidium*), snails (*Physella*)
Nonnative species: hydrilla, waterweed, Asiatic clam, flathead catfish, channel catfish
Major riparian plants: bald cypress, water tupelo, swamp black gum, sweetgum, water hickory, red maple, sycamore, oaks
Special features: broad forested floodplain swamp throughout the Coastal Plain
Fragmentation: several large dams in Piedmont
Water quality: major pollutants are sediments and nutrients from nonpoint inputs; pH = 6.9, alkalinity = 20 mg/L as CaCO₃, NO₃-N = 0.26 mg/L, total PO₄-P = 0.05 mg/L
Land use: 65% forest, 22% agriculture, 4% urban, 9% other
Population density: 35 people/km²
Major information sources: Swift et al. 1986, Garman and Nielsen 1992, Patrick 1996, GDNR 2001b

FIGURE 3.18 Mean monthly air temperature, precipitation, and runoff for the Savannah River basin.

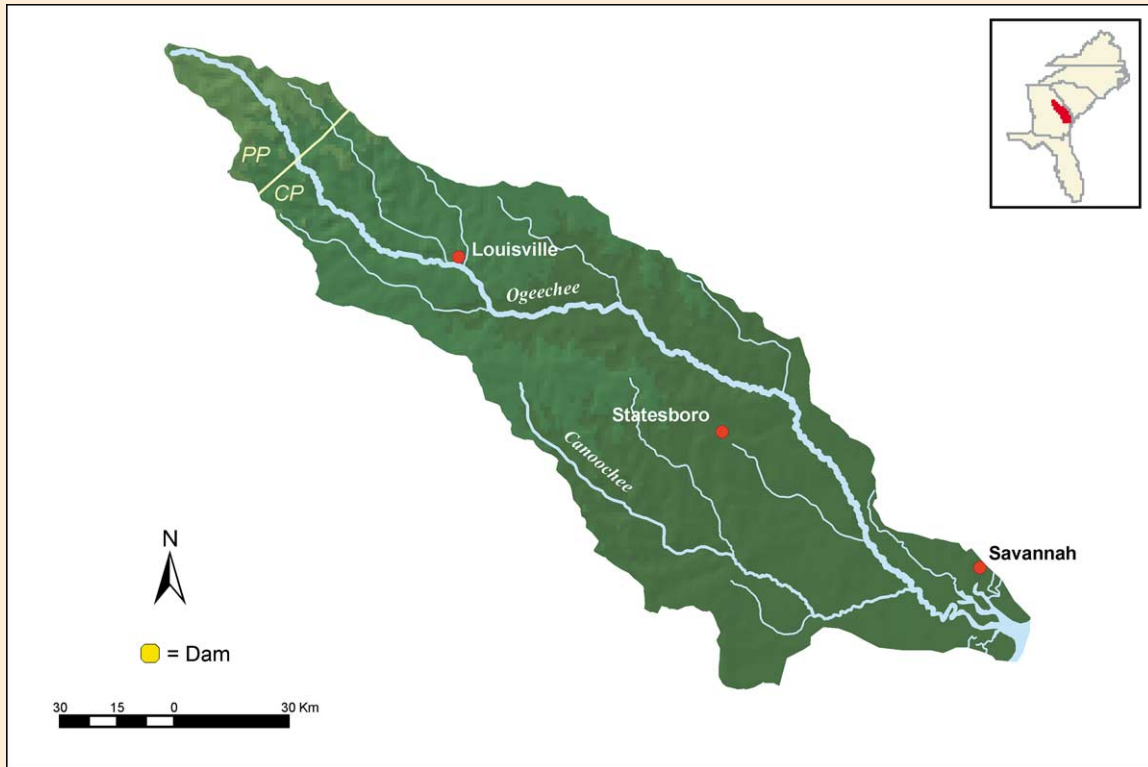

FIGURE 3.19 Map of the Ogeechee River basin. Physiographic provinces are separated by yellow line.

OGEECHEE RIVER

Relief: 200 m

Basin area: 13,500 km²

Mean discharge: 115 m³/s

River order: 6

Mean annual precipitation: 113 cm

Mean air temperature: 18°C

Mean water temperature: 19°C

Physiographic provinces: Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: South Atlantic

Terrestrial ecoregions: Southeastern Mixed Forests, Southeastern Conifer Forests, Middle Atlantic Coastal Forests

Number of fish species: >80

Number of endangered species: 6 fishes, 2 amphibians, 2 reptiles, 1 mussel

Major fishes: American eel, longnose gar, bowfin, snail bullhead, redbreast sunfish, spotted sunfish, bluegill, largemouth bass, chain pickerel, spotted sucker, shiners, American shad, black crappie, warmouth, redear sunfish, white catfish, chubs, darters, silversides

Major other aquatic vertebrates: cottonmouth, water snakes, softshell turtles, river cooter, American alligator, river frog, sirens, treefrogs, dusky salamanders, muskrat, river otter, beaver

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Chimarra*), stoneflies (*Perlesta*, *Paragnetina*, *Taeniopteryx*, *Pteronarcys*), mayflies (*Stenonema*, *Baetis*, *Isonychia*, *Ephemerella*, *Tricorythodes*, *Caenis*), dragonflies (*Neurocordulia*, *Boyeria*), hellgrammites (*Corydalus*), beetles (*Stenelmis*, *Macronychus*), crustaceans (*Lirceus*)

Nonnative species: Asiatic clam

Major riparian plants: swamp black gum, water tupelo, bald cypress, red maple, water oak, laurel oak, sweetgum, water hickory

Special features: broad forested floodplain swamp (>1 km width); extensive submerged wood habitat; one of few natural free-flowing rivers in coterminous 48 states

Fragmentation: no major dams

Water quality: free of major pollutants; pH = 7.0, alkalinity = 23 mg/L as CaCO₃, NO₃-N = 0.10 mg/L, total P = 0.05 mg/L

Land use: 54% forest, 17% forested wetlands, 18% agriculture, 1% urban

Population density: 30 people/km²

Major information sources: Swift et al. 1986, Meyer 1990, 1992, Benke 2001, Benke et al. 2000, GDNR 2001a

FIGURE 3.20 Mean monthly air temperature, precipitation, and runoff for the Ogeechee River basin.

FIGURE 3.22 Mean monthly air temperature, precipitation, and runoff for the St. Johns River basin.

ST. JOHNS RIVER

Relief: 107 m

Basin area: 22,539 km²

Mean discharge: 222 m³/s

River order: 5

Mean annual precipitation: 131 cm

Mean air temperature: 20°C

Mean water temperature: 22°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Florida

Terrestrial ecoregions: Southeastern Conifer Forests, Florida Sand Pine Scrub

Number of fish species: >75 freshwater, 115 euryhaline

Number of endangered species: 1 mammal, 4 fishes, 2 reptiles, 2 birds

Major fishes: bluegill, redbreast sunfish, American eel, channel catfish, white catfish, largemouth bass, black crappie, American shad, striped bass

Major other aquatic vertebrates: cottonmouth, water snakes, snapping turtle, mud turtle, musk turtle, Florida cooter, bullfrog, treefrogs, American alligator, river otter, muskrat, beaver, West Indian manatee, brown pelican, herons, egrets, ibis

Major benthic invertebrates: mayflies (*Callibaetis floridanus*, *Stenacron floridense*), caddisflies (*Oecetis*, *Hydroptila*, *Orthotrichia*, *Cyrmellus*), midges (*Chironomus*, *Glyptotendipes*), oligochaete worms (*Limnodrilus*), bivalves (*Corbicula*, *Sphaerium*, *Pisidium*), snails (*Physella*), crustaceans (*Hyalella*, *Gammarus*, *Penaeus*, *Callinectes*, *Rangia*, *Rhithropanopeus*)

Nonnative species: water hyacinth, hydrilla, Eurasian watermilfoil, common salvinia, parrot feather, Asiatic clam, nutria, numerous other plant and animal species

Major riparian plants: maidencane, pickerelweed, arrowhead, sawgrass, cattail, rush, cordgrass, coastal plain willow

Special features: channel-lake geomorphology; broad marsh floodplain; tidal influence far upriver; extremely low gradient

Fragmentation: no major dams on main stem, dam on Oklawaha River; altered hydroperiod due to water diversions

Water quality: pH = 7.5; alkalinity = 95 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.05 mg/L

Land use: 45% forest, 25% agriculture, 24% wetlands and water, 6% urban

Population density: 78 people/km²

Major information sources: Bass 1991, DeMort 1991, Garman and Nielsen 1992

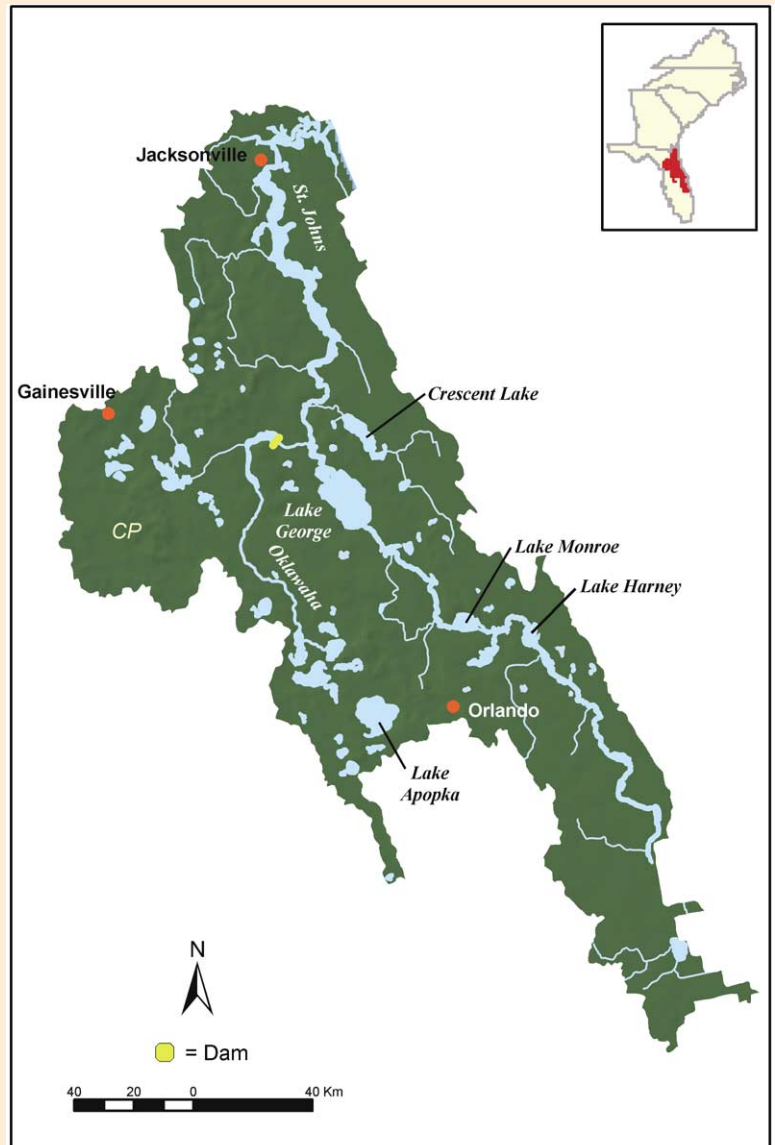

FIGURE 3.21 Map of the St. Johns River basin.

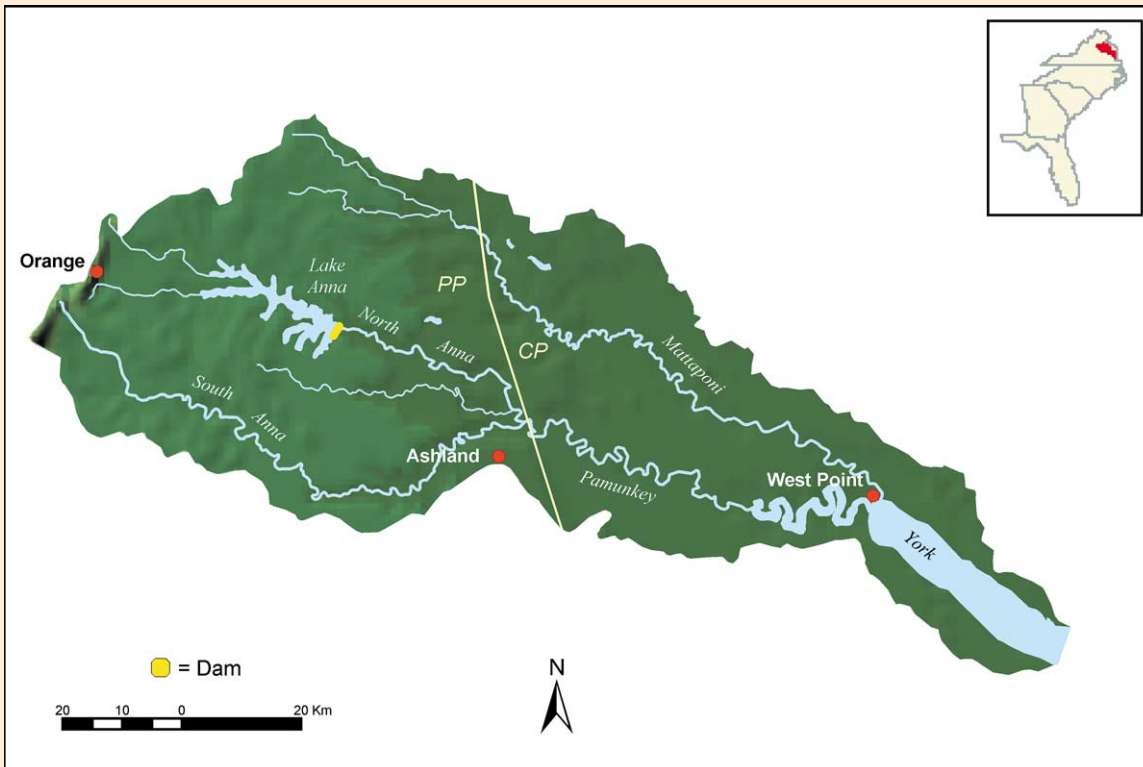

FIGURE 3.23 Map of the York River basin. Physiographic provinces are separated by yellow line.

YORK RIVER

Relief: 365 m

Basin area: 6892 km²

Mean discharge: 45 m³/s

River order: 6

Mean annual precipitation: 108 cm

Mean air temperature: 14°C

Mean water temperature: 15°C

Physiographic provinces: Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Chesapeake Bay

Terrestrial ecoregions: Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 75

Number of endangered species: 2 fishes, 1 amphibian, 4 mussels

Major fishes: longnose gar, American eel, American shad, blueback herring, pickerels, blue catfish, white perch, striped bass, bluegill, redbreast sunfish, largemouth bass, yellow perch

Major other aquatic vertebrates: northern water snake, brown water snake, painted turtle, musk turtle, mud turtle, red-bellied turtle, snapping turtle, muskrat, river otter, beaver

Major benthic invertebrates: mayflies (*Baetis*, *Stenonema*, *Eurylophella*, *Caenis*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Chimarra*, *Hydroptila*), hellgrammites (*Corydalus*), beetles (*Macronychus*), midges (*Rheotanytarsus*), crustaceans (*Caecidotea*), mussels (*Elliptio*, *Pisidium*, *Corbicula*), snails (*Physella*)

Nonnative species: common carp, grass carp, channel catfish, blue catfish, white crappie, black crappie, bluegill, smallmouth bass, largemouth bass, spotted bass, Asiatic clam

Major riparian plants: sycamore, swamp black gum, river birch, American elm, red maple, ash-leaf maple, bald cypress

Special features: strong anadromous fish runs and intact historical anadromous fish spawning grounds

Fragmentation: 1 major dam on primary tributary (North Anna River)

Water quality: pH = 6.9, alkalinity = 18 mg/L as CaCO₃, NO₃-N = 0.28 mg/L, PO₄-P = 0.08 mg/L

Land use: 73% forest, 19% agriculture, 8% urban

Population density: 54 people/km²

Major information sources: Jenkins and Burkhead 1994, http://www.dcr.state.va.us/waterways/the_problem/watersheds_and_you_p_york_river.htm

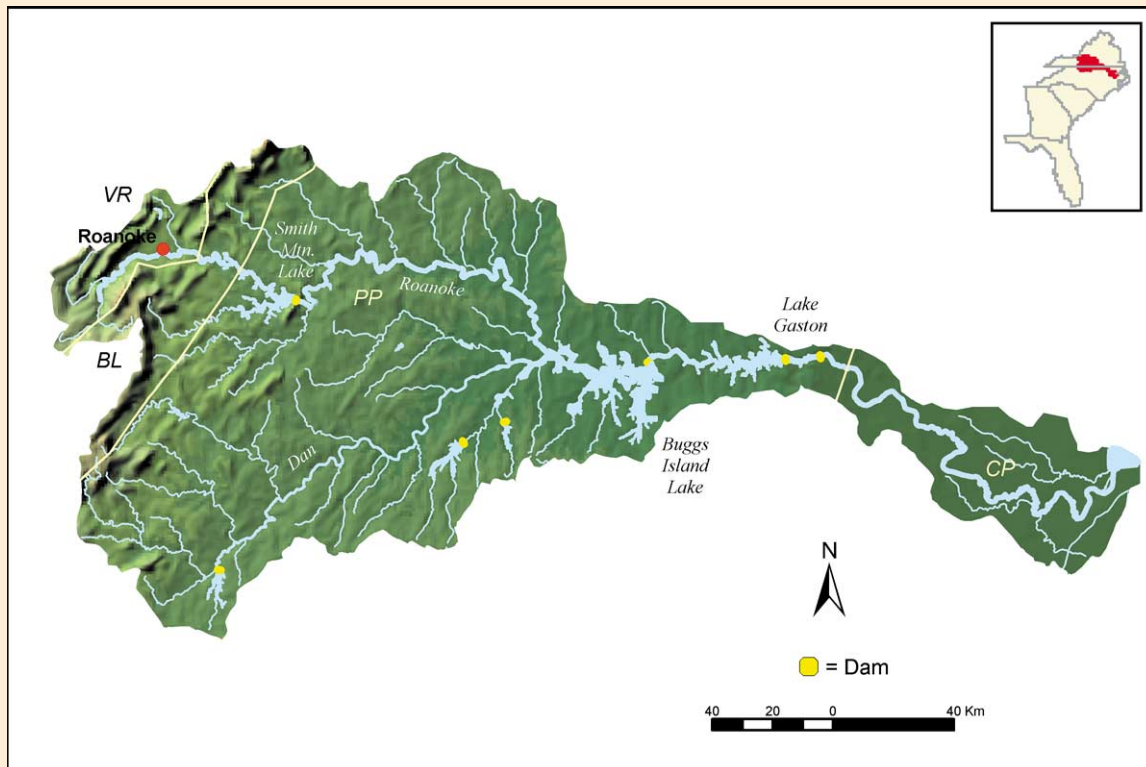

FIGURE 3.25 Map of the Roanoke River basin. Physiographic provinces are separated by yellow lines.

ROANOKE RIVER

Relief: 920 m

Basin area: 25,326 km²

Mean discharge: 232 m³/s

River order: 6

Mean annual precipitation: 108 cm

Mean air temperature: 14°C

Mean water temperature: 16°C

Physiographic provinces: Valley and Ridge (VR), Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: South Atlantic

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 119

Number of endangered species: 9 fishes, 2 amphibian, 7 mussels

Major fishes: American eel, American shad, hickory shad, blueback herring, alewife, gizzard shad, redhorses, shiners, darters, striped bass, white perch, redear sunfish, bluegill, smallmouth bass, largemouth bass, Roanoke bass, black crappie, yellow perch

Major other aquatic vertebrates: cottonmouth, water snakes, painted turtle, musk turtle, river cooter, sliders, mud turtle, snapping turtle, bull frog, muskrat, river otter, beaver

Major benthic invertebrates: mayflies (*Stenonema*, *Baetis*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Polycentropus*), hellgrammites (*Corydalus*), beetles (*Macronychus*), midges (*Rheotanytarsus*), damselflies (*Argia*), crustaceans (*Orconectes*), bivalves (*Elliptio*, *Corbicula*, *Pisidium*), snails (*Elimia*, *Somatogyrus*)

Nonnative species: Asiatic clam, smallmouth bass, rock bass, bluegill, flathead catfish, channel catfish, threadfin shad, walleye

Major riparian plants: sycamore, swamp black gum, American elm, red maple, ash-leaf maple, bald cypress, water tupelo, green ash, water ash, swamp chestnut oak

Special features: floodplain in the Coastal Plain supports one of the largest tracts of intact and largely undisturbed bottomland hardwood forests on the Atlantic coast; six endemic species of fishes occur in the basin

Fragmentation: strongly fragmented by large dams on main stem

Water quality: pH = 6.8, alkalinity = 32 mg/L as CaCO₃, NO₃-N = 0.16 mg/L, PO₄-P = 0.03 mg/L

Land use: 68% forest, 25% agriculture, 3% urban, 4% other

Population density: 31 people/km²

Major information sources: Jenkins and Burkhead 1994, NCDENR 2001

FIGURE 3.26 Mean monthly air temperature, precipitation, and runoff for the Roanoke River basin.

FIGURE 3.28 Mean monthly air temperature, precipitation, and runoff for the Great Pee Dee River basin.

GREAT PEE DEE RIVER

Relief: 1090 m

Basin area: 27,560 km²

Mean discharge: 371 m³/s

River order: 7

Mean annual precipitation: 111 cm

Mean air temperature: 17°C

Mean water temperature: 17°C

Physiographic provinces: Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: South Atlantic

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 101

Number of endangered species: 6 fishes, 1 reptile, 8 mussels (North Carolina only)

Major fishes: bowfin, American eel, American shad, blueback herring, gizzard shad, common carp, eastern silvery minnow, shiners, silver redhorse, channel catfish, striped bass, white perch, redbreast sunfish, bluegill, redear sunfish, largemouth bass, black crappie

Major other aquatic vertebrates: cottonmouth, northern water snake, brown water snake, mud turtle, snapping turtle, musk turtle, river cooter, slider, river frog, bull frog, muskrat, river otter, beaver

Major benthic invertebrates: mayflies (*Baetis*, *Caenis*, *Stenonema*, *Tricorythodes*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Hydropsyche*, *Oecetis*), beetles (*Macronychus*, *Stenelmis*), midges (*Rheotanytarsus*), black flies (*Simulium*), bivalves (*Corbicula*, *Pisidium*)

Nonnative species: Asiatic clam, flathead catfish, channel catfish

Major riparian plants: bald cypress, water tupelo, swamp black gum, sweetgum, water hickory, red maple, oaks

Special features: broad hardwood floodplain forests in Coastal Plain; Lumber River tributary is National Wild and Scenic River; Lumber and Lynch rivers are among few natural free-flowing rivers in coterminous 48 states

Fragmentation: several dams in Piedmont

Water quality: major pollutants are sediments and nutrients from nonpoint inputs; pH = 6.9, alkalinity = 22 mg/L as CaCO₃, NO₃-N = 0.46 mg/L, PO₄-P = 0.04 mg/L

Land use: 58% forest, 28% agriculture, 8% urban, 6% other

Population density: 49 people/km²

Major information source: Hocutt et al. 1986

FIGURE 3.29 Map of the Santee River basin. Physiographic provinces are separated by yellow lines.

SANTEE RIVER

Relief: 1789 m

Basin area: 39,500 km²

Mean discharge: 434 m³/s

River order: 7

Mean annual precipitation: 125 cm

Mean air temperature: 17°C

Mean water temperature: 18°C

Physiographic provinces: Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: South Atlantic

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Southeastern Mixed Forests, Middle Atlantic Coastal Forests

Number of fish species: 125

Number of endangered species: 5 fishes, 2 reptiles

Major fishes: bowfin, American eel, American shad, blueback herring, gizzard shad, spotted sucker, shiners, channel catfish, striped bass, black crappie, redbreast sunfish, redear sunfish, bluegill, largemouth bass

Major other aquatic vertebrates: cottonmouth, water snakes, snapping turtle, mud turtle, musk turtle, river cooter, slider, river frog, bullfrog, muskrat, river otter, beaver

Major benthic invertebrates: mayflies (*Baetis*, *Caenis*, *Stenonema*, *Tricorythodes*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Hydropsyche*, *Oecetis*), beetles (*Ancyronyx*, *Macronychus*, *Stenelmis*), midges (*Rheotanytarsus*), black flies (*Simulium*), bivalves (*Corbicula*, *Sphaerium*), snails (*Physella*)

Nonnative species: Asiatic clam, flathead catfish, channel catfish, white crappie, hydrilla

Major riparian plants: sycamore, bald cypress, water tupelo, swamp black gum, sweetgum, red maple, hickories, oaks

Special features: second largest river basin on Atlantic coast of United States

Fragmentation: many dams on main stem and major tributaries

Water quality: pH = 6.9, alkalinity = 23 mg/L as CaCO₃, NO₃-N = 0.2 mg/L, total PO₄-P = 0.03 mg/L

Land use: 64% forest, 26% agriculture, 6% urban, 4% other

Population density: 65 people/km²

Major information sources: Hocutt et al. 1986, Patrick 1996

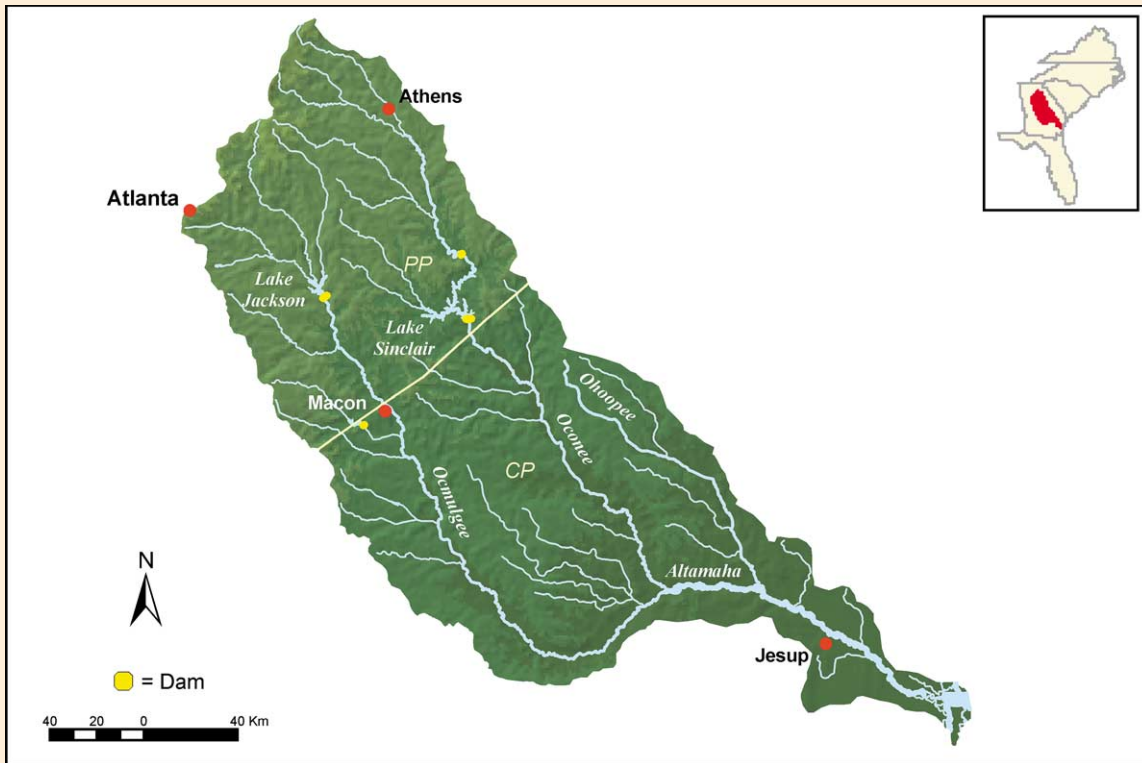

FIGURE 3.31 Map of the Altamaha River basin. Physiographic provinces are separated by yellow line.

ALTAMAHA RIVER

Relief: 372 m
 Basin area: 37,600 km²
 Mean discharge: 393 m³/s
 River order: 7
 Mean annual precipitation: 130 cm
 Mean air temperature: 19°C
 Mean water temperature: 20°C
 Physiographic provinces: Piedmont Plateau (PP), Coastal Plain (CP)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: South Atlantic
 Terrestrial ecoregions: Southeastern Mixed Forests, Southeastern Conifer Forests
 Number of fish species: 93
 Number of endangered species: 1 mammal, 12 fishes, 2 amphibians, 2 reptiles, 7 mussels, 1 crayfish
 Major fishes: bowfin, American eel, American shad, gizzard shad, chain pickerel, carp, minnows, shiners, silver redhorse, spotted sucker, carpsucker, bullhead catfish, channel catfish, black crappie, bluegill, redear sunfish, warmouth, largemouth bass, hogchoker
 Major other aquatic vertebrates: cottonmouth, water snakes, softshell turtles, river cooter, American alligator, river frog, sirens, treefrogs, dusky salamanders, West Indian manatee, muskrat, river otter, beaver
 Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Macrostemum*, *Chimarra*, *Neureclipsis*), mayflies (*Isonychia*, *Stenonema*, *Baetis*, *Tricorythodes*, *Caenis*), stoneflies (*Paragnetina*), dragonflies (*Neurocordulia*, *Boyeria*), damselflies (*Argia*), hellgrammites (*Corydalus*), beetles (*Stenelmis*), midges (*Polypedilium*, *Rheotanytarsus*), black flies (*Simulium*), bivalves (*Corbicula*, *Elliptio*)
 Nonnative species: Asiatic clam, flathead catfish
 Major riparian plants: swamp black gum, water tupelo, bald cypress, water hickory, red maple, sweetgum, oaks
 Special features: broad forested floodplain swamp; designated as a “Bioreserve” by the Nature Conservancy
 Fragmentation: dams in Piedmont portions of two primary tributaries (Ocmulgee and Oconee rivers); no main-stem dams
 Water quality: pH = 7.2; alkalinity = 30 mg/L as CaCO₃, total NO₃-N = 0.35 mg/L, total P = 0.09 mg/L
 Land use: 64% forest, 26% agriculture, 3% urban, 7% other
 Population density: 28 people/km²
 Major information sources: Hottell et al. 1983, Swift et al. 1986

FIGURE 3.33 Map of the Satilla River basin.

SATILLA RIVER

Relief: 107 m
 Basin area: 9143 km²
 Mean discharge: 65 m³/s
 River order: 6
 Mean annual precipitation: 126 cm
 Mean air temperature: 19°C
 Mean water temperature: 20°C
 Physiographic province: Coastal Plain (CP)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: Florida
 Terrestrial ecoregion: Southeastern Conifer Forests
 Number of fish species: 52
 Number of endangered species: 2 fishes, 1 amphibian, 2 reptiles, 1 mussel

Major fishes: bowfin, American eel, chain pickerel, spotted sucker, channel catfish, yellow bullhead, black crappie, bluegill, redbreast sunfish, warmouth, largemouth bass, brook silverside, eastern mosquitofish, topminnow, pirate perch, spotted sunfish, minnows, darters

Major other aquatic vertebrates: cottonmouth, water snakes, softshell turtles, river cooter, loggerhead musk turtle, American alligator, bullfrog, treefrogs, dusky salamanders, river otter, muskrat, beaver, West Indian manatee

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Macrostemum*, *Chimarra*), stoneflies (*Perlesta*, *Acroneuria*), mayflies (*Stenonema*), dragonflies (*Neurocordulia*, *Boyeria*), hellgrammites (*Corydalus*), beetles (*Stenelmis*, *Ancyronyx*), black flies (*Simulium*), midges (*Rheotanytarsus*, *Polypedilium*, *Rheosmittia*)

Nonnative species: flathead catfish

Major riparian plants: swamp black gum, water tupelo, bald cypress, water hickory, river birch, black willow, red maple

Special features: broad forested floodplain swamp; one of few natural free-flowing rivers in coterminous 48 states

Fragmentation: no dams on main stem; proposed titanium mining in floodplain near Atkinson

Water quality: pH = 5.8; alkalinity = 4 mg/L as CaCO₃, NO₃-N = 0.19 mg/L, PO₄-P = 0.05 mg/L

Land use: 72% forest, 26% agriculture, 1% urban, 1% other

Population density: 11 people/km²

INTRODUCTION

The river basins of the eastern Gulf Coast lie west of the Atlantic slope and east of the Mississippi River (Fenneman 1938). The climate of the region is moderate, with warm summers, mild winters, and abundant rainfall. The region has abundant water resources, including seven major rivers that arise and flow through five physiographic provinces in five states to empty into the Gulf of Mexico (Fig. 4.2). Eastern Gulf Coast rivers encompass a rich variety of aquatic habitats and resources. In addition to the many upland streams and large rivers, there are large swamps, such as the Okefenokee Swamp and the Mobile River Delta, wide floodplain swamps, and oxbow lakes, which occur along all of the major rivers and many of the smaller coastal plain rivers. Limestone springs derived from the Floridan aquifer arise in southwestern Georgia, southeastern Alabama, and northern Florida. Today, the main stems of many major rivers of the eastern Gulf are

severely fragmented by numerous hydroelectric and navigation dams. Their main-stem channels have been deepened, and many riverine fauna have been replaced by lentic (reservoir) fauna (Ward, Ward, and Harris 1992). At the lower end of many basins are moderate to large estuaries, such as the Apalachicola, Mobile, Choctawhatchee, and Pearl, which are now, or were at one time, important centers of commercial and recreational fisheries.

Humans have inhabited these river basins for at least 12,000 years. Although hunter-gatherer societies occupied much of this time, the more sedentary lifestyle of the Mississippian culture dominated the southeastern region from 900 to 1500, reaching a peak between 1200 and 1400 (Jenkins and Krause 1986). By the time of the arrival of the first Europeans, the expansive Mississippian culture was already in decline, largely attributed to population growth that outstripped available resources, intense intertribal competition, and climate change (Scarry 1996). The important tribes in the region were the Creek (Upper and Lower), Choctaw, Chickasaw,

FIGURE 4.2 Gulf Coast rivers of the southeastern United States that are covered in this chapter.

Cherokee, Apalachee, and Timucua. The first European exploration was by the Spanish, and later colonization was by the Spanish, French, and English, who all partnered with Native Americans to vie for control of important lands, especially commercial and military corridors such as rivers and bays. After the war with the French in 1756, the English gained official control after the Treaty of Paris ceded land east of the Mississippi to England in 1763 (Jackson 1995).

Of the seven major rivers that reach the eastern Gulf of Mexico, four will be described in some detail: the Suwannee, Apalachicola, Mobile, and Pearl. A Mobile River tributary, the Cahaba River, also will be covered in detail. Abbreviated descriptions of physical and biological characteristics are given for

the remaining three rivers that reach the Gulf of Mexico (Pascagoula, Escambia–Conecuh, and Choctawhatchee), as well as two other tributaries of the Mobile River (Upper Tombigbee and Sipsey) and one of the Apalachicola River (Flint).

Physiography and Climate

The dominant physiographic province through which the rivers flow is the Coastal Plain (Fenneman 1938), more specifically the sections named the Eastern Gulf Coastal Plain and the Floridan. The region includes catchments from the Pearl River basin in the west to the Suwannee River in the east, extending 160 to 320 km inland from the present coastline and the same distance offshore in the Gulf of Mexico as the

continental shelf. The Coastal Plain is an elevated sea bottom with relief less than 150 m (Hunt 1967). In general, the formation dips seaward, and progressively younger sediments of Cretaceous, Tertiary, and Quaternary age trend north to south. During the last 60 million years the shores of the Gulf of Mexico have advanced and receded from what is now the northern edge of the Coastal Plain south to its present location (Hunt 1967). The Cretaceous-age shoreline that now separates the Eastern Gulf Coastal Plain from the Appalachian Highlands is a crescent-shaped boundary known as the Fall Line. In the eastern Gulf region it stretches from mid-Georgia through Alabama, intersecting the cities of Macon, Columbus, Montgomery, and Tuscaloosa before it turns northward into northeastern Mississippi. The Fall Line is characterized by an abrupt change in river channel gradient, as either falls or shoals, making further upstream commercial navigation impossible. Now, however, these shoals and falls on the larger rivers are submerged beneath reservoirs.

The Piedmont, Appalachian Plateau, and Valley and Ridge physiographic provinces lie upgradient of the Fall Line. The Appalachian Plateau is an area of deeply dissected terrain, where incised canyons and steep slopes have formed. Surface rocks are mostly sandstone of Pennsylvanian age and are often coal-bearing (Adams et al. 1926). The Piedmont is a gently rolling upland underlain with igneous and metamorphic crystalline rocks of Paleozoic age. Rock types are mainly schist, gneiss, granite, and quartzite. The Valley and Ridge is characterized by folded terrain trending northeast to southwest. Underlying rocks are carbonate overlain by sandstone (Adams et al. 1926). Carbonate is often exposed in valley bottoms where erosion has removed the overlying sandstone caps. The headwaters of the Mobile and Apalachicola rivers arise in the Blue Ridge province. However, these very steep terrains comprise <1% of the basins.

The majority of soils of the eastern Gulf Coast river basins are classified as ultisols. Such soils lie south of the advance of the last glaciation and develop in humid climates with tropical to subtropical temperatures and under forested or forested/grassland conditions. They are characterized as intensely weathered, low in basic cations (therefore acidic), and with clay deposition in the B horizon. Indeed, the red hills, so prominent in outcrops across the south, are exposed B horizons. In an earlier classification system, these soils were identified as Yellow and Red Podzolics, containing high concentrations of iron. Soils vary in depth, but

typically develop over crystalline rock, such as sandstone, shale, limestone, granite, gneiss, and schist. Coastal Plain sediments, in some places up to 1219 m thick, originated principally from recent marine sediments, with sand, sandy limestone, and clays predominating. Alluvial soils border all the larger Coastal Plains river channels.

The climate of the eastern Gulf region is generally warm and humid, with long summers and mild winters. River basins span 4 to 5 degrees of latitude, generating a north-south temperature gradient with coolest average annual temperatures in the mountains of northern Georgia (15°C) and warmest temperatures near the Gulf Coast (21°C). Rainfall is abundant, with greater precipitation along and near the coast. Average annual rainfall is 150 to 165 cm along the Gulf Coast but declines inland to 120 to 135 cm. Drier inland areas occur in central Georgia, whereas wetter areas are westward into Mississippi. Orographic effects in the Blue Ridge Mountains of northern Georgia result in higher precipitation (150 cm) than is the case in the lower elevations of the Piedmont (Couch et al. 1996).

Basin Landscape and Land Use

All basins described in this chapter are in the Temperate Deciduous Forest biome, where abundant rainfall and high humidity support a heavily forested region. Rivers drain four terrestrial ecoregions (Ricketts et al. 1999) that are dominated by Southeastern Mixed Forests and Southeastern Conifer Forests. The Southeastern Conifer Forests extend along the Gulf Coast from southeastern Louisiana to the Florida peninsula. Once composed mostly of longleaf pine that was maintained by understory fires, these forests are now dominated by mixed hardwoods and pine. Fire suppression, agriculture, and timbering have led to this shift in species composition. Northward lies the Southeastern Mixed Forests. Dominated by oak, hickory, and pine, this ecoregion extends in a band across Mississippi, Alabama, and Georgia and then further northeastward to Maryland. The northern area of the Mobile River basin west of the Appalachian Mountains contains vegetation of the Appalachian Mixed Mesophytic Forests. Lower-elevation forests are dominated by oaks, hickories, and magnolia, but forests may contain more than 30 canopy species. The northeastern portions of the Mobile River and the upper Apalachicola basin contain deciduous vegetation of the Appalachian/Blue Ridge Forests. As a result of a great diversity of soils, topography, climate, and

long-term geologic stability, these forests contain some of the most species-rich faunal and floral communities of any of the world's temperate forests. Depending on elevation, vegetation is dominated either by mixed oaks or spruce forests.

A common misperception among many who have not traveled in the southeastern United States is that the landscape is dominated by plantations and row crops. Although there are some areas that are heavily agricultural, most of the eastern Gulf Coast rivers flow through forested or wetland landscapes. The major basins vary in forested land cover from 68% in the Mobile drainage to 38% in the Suwannee (G. M. Ward, unpublished data). Timber production is a major industry throughout the south, which often dictates forest composition. The Mobile River basin is dominated by deciduous and mixed deciduous forests, whereas the Pearl River and rivers flowing through Georgia and Florida drain land covered mainly by evergreen and mixed forests. Forested wetlands also constitute an important land-cover type in the Suwannee, Pearl, and Mobile river basins, which contain wetlands dominated by woody vegetation that constitute 22%, 12%, and 10%, respectively, of land cover in the basins. These percentages are mostly driven by the sizes of the basins, particularly the amount of upland landscape present in the catchments.

Most agriculture occurs in the coastal plain region's eastern Gulf Coast river catchments. The deep, fertile soils and abundant rainfall of the area support row crops and hay/pasture cover types. Recently constructed land-use coverage data from the 1990s (Vogelmann et al. 2001) show that, on average, basins in the eastern Gulf Coast region contain ~25% agricultural land. The minimum percentage occurs in the Mobile River basin, which has only 18% agricultural land cover. Row crops are more abundant than hay/pasture lands from the Choctawhatchee River east (16% to 22% versus 8% to 11%), whereas hay/pasture is more prevalent from the Escambia River west to the Pearl River (G. M. Ward, unpublished data).

Urban land cover is not abundant in any basin as a percentage of total area, but the Apalachicola and Mobile rivers contain sizeable urban centers. The city of Atlanta lies near the headwaters of both rivers, and Birmingham lies in the heart of the Mobile River basin. Population pressures on these two rivers are dramatic. In addition to water-quality problems caused by sediment and domestic effluents, both rivers are now part of a legal battle over water-allocation rights. Atlanta has joined other cities in

more arid regions of the world as an area that has outstripped its capacity to provide enough water to support growth. The proposals by Atlanta to remove substantially more water from the Chattahoochee and Coosa rivers than is consistent with current agreements has prompted the threat of litigation by Alabama and Florida. Removal of water from the Chattahoochee River threatens the commercial fisheries industry in the Apalachicola estuary in Florida, whereas the removal of water from the Coosa River (upper Mobile River basin) threatens to stifle future growth in Alabama.

The Rivers

There are five freshwater ecoregions within the eastern Gulf of Mexico region, arranged by longitude. These include portions of the Mississippi Embayment and Florida ecoregions, all of the Mobile Bay and Apalachicola ecoregions, and much of the Florida Gulf ecoregion. Two of these, the Mobile Bay and the Apalachicola, follow watershed boundaries of the Mobile and Apalachicola river basins, whereas the remaining three ecoregions include multiple river basins.

The eleven rivers covered in this chapter vary widely in size, hydrology, geomorphology, and water chemistry, but experience a similar climate and exhibit many biological similarities. All rivers in this region flow from north to south into the Gulf of Mexico, and all are located between 84°W and 91°W longitude and 30°N and 35°N latitude (see Fig. 4.2). The seven rivers that reach the Gulf of Mexico drain over 265,000 km², with an approximate combined flow of 4000 m³/s. These seven basins range in size from 11,000 to 111,000 km² and in discharge from 200 to 1914 m³/s. All 11 basins covered in this chapter lie, either completely or substantially, in Coastal Plain sediments. The two largest river basins in the region extend northward to the Appalachian Highlands and Tennessee River divide, whereas all others arise in the Coastal Plain (see Fig. 4.2).

The Mobile and Apalachicola rivers drain high-gradient mountain and upland areas in Tennessee, Georgia, and Alabama before crossing into the gently rolling topography of the Coastal Plain. These rivers flow through a diversity of geologic material of variable geologic age and variable physiography. The rivers here are ancient. Thus, the upper portions of the two largest basins are much older than the southern parts. The Coastal Plain portions of the eastern Gulf rivers became exposed at approximately the same time period. Therefore, they are of similar ages

and possess many physiographic characteristics in common. The rock types in the upland areas were formed hundreds of millions of years ago (Lineback 1973). It is likely that a number of the rivers in the region that traverse these upland areas are much more than 25 million years old and, therefore, older than the oldest extant lake in the world, Lake Baikal (Martens 1997). As a result of climate, age, and geologic and physiographic diversity, the flowing waters of the eastern Gulf are one of the most biologically diverse regions in North America (Ward, Ward, and Harris 1992, Lydeard and Mayden 1995).

The upper portions of the Apalachicola and Mobile basins flow through channels with bedrock, boulder, and cobble substrata, whereas Coastal Plain portions of all rivers are low gradient and slow flowing, with sandy substrata and substantial amounts of woody debris. Several rivers have blackwater streams, for example, the Escatawpa (a tributary of the Pascagoula River) and other small, coastal rivers not further described (e.g., the Blackwater River in Florida).

The signature biological characteristic of all basins is the breadth of biological diversity. This diversity is most evident in the fishes, mollusks, crayfishes, and caddisflies. Explanations note that both the Mobile and Apalachicola basins are relatively large, geologically old, and physiographically and geologically diverse. The region has not been glaciated and may at one time have had hydrological connections to what is now the Tennessee drainage.

All the river systems described here are substantially impacted by human activities and face continuing threats. Throughout the history of the eastern Gulf Coast region, rivers have been used for transportation, food, and hydropower generation (mechanical and electrical), as well as for domestic, agricultural, and industrial water supply. During the 1800s river corridors were a major component of the economic system, primarily for transport of cotton to seaports such as Mobile, Alabama, and Apalachicola, Florida (Willoughby 1999). Upstream travel was halted at the Fall Line (e.g., Falls of the Chattahoochee), the boundary between the Coastal Plain and upland regions, because of the occurrence of shoals and waterfalls. Cities developed near the Fall Line as initial transportation portals to downstream coastal ports.

The Mobile and Apalachicola rivers are highly fragmented, both along their main stems and in their major tributaries, because of the historic emphasis on transportation and use of the rivers for other economic purposes. Since colonial times the energy of the

rivers has been harnessed to produce power for industrial and commercial uses. During the antebellum period, wing dams were often constructed to divert water through factories to drive machinery in grist mills and iron foundries. The first dam for hydroelectric power generation in the Mobile River basin was completed in 1914 (Owen 1949) and was soon followed by one on the Apalachicola River (Willoughby 1999). Improvements for navigation in the Mobile River basin, authorized by Congress in 1874, came to fruition in 1895 with completion of a lock and dam on the Black Warrior River (Mettee et al. 1989).

Today, the main stems of virtually all the major rivers of the eastern Gulf are severely fragmented by numerous dams for hydroelectric power and navigation. Their main-stem channels have been deepened, and many riverine fauna have been replaced by lentic (reservoir) fauna (Ward, Ward, and Harris 1992). Coastal Plain rivers are, however, less fragmented, but only the Sipsey, Choctawhatchee, Pascagoula, and Suwannee are free-flowing, and within the Mobile River basin the Cahaba River contains only one small impoundment in the most upgradient head waters.

MOBILE RIVER

“Opposite this bluff, on the other side of the river, is a district of swamp or lowland, the richest I ever saw, or perhaps anywhere to be seen: as for the trees, I shall forbear to describe them, because it would appear incredible; let it suffice to mention that the Cypress, Ash, Platanus, Liquidambar, and others are by far the tallest, straightest, and every way the most enormous that I have seen or heard of.”

William Bartram, describing the Mobile River Delta, north of Mobile Bay, in *Travels through North & South Carolina, Georgia, East and West Florida* (1791; Doren 1928).

The Mobile River system, which drains land in Alabama, northwestern Georgia, southeastern Tennessee, and northeastern Mississippi, is the largest basin in the eastern Gulf region (Fig. 4.12) and one of the largest in North America (see Table 1.1). The headwaters lie in the mountains of northern Georgia, northern Alabama, and the Coastal Plain of northeastern Mississippi. The river drains south through forests and agricultural lands, eventually flowing through a large forested swamp delta north of the city of Mobile, Alabama (Fig. 4.1). The river then flows into Mobile Bay before discharging into the Gulf of Mexico.

The Mobile River system is composed of seven major rivers (see Fig. 4.12). Officially, only the 80 km reach north of Mobile Bay is known as the Mobile River, formed by the convergence of the Alabama and the Tombigbee rivers. The Tombigbee River receives two major tributary rivers, the Black Warrior River and the Sipsey River. The Alabama River has three major tributaries, including the Cahaba River, which enters near Selma, Alabama, as well as the Tallapoosa and Coosa rivers, which meet near Wetumpka, Alabama. Seventy-one percent of the basin lies in Alabama, 14% in Mississippi, 13% in Georgia, and 2% in Tennessee.

European exploration of the Mobile River basin began in the mid-sixteenth century. From 1539 to 1543, Spanish explorer Hernando De Soto led a 5635-km trek that originated in northern Florida and followed many rivers throughout the southeastern region. The journey eventually contributed to the earliest known map that detailed interior regions of North America, including locations of major rivers (Clayton et al. 1993a, 1993b; Hudson 1993; Galloway 1997). At the time, over 30 Native American groups were documented that occupied villages clustered along major waterways in Georgia, Alabama, Mississippi, and Florida (Swanton 1953). Many river names in the region are derived from the languages of these Native American groups (Read 1984).

During the latter part of the seventeenth and eighteenth centuries the French established forts within much of the basin, typically in strategic areas along the Tombigbee and Alabama rivers, in order to secure trading routes. In 1702, Pierre LeMoyne d'Iberville established a settlement on the northwest shoreline of Mobile Bay that he named Fort Louis de la Louisiane, but which was more commonly called La Mobile, "the rowers" (present-day Mobile), after the Native Americans in the area (McWilliams 1981). Conflicts between French traders and later English settlers were commonplace in the latter 1700s and early 1800s as immigrants chose wooded regions and river bottom lands for their homes and farms. However, battles with Native Americans largely ended in March 1814, when Andrew Jackson led a U.S. victory at Horseshoe Bend, so named because of its location on a curve in the Tallapoosa River (Jackson 1995).

Physiography, Climate, and Land Use

The physiography of the Mobile Basin is quite varied and, geologically, the basin is among the most diverse

on the continent (see Fig. 4.12). Elevations range from approximately 1250 m asl in the Blue Ridge (BL) physiographic province in the northeastern headwaters to sea level at Mobile, Alabama. Much of the basin (56%) is in the Coastal Plain (CP) province and therefore occurs at elevations <150 m asl. Sixteen percent each lies in the Appalachian Plateau (AP) and Piedmont (PP) provinces, with 12% in the Valley and Ridge (VR). Rocks in the upper basin are of Paleozoic age (Lineback 1973). Sandstones and shales of Pennsylvanian age are present in the Appalachian Plateau, whereas carbonate, shale, and sandstone rocks dominate the Valley and Ridge. Crystalline igneous and metamorphic rocks, such as schists, slate, granites, gneiss, and quartzite, underlie the Piedmont and Blue Ridge (Lacefield 2000). In the upper Mobile River basin, riverine precursors of the present-day upper Black Warrior, Cahaba, upper Coosa, and Tallapoosa rivers may well have flowed since Mesozoic times (65 to 245 million years ago). Over the past several 100 million years the Mobile River basin has been altered by geological events that have reconfigured the land, altered drainage patterns, and changed sea levels. Close phylogenetic linkages between fishes in the Mobile and Tennessee drainages clearly suggest stream capture of Tennessee streams by an eroding Mobile drainage. In the Coastal Plain, unconsolidated sands, gravels, clays, and limestone of Cretaceous to Tertiary age are present. Portions of eastern Gulf drainages have been periodically inundated by oceanic transgressions, and at other times the Coastal Plain has extended into the Gulf of Mexico well past its present-day coastline. The last high-sea period was during the Miocene, 5 to 20 million years ago.

The Mobile River Basin lies in four terrestrial ecoregions. A small portion of the lower basin along the Mobile River floodplain and delta lies in Southeastern Conifer Forests. Although the uplands of this ecoregion were historically dominated by longleaf pine, the vast lowland delta region consisted primarily of cypress swamps. Upgradient, to the northern edge of the Coastal Plain, lie Southeastern Mixed Forests, dominated by oak, hickory, and pines. Mid-elevations in the Piedmont and Appalachian Plateau are covered by Appalachian Mixed Mesophytic Forests, consisting primarily of oaks, hickories, magnolia, elm, and pines. At higher elevation in the northeastern portions of the basin lie Appalachian Blue Ridge Forests, dominated by mixed oaks and other hardwoods.

The climate in the region is warm and humid. Mean annual air temperatures range from 21°C near

the coast to 15.5°C in the northern part of the basin. Maximum summer monthly air temperatures occur in July and August, and winters are generally mild, with a minimum in January (see Fig. 4.13). Average annual precipitation ranges from 127 to 152 cm. Snowfall is not an important contribution over the majority of the basin but can be more significant at higher elevations in Georgia and Tennessee. The highest precipitation is concentrated in southern Alabama, near the coast. Only slight seasonal variations in rainfall occur within the Mobile Basin, with January through March somewhat higher than September through October (see Fig. 4.13). Summer precipitation exhibits substantial interannual variability, highly dependent on the extent of convective rainfall and tropical storm activity.

The basin is mostly forested (68%; G. M. Ward, unpublished data). Forest types include hardwoods and mixed deciduous-coniferous in the northern parts of the basin contrasted with mostly pine forest in the Coastal Plain. Agricultural land that supports row crops (corn, soybeans, hay, and cotton) and confined animal feeding operations (poultry and livestock) constitute 18% of the basin. Wetlands cover approximately 7% of the basin, mostly confined to the Coastal Plain. Urban land use is a small fraction of the total basin area (<2%), but a population of 4.9 million resides in the basin. Major population centers in Alabama include Birmingham, Mobile, Montgomery, and Tuscaloosa. Significant population pressures increasingly occur throughout the basin, particularly from the Birmingham and Atlanta areas.

River Geomorphology, Hydrology, and Chemistry

Drainage network type and substrate composition in Mobile River channels are determined by the parent material through which the river flows. Because the Tombigbee River arises in the sandy, unconsolidated Coastal Plain, the main-stem channel is low gradient and sediments are fine sand, silt, and mud. Headwater and main-stem channels for other major tributaries arise in rocky, bedrock-dominated areas in the Appalachian Plateau, Valley and Ridge, and Piedmont (Ward, Ward, Harlin et al. 1992). Higher-gradient headwater streams (>1 m/km) as well as downstream channels are dominated by bedrock downstream to the Fall Line. At present, only the main channel of the Cahaba River remains unaltered. Below the Fall Line, channel slopes are very low

(12 cm/km) and substrates in all rivers consist of fine sand, silt, and mud.

River channels flowing through Coastal Plain sediments are typically low gradient and meander through floodplain and bottomland forests. The main stem of the Mobile River below the confluence of the Alabama and Tombigbee rivers is flanked by a wide alluvial plain deposited over Holocene time (the last 10,000 years) (Smith 1988). The main channel divides a few kilometers downstream into the Mobile and the Tensaw rivers (see Fig. 4.1) and then divides further into a complex of distributaries before emptying into Mobile Bay. This southernmost part of the Mobile River basin is known as the Mobile River Delta and covers about 100,000 to 140,000 ha. Vegetation within the Delta is composed of 87% forested wetlands, 9% marshes, and 3% submersed grass beds (Stout et al. 1982). Once dominated by cypress, the last two centuries have resulted in a shift to dominance by water tupelo.

Mean annual flow of the Mobile River is approximately 1914 m³/s. Fifty-two percent (995 m³/s) is contributed by the Alabama River and 47% (899 m³/s) is from the Tombigbee River. The principal tributary to the Tombigbee River, the Black Warrior River, drains the Appalachian Plateau and contributes 277 m³/s. Major tributaries to the Alabama River, the Cahaba, Coosa, and Tallapoosa rivers, have a combined flow of 680 m³/s. Peak runoff occurs in March, coinciding with a period of high precipitation (see Fig. 4.13). Summer base flow in the river is typically reached by early July and remains stable until early winter. Variations in summer-fall precipitation appear to have little influence on stream flow, as most of this moisture is either lost to evapotranspiration or remains stored in soil.

Water chemistry in the basin varies greatly, largely as a function of the underlying parent material from which it originates (G. M. Ward, unpublished data). Waters from the Coastal Plain are naturally low in alkalinity (<2 mg/L as CaCO₃) and specific conductance (<20 μS/cm) and are approximately circumneutral in pH. Waters originating in the Appalachian Plateau have similar low ionic strength because the sandstone cement is largely silica rather than carbonate. Where carbonate terrain is exposed (e.g., in many areas in the Valley and Ridge physiographic province as well as parts of some other provinces), ionic strength of the water increases and is reflected in alkalinity values above 100 mg/L as CaCO₃, specific conductance >100 μS/cm, and pH >7.5. Chemistry of Piedmont water tends to be intermediate in values for pH (~7.0 to 7.5) alkalinity (16 to 17 mg/L

as CaCO₃), and specific conductance (33 to 39 μS/cm) compared to water in streams and rivers from other provinces in the basin.

River Biodiversity and Ecology

The Mobile River basin lies in the Mobile Bay freshwater ecoregion. Abell et al. (2000) list the species richness of fishes, mussels, and crayfishes in this ecoregion as being globally outstanding. Largely as a result of its size, age, geological and physiographical heterogeneity, and absence of past glaciation, the biodiversity of many groups of freshwater fauna within Alabama and the Mobile River is among the greatest in North America and for some groups the greatest biodiversity worldwide (Lydeard and Mayden 1995, Stein et al. 2000). Some of that biodiversity was lost as a result of habitat modification as the river was harnessed for hydroelectric power and navigation over the past century. Many additional species of fishes and mollusks are on the decline and face extinction. Table 4.1 provides data for species richness for the Mobile River system and for the state of Alabama.

Algae and Cyanobacteria

Few published investigations have focused on the algae in large rivers of the Mobile River system. Diatoms and green algal communities dominate the phytoplankton in the highly regulated Black Warrior River, with much less representation from cyanobacteria, euglenoids, cryptophytes, and dinoflagellates (Ratnasabapathy and Deason 1977, Joo 1990). Generally similar phytoplankton composition was reported for Weiss Reservoir, an impoundment on the Coosa River, where diatoms dominate in winter and spring months, and green algae were more abundant in summer and fall (Bayne, Seesock, Emmerth et al. 1997). Common genera included algae tolerant of organic pollution such as *Ankistrodesmus*, *Chlamydomonas*, and *Melosira*. Periphyton communities in

large rivers are typically dominated by diatoms and green algae, although substantial numbers of cyanobacteria can also occur at some sites.

Plants

Riparian plant assemblages along the main-stem channels in the Mobile River differ greatly depending on whether a location is above or below the Fall Line. Above the Fall Line, river channels have very narrow or nonexistent alluvial areas. Riparian vegetation includes river birch, American hornbeam, American sycamore, American holly, American beech, sweetgum, yellow poplar, red maple, and black gum. Below the Fall Line, rivers flow through unconsolidated Cretaceous and Tertiary sediments. Here, channels meander and overbank flows are more common than in upgradient areas. As a result, bottomland hardwood forests and swamp forests are predominant. Common riparian species are bald cypress, eastern cottonwood, water oak, southern red oak, swamp tupelo, water tupelo, and Carolina ash.

Invertebrates

Of the 335 species of North American crayfishes (Abell et al. 2000), 81 species (21%) are known from Alabama (www.natureserve.org/explorer 2002), and 60 (17%) can be found in the Mobile River system (see Table 4.1) (Abell et al. 2000). Common crayfishes inhabiting the basin are *Oronectes (Hespericambarus) perfectus*, *Oronectes (Tridellecens) holti*, and *Procambarus (Pennides) versutus* (McGregor et al. 1999).

Historically, the freshwater gastropod fauna of the Mobile River system was represented by nine families and 118 species, making it one of the most diverse basins for this group worldwide (see Table 4.1) (Bogan and Pierson 1993b). The centers of richness were the Coosa River (82 species) and the Cahaba River (36 species). The fauna included six endemic genera: *Tulotoma* (Viviparidae), *Clappia*,

TABLE 4.1 Summary of faunal species richness in the Mobile River system.

	Crayfishes	Mussels	Snails	Turtles	Fishes
Species in North America	335	283	342	44	792
Species in Alabama (%)	81 (21)	171 (58)	147 (43)	23 (52)	303 (38)
Species in Mobile River basin (recent/historic)	60	75	80/118	20	236
Species endemic to Alabama watersheds, including adjoining states	NA	58	113	5	106
Mobile River species endangered or threatened	NA	19	7	3	12

Modified from Bogan and Pierson 1993a, 1993b; Lydeard and Mayden 1995; and Abell et al. 2000.

Lepyrium (Hydrobiidae), *Gyrotoma* (Pleuroceridae), *Amphigyra*, and *Neoplanorbis* (Planorbidae). The Pleuroceridae was the most diverse family (76 species), with the genera *Pleurocera*, *Leptoxis*, and *Elimia* exhibiting their greatest radiation in the Coosa River drainage. Unfortunately, recent surveys of the aquatic gastropod fauna (Bogan and Pierson 1993b) have documented population declines, decreases in species' ranges, and the loss of a major portion of gastropod diversity, especially in the Coosa River, where 26 species are now presumed extinct. These include all six recognized species of *Gyrotoma* and all but one species of *Leptoxis*. The endemic genus *Tulotoma*, formerly widespread in the main channel of the Alabama and Coosa rivers, was until recently presumed extinct (Hershler et al. 1990).

Freshwater mussels (also known as naiads, unionids, or clams) are worldwide in distribution but reach their greatest diversity in North America. In particular, the southeastern United States and the Mobile River system are "hotspots" of that diversity. Of the 283 species of North American freshwater mussels (Williams et al. 1993), 171, or 58%, are found in rivers of Alabama, with 75 species in the Mobile River system alone. Historically, all the major tributary rivers in the Mobile River system contained large and diverse assemblages of mussels. Many species have distributions limited to one or only a few narrow drainages. Many of these are endemic. There are 11 species of mussels endemic to Alabama and 58 species that are endemic to watersheds within Alabama or adjoining states. These numbers do include, however, species from the Tennessee River, an area not strictly covered by the present description.

As of 1994, of 171 mussel species previously documented in Alabama, 28 were extinct, 51 endangered, 20 threatened, and 37 of special concern (for a total of 131, or 78%). Fourteen of the extinctions (*Pleurobema* spp.) were from the Mobile River system (Neves et al. 1997). The decline in mussel biodiversity has been attributed to habitat degradation from impoundment, channel modifications, sediment deposition, and toxic effluents (Williams et al. 1992). Some common mussels collected frequently in the Mobile River system, specifically the Alabama and Lower Tombigbee rivers, are the southern fatmucket, yellow sand shell, little spectaclecase, Alabama orb, and bleufer (McGregor et al. 1999).

Flow alterations to the main-stem channels in the Mobile River system have greatly simplified the aquatic insect fauna of these channels. In the Tombigbee and Black Warrior rivers the large river mayflies,

such as *Hexagenia*, *Pentagenia vittegera*, and *Tortopus*, were common, as were *Hydropsyche* spp. and *Potamyia flava* among the caddisflies (U.S.A.C.E. 1987). Where unimpounded, river channel faunas are much richer. Frequently encountered are the stoneflies *Acroneturia* and *Isoperla* and the mayflies *Hexagenia*, *Stenacron*, *Stenonema*, and *Isonychia*. The caddisflies of the Mobile River system have been extensively surveyed by Harris et al. (1991). Light trap collections at 63 sites on the major rivers yielded 91 species in 31 genera from 11 families. The most commonly encountered genera were *Hydropsyche*, *Potamyia*, *Cheumatopsyche*, *Hydroptila*, *Ceraclea*, and *Oecetis*.

Vertebrates

The Mobile River basin supports 236 species of fishes, of which approximately 47 species are endemic (Mettee et al. 1996, Boschung and Mayden 2004). The fish community of the Mobile River basin consists of 26 families occurring in the nonestuarine portion of the river (Mettee et al. 1996, Boschung and Mayden 2004). Species from an additional 17 families of marine or brackish-water fishes can be found in the Mobile Delta and in the lower portions of the basin's rivers below the Fall Line. Migratory anadromous and catadromous species found in the basin include Gulf sturgeon, American eel, and Alabama shad. The families Cyprinidae, Percidae, Catostomidae, and Centrarchidae comprise over 56% of primary freshwater fishes found in the basin (Mettee et al. 1996, Boschung and Mayden 2004). Among these families, the Cyprinidae (54 species) and Percidae (48 species) are the dominant families. Two species are more commonly found in rivers above the Fall Line (Alabama shiner, riffle minnow), and seven species are more common in rivers below the Fall Line (pretty shiner, undescribed speckled chub, silver chub, emerald shiner, silverside shiner, fluvial shiner, and bluntnose minnow). Fourteen species of minnows are endemic to the rivers and streams of the basin, including the endangered Cahaba shiner and threatened blue shiner (Mettee et al. 1996, Boschung and Mayden 2004).

Similar to minnows, two species of darters (black-banded darter and Mobile logperch) are common throughout the rivers of the Mobile River basin. No species of darters are restricted to large rivers above the Fall Line. In contrast, six species (naked sand darter, southern sand darter, crystal darter, rock darter, river darter, and saddleback darter) are found in rivers below the Fall Line. Of the 25 species of darter endemic to this area, 3 species (southern

sand darter, rock darter, and Mobile logperch) are primarily riverine species (Mettee et al. 1996, Boschung and Mayden 2004).

Although the Centrarchidae (sunfishes and basses, 17 species) and Catostomidae (suckers, 13 species) are not as diverse as the Cyprinidae and Percidae, these fishes are widespread throughout the basin. All species of sunfishes and basses are the object of recreational fisheries, although most fishing effort is focused on largemouth bass, striped bass, black and white crappie, various sunfishes, and channel and blue catfish.

The Alabama sturgeon is the rarest riverine fish in North America and is endemic to this basin (Mettee et al. 1996, Boschung and Mayden 2004). An extensive commercial fishery existed for the Alabama sturgeon during the late 1800s and early 1900s. However, by the last decade of the twentieth century only nine specimens were collected, indicating an extreme decrease in abundance over the last century (Mayden and Kuhajda 1996). This species received a considerable amount of media and political attention prior to the U.S. Fish and Wildlife Service listing this species as endangered in 2000 (Scharpf 2000).

The Mobile River basin supports many species of reptiles, amphibians, mammals, and birds (see Table 4.1). Over 50% of the North American turtle fauna can be found in Alabama, and 45% can be found in the Mobile River system. Reptiles associated with large rivers in the basin include the American alligator, alligator and common snapping turtles; common, stripeneck, and flattened musk turtles; eastern mud turtle; southern and northern black-knobbed map turtles; Alabama map turtle; Eastern chicken turtle; Southern painted turtle; yellowbelly and red-eared sliders; Alabama redbelly turtle, Gulf Coast smooth softshell turtle; Gulf Coast spiny softshell; cottonmouth, and yellowbelly and diamondback water snakes. The flattened musk turtle (federally listed as threatened), southern and northern black-knobbed map turtles, and the Alabama redbelly turtle (federally listed as endangered) are endemic to the basin. A variety of amphibians, including frogs, salamanders, newts, sirens, and amphiuma, are found throughout the basin. Mudpuppies can be found in many rivers. Mammals commonly found throughout the basin include the American mink, beaver, and river otter. Many federal and state wildlife management areas and wildlife refuges occur in the basin and offer opportunities for observing migratory waterfowl, bald eagles, osprey, brown and American white pelicans, and cormorants.

Ecosystem Processes

The primary research focus in rivers of the Mobile River system has been on faunistic studies, mostly of fishes and mollusks, with relatively little information on ecosystem processes, although limited information is available on several main-stem reservoirs. A variety of chemical and biological indicators show that reservoirs are becoming more eutrophic in response to enhanced nutrient levels (Bayne, Weesock, Reutebuch et al. 1997, Bayne, Seesock, Emmerth et al. 1997). Lake Neely Henry, a shallow reservoir with a large surface area (maximum depth 3.3 m, surface area 4547 hectares) on the Coosa River serves as a drinking-water source and a recreation area for nearby towns (Bayne, Weesock, Reutebuch et al. 1997). Since 1948 it has been receiving industrial and municipal pollution that has caused water-quality problems. Excessive growth of phytoplankton in response to both high phosphorus and nitrogen concentrations has resulted, and phytoplankton primary productivity values ($>1 \text{ g m}^{-2} \text{ d}^{-1}$) place it in the eutrophic category. A similar reservoir, Weiss Lake, is just upgradient from Lake Neely Henry and also has problems associated with excess nutrient inputs as well as toxic contaminants (Bayne, Seesock, Emmerth et al. 1997). Both chlorophyll *a* concentrations and phytoplankton primary productivity indicate that this reservoir is also eutrophic.

Human Impacts and Special Features

The Mobile River is one of the largest river basins in North America and stands out among all rivers in North America for its geological and biological diversity. A huge diversity of fishes, mollusks, and crayfishes exists within its headwaters, tributary rivers, and main stem. Although flow in many of the rivers has been altered, two important tributaries, the Sipsey and Cahaba rivers, have remained unaltered. Two areas within the basin now have federal protection, the Little River Canyon in northeast Alabama and the Sipsey Wilderness in northwest Alabama. Much of the swamplands in the Mobile River Delta also remain relatively undeveloped, and recently thousands of hectares have received state protection.

The Mobile River is a highly fragmented system, as illustrated by the history of the Black Warrior River. Before the 1890s, commercial river navigation was possible only as far north as Montgomery (on the Alabama River) and Tuscaloosa (on the Black

Warrior River). Even travel to these cities was restricted to high-flow winter months because of low water levels during other times of the year and the large number of shoals and debris jams (Mettee et al. 1989). Prior to navigational improvement, surveys of the Black Warrior River by the U.S.A.C.E in the 1870s and 1880s documented in detail the numbers of shoals, bars, debris dams, and snags present along the channel of the Black Warrior River (U.S. House 1875, U.S. Senate 1881). They also showed that the river width decreased from approximately 122m at the Fall Line near Tuscaloosa to only 46m at Demopolis, 80km downstream. The first generation of locks and dams on the Lower Tombigbee and Black Warrior rivers was completed in 1895. By 1915, 17 dams had been constructed and linked the port of Mobile to the iron- and steel-producing region near Birmingham.

The upper reaches of two major tributary rivers, the Coosa and Tallapoosa, are also highly fragmented by the presence of hydroelectric power dams. In the early 1900s, the precursor of what is today the Southern Company privately financed and constructed a series of dams. These large impoundments on the main stems of both the Coosa and Tallapoosa rivers and their regulated outflows have completely altered the habitat and natural hydrologic regimes of the rivers.

The Alabama–Coosa–Tallapoosa (ACT) sub-basin in the Mobile River system and the Apalachicola–Chattahoochee–Flint (ACF) basin in neighboring Georgia and Florida are currently the intense focus of bitter interstate water-allocation conflicts among Alabama, Georgia, and Florida. One contentious issue is that water transfer out of the ACT basin and into the ACF basin for use by Atlanta may cause insufficient instream flow within the Mobile basin, which will lead to impairment of downgradient rivers and Mobile Bay. This issue in the context of human impacts on the ACF will be discussed in another section of this chapter.

Historically, streams and rivers in the Mobile River basin existed with little turbidity. However, high concentrations of suspended solids from non-point-source agricultural runoff, urbanization and development, and point-source effluents are now major perturbations. Ryan (1969) estimated sediment yields in the Mobile River of 4.263 billion kg annually from suspended sediments (range of 1.814 billion to 7.257 billion kg). Bedload was as much as 0.453 billion kg, 30% of which was retained in the Mobile Delta and 70% transported into Mobile Bay.

Although yields over the last 50 years may be lower than those in the first half of the twentieth century (due to reductions in agricultural acreage and increased forest cover), recent increased mining activity and construction due to urbanization in the basin have very likely led to higher loads.

Complicating the issue of sediment transport is the potential downgradient impact of the many dams now in place on the major tributaries in the Mobile River system. Changes in types of sediment carried to the Mobile Delta may result from dams because it is unclear whether dams trap both large and fine sediments or only large, heavy sand particles, which would leave small particles in transport. As a result of heavy sediment loading from both dam outflow and other sources, the capacity of the Delta to trap sediment may diminish over time, decreasing its effectiveness as a sediment and nutrient sink. The regulated outflow from many upgradient dams also poses threats to the natural seasonal periodicity of fresh water/salt water ebb and flow in Mobile Bay, which may cause shifts in the zone of saline and fresh water mixing (Delta Project 1998, Mobile Press Register 1998; www.al.com/specialreport/mobileregister/?delta.html).

CAHABA RIVER

The Cahaba River is a 6th order tributary to the Alabama River of the Mobile basin and one of the longest free-flowing rivers in the eastern Gulf region. From its headwaters northeast of Birmingham (Fig. 4.14), the Cahaba River flows in a generally southward direction for 304 km until joining the Alabama River near Selma, Alabama. It is one of the most biologically striking and most threatened rivers in the eastern Gulf region, important because of its lack of impoundments; the large fish, mussel, and gastropod fauna that reside there; and the threats to this fauna and general water quality from population pressures emanating primarily from the city of Birmingham. Active grassroots environmental movements, such as the Alabama Rivers Alliance and the Cahaba River Society, have emerged in the region recently and have become persuasive and effective advocates for preservation, balanced growth, and environmental education. Among the rivers in the Mobile River system, protection of the Cahaba River is a very high priority.

The resettlement history within the Cahaba River basin is similar to that described for the Mobile River

basin. In addition to those comments about woodland and Mississippian cultures, the Cahaba River was a natural boundary separating two major tribes inhabiting the region. Choctaws were dominant to the west and Creek Indians to the east. The name “Cahaba” was apparently derived from the Choctaw language, meaning “waters above.” This has been variously interpreted as meaning water from the sky, or from mountain springs, or as a gift from above. The most well-known event of de Soto’s expedition through the southeastern United States took place within this basin. The Battle of Mabila (1540) was a confrontation between the Spanish and the head of one of the most powerful remaining chiefdoms of the region, the imposing Chief Tascaluza. Because of harsh treatment from the Spanish, Chief Tascaluza and his warriors engaged de Soto’s soldiers in a battle, likely near the confluence of the Cahaba and Alabama rivers, that resulted in thousands of Native American deaths and was the bloodiest battle in North America until the Civil War (Jackson 1995). The unequivocal siting of this battle, however, remains a fascinating mystery (Hudson 1993, Jackson 1995).

Physiography, Climate, and Land Use

The Cahaba River arises from seeps and springs on Mt. Cahaba in St. Clair County, northeast of Birmingham. The headwaters of the Cahaba lie in the Valley and Ridge (VR) physiographic province, a series of parallel southeastern to northeastern-oriented ridges formed by massive sandstone and conglomerate beds of the Pottsville and Parkwood formations (Pierson et al. 1989). Downstream the river crosses the Fall Line into the Coastal Plain (CP) province near Centreville, Alabama, approximately 144 km from its headwaters. The river then passes through two Coastal Plain physiographic districts, the Fall Line Hills and the Black Belt. The terrain just downgradient from the Fall Line, the Fall Line Hills, is dissected upland by a few broad or flat divides (Fenneman 1938). Altitudes of the ridges reach 213 m asl but decline to the south and southwest. Much of the area consists of unconsolidated sands of Cretaceous age carved to maturity by valleys 30 to 60 m deep. South of the Fall Line Hills lies the Black Belt, so named for the deep, black soil formed on the underlying Selma chalk formation. Here, ridges occur 20 m above stream channels. The large rivers that traverse this district have cut down through the chalk and eroded deep channels (Fenneman 1938), as evidenced by the high bluffs along the Tombigbee River. Surface-water supplies are rather deficient.

Therefore, small streams are not numerous, and many are intermittent.

The Cahaba River basin lies in two terrestrial ecoregions, the Appalachian Mixed Mesophytic Forests and the Southeastern Mixed Forests. In Alabama, the northern border of the Southeastern Mixed Forests closely corresponds to the Fall Line. Below the Fall Line, the vegetation in the basin is largely oak, hickory, and pines. Above the Fall Line, vegetation in the Appalachian Mixed Mesophytic Forests consists primarily of oaks, hickories, magnolia, elm, and pines.

Climate of the basin is humid and subtropical, with an average annual temperature of 16.7°C and average monthly temperatures ranging from 5°C in January to 26°C in July (Fig. 4.15). Annual rainfall averages 138 cm. There are no strong seasonal trends in precipitation, but lowest rainfall typically occurs in late summer–early fall and highest in winter–early spring (see Fig. 4.15).

Land cover in the basin is mostly forests (77%; G. M. Ward, unpublished data). The upper basin contains rocky terrain and shallow soils. Although agriculture accounts for 11% basinwide, it is much more extensive in the lower half of the basin, which lies in the Coastal Plain. Row crops, such as corn, cotton, hay, and wheat, are the major cover types. Riparian wetlands (6%) flank the river throughout the Coastal Plain. Land use in the upper Cahaba River basin is increasingly urban. Birmingham continues to expand, and although urban areas now comprise only 2% of the land cover, rapidly expanding suburban and other commercial developments along the Cahaba River seriously threaten the drinking-water supply for almost a million residents.

River Geomorphology, Hydrology, and Chemistry

The headwaters of the Cahaba River derive from local precipitation in sandstone-dominated terrain at an altitude of 300 m. The channel falls approximately 200 m from its headwaters until reaching the relatively low-gradient reaches lying in the Coastal Plain (1.3 m/km). Stream channels in the headwaters are narrow and bedrock-boulder dominated, and as a result of faulting, the stream network pattern is rectangular. Further downstream, river widths increase, but high bluffs constrain the channel and prevent floodplain development. Large shoal areas are common, many of which support stands of aquatic plants (Fig. 4.3). Downstream, sandstone bluffs give way to carbonate outcrops where the river has

FIGURE 4.3 Cahaba River at “Lily Shoals” near Marvel, Alabama, southwest of Birmingham, with the shoals spider lily (or Cahaba lily) in bloom (PHOTO BY BETH MAYNOR YOUNG).

eroded through the younger, overlying Pottsville sandstone. As a result of differential weathering, small tributary basins exhibit resistant chert caps on the ridges and carbonate exposures in the streambeds. As the river passes over the Fall Line near Centreville, the bluffs diminish, channel slopes decline to approximately 20cm/km, and a wide channel with slower flow develops. The unconsolidated alluvial sediments of the Coastal Plain allow the lower Cahaba River to meander across a wide floodplain. The channel of the lower Cahaba is wide (50m) and deep (4 to 6m) with shear banks. The many point bars consist of gravel mixed with sand.

The Cahaba River drains 4730km², with mean daily flows of 80m³/s. The upper basin is primarily precipitation fed, whereas the lower basin in the Coastal Plain receives substantial contributions of groundwater (Pierson et al. 1989). Maximum flows (see Fig. 4.15) occur from February to April (141 to 177m³/s), and low flows occur in September or October (~25m³/s), largely the result of lower rainfall and increased evapotranspiration. Of the 138 cm of precipitation, 56 cm (40%) is contained in runoff.

The stream-water chemistry in the Cahaba at any one location is determined by the proportional mixture of the effects of weathering in the surround-

ing basin and the influences of upstream human activity. The mostly pristine headwaters above Birmingham are slightly alkaline pH (7.2 to 7.7), relatively low specific conductance (30 to 160 $\mu\text{S}/\text{cm}$), low alkalinity (15 to 35 mg/L as CaCO_3), low $\text{NO}_2\text{-N} + \text{NO}_3\text{-N}$ (0.025 to 0.307 mg/L), and $\text{PO}_4\text{-P}$ (0.002 to 0.01 mg/L) (Shepard et al. 1994). However, over a distance of 80 km downgradient from the headwaters, 26 large sources of domestic sewage and industrial discharges contribute substantial amounts of nitrogen and phosphorus to the river. By the time the Cahaba River reaches the Coastal Plain, pH increases slightly (7.3 to 8.3), as does specific conductance (100 to 225 $\mu\text{S}/\text{cm}$), alkalinity (50 to 110 mg/L as CaCO_3), $\text{NO}_2\text{-N} + \text{NO}_3\text{-N}$ (0.25 to 0.30 mg/L), and $\text{PO}_4\text{-P}$ (0.003 to 0.025 mg/L). Although waters of unperturbed streams in the Coastal Plain typically have very low ionic strength and low inorganic N and P (<0.025 mg/L N and <0.005 mg/L P), water chemistry near the mouth of the Cahaba River reveals substantially increased $\text{NO}_2\text{-N} + \text{NO}_3\text{-N}$ (0.28 to 0.64 mg/L), likely from agricultural runoff.

River Biodiversity and Ecology

The Cahaba River lies within the Mobile Bay ecoregion, an area that encompasses the entire Mobile river drainage (Abell et al. 2000). The Cahaba River is located in the approximate center of the ecoregion. Except for the issue of river fragmentation, many of the characteristics of the entire ecoregion are shared with the Cahaba River. Issues associated with land-use change, degraded water quality, and water allocation are challenges facing conservationists within the basin. For a river of its size, the Cahaba River supports an incredible diversity of aquatic life. Information on fishes, mussels, gastropods and caddisflies is the most complete. However, our knowledge of many other groups, which have not been systematically inventoried, is much less complete. Unfortunately, the number of extinct, endangered, or threatened species is also high.

Algae and Cyanobacteria

The main channel of the Cahaba is open and receives full sun. Predominant periphytic algae include diatoms (*Melosira*, *Cymbella*, and *Fragilaria*), green algae (*Cladophora*, *Ulothrix*, *Spirogyra*, *Mougeotia*, *Chaetophora*, and *Stigeoclonium*), and cyanobacteria (*Schizothrix*, *Rivularia*, *Anabaena*, *Cylindrospermum*, and *Microcoleus*). In areas near and downstream of Birmingham, diatom diversity is low and *Cladophora* has become the most dominant

and widespread alga in the Cahaba River channel, largely as a result of overgrowth due to high nutrient concentrations emanating from the surrounding urban and suburban landscape, including wastewater treatment plants (Howard et al. 2002).

Plants

Shallow shoals within the main stem are often occupied by an abundance of aquatic vascular plants. Perhaps most visually striking is the presence of the shoals spiderlily (or Cahaba lily), which blooms with a profusion of large white blossoms in May (see Fig. 4.3). Once more widely distributed than now, the Cahaba lily exists in only a very limited number of shoals and is considered endangered. American water willow is frequently found in association with shallow shoals as well as along the channel margin. In the faster flowing midchannel areas, riverweed can be found on bedrock and large boulders. The moss *Fontinalis* is also frequently found on the streambed, typically in association with *Cladophora*. The channel upstream of the Fall Line is largely constrained by rocky bluffs and has little riparian development. However, downstream of the Fall Line the channel meanders through soft alluvial sediments and is flanked by bottomland hardwood forests containing water tupelo, bald cypress, pine, American hornbeam, American beech, southern red oak, water oak, live oak, yellow poplar, sweetgum, American sycamore, American holly, and red maple, among other species.

Invertebrates

The Cahaba River harbors a wide array of insects, mussels, and gastropods. The earliest survey of mussel diversity in the Cahaba River was conducted by Henry van der Shalie (1938). Forty-two species were identified at that time, but a later resurvey by Baldwin (1973) recorded only 31 species. By 1994, only 27 species were documented (Shepard et al. 1994). At present, 20 species appear to have stable populations, including the Alabama orb, southern fatmucket, yellow sandshell, little spectaclecase, and the nonnative Asiatic clam. Nine species are considered threatened or endangered.

Historically, the Cahaba River supported 36 species of gastropods. Bogan and Pierson (1993a) concluded that by 1993 the gastropod fauna in the Cahaba had declined 33%. They listed 24 species, including 16 species that were candidates for listing as threatened or endangered species. Morales (1990) listed 10 gastropods (*Elimia cahabensis*, *E. clara*, *E. pupoidea*, *E. showalteri*, *Leptoxis*, *Somatogyrus*,

Physella, *Ferissia*, *Micromenetus*, and *Fossaria*) from a single riffle habitat in the 5th order Little Cahaba River, a major tributary to the main-stem Cahaba. This study found a trend toward increasing gastropod species richness with increasing stream order.

The high diversity of invertebrates in the Cahaba River extends to aquatic insects as well. Harris et al. (1991) recorded 342 species of caddisflies in the state of Alabama, approximately 25% of the North American fauna. The Cahaba River basin contained 156 species. At 16 sites along the main stem of the Cahaba, Harris et al. recorded 13 families, 37 genera, and 120 species. Species densities at these main-stem sites ranged from 25 to 59 species per site. The most abundant families were Hydropsychidae, Polycentropodidae, and Hydroptilidae. The genera, *Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Ceraclia*, and *Cyrnellus* were commonly collected. Faunistic studies of other orders are not as complete, and accurate richness estimates for the Cahaba River are not now available. However, frequently encountered noncaddisfly genera in the main river are the damselfly *Enallagma*; the stoneflies *Acroneuria*, *Isoptera*, and *Perlesta*; the mayflies *Baetis*, *Stenacron*, *Stenonema*, *Eurylophella*, *Serratella*, and *Isonychia*; the riffle beetles *Macronychus* and *Stenelmis*; and chironomid midges (e.g., *Ablabesmyia*, *Polypedilum*, and *Rheotanytarsus*).

Vertebrates

The fish fauna of the Cahaba River is more diverse than any other comparably sized river in North America. There are 135 species of fishes in the Cahaba River basin, predominantly cyprinids (36 species) and percids (23 species) (Mettee et al. 1996; Boschung and Mayden 2004). Commonly encountered minnows include bluehead and river chub, largescale stoneroller, and Alabama and blacktail shiner; common darters include greenbreast, rock, speckled, and blackbanded darter and Mobile logperch. The Cahaba River has several species listed as endangered, threatened, or vulnerable, including the Alabama sturgeon, Cahaba shiner, Coosa madtom, goldline darter, crystal darter, and freckled darter (Warren et al. 2000); the Cahaba shiner was thought to be endemic to the Cahaba River, but another population was recently discovered in the Locust Fork of the Black Warrior River (Boschung and Mayden 2004). The blue shiner and Alabama shad have been extirpated from this system, and the relative abundances of disturbance-sensitive species, such as the coal and greenbreast darters and Cahaba shiner, have declined due to the effects of extensive urbanization

in the upper portion of the river, which flows through the Birmingham metropolitan area (Onorato et al. 2000). In contrast, the relative abundances of sunfishes have increased in the Cahaba River, possibly due to increased reservoir habitat resulting from the formation of Lake Purdy on the “upper” Little Cahaba River.

Although sunfishes and basses (15 species) and catfishes (11 species) are not as diverse as minnows and darters, these fishes are widespread throughout the Cahaba River drainage. All species of sunfishes, basses, and catfishes are the object of recreational fisheries, although most fishing effort is focused on largemouth bass, black and white crappie, various sunfishes, and channel, blue, and flathead catfish.

The Cahaba River, its tributaries, and the basin support many species of reptiles, amphibians, mammals, and birds. Reptiles associated with the Cahaba River proper include alligator and common snapping turtles, common and stripenneck musk turtles, Eastern mud turtle, Alabama map turtle, Northern black-knob sawback map turtle, Eastern chicken turtle, Southern painted turtle, river cooter, yellowbelly and red-eared sliders, Gulf Coast smooth softshell turtle, Gulf Coast spiny softshell turtle, cottonmouth, yellowbelly, and diamondback water snakes. A variety of amphibians, including frogs, salamanders, newts, and sirens, are found throughout the basin; mudpuppies, or waterdogs, can be found in the main-stem Cahaba River. Mammals commonly found in the basin include beaver, mink, raccoon, and river otter. Cahaba River Wildlife Management Area, Cahaba River National Wildlife Refuge, and Talladega National Forest offer opportunities for bird watching along the Cahaba River, especially for migratory waterfowl and bald eagles.

Ecosystem Processes

Relatively little is known regarding most ecological processes within the main stem of the Cahaba River. Above the Fall Line, the main channel of the Cahaba River is constricted but receives full sun and is shallow with mostly bedrock/cobble substrates. Consequently, benthic processes likely predominate. Historically, the river has run clear, but now significant erosion and sedimentation from the Birmingham area increasingly threaten the physical and biological structure of the system. Below the Fall Line, the river is deeper, with unconsolidated sediments. Certainly, water-column processes would be more important here than above the Fall Line. Because of the lack of impoundments, there is high connectivity between

the river and the adjacent floodplain, although agricultural use of bottomland areas is common.

Human Impacts and Special Features

The Cahaba River is one of the longest free-flowing rivers in the eastern Gulf region and is noted for its incredible biological diversity, geologic diversity, and scenic beauty. The locale is attractive to humans as a place to live and work, which is currently the main threat to the Cahaba. The river flows through the heart of one of the fastest growing commercial and residential areas in the region, and the vast majority of land along the river is privately held. Consequently, little is contained within preservation areas. In 2000, however, the U.S. Congress established the Cahaba River Wildlife Refuge, and has subsequently appropriated funds to purchase 1415 ha along a 5.6 km reach of critically important river habitat. Protection of habitat for the goldline darter, Cahaba shiner, round rocksnail, and cylindrical lioplax snail are among the management objectives.

Although many reaches of the main-stem Cahaba and tributaries are classified in the Nationwide Rivers Inventory (but not protected), several main-stem reaches and tributaries are included in the state's 303(d) list as severely impaired. Shades Creek and Bucks Creek are two large tributary creeks that receive industrial and domestic sewage effluents from around Birmingham, delivering these effluents to the Cahaba main stem. Recent studies by the EPA (Howard et al. 2002) document these impacts. Many parts of the wastewater transport system in Birmingham have been leaking for decades, and the city is now under a federal court order to upgrade the sewer system and come into compliance with clean water standards.

In addition to excessive nutrient inputs and periphytic growth in the Cahaba, excessive sediment loading from construction sites and suburban development near Birmingham has negatively impacted the river downstream. Large amounts of fine sediments are visible in channel storage and in transport following rain events. Evidence of declines in fish species richness throughout the upper Cahaba from historical levels has been developed by Onorata et al. (2000). Most at risk are crevice spawning fish species that lose oviposition sites, as well as the aquatic insects that use the spaces for habitat.

Unlike many of the other major tributaries in the Mobile River system, fragmentation of the Cahaba River is not a major issue. Only one impoundment exists (Lake Purdy; see Fig. 4.14), located in a head-

water tributary. Water is stored here for withdrawal by Birmingham during summer, when Cahaba River surface flow is too low to support withdrawals directly from the main channel. As a result of the use of the Cahaba River as the primary water supply for Birmingham, the quantity and quality of drinking water are now of primary environmental concern in the upper Cahaba Basin. The city has now reached the maximum amount it can withdraw at the current intake site on the river. Thus, other sources are being sought. At the same time, the basin surrounding the water source is undergoing rapid development. The threat of degradation to the city's water supply caused by additional sewage disposal and erosion is great. Currently, efforts are in place to build a coalition of support among several political units (Birmingham, several small cities, Jefferson County) to produce a land-use development plan for the upper basin that can be a guide for a more balanced economic growth pattern and the preservation of water quality in the upper Cahaba River basin.

APALACHICOLA- CHATTAHOOCHEE-FLINT RIVER SYSTEM

The Apalachicola River is formed by the confluence of two large tributaries, the Chattahoochee and Flint rivers, near the Georgia-Florida state line (Fig. 4.16). These rivers meet at what is now Lake Seminole, a 15,200 ha reservoir formed by the Jim Woodruff Lock and Dam. Below the lake the Apalachicola River flows southward for 170 km to Apalachicola Bay and on to the Gulf of Mexico. The basin occupies an area of 50,688 km² between the Atlantic Slope and the Mobile River catchment and is the 21st largest river basin in the coterminous United States (Leopold 1994). The entire basin is often called the ACF river system.

The 692 km Chattahoochee River originates in northeastern Georgia, flows southwest past Atlanta, then south to Lake Seminole, forming the border between Alabama and Georgia (see Fig. 4.16). The upper Chattahoochee is a free-flowing, high-gradient river, whereas the middle Chattahoochee is highly fragmented. The headwaters of the Flint River arise just south of Atlanta. The Flint drains substantial amounts of agricultural land in central and southwestern Georgia, flowing 560 km in a south-southwest direction into Lake Seminole. Major tributaries include Ichawaynochaway, Chickasawhatchee, Kinchafoonee, and Muckalee creeks.

Below Lake Seminole, the Apalachicola River floodplain, the largest in Florida, is 114 km long and 1.6 to 8 km wide. The floodplain covers 453 km² from the outlet at Lake Seminole to the point of tidal influence, approximately 40 km above Apalachicola Bay (Light et al. 1998). Much of the Apalachicola catchment lies in Georgia (73%). The remainder is divided between Alabama (14%) and Florida (13%) (Couch et al. 1996). The Chattahoochee catchment occupies 22,714 km², or 44%, of the basin, and the Flint River occupies 21,911 km², or 43%. The area south of Lake Seminole covers 6734 km², or 13%, of the basin.

Early settlement of the ACF basin by humans occurred at the same time as other river systems in the southeastern region (>12,000 years ago). The native peoples depended primarily on a hunting-gathering lifestyle prior to developing into the agriculturally based Mississippian culture. By the 1700s the Creek Indians (Muskogean) emerged as the dominant group in the ACF region as well as most of present-day Georgia and Alabama. “Creek” was a term used by the English to describe them because they lived along rivers and streams, whereas “musco-gee,” a Native American term, denoted “flooded land.” The Creek towns were grouped in two areas defined by upper and lower trading routes. (Smith 2004). The Lower Creeks encompassed villages from the lower ACF valleys and were especially powerful in the southeastern region (Worth 2000).

Another distinctive group of this region, the Apalachee Indians, occupied land in the Florida panhandle east of the lower part of the Apalachicola basin (McEwan 2000). The Apalachees established several village centers, which de Soto and his band encountered when they overwintered in the area in 1539–1540. After initial battles with de Soto and other Europeans, the Apalachees eventually established a more cordial relationship with the Spanish before their villages were devastated by attacks from Creek and English combatants by the early 1700s (McEwan 2000).

Physiography, Climate, and Land Use

The path of the ACF river system flows through three physiographic provinces (see Fig. 4.16). These include a small portion of the Blue Ridge (BL) (<1%), the Piedmont Plateau (PP), and the Coastal Plain (CP). The headwaters of the Chattahoochee River arise in the Blue Ridge, a region of rugged mountains and ridges that range from 914 to 1067 m asl. Much

of the upper and middle Chattahoochee basin lies in the Piedmont. Below Columbus, Georgia, the river flows through hilly, Coastal Plain terrain until reaching Lake Seminole. The headwaters of the Flint begin in the upper Piedmont near Atlanta, although the majority of the river lies in the Coastal Plain. In southern Georgia, the river traverses karst topography, the Dougherty Plains, which is characterized by outcrops of Ocala and Suwannee limestone. Sinkholes with associated ponds and marshes are present, as are small, but often intermittent, streams. Below Lake Seminole the Apalachicola River is bounded on the east by steep bluffs through a region named the Tallahassee Hills and on the west by the Marianna Lowlands. The river then reaches the Gulf Coast Lowlands, where the floodplain widens to 5 to 8 km (Couch et al. 1996).

The ACT system lies in three terrestrial ecoregions. The lowest portion of the ACF basin, from above Lake Seminole to the Gulf of Mexico, lies within Southeastern Conifer Forests. This ecoregion is dominated by pine and mixed hardwoods. The broad floodplain of the Apalachicola River occurs here. Upgradient, Southeastern Mixed Forests, dominated by oak, hickory, and pines, covers much of the Flint and Chattahoochee basins. At higher elevations in the northeastern portion of the Chattahoochee River lie Appalachian/Blue Ridge Forests, dominated by mixed oaks and other hardwoods.

Climate in the ACF basin is characterized as warm and humid. Average annual temperatures range from 16°C in the north to 21°C in the south. Winter temperatures range from 4.5°C to 12°C, and summer maxima reach 24°C to 27°C. The mean annual temperature at Columbus, Georgia, is 18.3°C (Fig. 4.17). Precipitation is high (140 cm/yr) in the northern mountains as a result of orographic lifting of moist air from the Gulf of Mexico. High precipitation also occurs in coastal areas, which have an annual average of 152 cm (Couch et al. 1996). Mean annual precipitation at Columbus is 128 cm and is spread relatively evenly throughout the year, although somewhat lower in September and October (see Fig. 4.17). The lowest rainfall occurs in the Flint River basin, where average annual precipitation is 114 cm. Almost all of the precipitation is rain, with significant snowfall occurring in only a small northern portion of the basin.

Three major soil orders occur within the basin. Like much of the eastern Gulf region, ultisols cover the Piedmont and much of the Coastal Plain. However, a significant portion of the Flint River basin contains entisols. These geologically young

soils are often infertile and drought prone because they are deep, sandy, and highly erosive (Couch et al. 1996). Poorly drained spodosols occur along the Apalachicola River.

Land use in the ACF basin is 55% forest, 25% agriculture, 10% wetlands, and <3% urban (G. M. Ward, unpublished data). Forestlands consist of second-growth timber (mixed deciduous, coniferous) and planted pine plantations. Approximately 25% of forest cover is silviculture, concentrated in northern Florida, the Piedmont south of Atlanta, and the Coastal Plain near the Fall Line. Agriculture is a mixture of primarily row crops (peanuts, corn, soybeans, and cotton), pasture, orchards, and confined animal feeding operations. Row-crop agricultural acreage has been on the decline in recent decades, but there have been increases in poultry and livestock production. Row crops dominate in the Coastal Plain, whereas pastures and poultry/livestock production dominate in the Piedmont.

River Geomorphology, Hydrology, and Chemistry

The Chattahoochee River arises in steep, mountainous terrain in north Georgia. Northeast-trending ridge lines strongly control the direction of flow of the Upper Chattahoochee to the southwest. The presence of fractures causes the main channel and its tributaries to follow a rectangular drainage pattern. Upper reaches are characterized by high gradients and numerous waterfalls. Above Lake Lanier, a reservoir created by Buford Dam north of Atlanta, Georgia, the river is free-flowing, with an average slope of 6.1 m/km (Fig. 4.4). River elevation drops 30 m below Buford Dam, and the Chattahoochee flows again south-southwest, falling approximately 100 m over 200 km to West Point Lake. West of Atlanta at the Alabama–Georgia state line the Chattahoochee turns south and flows through more rolling topography. The “Falls of the Chatta-

FIGURE 4.4 Chattahoochee River (Apalachicola system) below Buford Dam (Lake Lanier), north of Atlanta. Note tan waterline on cliffs indicates daily/weekly fluctuations in water level from hydropower releases (PHOTO BY A. C. BENKE).

hoochee” near Columbus, Georgia, denote the junction of the Piedmont and the unconsolidated Cretaceous and Tertiary sediments of the Coastal Plain (Couch et al. 1996). These falls are now submerged as a result of an impoundment but were similar to others along major rivers in Alabama where sharp river gradients limited further commercial transportation upstream. Below the W. F. George Reservoir, the Chattahoochee River winds slowly through Coastal Plains sediments until meeting Lake Seminole. Channel gradients here are similar to other Coastal Plain rivers, approximately 35 cm/km.

Geomorphologically, the Flint River traverses three distinct zones (Hicks and Opsahl 2004). Between the headwaters and the Fall Line, the Upper Flint River has broad riparian floodplains and moderate slopes (63 cm/km) throughout much of its length. However, in the lower reaches of the upper Flint the river valley narrows, the gradient steepens (5.2 m/km) into white-water rapids, and rocky shoals provide habitat for aquatic communities derived from both the Piedmont and Coastal Plain. Because the river is underlain by crystalline rocks, bedrock and cobble substrates are common. Below the Fall Line, the river exhibits deeply incised sandy banks and wide floodplains. The Middle Flint River is deep, wide, and slow, with soft, sandy sediments. Channel slopes again lessen (28 cm/km) to that typical of Coastal Plains Rivers. Overbank flows are common, and a broad alluvial floodplain has formed. Below Lake Blackshear, the lower Flint River traverses Ocala limestone and the river sediment shifts from sand to rocky limestone shoals. Here in the lower Flint River, unlike other eastern Gulf coastal basins (Suwannee River excepted), many springs emerge from the underlying Floridan aquifer. The largest, Radium Springs, discharges $>3\text{ m}^3/\text{s}$. Downstream at Bainbridge, Georgia, the shoals are submerged, and the river is again wide, slow, and deep before disappearing into Lake Seminole. Below Lake Seminole, the Apalachicola River is a wide, low-gradient floodplain river (7 cm/km) before emptying into Apalachicola Bay, an estuary widely known for its fishery and shellfish production.

The mean daily discharge of the Apalachicola River at Sumatra, Florida, is $759\text{ m}^3/\text{s}$, ranging from a high of $5041\text{ m}^3/\text{s}$ to a low of $164\text{ m}^3/\text{s}$ (Couch et al. 1996). Eighty percent of the flow of the Apalachicola is contributed by the Chattahoochee and Flint rivers. The Chipola River, a primarily spring-fed tributary, contributes 11%, and the remaining $<10\%$ is derived from groundwater and overland flow. Because of higher precipitation, the

Chattahoochee basin provides more runoff than the Flint River in most years. This is reversed in extremely dry years, when groundwater inputs to the Flint River result in more discharge than that of the Chattahoochee (Couch et al. 1996). Throughout the ACF basin, highest flows occur from January to April, when precipitation is high, and evapotranspiration is low (see Fig. 4.17). Low-flow periods occur from September through November. River flow in the Chattahoochee and Flint is largely precipitation driven, but substantial groundwater inputs are derived from the Floridan aquifer (karstic Ocala limestone) in southern Georgia, particularly in the Flint River basin. Undoubtedly, river hydrographs throughout the regulated sections of the ACT basin are modified by reservoir operations and surface/groundwater extractions (particularly in the Flint).

Water-quality investigations on the ACF basin have recently been conducted (1992–1995) as part of the USGS NAWQA program (Frick et al. 1998). Upstream of Atlanta, $\text{NO}_3\text{-N}$ concentrations (given as 25th to 75th percentile) in the Chattahoochee River ranged from 0.1 to 0.3 mg/L, whereas downstream of Atlanta concentrations increased to 1 to 2 mg/L. Apalachicola River concentrations ranged from 0.3 to 0.5 mg/L. Total phosphorus concentrations in the Chattahoochee River upstream of Atlanta ranged from 0.1 to 0.2 mg/L, whereas downstream of Atlanta total phosphorus concentrations greatly increased to 0.7 to 1.5 mg/L. Apalachicola River total phosphorus concentrations ranged from 0.2 to 0.4 mg/L.

River Biodiversity and Ecology

The Apalachicola River basin lies within the Apalachicola freshwater ecoregion (Abell et al. 2000). This ecoregion contains all of the Apalachicola basin as well as the nearby Ecofina River and differs from adjacent ecoregions by having its headwaters well above the Fall Line. As a consequence, the Apalachicola ecoregion is distinct from nearby coastal drainages by having a much richer diversity of fishes, mollusks, crayfishes, and herpetofauna.

Algae and Cyanobacteria

Periphyton communities in the Chattahoochee River are typically dominated by diatoms and green algae mixed with cyanobacteria and dinoflagellates at some sites. Abundances generally increase down-

river compared to the most upgradient sites (Environmental Protection Division 1974, 1984). Multiple years of periphyton sampling in the Flint River indicate that periphyton communities are typically dominated by diatoms, with fewer numbers of green algae and cyanobacteria (Environmental Protection Division, 1978, 1981, 1984). Cyanobacteria at some sites outnumbered green algae in the periphyton.

Plants

As was the case in the Cahaba River, shoals in the Flint River along the Fall Line support stands of the shoals spider lily. Historically known from South Carolina to Alabama, these now endangered plants are highly specialized for life in rapidly flowing habitats and are noted for large, showy, white flowers that are highly fragrant. Along the Flint River other aquatic macrophytes are also present, such as riverweed, cattails, bur-reed, coontail, and water primrose. Near Lake Seminole along the Flint River are water hyacinth, arrowhead, and water pennywort. The alluvial corridors of the lower Flint and Chattahoochee rivers are dominated by bottomland forests, with cypress, oaks, pines, sycamore, sweetgum, and willow. Bottomland forests along the Apalachicola River contain water tupelo, swamp tupelo, Ogeechee tupelo, bald cypress, Carolina ash, water hickory, sweetgum, overcup oak, green ash, and sugarberry (Leitman et al. 1983). In depressions and low-elevation areas, stands of tupelo and cypress (swamps) exist, some inundated year round, but others may lack standing water during the October–November dry period (Light et al. 1998). Near the mouth of the Apalachicola River lowland forests give way to freshwater and salt marshes around Apalachicola Bay. Here, sawgrass and cattails dominate freshwater marshes and needlegrass rush, smooth cordgrass, and saltgrass dominate the salt marshes.

Invertebrates

With the exception of the mollusks and crayfishes, knowledge of the richness and distribution of invertebrates in the ACF is limited (Couch et al. 1996). Thirty crayfish species were recorded by Hobbs (1942, 1981), 15 in the Apalachicola and 20 in the Chattahoochee/Flint. Six species each are endemic to the Flint and to the Chattahoochee. Hobbs and Hart (1959) reported 21 species of crayfishes from the Apalachicola River portion of the basin. The karst topography of southern Georgia also provides habitat for a diverse subterranean faunal assemblage. Two well-known troglobites (cave-dwelling species) from southwestern Georgia are the

blind cave salamander and the Dougherty cave crayfish (Golladay and McIntyre 2004).

Historically, as many as 33 species of mussels and 83 species of freshwater snails have been found in the ACF basin (Box and Williams 2000, Nordlie 1990, Thompson 1984). The Apalachicola, Flint, and Chattahoochee were all rivers with large mussel faunas. Twenty-nine species of mussels are known from the Flint River and 30 from the Chattahoochee (Box and Williams 2000). Recent surveys in the Flint relocated 22 species, but only 5 in the Chattahoochee. Species commonly encountered are eastern elliptio, elephantear, yellow sandshell, and round pearlshell. From the earliest collections of mollusks from the ACF in 1834, taxonomists recognized that the ACF fauna differed substantially from that of the Atlantic slope and that of more western Gulf of Mexico basins. To an extent, there is mixing of species from adjacent basins, but there is additional uniqueness in the species composition beyond simple mixing. Clench and Turner (1956), noting the numerous close phylogenetic relationships of the ACF fauna with faunas in other river systems, concluded that the northwest Florida mollusk fauna was originally derived from areas northwest of the rivers, very likely the Coosa–Alabama and Tennessee rivers.

The free-flowing upper Chattahoochee River has a rich aquatic insect fauna, typical of the region. Stoneflies, such as *Paragnetina*, and mayflies, such as *Stenonema* and *Baetis*, are common, as are net-spinning caddisflies (*Hydropsyche* and *Cheumatopsyche*). Chironomid midges, such as the net-spinning *Rheotanytarsus*, are frequently encountered. Downstream, below river impoundments and near urbanized areas, the aquatic insect fauna is restricted to chironomids and oligochaete worms. Downstream in the Coastal Plain, below impacts of most of the impoundments, the mayflies *Stenonema*, *Tricorythodes*, and *Baetis*, the caddisfly *Cyrnellus*, and many species of chironomids can be found (Environmental Protection Division 1974) associated with fine sediments, woody debris, and aquatic plants.

Vertebrates

The Apalachicola River basin supports more species of freshwater fishes than do adjacent Coastal Plain river basins because its headwaters lie well above the Fall Line (Swift et al. 1986). Sixteen families and 104 species of freshwater and estuarine fishes are found in the Apalachicola River basin (Swift et al. 1986, Page and Burr 1991, Abell et al. 2000). Of the nine species endemic to the Apalachicola River basin, three species (greater

jumprock, grayfin redbhorse, and shoal bass) are found primarily in medium to large rivers. Several estuarine species, particularly killifishes and gobies, occur in the lower, brackish-water portions of the river. Migratory anadromous and catadromous species found in the Apalachicola River include Gulf sturgeon, American eel, and Alabama shad. These species were once abundant in this system, but construction of the Jim Woodruff Lock and Dam has reduced their migration routes and access to spawning grounds (Livingston 1992).

The families Cyprinidae (26 species), Centrarchidae (14 species), and Ictaluridae (8 species) comprise approximately 46% of primary freshwater fishes found in the Apalachicola River basin. Only six species of darters are found in the Apalachicola and Flint rivers; the blackbanded darter is widespread throughout these rivers. Two introduced minnows, common and grass carp, are common in the river below Jim Woodruff Lock and Dam. All species of sunfishes, basses, and catfishes are the object of recreational fisheries in the Apalachicola River drainage, although most fishing effort is focused on largemouth bass, redeye bass, shoal bass, black and white crappie, various sunfishes, and channel and blue catfish. The Apalachicola River has produced state fishing records for common carp, redeye bass, spotted bass, striped bass, and white bass (Florida Fish and Wildlife Conservation Commission 2003).

The Apalachicola River basin supports the highest species density of terrestrial and aquatic amphibians and reptiles in all of North America north of Mexico (Livingston 1992). Reptiles associated with the Apalachicola River basin include American alligator, redbelly water snake, brown water snake, cottonmouth, snapping turtle, alligator snapping turtle, Barbor's map turtle (endemic to the Apalachicola River basin), river cooter, Florida cooter, Florida redbelly turtle (westernmost population), yellowbelly slider, striped mud turtle, common musk turtle, Florida softshell turtle, and Gulf Coast spiny softshell turtle. A variety of amphibians, including frogs, salamanders, newts, sirens, and amphiuma, are found throughout the basin.

Mammals commonly found in the rivers of the Apalachicola River basin include beaver, mink, raccoon, and river otter; the West Indian manatee is seen only rarely in the Apalachicola River (Lefebvre et al. 1989). Along the Apalachicola River, The Nature Conservancy's Apalachicola Bluffs and Ravines Preserve, Apalachicola National Forest, and Apalachicola Wildlife Management Area offer opportunities for viewing wildlife. These areas

provide feeding, resting, and winter habitat for many migratory bird species, including brown and American white pelicans, osprey, and cormorants. Bald eagles, Mississippi kites, and swallow-tailed kites can frequently be seen in these wildlife reserves.

Ecosystem Processes

Within the Apalachicola River floodplain are a wide variety of aquatic habitats that vary in character based on elevation above the main channel and specific geomorphic features, which may be linked to elevation and hydrology. Light et al. (1998) examined the quantity and variety of aquatic habitats within the floodplain in relation to river discharge. They concluded that during annual high water periods ($>1400\text{ m}^3/\text{s}$), 95% of the floodplain surface is inundated, connected to the main channel, and all habitats are flowing. As flows decrease, less of the floodplain terraces are inundated and higher-elevation streams cease to flow. At median annual flow ($464\text{ m}^3/\text{s}$), only 10% of the floodplain is connected to aquatic habitat, mostly backwater tupelo–cypress swamps. At median annual low flow $<1\%$ of the floodplain is inundated and there is little connectivity to the river. At very low flow, on average once every 20 years, only isolated aquatic habitats are present, again comprised mostly of backwater tupelo–cypress swamps. In an altered flow regime, as would certainly be the case if Atlanta were to withdraw large amounts of water from the Chattahoochee River, substantial disconnections between the floodplain and river would occur. Certainly there would be losses of bottomland forest as mortality and recruitment patterns of forest trees changed. Fish community structure would also likely change.

The Joseph W. Jones Ecological Research Center, an 11,800 ha ecological reserve located along the Flint River in southwestern Georgia, maintains active freshwater research that includes investigations of lime-sink wetlands, seasonally flooded riparian zones, swamps, streams, and rivers in the region. The lower Flint River and its floodplain, for example, have been the sites of studies that have resulted in a better understanding of the roles of intact, forested floodplains in mitigating the effects of large floods (Michener et al. 1998). During major floods, intact forested floodplains reduce sediment and nutrient loading and increase stream biotic integrity through inputs of coarse woody debris. Fauna such as fishes and mussels are extraordinarily resilient to extreme flooding, very likely because of flow mitigation and other effects (e.g., presence of refugia) of the intact Flint River floodplain. Other studies in this region

have indicated that reduction of particulate organic matter (POM) in rivers during reduced flow and drought conditions may result in long-term declines in secondary production for those food web components that depend on detrital resources (Golladay 1997, Golladay et al. 2000).

Human Impacts and Special Features

The Apalachicola River is the second largest source of flow into the eastern Gulf of Mexico. The basin is large, extending from the Gulf of Mexico to the Blue Ridge, and supports a large estuarine fishery in Apalachicola Bay, agricultural water needs, and river transportation, as well as a large and growing urban population around Atlanta. It is noted for its richness of fishes, herpetofauna, and mollusks. For years, river water quality has been in decline, but citizen-based efforts are now underway to reverse that trend, and improvements have been seen (Couch et al. 1996).

Recent U.S. Geological Survey studies of the ACF basin have concluded that land use has played an important role in determining the concentrations of nutrients and metals in stream water and sediments (Frick et al. 1998). $\text{NO}_3\text{-N}$, $\text{NH}_4\text{-N}$, and $\text{PO}_4\text{-P}$ concentrations are highest in tributaries draining catchments dominated by poultry production and urban and suburban land use. Nutrient signals are strongest during high flow conditions. Similar results were found for the main-stem Chattahoochee River downstream from Atlanta. Low nutrient concentrations predominated in parts of the river draining relatively undisturbed forested land as well as in the Chattahoochee River upstream from Atlanta and in the Apalachicola River near its mouth.

Although urban and suburban land use usually accounts for only a small fraction of basin area, their impacts on river water quality far exceed their proportionality in land area. As the percentage of urban land use increases within a watershed, nutrients, pesticides, trace elements, and organic compounds occur at higher concentrations in streams. Highest concentrations of Hg, Zn, Pb, and Cd in riverbed sediments occur in urban and suburban watersheds draining portions of metropolitan Atlanta and Columbus, Georgia, as well as in main-stem reservoirs downstream from Atlanta. Concentrations increase in direct proportion to the amount of industrial land and transportation corridors that occur in these watersheds. The source of these metals is storm-water runoff from impervious surfaces as well as

local and regional industrial emissions. Analyses of sediment cores from reservoirs downstream from urban areas reveal that metals reached maximum concentrations during the late 1960s and mid-1970s but began to decline after the mid-1970s.

River flow in the Chattahoochee–Flint system is heavily regulated by dams. Thirteen reservoirs occur on the Chattahoochee River, four of which are large (Couch et al. 1996). Two of the three dams on the Flint River have also created large impoundments. Dams are primarily used for hydropower, navigation, and domestic water supplies, particularly for Atlanta. Although annual flow has not been substantially altered, daily flow variations can be great as dams supplement power supplies during periods of peak electrical usage. For example, below the Buford Dam (Lake Lanier) in January 2004 the typical 24-hr fluctuation in gage height was 1.2 m and the 24-hr variation in discharge was about tenfold (approximately 18 to 180 m^3/s) (see Fig. 4.4).

Water use and water allocation are major issues within the basin. Surface-water withdrawals for use in Atlanta and groundwater withdrawals for irrigation, primarily in the Flint River basin, are already substantial, and future demand is expected to increase. In 1990, 7.9 million m^3 of water were removed from the ACF basin daily (Marella et al. 1993), most for use in Georgia (82%). In 2000, approximately 1.75 million m^3 were withdrawn for public water supplies in the Atlanta area, largely from surface water sources (<http://gaz.er.usgs.gov/gawater/waterusega.cfm>). In the Coastal Plain, particularly in the Flint River basin, groundwater extractions for irrigation have converted many permanent streams and wetlands into intermittent ones (S. Golladay, personal communication). Approximately 20% of surface- and groundwater extractions are not returned to either surface or ground water.

The ACF river basin and the Alabama-Coosa-Tallapoosa (ACT) river subbasin of the Mobile River system are currently linked in water-allocation conflicts that include Alabama, Georgia, and Florida. Rivers in both basins have headwaters in northern Georgia that are used as a water source for Atlanta. Downgradient portions of these rivers in Alabama and Florida discharge into economically and recreationally important estuaries. Water-supply needs to support the explosive growth of Atlanta have driven a request to withdraw significantly more water from the ACT and ACF than previous agreements have allowed. Atlanta's thirst, if satiated, is expected to have far-reaching negative effects on downgradient

communities and economic interests. To address this issue, the ACT and ACF compacts were passed by Congress in November 1997, “for the purposes of promoting interstate comity, removing causes of present and future controversies, equitably apportioning the surface waters of the ACT–ACF compact engaging in water planning, and developing and sharing common data bases.” Despite repeated efforts to complete negotiations in the years since the compacts were passed, formal agreements among the states were not yet completed in early 2004. In 2000, American Rivers listed the tristate river basins (ACT and ACF) among 13 of the most endangered rivers in the United States with threats from water withdrawals, dams, urban sprawl and nonpoint pollution. The ACT–ACF conflict is the first example of a water-allocation dispute of this scope in a humid, wet region of the world. It reinforces the view of many that maintenance of sufficient amounts of high-quality fresh water for human use is and will remain the most critical issue of the twenty-first century (e.g., Postel 1996, Postel et al. 1996).

PEARL RIVER

The Pearl River basin occupies an area of 21,999 km² between the Pascagoula and Mississippi rivers. The basin lies entirely in the Coastal Plain (CP), mostly in the state of Mississippi, but with a portion of the southwestern quadrant in Louisiana (Fig. 4.18). The headwaters arise in rolling hills in east-central Mississippi and the river forms at the confluence of Nanawaya and Tallahaga creeks. Other significant tributaries include the Yockanookanay and Strong rivers and Bogue Chitto Creek. Along much of its length the river is bordered by wide bottomland forests, backwaters, and floodplain swamps (Fig. 4.5). The timber industry and manufacturing of wood products dominate the economy of the lower basin, whereas poultry and soybeans are major parts of the upper basin economy.

Prior to the arrival of Europeans, the Choctaw Indians were the dominant Native Americans in the Pearl River basin. Their lands were bounded by Chickasaw Indians to the north, Creek Indians to

FIGURE 4.5 Pearl River near Slidell, Louisiana (PHOTO BY G. M. WARD).

the east, and the Mississippi River on the west. The Choctaw language is linguistically part of the Muskogean family of tribes, which included Creeks, Chickasaws, Seminoles, and Apalachi. The Muskogean tribes were thought to number more than 250,000 before contact with Europeans, and the Choctaw were considered the largest fraction. Population estimates for the Choctaws in 1685 were approximately 28,000 (Johnson 2000) but declined to 14,700 by 1790. The first European contact was the Hernando de Soto expedition of 1539 to 1543. After de Soto's travels through Mississippi, there was no European contact with interior southeastern Native Americans for more than 100 years. The second contact with the Choctaw was the French from Louisiana (Woods 1980) and the English from Charles Town (later Charleston, South Carolina) (Johnson 2000). The early English trade interest was for slaves, whereas the French needed a stable commodities trade for the survival of a new colony at Fort Biloxi. Pierre LeMoynes d'Iberville established the Biloxi colony in 1702 to counter the Spanish economic and military presence in Florida (McWilliams 1981, Thigpen 1965). During his early explorations along the Gulf Coast, d'Iberville is credited with naming the Pearl River after the pearls his soldiers found near the mouth of the river.

Recognizing the value of the Pearl River as a transportation corridor into the wilderness, the French explored and mapped the river in 1731, establishing a trading post near present-day Jackson, Mississippi. The wide river made shipping easy. By the 1830s, when cotton and timber industries began to flourish, steamboats plied the river far upstream, and the river was an invaluable economic asset for shipping crops to ports on the Gulf Coast (Thigpen 1965). The virgin hardwood and pine forests were cut and the river was used to raft logs from the interior down to mills on the coast (MDEQ 2000). Economic growth was halted by the Civil War, and the economy remained in ruins for decades afterward. The depressed economy greatly reduced river traffic, and the region soon depopulated. It was not until the mid-1900s that the region began to recover. A rejuvenated timber industry led this growth, but by that time the river was no longer the vital transportation corridor it once had been.

Physiography, Climate, and Land Use

The Pearl River drains Quaternary and Tertiary clastic sediments (primarily sand and clay) of the Eastern Gulf section of the Coastal Plain (CP) phys-

iographic province (Hudson and Moussa 1997). Sediments in much of the northern and southern portions of the basins are very sandy and porous, acting as aquifer recharge areas (Lang 1972). One physiographic district, the Jackson Prairie, is underlain by mostly clay formations, permitting the siting of the basin's major impoundment, Ross Barnett Reservoir.

Two terrestrial ecoregions lie in the basin. Approximately the upper half of the basin is within the Southeastern Mixed Forests. Dominant vegetation is hardwoods, such as oaks, sweetgum, black gum, water tupelo, beech, hickory, and yellow poplar, as well as loblolly, shortleaf, and longleaf pine. The lower half of the basin is covered by the Southern Conifer Forests. Canopy vegetation is primarily loblolly, longleaf, and slash pine, as well as live oak, magnolia, pecan, sweetgum, black gum, and water tupelo.

The climate in central and southern Mississippi is humid subtropical. Annual rainfall is high, averaging 132 cm in the northern portion of the basin and 163 cm near the Gulf Coast (Green 2000). November through April are the wettest months (11 to 15 cm/mo), whereas August through October are the driest (8 to 9 cm/mo) (Fig. 4.19). Mean annual temperature at Jackson, Mississippi, is 17.7°C, with mean monthly temperature exceeding 27°C in midsummer and falling to 7°C in January (see Fig. 4.19).

Much of the Pearl River basin remains forested (58%), with 25% agriculture, 12% wetland, and <2% urban or suburban (G. M. Ward, unpublished data). The main population center is the capital city, Jackson, with a regional population of 202,000. Mississippi is one of the least urbanized states in the United States and, in general, the basin is not densely populated, with approximately 31 people/km².

River Geomorphology, Hydrology, and Chemistry

The Pearl River arises in Neshoba County, Mississippi, flowing southwesterly for 209 km to Jackson. The Ross Barnett Dam is located about 5 km northeast of Jackson, creating the only large impoundment in the basin (see Fig. 4.18). Below Jackson, the river turns south and continues for an additional 375 km before dividing into two major distributaries, the East and West Pearl rivers. This final 75 km is a complex of interconnected channels that eventually empty into Lake Borgne, which is connected to the Gulf of Mexico via the Mississippi Sound near Slidell,

Louisiana. The lower 98 km of the river forms a boundary between Mississippi and Louisiana.

The Pearl River, a 6th order river, falls 210 m from its headwaters in east-central Mississippi to the Gulf of Mexico coast, with an average slope of 19 cm/km. The channel varies in width from 30 to 300 m (Wiche et al. 1988) and is characterized by tortuous bends, shoals, heavily vegetated banks, and other obstructions that restrict flow. The river bed is composed primarily of sand and silt. The valley bottom is comprised of multiple interconnecting channels separated by densely vegetated islands. Many channels are stagnant at low water but are active during periods of high stage (Hudson and Moussa 1997).

The mean daily discharge of the Pearl River, 373 m³/s, makes it the fourth largest runoff reaching the eastern Gulf of Mexico. As with other basins in the region, flows are high from December to May and low through summer and fall (see Fig. 4.19). The highest mean monthly runoff occurs in March and the lowest in September. Although the precipitation pattern is not strongly seasonal, periods of low flow coincide with slightly lower rainfall, maximum temperatures, and higher evapotranspiration.

Because the Pearl River drains Coastal Plain sediments, ionic strength of the water is not high. Specific conductance values range from 50 to 150 μ S/cm (<http://nwis.waterdata.usgs.gov/la/nwis/gwdata> 2003). Long-term average data from a USGS water-quality station at Bogalusa, Louisiana, reveal that pH was 6.5, PO₄-P was 0.026 mg/L, and NO₃-N + NO₂-N was 0.213 mg/L. Although the Pearl River was once described as crystal clear, the upper two-thirds is now often turbid (http://www.ms.water.usgs.gov/ms_proj/eric/pearl.html 2003). As with other rivers draining into the Gulf of Mexico, the majority of sediment transport in the Pearl occurs during frequent moderate discharge events (Hudson and Moussa 1997). In the lower portion of the basin, mean monthly water temperature varies between 10°C and 26°C.

River Biodiversity and Ecology

The Pearl River basin is located entirely within the Mississippi Embayment Freshwater ecoregion (Abell et al. 2000). The ecoregion is generally noted for a large richness of fishes and moderate richness in mussels and crayfishes. Although the Mississippi Embayment Freshwater ecoregion extends over an area much larger than just the Pearl River basin, the biological characteristics of the Pearl River coincide closely with those of the larger ecoregion. Fish spe-

cies richness in the basin is particularly high, with 119 species known to occur. Crayfish endemism is also high.

Plants

Certainly the most visually striking aspect of the Pearl River is the vast riparian bottomland forests and riparian swamp wetlands that flank the river. Because the river lies in Coastal Plain sediment for its entire distance, such forests trace the entire length of the river but enlarge substantially below Jackson. The Mississippi Natural Heritage Program (2002a) has identified 63 nonmarine plant communities statewide, categorized according to the dominant species and habitat characteristics. The three major categories that include riverine-related vegetation include Riverfront Forests/Herblands, Wet Palustrine, and Swamp Forests. Within the Riverfront Forests/Herblands category, the three most abundant communities are dominated by eastern cottonwood, black willow, river birch, sycamore, and silver maple. The Wet Palustrine category is composed of several bottomland hardwood forests communities. Dominant species are laurel oak, willow oak, water oak, sugarberry, American elm, green ash, overcup oak, and water hickory. Swamp Forest is composed of eight communities that have standing water for much of the year and are dominated by various combinations of bald cypress, pond cypress, black gum, water hickory, overcup oak, water tupelo, sweetbay, red maple, and slash pine.

Invertebrates

Historically, the Pearl River contained an abundance of mussels and crayfishes. The Mississippi Natural Heritage Program (2002b) lists 51 species of unionid mollusks and 36 species of crayfishes from the state of Mississippi on its special animals tracking list, which indicates that these species are of special concern because of their rarity or vulnerability to habitat perturbation. The list included aquatic insects as well, with two mayflies, ten dragonflies, two stoneflies, and one caddisfly. Recent preliminary surveys in the upper Pearl and Pascagoula rivers (Haag and Warren 1995) suggest perhaps 18 species of mussels could be present in the Pearl River drainage. Some commonly encountered species would be the pondshell, giant floater, and yellow sandshell. Given the substrate and flow similarities among Coastal Plain rivers along the eastern Gulf of Mexico, invertebrate communities from the Pearl are likely to be similar to those in the Pascagoula River. Sandy sediments, woody debris, and accumulations

of fine and particulate organic matter are substrates where one would likely encounter the majority of riverine aquatic insects. Particularly abundant would be the mayflies *Stenonema*, *Baetis*, *Caenis*, *Tricorythodes*, and *Isonychia*. Stoneflies, such as *Paragnetina*, *Neoperla*, and *Acroneuria*, and caddisflies, such as *Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Chimarra*, and *Ceraclea*, would also be numerous here.

Vertebrates

The Pearl and Pascagoula rivers of southern Mississippi mark the westernmost extent of many fish species associated with the Mobile River basin and adjoining coastal river basins (Swift et al. 1986, Mettee et al. 1996, Ross 2001). The Pearl River and lower Mississippi River also form a biogeographic divide between several closely related sister species (e.g., blue sucker and southeastern blue sucker). The fish community of the Pearl River consists of 18 families and 119 species that occur in the nonestuarine portion of the river (Ross 2001). Several estuarine species, particularly killifishes and gobies, occur in the lower, brackish-water portions of the river. Migratory anadromous and catadromous species found in the Pearl River include Gulf sturgeon, American eel, and Alabama shad.

The families Cyprinidae, Percidae, Ictaluridae, and Centrarchidae comprise over 66% of primary freshwater fishes found in the Pearl River (Ross 2001). The Cyprinidae (28 species) and Percidae (23 species) are the dominant families found in this system. The most common cyprinids are the black-tail shiner, silverjaw minnow, cypress minnow, speckled chub, silver chub, emerald shiner, and bullhead minnow. Common percids include harlequin darter, brighteye darter, speckled darter, dusky darter, river darter, Gulf logperch, and saddleback darter. Other darters less frequently encountered in the Pearl River drainage, either because of their preference for faster, deeper water or because of population reductions, include the crystal darter, freckled darter, and pearl darter. The Pearl darter is endemic to the Pearl and Pascagoula River drainages; however, populations in the Pearl River may be extirpated because of extensive shoreline development and cultivation (Ross 2001).

Although the Centrarchidae (sunfishes and basses, 15 species) and Ictaluridae (catfishes, 13 species) are not as diverse as the Cyprinidae and Percidae, these fishes are widespread throughout the Pearl River drainage. All species of sunfishes, basses, and catfishes are the object of recreational fisheries

in the Pearl River drainage, although most fishing effort is focused on largemouth bass, black and white crappie, various sunfishes, and channel and blue catfish. Ross Barnett Reservoir, on the upper Pearl River, has produced state fishing records for smallmouth buffalo, paddlefish, and bowfin (www.mdwfp.com/fishing_records.asp 2002).

The Pearl River, its tributaries, and the basin support many species of reptiles, amphibians, mammals, and birds. Reptiles associated with the Pearl River proper include American alligator, alligator snapping turtle, common snapping turtle, stripe-neck musk turtle, ringed map turtle (endemic to the Pearl River; federally listed as threatened), Gulf Coast spiny softshell turtle, and cottonmouth. A variety of amphibians, including frogs, salamanders, newts, sirens, and amphiuma, are found throughout the basin; mudpuppies can be found in the main-stem Pearl River. Mammals commonly found in the river include raccoon and river otter. Three Mississippi Wildlife Management Areas (WMA) (Nanah Waiya, Pearl River, and Lower River) and the Bogue Chitto National Wildlife Refuge (NWR) offer opportunities for bird watching throughout the Pearl River basin. Lower River WMA and Bogue Chitto NWR provide feeding, resting, and winter habitat for many migratory bird species, including brown and American white pelicans, osprey, and cormorants. National attention has been given recently to the swamps of the lower Pearl River because of a putative sighting of an ivory-billed woodpecker, which were thought to have been extinct since 1951. The initial sighting remains unconfirmed, and subsequent expeditions into this area to locate ivory-billed woodpeckers have been unsuccessful.

Ecosystem Processes

No ecosystem scale studies have occurred on the Pearl River. However, given the nature of the river, some ecosystem properties can be assumed. South of Jackson, along the middle Pearl River, lies a wide floodplain of bottomland forests and swamps that is still substantially connected with the main-stem river. However, in the lower Pearl, numerous hydrologic-control structures designed for flood protection occur in low-lying areas along the river near Picayune, Mississippi. The bottomland forests have historically been very productive. Descriptions of Native American life in the bottomland forests along the Pearl River refer to thousands of springs and swamp streams teeming with fishes and an abundance of bear, fox, panther, deer, beaver, and wolf, among many others (Thigpen 1965, Bremer n.d.). The river

runs deep, and often very turbid, particularly after storms. The streambed substrata consist of sand and fine organic material, but coarse woody debris is present along the river banks. The majority of primary production and any intense invertebrate secondary production would likely occur along the river edges and in the floodplain during periods of inundation. The many snags along the banks and the high floodplain connectivity would provide an abundance of habitat and cover for fishes and invertebrates.

Human Impacts and Special Features

The Pearl River is an example of a large coastal river arising within and flowing through unconsolidated Coastal Plain sediments. Relief in the basin is low, thus river channel gradients are also low. High annual precipitation, a large volume of runoff, and low relief lead to frequent flooding. Wide floodplain forests exist all along the length of the river. Weathering of the largely silicate sediments results in low ionic and nutrient content in river waters under natural conditions. Despite the relatively low density of human population, past human activity in the basin has changed the river water from one noted for its clarity to one noted for the sediment it carries. Despite this fact, the river and its adjacent bottomland forest retain a sense of wildness and allure. Indeed, the lower Pearl River is an incredible maze of branching channels winding through a labyrinth of wild cypress swamps and marshlands.

Although the Pearl River does not exhibit extensive fragmentation as do many other eastern Gulf Coast rivers, significant river modifications have taken place. Near Jackson, the Ross Barnett Reservoir was constructed on the river main stem to provide for recreation, flood control, and water supply. It has a surface area of 135 km² and a storage capacity of 382 hm³ (Spiers and Dalsin 1972). In the lower basin, periodic flooding on the Pearl River has long been an important regional issue, but only in the past several decades has property loss been significant. Major engineering projects on the lower Pearl River, completed by the U.S. Army Corps of Engineers, effectively rerouted river flow away from economically sensitive areas. However, following completion of the diversion project, the original east river channel dried up completely during low flow periods of the year. The USACE has now installed weirs to protect cities but also maintains year-round flow in the East Pearl River (MDEQ 2000).

In general, water quality is rated as fair in the upper Pearl basin and fair to good in the lower basin

(MDEQ 2000). However, like most rivers in North America, water quality in the Pearl River has been substantially impacted by human activities. The main pollutants of concern in the Pearl River basin included siltation, organic enrichment, excess nutrients, pesticides, and pathogens (MDEQ 2000). Other listed causes of significant impairment to streams in the basin were mercury, low pH, and PCBs. Both nonpoint-source inputs, such as agriculture, timber, and urbanization, and point-source inputs, such as industrial, manufacturing and municipal discharges, oil and gas production, and mining, are important components of water-quality impairments in the basin.

Row-crop agriculture and timber industries have long histories in the basin. Improper management of forages, corn, soybeans, and cotton has led to substantial inputs of sediments, nutrients, and pesticides into streams and rivers. During the past 50 years, the amount of row-crop acreage has decreased, replaced by timber production. The primary nonpoint-source input related to the timber industry in Mississippi is sediment loading to streams from forest roads, skid trails, and other activities that expose mineral soil (MDEQ 2000). More recently, negative water-quality impacts of urbanization and confined animal feeding operations, such as poultry and cattle, have been increasing in prominence. The Pearl River basin remains mostly rural, but growth throughout the basin, particularly around Jackson, has significantly increased the loading of fertilizer, pesticides, oils and greases, and heavy metals. Sediment loading from construction sites is perhaps the most serious urban impact problem (MDEQ 2000). Eroding stream channels further increase sediment loads and result in more river habitat losses.

Municipal and industrial point-source discharges into the Pearl River are also an important component of water-quality degradation within the basin. The majority of outfalls on the river are located south of Jackson (MDEQ 2000). North of Jackson, the river is less impacted because the city draws the majority of its municipal water supply from Ross Barnett Reservoir, which lies on the river main stem. At present, 122 industrial and 5 industrial park dischargers hold NPDES permits within the basin, which include timber products and energy production, chemical, agricultural, and metal manufacturing, oil and gas producers, and sand/gravel mines. Hazardous waste sites also pose potentially serious localized health problems within the basin (MDEQ 2000). There are 230 known sites where hazardous waste releases (both planned and unplanned) have

FIGURE 4.6 Lower Suwannee River (PHOTO BY TIM PALMER).

occurred, and another 637 facilities that generate quantities of hazardous materials that are stored on site. At present, contamination is largely a surface-water issue in the Pearl River basin, but the potential for groundwater contamination remains a threat.

SUWANNEE RIVER

The Suwannee River is a 6th order river that originates as a blackwater stream in the Okefenokee Swamp in southern Georgia (Fig. 4.20). From there the river flows in a generally southward direction for 394 km through north Florida and empties into the Gulf of Mexico. The drainage network is composed of the upper Suwannee plus three major tributaries, the Alapaha, Withlacoochee, and Santa Fe rivers. The Withlacoochee and Alapaha both arise in southern Georgia, flowing south-southeast to their confluence with the upper Suwannee near Ellaville, Florida. Below Ellaville, the middle Suwannee River runs south and east for approximately 158 km to its confluence with the Santa Fe River below the town of Branford, Florida. Below this junction, the lower

Suwannee widens and the floodplain broadens before the river reaches the Gulf of Mexico (Fig. 4.6). Below the confluence with the Withlacoochee, the Suwannee is navigable to Ellaville, once the head of commercial steamboat navigation.

Before the arrival of the Spanish, approximately 35 local chiefdoms, referred to as the Timucua, occupied land between the Apalachee tribes on the west and the Atlantic Ocean on the east (Milanich 2000). The Suwannee River cultures are thought to have been established more than a thousand years before the arrival of the Spanish. Linguistic studies suggest that the Timucua were derived from South America, but the archaeological evidence clearly indicates a southeast origin. Prior to the arrival of the Spaniards there were an estimated 200,000 Timucua occupying the northern third of peninsular Florida as well as southeastern Georgia as far as the Altamaha River. They farmed in the summer and in winter utilized the bays and rivers for shellfish and snails. The Timucua were the first tribes in what became known as La Florida to be encountered by the Spanish expeditions of Navarez and de Soto. The Timucua had continual contact with Europeans until their demise in the mid-

1700s, caused primarily by other natives, who sold the Timucua as slaves to the English.

Physiography, Climate, and Land Use

The Suwannee River basin lies within the Coastal Plain (CP) physiographic province, an area with relatively little relief. Upper reaches of the Suwannee drainage lie within the Tifton uplift and Okefenokee basin physiographic units. The Tifton uplift is a plain of low relief with uplands lying 15 to 60 m above relatively narrow valleys. The Okefenokee basin is characterized by very low relief, numerous and extensive swamps, and local sand ridges. Sediments of the upper Suwannee River basin are of marine origin and typical of Coastal Plain basins. They are highly weathered and poorly consolidated, dominated by sands, clays, and gravels of Miocene to Holocene age (Environmental Protection Division 2002). Soil types in the Suwannee River basin vary depending on elevation and underlying geology. Soils in the Alapaha River basin are well-drained, with loamy-sand surface soils and loamy subsoils, whereas those in the Withlacoochee are less well-drained spodosols (sandy soils where a layer of aluminum and organic matter has accumulated due to the poor drainage). Further eastward in the Okefenokee Swamp, soils are highly organic, extremely acid, and saturated or covered with water much of the year.

The hydrological and biological characteristics of the Suwannee River are intimately tied to the physiography and underlying geology of the region. What is now the panhandle and peninsula of Florida is the emergent portion of a larger geologic feature called the Floridan Plateau, which consists of sand, clay, and limestone strata to a depth of a kilometer or more (Rosenau et al. 1977). The upper part of these limestone and dolomite deposits contains an extensive aquifer that covers all of Florida as well as portions of southeast Alabama, southern Georgia, and southwest South Carolina. In Florida it is known as the Floridan aquifer. Principally an artesian aquifer, the Floridan aquifer contains large volumes of solution channels, caverns, and sinkholes through which surface water exits and enters the system. Impermeable surface deposits confine much of the Floridan aquifer, but in the Suwannee and nearby basins these deposits have been eroded to expose large numbers of springs emanating from the underlying aquifer.

The Suwannee basin lies completely within the Southeastern Conifer Forests terrestrial ecoregion. In Georgia, the basin is contiguous with well-known longleaf pine forests of southeastern Alabama and

southwestern Georgia. However, little is left of the native stands, and the region now contains many species of pine as well as mixed oak–pine forests. Much of the original conifer and hardwood forest has been replaced by commercial forests, largely converted into commercial pine species. In the upper Suwannee basin in Georgia, 62% of forestland is in commercial forest (Environmental Protection Division 2002). In Florida, the upper Suwannee was historically dominated by north Florida flatwoods, upland hardwood hammocks, longleaf pine–turkey oak hills, and swamp hardwoods/shrub bogs (SRWMD 2001). The middle Suwannee regions contained longleaf pine–turkey oak, mixed hardwoods and pine, upland hardwood hammocks, and swamp hardwoods.

Climate in the Suwannee River basin is characterized by hot summers, mild winters, and abundant rainfall. Air temperature patterns for the Suwannee River basin are similar to that of the other eastern Gulf basins. Mean annual temperature for the basin is 20.2°C and ranges from 18.3°C in upper portions of the basin to 22.2°C in the south. Typical mean daily air temperature for the warmest months, July to August, is 27°C, and for the coolest month, January, is 11°C (see Fig. 4.21). Mean annual precipitation (134 cm) is similar to other eastern Gulf basins and ranges from 114 cm/yr in Georgia to 142 cm/yr in Florida. Precipitation occurs as rainfall, and basinwide is relatively evenly distributed throughout the year, although midsummer to late fall may be somewhat drier (see Fig. 4.21). Interestingly, near the Gulf Coast (Wilcox, Florida), numerous convectional thunderstorms in summer form a pattern whereby maximum precipitation occurs from June through August.

The eastern headwaters of the Suwannee basin are protected within the Okefenokee Wildlife Refuge. South of the refuge are extensive swamps, little agriculture, and little urbanization. In the western headwaters, the Withlacoochee and Alapaha rivers, agriculture is much more abundant, and there are many small cities. Some subbasins are up to 80% agriculture. Although agriculture has had little impact on many main-stem riparian areas, smaller tributaries have had substantial riparian vegetation removed. Much of the Suwannee basin remains forested (38%), although a significant fraction is in managed pine plantations (G. M. Ward, unpublished data). Of the remainder, 30% was in agriculture, 22% was wetland, and <1% urban or suburban. The main population centers are Lake City, Florida, and Valdosta, Georgia.

River Geomorphology, Hydrology, and Chemistry

Knowledge of the underlying geology of the Suwannee River basin is important to understanding its geomorphology, hydrology, and water chemistry. The Suwannee River has a rather complex geomorphology reflecting headwaters that lie in either Coastal Plain uplands, swamps, or spring runs. The headwaters of the upper Suwannee River arise from the Okefenokee Swamp. The main-stem river (upper Suwannee) and two major western tributaries, the Withlacoochee and Alapaha rivers, all flow initially over low-permeability sediments in Georgia that limit groundwater recharge and permit permanent flow. Streambed sediments in the Alapaha and Withlacoochee rivers are composed of fine sand or mud, but where the stream has eroded down to the underlying rock the streambed may be composed of limestone bedrock and cobble. Downstream of the Georgia–Florida boundary the sediments underlying the riverbed in all channels change to a porous, karstic formation called Ocala limestone. The formation contains numerous solution channels and sinkholes within the main channels. At low flow, sinkholes in the Alapaha and Santa Fe rivers absorb all of the flow from their upper segments, leaving the lower portion of these tributaries dry for several months at a time. From the point of groundwater recharge, the stream emerges several kilometers downstream (U.S. Study Commission 1963, SRWMD 2001). The main-stem Suwannee River and many of its tributaries have deeply incised channels where the stream has cut through the shallow overburden and into the underlying limestone. Limestone outcrops line the banks of the Upper Suwannee, and the riverbed may be sandy or limestone bedrock. White sand beaches often occur in the bends of the river. Low falls may occur where limestone shoals have been highly eroded. Channel slopes in the Suwannee are quite low. From the outlet of the Okefenokee Swamp at 28 m asl the river falls 13 m over the first 80 km (16 cm/km) to a point near Ellaville. Over the last 314 km to the Gulf of Mexico channel slope is only 5 cm/km.

The Suwannee River is the second largest river in Florida, with a mean annual flow of 294 m³/s. High flows occur in mid to late spring and low flows in November and December (see Fig. 4.21). The upper reaches of the Suwannee tend to have more flow variability, whereas the lower reaches are more stable, primarily a result of the hydrologic buffering offered by the many springs that enter the middle and lower

Suwannee (Mattson et al. 1995). At times flow in the lower Suwannee consists entirely of spring inputs. Among the eastern Gulf Coast rivers described in this chapter, the Suwannee River has the lowest annual runoff (36 cm) and the lowest runoff as a percentage of rainfall (27%). At least two explanations are possible. One is a higher rate of evapotranspiration. Given the amount of wetland habitat and the warm, long summers, higher evapotranspiration is certainly a possibility, although studies such as Bidlake et al. (1995) from peninsular Florida would not support a rate higher than other eastern Gulf basins. Another possibility is greater infiltration into the underlying aquifer and subsequent subsurface transfer of water to other basins or the sea. Certainly, surface watershed boundaries in the Suwannee River are not likely to coincide with subsurface water divides.

The chemistry of Suwannee River water varies substantially from north to south along the river's course as a result of changes in the underlying geology. Water entering the Suwannee River from the Okefenokee Swamp is characteristic of the swamp itself, highly stained (200 to 600 Pt/Co units), acidic (pH 3.2 to 7.4), low alkalinity (0.50 to 23 mg/L as CaCO₃), and low conductivity (50 to 122 μ S/cm) (Mattson et al. 1995). Water from the Withlacoochee, derived from runoff in upland areas of southern Georgia, has a lower color (10 to 250), is circumneutral (pH 6.6 to 7.4), with higher alkalinity (15 to 120) and conductivity (82 to 258). As the river flows downstream, spring inputs contribute substantial quantities of calcareous water containing high concentrations of calcium, magnesium, and bicarbonates, which increase the pH (7.1 to 8.3), alkalinity (110 to 160), and conductivity (138 to 364) in downstream reaches. Historical patterns for nitrogen and phosphorus are more difficult to discern due to the long-term loading from agricultural and industrial sources along the river. From 1989 to 1991, total N in the lower Suwannee ranged from 0.31 to 1.69 mg/L and total P ranged from 0.05 to 0.57 mg/L.

River Ecology and Biodiversity

The Suwannee lies entirely within the Florida freshwater ecoregion (Abell et al. 2000). The northern boundary of this ecoregion follows the northern edge of the Suwannee River basin and includes coastal rivers west to the Apalachicola River and all of peninsular Florida. The Suwannee River is typical of the ecoregion in containing a wide variety of habitats, including upland and lowland streams, swamps, and

springs. Unlike other eastern Gulf rivers, the numerous large springs derived from the Floridan aquifer harbor a rich and endemic crayfish fauna. But in contrast to other rivers described earlier, the fish and mollusk fauna of the Suwannee are not particularly rich.

Algae and Cyanobacteria

Large spring-fed streams in north central Florida, such as Ichetucknee Springs, have long been known for their abundance and high productivity of algae and submerged macrophytes. Spring-fed tributaries in the Suwannee drainage were included in the periphyton classification scheme of Whitford (1956), in which the lower Santa Fe River and Ichetucknee Springs were characterized as a *Cocconeis-Stigeoclonium* type. Within the type, diatoms dominated, with the genus *Stigeoclonium* a subdominant. More recent studies by Mattson et al. (1995) in the lower Suwannee and Santa Fe rivers revealed that algal communities attached to glass slides were heavily dominated by diatoms, particularly *Achnanthes*, *Cocconeis*, *Gomphonema*, *Melosira*, *Navicula*, and *Synedra*. Green algae were represented by *Protoderma viride*, *Scenedesmus acuminatus*, and *Stigeoclonium* sp.

Plants

The large spring-fed tributaries in the Suwannee drainage also have large stands of aquatic plants. For example, the Ichetucknee Springs complex contains 12 species of submerged macrophytes (Nordlie 1990). The lower Santa Fe River, into which the Ichetucknee Springs complex drains, is dominated by muskgrass (the multicellular alga *Chara* spp.), loose watermilfoil, American eelgrass, and springtape (Mattson et al. 1995).

Perhaps the most visible characteristic of the riparian vegetation along the Suwannee River is cypress trees. Bald cypress can be found along the main channel and in sloughs, backwaters, and tributaries along the length of the Suwannee, Alapaha, and Santa Fe rivers (Duryea and Hermansen 2000). A recent study concluded that 77 tree, shrub, and woody vine species were present in the lower Suwannee River riparian and bottomland areas, a high species richness relative to other wetland forests (Light et al. 2002). Fourteen forest types were identified, which could be generalized into three categories: riverine high bottomland hardwoods dominated by live oak; riverine low bottomland hardwoods dominated by five species of oak, the most important being laurel oak; and riverine

swamps, occurring in the lowest and wettest areas, dominated by bald cypress.

Invertebrates

Sand, wood, submerged macrophytes, and limestone outcrops constitute the primary substrates available for invertebrates in the Suwannee River and its major tributaries. In the upper tributaries, mayflies, such as *Stenonema*, *Caenis*, *Baetis*, *Tricorythodes*, and *Habrophlebiodes* are commonly found. Stoneflies, such as *Neoperla*, *Acro-neuria*, and *Perlinella*, as well as caddisflies, such as *Hydropsyche*, *Cheumatopsyche*, *Macrostemum*, and *Chimarra*, are abundant (Environmental Protection Division 1973). Hester-Dendy samplers from the upper and lower Santa Fe River accumulated 20 to 40 taxa, consisting primarily of chironomid midges, mayflies (Heptagenidae, Tricorythodidae, and Baetidae), and hydropsychid caddisflies (Mattson et al. 1995). Samplers in spring-influenced reaches also included *Elimia*, hydrobiid snails, limpets, and crustaceans, particularly *Hyallolella azteca*. Communities on woody substrates were substantially more species rich than softer, sandy substrates. Sandy substrates in the lower Santa Fe River harbored chironomids, oligochaete worms, and mollusks, including *Campeloma* and *Corbicula*, as well as sphaeriid (*Sphaerium*, *Musculum*) and unionid clams (*Elliptio*, *Villosa*). Macrophyte beds were dominated by chironomids, particularly *Dicrotendipes*, mayflies (*Baetidae*, *Tricorythodes albilineatus*), and *H. azteca*. The Suwannee River system also harbors a troglobytic fauna, found in the many springs and sinkholes (Nordlie 1990). Most of the fauna are crustaceans (Amphipoda, Isopoda, and Decapoda) and have highly restricted distributions. Biodiversity in the Suwannee River appears to be greatly influenced by inputs from calcareous streams. Certain taxa groups, particularly mayflies, mollusks, and oligochaetes, exhibit increased species richness and increased abundance in waters with increasing alkalinity.

Vertebrates

The Suwannee River forms a divide between the fish faunas of the panhandle and peninsular Florida; approximately 50% of Florida's native freshwater fish species occur in or west of the Suwannee River drainage (Bass 1991). Species differences between the two areas are due to the loss of certain species, especially minnows, in peninsular Florida (Bass 1991). Seventeen families and 81 species of freshwater and estuarine fishes are found in the Suwannee River

drainage (Swift et al. 1986, Page and Burr 1991, Abell et al. 2000). There are no endemic fish species in the Suwannee River; the Suwannee bass, however, is restricted to the Suwannee River and Ochlockonee River drainages (Page and Burr 1991). Several species of euryhaline fishes, particularly topminnows and killifishes, occur in the lower portions of the river. Migratory anadromous and catadromous species found in the Suwannee River include Gulf sturgeon, striped bass, American eel, and Alabama shad; the Suwannee River is the easternmost limit in the distribution of Alabama shad (Page and Burr 1991).

The Cyprinidae (12 species), Centrarchidae (14 species), and Ictaluridae (9 species) comprise approximately 60% of primary freshwater fishes found in the Suwannee River basin; the redbreast sunfish is the most numerically abundant fish in this river (Bass 1991). All species of sunfishes, basses, and catfishes are the focus of sport fisheries. The Suwannee River has produced state fishing records for the Suwannee bass, redbreast sunfish, and spotted sunfish (<http://floridafisheries.com/Fishes/sci-name.html> 2003).

There are no endemic species of reptiles or amphibians in the Suwannee River; the Suwannee cooter, however, has a restricted distribution and is found primarily in the Suwannee River south to the vicinity of Tampa Bay (Conant and Collins 1991). Reptiles commonly found in the Suwannee River include the American alligator, alligator snapping turtle, Florida softshell turtle, Florida snapping turtle, Suwannee cooter, Florida cooter, Florida redbelly turtle, Florida cottonmouth, Gulf saltmarsh snake, redbelly, banded, brown, and Florida green water snakes, and the North Florida swamp snake. A variety of amphibians, including frogs, salamanders, newts, sirens, and amphiuma, are found throughout the Suwannee River drainage (Conant and Collins, 1991).

Mammals commonly found in the Suwannee River include beaver (found primarily in the upper river basin), mink, raccoon, river otter, and the West Indian manatee. Manatees are especially common during the winter at Manatee Springs State Park, which provides a boardwalk and viewing deck for observation of these animals. Suwannee River State Park lies at the confluence of the Suwannee and Withlacoochee Rivers; beavers are commonly seen in this area.

A number of migratory and resident birds can be found in the Suwannee River drainage, including brown and American white pelicans, osprey, cormorants, anhingas, swallow-tailed kites, and bald eagles.

Ecosystem Processes

A number of studies of primary productivity of spring runs in northern Florida have been published. Although located in a drainage adjacent to the Suwannee River, Silver Springs is perhaps the most notable spring study, because it was one of the first to examine primary production in a large flowing-water system (Odum 1957a). First-magnitude springs here are noted for stable temperatures, nutrient-rich water, and stable hydraulic conditions. It is exactly these conditions that lead to high standing-stock biomass and high productivity of aquatic macrophytes and periphyton. Primary productivity in Silver Springs was calculated to be $>3000 \text{ g C m}^{-2} \text{ yr}^{-1}$, mostly by a single aquatic plant population, the awl-leaf arrowhead, and its attached epiphytes (Odum 1957a). Gross primary production measurements from five first-magnitude springs in northern Florida (including springs within the Suwannee basin) ranged from 2 to $24 \text{ g C m}^{-2} \text{ d}^{-1}$ (Nordlie 1990, recalculated from Odum 1957b). From Manatee Springs, a first-magnitude spring in the lower Suwannee, a value of $7.28 \text{ g C m}^{-2} \text{ d}^{-1}$ was reported. From these and other studies, there is ample evidence that Florida spring ecosystems are among the more productive aquatic ecosystems in the world (e.g., Duarte and Canfield 1990).

Northern Florida freshwater swamps also exhibit high primary productivity. Typically, floodplain swamps exhibit the highest net primary productivity, whereas cypress swamps, supplied primarily by rainfall, are much less productive. Spring-run swamps are intermediate. Regulation of primary productivity appears to be related to nutrient delivery rates through stream flow. Riverine and floodplain swamps receive nutrient subsidies from overbank flows, and spring-run swamps from groundwater (Ewel 1990). Primary productivity (above ground net primary production) in Florida cypress swamps ranges from 700 to $1600 \text{ g m}^{-2} \text{ yr}^{-1}$ (Mitsch and Gosselink 2000). Hydrological, biochemical, and productivity studies in the Okefenokee Swamp indicate that secondary productivity of bacteria and fishes is also high in this blackwater ecosystem (Blood 1981).

Human Impacts and Special Features

The Suwannee River is distinctive among eastern Gulf Coast rivers in that its headwaters arise in a large swamp ecosystem, the Okefenokee Swamp. The Okefenokee is a 2250 km^2 wilderness that has been protected since 1937 and is now part of the National Wilderness Protection System. Although there were

attempts to commercialize the Okefenokee Swamp in the late 1800s and early 1900s, all failed. However, remnant canals and other commercial infrastructure of the time can still be seen. Ecological habitats in the Okefenokee include deep pools of highly stained water with cypress trees dominant, floating islands (hammocks) covered with trees and shrubs, open grassland prairies, and mats of floating peat. The Okefenokee is drained by two rivers, the St. Marys and the Suwannee, with most of the water carried by the latter.

The signature characteristic of the Suwannee River is the large number of springs that flow into the river. These springs greatly influence river hydrology, geochemistry, and biota. The upper, middle, and lower Suwannee as well as major tributary rivers are fed by hundreds of large and small springs that flow from the underlying Floridan aquifer. At least 97 have been named, including eight first-magnitude springs (those with a discharge $>2.8 \text{ m}^3/\text{s}$). Of the 27 first-magnitude springs in Florida, 30% are in the Suwannee basin. Some of the more well-known springs are Suwannee Springs, Manatee Springs, and Ichetucknee Springs. Recharge of these aquifers occurs in southern Georgia, the northern Florida panhandle, and central Florida.

Despite the pristine nature of much of the Suwannee River basin, serious environmental challenges exist, particularly nitrate and phosphate contamination of surface and ground water. Phosphate rock is mined in the upper Suwannee basin in Florida, leading to substantial surface-water loadings from the mining operations. Substantial loading of phosphate also occurs in the Withlacoochee River as a result of agricultural runoff. High concentrations of nitrate have been found in surficial aquifers and surface waters of the Suwannee River. Nitrate concentrations in excess of the EPA drinking water standard (10 mg/L) have been found in 33% of groundwater wells tested in agriculturally dominated landscapes in the Suwannee River basin (Berndt et al. 1998). Concentrations were highest in shallow wells in agricultural settings as compared to mixed-use, forested, or urban settings. Wells near row-crop agriculture and confined animal feeding operations were most impacted. Fortunately, these shallow groundwaters lie above the upper Floridan Aquifer, which serves as the drinking-water source for many residents of the basin. It is, however, obvious that the drinking-water aquifer for this region is at serious risk of contamination. Surface-water nitrate concentrations tended to be lower than groundwater, but in agricultural settings, such as the Withlacoochee

River, surface-water nitrate concentrations were up to 0.25 mg/L. Nitrate loading to the lower Suwannee River from springs is a major concern. During low-flow periods spring input can contribute 100% of downgradient discharge. Many of these springs contain nitrate concentrations between 1 and 2 mg/L, raising the possibility of surface-water degradation in this portion of the Suwannee, highly prized for its recreational value. Interestingly, at high flows the river can recharge the underlying Floridan aquifer, potentially introducing contaminants to the groundwater directly from the river (Crandall et al. 1999).

In order to protect and conserve the Suwannee River from environmental threats, the Suwannee River Water Management District (SRWMD) has been very active over the past few years, acquiring sizeable amounts of riparian habitat for conservation and flood control. At present, the SRWMD owns 41,100 ha in the basin, including 63% of river frontage in the upper Suwannee. Land-acquisition plans are in place to continue purchase of critical riparian areas to protect the main-stem river and important springs and spring runs.

ADDITIONAL RIVERS

The Choctawhatchee River is an alluvial river that arises in southeast Alabama and flows southward through a rolling, rural, and largely forested landscape into Choctawhatchee Bay in northwest Florida (Fig. 4.22). It is one of the longest free-flowing rivers (273 km) in the southeastern United States. The major tributaries in Alabama derive their flow from local precipitation that is low in ionic content, whereas the principal tributaries in Florida receive flow from calcium-rich springs of the Floridan aquifer. The river corridor is undeveloped and fringed by biologically rich bottomland hardwood forests, marshes, and tupelo-cypress swamps (Fig. 4.7). A general decline in invertebrate and fish biodiversity has occurred over the past decades, with much of the historically known mussel fauna either lost or in decline (Blalock-Herod et al. 2000). Overall, river water quality is good, but sedimentation is a major threat to economically valuable commercial and recreational fisheries and shellfisheries in Choctawhatchee Bay.

The Escambia River originates as the Conecuh River in the gently rolling Coastal Plains hills of south-central Alabama (Fig. 4.24). Four major tributaries join the Conecuh River on its southwestern path before it crosses into Florida and becomes the

FIGURE 4.7 Choctawhatchee River at High Bluff, Alabama, west of Dothan (PHOTO BY BETH MAYNOR YOUNG).

Escambia River that flows south through the Florida panhandle to Escambia Bay (Fig. 4.8). Water in the main stem is deep and slow moving, with channels flanked by lowland hardwood forests and tupelo–cypress swamps. Two impoundments used for hydroelectric power occur in the Conecuh River. Water quality is good, although dairy and agricultural runoff, silviculture, urbanization, and municipal/industrial wastewater discharges are threats. Escambia Bay once had a thriving commercial and recreational fishery and shellfishery, much of which is now lost as a result of pollution. A sizable population of the threatened Gulf sturgeon (*Acipenser*

oxyrinchus desotoi), once thought lost to this river, is found in the upper reaches, which the U.S. Fish and Wildlife Service (2002) proposes to list as critical habitat.

The Flint River (Fig. 4.9), located in central Georgia, drains parts of the Piedmont and Coastal Plain. The main stem flows from south of Atlanta south to Lake Seminole (Fig. 4.26). Information about the hydrology, geomorphology, and biota of the Flint River system is provided in the section on the Apalachicola–Chattahoochee–Flint river system in this chapter. Water quality within the basin is generally good. However, threats to water quality

FIGURE 4.8 Escambia River in the western panhandle of Florida, upstream from Pensacola (PHOTO BY BETH MAYNOR YOUNG).

include nonpoint-source loadings, such as erosion and sedimentation, agriculturally derived nutrient loading, metals in urban runoff, and fecal coliform bacteria in both urban and rural runoff. Also, large amounts of water withdrawn for irrigation from both surface water and the upper Floridan aquifer threaten water availability. Anticipated future demands from industry, agriculture, and municipalities in the basin, especially Atlanta, may be difficult to satisfy with existing supplies.

The Pascagoula River arises in sandy, low-rolling hills of the Coastal Plain of southeastern Mississippi and empties into the Gulf of Mexico. The main stem is formed by the confluence of several tributaries (Fig. 4.28), and one of them, Black Creek, is a National Wild and Scenic river. Slow flowing and low gradient, the Pascagoula River flows through low, broad floodplains dominated by bottomland hardwood forests and tupelo-cypress swamps (Fig. 4.10). The basin is mostly covered by coniferous and mixed deciduous forests, and silviculture is an important industry. Fragmentation of the river by dams and reservoirs is low, although water extractions occur

for irrigation, livestock production, and industry. Although most streams in the basin are clear water, the Escatawpa River, which joins the main stem near the coast, is a blackwater stream. Water quality is generally good, except near industrial outfalls and population centers. Mercury contamination in bass and catfish has caused consumption advisories since 1996 throughout the main stem (Mississippi Department of Environmental Quality 2001).

The Tombigbee River is one of the two major tributaries of the Mobile River system. Upstream of its confluence with the Black Warrior River, the Tombigbee is referred to as the Upper Tombigbee River (Fig. 4.30). Free flowing until the 1970s and noted for its high diversity of fishes and mollusks, construction of the Tennessee-Tombigbee Waterway has had a major hydrologic and ecologic impact on the river. Dedicated in 1985, the waterway is 377 km of channelized river that traverses parts of west-central Alabama and northeastern Mississippi, connecting the upper Tombigbee River with the Tennessee River, a connection that created a commercial transportation route between Mobile, Alabama, and the

FIGURE 4.9 Flint River near Thomaston, Georgia, west of Macon; wide and shallow section of river upstream from Yellow Jacket Shoals (PHOTO BY BETH MAYNOR YOUNG).

Mississippi River basin. Hydrologic alterations included 10 locks and dams, river meanders that were cut off (creating many new oxbow lakes), newly dredged channels that completely bypassed small upstream reaches, and a canal across the watershed divide. The decision to construct the waterway and its projected benefits remain controversial. It is lauded as an important transportation route that has also opened lake recreational areas and education centers. However, the actual economic impact is questionable, whereas the environmental consequences have been profound. The channelization has separated the upper Tombigbee River from its flood-

plain, dramatically reduced the diversity of riverine fauna, and made the Mobile basin more vulnerable to invasion by nonnative species.

In contrast to the environmental alteration of the upper Tombigbee River, the Sipsey River is a free-flowing tributary winding through the Coastal Plain in west-central Alabama before joining the upper Tombigbee (Fig. 4.30). The main stem is low gradient and flows through extensive marshes, bottomland hardwood floodplains, and tupelo-cypress wetlands. As with other undeveloped Coastal Plain rivers, the Sipsey River has substantial quantities of snag habitat (Fig. 4.11). Although the main stem is

FIGURE 4.10 Pascagoula River: Oxbow Lake near confluence of Chickasawhay and Leaf rivers (PHOTO BY BETH MAYNOR YOUNG).

without major tributaries, it often consists of multiple parallel channels, many of which dry in summer but are filled and swiftly moving during winter. The river is ecologically significant because of a lack of impoundments and a rich fauna that includes 35 species of mussels and 91 species of fishes. To protect some of this biological diversity, Alabama recently purchased 1214km² of bottomland forest and swampland bordering the river. Ionic strength of the water is low, and water quality is considered good, although municipal wastewater discharges around several small cities create localized inputs high in organic matter and inorganic nitrogen. Urban

development, logging, agriculture, and mining in the basin have increased sediment load over the years.

ACKNOWLEDGMENTS

The extraordinary photograph of the Cahaba and several other rivers described in this chapter are those of Beth Maynor Young. We greatly appreciate her generosity through the contribution of these images. We also appreciate data provided by Fred Howell, University of Southern Mississippi; Tom Kennedy, University of Alabama; and Robert A. Mattson, Suwannee River Water Management District. Our knowledge of the region has greatly benefited

FIGURE 4.13 Mean monthly air temperature, precipitation, and runoff for the Mobile River basin.

MOBILE RIVER

Relief: 1278 m

Basin area: 111,369 km²

Mean discharge: 1914 m³/s

River order: 8

Mean annual precipitation: 128 cm

Mean air temperature: 17.4°C

Mean water temperature: 19.9°C

Physiographic provinces: Coastal Plain (CP), Valley and Ridge (VR), Appalachian Plateau (AP), Piedmont Plateau (PP), Blue Ridge (BL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mobile Bay

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Appalachian Mixed Mesophytic Forests, Southeastern Mixed Forests, Southeastern Conifer Forests

Number of fish species: 236

Number of endangered species: 12 fishes, 3 reptiles, 19 mussels, 7 snails

Major fishes: paddlefish, Gulf sturgeon, Alabama sturgeon, gars, shads, highfin carpsucker, southeastern blue sucker, spotted sucker, river redhorse, golden redhorse, blacktail redhorse, channel catfish, flathead catfish, white bass, striped bass, warmouth, green sunfish, bluegill, longear sunfish, spotted bass, largemouth bass, white crappie, black crappie, freshwater drum

Major other aquatic vertebrates: river otter, American alligator, cottonmouth, diamondback water snake, alligator snapping turtle, common snapping turtle, flattened musk turtle, southern black-knobbed map turtle, Alabama map turtle, southern painted turtle, Alabama redbelly turtle, spiny softshell turtle, yellowbelly slider, red-eared slider

Major invertebrates: mollusks (rough fatmucket, southern fatmucket, yellow sandshell, little spectaclecase, Alabama orb, bleufer, *Pleurocera*, *Leptoxis*, *Elimia*), mayflies (*Hexagenia*, *Stenacron*, *Stenonema*, *Isonychia*, *Baetis*), stoneflies (*Acroneuria*, *Perlesta*, *Isoperla*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Ceraclea*, *Oecetis*)

Nonnative species: common carp, silver carp, bighead carp, grass carp, red shiner, fathead minnow, muskellunge, rainbow trout, brown trout, brook trout, palmetto bass, smallmouth bass, yellow perch, blue tilapia, white catfish, goldfish

Major riparian plants: bald cypress, eastern cottonwood, swamp cottonwood, mockernut hickory, river birch, American hornbeam, American beech, southern red oak, water oak, live oak, American elm, yellow poplar, sweetgum, American sycamore, American holly, red maple, black gum, water tupelo, swamp tupelo, Carolina ash

Special features: largest flow into eastern Gulf of Mexico and 5th largest of rivers in United States that reach the sea; high diversity of fishes, turtles, mollusks, insects; high levels of endemism and high levels of threatened/endangered species; large pristine forest at mouth

Fragmentation: 36 major dams

Water quality: pH = 7.3, alkalinity = 40.8 mg/L as CaCO₃, NO₃-N = 0.27 mg/L, PO₄-P = 0.02 mg/L

Land use: 68% forest, 18% agriculture, 7% wetland, <2% urban, 5% other

Population density: 43.9 people/km²

Major information sources: Boschung and Mayden 2004, Johnson et al. 2002, Harris et al. 1991, Lydeard et al. 2003

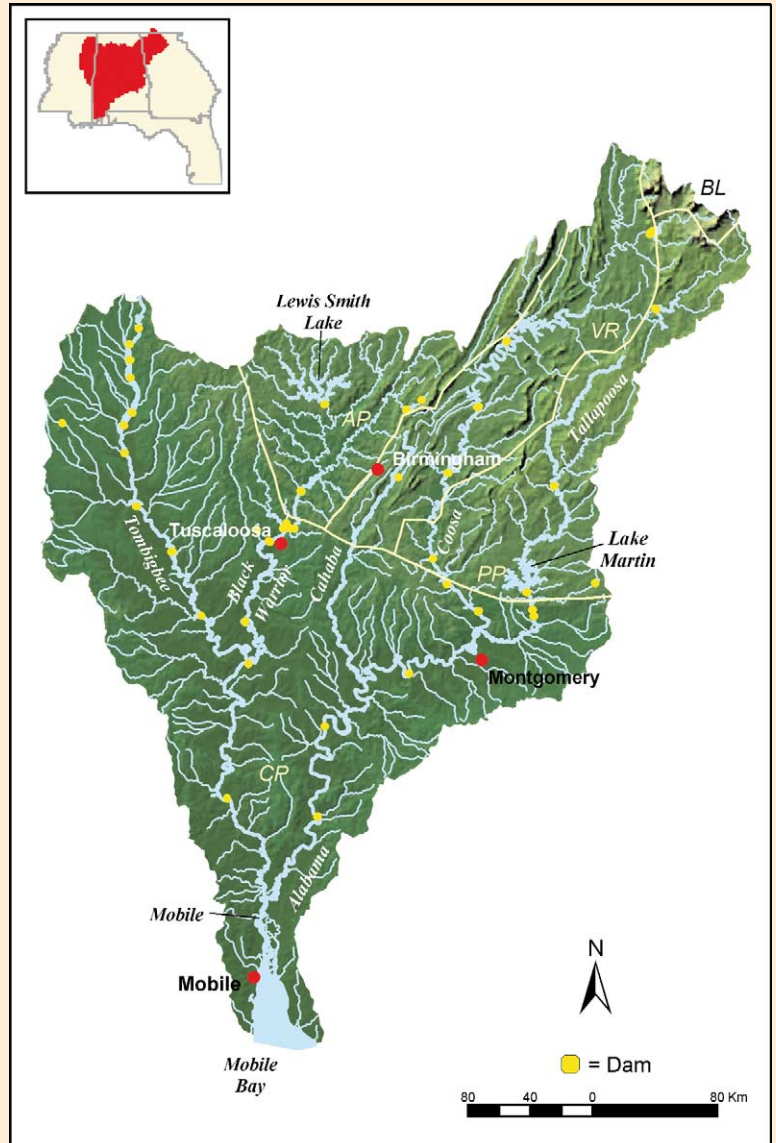

FIGURE 4.12 Map of the Mobile River basin. Physiographic provinces are separated by yellow lines.

FIGURE 4.15 Mean monthly air temperature, precipitation, and runoff for the Cahaba River basin.

CAHABA RIVER

Relief: 274 m

Basin area: 4730 km²

Mean discharge: 80 m³/s

River order: 6

Mean annual precipitation: 138 cm

Mean air temperature: 16.7°C

Mean water temperature: 18.1°C

Physiographic provinces: Valley and Ridge (VR),
Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mobile Bay

Terrestrial ecoregions: Southeastern Mixed Forests,
Appalachian Mixed Mesophytic Forests

Number of fish species: 135

Number of endangered species: 3 fishes, 4 mollusks

Major fishes: paddlefish, Alabama sturgeon, gars, shads, blacktail shiner, quillback, highfin carpsucker, southeastern blue sucker, spotted sucker, river redhorse, golden redhorse, blacktail redhorse, blue catfish, channel catfish, flathead catfish, white bass, warmouth, green sunfish, bluegill, longear sunfish, spotted bass, largemouth bass, white crappie, black crappie, freshwater drum

Major other aquatic vertebrates: river otter, American alligator, alligator snapping turtle, common snapping turtle, common musk turtle, stripeneck musk turtle, eastern mud turtle, Alabama map turtle, northern black-knob sawback map turtle, Gulf Coast smooth softshell turtle, Gulf Coast spiny softshell turtle, southern painted turtle, river cooter, cottonmouth water snake, yellowbelly water snake, diamondback water snake

Major invertebrates: mollusks (southern fatmucket, Alabama orb, elephant ear, bleufer, three-horned wartyback, *Elimia*, *Pleurocera*, *Leptoxis*, *Somatogyrus*), mayflies (*Stenacron*, *Stenonema*, *Tricorythodes*, *Eurylophella*, *Serratella*), stoneflies (*Acronuria*, *Perlesta*, *Isoperla*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Cyrmellus*, *Ceraclea*)

Nonnative species: grass carp, common carp, fathead minnow, white catfish, palmetto bass, smallmouth bass, Asiatic clam

Major riparian plants: bald cypress, eastern cottonwood, swamp cottonwood, mockernut hickory, river birch, American hornbeam, American beech, southern red oak, water oak, live oak, American elm, yellow poplar, sweetgum, American sycamore, American holly, red maple, black gum, water tupelo, swamp tupelo, Carolina ash

Special features: longest free-flowing river in southeastern Gulf Coast region; most fish species for its size in North America; very high mollusk diversity

Fragmentation: small impoundment in headwater tributary

Water quality: pH = 7.7, alkalinity = 84.0 mg/L as CaCO₃, NO₃-N = 0.34 mg/L, PO₄-P = 0.02 mg/L

Land use: 77% forest, 11% agriculture, 6% wetland, 2% urban, 4% other

Population density: 33 people/km²

Major information sources: Pierson et al. 1989, Bogan and Pierson 1993a, Onorato et al. 2000, Shepard et al. 1994

FIGURE 4.14 Map of the Cahaba River basin. Physiographic provinces are separated by yellow line.

FIGURE 4.17 Mean monthly air temperature, precipitation, and runoff for the Apalachicola River basin.

APALACHICOLA- CHATTAHOOCHEE- FLINT RIVER

Relief: 1066 m

Basin area: 50,688 km²

Mean discharge: 759 m³/s

River order: 8

Mean annual precipitation: 128 cm

Mean air temperature: 18.3°C

Mean water temperature: 20.6°C

Physiographic provinces: Blue Ridge (BL), Piedmont Plateau (PP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Apalachicola

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Appalachian Mixed Mesophytic Forests, Southeastern Mixed Forests, Southeastern Conifer Forests

Number of fish species: 104

Number of endangered species: 1 fish, 1 reptile

Major fishes: Gulf sturgeon, longnose gar, American eel,

Alabama shad, gizzard shad, Apalachicola redhorse, channel catfish, white catfish, yellow bullhead, brown bullhead, spotted bullhead, striped bass, largemouth bass, shoal bass, black crappie, redbreast sunfish, warmouth, bluegill

Major other aquatic vertebrates: river otter, American alligator, cottonmouth, alligator snapping turtle, Barbor's map turtle, striped mud turtle, common musk turtle, Florida softshell turtle, Gulf Coast spiny softshell turtle, Florida redbelly turtle, Florida cooter, river cooter, yellowbelly slider, Alabama waterdog

Major invertebrates: mollusks (eastern elliptio, variable spike, little spectaclecase, elephantear, *Campeloma*, *Elimia*, *Viviparus*, *Lioplax*, *Planorbella*), mayflies (*Hexagenia*, *Stenonema*, *Baetis*, *Caenis*), stoneflies (*Acroneuria*, *Neoperla*, *Paragnetina*, *Perlesta*, *Clioperla*, *Taeniopteryx*), caddisflies (*Ceraclea*, *Cheumatopsyche*, *Hydropsyche*, *Oecetis*)

Nonnative species: common carp, grass carp, green sunfish, orange spotted sunfish, walking catfish, goldfish, tilapia, Asian swamp eel, Asiatic clam

Major riparian plants: water tupelo, Ogeechee tupelo, bald cypress, Carolina ash, swamp tupelo, sweetgum, overcup oak, planer tree, green ash, water hickory, diamond-leaf oak, American elm, American hornbeam, water oak, red maple, sweetbay

Special features: second largest drainage into eastern Gulf of Mexico, high diversity of channel gradients and geology; historically diverse mollusk, crayfish, and fish fauna

Fragmentation: highly fragmented, with 16 main-stem dams, 13 on Chattahoochee River and 3 on Flint River

Water quality: pH = 7.4, alkalinity = 37.9 mg/L as CaCO₃, NO₃-N = 0.33 mg/L, PO₄-P = 0.02 mg/L

Land use: 55% forest, 25% agriculture, 10% wetland, 2% urban, 8% other

Population density: 51.3 people/km²

Major information sources: Box and Williams 2000, Clench and Turner 1956, Conant and Collins 1991,

www.gwf.org/protectedanimals.htm 2002a, Leitman et al. 1983, www.nanfa.org/NANFAregions/ga/ga_fw_fishes.htm 2002, Myers and Ewel 1990

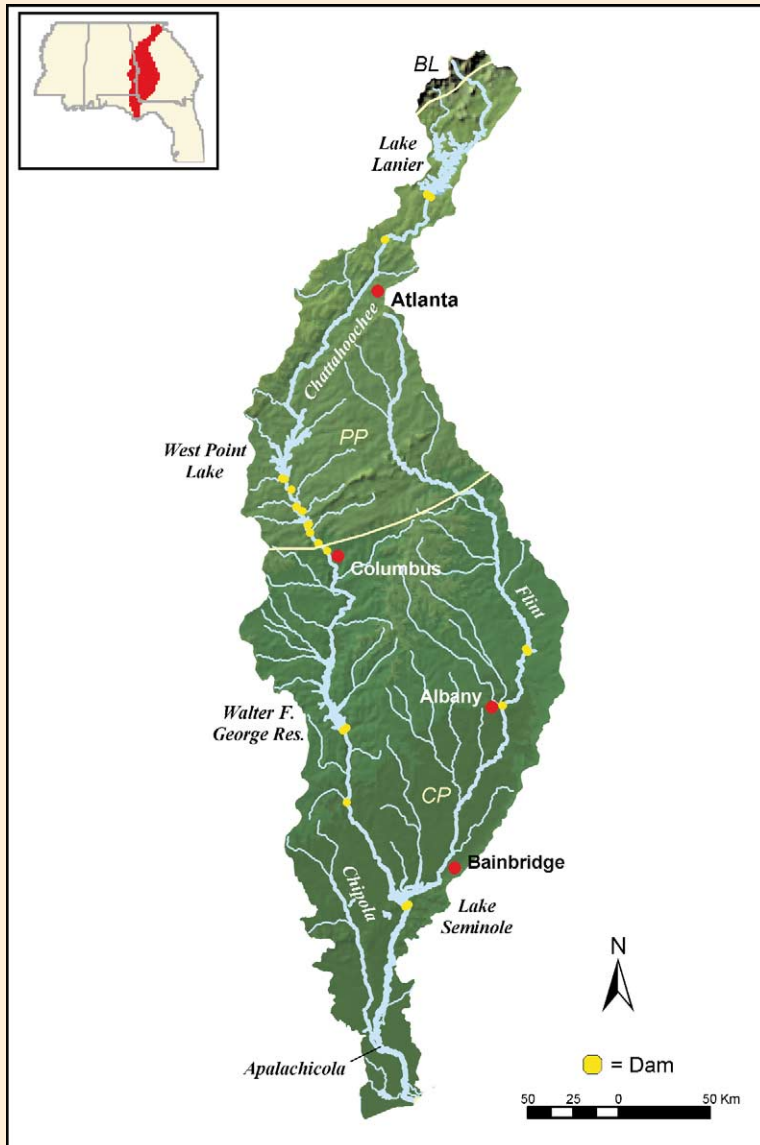

FIGURE 4.16 Map of the Apalachicola River basin. Physiographic provinces are separated by yellow lines.

FIGURE 4.19 Mean monthly air temperature, precipitation, and runoff for the Pearl River basin.

PEARL RIVER

Relief: 210 m

Basin area: 21,999 km²

Mean discharge: 373 m³/s

River order: 6

Mean annual precipitation: 142 cm

Mean air temperature: 17.8°C

Mean water temperature: 19.2°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi Embayment

Terrestrial ecoregions: Southeastern Mixed Forests,
Southeastern Conifer Forests

Number of fish species: 119

Number of endangered/threatened species: 1 fish,
2 reptiles, 1 mussel

Major fishes: paddlefish, Gulf sturgeon, alligator gar, gizzard shad, highfin carpsucker, southeastern blue sucker, smallmouth buffalo, blacktail redhorse, yellow bullhead, channel catfish, flathead catfish, warmouth, green sunfish, bluegill, longear sunfish, redspotted sunfish, spotted bass, largemouth bass, white crappie, black crappie, drum

Major other aquatic vertebrates: river otter, American alligator, alligator snapping turtle, common snapping turtle, stripe-neck musk turtle, Pascagoula map turtle, ringed map turtle, Gulf Coast spiny softshell turtle, cottonmouth

Major invertebrates: mollusks (paper pondshell, giant floater, *Lampsilis teres*, Asiatic clam, *Viviparus*), mayflies (*Stenonema*, *Baetis*, *Caenis*, *Tricorythodes*, *Isonychia*), stoneflies (*Paragnetina*, *Acroneuria*, *Neoperla*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Chimarra*, *Ceraclea*)

Nonnative species: fathead minnow, common carp, goldfish, Asiatic clam

Major riparian plants: eastern cottonwood, black willow, river birch, sycamore, silver maple, laurel oak, willow oak, water oak, sugarberry, American elm, green ash, overcup oak, water hickory, bald cypress, pond cypress, black gum, water hickory oak, water tupelo, sweetbay, red maple, slash pine

Special features: low-gradient Coastal Plain river with swamps and wide floodplain forests; large coastal estuary; high fish species richness

Fragmentation: one large impoundment, Ross Barnett dam, near Jackson, Mississippi

Water quality: pH = 6.4, alkalinity = 11.2 mg/L as CaCO₃, NO₃-N = 0.21 mg/L, PO₄-P = 0.03 mg/L

Land use: 58% forest, 24% agriculture, 12% wetland, <2% urban, 3% other

Population density: 42 people/km²

Major information sources: Boschung and Mayden 2004, Conant and Collins 1991, Mount 1975, Ross 2001, Swift et al. 1986

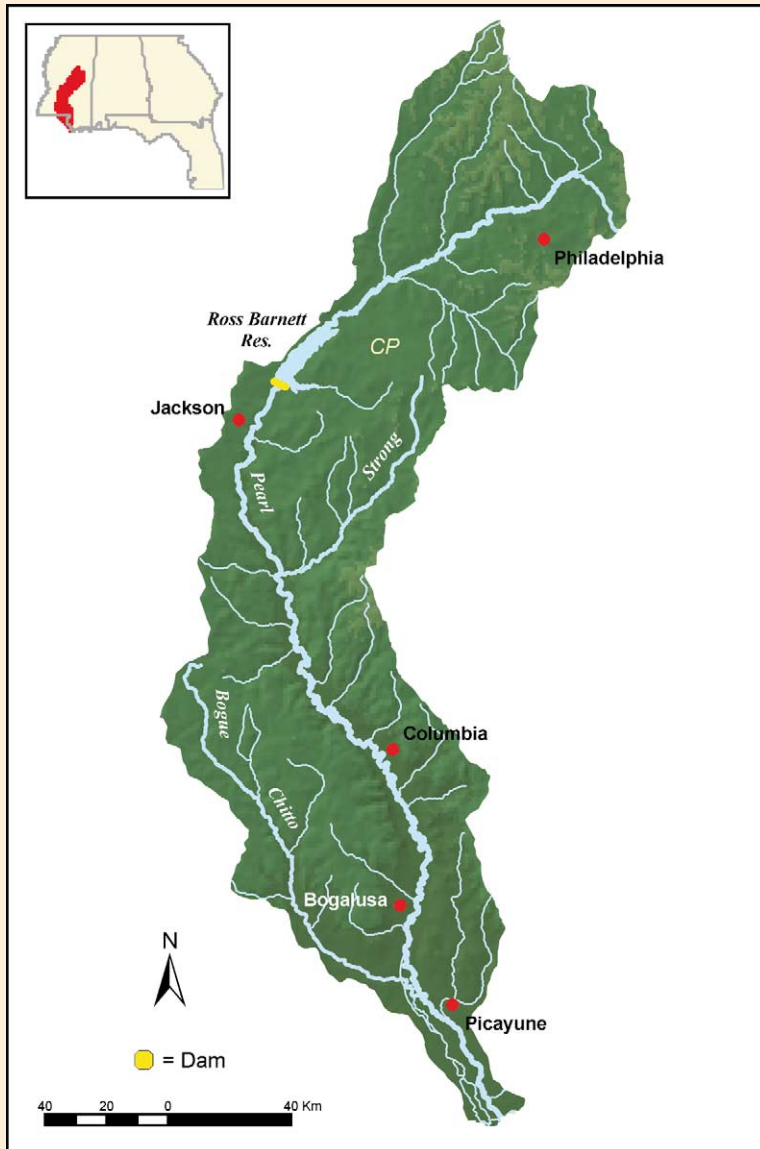

FIGURE 4.18 Map of the Pearl River basin.

FIGURE 4.21 Mean monthly air temperature, precipitation, and runoff for the Suwannee River basin.

SUWANNEE RIVER

Relief: 140m

Basin area: 24,967km²

Mean discharge: 294 m³/s

River order: 7

Mean annual precipitation: 134cm

Mean air temperature: 20.2°C

Mean water temperature: 19.7°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Florida Gulf

Terrestrial ecoregion: Southeastern Conifer Forests

Number of fish species: 81

Number of endangered species: 1 fish

Major fishes: Gulf sturgeon, longnose gar, Florida gar, gizzard shad, threadfin shad, blacktail shiner, spotted sucker, channel catfish, white catfish, flathead catfish, snail bullhead, yellow bullhead, brown bullhead, spotted bullhead, striped bass, Suwannee bass, largemouth bass, black crappie, warmouth, redbreast sunfish, spotted sunfish, bluegill

Major other aquatic vertebrates: river otter, West Indian manatee, American alligator, alligator snapping turtle, Florida snapping turtle, Florida softshell turtle, Florida redbelly turtle, Suwannee cooter, Florida cooter, Florida cottonmouth, Gulf saltmarsh swamp snake, North Florida swamp snake, redbelly water snake, banded water snake, Florida green water snake, brown water snake

Major invertebrates: mollusks (*Elliptio*, *Villosa*, *Quincucina*, *Musculium*, *Campeloma*, *Elimia*, *Lioplax*, *Micromenetus*, *Notogilla*), mayflies (*Baetis*, *Pseudocloeon*, *Stenacron*, *Stenonema*, *Tricorythodes*), stoneflies (*Acroneuria*, *Neoperla*, *Attaneuria*, *Paragnetina*, *Perlesta*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Ceraclea*, *Oecetis*, *Chimarra*)

Nonnative species: American shad, grass carp, blue catfish, flathead catfish, wiper, Asiatic clam

Major riparian plants: bald cypress, water elm, swamp laurel oak, overcup oak, live oak, sand live oak, sweetgum, river birch, planer tree, cabbage palm, red maple, water tupelo

Special features: large free-flowing Coastal Plain river with headwater swamps (Okefenokee Swamp); swamps and wide floodplain forests in mid and lower reaches; large hydrologic inputs from many springs flowing from underlying Floridan aquifer

Fragmentation: no impoundments

Water quality: pH = 7.0, alkalinity = 116.3 mg/L as CaCO₃, NO₃-N = 0.50 mg/L, PO₄-P = 0.20 mg/L

Land use: 38% forest, 30% agricultural, 22% wetland, 1% urban, 9% other

Population density: 22 people/km²

Major information sources: Bass et al. 2003, <http://nas.er.usgs.gov/fishes/index.html> 2003, Myers and Ewel 1990, www.flmnh.ufl.edu/natsci/herpetology/FL-GUIDE/Flaherps.htm 2003, Mattson et al. 1995, Light et al. 2002

FIGURE 4.20 Map of the Suwannee River basin.

FIGURE 4.23 Mean monthly air temperature, precipitation, and runoff for the Choctawhatchee River basin.

CHOCTAWHATCHEE RIVER

Relief: 179 m

Basin area: 12,033 km²

Mean discharge: 212 m³/s

River order: 6

Mean annual precipitation: 144 cm

Mean air temperature: 18.7°C

Mean water temperature: 20.0°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Florida Gulf

Terrestrial ecoregions: Southeastern Conifer Forests, Southeastern Mixed Forests

Number of fish species: 80

Number of endangered species: 1 fish

Major fishes: Gulf sturgeon, spotted gar, longnose gar, American eel, Alabama shad, gizzard shad, threadfin shad, blacktail shiner, quillback, highfin carpsucker, blacktail redhorse, yellow bullhead, brown bullhead, channel catfish, striped bass, warmouth, bluegill, green sunfish, longear sunfish, spotted bass, largemouth bass, black crappie

Major other aquatic vertebrates: river otter, American alligator, Alabama waterdog, Florida cottonmouth, eastern cottonmouth, brown water snake, alligator snapping turtle, Florida softshell turtle, Gulf Coast spiny softshell turtle, common snapping turtle, eastern chicken turtle, mud turtle, stripeneck musk turtle, loggerhead musk turtle, yellowbelly turtle, Florida cooter, river cooter, stinkpot

Major invertebrates: mollusks (little spectaclecase, southern rainbow, variable spike, yellow sandshell, *Campeloma*, *Lioplax*, *Pomacea*, *Viviparus*), mayflies (*Isonychia*, *Leptophlebia*, *Eurylophella*), stoneflies (*Neoperla*, *Paragnetina*, *Perlesta*, *Clioperla*, *Isoperla*, *Taeniopteryx*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Oecetis*, *Phylocentropus*)

Nonnative species: grass carp, common carp, palmetto bass, yellow perch, unidentified pacu (*Colossoma* or *Piaractus*), Asiatic clam

Major riparian plants: bald cypress, pond cypress, black gum, water tupelo, swamp tupelo, Ogeechee tupelo, sweetgum, red maple, sweetbay, river birch, black titi, red titi, Atlantic white cedar, eastern cottonwood, swamp cottonwood, mockernut hickory, water hickory, American beech, water oak, live oak, overcup oak, American elm, yellow poplar, American sycamore

Special features: low-gradient Coastal Plain river with swamps and wide floodplain forest; one of few free-flowing southeastern Gulf of Mexico rivers; flows through lightly populated landscape into commercially valuable estuary

Fragmentation: no impoundments

Water quality: pH = 7.5, alkalinity = 34.8 mg/L as CaCO₃, NO₃-N = 0.17 mg/L, PO₄-P = 0.02 mg/L

Land use: 57% forest, 25% agriculture, 9% wetland, 1% urban, 8% other

Population density: 17.8 people/km²

Major information sources: Blalock-Herod et al. 2000, Boschung and Mayden 2004, www.flmnh.ufl.edu/natsci/herpetology/FL-GUIDE/Flaherps.htm 2003, <http://nas.er.usgs.gov/fishes/index.html> 2003

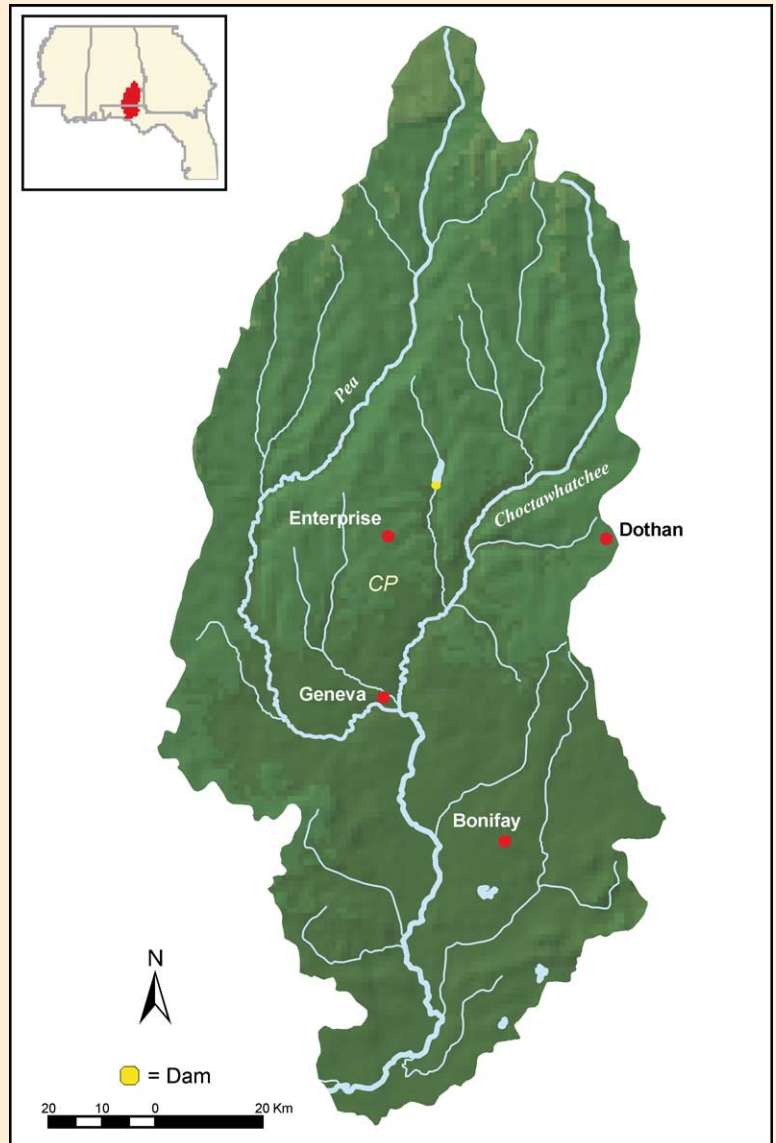

FIGURE 4.22 Map of the Choctawhatchee River basin.

FIGURE 4.25 Mean monthly air temperature, precipitation, and runoff for the Escambia–Conecuh River basin.

ESCAMBIA–CONECUH RIVER

Relief: 180 m

Basin area: 10,963 km²

Mean discharge: 196 m³/s

River order: 6

Mean annual precipitation: 164 cm

Mean air temperature: 18.0°C

Mean water temperature: 20.4°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Florida Gulf

Terrestrial ecoregions: Southeastern Conifer Forests, Southeastern Mixed Forests

Number of fish species: 102

Number of endangered species: 0

Major fishes: Gulf sturgeon, spotted gar, longnose gar, Alabama shad, gizzard shad, threadfin shad, blacktail shiner, quillback, highfin carpsucker, river redhorse, blacktail redhorse, yellow bullhead, brown bullhead, channel catfish, flathead catfish, striped bass, warmouth, bluegill, green sunfish, longear sunfish, spotted bass, largemouth bass, black crappie

Major other aquatic vertebrates: river otter, American alligator, Alabama waterdog, Florida cottonmouth, eastern cottonmouth, brown water snake, alligator snapping turtle, Florida softshell turtle, Gulf Coast spiny softshell turtle, common snapping turtle, eastern chicken turtle, mud turtle, Escambia map turtle, loggerhead musk turtle, stripeneck musk turtle, yellowbelly turtle, Florida cooter, river cooter, stinkpot

Major invertebrates: mollusks (*Somatogyrus*, *Pomacea*), mayflies (*Baetis*, *Isonychia*, *Leptophlebia*, *Hexagenia*, *Eurylophella*), stoneflies (*Acronuria*, *Neoperla*, *Attaneuria*, *Paragnetina*, *Clioperla*, *Isoperla*), caddisflies (*Ceraclea*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Oecetis*, *Oxyethira*, *Phylocentropus*)

Nonnative species: grass carp, common carp, palmetto bass

Major riparian plants: bald cypress, eastern cottonwood, swamp cottonwood, mockernut hickory, river birch, American hornbeam, American beech, southern red oak, water oak, live oak, American elm, yellow poplar, sweetgum, American sycamore, American holly, red maple, black gum, water tupelo, swamp tupelo, Carolina ash

Special features: low-gradient Coastal Plain river with swamps and wide floodplain forests in lower reaches; empties into a once productive estuary

Fragmentation: largely free flowing, although two moderate-size impoundments on main stem

Water quality: pH = 7.3, alkalinity = 24.3 mg/L as CaCO₃, NO₃-N = 0.11 mg/L, PO₄-P = 0.02 mg/L

Land use: 72% forest, 15% agriculture, 7% wetland, <1% urban, 5% other

Population density: 33 people/km²

Major information sources: Boschung and Mayden 2004, Conant and Collins 1991, www.flmnh.ufl.edu/natsci/herpetology/FL-GUIDE/Flaherps/htm 2003, Mount 1975, <http://nas.er.usgs.gov/fishes/index.html> 2003

FIGURE 4.27 Mean monthly air temperature, precipitation, and runoff for the Flint River basin.

FLINT RIVER

Relief: 294 m

Basin area: 22,377 km²

Mean discharge: 283 m³/s

River order: 7

Mean annual precipitation: 126 cm

Mean air temperature: 18.2°C

Mean water temperature: 19.8°C

Physiographic provinces: Coastal Plain (CP), Piedmont Plateau (PP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Apalachicola

Terrestrial ecoregions: Southeastern Conifer Forests, Southeastern Mixed Forests

Number of fish species: 71

Number of endangered species: 1 fish, 1 reptile, 3 mollusks

Major fishes: Gulf sturgeon, longnose gar, American eel, Alabama shad, gizzard shad, spotted sucker, Apalachicola redbhorse, greater jumprock, channel catfish, white catfish, snail bullhead, brown bullhead, spotted bullhead, yellow bullhead, striped bass, black crappie, shoal bass, largemouth bass, warmouth, redbreast sunfish, bluegill

Major other aquatic vertebrates: river otter, American alligator, Alabama waterdog, redbelly water snake, brown water snake, cottonmouth, snapping turtle, alligator snapping turtle, Barbor's map turtle, Florida redbelly turtle, striped mud turtle, common musk turtle, Florida softshell turtle, Gulf Coast spiny softshell turtle, Florida cooter, river cooter, yellowbelly slider

Major invertebrates: mollusks (*Elliptio*, *Toxolasma*, *Unio*, *Elimia*, *Lioplax*, *Villosa*), mayflies (*Stenonema*, *Tricorythodes*, *Baetis*), stoneflies (*Paragnetina*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Cyrmellus*)

Nonnative species: common carp, grass carp, flathead catfish, green sunfish, orange spotted sunfish, spotted bass, striped bass, goldfish, tilapia, walking catfish, Asian swamp eel

Major riparian plants: spruce pine, eastern hemlock, river birch, American hornbeam, American beech, white oak, water oak, laurel oak, American elm, sugarberry, umbrella magnolia, sweetbay, yellow poplar, sweetgum, American sycamore, red maple, box elder, water tupelo, black gum

Special features: second largest tributary to Apalachicola; karst terrain in lower reaches; habitat for Gulf sturgeon

Fragmentation: three dams, two large reservoirs on main stem for hydroelectric production

Water quality: pH = 7.3, alkalinity = 33.0 mg/L as CaCO₃, NO₃-N = 0.474 mg/L, PO₄-P = 0.030 mg/L

Land use: 49% forest, 34% agriculture, 9.5% wetland, 1.5% urban, 5% other

Population density: 26.8 people/km²

FIGURE 4.29 Mean monthly air temperature, precipitation, and runoff for the Pascagoula River-Black Creek River basin.

PASCAGOULA RIVER-BLACK CREEK

Relief: 198 m

Basin area: 24,599 km²

Mean discharge: 432 m³/s

River order: 6

Mean annual precipitation: 156 cm

Mean air temperature: 18.7°C

Mean water temperature: 19.7°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi Embayment

Terrestrial ecoregions: Southeastern Mixed Forests, Southeastern Conifer Forests

Number of fish species: 114

Number of endangered species: 1 fish, 2 reptiles

Major fishes: paddlefish, Gulf sturgeon, spotted gar, longnose gar, gizzard shad, highfin carpsucker, southeastern blue sucker, smallmouth buffalo, blacktail redhorse, yellow bullhead, channel catfish, flathead catfish, shadow bass, warmouth, green sunfish, bluegill, redspotted sunfish, spotted bass, largemouth bass, white crappie, black crappie, freshwater drum

Major other aquatic vertebrates: beaver, river otter, mudpuppy, cottonmouth, American alligator, alligator snapping turtle, common snapping turtle, stripedneck musk turtle, Pascagoula map turtle, yellow blotched map turtle, Gulf Coast spiny softshell turtle

Major invertebrates: mollusks (threeridge, elephantear, *Lampsilis teres*, ebonyshell, giant floater, paper pondshell, Asiatic clam, *Viviparus*), mayflies (*Stenonema*, *Baetis*, *Caenis*, *Tricorythodes*, *Isonychia*), stoneflies (*Paragnetina*, *Neoperla*, *Acroneuria*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Hydroptila*, *Chimarra*, *Ceraclea*)

Nonnative species: bigheaded carp, fathead minnow, pirapitinga, *Tilapia* spp.

Major riparian plants: eastern cottonwood, black willow, river birch, sycamore, silver maple, laurel oak, willow oak, water oak, sugarberry, American elm, green ash, overcup oak, water hickory, bald cypress, pond cypress, black gum, water hickory oak, water tupelo, sweetbay, red maple, slash pine

Special features: low-gradient blackwater ecosystem with swamps and wide floodplain forests; free flowing; 34 km reach of Black Creek classified as Wild and Scenic

Fragmentation: no dams on main stem or major tributaries

Water quality: pH = 6.2, alkalinity = 13.1 mg/L as CaCO₃, NO₃-N = 0.09 mg/L, PO₄-P = 0.10 mg/L

Land use: 66% forest, 17% agriculture, 11% wetland, <1% urban, 5% other

Population density: 29 people/km²

Major information sources: Boschung and Mayden 2004, Conant and Collins 1991, www.flmnh.ufl.edu/natsci/herpetology/FL-GUIDE/Flaherps/htm 2003, Mount 1975, <http://nas.er.usgs.gov/fishes/index.html> 2003

FIGURE 4.31 Mean monthly air temperature, precipitation, and runoff for the Upper Tombigbee River basin.

UPPER TOMBIGBEE RIVER

Relief: 245 m

Basin area: 18,800 km²

Mean discharge: 336 m³/s

River order: 6

Mean annual precipitation: 134 cm

Mean air temperature: 18.7°C

Mean water temperature: 18.8°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mobile Bay

Terrestrial ecoregion: Southeastern Mixed Forests

Number of fish species: 122

Number of endangered species: 1 fish, 5 mussels

Major fishes: paddlefish, Alabama sturgeon, gars, shads, quillback, highfin carpsucker, smallmouth buffalo, southeastern blue, spotted sucker, river redhorse, golden redhorse, blacktail redhorse, blue catfish, channel catfish, flathead catfish, warmouth, green sunfish, bluegill, longear sunfish, redear sunfish, redspotted sunfish, spotted bass, largemouth bass, white crappie, black crappie, freshwater drum

Major other aquatic vertebrates: river otter, American alligator, alligator snapping turtle, common snapping turtle, common musk turtle, stripeneck musk turtle, eastern mud turtle, northern black-knob sawback map turtle, eastern chicken turtle, southern painted turtle, Gulf Coast smooth softshell turtle, spiny softshell turtle, river cooter, red-eared slider, cottonmouth, yellowbelly water snake, diamondback water snake

Major invertebrates: mollusks (ebonyshell, Alabama orb, fragile papershell, threehorn wartyback, yellow sandshell, Asiatic clam, *Elimia*, *Somatogyrus*, *Lioplax*), mayflies (*Hexagenia*, *Stenonema*, *Baetis*, *Heptagenia*, *Tricorythodes*, *Isonychia*), stoneflies (*Neoperla*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Chimarra*, *Cyrenellus*)

Nonnative species: grass carp, common carp, smallmouth bass, palmetto bass, yellow perch, Asiatic clam

Major riparian plants: bald cypress, eastern cottonwood, swamp cottonwood, mockernut hickory, river birch, American hornbeam, American beech, southern red oak, water oak, live oak, American elm, yellow poplar, sweetgum, American sycamore, American holly, red maple, black gum, water tupelo, swamp tupelo, Carolina ash

Special features: historically noted for diverse fish and mussel fauna; currently Upper Tombigbee is location of Tennessee–Tombigbee waterway connecting Mobile and Tennessee river systems

Fragmentation: numerous navigational locks and dams part of Tennessee–Tombigbee Waterway

Water quality: pH = 7.2, alkalinity = 43.0 mg/L as CaCO₃, NO₃-N = 0.27 mg/L, PO₄-P = 0.06 mg/L

Land use: 64% forest, 20% agriculture, 12% wetland, 2% urban, 2% other

Population density: 18 people/km²

Major information sources: Boschung and Mayden 2004, Mettee et al. 1996, McGregor et al. 1999

SIPSEY RIVER

Relief: 229m

Basin area: 2044 km²

Mean discharge: 34 m³/s

River order: 5

Mean annual precipitation: 139 cm

Mean air temperature: 17.0°C

Mean water temperature: 17.1°C

Physiographic provinces: Coastal Plain (CP),
Appalachian Plateau (AP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mobile Bay

Terrestrial ecoregion: Southeastern Mixed Forests

Number of fish species: 91

Number of endangered species: none

Major fishes: spotted gar, longnose gar, gizzard shad, threadfin shad, blacktail shiner, quillback, smallmouth buffalo, Alabama hog sucker, spotted sucker, river redhorse, golden redhorse, blacktail redhorse, channel catfish, warmouth, bluegill, longear sunfish, redear sunfish, redspotted sunfish, spotted bass, largemouth bass, freshwater drum

Major other aquatic vertebrates: river otter, cottonmouth, yellowbelly water snake, diamondback water snake, American alligator, alligator snapping turtle, common snapping turtle, common musk turtle, stripeneck musk turtle, northern black-knob sawback map turtle, eastern chicken turtle, southern painted turtle, Gulf Coast smooth softshell turtle, spiny softshell turtle, river cooter, red-eared slider

Major invertebrates: mollusks (southern fatmucket, yellow sandshell, little spectaclecase, Alabama orb, bleufer), mayflies (*Isonychia*, *Eurylophella*, *Serratella*, *Baetis*, *Caenis*), stoneflies (*Acronuria*, *Perlesta*, *Isoperla*, *Neoperla*, *Taeniopteryx*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Ceraclea*, *Oecetis*, *Chimarra*)

Nonnative species: common carp

Major riparian plants: bald cypress, eastern cottonwood, swamp cottonwood, mockernut hickory, river birch, American hornbeam, American beech, southern red oak, water oak, live oak, American elm, yellow poplar, sweetgum, American sycamore, American holly, red maple, black gum, water tupelo, swamp tupelo, Carolina ash

Special features: lightly populated low-gradient Coastal Plain river with swamps and wide floodplain forests; high diversity of fish and mollusks

Fragmentation: no impoundments

Water quality: pH = 5.9 to 7.7, alkalinity = 4 to 28 mg/L as CaCO₃, NO₃-N = 0.35 mg/L, PO₄-P = 0.03 mg/L

Land use: 75% forest, 10% agriculture, 9% wetland, <1% urban, 5% other

Population density: 11 people/km²

LITERATURE CITED

INTRODUCTION

River catchments flowing into the Texas portion of the Gulf of Mexico encompass a broad geographic area, with latitude ranging from around 38°N in southern Colorado to 25°N in northern Mexico and longitude ranging from about 108°W in western New Mexico to 93°W in western Louisiana (Fig. 5.2). The northwestern part of the region includes the southern Rocky Mountains and the southeastern portion includes the flat coastal areas along the Gulf of Mexico. The region is traversed by a strong decreasing rainfall gradient from east to west and a temperature gradient from north to south that strongly influences vegetation, land use, and river flow. Western rivers originating in Colorado and New Mexico are snowmelt dominated and flow from snow-fed perennial streams. These rivers encounter increasingly arid conditions as they flow southward through grasslands, shrublands, and deserts. Northeastern rivers of the western Gulf flow through prairies, pine forests, and cypress-lined bayous.

Rivers crossing the desert and semiarid western parts of the region produce considerably less discharge to the Gulf of Mexico than the rivers of east Texas. The diverse geology, physiography, and climate of the region have produced rivers that have variable geomorphic, hydrologic, chemical, and biological characteristics. Many of these rivers are of great length, with the Rio Grande, Brazos, Pecos, and Colorado among the hundred longest rivers in the world (World Almanac Books 2003).

Human habitation within catchments that flow into the western Gulf of Mexico dates back to the Clovis culture of Paleo-Indians nearly 12,000 years ago. Clovis culture was first discovered from excavations in the early 1930s near Clovis, New Mexico, in the Pecos River drainage basin. These big-game hunters are the earliest definitively dated human populations in the Americas. The Folsom culture also was an early hunting group of Paleo-Indians in the region and was present until about 2500 years ago. Highly developed Native American civilizations became established 1000 to 2000 years ago in both

FIGURE 5.2 Gulf Coast rivers of the southwestern United States described in this chapter.

the eastern and western areas of rivers flowing into the western Gulf of Mexico. The Caddoan period of 780 to 1260 years ago in the Sabine basin was the most southwestern example of the Mississippian mound-building culture. The Anasazi culture from 600 to 1700 years ago in the Rio Grande and Colorado basins established thriving cities and cultural centers. When early Spanish explorers visited the region in the sixteenth century, they found (1) Caddoan tribes in east Texas, (2) Tonkawa, Waco, Apache, Karankawa, and Comanche tribes in central and west Texas, (3) Pueblo, Hopi, Zuni, Navajo, and Apache tribes in New Mexico, and (4) Jumano, Pataragueye, and Coahuiltecan tribes in the Rio Grande border region between Texas and Mexico.

Eleven major rivers discharge into the western Gulf of Mexico from the United States, including the Rio Grande, which borders with Mexico. They are located in generally narrow catchments that are from two to five times longer than their average widths and they have generally developed dendritic drainage systems. Extending from southwest to northeast, the rivers are the Rio Grande, Nueces, Guadalupe/San Antonio, Lavaca, Colorado, Brazos, San Jacinto, Trinity, Neches, and Sabine. A subset of five major river systems that together cover a considerable range in natural diversity and human impacts is discussed within this region. These are the Rio Grande, Guadalupe/San Antonio, Colorado, Brazos, and Sabine. In addition, one-page summaries of physical and biological information are provided for four

(Pecos, Nueces, Trinity, and Neches) of the six additional rivers. Two major Mexican tributaries of the Rio Grande (Conchos and Salado) are described in Chapter 23.

Physiography and Climate

The rivers of the western Gulf of Mexico are found in areas of differing geography that include eight physiographic provinces (Hunt 1974). The Rio Grande basin contains seven of the eight physiographic provinces in the region. These provinces include the Southern Rocky Mountains (SR), Colorado Plateau (CO), Basin and Range (BR), Great Plains (GP), Coastal Plain (CP), Sierra Madre Occidental (SC), and the Sierra Madre Oriental (SO). The eighth physiographic province in the region is the Central Lowland (CL), in which parts of the Colorado, Brazos, and Trinity catchments are located. The Sabine and Neches drainage basins are completely within the CP, whereas the San Antonio/Guadalupe and Nueces basins include the CP and GP. The Colorado, Brazos, and Trinity catchments include the CL, GP, and CP, and the Pecos basin includes the SR, BR, and GP.

The Rio Grande in southern Colorado and New Mexico flows through the Rio Grande rift. The rift transects New Mexico from south to north and extends into the headwaters region of the Rio Grande in southern Colorado. The rift consists of a series of grabens (down-dropped blocks). In the northern part of the rift, ancient Precambrian rocks cap the massive uplifts of the Sangre de Cristo and Brazos ranges. Recent Tertiary and Quaternary volcanics are on the west side of the Rio Grande graben. In central New Mexico, uplifted blocks form the Sandia and Manzano mountains with capping Pennsylvanian limestones. In southern New Mexico, the rift is bordered by complex uplifted ranges of Precambrian, Paleozoic, or lower Tertiary rocks. The Rio Grande in New Mexico flows through valleys with Quaternary and young Tertiary sediments filling the rift, sometimes to depths exceeding 10 km.

The surface geology of Texas and eastern New Mexico reflects the more tectonically stable characteristics of this region in recent Earth history. Coastal Plain areas have surface geology of generally Quaternary, Pliocene, Miocene, Oligocene, and Eocene ages. Rich oil and gas deposits from Cretaceous, Permian, Pennsylvanian, Mississippian, Jurassic, and Triassic periods dominate the geology of central Texas, whereas the panhandle region of Texas is mostly of Pliocene, Miocene, Oligocene, and Permian

age. Complex heterogeneous surface geology predominates in west Texas and much of eastern New Mexico. Rivers of the western Gulf commonly flow through multiple geological provinces from headwaters to mouth.

Soils of the region are highly varied, reflecting strong climatic gradients, varying geologic ages and structures, and differential tectonics. Calcareous and/or gypsum-rich soils are common in the more arid parts of the region, and the pH of these soils is usually neutral or slightly basic. Prairie soils are commonly slightly acidic sandy to clayey loams. Forest soils of east Texas are generally light-colored, acidic loams. Soils of the coastal plains range from light-colored to light-brown acid loams of various textures and sands.

The climate of the region ranges markedly, from humid continental in eastern Texas, to humid subtropical in the south in Texas, to alpine in southern Colorado and northern New Mexico, to desert in southern New Mexico and western Texas. Mean monthly air temperatures range from -10°C in winter in the valleys of the headwater region of the Rio Grande to 30°C in the summer months on the Coastal Plain of Texas. Winter mean monthly temperatures range from 15°C near the mouth of the Rio Grande in southern Texas to -15°C in the mountains of southern Colorado where the headwaters of the Rio Grande originate. Annual rainfall ranges from greater than 125 cm in the easternmost basins to less than 20 cm in basins in central New Mexico and western Texas. Precipitation also increases from south to north in the western portion of the region, from the deserts of southern New Mexico and western Texas ($<20\text{ cm/yr}$) to mountain peaks of the Rocky Mountains in southern Colorado ($>125\text{ cm/yr}$). Precipitation occurs as rainfall in the Coastal Plain, with an increasing role for snowfall as elevation increases to the northwest. Tropical storms and hurricanes cause short periods of high precipitation, primarily during late summer and autumn throughout much of the region.

Basin Landscape and Land Use

The rivers of the western Gulf of Mexico pass through 16 highly diverse terrestrial ecoregions, which include forests, grasslands, prairies, savannahs, shrublands, and deserts (Ricketts et al. 1999). The Colorado Rockies Forests ecoregion is a high-elevation montane area in the northwestern portion of the region and includes the headwaters of the Rio Grande and Pecos River. The high-elevation plateau

of eastern New Mexico and the panhandle part of Texas are in the Western Short Grasslands ecoregion and include the headwaters of the Colorado and Brazos rivers. Three xeric shrubland or desert ecoregions are traversed by the Rio Grande: the Colorado Plateau Shrublands, Chihuahuan Desert, and Tamaulipan Mezquital. Along the lower Rio Grande is drainage from the Sierra-Madre Oriental oak–pine forests, Sierra-Madre Occidental pine–oak forests (Conchos drainage), Tamaulipan Pastizal, and Tamaulipan Matorral (around Monterrey). Four grassland, savanna, or shrubland ecoregions are located in central Texas. These ecoregions are the Edwards Plateau Savannas, the Central and Southern Mixed Grasslands, the Central Grassland/Forest Transition Zone, and the Texas Blackland Prairies. Gulf Coast terrestrial ecoregions include the East Central Texas Forests, Piney Woods Forests, and Western Gulf Coastal Grasslands.

Geomorphology of the rivers also varies markedly. Snowmelt-fed rivers like the Rio Grande originate in high-gradient montane regions with coarse substrates and high velocities. The Rio Grande also flows through an active tectonic rift valley. The Brazos and Colorado rivers start on or near the high plateau of eastern New Mexico and the Texas panhandle before passing through grasslands, prairies, savannahs, and forests. The San Antonio and Guadalupe rivers emerge as large springs from the karst region of the Edwards plateau. The Sabine River begins at a much lower elevation in mesic east Texas in a forested region with higher precipitation than the rest of the region.

The Rio Grande basin in southern Colorado is largely forested in the uplands, with agriculture in the San Luis Valley. After entering New Mexico, the Rio Grande basin is mountainous with canyonlands and valleys until entering the middle Rio Grande basin of central New Mexico. Agricultural land use in this region is focused along the riverine corridor, with grassland, shrubland, and forest moving away from the riverine corridor. Urban centers also are concentrated along the riverine corridor, with over half the population of New Mexico (almost one million people) living along this segment of the Rio Grande. South of Elephant Butte and Caballo reservoirs, the Rio Grande basin is a mix of agriculture along the river corridor, desert shrubland and grassland in the uplands, and urban centers in southern New Mexico, west Texas, and northern Mexico. Forested mountains, Chihuahuan desert, and riparian floodplain characterize the border region between Texas and Mexico. When the Río Conchos of Mexico

enters the Rio Grande (or Río Bravo del Norte), the river again flows continuously until a series of reservoirs impounds water for agricultural use in the lower Rio Grande basin.

The headwater region of the San Antonio River is largely urbanized, whereas the headwaters of the Guadalupe River begin in relatively undeveloped ranch lands. The spring-fed rivers and their tributaries are major attractions for cities like San Antonio and San Marcos. The springs at San Marcos are the most dependable springs in the region and are renowned for their biological diversity. Impoundments of these rivers provide for water supply, recreation, electrical power, and agriculture. Land use in the lower portions of these basins is largely agriculture, ranching, and wildlife refuges.

The Colorado and Brazos rivers arise near the Texas–New Mexico border and flow to the Gulf of Mexico. European-Americans from the eastern United States originally settled between these rivers on land grants to Stephen F. Austin. Early settlers first had to cross the Trinity River, which now connects Dallas–Fort Worth to Galveston Bay, just east of Houston, which lies at the mouth of the San Jacinto River. These three watersheds now contain more than half of the present population of Texas, and human activities have stressed the natural capacity of these rivers to cleanse themselves, especially in the Trinity and lower San Jacinto watersheds. Land use in these basins includes grazing land, irrigated cropland, and urban land. Urbanization is one of the most rapidly growing land uses in the Colorado, Brazos, and Trinity river basins.

The Sabine and Neches rivers drain the parts of Texas with the highest annual precipitation. The Sabine discharges the most water into the Gulf of Mexico of all the rivers of the western Gulf of Mexico. The Neches River basin contains a wealth of native plants and wildlife set aside as the Big Thicket National Preserve in 1974 and designated an International Biosphere Reserve by the United Nations Educational, Scientific, and Cultural Organization (UNESCO). Although presently fragmented, it forms corridors of old-growth bottomland hardwoods growing in soil enriched by frequent floods. Forestry, recreation, and petrochemicals are major land uses in the basins.

Dominant land use in basins that discharge into the western Gulf of Mexico shifts longitudinally. Eastern basins such as the Sabine and Neches are predominantly forested. The Trinity basin also is predominantly forested but with significant grasslands, croplands, and urban areas. Grasslands or

rangelands dominate in the central part of the region in catchments of the Brazos, Colorado, San Antonio/Guadalupe, and Pecos. Shrublands are the predominant land type in the most western and southern basins (Rio Grande and Nueces) of the region. Urbanization is rapidly changing the landscape in the region, with the Trinity and San Antonio/Guadalupe basins the most urbanized basins presently.

The Rivers

There are eight freshwater ecoregions within the western Gulf rivers of this chapter (Abell et al. 2000). These include the Upper Rio Grande in parts of Colorado, New Mexico, Texas, and Mexico; the Pecos in parts of New Mexico and Texas; the Lower Rio Grande in parts of Texas and Mexico; the Rio Conchos in Mexico; the Rio Salado in Mexico; the Rio San Juan in Mexico; the West Texas Gulf in Texas; and the East Texas Gulf in parts of Texas, Louisiana, and New Mexico.

The western rivers of the region (Rio Grande and Pecos) originate in the southern Rocky Mountains of Colorado and New Mexico (see Fig. 5.2). These rivers are high gradient, with hydrology dominated by spring snowmelt. Upper reaches of these rivers are higher gradient than other rivers in the region, with a rocky substratum of gravel, cobble, boulders, and bedrock. The western portions of the Rio Grande and the Pecos are in the Upper Rio Grande and the Pecos freshwater ecoregions, respectively (Abell et al. 2000). The lower Rio Grande, or Río Bravo del Norte as it is called in Mexico, is a separate freshwater ecoregion (Abell et al. 2000). This ecoregion encompasses much of the boundary between the United States and Mexico. The river in this part of the drainage basin is lower gradient, with tributaries from Mexico such as the Rio Conchos providing much of the flow.

Only one main river, the Nueces, is located in the West Texas Gulf freshwater ecoregion (Abell et al. 2000). Arising on the Edwards Plateau, this river passes through canyonlands in semiarid landscapes to the Gulf Coast area. The East Texas Gulf freshwater ecoregion (Abell et al. 2000) includes the San Antonio/Guadalupe, Colorado (Texas), Brazos, Trinity, Neches, and Sabine.

Annual peak flows in rivers like the Rio Grande and Pecos are quite predictable. Rivers originating from karst aquifers from the Edwards Plateau (San Antonio, Guadalupe, and Nueces) are spring fed and sustain strong base flow year-round. Flows in these

rivers become less predictable further downstream on the coastal plains. Peak flows in the rivers of eastern Texas are more unpredictable, with high flows possible throughout the year. Tropical storms can produce high flows in the fall, and heavy precipitation in winter and spring commonly results in floodplain forest swamps being inundated for weeks or months. However, natural flooding is substantially reduced or altered by dams and levees in upstream reaches in most rivers of the western Gulf of Mexico, and the lower reaches of these rivers are now channeled for navigation and irrigation.

An important natural feature of most lowland rivers of the Gulf Coast of Texas is the occurrence of wood (snags) as rivers undercut banks and support for trees fails. Large debris dams are documented in the history of several rivers in the region (Sabine, Colorado, Brazos, Trinity, and Neches). Navigation enhancement in the nineteenth century removed most of the major logjams that occurred naturally in the lowland portions of the rivers. Snags provided an important habitat, particularly for invertebrates, fishes, and reptiles, and thus likely enhanced overall biodiversity and faunal productivity. Unfortunately, wood has been removed from these rivers by snagboats for over a century because of hazards woody debris create for recreational and commercial navigation. More recently, the lower reaches of some of these rivers such as the Rio Grande have become choked with aquatic macrophytes, many nonnative to the region, and at times have ceased to flow to the Gulf of Mexico.

Rivers that discharge into the western Gulf of Mexico have considerable variability in their hydrology, chemistry, and biology. The Upper Rio Grande, Pecos, Lower Rio Grande, East Texas Gulf, and West Texas Gulf ecoregions are all considered to be continentally outstanding in their biological attributes (Abell et al. 2000). The current conservation status of the Pecos, West Texas Gulf, and East Texas Gulf ecoregions is vulnerable, whereas the Upper Rio Grande is endangered and the Lower Rio Grande is critical. Abell et al. (2000) anticipate that the Upper Rio Grande will become critical and the Pecos will become endangered within the next 20 years. Rivers of the Texas Gulf Coast contain more than 160 species of freshwater fishes, over 50 species of unionid mussels (Howells et al. 1996), and 38 species of crayfishes, although not all crayfishes are riverine species. At least 42 species of freshwater fishes and nine species of mussels are at risk of extinction. Major threats to rivers of the region are urban development, wastewater effluent, water extraction,

nonpoint-source pollution, nonnative species, and impoundments.

RIO GRANDE

The Rio Grande is 2830 km in length and is the 5th longest river in North America and 24th longest river in the world. Its headwaters begin at approximately 3700 m asl in the San Juan Mountains of southern Colorado. After entering New Mexico, the river bisects the state and then flows in a generally southeastern direction as it forms the shared border between Texas and Mexico before it empties into the Gulf of Mexico near Brownsville, Texas (Fig. 5.11). Because of its length, the Rio Grande travels through a wide variety of habitats, ranging from mountain forests to chaparral, high mountain desert, and lowland brush country. The watershed encompasses about 870,000 km²; however, a large proportion of the river's basin is arid or semiarid, with a number of endorheic (inwardly draining) subbasins such that only about half of the total area, or about 450,000 km², actually contributes to the river's overall flow.

The Rio Grande basin was home to the Clovis culture, a group of Paleo-Indians first known through artifacts unearthed near Clovis, New Mexico. The oldest Clovis cultural artifacts have been dated to about 12,000 years ago. Clovis groups were big-game hunters, and the earliest known definitively dated human populations in the Americas. The Rio Grande basin in New Mexico also was home to Anasazi culture from about 1700 to 600 years ago. Some of the descendants of the Anasazi culture that built the great ancient cities at Mesa Verde, Colorado, Chaco Canyon, New Mexico, and Canyon de Chelly, Arizona, are thought to have immigrated to the Rio Grande and Little Colorado during severe droughts in the thirteenth century. Many Indian pueblos that used the river for crop irrigation were present at the time of early Spanish exploration. Numerous thriving settlements were found along the Rio Grande in New Mexico by Spanish conquistadors in 1540. The region along the shared Texas–Mexico border also has had a long history of human habitation. Originally, major Indian groups inhabited the area and left numerous relics and pictographs throughout the region. The major tribes included the Jumanos, a group of primarily hunters and traders in the trans-Pecos region of western Texas, the Pataragueyes, a group of pueblo farmers along the Rio Grande near the El Paso area downstream to about Big Bend National Park, and the

Coahuiltecans, who were primarily hunter-gatherers in the south Texas brushlands region. Because of the remote location of this latter group, they had little contact with early Europeans. Other tribes that traveled through the area and traded with indigenous groups included various Apache and, later, Comanche tribes.

Spanish explorers first sighted the mouth of the Rio Grande in 1519 during the Spanish expeditions by Alonso Alvarez de Pineda, who sailed out of Jamaica. Stories of splendid cities and gold along the river sparked exploration by Captain Francisco Vasquez de Coronado in 1540 and 1541. Although his expedition failed to find gold, the expedition described pueblos along the Rio Grande and one of its main tributaries, the Pecos. In 1598 Don Juan de Onate began settlements along the Rio Grande in the El Paso area with 100 families and 300 single men. Missions and settlements developed along the river valley until 1680, when a Pueblo revolt drove the Spanish out of the upper Rio Grande. The Spanish returned in 1692 and brutally reasserted their dominance along the river and within the basin.

Spanish control of the region began to weaken with Anglo-American colonization of Texas in the early 1800s and the Mexican revolt against Spain that led to Mexican freedom in 1821. Political unrest in Mexico and increasing numbers of Anglo-Americans in Texas set the stage for the Texas Revolution in 1835. In 1836, Texas put forth a claim for the Rio Grande from mouth to source as the southwestern and western boundary of the Republic of Texas. The Rio Grande was finally recognized by Mexico as the Texas boundary with Mexico in the Treaty of Guadalupe Hidalgo in 1848 at the end of the Mexican War (Horgan 1984).

Physiography, Climate, and Land Use

The Rio Grande flows through seven physiographic provinces including the Southern Rocky Mountains (SR), Colorado Plateau (CO), Basin and Range (BR), Great Plains (GP), Coastal Plain (CP), Sierra Madre Occidental (SC), and Sierra Madre Oriental (SO) (see Fig. 5.11). Piñons, junipers, and sagebrush in the semiarid north of New Mexico give way to mesquite, creosote bush, cactus, and other drought-tolerant plants in the south of New Mexico and west Texas. The landscape in the lower basin is primarily hilly scrub and brush, gradually less hilly as the river approaches the Gulf of Mexico. Ricketts et al. (1999) show eight terrestrial ecoregions within the Rio Grande basin (Colorado

Rockies Forests, Colorado Plateau Shrublands, Chihuahuan Desert, Tamaulipan Mezquital, Sierra Madre Occidental pine–oak Forests, Sierra Madre Oriental oak–pine Forests, Tamaulipan Matorral, and Tamaulipan Pastizal).

Climate changes markedly from the headwaters to the mouth of the Rio Grande. Climate conditions in the San Luis Valley of southern Colorado are cold and dry below the San Juan Mountains, which hold the winter snows that sustain the headwater streams of the Rio Grande. Average temperatures in Alamosa, Colorado (37.45°N, 105.86°W), at 2297 m asl range from -9.6°C in January to 18.2°C in July. Annual average precipitation is 18.1 cm, with a peak in August and a minimum in February. Average temperatures in Albuquerque, New Mexico (35.03°N, 106.61°W), in the Middle Rio Grande of central New Mexico at 1617 m asl range from 1.2°C in January to 25.8°C in July (Fig. 5.12). Average annual precipitation is 21.5 cm, with a peak of 3.9 cm in August and a minimum of 1.0 cm in January (see Fig. 5.12). Average temperatures in El Paso, Texas (31.80°N, 106.40°W), in westernmost Texas at 1194 m asl range from 6.0°C in January to 27.9°C in July. Average annual precipitation is 21.8 cm, with a peak in August and a minimum in April. Average temperatures near the mouth of the Rio Grande at McAllen, Texas (30 m asl) range from 14.7°C in January to 29.8°C in August. Average annual precipitation is 57.7 cm, with peaks in May and September and a minimum in March. Climate in the basin ranges from cold temperate to subtropical along the 2830 km of the Rio Grande.

Land use in the Rio Grande basin includes forest (14%), cropland (5%), shrubland (43%), grassland (31%), and urban (7%). Most of the basin is either desert shrubland or desert grassland. Population density was recently estimated at 16 people/km² (Revenga et al. 1998). Urban areas are growing fast, with border towns between the United States and Mexico, such as El Paso, Juárez, Piedras Negras, Laredo, Nuevo Laredo, Brownsville, and Matamoros, growing particularly rapidly. Irrigated agriculture from the Rio Grande is most prevalent in the San Luis Valley of southern Colorado, the Middle Rio Grande and Mesilla valleys of New Mexico, and the lower Rio Grande Valley of southern Texas. Principal crops vary along the river, with Colorado and northern New Mexico growing potatoes and alfalfa, southern New Mexico and west Texas growing cotton, peppers, onions, and pecans, and the lower Rio Grande Valley growing citrus fruits, vegetables, and cotton.

River Geomorphology, Hydrology, and Chemistry

The headwaters of the Rio Grande begin along the continental divide in the San Juan Mountains in southern Colorado. The Rio Grande begins as a clear spring- and snow-fed mountain stream draining forested slopes. The river next passes through the San Luis Valley of southern Colorado. The Rio Grande then flows east and south into New Mexico through a canyon 113 km long and up to 250 m deep. The Rio Grande exits the canyon country and is impounded north of Albuquerque by Cochiti Dam, completed in 1975. The Rio Grande flows southward from Cochiti Reservoir through the Middle Rio Grande valley of central New Mexico to Elephant Butte Reservoir, completed in 1916 (Fig. 5.11). Elephant Butte is the largest reservoir in New Mexico.

The Rio Grande flows south from Elephant Butte Reservoir to Caballo Reservoir and into southern New Mexico. Approximately 32 km north of El Paso, Texas, the Rio Grande forms the New Mexico–Texas border. The river then trends generally southeasterly to the Gulf of Mexico, comprising the United States–Mexico border beginning in the El Paso/Juárez area. Below Presidio/Ojinaga, the Rio Grande increasingly flows through a more mountainous region, first continuing its southeasterly flow and then cutting northeast through the Big Bend country of Texas and Mexico. The northern portion of this large bend on the U.S. side of the border comprises Big Bend National Park and represents one of the most isolated environments within the U.S. National Park system. The Rio Grande cuts three spectacular sheer-walled canyons between 457 and 518 m in depth across this faulted region and then continues northeasterly for several hundred km until it again turns to the southeast for the remainder of its course (Fig. 5.1). Below Big Bend, Amistad Dam (completed 1969) and Falcon Dam (completed 1953) impound the Rio Grande along the border for irrigation and flood control. The Rio Grande increasingly has not reached the ocean as human consumption of river water increases in both the United States and Mexico. In the lowermost reach, the Rio Grande wanders sluggishly across the coastal plain to its delta on the Gulf of Mexico. The lowermost river delta area is primarily flat, with clay, loam, and sandy soils that have been transformed into a large agricultural area.

River gradient of the Rio Grande is greatest in reaches in northern New Mexico and southern Colorado ($>3\text{ m/km}$). Gravel, cobble, and boulders dominate the substrates in this reach. The Middle Rio

Grande in New Mexico has an average gradient of 91 cm/km from Cochiti Reservoir to Elephant Butte Reservoir. A shifting sand bottom was characteristic historically, but the dams and channelization have increased the extent of gravel and cobble in various portions of this reach. The reach from Elephant Butte to El Paso, Texas, is largely channelized and serves to deliver irrigation and municipal water from Elephant Butte and Caballo reservoirs. The average gradient is 57 cm/km. The reach from El Paso to Laredo, Texas, grows steeper (~70 cm/km) and includes the canyonlands of Big Bend National Park. The lowest gradients are in the Coastal Plains section of the river (~20 cm/km).

Geomorphology of the Rio Grande in New Mexico and Colorado is closely associated with the Rio Grande rift and human depletion of surface waters. Jones and Harper (1998) showed that channel avulsions (abrupt shifts in channel location) were common in segments of the Rio Grande in south-central Colorado before major discharge changes due to irrigated agriculture. Avulsions decreased from 19 (1875 to 1941) to 2 (1941 to present). The active channel of the Middle Rio Grande of central New Mexico decreased in area from 8973 ha in 1935 to 4345 ha in 1989 (Crawford et al. 1993). The historical Rio Grande in the southern Rio Grande rift in the Mesilla basin of southern New Mexico was an incised pebbly sand bedload stream prior to completion of Elephant Butte Dam in 1916 (Mack and Leeder 1998). Sand and silt now predominate. Major avulsions occurred in this reach of the Rio Grande between 1844 and 1912 but ceased after completion of Elephant Butte Dam. Channel geomorphology between Fort Quitman and Presidio, Texas, also has undergone major changes as upstream discharge has declined (Everitt 1993). Channel capacity has decreased and stabilized and the river has shortened, steepened, and migrated away from major tributaries. Nonnative riparian plant communities have invaded a majority of the now stabilized former river channel.

Hydrologically, Rio Grande peak flow historically occurred from April to June in the river above the confluence of the Río Conchos near Presidio, Texas, due to montane snowmelt in the mountains of southern Colorado and northern New Mexico. The Río Conchos is the largest tributary to the Rio Grande, and peak flows downstream of the confluence with the Río Conchos often occur in August, September, or October during the monsoons of northern Mexico. The principal tributaries of the Rio Grande are the Pecos, Devils, Chama, and intermittent

Puerco rivers in the United States and the Conchos, Salado, and San Juan rivers in Mexico.

Flow upstream of Cochiti Dam in New Mexico remains snowmelt dominated. Average flow at Otowi gage immediately upstream of Cochiti Reservoir based on a 97-yr record has been 43 m³/s, with peak flows most commonly in May. Discharge downstream of Cochiti Dam through Albuquerque, New Mexico, has averaged 34 m³/s, reflecting both reductions for agriculture and evaporation losses from the reservoir. The channelized Rio Grande flows about 300 km from the outlet of Cochiti Dam to Elephant Butte Reservoir, with additional agricultural diversions along the reach, sometimes causing the river bed to go dry.

Water release from Elephant Butte Dam is about 27 m³/s and is largely diverted for crop irrigation in southern New Mexico. Water reaching Texas and Mexico is diverted to the United States (~11 m³/s) as the main supply canal for El Paso and to Mexico (~2 m³/s) for irrigation of the Juarez Valley. There is a significant reduction in the flow of the Rio Grande following these diversions. Downstream from the El Paso/Juarez area, nearly all of the water remaining in the river stems from wastewater and agricultural return flows (Miyamoto et al. 1995, Schmandt et al. 2000). This limited amount of water provides the majority of the flow of the river for several hundred kilometers downstream to Presidio/Ojinaga, where the Río Conchos enters the Rio Grande. Annual average flow of the Rio Grande immediately above the Río Conchos confluence is only about 3 m³/s.

The Río Conchos historically contributed an average annual flow of about 30 m³/s of water into the Rio Grande at its confluence at the cities of Presidio and Ojinaga (but see Chapter 23), forming the main flow of the Rio Grande in the stretch between the confluence and Amistad Reservoir (Eaton and Hurlburt 1992, IBWC 1990, TNRCC 1994). The Pecos River and the Devils River historically contributed about 9 and 11 m³/s to the flow of the Rio Grande, respectively, although these flows have been reduced substantially. All of these flows are stored at Amistad International Reservoir. Amistad Dam, opened in 1968, averages an annual discharge of approximately 65 m³/s. Nearly half of this is taken into the Maverick Canal located 28 km south of Del Rio, Texas, for power generation and irrigation and most is returned to the river upstream of Eagle Pass, Texas. There are few diversions between Eagle Pass and Laredo, and the river discharges approximately 89 m³/s at Laredo, Texas. The Río Salado enters Falcon Reservoir downstream from Laredo with an

annual contribution of approximately $15\text{ m}^3/\text{s}$ for a combined flow of about $95\text{ m}^3/\text{s}$ at Falcon International Reservoir. Below Falcon Reservoir, the Río San Juan ($\sim 14\text{ m}^3/\text{s}$) flows into the Rio Grande from the Mexican side at Camargo. Two large diversions and numerous other pumps divert water between Rio Grande City and Brownsville, Texas, for irrigation and municipal supplies. Although mean virgin discharge of the Rio Grande probably exceeded $100\text{ m}^3/\text{s}$ by the time the river reached Brownsville (near the mouth), the current flow is only $\sim 37\text{ m}^3/\text{s}$. Much of this comes during flood events, in particular hurricanes and tropical storms (Miyamoto et al. 1995, Schmandt et al. 2000).

Irrigated agriculture is the primary use of the Rio Grande surface flow throughout the basin. Below Elephant Butte Reservoir, 35,200 ha of cropland are irrigated in New Mexico. In the El Paso and Juarez Valleys, approximately 17,000 ha are irrigated, and an additional 2000 ha are irrigated between Fort Quitman and Amistad Reservoir on the Texas side of the border. Between Amistad and Falcon reservoirs an estimated 16,300 ha are irrigated on the Texas side, mostly in Maverick County. Below Falcon Reservoir, irrigated agriculture is especially great; over 310,000 ha are irrigated on the Texas side and approximately 292,000 ha are irrigated on the Mexican side of the river. Evaporation from major reservoirs also is substantial in the region and has been estimated to exceed the quantity of water used for municipal purposes in the basin. Municipal water usage from the Rio Grande averages about $3\text{ m}^3/\text{s}$ on the Texas side and $1.5\text{ m}^3/\text{s}$ on the Mexican side. This usage is approximately 3% to 5% of the agricultural consumption of the river along this reach. Relatively few industrial users occur within the basin. The major industrial user of the Rio Grande is the Laredo Power Plant, which consumes only $0.05\text{ m}^3/\text{s}$. Population in the basin was about 13 million inhabitants as of 1990. The population along the Texas border increased by 27% between 1980 and 1990, and the Mexican population along the border increased 26% in those same years.

Runoff represents about 15% of precipitation in the high-elevation regions in the upper Rio Grande basin as measured in the Albuquerque reach (see Fig. 5.12). Snowmelt hydrology dominates in this portion of the basin, with peak runoff from April through June. Human appropriation of Rio Grande water increases downstream, and the basin is increasingly xeric in southern New Mexico and west Texas. The Rio Grande failed to reach the Gulf of Mexico for multiple months in 2002 and 2003. Evapotranspira-

tion, groundwater recharge, and human appropriation of Rio Grande water has resulted in less than 1% of basin precipitation reaching the Gulf of Mexico in recent years.

Water chemistry and water quality change markedly throughout the basin. Nutrient loading in the upper basin occurs in the Alamosa Valley of Colorado, from the wastewater treatment plant in Albuquerque, New Mexico, in the Mesilla Valley, and from the cities of El Paso, Texas, and Juarez, Mexico. The Upper Rio Grande from Colorado to El Paso, Texas, was a National Water Quality Assessment (NAWQA) site from 1992 to 1995 (Ellis et al. 1993, Carter and Porter 1997, Levings et al. 1998). Major findings include the increasing incidence of pesticides downstream, trace element elevations in the Creede, Colorado, mining district, an environmentally stressed fish community, and significant habitat degradation in many reaches. Total dissolved solids are a concern in the El Paso and Fort Quitman, Texas, reach due to evapotranspiration and naturally occurring sources of salinity derived from deep groundwater sources (Hibbs and Boghici 1999). Fecal coliforms, nutrients, low dissolved oxygen, pesticides, herbicides, metals, and organic contaminants are significant concerns in the borderlands between the United States and Mexico.

River Biodiversity and Ecology

The Rio Grande basin contains six freshwater ecoregions, including the Upper Rio Grande, Lower Rio Grande, Pecos, Rio San Juan, Rio Salado, and Rio Conchos (Abell et al. 2000). The Guzmán ecoregion is also part of the Rio Grande complex (Abell et al. 2000) but is endorheic and thus does not actually drain into the Rio Grande system. For such a large and important river basin, the biodiversity and ecology of the Rio Grande is not particularly well studied.

Algae and Cyanobacteria

Published information on the algal communities of the Rio Grande is sparse. *Cladophora*, *Zygnema*, and periphytic diatoms (*Synedra* and *Cymbella*) were common in the Pecos River (Davis 1980a). Dense growths of filamentous green algae (*Cladophora*, *Vaucheria*, and *Ulothrix*) also were reported on the streambed of the Pecos River in certain areas. Unpublished data from the Rio Grande NAWQA study by the USGS on the Rio Grande in southern Colorado and New Mexico found benthic diatoms (*Nitzschia*, *Navicula*, *Achnanthes*, *Cocconeis*, *Fragilaria*,

Staurosira, *Synedra*, *Amphora*, *Luticola*, *Caloneis*, and *Tryblionella*), cyanobacteria (*Oscillatoria*, *Spirulina*, *Schizothrix*, and *Lyngbya*), and green algae (*Cladophora*, *Closterium*, *Cosmerium*, *Pediastrum*, and *Scenedesmus*) to be common (Scott Anderholm, unpublished data).

Plants

Riparian vegetation changes along the considerable length of the Rio Grande. Lowland riparian areas in the upper Rio Grande of Colorado and central and northern New Mexico were historically dominated by cottonwoods, with willows and a variety of native shrubs (Snyder and Miller 1992, Ellis et al. 2002). Unfortunately, nonnative species increasingly dominate riparian areas in this region (Howe and Knopf 1991, Everitt 1998, Ellis et al. 2002). Saltcedar and Russian olive are particularly successful invaders. This has led to considerable research on the interactions between native and nonnative species and methods for control of invasive species (e.g., Shafroth et al. 1995; Taylor and McDaniel 1998; Taylor et al. 1999; Sprenger et al. 2001, 2002). Litter dynamics of native and nonnative vegetation in riparian areas also has been studied in detail (e.g., Molles et al. 1995, Ellis et al. 1999).

Nonnative species also play a major role in the riparian zones of southern New Mexico and western Texas. Saltcedar dominates much of the riparian areas until the confluence of the Rio Grande with the Rio Conchos. Dominant riparian tree species in the lower Rio Grande below the confluence of the Rio Conchos include mesquite, hackberry, cedar elm, anacua, black willow, and retama. Nonnative aquatic macrophytes, including water hyacinth and hydrilla, increasingly choke the channel of the lower Rio Grande (Everitt et al. 1999). Introduced grasses, such as Guinea grass and buffelgrass, also are becoming dominants in many areas of the riparian zone of the lower Rio Grande (Lonard et al. 2000).

Invertebrates

Data on the aquatic invertebrates of the Rio Grande are limited. Ward and Kondratieff (1992) reported 19 species of mayflies, 21 species of stoneflies, and 25 species of caddisflies occurring in the Colorado portion of the Rio Grande drainage. Sampling in the canyon country of the Rio Grande in northern New Mexico, Shaun Springer (New Mexico Environment Department, unpublished data) found the dominant taxa to be hydropsychid caddisflies; the

caddisflies *Brachycentrus*, *Leucotrichia*, and *Stactobiella*; the mayflies *Baetis tricaudatus* and *Tricorythodes*; and various true flies, such as *Atherix*, black flies, and chironomid midges (e.g., *Cricotopus*). Davis (1980b) sampled the aquatic invertebrates of the Rio Grande at seven sites in Texas from El Paso to Del Rio. Water quality and quantity varied substantively along this reach of the Rio Grande. Poor water-quality sites with lower mean diversity (e.g., El Paso, Zaragoza International Bridge, and Upper Presidio) were dominated by the Asiatic clam; oligochaete worms; the mayfly *Homoeoneuria*; the caddisfly *Cheumatopsyche*; the chironomids *Hydrobaenus*, *Dicrotendipes*, and *Cricotopus*; and other true flies (*Palpomyia tibialis*, psychodids, and the black fly *Simulium*). Sites with higher water quality and greater mean diversity (e.g., Lower Presidio, Santa Elena Canyon, Foster's Ranch, and Del Rio) were dominated by the caddisflies *Cheumatopsyche*, *Hydroptila*, and *Protophila*; the mayflies *Thraulodes*, *Traverella*, *Choroterpes mexicanus*, and *Tricorythodes*; the chironomids *Orthocladus* and *Cricotopus trifascia*; the black fly *Simulium*; and the Asiatic clam. Surface-active arthropod communities of the Rio Grande riparian forests also have been described (Ellis et al. 2000, Ellis et al. 2001). Nonnative isopods (*Armadillidium vulgare* and *Porcellio laevis*) were abundant, along with native crickets and carabid beetles.

The Rio Grande once had a much larger group of freshwater mussels (Unionidae) than are presently found. At least 16 species of unionid mussels once occurred within the Rio Grande drainage, but these are among the fastest declining groups in the basin, in part because of their environmental sensitivity and intolerance to degraded conditions. Some mollusks are expanding in the basin, such as the introduced and highly tolerant Asiatic clam, which are found to be locally abundant at sites throughout the Rio Grande (Howells 2001). Other common bivalves in the lower Rio Grande of Texas include paper pondshell, tampico pearly mussel, and yellow sandshell mussel (Neck and Metcalf 1988).

Vertebrates

Approximately 166 species of fishes have been found in the Rio Grande when both freshwater (86) and brackish water (80) species are considered. At least 34 of these species are considered rare or endangered and many appear on the endangered species list of the United States. Endangered species include shovelnose sturgeon, American eel, a number of minnows (Mexican stoneroller, Maravillas red shiner,

proserpine shiner, manatial roundnose minnow, Devils River minnow, Rio Grande chub, Chihuahua chub, Rio Grande silvery minnow, Chihuahua shiner, Rio Grande shiner, Pecos bluntnose shiner, Tamaulipas shiner, ornate shiner), two suckers (west Mexican redhorse, blue sucker), three catfishes (headwater catfish, Chihuahua catfish, and a unique form of blue catfish in the Rio Grande in west Texas), a trout (Rio Grande cutthroat trout), and four pupfish (Leon Springs pupfish, Comanche Springs pupfish, Pecos pupfish, Conchos pupfish). In addition, there are four livebearers (Big Bend gambusia, blotched gambusia, Pecos gambusia, and an undescribed species of gambusia from the Del Rio area), a darter (Rio Grande darter), and a number of coastal forms (opossum pipefish, snook, fat snook, river goby). Several species of fishes have gone extinct in the basin, including phantom shiner, bluntnose shiner, Amistad gambusia, and very likely blackfin goby.

The fishes of the Rio Grande basin are dominated by a rich minnow (Cyprinidae) assemblage. Where spring systems exist, unique components of pupfishes and livebearers are found. More than 16 families of fishes also are found in the nontidal portions of the basin (Miller 1977, Hubbs et al. 1991), excluding the mountain headwaters, and most localities also include one or two gars (Lepisosteidae), one or two species of shad, several suckers, several catfishes, sunfishes, a drum, and a single species each of *Astyanax* and *Cichlasoma*, species that are far better represented in more southern drainages. Compared to other western Gulf drainages, the darter fauna is greatly reduced; however, several species are found in limited areas in the basin. Dams along the river have greatly restricted the natural range of the American eel and greatly expanded the range of other species such as the inland silverside. One of the greatest problems for the fishes of the basin is the dewatering of the watercourse. This is especially evident in the region downstream from Albuquerque, New Mexico, and in the lowermost Rio Grande near its mouth, where its characteristic freshwater fauna has largely been replaced by estuarine and marine forms (Edwards and Contreras-Balderas 1991). The closing of the mouth in 2001 from lack of freshwater inflows has temporarily prevented the invasion of marine species into the lower watercourse.

Many bird species in the basin, such as the common yellow-throat, great blue heron, snowy egret, black-crowned night heron, white-faced ibis, belted kingfisher, and green kingfisher, are dependent on the Rio Grande. Aquatic reptiles of the Rio

Grande include the plainbelly water snake, bullfrog, Rio Grande leopard frog, snapping turtle, box turtle, and western ribbon snake. Beaver, mink, and nutria are found in the river, and the American alligator occurs in the Coastal Plain of the Rio Grande.

Ecosystem Processes

A major change in the Rio Grande in recent years has been the disconnection of the river from the floodplain (Molles et al. 1998). River–floodplain ecosystems are some of the most productive and diverse ecosystems in the world. Fragmentation of river channels by dams, diversions, and depletions reduces productivity and simplifies the structure of the riparian ecosystem. Elimination of the flood pulse in May and early June in the Rio Grande Valley of central New Mexico has reduced germination and establishment of native cottonwoods and willows, favored invasions by saltcedars and Russian olives, and increased the incidence and destructiveness of fires. Managed flooding as a restoration tool has been recommended to promote native populations and communities of plants and animals and to stimulate decomposition and nutrient cycling (Crawford et al. 1993, Molles et al. 1995, Molles et al. 1996, Molles et al. 1998).

Large numbers of overwintering birds in the Rio Grande basin influence nutrient cycling at the landscape scale. Kitchell et al. (1999) showed that wintering waterfowl were a major source of nutrients to riverine wetlands at Bosque del Apache National Wildlife Refuge in central New Mexico. Geese increased nutrient loading by up to 40% for total nitrogen and 75% for total phosphorus. Stable isotopes of nitrogen showed the importance of alfalfa and corn derived from foraging birds in the food webs of the ponds, with fishes and crayfishes deriving much of their nitrogen from these sources.

Water availability is a critical limiting resource in riverine corridors in arid and semiarid regions of the world. Dahm et al. (2002) examined the role of riparian evapotranspiration (ET) by native and nonnative riparian tree species in surface water losses of a 320 km reach of the Rio Grande in central New Mexico. Tower-based micrometeorological measurements using eddy covariance methodology were employed during the growing season to determine annual ET (74 to 123 cm/yr at two saltcedar and two cottonwood sites). Results were scaled to the 320 km corridor using satellite imagery and leaf area index (LAI) measurements. Riparian ET was estimated to

be between 20% and 33% of total surface water losses along this reach of the Rio Grande.

Human Impacts and Special Features

The Rio Grande has been called “Great River” because of its prominent role in the history of the American Southwest (Horgan 1984). The Rio Grande is the fifth longest river in North America after the Mississippi/Missouri, Mackenzie, Yukon, and St. Lawrence. The river basin is large at 870,000 km², and the “Great River” has been a major influence on Native American, Hispanic, and European cultures for centuries. Predictable snow-melt hydrology long provided the water, sediment, and nutrients for human agriculture along the riverine corridor.

The Rio Grande presently is one of the most impacted rivers in the world. Both water-quantity and water-quality issues are major concerns. The central portion of the Rio Grande from Elephant Butte and Caballo dams to the confluence of the Rio Conchos operates largely as a ditch for water delivery for agriculture and rapidly growing municipalities. Amistad and Falcon dams in the lower border reach further regulate flow and divert water for irrigation. The Rio Grande failed to reach the Gulf of Mexico in much of 2002 and 2003. Water-quality problems include elevated salinity, nutrients, bacteria, metals, pesticides, herbicides, and organic solvents. In addition, riparian areas in most parts of the basin are in decline, with nonnative species dominating in many reaches.

The segment of the Rio Grande from the Colorado state line southward for almost 110 km is designated as a National Wild and Scenic River. White-water rafting through gorges up to 250 m deep is a primary recreational opportunity. Bosque del Apache National Wildlife Refuge in central New Mexico is the winter home to tens of thousands of waterfowl, with large populations of snow geese and sandhill cranes. Chamizal National Memorial in El Paso, Texas, was established along the Rio Grande to commemorate peaceful settlement of a century-long boundary dispute between Mexico and the United States caused by migration of the Rio Grande river channel. The Rio Grande is again designated as a Wild and Scenic River for 315 km from the Coahuila/Chihuahua, Mexico, state border below its confluence with the Rio Conchos to the Terrell/Val Verde county line. Approximately 111 km of this segment of Wild and Scenic River makes up the boundary of Big Bend National Park.

SAN ANTONIO AND GUADALUPE RIVERS

The San Antonio River arises from a series of medium to small springs about 6 km north of downtown San Antonio, Texas. Although numbering more than 100, many of these springs flow only during periods of very wet weather. The river flows 288 km southeasterly until it joins the Guadalupe River near Tivoli, Texas, just before it empties into San Antonio Bay on the Gulf of Mexico (Fig. 5.13). The Guadalupe River rises as springs in two forks, the North Fork (30°06'N, 99°39'W) and South Fork (30°04'N, 99°20'W). After the confluence of the two forks near Hunt, Texas, the Guadalupe River proper flows southeast 368 km before reaching its mouth at San Antonio Bay (28°26'N, 96°48'W). The principal tributaries of the Guadalupe are the Comal and San Marcos rivers, which contain the two largest springs in the southwest. The Guadalupe flows across the Edwards Plateau, the Balcones fault line, and the Coastal Plain (Fig. 5.3). Together, the two rivers drain an area of 26,231 km². The spring flow of the San Antonio and the Guadalupe and their principal tributaries keeps the discharge of the rivers steadier than that of most western Gulf Coast rivers.

The San Antonio and Guadalupe basins have supported human habitation for nearly 10,000 years. Early Spanish explorers encountered Tonkawa, Waco, Lipan Apache, and Karankawa Indians. The San Antonio was probably first encountered by Spanish explorers in 1535, when Álvar Núñez Cabeza de Vaca crossed the San Antonio. The river was named for San Antonio de Padua on June 13, 1691. The present headwater areas of the San Antonio impressed Spanish missionaries, and the San Antonio de Valero Mission was established on the east bank of the river on May 1, 1718. Plentiful water for drinking, irrigation, and power made the San Antonio River the center of Spanish activities in the province of Texas. The name Guadalupe has been applied to at least the lower course of the Guadalupe River since 1689, when Alonso De León named the stream. Spanish settlement along the Guadalupe began in the 1720s, when several missions were established. Additional settlements along the river were established by settlers from Spain, Mexico, and the United States up through the beginning of the Texas Revolution in 1835. The first shot of the Texas Revolution occurred at Gonzales, Texas, on the south bank of the Guadalupe on October 2, 1835. The San Antonio River also played a prominent role in the

FIGURE 5.3 Guadalupe River above Rt. 311 (PHOTO BY TIM PALMER).

Texas Revolution. Numerous battles were fought along the San Antonio, including the Alamo, Concepción, and Grass Fight. The siege of Bexar and the Goliad Massacre also occurred in close proximity to the San Antonio River. After the Texas Revolution, settlements were begun further upstream on the Guadalupe River, including Seguin (1839), New Braunfels (1845 by German settlers), and Kerrville (1856). Construction of railroads in the 1880s through the middle and upper Guadalupe valley brought many new residents. Although early attempts at navigation on the Guadalupe were limited due to large snags and small waterfalls, its steady flow made the river attractive for hydropower and numerous dams were built beginning in the 1800s. Larger dams for flood control were built, with Canyon Lake, completed in 1964, a major source of flood control for the lower basin. During the latter 1800s, the San Antonio River was prominent in the development of the city of San Antonio. More than fifty bridges in the city now span the San Antonio and the river flows for 24 km through San Antonio, Texas. The Riverwalk or “Paseo de Río” in downtown San Antonio is one of the principal attractions of the city.

Physiography, Climate, and Land Use

The San Antonio and Guadalupe rivers flow through two physiographic provinces, the Great Plains (GP) and the Coastal Plain (CP). Originating from the Edwards Plateau section of the Great Plains province, the rivers flow through the highly dissected limestone of the Edwards Plateau, the rolling, hilly Blackland Prairies, and the low-relief Coastal Plain (see Fig. 5.13). Beginning in the Edwards Plateau, the rivers pass through four terrestrial ecoregions (Edwards Plateau Savannas, Texas Blackland Prairies, East Central Texas Forests, and Western Coastal Grasslands) as they descend to San Antonio Bay. Common upland vegetation types from the Edwards Plateau to the coast are juniper–oak–mesquite savannah, blackland prairie grasses, oak hickory forest, oak savannah, and coastal prairie grasses. Soils include dark calcareous stony clays and clay loams in the upper basin, light brown to dark gray acid sandy and clayey loams in the middle basin, and dark-colored neutral to slightly acid clay loams and clays in the lower basin.

Average annual temperature at San Antonio, Texas, is 20.3°C, with minimum average monthly temperature of 9.6°C in January and maximum average monthly temperature of 29.4°C in July. Average annual precipitation is 74 cm, with minimum

average monthly precipitation of 4.2 cm in January and maximum average monthly precipitation of 10.2 cm in May. Conditions are similar in the Guadalupe River basin. For example, annual average temperature at Cuero, Texas, is 21.0°C, with minimum average monthly temperature of 11.0°C in January and maximum average monthly temperature of 29.0°C in July and August (Fig. 5.14). Average annual precipitation is 81 cm, with minimum average monthly precipitation of 4.0 cm in March and maximum average monthly precipitation of 9.6 cm in May (see Fig. 5.14).

Land use in the San Antonio/Guadalupe basin is a mix of range (60%), agriculture (15%), and urban (25%). Population densities in 2000 ranged from 433 people/km² in the San Antonio area to 6 people/km² in rangeland-dominated counties. Overall, the basin averages approximately 85 people/km². Agricultural products include livestock, cotton, peanuts, vegetables, poultry, rice, and dairy products. Croplands increase from the headwaters to the mouth of the rivers. The cattle industry was important in this region in the early years of settlement, whereas sheep and goats now graze the sparse grasslands on the poor soils of the limestone uplift in the upper portions of the basin. Tourism and recreation are increasingly important aspects of land use throughout the basin. For example, people are rapidly buying up Hill Country (the commonly used name for the Edwards Plateau) property as tourism has begun to edge out agriculture as an economic base in the region. Urbanization with increased emphasis on recreation and tourism is expanding substantially in the San Antonio/Guadalupe drainage basin.

River Geomorphology, Hydrology, and Chemistry

The upper segments of the San Antonio and Guadalupe flow through limestone terrain. Limestone bluffs are interspersed with less confined river reaches. The rivers pass over the Balcones fault line with higher gradient reaches and occasional small waterfalls. After the Balcones Fault Zone, the rivers transition into the Coastal Plain, where they become low-gradient meandering systems with sand bars and wider, less-constrained channels, except where channeled by levees.

Springs from the Edwards Plateau and the Balcones Fault Zone sustain good base flow conditions in both the San Antonio and Guadalupe rivers throughout the year and especially during times of drought. A 38-year U.S. Geological Survey record for

the San Antonio near Elmendorf, Texas, has mean monthly flows that range from 11 m³/s in August to 27 m³/s in June. Mean values over approximately the same period for the Guadalupe River at Cuero, Texas, range from 32 m³/s in August to 92 m³/s in June, although these values were to some degree determined by the operation of Canyon Dam, for which construction began in 1958. Before this time, peak discharge occurred in May, rather than June, based on records from 1935 through 1957 at the Victoria gaging station. Mean discharge (38 years) for the San Antonio is about 21 m³/s and for the Guadalupe is about 58 m³/s, for an approximate total of 79 m³/s at their confluence just before emptying into San Antonio Bay. Annual runoff for the Guadalupe basin is about 14 cm, with the lowest monthly runoff (0.7 cm) in August and the highest (1.9 cm) in June (see Fig. 5.14). Runoff for the San Antonio basin is somewhat lower than for the Guadalupe. Base flows in the San Antonio during drought remain above 2 m³/s, with peak monthly mean flows as high as 240 m³/s during exceptionally wet periods. Flows are somewhat more variable in the Guadalupe River. The Guadalupe River at Cuero had minimum monthly flows of <3 m³/s during a strong drought in 1984 and maximum monthly flows of nearly 900 m³/s during an extremely wet month in October 1998. Flooding from rainfall and hurricanes is characteristic of this area. Long-term averages of monthly discharge show peak discharge in June and minimum discharge in August.

Water quality of the spring sources for the San Antonio and Guadalupe rivers is generally good; however, both rivers experience localized organic and chemical pollutant inputs from urban sources. The Edwards aquifer has had no major water-quality problems to date. The water chemistry reflects the karst nature of the aquifer, with calcium the major cation and bicarbonate the major anion. The chemistry of the Guadalupe and San Antonio rivers also shows a major influence of the large springs emanating from the limestone geologic units. The pH ranges from about 7.0 to 9.0. Specific conductance is normally in the 700 to 1100 μ S/cm range, except for drops to lower levels during storms. The dominant cations are calcium, sodium, and magnesium, and the dominant anions are bicarbonate, chloride, and sulfate. The water has high alkalinity (~200 mg/L as CaCO₃) and hardness (~300 mg/L as CaCO₃). Dissolved oxygen normally is between 3 and 14 mg/L. The rivers of the San Antonio/Guadalupe basin commonly show a shift from the primary influence of groundwater from springs to a more runoff-

dominated and anthropogenically influenced character as they flow from their sources to the downstream lowlands (Groeger et al. 1997).

River Biodiversity and Ecology

The San Antonio and Guadalupe are the westernmost rivers within the East Texas Gulf freshwater ecoregion, which includes all the remaining Texas rivers to the east (Abell et al. 2000). The Guadalupe River is considered to be particularly important in this ecoregion because of the number of endemic species, mostly associated with the karst bedrock of the Edwards Plateau.

Algae

Limited published information is available on the algae of the Guadalupe and San Antonio rivers. Sherwood and Sheath (1999) studied the macroalgae and epilithic diatoms of the San Marcos River and the Comal River, major tributaries of the Guadalupe. Twelve species of macroalgae were identified. Macroalgae included Cyanophyta (*Lyngbya taylorii*), Chlorophyta (*Cladophora glomerata*, *Dichotomosiphon tuberosus*, *Hydrodictyon reticulatum*, and *Oedogonium* sp.), Chrysophyta (*Tribonema regulare*), and Rhodophyta (*Audouinella pygmaea*, *Batrachospermum globosporum*, *B. involutum*, *Hildenbrandia angloensis*, *Sirodotia huillensis*, and *Thorea violacea*). Sixty-eight species of epilithic diatoms were identified during a 15-month seasonality study. Common genera of epilithic diatoms included *Achnanthes*, *Achnantheidium*, *Cocconeis*, *Denticula*, *Encyonema*, *Eunotia*, *Fragilaria*, *Gomphonema*, *Navicula*, *Nitzschia*, *Planothidium*, *Staurorsira*, and *Synedra*.

Plants

The mature forests of the San Antonio and Guadalupe rivers are dominated by pecan, Texas sugarberry, and bald cypress. The dominant riparian species all have eastern affinities and the floodplain forests of the Edwards Plateau represent the westernmost extension of their ranges. Other common riparian species are cedar elm, Virginia creeper, Texas persimmon, red mulberry, greenbrier, box elder, cottonwood, gum bumelia, and black walnut (Ford and Van Auken 1982; Bush and Van Auken 1984; Van Auken and Bush 1985, 1988). In secondary successional studies on terraces along the San Antonio River, recolonization occurred within five years of disturbance. Retama, mesquite, desert hackberry, huisache, and Texas sugarberry were early colonizers

and these, in addition to cedar elm, box elder, pecan, American elm, and gum bumelia, were important secondary colonizers that became more dominant after 25 years (Van Auken and Bush, 1985). Van Auken and Bush (1988) studied black willow and cottonwood along the edge of the San Antonio River. Highest densities were within 10 m of the river edge, but the largest trees were 15 to 20 m from the river edge. Periodic disturbance is apparently a requirement for maintaining black willow and cottonwood in these riparian forests.

Common native aquatic plants include fanwort, coontails, pennywort, water primrose, Illinois pondweed, grassy arrowhead, and water celery (Owens et al. 2001). In addition, a number of non-native aquatic plants have flourished in the head-spring areas, including hydrilla, elephant ears, East Indian hygrophylla, Eurasian watermilfoil, and water lettuce. There is one listed endangered species of aquatic plant in the basin. Texas wild rice is known only from the San Marcos River spring run, associated with the Edwards aquifer, and presently is a listed endangered species. Texas wildrice faces threats from dewatering of the aquifer upon which the San Marcos springs depends, impacts from recreational users, impacts from nonnative organisms (especially from nonnative aquatic plants and mammals), habitat modifications, and problems stemming from inhabiting an urban stream.

Invertebrates

Common aquatic invertebrates of the San Antonio and Guadalupe rivers include caddisflies (*Chimarra*, *Cheumatopsyche*, *Oxyethira*, *Smicridea*, *Hydroptila*, *Atopsyche erigia*), mayflies (*Dactylobaetis mexicanus*, *Leptohyphes vesusus*, *Tricorythodes albilineatus*, *T. curvatus*, *Choroterpes mexicanus*, *Thraulodes gonzalesi*, *Baetodes alleni*), aquatic beetles (*Microcyloepus pasillus*, *Hexacyloepus ferruginus*, *Neelmis caesa*), and chironomid midges (*Cricotopus*, *Rheotanytarsus exiguus*, *Polypedilum convictum*, *Orthocladius*, *Pseudochironomus*). Short (1983) described the normally spring-dwelling caddisfly *Atopsyche erigia* from tailwaters of dams on the Guadalupe River. McCafferty and Provonsha (1993) described the new mayfly species *Baetodes alleni*, a large larval mayfly from the Guadalupe River. Other common aquatic invertebrates include true flies (*Hemerodromia*), true bugs (*Ambrysus circumcinctus*), amphipod crustaceans (*Hyallolella azteca*), and hellgrammites (*Corydalus cornutus*).

Young and Bayer (1979) carried out a detailed study of dragonfly nymphs (Odonata: Anisoptera) of the Guadalupe River drainage basin. They collected samples from 56 lotic and 14 lentic sites and found 44 species of dragonfly nymphs. When combined with specimens and descriptions from historic collections, a total of 61 species have been described for the Guadalupe River basin.

Fifteen species of mussels have been reported from the San Antonio and Guadalupe river basins. Two species are considered rare (Texas pimpleback and false spike). One species, the golden orb, is a species of concern among the mussels in the basin (Howells et al. 1996). The introduced Asiatic clam occurs widely in the basin. In addition, three endangered species of aquatic invertebrates are associated with threatened springs and cave ponds associated with the Edwards aquifer: Comal Springs dryopid beetle (*Stygoparnus comalensis*), the Comal Springs riffle beetle (*Heterelmis comalensis*), and the Peck's cave amphipod (*Stygobromus pecki*) (www.edwardsaquifer.net/species.html).

Vertebrates

Eighty-eight species of fishes have been found in the Guadalupe and San Antonio rivers and their tributaries, of which 28 are nonnative. One species, the San Marcos gambusia, is extinct, four fish species are endangered, and two fish species are of concern. The endangered fish species are the headwater catfish, the endemic widemouth blindcat, toothless blindcat, and fountain darter, which is also listed as federally endangered. The widemouth blindcat and toothless blindcat are unique in that they inhabit the Edwards aquifer beneath the city of San Antonio. The fish species of concern are the Guadalupe bass and the blue sucker. The Guadalupe bass, the official state fish of Texas, is a central Texas endemic species of bass that has been shown to hybridize with nonnative smallmouth bass (Edwards 1979).

Where the rivers flow over the Cretaceous-age limestone bedrock of the Edwards Plateau there is a mixture of riffles and pools, and fishes tend to segregate within these mesohabitats. Pool habitats contain a variety of sunfishes, including largemouth bass, Guadalupe bass, bluegill, longear sunfish, redear sunfish, and the nonnative redbreast sunfish. Where significant springflows are present, such as the San Marcos River, spotted sunfish also are found abundantly. Other pool inhabitants include minnows, such as blacktail and red shiners, and central stonerollers, gray redhorse, channel catfish, western mosquitofish, and the nonnative Rio Grande cichlid.

Riffles are often inhabited by Texas shiners, young stonerollers, young flathead catfish, several darters (including the dusky, orangethroat, and greenthroat darters), and the Texas logperch. In more downstream reaches of the San Antonio/Guadalupe basin, the Guadalupe bass is replaced by the spotted bass, the greenthroat darter is replaced by the bluntnose darter, and the river darter replaces the dusky darter. In addition, more large river-adapted species such as spotted and alligator gars, gizzard and threadfin shads, bullhead minnows, and a variety of suckers (such as the river carpsucker and the smallmouth buffalo) are more commonly encountered (Hubbs et al. 1953, Young et al. 1973).

Edwards (2001) has shown that nonnative fishes in the upper San Antonio River are having a substantial impact upon native fishes. Seven native species were captured, including the western mosquitofish, three shiners (Texas, red, and mimic shiners), and three sunfishes (largemouth bass, longear sunfish, and spotted sunfish). Eleven nonnative species were taken from the same area. These nonnatives made up 61% of the species, 17% of the individuals, and 62% of the biomass. Some noticeable native species were missing from the assemblage, including a complete absence of the orangethroat and greenthroat darters, the Texas logperch, the native catfish, and the Guadalupe bass. Urban areas in the upper basin are thought to have a major impact upon the conditions leading to this assemblage of fishes in the upper San Antonio.

Aquatic nonfish vertebrates include the cottonmouth, diamondback and plainbelly water snakes, American alligator, Gulf Coast toad, North American bullfrog, Texas river cooter, red-eared slider, an occasional beaver, the even rarer river otter, and the ever-present and widespread nonnative nutria. Other endangered vertebrate species in the basin include the golden-cheeked warbler, whooping cranes near the coast, and the Texas blind salamander. The threatened San Marcos salamander also is endemic in the basin. In addition, the endemic Cagle's map turtle of the Guadalupe River is a candidate for listing.

Ecosystem Processes

Stanley et al. (1990) assessed nutrient limitation of periphyton and phytoplankton in the upper Guadalupe River. Nutrient-diffusing substrates were used to study periphyton responses, and nutrient amendments to glass bottles were used to study the response of phytoplankton. Most of the nutrient-diffusing experiments showed greater periphyton chlorophyll *a* when phosphorus was added to the

substrate. More variability was noted in the bottle experiments for phytoplankton response, but the more responsive nutrient was nitrogen. In general, phytoplankton tended to be nitrogen limited and periphyton tended to be phosphorus limited in the upper Guadalupe River.

Epperson and Short (1987) studied annual production of the predaceous stream hellgrammite *Corydalus cornutus* (Megaloptera) in the Guadalupe River. Annual production at five sites decreased from upstream to downstream. Production values decreased from 22.9 to 4.6g AFDM m⁻²yr⁻¹. These production values are some of the highest reported for a single species of aquatic insect.

Human Impacts and Special Features

The Edwards aquifer is a vast groundwater ecosystem that contains one of the most diverse, unique, and significant biological assemblages in the world and feeds the two largest and most stable spring systems in the western Gulf Coast region. Because of the constancy of the water temperatures and flows of the San Marcos and Comal rivers, a unique and extremely diverse group of endemic organisms have also developed in these ecosystems. Many of the species found in these systems are found nowhere else. These springs and the ecosystems that support them are the main habitats for which the first ecosystem-based endangered species recovery plan was developed. This plan attempts to protect the threatened and endangered species of aquatic plants and animals from loss of habitat due to reduced spring flows resulting from increased pumping and subsequent draw down of the Edwards aquifer, as well as threats from nonnative species, recreation, and modifications such as dams, bank stabilization, and control of aquatic vegetation and factors that decrease water quality (U.S. Fish and Wildlife Service 1996). The aquifer also serves agricultural, industrial, recreational, and domestic needs for about two million people, including the cities of San Antonio, San Marcos, and New Braunfels. Numerous other springs are also present in the San Antonio/Guadalupe basin due to the highly fractured nature of the Cretaceous-age limestone karst topography. In Texas, where right of capture is the main law applied to groundwater use, there is a growing trend for major aquifer authorities to research and manage groundwater reserves and withdrawals. The Guadalupe Delta Wildlife Management Area, Matagorda Island Wildlife Conservation Area, and Aransas National Wildlife Refuge provide habitat for

wintering whooping cranes, 19 endangered or threatened species, and 300 species of birds.

The San Antonio and Guadalupe rivers are no longer free flowing. A number of dams for flood control and water storage are located throughout their river courses. Canyon Dam, the largest on the Guadalupe River, has had a profound effect, especially below the dam due to hypolimnetic release flows that have dramatically changed downstream water-temperature regimes. In a comparison of the fishes immediately above and below Canyon Reservoir and from preimpoundment surveys completed 25 years earlier, Edwards (1978) found that species such as Guadalupe bass, channel catfish, speckled chub, mimic shiner, Rio Grande cichlid, longnose gar, gizzard shad, and redear sunfish were either absent or very limited below the dam. Other species, such as orangethroat darters, have become extremely abundant and have extended their normal late winter and spring spawning season to nearly year-round spawning in the tailrace waters. A put-and-take trout fishery has been established in this area below the dam.

Because of the tremendous growth of the region in the past century and the long history of human habitation, water has been increasingly pumped from the Edwards aquifer, placing stress on the biological resources within the aquifer and the river biota as well. In times of severe drought, spring flows from the Edwards aquifer, especially into the San Marcos River, provide the major source of water for the downstream portion of the Guadalupe River and to the estuaries at their terminus. Although the dams minimize water-level fluctuations following storm-related flood events, significant flooding in the San Antonio/Guadalupe basin occurred during severe storms in 1998 and 2000. In addition, as cities using the waters from the San Antonio and Guadalupe rivers have grown, urban pollution has become a more frequent and persistent problem. Similarly, the long-term increase in the number of nonnative species is having a negative impact upon the native biological assemblages in these rivers.

COLORADO RIVER

The basin of the Colorado River of Texas begins in the very arid region of southeastern New Mexico and western Texas, where rainfall is infrequent and streams are intermittent (Fig. 5.15). Bending southeastward, the river flow becomes permanent through increased rainfall and freshwater spring flows from

the Edwards Plateau as it winds through the karst topography of Cretaceous limestone known as the “Texas Hill Country.” The area is dotted with rural farms, ranches, and fruit orchards, but ironically “ranchettes” and suburbs have grown rapidly as people “escape” from increasing urbanization. The state capital of Texas, Austin, is situated where the Colorado River exits the hill country at the Balcones Escarpment and enters the Coastal Plain on its way to Matagorda Bay. What were once dry-land cotton and grain fields in the lower Colorado River have become irrigated rice fields and row crops, as cotton and sorghum farming have moved upriver where surface water is supplemented by pumping from the Ogallala aquifer. Total river length is approximately 1560 km, with a drainage area of about 103,300 km² (roughly the area of Kentucky). The name Colorado, Spanish for red, is evidently a misnomer because the river is clear and appears to have been so at the time of exploration by Cabeza de Vaca in the 1530s. Consensus is that the name Colorado was applied to the Brazos but the names were interchanged during the seventeenth-century period of Spanish exploration and the name was well established before the end of Spanish Texas following the successful Mexican War of Independence from Spain in 1821.

Paleo-American Indians in this area included the Folsom culture that hunted a now-extinct form of giant bison using only spears and spear-throwers. These cultures waned by 2500 years ago and became integrated into the many more localized Archaic hunter and gatherer cultures. Later infused by cultures from Central and South America, these tribes grew into the agricultural and pottery-making cultures of the Neo-American stage. Comanches also lived along the upper Colorado River and were among the first of the Plains Indians to use horses to raid other tribes and white settlers along the river. Lipan Apaches were found along the western basin, and they got along with the immigrating white Texans, in part by fighting against the Comanches. The Tonkawas, who settled along the main river and tributaries of the Colorado River in the Edwards Plateau, also fought against the Apaches with white settlers. Several Karankawa tribes lived along the coast and had little contact with European settlers, apart from Cabeza de Vaca (1528–1536) and La Salle (1685–1689), until 1720, when French and Spanish expeditions fought over this territory. When European diseases took their toll, the remaining Karankawa and Tankawa people were rounded up and given some lands, but they were later expelled from Texas to Indian Territory in present-day Okla-

homa. Little Hispanic influence occurred, partly because the early colonists of Texas from the United States and Central Europe settled near the banks and mouth of the Colorado.

Physiography, Climate, and Land Use

The Colorado River mostly drains the Great Plains (GP) physiographic province, with a small amount from the Central Lowlands (CL), and finally enters the Coastal Plain (CP) (see Fig. 5.15). Major biomes include Temperate Grasslands and Temperate Deciduous Forests, and terrestrial ecoregions include the Western Short Grasslands, Central and Southern Mixed Grasslands, Edwards Plateau Savannas, Texas Blackland Prairies, East Central Texas Forests, Western Gulf Coastal Grasslands, and Central Forest/Grassland Transition Zone. Native vegetation from headwaters to mouth includes plains grassland, desert shrub, mesquite savanna, juniper–oak–mesquite savanna, blackland prairie grasses, oak–hickory forest, oak savanna, and coastal prairie grasses.

Climate varies considerably along the Colorado River basin. In the upper basin, annual mean temperature in Ballinger, Texas, is 18.3°C and monthly mean temperature ranges from 7°C to 28°C; annual mean precipitation is 61 cm and monthly mean precipitation ranges from 3 cm during November through March to 9.8 cm in May. Further south in Austin, Texas, annual mean temperature is 20.3°C and monthly mean temperature ranges from 9°C in January to 29°C in July and August; annual mean precipitation is 82 cm and monthly mean precipitation ranges from 4.7 cm in July to 11.8 cm in May (Fig. 5.16). In the lower basin at Matagorda, annual mean temperature is 21.5°C and monthly mean temperature ranges from 12°C to 29°C; annual mean precipitation is 112 cm and monthly mean precipitation ranges from 5.7 cm in March to 14.3 cm in August.

Land use in the basin is 55% range, 30% agriculture, and 15% urban. Major crops include cotton and grains such as sorghum and rice, and livestock (goats, sheep, horses, and cattle), dairy, and poultry are additional important agricultural activities. The upper basin was estimated to be 19% cropland in 1985, with most of the rest of the upper basin consisting of mesquite and rangeland/prairie grasses (Shirinian-Orlando and Uchrin 2000) supporting cattle ranging among oil wells on the Permian Basin–influenced landscape. Major towns along the Colorado include Big Spring, Ballinger, Austin,

Wharton, Bay City, and Matagorda. Population densities in 2000 for counties within the basin averaged 35 people/km² and ranged from 3 to 88 people/km².

River Geomorphology, Hydrology, and Chemistry

The Colorado River along its upper reaches does not flow year-round until its confluence with the Concho River at O. H. Ivie Lake (see Fig. 5.15). Downstream of Big Spring, in the upper reach, it passes through rolling prairies with shallow and variable flow in a generally low-gradient channel (50 cm/km). The middle basin includes several more constrained reaches as the river passes through the Hill Country and the Llano Uplift. The river reach just upstream of Lake Buchanan flows through high limestone bluffs over a bed of bedrock and gravel. Within the Pedernales and Llano rivers and smaller tributaries that enter the Colorado River below Lake Buchanan, white-water enthusiasts can experience reaches of white water as well as gently meandering streams. Below Austin the channel is wide and water moves slowly over a bed of sand and gravel (Fig. 5.4). As it becomes a coastal river, it develops steeper banks and large sand bars that dissect the deep alluvial sediments. Baker and Penteado-Orellana (1977) studied the alluvial sediments of the lower Colorado River and showed that Quaternary climate in central Texas alternated between arid and humid phases, with the recent transition to humid conditions accompanied by more uniform stream-flow characteristics.

Hydrology of the Colorado River also changes substantially as the river moves from intermittent headwaters to its mouth. Average annual discharge to the Gulf of Mexico is about 75 m³/s. Interestingly, discharge of the Colorado River of Texas at its mouth now exceeds the average discharge of the more famous Colorado River as it discharges into the Gulf of California (Chapter 11). Specifically, the “big” Colorado at one time had a virgin discharge of 550 m³/s but now discharges only about a mean of 40 m³/s because of extractions and interbasin transfers and often goes dry before reaching the sea. River flow of the Colorado River of Texas is highly variable. For example, mean monthly discharge near the mouth of the Colorado has ranged from 2 m³/s during the drought of the early 1950s to 1200 m³/s during the winter floods of 1992. Average monthly peak discharge at the mouth occurs in June (~127 m³/s), with low flows normally occurring in August (~23 m³/s). These are relatively low discharge values for a basin this size, giving a very low annual runoff of only

FIGURE 5.4 Colorado River at Wharton, Texas (PHOTO BY TIM PALMER).

about 3 cm (see Fig. 5.16). The large difference between precipitation and runoff is probably due to evapotranspiration, but there may be groundwater and irrigation losses as well.

Water chemistry reflects both climatic variation and land-use patterns within the basin. The Upper Colorado basin suffers from salinization of soil, groundwater, and surface water (Slade and Buszka 1994, Shirinian-Orlando and Uchrin 2000). Total dissolved solids for the Upper Colorado River have exceeded 12,000 mg/L, with values above 1000 mg/L commonly reported. Along with natural salt deposits, activities associated with oil and gas exploration and production are another major source of dissolved solids. Water-quality concerns in the middle basin involve periodic excursions of low dissolved oxygen (<3.0 mg/L) and high $\text{NO}_3\text{-N} + \text{NO}_2\text{-N}$ (>2.8 mg/L). High chlorophyll *a* (>21.4 $\mu\text{g/L}$) for reservoirs in the Highland Lakes region due to nonpoint nutrient sources causes periodic decreased visibility. The lower basin below Austin has shown improved water quality in the past decade as a result of improved

wastewater treatment facilities. Contact recreation (e.g., swimming), however, is often discouraged due to high counts of fecal coliform bacteria. Water-quality problems in the Austin area have led to studies on meeting dissolved oxygen standards by using pollution-offset permits to lower biological oxygen demand in the river (Letson 1992). Maintaining adequate downstream flow also is a concern and models of the Lower Colorado have been used to manage drought (Martin 1991) and predict discharge using a linked geographic information system (GIS)/hydrologic model (Rosenthal et al. 1995).

River Biodiversity and Ecology

The Colorado River is located within the East Texas Gulf freshwater ecoregion, an area stretching from the San Antonio/Guadalupe basin to the Sabine (Abell et al. 2000). In general, the biodiversity and ecology of the Colorado are not well studied, although the distribution of vertebrates, fishes in particular, is fairly well known.

Algae

Little information is available on the algae of the Colorado River, but reservoirs on the Colorado have suffered from episodic blooms of the golden alga *Prymnesium parvum*. The algae give the water a yellowish tint and have been responsible for fish kills numbering in the hundreds of thousands. E. V. Spence Reservoir on the upper Colorado (see Fig. 5.15) has been especially affected by this alga.

Plants

In the upper river, the saline waters have influenced riparian vegetation, where nonnative saltcedar now grows extensively. In the middle basin, riparian vegetation includes elm, willow, sycamore, and buttonbush. In backwater habitats, bald cypress and such macrophytes as smartweed, spiderlily, arrowhead, and white waterlily are found. Nonnative macrophytes include hydrilla, Eurasian watermilfoil, and water hyacinth from the middle and lower Colorado River, curly pondweed and water spangles in the middle Colorado, and water lettuce in the lower Colorado. The lower basin, once the site of massive logjams derived from lowland riparian vegetation, is now primarily a mixed hardwood riparian forest.

Invertebrates

Few studies have characterized the invertebrates of the Colorado River in Texas. As part of the ecoregion assessment project for EPA Region VI, macroinvertebrates that characterize least-disturbed streams are listed in Bayer et al. (1992). In most western streams of the Colorado basin, EPT (Ephemeroptera–Plecoptera–Trichoptera) indices are predominantly due to mayflies and caddisflies, but range widely. In small headwaters streams where salinity is high and conditions are harsh, EPT values are near 7 in assemblages dominated by salinity-tolerant clams (*Sphaerium*) and oligochaete worms (*Limnodrilus*). EPT values reach 23 in larger streams with a wider range of habitats and more permanent flow, with predominantly salinity-intolerant species, including the shiny peaclam, caddisflies (*Helicopsyche*, *Cheumatopsyche*), and beetles (*Microcyloepus pusillus*, *Stenelmis cheryl*). Spring-fed streams of the Edwards Plateau region have EPT indices of 15 to 18 and are characterized by salinity-intolerant species of mayflies (*Tricorythodes albilineatus*), caddisflies (*Chimarra*, *Hydroptila*), chironomid midges (*Polypedilum convictum*, *Rheotanytarsus exiguous*), predatory ceratopogonid midges (*Probezzia*), and

damselflies (*Argia*). In streams of the Coastal Plain, additional species include mayflies (*Caenis*, *Fallceon quilleri*, *Stenacron*), beetles (*Stenelmis occidentalis*), limpets (two-ridged ramshorn), and tubificid worms (*Nais pardalis*, *N. communis*).

The native ranges of several crayfish species include the Colorado River drainage (*Cambarellus shufeldtii*, *Procambarus clarkii*, *P. acutus acutus*, and *Orconectes palmeri longimanus*). The Cajun dwarf crayfish is a Texas endemic with a small range that includes the Colorado River coastal region. Prehistoric inhabitants of the Colorado River drainage used freshwater mussels for shells, meat, and pearls, as did early Spanish and European settlers, especially along the Concho and Llano rivers. Fifteen species of mussel have been reported from the Colorado River (Howells et al. 1996). Common or widely distributed species include giant floater, paper pondshell, giant washboard, bleufers, southern mapleleaf, Texas lilliput, pistolgrip, and tapered pondhorn. Four species are considered rare (smooth pimpleback, Texas pimpleback, false spike, Texas fawnsfoot), and Texas fatmucket and golden orb are species of concern. The introduced Asiatic clam occurs throughout much of the riverine corridor, and native fingernail clams and peaclams, although widely distributed, are less common.

Vertebrates

There are 98 species of fishes in the Colorado River, of which 26 are nonnative. Common species in more saline and harsh summer environments of the upper Colorado River are red shiner, fathead minnow, western mosquitofish, channel catfish, and green sunfish. In fresher water and spring-fed streams, blacktail shiner, central stoneroller, bullhead minnow, roundnose minnow, Texas shiner, sand shiner, mimic shiner, gray redhorse, orangethroat darter, Texas logperch, bluegill, longear sunfish, redear sunfish, and largemouth bass are more abundant. In lowland streams nearer the coast, dominant fishes include pugnose minnow, yellow bullhead catfish, tadpole madtom, pirate perch, dusky darter, warmouth, white crappie, spotted gar, river carp-sucker, and gizzard shad. Nonnative redbreast sunfish and Rio Grande cichlid have been introduced widely. The blue sucker occurs in the larger river, and Guadalupe bass (state fish of Texas) occurs in streams of the Edwards Plateau; both are listed as Texas species of concern.

Common aquatic snakes include the diamond-back water snake, plainbelly water snake, and cot-

tonmouth. The endangered Concho water snake has one of the smallest ranges of any North American snake species, approximately 25 km of impounded shoreline and 396 km of streams within the upper Colorado River basin. The endangered, neotenic, Barton Springs salamander lives wholly within Zilker Park in Austin, Texas, but a captive breeding program by the U.S. Fish and Wildlife Service maintains populations in the Dallas, Texas, Aquarium and the Midwest Science Center in Columbia, Missouri. In the warm seasons, Strecker's chorus frog and plains and southern leopard frogs are seen and heard. Turtles frequently seen on woody debris along the riverbank include red-eared slider, common snapper, stinkpot, Texas river cooter, and yellow mud and Texas map turtles. Both smooth and spiny softshell turtles are common along the river, and American alligators are seen closer to the coast.

The Colorado River basin is home to numerous bird species, including many threatened and endangered species associated with the river. The rare green kingfisher and more common belted kingfisher are found here. Wood ducks and shorebirds flock to reservoirs of the high plains during winter. Near the coast, Attwater's Prairie Chicken National Wildlife Refuge and Eagle Lake are home to thousands of ducks and geese during winter. Whooping cranes, white-faced ibis, reddish egrets, piping plovers, brown pelicans, wood storks, and 37 species of shorebirds can be viewed along the Matagorda Peninsula at the mouth of the Colorado River.

Ecosystem Processes

Very little ecosystem research has been reported from the Colorado River basin. However, filter feeders are the most abundant macroinvertebrate guild, followed by gatherers and grazers, then predators, and finally shredders and miners, based on the Texas Clean Rivers surveys (Bayer et al. 1992). This suggests a strong influence of smaller size fractions of particulate organic matter as energy sources. This is consistent with the arid climate across the primarily western headwaters, where meager gallery forests and prairie grasses grow along intermittent and shallow headwater streams. In addition, range and croplands augment nutrient supplies, supporting the growth of stream periphyton in these shallow and well-lighted streams and rivers.

Human Impacts and Special Features

Among the more interesting features of the Colorado River is that it begins its flow among the rolling

prairies but then flows through scenic canyons in the Edwards Plateau. The river and its tributaries pass through a large region of metamorphic and igneous rock (the Llano Uplift), with spectacular reddish granite. The state capitol in Austin was built using granite from the area. Below Austin, the river widens and slowly meanders to the coast. All along its length, however, the nature of the Colorado River has been greatly altered, particularly by dams, pollution, and introduction of nonnative species.

Attempts were made to make the Colorado River navigable by removing large logjams that hindered transportation in the mid-1800s. After the Civil War, the Colorado River was no longer used for transportation, and 25 reservoirs now make it the most heavily dammed river in Texas. Three large reservoirs, Lake J. B. Thomas, E. V. Spence Reservoir, and O. H. Ivie Reservoir are located on the upstream portion of the river (see Fig. 5.15). Below O. H. Ivie Reservoir the modified flow regime and reduced sediment load has increased channel downcutting and artificial riffles have been constructed to provide shallower flowing habitat to facilitate foraging by the endangered Concho water snake.

The Highland Lakes region of central Texas consists of seven reservoirs along 137 km of river northwest of Austin (see Fig. 5.15). The seven lakes from upstream to downstream are Lake Buchanan, Inks Lake, Lake LBJ, Lake Marble Falls, Lake Travis, Lake Austin, and Town Lake. Urbanization in the Austin area has increased rapidly, and the number of water surveys reporting excessive coliform bacterial counts due to nonpoint pollution sources also has increased. The total volume of water from the Colorado River is overallocated, but flow management takes advantage of asynchronous demands within the drainage basin. Hydropower and flood-control influence discharge downstream of the Highland Lakes. Despite flood-control dams, flooding still occurs in the uplands following intense thunderstorms, when rain rapidly washes across limestone bedrock and through permeable soils. Flooding also occurs associated with hurricanes in the Coastal Plain. Flows are provided to irrigate cotton, sorghum, and rice fields and to augment municipal and industrial water supplies during dry periods. This is reflected in average monthly runoff in summer, as average monthly runoff increases in summer despite lower rainfall because dam releases satisfy water users downstream.

Several fish species have been introduced either as bait or sport fishes. The genetic integrity of Guadalupe bass (the Texas state fish) has been introgressed by nonnative smallmouth bass that have been

stocked as a cool water game species. Other stocked nonnative game fish include walleye, sauger, northern pike, striped bass, and rainbow trout. Nonnative aquatic plants have become established following introductions via ornamental water gardens, aquaria, and transport on boats and trailers. These include water hyacinth, hydrilla, water lettuce, Eurasian watermilfoil, and alligatorweed. Nonnative grass carp has been introduced to control overgrown vegetation in reservoirs, but only sterile certified triploids are permitted. Blue tilapia is commonly found in cooling reservoirs and warm backwaters, having escaped from aquaculture facilities or illegally introduced as food fish or bait. Common carp are widespread, having been introduced from Europe and China as food fish in the 1800s. Many mistakenly believe that common carp are native to the Colorado River.

BRAZOS RIVER

Thirsty Spaniards called the river “Los Brazos de Dios” (the arms of God) and Native Americans called the river Tokonohono. The Brazos River arises at the confluence of the Salt Fork and Double Mountain Fork (33°16'N, 100°01'W) and flows about 1390 km southeasterly across Texas to its mouth on the Gulf of Mexico southwest of Houston (Fig. 5.17). The Brazos has the greatest channel length entirely within Texas and is the third longest of all Texas rivers. Its drainage basin is about 115,600 km², with 94% in Texas. The Brazos heads in New Mexico, and its forks drain much of the southern panhandle and parts of west Texas surrounding Lubbock, Texas, on the Llano Estacado. Both dry, hot summers and sudden icy winds and winter blizzards color and shape the landscape, and long cycles of drought often are devastating to inhabitants.

Although commonly appearing like a sun-scorched desert in summer, showers change the land into a rich green carpet of buffalo, grama, and bunch grasses that once supported large numbers of buffalo, pronghorn antelope, and deer. Little is known archaeologically of the Paleo-Indians that would become the nomadic Apache Plainsmen who hunted here before acquiring horses. The Apaches also gardened and traded with agricultural Pueblo Indians to secure their livelihood and to adapt to the erratic and unpredictable movement patterns of buffalo herds. Living in small villages, the Apaches were eventually displaced by mounted Comanches who raided from the north and by the Spanish from the south. Comanches lived in the Brazos catchment in loose bands and

camped along the rivers, but they rarely ate fishes or fowl unless starving.

Brackish water, red clay, and ancient sand and silt washed down from the Rocky Mountains discouraged travelers and settlers along the Salt Fork of the Brazos. Downstream, the freshwater of the White River emerging from Blanco Canyon improved river conditions substantially. This is the area where Coronado likely staged his search for Quivira and the seven cities of Cibola in 1541. The river exits through the palisades of the Staked Plain and drops into the Central Lowlands, topographically flat except for occasional sandstone buttes and towers. A largely Hispanic population now farms croplands and controls the irrigation systems. Longhorn and other cattle, oil, and gas production dominate the rangeland north of Abilene, Texas. After the Clear Fork enters the Brazos west of Fort Worth, Texas, and leaves the Central Lowlands, the Brazos briefly re-enters the Great Plains and then flows more southward to Waco, Texas, and onto the Coastal Plain.

Downstream of Waco, the Brazos meanders through bottomland hardwoods and sandy floodplains renewed by periodic excursions over natural river levees. The native people called Tonkawas (meaning “they all stay together”) by the Wacos in this area and called Tickanwatic by themselves (meaning “the most human of people”) lived as clans in this region. Part of the Plains prehorse culture, these clans hunted buffalo and small game animals, fished, used dogs as pack animals and food, and had no agriculture, but gathered pecans, acorns, herbs, fruit, and seeds along the river. The timid Tonkawas, reduced in number by disease and raiding Comanches, were forced out of this area in the nineteenth century by European settlers.

Spanish explorers first recorded the mouth of the Brazos River in 1519. Early maps located fords on the Brazos, but Spanish activity was limited within the basin. The Brazos played a prominent role in the history of modern Texas. European settlement began in December 1821, when the first of Stephen F. Austin’s settlers arrived at the mouth of the Brazos. Early Anglo-American settlers located their first capital at Washington-on-the-Brazos, where the Navasota River enters the Brazos south of College Station, Texas. Steam navigation reached the Brazos around 1830 and serviced inland cities up to 400 km upriver from the Gulf of Mexico.

Physiography, Climate, and Land Use

The Brazos flows through three physiographic provinces beginning with the Great Plains (GP) of the

Texas panhandle and eastern New Mexico (see Fig. 5.17). The Brazos then passes through the Central Lowlands (CL), emerges back into the Great Plains, and then flows across the Coastal Plain (CP) province into the Gulf of Mexico. The Brazos also passes through six terrestrial ecoregions along its course: Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest/Grassland Transition Zone, Texas Blackland Prairies, East Central Texas Forests, and Western Gulf Coastal Grasslands (Ricketts et al. 1999). Although much of the basin is modified by ranching and agriculture, natural upland vegetation begins with bunched growth forms, including short grasses adapted to seasonal drought, fire, and grazing, such as grama and buffalo grass, then mixed grasses, such as little bluestem and western wheatgrass, and then taller grasses, such as Indian grass, on the Blackland Prairie and riparian trees, such as cottonwood, hackberry, and elm. When the river enters the East Central Texas Forests ecoregion, it includes a greater dominance of upland trees, such as post and blackjack oaks, and in the bottomlands black and mockernut hickories and pecan. Vegetation in the Western Gulf Coastal Grasslands shifts from upland tallgrass species to those found in more saline soils, such as gulf cordgrass, sedges, and rush, bulrush, and salt grass.

Climate varies greatly from the upper basin in the high plains to the middle basin in the prairies and woodlands to the coastal plains of the lower basin. For example, average annual temperature and rainfall at Lubbock in the upper Brazos Basin are 15.6°C and 47cm, respectively, with average monthly temperatures ranging from 4°C to 27°C and monthly precipitation ranging from 1.4cm in January to 7.0cm in May. Average annual temperature and rainfall at Waco, in the central Brazos Basin, are 19.2°C and 81cm, respectively. Mean monthly temperatures range from 7°C in January to 30°C in July and August and monthly precipitation ranges from 4.4cm in January to 12.0cm in May (Fig. 5.18). The lower Brazos basin has greater precipitation and warmer temperatures. Freeport, at the mouth of the Brazos, has an average annual temperature of 20.9°C and an average annual precipitation of 128cm. Monthly mean temperatures at Freeport range from 11.4°C in January to 28.8°C in July and August, with peak precipitation of 18.4cm in September and minimum precipitation of 6.6cm in March.

Land use in the basin is a mix of grazing, agriculture, and urban development, with remnants of native vegetation throughout the region. The basin is approximately 57% grassland, 24% cropland, 16%

urban and suburban, and 3% forest. Major cities in the Brazos basin are Lubbock, Abilene, Waco, Temple, College Station, and Freeport. Houston abuts the region on the east near the river mouth. Cattle, cotton, grain sorghum, and wheat are grown in the upper basin. The middle basin produces peanuts, dairy products, livestock, poultry, and grains. The lower basin produces rice, cotton, livestock, poultry, and dairy products.

River Geomorphology, Hydrology, and Chemistry

The Brazos River shows varied geomorphic characteristics as it crosses Texas. The Upper Brazos of the high plains is generally a broad, shallow, sandy, spatially intermittent river in short grass country. Canyonlands exist at the breaks of the Llano Estacado and the Caprock escarpment. The Middle Brazos was relatively unspoiled until numerous dams were constructed in this section of the river beginning in the 1940s and continuing through the 1980s (Gillespie and Giardino 1996). Much of the Brazos was entrenched and confined in narrow valleys with steep sides or bluffs. Near Waco the topography changes to gently rolling hills and the river is less constrained. The Lower Brazos of the Coastal Plain becomes a deep, broad river in agricultural lands (Fig. 5.5). The Brazos starts at an elevation of 450m asl and stream gradients diminish from 66cm/km to 9cm/km as the river flows from its headwaters to the mouth.

There have been some detailed geomorphic studies of the Brazos River. Gillespie and Giardino (1996) examined migratory rates of meanders in the Middle and Lower Brazos as the river adjusts to numerous dams built recently on the main stem and tributaries. This research discussed the effects of flow regulation on channel stability and determined an index to assess channel stability where flow alteration is occurring. Gillespie and Giardino (1997) included data for 125 bends over 260km in the Middle and Lower Brazos from the 1930s to 1988. Migration rate has decreased substantially as regulated flows have diminished peak flows and reduced suspended sediment loads. Ratzlaff (1981) studied the mechanisms of meander development and cutoff in the Brazos. Blackburn et al. (1982) studied the role of saltcedar on sedimentation in the Upper Brazos. Flow regulation through dams and invasion by nonnative plant species into riparian zones are modifying the geomorphology of the Brazos River. Saltcedar infes-

FIGURE 5.5 Brazos River at Rt. 105 near College Station, Texas (PHOTO BY TIM PALMER).

tations in the Upper Brazos are affecting channel structure, sediment deposition, and river hydrology. Channel width has been reduced by about 90 m in a 129-km river reach from Clear Fork to Seymour. Approximately 3 m of deposition has occurred within the saltcedar-infested channel reaches, and higher flood stages now occur for similar flow volumes such that inundation patterns are substantially larger now for comparable flows.

Mean discharge for the Brazos River is $249 \text{ m}^3/\text{s}$. Given the large size of the basin, however, runoff is quite low, ranging from only 0.2 cm/mo during the winter to 0.8 cm/mo in May (see Fig. 5.18). The annual total runoff of about 4 to 5 cm is only 5% of annual precipitation and indicates high evapotranspiration and other losses. The discharge regime is strongly regulated by the dams upstream of Waco on both a daily and seasonal basis, with daily discharge commonly being reduced to $<1 \text{ m}^3/\text{s}$ below Lake Whitney Dam.

Water chemistry reflects the predominant marine clays, limestone and sandstone geology, and agricultural land use. Water is mildly alkaline and salty (pH 7.6, alkalinity 133 mg/L as CaCO_3 , specific conduc-

tance $733 \mu\text{S}/\text{cm}$) due to marine salts deposited in the region of the upper basin as an ancient inland sea evaporated. Nutrient loading (dairy farms) in the middle basin causes late summer algal blooms, especially in intermittent reaches. In recent years, toxic blooms of golden alga linked to nutrient loading in some reservoirs have caused multiple fish kills. Water-quality parameters of primary concern in the basin include natural salinity, atrazine, perchlorate, phosphorus, dairy wastes, and dissolved oxygen.

River Biodiversity and Ecology

The Brazos River flows through the East Texas Gulf freshwater ecoregion (Abell et al. 2000). Unfettered by dams downstream of Waco, the rich biodiversity in the lower drainage is contained in habitats maintained by natural fluvial processes.

Algae and Cyanobacteria

Little published information is available on the algae of the Brazos River. A general survey done for the Brazos River Authority in early fall (Winemiller and Gelwick 1999) lists tentative genera of diatoms

(*Nitzschia*, *Navicula*, *Cymbella*, *Gomphonema*, *Diatoma*, *Synedra*, *Navicula*, *Tabellaria*, *Cocconema*, *Cosmarium*), unicellular green algae (*Ankistrodesmus*, *Characium*), filamentous green algae (*Rhizodinium*, *Cladophora*, *Oedogonium*, *Spirogyra*, *Tribonema*, *Mougeoutia*, *Ulothrix*), and cyanobacteria (*Anabaena*, *Oscillatoria*). There has been recent concern about a toxic golden alga (*Prymnesium parvum*) in reservoirs of the Brazos Basin. This golden alga is usually found in estuaries, but it now has been found in numerous inland water bodies throughout Texas. Possum Kingdom Lake on the Brazos was especially affected in 2000 and 2001, with thousands of fishes killed.

Plants

Riparian vegetation in the Upper Brazos was dominated by obligate and facultative phreatophytes, such as mesquite, baccharis, cottonwood, willow, elm, hackberry, and sumac (Blackburn et al. 1982). Nonnative saltcedar has increasingly affected riparian areas in the Upper Brazos (Busby and Schuster 1971, Blackburn et al. 1982). Blackburn et al. (1982) estimated that coverage by saltcedar in the Upper Brazos from the confluence of Clear Creek to Seymour (129 km) changed from small patches in the 1930s to 57% of the original river channel by 1979. Early settlers described the Middle Brazos as wooded sections frequently containing great pecan and oak trees interspersed with more open country with broad prairies. The Lower Brazos originally passed through forests, transporting snags and forming debris dams throughout much of its lower reach. Today it is partially channelized by levees, with sand margins and mixed riparian forests.

Macrophytes such as water willow are generally limited to shallow, sluggish, or slow-flowing margins of streams. Other native plants in oxbows, ponds, and reservoirs include spatterdock, water shield, duckweed, arrowhead, eelgrass, water primrose, Illinois pondweed, spikerush, and water stargrass. Many of these are being planted in an attempt to establish native species before introduced nonnative species become further established. Two nonnative macrophytes that occur in both the Middle and Lower Brazos drainage are alligatorweed and hydrilla. In addition, nonnative water hyacinth, water lettuce, dotted duckweed, and giant salvinia have been reported in the lower drainage.

Invertebrates

Kenneth Stewart and colleagues at the University of North Texas have studied the aquatic insects of

the Brazos drainage basin in north-central Texas, with particular emphasis on caddisflies. Forty-two species of caddisflies distributed among nine families were reported in the Middle Brazos River and tributaries (Moulton et al. 1993). At a site downstream of Possum Kingdom Lake on the Brazos River, 4 of 22 species were particularly abundant and productive (*Hydropsyche simulans*, *Cheumatopsyche lasia*, *Cheumatopsyche campyla*, and *Chimarra obscura*). This study brought the total of known caddisfly species in Texas to 106, with 8 new species described from Texas and the Brazos drainage. Cloud and Stewart (1974) studied caddisfly drifting behavior in the Brazos and found *Cheumatopsyche campyla*, *C. lasia*, and *Hydropsyche simulans* dominating caddisfly drift.

Surveys for the statewide Clean Rivers Program (Bayer et al. 1992) also provide information on least disturbed streams in the Brazos basin. EPT indices range from 4 to 7 in the uppermost reaches in the Great Plains north and west of Abilene, where harsh, hot summers, high salinity, and cold winters limit populations. Predominant species are chironomid midges (*Polypedilum scalaenum*, *P. convictum*, *Rheotanytarsus exiguus*, *Cryptochironomus fulvus*), biting midges (*Bezzia*), caddisflies (*Cheumatopsyche*), tolerant oligochaete worms (*Limnodrilus hoffmeisteri*), and beetles (*Stenelmis sexlineata*, *S. occidentalis*, *Berosus subsignatus*). EPT indices range from 8 to 12 in the more mesic Central Lowlands north of Waco, where streams run through croplands and post oak–juniper forests. Here, assemblages are dominated by salinity-intolerant species of caddisflies (*Chimarra*), chironomids (*Orthocladius*, *Cricotopus bicinctus*), beetles (*Psephenus texanus*), and mayflies (*Stenonema*). Other common species include caddisflies (*Hydroptila*), chironomids (*Tanytarsus glabrescens*, *T. guerlus*), mayflies (*Choroterpes mexicanus*, *Fallceon quilleri*), stoneflies (*Perlesta placida*, *Neoperla clymene*), and damselflies (*Argia*). EPT indices range from 10 to 18 in the lower reaches of the Central Lowlands north and west of Temple, before the Brazos reenters the Great Plains. Streams run through diversified croplands, ranches, and pastures. Most abundant species include mayflies (*Thraulodes gonzalesi*, *Tricorythodes albilineatus*), caddisflies (*Chimarra*, *Cheumatopsyche*, *Oxyethira*), and chironomids. Additional chironomids in the lower Central Lowlands include *Dicrotendipes neomodestus* and *Pseudochironomus*. EPT indices range from 9 to 14 in the Coastal Plain streams between Waco and College Station, where post oak woods and bottomlands were cleared for crops. Abundant

species include caddisflies (*Smicridea*, *Cheumatopsyche*), mayflies (*Fallceon quilleri*), tipulid flies (*Hexatoma*), chironomids (*Pentaneura*, *Meropelopia*), and predatory dragonflies (*Brechmorhoga mendax*, *Erpetogomphus*). In streams heavily impacted by cropland and livestock, EPT indices range from 0 to 5 and are dominated by poor-water-quality tolerant species of oligochaete worms (*Dero digitata*, *Limnodrilus maumeensis*, *L. hoffmeisteri*, *Quistadrilus multisetosus*) and phantom midges (*Chaoborus*). EPT indices range from 8 to 12 in streams west of Houston, where former grasslands are now used for rice and pasture. Common species include caddisflies (*Cheumatopsyche*), mayflies (*Baetis pygmaeus*), beetles (*Stenelmis occidentalis*), and limpets (creeping ancyloid).

Crayfish species in the Brazos Basin include *Cambarellus puer*, *C. texanus*, *Fallicambarus hedgpethi*, *Orconectes causeyi*, *O. palmeri longimanus*, *O. virilis* (virile crayfish), *Procambarus acutus acutus*, and *P. clarkii* (red swamp crayfish). Nineteen species of mussels have been described in the Brazos drainage, including bleufer, western pimpleback, pistolgrip, southern mapleleaf, Texas lilliput, pondhorn, and tapered pondhorn. Three species are presently rare (smooth pimpleback, false spike, and Texas fawnsfoot), and one species is of concern (golden orb). The nonnative Asian clam, now abundant in the Brazos drainage, was probably introduced in 1972 and 1973 and was widespread and abundant by 1980 (Fontanier 1982).

Vertebrates

There are 93 species of fishes in the freshwaters of the Brazos Basin. Dominant species in the most western streams with highest salinities and intermittent flows are Red River pupfish, plains killifish, plains minnow, and smalleye shiner (now a candidate for listing due to reduced populations downstream of dams). Additional common species eastward into the Central Lowlands where flow is more permanent include red shiner, bullhead minnow, channel catfish, bluegill, green sunfish, orangespotted sunfish, largemouth bass, and mosquitofish. Pool-riffle habitat heterogeneity increases in the Central Lowlands around Abilene, where woody debris and overhanging vegetation contribute additional cover and terrestrial sources of prey. Additional common fishes in the Central Lowlands include the central stoneroller minnow, yellow and black bullhead catfish, blacktail shiner, golden shiner, mimic shiner, sharpnose shiner (a candidate for listing due to populations reduced above dams), redear sunfish, spotted bass, blackstripe

topminnow, and orangethroat darter. Larger streams also contain dusky darter, smallmouth buffalo, spotted sucker, flathead catfish, and longnose gar. As the Brazos flows onto the Coastal Plain below Waco, the river forms numerous oxbows, sloughs, and swamps with abundant vegetation. Species adapted to these habitats and seasonal flooding become more abundant. These fishes include banded pygmy sunfish, pirate perch, slough darter, tadpole madtom, gizzard shad, warmouth, white crappie, and spotted gar.

Twenty-one nonnative fish species have been introduced, including species for sport (northern pike, sauger, walleye, rainbow trout, striped bass, smallmouth bass, Rio Grande cichlid), food (common carp, blue tilapia), bait (rudd), and prey (inland silverside). Two minnow species (smalleye shiner and sharpnose shiner) are candidates for federal listing, and the blue sucker (primarily found in large rivers) is listed as a Texas species of concern.

Common aquatic snakes in the Brazos Basin include cottonmouth, copperhead, water snakes (broad-banded, diamondback, green, and blotched), and glossy crayfish snake. The Harter's water snake is restricted to the upper Brazos River drainage. It is found in about 303 km of stream plus two reservoirs. It and the other subspecies (Concho water snake) are the only endemic Texas snakes (Scott et al. 1989). Common amphibians include cricket and green frogs, spotted and Strecker's chorus frogs, and Rio Grande, southern, and plains leopard frogs. Turtles include Texas and Ouachita map turtles, red-eared slider, and stinkpot. Midland smooth and spiny softshell turtles and American alligators are more common in the Lower Brazos. The Lower Brazos also is a haven for birds. Freeport usually wins the unofficial competition for most bird species seen in Texas (>200), which include the rare masked duck (usually found in the West Indies and Mexico). Tens of thousands of ducks, geese, and shorebirds winter along the southern shores of the Brazos. Beaver "slides" along the river and drifting "beaver sticks" indicate their activities throughout the basin. Nonnative nutria also have become residents in the Lower Brazos.

Ecosystem Processes

Limited ecosystem research has been carried out on the Brazos River. Clean Rivers Surveys indicate numerical dominance by macroinvertebrate guilds of filterers and grazers, followed by gatherers, miners, and finally predators (Bayer et al. 1992). These data suggest the importance of FPOM as an energy source. Winemiller et al. (2000) reported that oxbow lakes in the

Middle–Lower Brazos riverine corridor were eutrophic, with chlorophyll *a* levels of 15 to 640 $\mu\text{g/L}$. Rates of nutrient recycling measured at the water–sediment interface of two oxbows near College Station were among the highest reported for freshwater ecosystems (J. B. Cotner, University of Minnesota, unpublished data). Oxbows trap sediment as the velocity of floodwaters declines, and nutrient mineralization rates are extremely high (Shormann and Cotner 1997). Total dissolved nitrogen was inversely correlated with species diversity, indicating that the most nutrient-rich systems were also relatively harsh habitats and limiting to many fish species. Research on a Navasota River tributary (Carter Creek) dominated by wastewater effluent from multiple sources indicated that algae were not nutrient limited, but rather were constrained primarily by frequent scouring events. Late successional stages (dominated by cyanobacteria) were reached only during brief periods of low or no rainfall. Moulton et al. (1993) reported very high rates of secondary production by caddisflies in the Middle Brazos River west of Fort Worth. Production rates from 1980 to 1982 averaged 55 g AFDM $\text{m}^{-2}\text{yr}^{-1}$, with average monthly densities around 16,000 individuals/ m^2 . These production rates and standing stocks are among the highest measured for stream insects (Benke 1984), suggesting overall production of aquatic invertebrates is high.

Human Impacts and Special Features

Characteristics of the Brazos River change greatly over its length. From the Brazos de Dios across the high Llano Estacado of the Great Plains, where it flows only intermittently in the summer and rarely freezes in the winter because of its high salinity, the Brazos cuts through canyonlands and briefly enters the Central Lowlands before crossing back into the Great Plains and finally onto the flat Coastal Plain.

Upstream, populations of minnows that depend on seasonal high flows for upstream movement and reproduction have been reduced by both harsh environmental conditions and disruption of flows caused by damming and irrigation (Wilde and Ostrand 1999). John Graves (1960), in *Goodbye to a River*, wrote a moving tribute to natural free-flowing rivers and points to the cumulative consequences of building dams on rivers like the Brazos. There are more than a dozen reservoirs within the Brazos basin (see Fig. 5.17). Examples include Possum Kingdom, Granbury, and Whitney, which capture water just after the forks of the Brazos join. Apart from Lake

Brazos (formed by a low-head dam at Waco), the main stem of the Brazos in the lower basin flows freely for over 640 km to the Gulf of Mexico, due in part to the shallow gradient of the Coastal Plain. Wide meanders have formed many oxbow lakes at various distances from the present main stem of the river, which reflects their various histories of inundation and reconnection to the river. The Brazos River, deprived of much of its sediments by many dams, has cut deeper into its channel, and less frequently reconnects with the oxbow lakes. The centennial flood of 1992 had a major impact on these oxbow lakes and their biota, providing a significant source of recruitment to the river fishes assemblage (Winemiller et al. 2000).

Few towns have grown up along the lower river because floods still come often enough that they carry away property and huge sections of riverbank. However, growing cities (Fort Worth and Houston) outside the Brazos drainage basin have either already captured Brazos water or plan to do so in the near future. The addition of an off-channel reservoir for water pumped from the Brazos is presently planned to supply water for Houston. A major concern of this proposed project is that flows will be severely reduced during critical periods in the summer. In addition, sediment from the main channel of the Lower Brazos has been utilized extensively as a source of sand for construction of infrastructure in southeast Texas. Concern has recently arisen over sand removal and effects of this practice on sediment transport to the Gulf of Mexico and ultimately beach erosion on the coast.

SABINE RIVER

The Sabine River draws its name from the Spanish word for cypress. It arises from low hills northeast of Dallas, Texas, in three main branches (Cowleech Fork, Caddo Fork, and South Fork) and flows approximately 890 km to the Gulf of Mexico (Fig. 5.19). The former juncture of these three branches is now inundated by Lake Towakoni, constructed in 1958. A fourth branch, Lake Fork Creek, joins the main river about 64 km downstream of the former juncture of the other three branches. The Sabine initially flows southeasterly through fertile east Texas farmland of the blackland prairies, which supports sorghum, cotton, beef and dairy cattle, sheep, and poultry. Then it flows through the timberlands, where logging is the major industry, and eventually turns south to flow through Toledo Bend Reservoir, where

the Sabine becomes part of the Texas and Louisiana border at the 32nd parallel. The total drainage basin is approximately 25,270 km², with about three-quarters in Texas and one-quarter in Louisiana (see Fig. 5.19). As the Sabine descends deeper into the coastal prairie, it forms a maze of wetlands, with massive trees draped in Spanish moss. Running a parallel course, the Neches River to the west joins the Sabine at Sabine Lake, which empties into the Gulf of Mexico through Sabine Pass. Annual discharge from the Sabine River into the Gulf of Mexico makes it the largest river in Texas by volume (Bartlett 1984).

Archaeological excavations have discovered human habitation within the Sabine River basin, beginning with the 12,000-year-old Clovis culture. The Caddo period, from about 780 to 1260 years ago, was a peak of Indian development in the region. Caddo Indians were a loose confederation of more than two dozen tribes allied to the Natchez tribes of the Lower Mississippi Valley who shared a common language and culture that indicated their likely ancestral migration from the Caribbean along the Gulf Coast during prehistoric times. Living in permanent farming villages, they built flat-topped earthen temple mounds and grass houses and achieved the highest level of cultural development of any Texas Indian tribe. Their civilization spread west to the Trinity River and east to the Atlantic Coast. They fished using spears, nets, and trotlines, methods still used today, and wove reed baskets, made various types of pottery, and made bows made of *bois d'arc* (Osage orange). Tribes speaking Atakapan (meaning “cannibal” in the Choctaw language) included the Bidai, Deadose, Patiri, and Akiosa, who lived along the middle and lower Sabine River and Sabine Lake. They tattooed their bodies and faces, used dugout canoes, hunted and fished, and gathered bird eggs and shellfish. Following frequent contact with Europeans from the sixteenth to eighteenth centuries, these civilizations collapsed due to epidemic diseases.

In the early 1800s, displaced Cherokee people began moving into East Texas. Treaties, first by Mexicans, then by Sam Houston and the Texas Republic, had promised them land between the Neches and Angelina rivers. Nevertheless, the Texas federal government voided the treaties and the Cherokees were removed to Indian Territory north of the Red River in Oklahoma. The Alabama and Coushatta Indians migrated to the Neches and Trinity River basins from the southeastern United States after the French and Indian War ended in 1763. Of all tribes who once lived in East Texas, only the migrant Alabama–Coushatta confederation currently holds

territory. Their reservation is on the north edge of the Big Thicket National Preserve (primarily located along the Neches River, west of Lake Steinhagen), itself a remnant of the primitive Big Thicket Region that once stretched from the Sabine River to the Brazos and from Lufkin to Houston and Beaumont.

The first European to view the Sabine was the Spanish explorer and cartographer Alonso de Piñeta in 1519. The Spanish explorer Domingo Ramón gave the river its name in 1716. The importance of the Sabine grew after the United States acquired the Louisiana Territory (1803) from the French. The Adams–Onís Treaty of 1819 passed ownership of Florida to the United States and the Sabine River was the boundary between the United States and Spanish Texas to 32°N latitude. During the Civil War the Battle of Sabine Pass in 1863 was an important Confederate victory that kept the Sabine open for transport through the Union blockade.

Physiography, Climate, and Land Use

The maximum width of the Sabine River drainage basin is only about 72 km, and the basin is fully within the Coastal Plain (CP) physiographic province (see Fig. 5.19). This area corresponds to the Texas Blackland Prairies, East Central Texas Forests, Piney Woods Forests, and Western Gulf Coastal Grassland terrestrial ecoregions of Ricketts et al. (1999). Soils are generally light-colored acid sandy loams, clay loams, and sands with light brown to dark gray loams and dark-colored calcareous clays in the upper basin. The high diversity of vegetation within the lower basin reflects the geological history within the Big Thicket region, formed by changing climate and multiple advances and recessions of ocean shorelines, which mixed and overlaid different soil types. Dominant plant species are longleaf, shortleaf, and loblolly pines, American beech, bald cypress, swamp tupelo, basket oak, American sycamore, river birch, sweetgum, black willow, and water oak trees, along with palmettos (some up to 3 m tall), Spanish moss, eastern grama grasses, Indian grass, and panicum.

Annual mean air temperature in the basin is about 18°C, with monthly mean temperatures typically from 7°C to 28°C annually. For example, Carthage, Texas, averages 7°C in January and 28°C in July (Fig. 5.20). Annual precipitation averages 127 cm as rainfall, with a range of about 100 to 145 cm throughout the basin. Long-term records in Carthage report the greatest precipitation of 13.1 cm on average in May and lowest precipitation of 6.4 cm on

average in August, although precipitation is relatively evenly distributed throughout the year.

The landscape is still largely rural but is greatly influenced by agriculture and silviculture. The basin is approximately 67% forest, 15% grassland, 10% agriculture, and 8% urban. Mean population density within the Sabine River basin is 18 people/km² but varies considerably across the basin, from large expanses with <6 people/km² to urbanized areas of >160 people/km². The economic base in the Sabine drainage basin traditionally has been petroleum. Field production is centered around Longview, Texas, whereas petrochemical refining and transportation as well as offshore oil-rig construction dominate the economy at Port Arthur on Sabine Pass (Ridenour 1998), which with Orange and Beaumont form the “Golden Triangle” of oil refining and export in east Texas.

River Geomorphology, Hydrology, and Chemistry

The Sabine River channel is characterized by flat slopes (mean gradient of 22 cm/km) and wide, forested floodplains (Fig. 5.6). The Sabine River arises at an elevation of 198 m asl and is joined by various tributaries before entering Lake Tawakoni behind Iron Bridge Dam at an elevation of about 134 m asl. Below the dam, the Sabine River flows through Texas to Toledo Bend Reservoir on the Texas and Louisiana border at an elevation of about 52 m asl. Toledo Bend Reservoir is a large impoundment covering about 75,480 ha, making the reservoir the largest body of water in Texas and in the South. The Sabine River then flows south to Sabine Lake, which is formed by the confluence of the Neches and Sabine rivers at about 2 m asl. The lake is drained by the Intracoastal Waterway and Sabine Pass into the Gulf of Mexico.

Annual discharge of the Sabine is 238 m³/s and of the Neches is 179 m³/s through Sabine Lake into the Gulf of Mexico. Average runoff during the period from 1941 to 1967 was about 2.07 cm/mo. The Sabine River maintains strong flows most of the year (see Fig. 5.20). High rainfall rates in spring produce frequent flooding of low-lying areas, and large floods occur on average with about a five-year return interval. Tropical storms, which come from midsummer through autumn, result in flooding along the lower river. Floods generally rise and fall slowly. The low parts of the Sabine Basin often remain inundated for days or weeks during floods. The two large reservoirs

FIGURE 5.6 Sabine River below Rt. 12 upstream of Orange, Texas (PHOTO BY TIM PALMER).

(Lake Tawakoni at the junction of the South and Cowleech forks and Toledo Bend Reservoir on the Texas and Louisiana border) provide some flow regulation. For example, discharge from Toledo Bend Reservoir is generally highest from January through March, in anticipation of spring rainfall, and lowest from September through November to retain floodwaters produced by tropical storms. However, this only slightly dampens the expected seasonal flow patterns (see Fig. 5.20).

Water chemistry of the Sabine River reflects a lowland river in a high-precipitation zone. Mean annual water temperature is 21°C. Mean pH is 6.7, mean conductivity is 145 μS/cm, and mean alkalinity is 19 mg/L as CaCO₃. Water-quality concerns within the basin include periodically low dissolved oxygen levels (<2 mg/L), routinely low dissolved oxygen (<4 mg/L), high chemical oxygen demand (>80 mg/L), high total organic carbon (>40 mg/L), high nutrient levels (NH₄-N > 1.6 mg/L, NO₃-N + NO₂-N > 3.9 mg/L,

and $\text{PO}_4\text{-P} > 0.9 \text{ mg/L}$), high fecal coliforms (>3000 colonies/100mL), and the presence of the herbicide atrazine. Water-quality problems are likely due to municipal and industrial wastewater discharge and stormwater runoff from agricultural, industrial, and urban areas.

River Biodiversity and Ecology

The Sabine is the easternmost large-river basin within the East Texas Gulf freshwater ecoregion of Abell et al. (2000). Aside from biological surveys and water-quality assessments, relatively little information is available on the ecology of the Sabine River.

Plants

Below Toledo Bend Reservoir is an extensive reach of sandy river crossed by only one road and lined by southern bald cypress in the lower 80 km of the river. Other common lowland tree species include sweetgum, water oak, black gum, water tupelo, magnolia, elm, cottonwood, hickory, walnut, maple, American beech, and ash. Submerged and emergent native aquatic plants include arrowhead, smartweed, and buttonbush. Spiderlily, with its narrow, elongated white petals, is a distinctive member of the Amaryllis family, seen commonly along streams and marshy places, where it forms large colonies as bulbs divide. Nonnatives of concern include hydrilla, water hyacinth, water lettuce, Eurasian watermilfoil, alligatorweed, torpedo grass, and giant salvinia. In human-built reservoirs and ponds, conditions are especially ideal for nonnative floating and submerged species because there are few native competitors. Nonnatives are often spread during floods and by hitchhiking on recreational vehicles and equipment.

Invertebrates

Very little published information exists on the aquatic invertebrates of the Sabine River. We examined data from the Texas Clean Rivers Program for surveys of least-disturbed streams above and below Toledo Bend Reservoir (Bayer et al. 1992). EPT indices ranged from 5 to 12. Abundant species in more sluggish silt-bottom areas included chironomid midges (*Rheotanytarsus exiguous*, *Stenochironomus*, *Tanytarsus guerlus*, *T. glabrescens*), oligochaete worms (*Limnodrilus hoffmeisteri*), and isopod crustaceans (*Asellus laticaudatus*). In tannin-stained systems with abundant woody debris, cypress knees, and roots, common species included snails (*Campeleoma decisum*), caddisflies (*Hydropsyche* and *Cheumatopsyche*), beetles (*Stenelmis grossa* and

Macronychus glabratus), dobsonflies (*Corydalus cornutus*), and mayflies (*Caenis*).

There are 32 species of mussels in the Sabine River (Howells et al. 1996; Howells 1997, 2001). Common species include threeridge, giant floater, paper pondshell, Louisiana fatmucket, yellow sandshell, fragile papershell, pond mussel, washboard, threehorn wartyback, bankclimber, bleufer, southern mapleleaf, western pimpleback, lilliput, Texas lilliput, tapered pondhorn, and pondhorn. Rock pocket-book also is widely distributed but typically rare to uncommon in collections. Round pearlshell typically occurs in lower reaches of coastal rivers like the Sabine near the freshwater-saltwater interface but is becoming more abundant in irrigation canals and reservoirs. Fawnsfoot and deertoe reach the southeastern limits of their ranges in eastern Texas. Little spectaclecase apparently was once more abundant in many streams of the Sabine basin but has declined in recent years. A number of unionids are extremely rare. Three species of concern due to declining abundance are southern hickorynut, Texas heelsplitter, and Louisiana pigtoe. Declines are likely due to increasing abundance of the highly successful nonnative Asiatic clam and degraded water quality. Considerable concern exists within the basin that the nonnative zebra mussel will soon invade.

Crayfish species in the Sabine River include *Falli-cambarus hedgpethi*, *Faxonella beyeri*, *Orconectes difficilis* (painted crayfish), *O. lancifer* (stilt crayfish), *O. nais*, *O. palmeri longimanus*, *Procambarus acutus acutus*, *P. dupratzi*, *P. simulans*, and two commercially important species, *P. clarkii* (red swamp crayfish) and *P. zonangulus* (the white river crayfish). *Procambarus kensleyi* occurs in the Sabine, Neches, Trinity, and San Jacinto rivers. It was classified as a species of special concern by the American Fisheries Society Endangered Species Committee (Taylor et al. 1996). The Kisatchie stream crayfish (*Orconectes maletae*) also is threatened, and the Brazoria crayfish (*Procambarus brazoriensis*) and *Procambarus nigricinctus* are considered endangered in the Sabine River basin.

Vertebrates

The Sabine River is home to 104 species of freshwater fishes. Based on surveys for the Clean Rivers Program (Bayer et al. 1992) upstream of Toledo Bend Reservoir, common or widely distributed native fish species included red shiner, blacktail shiner, ribbon shiner, weed shiner, bullhead minnow, yellow bullhead catfish, tadpole madtom, green sunfish, war-mouth, bluegill, longear sunfish, redear sunfish,

spotted sunfish, largemouth bass, pirate perch, blackspotted topminnow, bluntnose darter, slough darter, and dusky darter. Downstream of Toledo Bend Reservoir additional species included spotted gar, cypress minnow, Mississippi silvery minnow, golden shiner, mimic shiner, banded pygmy sunfish, dollar sunfish, bantam sunfish, spotted sunfish, black crappie, blackstripe topminnow, western mosquitofish, scaly sand darter, and mud darter.

Sixteen species of fishes are nonnative in the Sabine River basin, including game species (striped bass, smallmouth bass, rainbow trout, redbreast sunfish, sauger, and walleye), and species used as bait (rudd and goldfish), forage (inland silversides), food (common carp), weed control (grass carp), and other nongame species (Mexican tetra). The paddlefish is endangered in Texas, and an active stocking program is in place to try to revitalize the species upstream of Toledo Bend. The blue sucker, creek chubsucker, and western sand darter are additional fish species of concern.

A wide array of bird species (e.g., brown pelican, great blue heron, little blue heron, tricolored heron, great egret, snowy egret, white ibis, wood stork, and spotted sandpiper) occur along the Sabine River. The J. D. Murphree Wildlife Management Area on Taylor Bayou, which enters Sabine Lake from the west, contains alligator, river otter, beaver, nutria, muskrat, white-faced ibis, anhinga, purple gallinule, common snipe, and the largest population of canvasback ducks in Texas. Common turtle species include common snapper, Mississippi mud turtle, and red-eared slider, and less-common species of note include alligator snapping turtle, razorback musk turtle, Sabine map turtle, smooth softshell, and pallid spiny softshell. Nonvenomous water snakes commonly found are yellowbelly, diamondback, green, and broad-banded. The venomous cottonmouth is commonly seen curled up in root wads and on semisubmerged logs or tree branches overhanging the river. The Gulf Coast waterdog, southern and plains leopard frogs, and cricket frog also occur in the Sabine drainage.

Ecosystem Processes

The broad, flat, well-vegetated watershed of the Sabine River floodplain includes a diverse assemblage of clay- and sand-bottom streams and blackwater habitats (Bianchi et al. 1996). Clean Rivers Program surveys of least-disturbed streams in the Sabine system indicate that invertebrate filter feeders and collector-gatherers dominate the macroinvertebrate assemblages, followed by miners, shredders, grazers,

and finally predators. This reflects the heavy shade of the riparian habitats and instream substrata that provides little habitat for growth of periphyton. The streams and rivers of the Sabine basin rely largely on allochthonous energy sources. Bianchi et al. (1996) studied some of these habitats concerning dissolved organic carbon and flux of methane to the atmosphere. Plant-mediated transport of methane was important, with large spatial variability in fluxes. Methane emission rates were highest after the longest period of flooding during the sampling period. DOC concentrations were very high, with values between 15 and 50 mg C/L.

Ridenour (1998) modeled biological oxygen demand (BOD) on the Sabine River at two gages downstream from a point source located in Longview. The model also evaluated the amount of remaining BOD entering Toledo Bend Reservoir under different flow regimes. Hydraulic geometry, discharge, and temperature were critical inputs to the model. The fraction of BOD remaining in the river as it entered the reservoir was greatest in the winter and spring, with discharge about twice as important as temperature in accounting for the difference.

Human Impacts and Special Features

The western edge of the drainage of the Sabine River (at about the level of Toledo Bend Reservoir) and south to near Houston and Beaumont contains a rich and diverse biological heritage that developed upon ancient sand dunes and beaches of a fossil sea bottom. The swamps and bogs are remnants of prehistoric lagoons and ponds that were created when dunes trapped retreating seawater between ice ages. However, loss of these freshwater wetlands in the lower reaches of the Sabine is an ongoing ecosystem concern (White and Tremblay 1995). Since the 1950s, more than 5000 ha of vegetated wetlands have been submerged due to subsidence in the Sabine Lake region. Human-induced contributions to subsidence include groundwater withdrawal and oil and gas extraction.

Urbanized areas and industries in the lower river cause the most significant water-quality problems in the basin. Sources of concern are oil refineries, petrochemical plants, and dredged deep-water canals constructed near the end of the nineteenth century for shipping. Intensive agriculture in parts of the basin also has caused periodic water-quality problems in the upper reaches of the Sabine River.

Nonnative species also have had significant impacts on the Sabine drainage basin. The Asiatic

clam is abundant throughout the riverine corridor and may be a key species in terms of the effects of its filter feeding on ecosystem functions such as nutrient cycling and trophic dynamics. The Asiatic clam also may be a factor in the decline of many of the indigenous species of unionid mussels. Additional declines of mussels are linked to increased silt loading and floods following clear-cutting of timber on sandy soils or overgrowth of littoral habitats by nonnative aquatic vegetation (hydrilla, water hyacinth, and giant salvinia). The introduction of a number of game fishes, such as walleye, striped bass, and smallmouth bass, is likely to have negatively affected native fish populations in the basin. Ironically, however, consumption advisories exist for game fishes. Game fishes accumulate mercury in their flesh due to anthropogenic changes within the sediments of impounded waters, which influence the toxicity of metals despite their natural occurrence in the basin.

An additional anthropogenic disturbance that has had a major impact on the ecology of the Sabine River is the construction of large hydropower and flood-control reservoirs on the main river (Lake Tawakoni and Toledo Bend), as well as multiple tributary reservoirs. These dams are barriers to migratory fishes, halting previously large runs of anadromous and catadromous fishes (paddlefish and American eel), as well as seasonal movements of striped mullet. Along with water-quality and habitat degradation in the lower river and its tributaries, the dams have caused populations of these species to steadily decline. Recent stocking programs (e.g., paddlefish) and planned construction of fish passages have focused on revitalizing stocks and restoring access to the river. Large reservoirs also can influence upstream tributaries by limiting movement (due to higher populations of piscivores and unfavorable lentic habitats) of more fluvial species that move among headwater streams to maintain populations, or require downstream movement to larger habitats to complete their life cycles. Upstream populations of lentic species can be artificially supplemented from downstream populations that thrive in reservoirs.

ADDITIONAL RIVERS

The Pecos River begins in the Sangre de Cristo Mountains of northern New Mexico and flows through temperate forest, grassland, and desert before joining the Rio Grande on the Mexican border (Figs. 5.21 and 5.7). The Pecos River drops about 3350 m along its course of 1175 km. The river course

FIGURE 5.7 Upper Pecos River, New Mexico (PHOTO BY TIM PALMER).

is over 300 m below the surrounding land in much of the northern reaches. In places, the river disappears into the porous rock layers and emerges downstream. The river is dammed at Alamogordo Reservoir, McMillan Lake, Avalon Lake, and Red Bluff Reservoir. The Pecos flows through a beautiful, steep-sided, twisting canyon in the lower reaches before joining the Rio Grande. Water delivery from New Mexico to Texas from the Pecos has been contentious over the years, as the river is heavily appropriated for agricultural and urban use (Hayter 2002). This large but extremely arid basin (annual precipitation of 28 cm at Pecos, Texas), with high evapotranspiration and heavy water extraction, results in very little discharge into the Rio Grande ($2 \text{ m}^3/\text{s}$), with an annual runoff of $<0.1 \text{ cm}$.

The Nueces River arises at an altitude of 730 m on the Edwards Plateau of southwest Texas and flows in a generally southeasterly direction to the Gulf of Mexico (Figs. 5.23 and 5.8). The Nueces is the only

FIGURE 5.8 Nueces River near its headwaters at the north Barksdale Highway 335 (PHOTO BY R. EDWARDS).

FIGURE 5.9 Trinity River below Livingston Dam, Texas (PHOTO BY TIM PALMER).

major river basin within the West Texas Gulf freshwater ecoregion (Abell et al. 2000). Pecan trees along the river gave rise to the Spanish name. The river course and drainage basin are in a predominantly rural area of Texas. The river carves distinctive canyonlands as it descends the Balcones escarpment. Below the Balcones escarpment, the river flows through the Coastal Plain in cattle-ranching country. A major dam blocks the river, forming Lake Corpus Christi in the lower reach. Below the dam the Nueces is a meandering river in its lower course, with citrus and truck farming. The Nueces River enters the Gulf of Mexico at Nueces Bay, an arm of Corpus Christi Bay. Although not as arid as the Pecos River, annual runoff is still low at 1.6 cm, producing a discharge of only 20 m³/s (see Figs. 5.24).

The Trinity River is entirely within the state of Texas, arising south of Wichita Falls and flowing 815 km to Galveston Bay (Fig. 5.25). The river flows initially southeast to Fort Worth, where the Clear Fork joins the West Fork. The Trinity continues eastward to Dallas and then flows south-southeast to Trinity Bay, the northeastern arm of Galveston Bay (Fig. 5.9). Several large dams dot the Trinity River catchment and many large urban areas occur along the river course. With an annual precipitation of 115 cm, the discharge is quite high at 222 m³/s, even though annual runoff (16 cm) represents only 14% of precipitation (see Fig. 5.26).

The Neches River arises at an elevation of 150 m in the rolling hills of the Eastern Timbers area of Texas and flows 666 km to the Gulf of Mexico (Fig. 5.27). The river initially flows southeast through mixed hardwood and southern pine forests (Fig. 5.10). The river turns south near Jasper and flows into low-lying coastal prairie near Beaumont, Texas. Rice agriculture and oil industry dominate along this portion of the Neches River. The Sabine–Neches deepwater channel links Beaumont with Sabine Lake, which in turn accesses Port Arthur, the Gulf Intra-coastal Waterway, and the Gulf of Mexico. Precipitation in the basin is high at 136 cm, distributed fairly evenly throughout the year (see Fig. 5.28). About 16% of precipitation appears as runoff, which is highest in winter and spring. Several large reservoirs have been constructed in the basin, the largest of which is Sam Rayburn Lake, located on the Angelina tributary (see Figs. 5.27).

ACKNOWLEDGMENTS

We wish to thank the many individuals who provided information for this chapter. Jim Thibault was instrumen-

FIGURE 5.10 Neches River above Rt. 59, Texas (PHOTO BY TIM PALMER).

tal in putting together much of the data on each river basin and proofread the entire manuscript. Scott Anderholm provided data on water quality and algae in the Rio Grande. Shann Springer provided unpublished data on the aquatic invertebrates of the Rio Grande in New Mexico. David Bauer provided a detailed bibliography on the aquatic invertebrates of Texas. Diana Northup assisted with the literature review for the chapter. In addition, numerous other colleagues helped assemble necessary information for this survey. We sincerely thank all who helped assemble the material in this chapter.

FIGURE 5.12 Mean monthly air temperature, precipitation, and runoff for the Rio Grande basin.

RIO GRANDE

Relief: 4272 m

Basin area: 870,000 km² (~450,000 km² contributing water)

Mean discharge: 37 m³/s (virgin >100 m³/s)

River order: 7

Mean annual precipitation: 21 cm

Mean air temperature: 13°C

Mean water temperature: 14°C

Physiographic provinces: Southern Rocky Mountains (SR), Colorado Plateau (CO), Basin and Range (BR), Great Plains (GP), Coastal Plain (CP), Sierra Madre Occidental (SC), Sierra Madre Oriental (SO)

Biomes: Desert, Temperate Grasslands, Temperate Mountain Forest, Mexican Montane Forest

Freshwater ecoregions: Upper Rio Grande, Lower Rio Grande, Pecos, Rio San Juan, Rio Salado, Rio Conchos

Terrestrial ecoregions: 8 ecoregions (see text)

Number of fish species: ≥86 freshwater, ≥80 estuarine

Number of endangered species: ≥16 fishes, several mollusks, 6 birds

Major fishes: Rio Grande cutthroat trout, red shiner, Rio Grande silvery minnow, fathead minnow, white sucker, blue sucker, river carpsucker, western mosquitofish, largemouth bass, bluegill, longnose gar, threadfin shad, Rio Grande shiner, Tamaulipas shiner, longnose dace, Mexican tetra, sailfin molly, Amazon molly, longear sunfish, Rio Grande cichlid

Major other aquatic vertebrates: common yellow-throat, great blue heron, snowy egret, black-crowned night heron, white-faced ibis, belted kingfisher, green kingfisher, plainbelly water snake, American alligator, beaver, mink, nutria, bullfrog, Rio Grande leopard frog, snapping turtle, painted turtle, box turtle, western ribbon snake

Major benthic invertebrates: caddisflies (*Cheumatopsyche*, *Brachycentrus*, *Leucotrichia*, *Stactobiella*, *Hydroptila*, *Protoptila*), mayflies (*Baetis tricaudatus*, *Tricorythodes*, *Thraulodes*, *Traverella*, *Choroterpes mexicanus*), chironomid midges (*Cricotopus*, *Orthocladus*), other true flies (*Atherix*, *Simulium*), Asiatic clam

Nonnative species: ≥23 fishes (common carp, blue tilapia, inland silversides); saltcedar, Russian olive, Siberian elm, white mulberry, Guinea grass, buffelgrass, water hyacinth, hydrilla, water lettuce, alligatorweed, Asiatic clam, nutria

Major riparian plants: cottonwoods, willows, saltcedar, Russian olive, mesquite, hackberry, cedar elm, anacua, black willow, retama, Guinea grass, buffelgrass

Special features: Bosque del Apache National Wildlife Refuge, Chamizal National Memorial, Big Bend National Park, National Wild and Scenic River designation for segments in New Mexico and Texas

Fragmentation: highly fragmented, with five main-stem and numerous tributary dams

Water quality: variable, but generally decreasing downstream; salinity problems in southern New Mexico and western Texas; pH = 8.0, conductivity = 377 μS/cm, mean alkalinity 136 mg/L as CaCO₃ at Albuquerque

Land use: 14% forest, 5% cropland, 7% urban, 43% shrubland, 31% grassland

Population density: 16 people/km²

Major information sources: Hubbs et al. 1991, Revenga et al. 1998

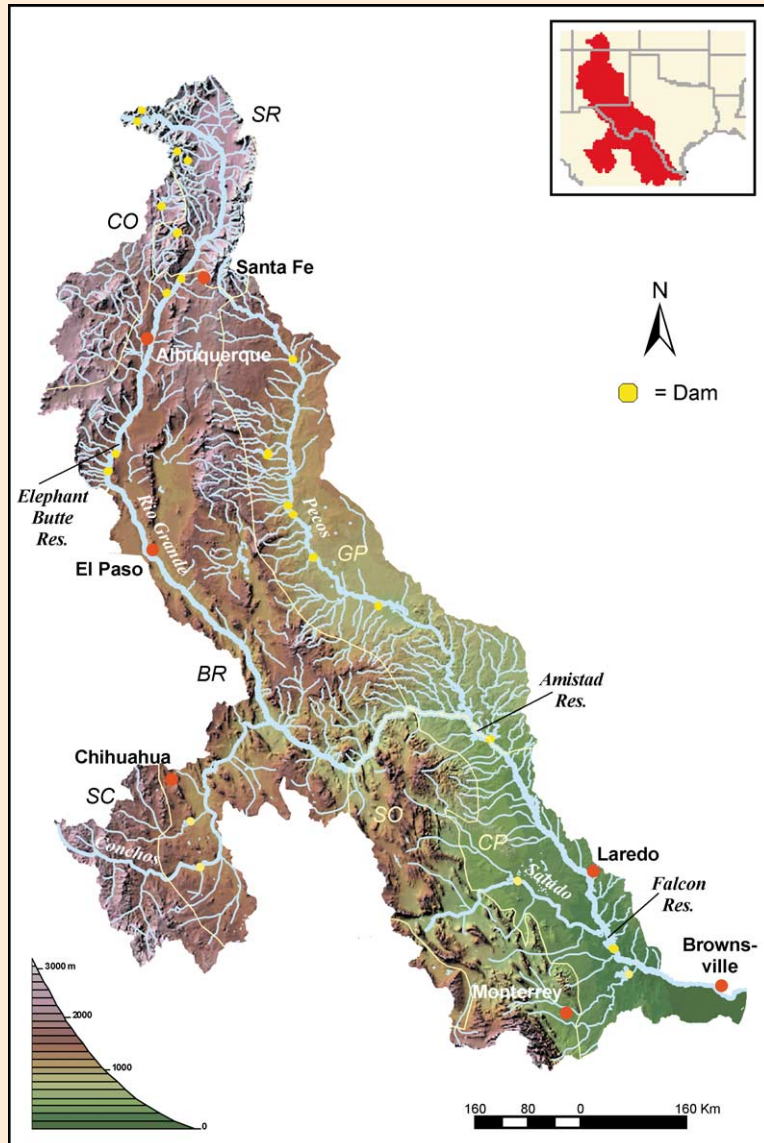

FIGURE 5.11 Map of the Rio Grande basin. Physiographic provinces are separated by yellow lines.

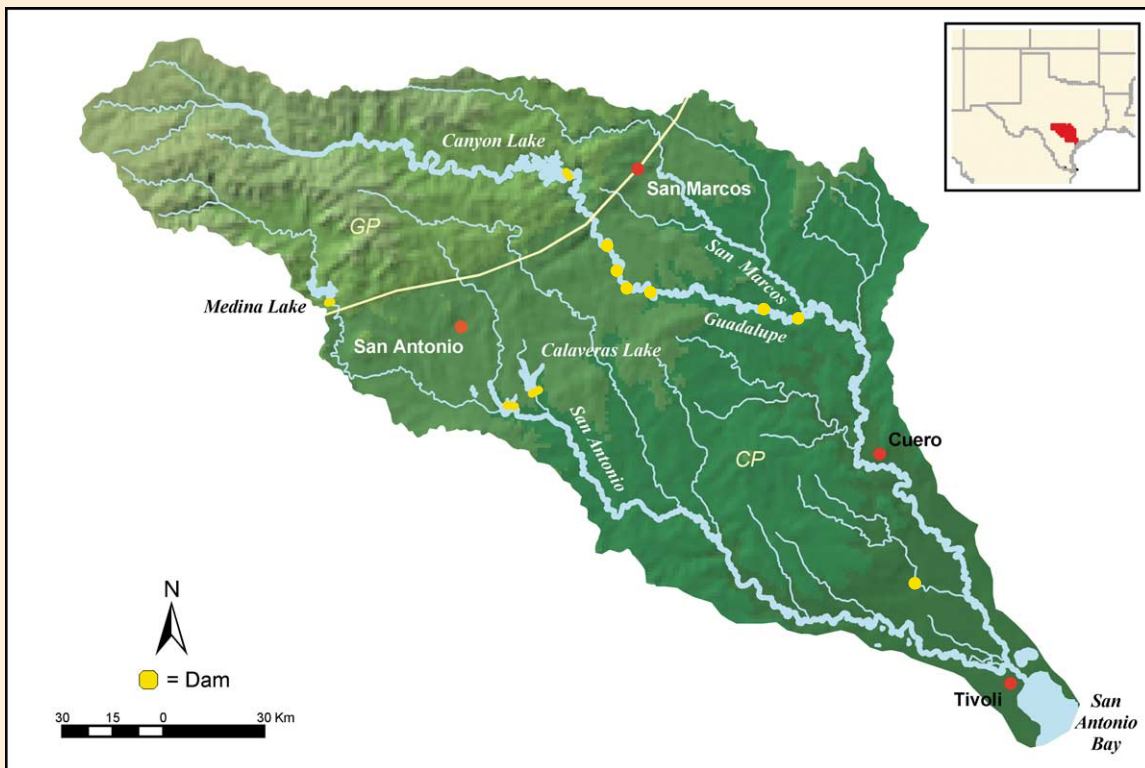

FIGURE 5.13 Map of the Guadalupe-San Antonio River basin. Physiographic provinces are separated by a yellow line.

SAN ANTONIO AND GUADALUPE RIVERS

Relief: 700 m

Basin area: 26,231 km²

Mean discharge: 79 m³/s

River order: 7

Mean precipitation: 81 cm

Mean air temperature: 21°C

Mean water temperature: 23°C

Physiographic provinces: Great Plains (GP), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: East Texas Gulf

Terrestrial ecoregions: Edwards Plateau Savannas, Texas Blackland Prairies, East Central Texas Forests, Western Gulf Coastal Grasslands

Number of fish species: ≥88 (60 native)

Number of endangered species: ≥7 fishes, several amphibians, 3 spring/cave pool-associated aquatic insects, 1 plant

Major fishes: largemouth bass, Guadalupe bass, bluegill, longear sunfish, redear sunfish, spotted sunfish, blacktail shiner, red shiner, central stonerollers, gray redhorse, channel catfish, western mosquitofish, Texas shiner, Texas logperch, river carpsucker, smallmouth buffalo, spotted bass, dusky darter, orangethroat darter, greenthroat darter, bluntnose darter, river darter

Major other aquatic vertebrates: beaver, northern parula warbler, prothonotary warbler, Louisiana waterthrush, great blue heron, snowy egret, white-faced ibis, belted kingfisher, green kingfisher, American alligator, Texas map turtle, Cagle's map turtle, smooth softshell turtle, spiny softshell turtle, plainbelly water snake, Western cottonmouth, nutria, mink

Major benthic invertebrates: caddisflies (*Chimarra*, *Cheumatopsyche*, *Atopsyche*, *Hydroptila*), mayflies (*Dactylobaetis*, *Tricorythodes*, *Choroterpes*, *Thraulodes*), beetles (*Microcylloepus*, *Hexacylloepus*, *Neoelmis*), chironomid midges (*Cricotopus*, *Rheotanytarsus*), true bugs (*Ambrysus*), amphipod crustaceans (*Hyallela*), hellgrammites (*Corydalus*)

Nonnative species: at least 27 fishes (tilapia, crappie, walleye, smallmouth bass, goldfish, grass carp), nutria, Asiatic clam, ramshorn snail, elephant ears, alligatorweed, water hyacinth, hydrilla, water lettuce

Major riparian plants: pecan, Texas sugarberry, bald cypress, cedar elm, Virginia creeper, Texas persimmon, red mulberry, greenbrier, box elder, black walnut, cottonwood, gum bumelia, black willow, American elm

Special features: large artesian aquifers (associated with Edwards aquifer), San Marcos spring

Fragmentation: major dam on Upper Guadalupe (Canyon); smaller dams on San Antonio

Water quality: generally good; pH = 7.0 to 9.0, alkalinity ~200 mg/L as CaCO₃, specific conductance 700 to 1100 μS/cm

Land use: 60% range, 15%, agriculture, 25% urban

Population density: 85 people/km²

Major information sources: Hubbs et al. 1991, Guadalupe-Blanco River Authority (<http://www.gbra.org/>), San Antonio River Authority (<http://www.sara-tx.org>)

FIGURE 5.14 Mean monthly air temperature, precipitation, and runoff for the Guadalupe-San Antonio River basin.

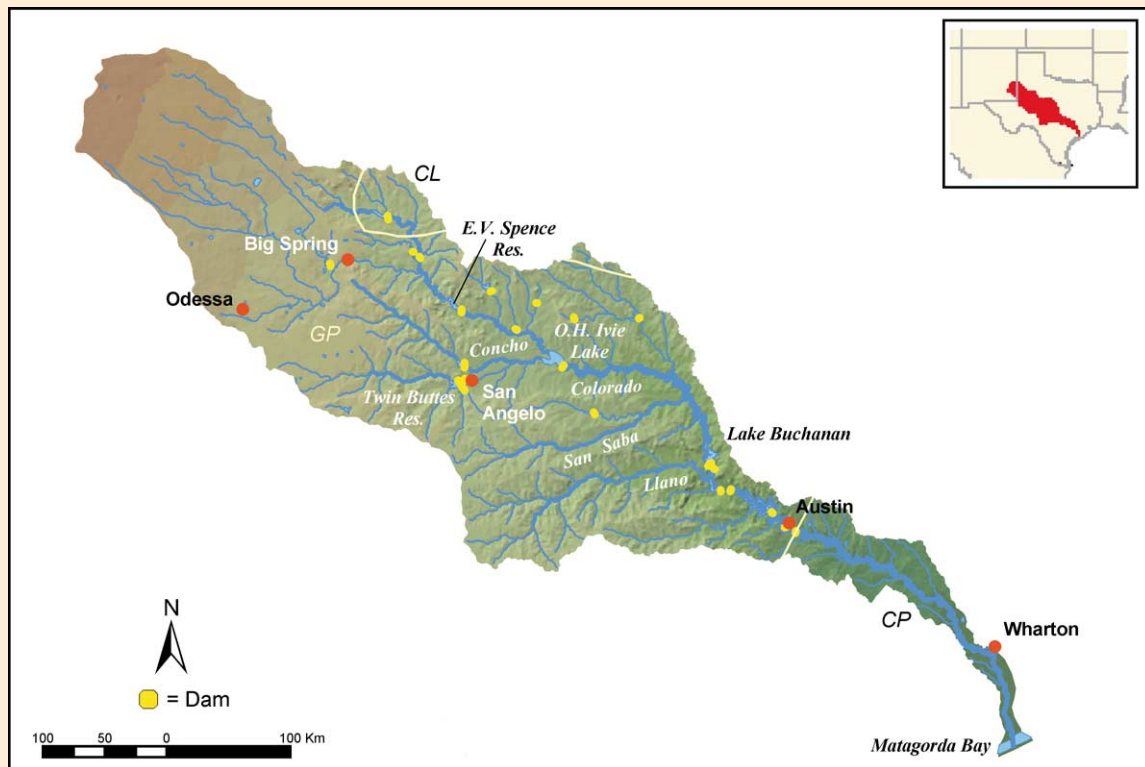

FIGURE 5.15 Map of the Colorado River basin. Physiographic provinces are separated by yellow lines.

COLORADO RIVER

Relief: 1195 m

Basin area: 103,341 km²

Mean discharge: 75 m³/s

River order: 7

Mean annual precipitation: 82 cm

Mean air temperature: 20°C

Mean water temperature: 22°C

Physiographic provinces: Central Lowland (CL), Great Plains (GP), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: East Texas Gulf

Terrestrial ecoregions: seven ecoregions (see text)

Number of fish species: >98 (72 native)

Number of endangered species: >4 fishes, 2 salamanders, 1 snake, 5 mussels

Major fishes: spotted gar, longnose gar, red shiner, bullhead minnow, central stoneroller minnow, suckermouth minnow, blue sucker, gray redhorse, yellow bullhead, channel catfish, blue catfish, western mosquitofish, blackstripe topminnow, longear sunfish, spotted bass, Guadalupe bass, orangethroat darter, greenthroat darter, Texas logperch, bigscale logperch

Major other aquatic vertebrates: beaver, great blue heron, snowy egret, white-faced ibis, belted kingfisher, green kingfisher, Texas map turtle, Texas River cooter, red-eared slider, smooth softshell turtle, spiny softshell turtle, American alligator, plainbelly water snake, Concho water snake, Harter's water snake, western cottonmouth, gray treefrog, cricket frog, southern leopard frog

Major benthic invertebrates: caddisflies (*Cheumatopsyche*, *Helicopsyche*, *Hydroptila*), mayflies (*Tricorythodes*, *Caenis*), beetles (*Stenelmis*), damselflies (*Argia*), hellgrammites (*Corydalus*), chironomid midges (*Rheotanytarsus*, *Tanytarsus*), crayfishes (*Cambarellus*, *Procambarus*), snails (*Physa*), bivalves (*Sphaerium*, Texas fatmucket, Texas pimpleback, Texas fawnsfoot)

Nonnative species: common carp, grass carp, rudd, walleye, northern pike, nutria, saltcedar, water hyacinth, hydrilla, water lettuce, giant salvinia, Eurasian watermilfoil, alligatorweed

Major riparian plants: live oak, red oak, sugarberry, sycamore, elm, black willow, eastern cottonwood, pecan

Special features: three reaches are Texas Natural Rivers System candidates by U.S. Park Service; 18-m Gorman Falls upstream of Lake Buchanan; class IV rapids at Crabapple Creek; 15-m falls into collapsed grotto at Hamilton Pool Preserve

Fragmentation: most heavily dammed river in Texas (25 hydroelectric and water-supply reservoirs)

Water quality: pH = 7.9, alkalinity = 163 mg/L as CaCO₃, specific conductance = 528 μS/cm, occasional fish kills from storm runoff and low oxygen, salinity problems in upper basin, toxic golden alga in some reservoirs

Land use: 55% range, 30% agriculture, 15% urban

Population density: 35 people/km²

Major information sources: Hubbs et al. 1991, Bayer et al. 1992, Howells et al. 1996, Linam et al. 2002, Lower Colorado Water Authority (<http://www.lcra.org>), Upper Colorado Water Authority (<http://www.ucratx.org>)

FIGURE 5.16 Mean monthly air temperature, precipitation, and runoff for the Colorado River basin.

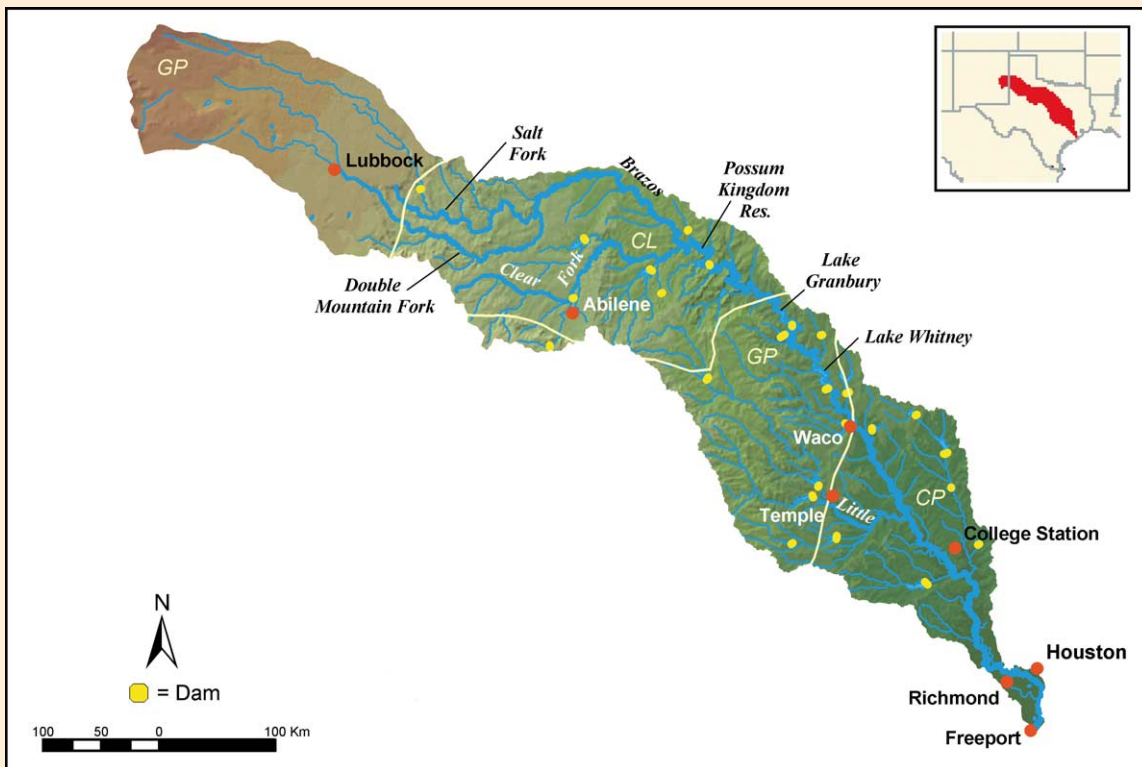

FIGURE 5.17 Map of the Brazos River basin. Physiographic provinces are separated by yellow lines.

BRAZOS RIVER

Relief: 1204 m

Basin area: 115,566 km²

Mean discharge: 249 m³/s

River order: 8

Mean annual precipitation: 81 cm

Mean air temperature: 19°C

Mean water temperature: 21°C

Physiographic provinces: Central Lowland (CL), Great Plains (GP), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: East Texas Gulf

Terrestrial ecoregions: six ecoregions (see text)

Number of fish species: >93 (≥72 native)

Number of endangered species: >4 fishes, 4 mussels

Major fishes: longnose gar, spotted gar, western mosquitofish, blackstripe topminnow, red shiner, blacktail shiner, ribbon shiner, pugnose minnow, bullhead minnow, bluegill, green sunfish, longear sunfish, white crappie, largemouth bass, spotted bass, slough darter, orangethroat darter, tadpole madtom, channel catfish, blue catfish, flathead catfish, smallmouth buffalo, river carpsucker

Major other aquatic vertebrates: beaver, river otter, Harter's water snake, great blue heron, snowy egret, black-crowned night-heron, white-faced ibis, kingfishers, softshell turtles, American alligator, plainbelly water snake, western cottonmouth

Major benthic invertebrates: caddisflies (*Cheumatopsyche*), mayflies (*Choroterpes*, *Tricorythodes*), chironomid midges (*Tanytarsus*, *Rheotanytarsus*), beetles (*Stenelmis*), crayfishes (*Cambarellus puer*, *Procambarus acutus*), bivalves (bleufer, washboard, Texas lilliput, *Sphaerium transversum*), snails (*Physella virgata*), oligochaete worms (*Limnodrilus*, *Dero*)

Nonnative species: ≥21 fishes (grass carp, striped bass, rainbow trout, redbreast sunfish, rudd), saltcedar, Asiatic clam, nutria, water hyacinth, hydrilla, giant salvinia, Eurasian watermilfoil, alligatorweed

Major riparian plants: baccharis, cottonwood, willow, elm, hackberry, pecan, sumac, poison ivy, arrowhead, eelgrass, water primrose, Illinois pondweed, spikerush, water star grass

Special features: Llano Estacado; Blanco Canyon; dinosaur tracks in Paluxy River bank; class III rapids at Tonkawa falls west of Waco; floods reconnect river with floodplain oxbow lakes in lower river

Fragmentation: highly fragmented river, with 132 large dams in basin

Water quality: pH = 7.6, alkalinity = 133 mg/L as CaCO₃, specific conductance = 733 μS/cm, natural salinity high in upper basin, nutrient loading (dairy farms) in middle basin, toxic golden alga in some reservoirs

Land use: 3% forest, 24% cropland, 16% urban, 57% grassland

Population density: 20 people/km²

Major information sources: Hubbs et al. 1991, Bayer et al. 1992, Howells et al. 1996, Linam et al. 2002, Revenga et al. 1998, Brazos River Authority (<http://www.brazos.org>)

FIGURE 5.18 Mean monthly air temperature, precipitation, and runoff for the Brazos River basin.

FIGURE 5.20 Mean monthly air temperature, precipitation, and runoff for the Sabine River basin.

SABINE RIVER

Relief: 198 m

Basin area: 25,268 km²

Mean discharge: 238 m³/s

River order: 8

Mean annual precipitation: 127 cm

Mean air temperature: 18°C

Mean water temperature: 21°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: East Texas Gulf

Terrestrial ecoregions: Texas Blackland Prairies, East Central Texas Forests, Piney Woods Forests, Western Gulf Coastal Grasslands

Number of fish species: >104 (≥88 native)

Number of endangered species: >4 fishes, 2 crayfishes

Major fishes: bowfin, spotted gar, alligator gar, freshwater drum, river carpsucker, blacktail redhorse, flier, creek chubsucker, grass pickerel, golden topminnow, blackspotted topminnow, brook silverside, white bass, yellow bass, dollar sunfish, redear sunfish, largemouth bass, spotted bass, black crappie, scaly sand darter, goldstripe darter, cypress darter, bigscale logperch

Major other aquatic vertebrates: alligator snapping turtle, Sabine map turtle, smooth softshell turtle, spiny softshell turtle, American alligator, Gulf Coast waterdog, pickerel frog, green water snake, western cottonmouth, wood duck, canvasback, bald eagle, white-faced ibis, anhinga, great blue heron, snowy egret, purple gallinule, belted kingfisher, river otter, nutria

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*), hellgrammites (*Corydalus*), beetles (*Stenelmis*), chironomid midges (*Tanytarsus*, *Rheotanytarsus*, *Stenochironomus*), mayflies (*Caenis*), crayfishes (*Orconectes causeyi*, *Procambarus clarkii*), amphipod crustaceans (*Gammarus*), bivalves (Texas pigtoe, threeridge, little spectaclecase)

Nonnative species: ≥15 fishes (walleye, smallmouth bass, common carp, grass carp, rudd, striped bass, Mexican tetra), Asiatic clam, nutria, water hyacinth, hydrilla, giant salvinia, water spangles, Brazilian waterweed, Eurasian watermilfoil, parrotfeather, duck lettuce, alligatorweed, torpedo grass

Major riparian plants: bald cypress, sweetgum, water oak, black gum, water tupelo, magnolia, elm, cottonwood, hickory, walnut, maple, American beech, ash, palmetto, arrowhead, smartweed, buttonbush, spiderlily

Special features: 32 mussel species, scenic reach for 80 km below Toledo Bend Reservoir, Blue Elbow Swamp near Orange

Fragmentation: highly fragmented due to both low- and medium-head dams; Toledo Bend Reservoir is largest in the south

Water quality: pH = 6.7, alkalinity = 19 mg/L as CaCO₃, specific conductance = 145 μS/cm; problems include low oxygen, high fecal coliforms, nutrient enrichment, atrazine, mercury

Land use: 67% forest, 10% agriculture, 8% urban, 15% grassland

Population density: 18 people/km²

Major information sources: Hubbs et al. 1991, Bayer et al. 1992, Howells et al. 1996, Linam et al. 2002, Sabine Water Authority (<http://www.sra.dst.tx.us>)

FIGURE 5.22 Mean monthly air temperature, precipitation, and runoff for the Pecos River basin.

PECOS RIVER

Relief: 4012 m

Basin area: 113,960 km²

Mean discharge: 2 m³/s (virgin ≥9 m³/s)

River order: 5

Mean precipitation: 28 cm

Mean air temperature: 18°C

Mean water temperature: 21°C

Physiographic provinces: Southern Rocky Mountains (SR), Basin and Range (BR), Great Plains (GP)

Biomes: Temperate Mountain Forest, Deserts, Temperate Grasslands

Freshwater ecoregion: Pecos

Terrestrial ecoregions: Colorado Rockies Forests, Western Short Grasslands, Chihuahuan Desert, Colorado Plateau Shrublands

Number of fish species: ≥70

Number of endangered species: ≥12 fishes, 3 snails, and 1 amphipod proposed for listing

Major fishes: red shiner, inland silverside, Pecos pupfish, western mosquitofish, rainwater killifish, roundnose minnow, proserpine shiner, channel catfish, Rio Grande cichlid, Mexican tetra, green sunfish, largemouth bass

Major other aquatic vertebrates: great blue heron, snowy egret, black-crowned night-heron, white-faced ibis, belted kingfisher, green kingfisher, plainbelly water snake, beaver, muskrat

Major benthic invertebrates: caddisflies (*Ithytrichia*, *Cheumatopsyche*, *Hydroptila*), mayflies (*Choroterpes*, *Thraulodes*, *Tricorythodes*, *Traverella*), beetles (*Berosus*), true bugs (*Cryphocricos*), chironomid midges (*Tanytarsus*, *Dicrotendipes*, *Pseudochironomus*, *Microtendipes*, *Cricotopus*), amphipod crustaceans (*Hyallela azteca*)

Nonnative species: ≥19 fishes (grass carp, goldfish, common carp, rudd, rainbow trout, white crappie, walleye, smallmouth bass, redear sunfish), saltcedar, Russian olive, water hyacinth, hydrilla, Eurasian watermilfoil, alligatorweed

Major riparian plants: saltcedar, mesquite, cottonwood, four-winged saltbush, Russian olive, willow

Special features: Bitter Lake National Wildlife Refuge with high biodiversity of dragonflies and damselflies; river passes through deep gorges within limestone terrain

Fragmentation: several impoundments, including Red Bluff Reservoir upstream of Pecos, Texas; major water diversions near Pecos and Grandfalls

Water quality: pH = 7.9, alkalinity = 127 mg/L as CaCO₃, specific conductance = 3326 μS/cm, salinity problems in lower basin, toxic golden alga in reservoirs

Land use: 40% shrubland, 45% grassland, 10% agriculture, 3% forest, 2% urban

Population density: 3 people/km²

Major information sources: Davis 1980a, Hubbs et al. 1991, Hayter 2002

FIGURE 5.23 Map of the Nueces River basin. Physiographic provinces are separated by a yellow line.

NUECES RIVER

Relief: 730 m
 Basin area: 43,512 km²
 Mean discharge: 20 m³/s
 River order: 7
 Mean precipitation: 61 cm
 Mean air temperature: 21°C
 Mean water temperature: 23°C
 Physiographic provinces: Great Plains (GP), Coastal Plain (CP)
 Biome: Temperate Grasslands
 Freshwater ecoregion: West Texas Gulf
 Terrestrial ecoregions: Edwards Plateau Savannas, Tamaulipan Mezquital, East Central Texas Forests, Western Gulf Coastal Grasslands

Number of fish species: ≥66

Number of endangered species: ≥3 fishes

Major fishes: longnose gar, spotted gar, Mexican tetra, Nueces roundnose minnow, plateau shiner, Texas shiner, channel catfish, sailfin molly, western mosquitofish, largemouth bass, longear sunfish, bluegill, greenthroat darter, Rio Grande cichlid

Major other aquatic vertebrates: beaver, great blue heron, snowy egret, white-faced ibis, belted kingfisher, green kingfisher

Major benthic invertebrates: caddisflies (*Chimarra*, *Cheumatopsyche*, *Hydroptila*), mayflies (*Fallceon*, *Dactylobaetis*, *Tricorythodes*, *Choroterpes*, *Thraulodes*), beetles (*Microcyloepus*, *Hexacyloepus*, *Neoelmis*), chironomid midges (*Cricotopus*, *Rheotanytarsus*), true flies (*Hemerodromia*, *Simulium*), amphipod crustacean (*Hyallela*), hellgrammites (*Corydalus*)

Nonnative species: ≥20 fishes (goldfish, grass carp, common carp, golden shiner, rudd, rainbow trout, inland silverside, striped bass, smallmouth bass, Guadalupe bass, walleye, Rio Grande cichlid)

Major riparian plants: pecan, Texas sugarberry, bald cypress, cottonwood, black willow, cedar elm, Texas persimmon, red mulberry, greenbrier, box elder, black walnut, American elm

Special features: arises from springs in Edwards Plateau, tricanyon area of Nueces, Frio, and Sabinal highly scenic

Fragmentation: two major reservoirs in lower basin

Water quality: pH = 7.8, alkalinity = 142 mg/L as CaCO₃, specific conductance = 1211 μS/cm

Land use: 55% shrublands, 25% rangelands, 15% agriculture, 5% urban

Population density: 16 people/km²

Major information sources: Hubbs et al. 1991, Nueces River Authority (<http://www.nueces-ra.org>)

TRINITY RIVER

Relief: 362 m

Basin area: 46,540 km²

Mean discharge: 222 m³/s

River order: 7

Mean annual precipitation: 115 cm

Mean air temperature: 19°C

Mean water temperature: 21°C

Physiographic provinces: Central Lowland (CL), Great Plains (GP), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: East Texas Gulf

Terrestrial ecoregions: Central Forest/Grassland Transition Zone, Texas Blackland Prairies, East Central Texas Forests, Piney Woods Forests, Western Gulf Coastal Grasslands

Number of fish species: ≥99

Number of endangered species: 3 fishes, 1 crayfish, 3 mussels

Major fishes: spotted gar, threadfin shad, channel catfish, freckled madtom, pirate perch, river carpsucker, smallmouth buffalo, red shiner, ribbon shiner, weed shiner, bullhead minnow, pugnose minnow, golden topminnow, blackstripe topminnow, western mosquitofish, dollar sunfish, largemouth bass, spotted bass, white crappie, bluntnose darter, slough darter, dusky darter

Major other aquatic vertebrates: beaver, nutria, American alligator, cottonmouth, yellow-bellied water snake, diamondback water snake, red-eared slider, Texas river cooter, common snapping turtle, cricket frog, green treefrog, gray treefrog, southern leopard frog, bald eagle, osprey, anhinga, wood duck, pintail, canvasback, great blue heron, greenback heron

Major benthic invertebrates: caddisflies (*Cheumatopsyche*, *Chimarra*), mayflies (*Caenis*, *Isonychia*, *Heptagenia*), beetles (*Stenelmis*), chironomid midges (*Stictochironomus*), true bugs (*Rhagovelia*), bivalves (Louisiana fatmucket, yellow sandshell, bleufer, western pimpleback, tapered pondhorn)

Nonnative species: 20 fishes (grass carp, common carp, rudd, northern pike, rainbow trout, inland silverside, striped bass, redbreast sunfish, smallmouth bass, walleye, blue tilapia), nutria, Asian clam, hydrilla, water hyacinth, giant salvinia

Major riparian plants: red maple, river birch, water hickory, pecan, black hickory, hackberry, honey locust, water elm, water oak, sumac, black willow, American elm, water willow, water-pennywort, smartweed, bulrush, cattail, sedge, spikerush

Special features: Trinity River National Wildlife Refuge (permanently flooded swamps); Richland Creek and Keechi Creek Wildlife Management Areas (numerous periodically flooded oxbows)

Fragmentation: highly fragmented, with 21 major reservoirs in basin

Water quality: pH = 7.5, alkalinity = 109 mg/L as CaCO₃, specific conductance = 594 μS/cm, pollution near cities and agricultural areas due to low oxygen, high fecal coliforms, high total dissolved solids, algal blooms, atrazine, pesticides/PCBs, metals

Land use: 35% forest, 15% cropland, 30% urban, 20% grassland

Population density: 98 people/km²

Major information sources: Hubbs et al. 1991, Bayer et al. 1992, Howells et al. 1996, Linam et al. 2002, Trinity River Authority (<http://www.trinityra.org/trahp.htm>)

INTRODUCTION

LOWER MISSISSIPPI RIVER

WHITE RIVER

BUFFALO NATIONAL RIVER

BIG BLACK RIVER

YAZOO RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The Mississippi River basin is the largest in North America (~3.27 million km²; Baker et al. 1991, Karr et al. 2000) and the 3rd largest in the world, exceeded in area only by the Amazon basin in South America and the Congo in Africa (Leopold 1994). It extends from 37°N to 29°N latitude, covers nearly 14% of the North American continent, and drains 41% to 42% of the area of the conterminous United States. The Mississippi River, at 6693 km, is second only to the Nile in length. Its estimated virgin discharge of 18,400 m³/s ranks 9th in the world (Leopold 1994, Dynesius and Nilsson 1994). The Lower Mississippi River (LMR) extends from the confluence with the Ohio River at Cairo, Illinois, at Rkm 1536, where the bed is about 100 m asl, to the Gulf of Mexico (Fig. 6.2). Unlike all other rivers considered in this book, the LMR main stem receives most of its flow from major upstream tributaries that are considered in other chapters: the Missouri River (Chapter 10), the Upper Mississippi River (Chapter 8), and the Ohio River (Chapter 9). The basin area of the LMR and its tributaries is about 880,000 km². The focal

area for this chapter (460,000 km²) excludes the upper and middle reaches of the Arkansas and Red rivers, which enter this area from the west (see Chapter 7), and roughly corresponds to three freshwater ecoregions: Mississippi Embayment (excluding the Pearl River, which enters directly into the Gulf of Mexico east of the Mississippi), Ozark Highlands, and Ouachita Highlands (Abell et al. 2000). Thus, this area includes drainages that cover most of Arkansas, Mississippi, and Louisiana and portions of southern Missouri, western Tennessee, and western Kentucky.

The LMR has a long history of human habitation for this continent: as long as 16,000 years ago as indicated by artifacts in the basin. The last major cultural development by Native Americans initiated in the eastern United States was the Mississippian. The Mississippian culture developed from the Caddoan along the LMR from the eighth century through the middle of the thirteenth century. The new agricultural methods, religious practices, and social concepts resulted in a sedentary society that built earthen mounds with wooden buildings on them, often surrounded by walled fortifications with timber palisades

FIGURE 6.2 Lower Mississippi River and its tributaries covered in this chapter.

and bastions. At the time Europeans arrived, clans of Choctaw, Chippewa, Koroa, Taensa, Chickasaw, Tunica, Yazoo, Pascagoula, Natchez, Biloxi, Alibamu, and many others lived in the LMR valley and successfully exploited the abundant natural resources of the rivers and their wetlands. Although first explored by the Spanish beginning with Hernando de Soto, the LMR was first settled by the French. La Salle claimed the river basin for France in 1682. France ceded it to Spain in 1762, but in 1800, Napoleon Bonaparte managed to take it back again. France sold the “Louisiana Purchase” to the United States, doubling its size, for about \$20 million in 1803. This land area includes the entire Mississippi River basin west of the main channel, which is a large majority of the basin. Early transportation on the rivers of the region was primarily downstream by canoes, and later by flat-

boats. Keelboats were narrower and more streamlined, and were paddled, pushed, sailed, and pulled with ropes upstream with considerable expenditure of effort. The first steamboat paddle wheeler (the *New Orleans*, built in Pittsburgh, Pennsylvania) plied the LMR beginning in 1811 and survived the New Madrid earthquakes that occurred the same year. The earthquakes realigned much of the river channel, causing it to flow northward for several days, and also created Reelfoot Lake in northwestern Tennessee, the site of a biological field station from 1931 to 1969. An era when huge cotton plantations were owned by rich caucasian families using African-American slave labor coincided with the history of steam-powered paddle wheelers in the Mississippi River and its tributaries. This era (antebellum South) was ended after about 50 years by the Civil War.

The Acadian people, who came to be known as Cajuns, settled the swamps of southern Louisiana, especially in the Atchafalaya basin, in 1755 during the French and Indian War, when they were forced to leave the Acadia region of Canada by the British. Cajuns have been, and many remain, industrious modern hunter-gatherers of wildlife (shrimp, crayfish, oysters, fishes, waterfowl, nutria) from the productive rivers, estuaries, and bayous, but also grow a variety of crops, including corn, yams, sugar cane, and melons. More recently many Cajuns have become rather wealthy working in the oil fields and petrochemical industries that have developed in the LMR delta. Thus, Cajuns have had a major impact on the LMR.

In this chapter we will focus on the LMR main stem and four of its tributaries: the White, Buffalo, Yazoo, and Big Black rivers. Five additional rivers that are entirely within this region are also addressed but will receive less attention: the Atchafalaya, Cache, Ouachita, Saline, and Current. Of these nine tributaries, seven are west of the Mississippi and two (Yazoo and Big Black) enter from the east.

Physiography and Climate

Besides the regions containing its upstream tributaries, the LMR drains from three physiographic provinces that are very distinct: Coastal Plain (CP), Ouachita province (OP), and Ozark Plateaus (OZ) (Fig. 6.8). The Coastal Plain is a large, flat plain of deep, fine alluvial deposits. It has a large variety of habitats despite lack of much topographic relief or coarse substrates. The Ozark Plateaus are highlands consisting of an area of uplifted plateaus composed of nearly horizontal strata of limestones, sandstones, and shales that have been radially eroded to form steep valleys. The Ozark Plateaus are characterized by karst topography, with numerous caves and springs. The Ouachita province is an area of east-west trending ridges and valleys extending through west-central Arkansas south of the Arkansas River into east-central Oklahoma. The Ouachita Mountains are similar topographically to the Appalachian Mountains but not as tall (152 m to 853 m asl). The region is complex stratigraphically and lithologically, with many folds and faults caused by uplifts through formerly horizontal deposits of sandstones, shales, and novaculites (Cronis 1930). Quartz crystals and flat stones suitable for building are abundant, and some coal is found in the Ouachitas, so there are many small mines in the area to extract these resources.

The climate of this entire region ranges from temperate midcontinental in the northern and western portions to subtropical and very humid in the south. The mean annual temperature is about 16°C, with an annual range from 0°C to 35°C. Rainfall ranges from just over 100 cm/yr in the west to over 160 cm/yr in the warm, moist delta region of southern Louisiana. Heavy rains can occur at any time of year, but winter to early summer is the wettest, and late summer to mid-fall is the driest. As a result of somewhat lower precipitation and higher evapotranspiration during the summers, many headwater streams are ephemeral or intermittent. Hurricanes occasionally lash the coast of Louisiana and Mississippi, and tornados are common throughout the region. These storms seriously impact fisheries in the productive Mississippi delta region and Atchafalaya basin by making the backwaters and swamps anoxic for many weeks afterward (Sabo et al. 1999).

Basin Landscape and Land Use

The LMR basin contains parts of six terrestrial ecoregions as depicted by Ricketts et al. (1999): Central U.S. Hardwood Forests, Ozark Mountain Forests, Piney Woods Forests, Southeastern Mixed Forests, Western Gulf Coastal Grasslands, and Mississippi Lowland Forests. Unlike most of the Upper Mississippi River basin, most of which occurs in grasslands, the LMR basin occupies an area where the climax vegetation of most of the region is forest, although 77% of the forests are presently cleared (Mitsch and Gosselink 1993) for agricultural production and other uses.

Vegetationally, the natural landscape of the LMR region was forested but interspersed with prairies. The vegetation was, and continues to be, a complex, patchy mosaic, with the floral composition of each patch resulting principally from soil type, climate, frequency and duration of inundation, fire history, and the long history of anthropogenic disturbance (Williams 1992, Pyne 1997). More recently, protection from flooding and fire disturbances has changed the vegetational landscape of the LMR region. Presently 50% to 90% of the obvious vegetation consists of diverse crops of food and fiber dominated by cotton, soybeans, rice, maize, and loblolly pine. The deciduous forests in the basin are diverse and vary among ecoregions, but generally they are composed of oaks and hickories, with gums, hackberries, sycamores, birches, and willows becoming more abundant nearer to water. Some of the same genera, but different species, occur in swamps (e.g.,

Nuttall's oak, live oak, and water hickory), with bald cypress and water tupelo replacing them in the wettest areas. Longleaf pines were dominant to subdominant in some areas with sandy, acid soils, but they have been extensively replaced by faster-growing loblolly pines by silviculturalists.

Grasslands in the LMR region were very diverse, but tall grass prairies dominated by big and little bluestem, Indian grass, and switch grass were most common. The prairies often blend into savannas formed by scattered longleaf pines. Further south these grasses are replaced by panic grasses, sea oats, a large variety of sedges including sawgrass, and other species that can withstand wetter, tighter soils and more saline conditions. Palmettos are a common understory species in many areas of the southern Coastal Plain.

Wetlands of a large variety of types occur in this area, primarily along the larger river courses, and are integral components of the riverine ecosystems. The floodplain of the LMR is one of the largest in the world and contains 36,000 km² of wetland habitats. The Lower Mississippi main stem has 26 tributary streams and 242 lakes >8 ha in surface area located in its floodplain. Many of these are oxbow lakes and back swamps that form behind natural levees in the floodplains of the larger rivers (Mississippi, Arkansas, White, Yazoo, Big Black, Cache, St. Francis, Tensas, Atchafalaya). Large areas of wetland associated with these rivers are known as bottomland hardwood forests, which are a type of swamp. Nuttall's oak, pin oak, and hackberry trees dominate higher ground in the bottomland forests, with willows, cypress, and water tupelo in the areas that are flooded for longer periods. The Atchafalaya River basin alone has the 3rd largest continuous wetland area in the United States and contains about 30% of all bottomland hardwood forests in the Mississippi Alluvial Plain. The Black Swamp in the Cache River basin is another vast (60,000 ha) bottomland hardwood wetland in the LMR (Kress et al. 1996).

More of the agricultural land is maintained as cleared fields for row-crop production in the rich lowlands of the Coastal Plain region than in the Ozark Plateaus and Ouachita province. In the Upper Gulf Coastal Plain, comprising the northeastern third of the Mississippi Embayment, agriculture makes up 54% of land use (Gonthier 2000). In the remainder, which is the Mississippi Alluvial Plain, 80% is used for row-crop agriculture. Silviculture of loblolly pine in the Ouachita province and various hardwoods (e.g., oaks) in the Ozark Plateaus remains a dominant land use where the hill slopes and soil types are

not suitable for other forms of agricultural production. Thus, about half of these regions remain forested. Native Americans of the Mississippian culture deforested much of the Coastal Plain in the thirteenth century for fuel and building material. Other Native Americans were largely responsible for maintaining extensive prairies in the Ozark and Ouachita highlands by use of fire before Europeans colonized the area and began fire-control practices. Some of the fires were accidental, but others were set to provide fresh grazing to attract American bison (and later to provide grasses for their horses), to provide areas for growing vegetables (primarily beans, corn, and squash), to harass enemies, to control ticks and insects, and to drive animals during hunting expeditions. European diseases introduced by the de Soto expedition and others devastated the Native Americans, which allowed forests to regrow before extensive exploration and colonization by Europeans.

The LMR valley is highly productive land and has been cleared for intensive farming to produce cotton, soybeans, rice, and corn. Row-crop production of these plants dominates the LMR Coastal Plain. The fertilizers, pesticides, and herbicides used to grow these crops, and sediments from the plowed fields, are washed into the river. A typical form of privately owned agricultural operation in the Interior Highlands (Ozark Plateaus and Ouachita province) consists of a confined animal production facility for poultry or swine combined with pastures for beef cattle production. The manure from the confined animals and litter (rice hulls, shavings) used in the buildings are spread on the pastures to fertilize grasses for cattle. Part of the grassland is protected from grazing, cut, and baled as hay to be fed in winter. Other types of farms are present (dairies, orchards, vineyards, etc.), but they collectively comprise less than 5% of land use. The pastures that receive the manure from the extensive confined animal production facilities are often adjacent to streams, and runoff from these fields contributes substantial quantities of nonpoint-source nutrients (organic matter as well as nitrates and phosphates). The cattle that graze the pastures have access to the streams and are a source of physical disturbance as well as enriching nutrients. Silviculture, especially of loblolly pine, also contributes nonpoint-source pollution.

The Rivers

The Mississippi River main stem is obviously the primary river of this region. After the confluence with

the Missouri River the Mississippi is a 10th order river and retains this size designation throughout the Lower Mississippi reach. The three largest tributaries (Arkansas, White, and Red rivers) are all 7th order rivers that enter from the west. The Yazoo River entering from Mississippi is a 6th order stream, but with less flow than the others. As the rivers in this region approach the Mississippi River, they all take on the character of large, lowland rivers; they are influenced by crossing the relatively flat plain of fine alluvial deposits called the Mississippi Delta. However, many of them originate in highlands and are much different in their headwaters and midreaches. Those coming from the east originate just beneath the western slopes of the Appalachian Mountains but are all wholly contained within the Coastal Plain physiographic province or Mississippi Embayment freshwater ecoregion. Those from the west have such diverse origins as the Ozark Plateaus (White, St. Francis), southern Rocky Mountains (Arkansas), Ouachita province (Ouachita), and Great Plains (Red). Streams that arise within the lowlands of the Coastal Plain (e.g., Homochitto, Cache) do not have the dramatic changes in character along their lengths that are characteristic of those entering the Mississippi from the west.

Although several classifications of aquatic habitats in the Mississippi River valley exist (Baker et al. 1991), the habitats seem to vary principally in flow rate, depth, frequency of connection to the river, permanence, and riparian influence. The extent and relative abundance of the different habitat types change with river stage. Construction of levees, floodways, cutoffs, dikes, revetments, locks and dams, and tributary basin modifications by the U.S. Army Corps of Engineers (USACE) to control floods and allow shipping and barge traffic has altered the relative percentages of the different types of habitat and formed novel habitat types (Baker et al. 1991). Maintenance of a single, large, relatively straight, deep channel in the Mississippi, Arkansas, White, and Yazoo rivers has likely had significant impacts on the fishes, macroinvertebrates, and other biota, but these impacts are not well documented, principally because of the difficulties involved in studying the biota of large rivers.

The Mississippi River presently has a meandering channel form (although highly artificially regulated), but it and other large North American rivers have alternated between meandering and braided channel forms for about two million years as climatic conditions changed amounts of runoff and sedimentation (Saucier 1968). During periods of high sedimentation

(as from glacial outwash) and diminished runoff, braided channel patterns developed because flows were insufficient to move the bedload and instead divided into multiple, anastomosing, shallow channels across the top of the deposits. Braided channels have a different array of habitat types from meandering channels. The main-stem Lower Mississippi and its larger tributaries (Arkansas, White, Yazoo, etc.) did not have the same type of channel form simultaneously, thus providing a larger variety of habitat types for riverine fauna in this region. The lower Arkansas River presently has a braided channel form. This is especially obvious below the artificial cutoff to the White River that facilitates barge traffic. Above this point, dredging and other control measures by the USACE maintain one large channel resembling a meandering channel form to the inland terminus of the McClellan-Kerr Navigation System near Tulsa, Oklahoma, upstream of which the river channel remains braided. Thus, in the LMR the diverse array of habitats seen along river continua from headwaters to downstream reaches is enhanced by variation in channel form of the large rivers through space and time, as well as by the variety of floodplain habitat types.

Wetlands are an important riverine habitat in the region, although the wetlands in the LMR have been largely isolated from the large rivers by construction of levees and substantially reduced in area by clear cutting, draining, impounding, and channelization. Wetlands associated with the Ozark and Ouachita upland streams are much less extensive, but are important ecological components of the watershed ecosystems. Many of the Ozark streams larger than 3rd order have well-developed floodplains complete with floodplain ponds and small oxbow lakes used as spawning and nursery areas by several species of fishes (e.g., white crappie, common carp, black and yellow bullhead catfish).

The smaller rivers of the LMR region range from clear, cool, mountain streams with bedrock outcroppings, coarse gravel bedloads, and moderate slopes that are influenced by karst limestone topography, like the Buffalo, Current, and Kings rivers of the Ozark Highlands, to those that originate in the comparatively low lands of the Coastal Plain, with fine, alluvial substrate, higher turbidity, and very modest slope (Big Black, Yazoo, Homochitto), with many others of distinctive character somewhere in between (e.g., Ouachita and Saline rivers in the Ouachita province). Streams of the Ouachita province resemble those of the Ozark Plateaus in some respects (cool, clear, gravel bed, intermittent headwaters), but

the Ouachita province lacks limestone, so Ouachita streams have less alkalinity ($\sim 20 \mu\text{S}/\text{cm}$ specific conductance), and this renders them less productive. The formerly horizontal stratigraphy of the Ouachitas has been uplifted and folded, so Ouachita streams have a less predictable shape than those in the Ozark Plateaus. Also, pine trees occur in the riparian zones of Ouachita streams but not of Ozark streams.

The Atchafalaya River distributary and its associated wetlands are unique. It is a distributary of the LMR that is about 224 km long and is made up largely of several old, interconnected, Mississippi River channels (oxbow lakes). In its natural state, the Atchafalaya was simply the primary watercourse in a complex system of interconnecting bayous in a large swamp. The USACE has extensively modified the Atchafalaya basin to enhance its use as an overflow outlet for the Mississippi River main channel, including water-control structures, levees, dikes, and revetments. The Atchafalaya River is further complicated because it has captured the Red River, which was a tributary to the Mississippi. The basin is very flat, so flow direction in side channels (locally called bayous) of the Atchafalaya basin often depend on comparative inputs from the Red River and the Mississippi River as controlled by USACE flood-control structures.

Reservoirs are a major feature of rivers in the Ozark and Ouachita highlands. They are as aneurisms in the streams and rivers. Many reasons have been given to justify their construction, including flood control, hydroelectric power generation, municipal water supply, recreation, and economic development. Reservoirs are also justified by the need for water for steam and cooling for electricity generating plants powered by fossil fuels and nuclear power. Many of the older reservoirs were built by the Works Progress Administration (WPA) and/or Civilian Conservation Corps (CCC) in the 1930s. Most of the larger reservoirs have since been constructed by the USACE, but the Arkansas Game and Fish Commission has continued to build many smaller ones using federal subsidies provided from taxes on sales of fishing equipment (Pittman-Robertson Act funds). Most of the larger reservoirs have deep-release structures, and the waters from them have altered temperature cycles both annually (dampened) and daily (increased in summer). To mitigate loss of warmwater fish habitat, various species of trout are stocked in these tail waters. Some provide only put-and-take fisheries, but others have reproducing populations of various species of trout. Reservoirs are less numerous in the Coastal Plain,

primarily because sites for them are less numerous in the flatter terrain. The highest elevations in Mississippi and Louisiana are 246 m and 163 m asl, respectively.

As the largest river basin in North America, fish diversity in the Mississippi River is expectedly high. At least 375 freshwater species in 31 families are found in the entire basin (Burr and Mayden 1992, Revenga et al. 1998, Abell et al. 2000). Inclusion of the predominantly marine species that exploit the rich estuaries where the river meets the Gulf of Mexico (e.g., striped mullet, bay anchovy) would add another 50 to 60 species to this count. The LMR section includes three freshwater ecoregions: the Mississippi Embayment, the Ozark Highlands, and the Ouachita Highlands (Abell et al. 2000). The Mississippi Embayment alone has 206 species of freshwater fishes, making it comparable to other freshwater ecoregions with more than 200 species, such as the Teays–Ohio, Tennessee–Cumberland, and Mobile Bay (Abell et al. 2000, Boschung and Mayden 2004). The Ozark Highlands and Ouachita Highlands freshwater ecoregions add to the already rich fish diversity of the Mississippi Embayment. Together, these ecoregions are also extremely rich in mollusks, crayfish, and aquatic herpetofauna. The Ozark Highlands and Ouachita Highlands have a remarkably diverse crayfish fauna, including six species of stygobitic (cave-adapted) forms (Abell et al. 2000). Although the large rivers of this region have experienced dramatic changes through geologic (and thus, evolutionary) time, the diverse endemic aquatic fauna indicates that the rivers were not all simultaneously disturbed. Many fish species have had a continuous presence here since at least the Miocene (Baker et al. 1991). Refugia were present for the organisms somewhere in the basin even during successive embayments; thus, survivors could recolonize the entire region from these refugia after disturbances. The Ozark and Ouachita highlands escaped recent inundations that occurred in the Mississippi Embayment freshwater ecoregion and were south of the maximum extent of glaciation, allowing survival of endemics (Gordon et al. 1979). The LMR basin provides habitat for numerous species of waterfowl and other avifauna that use the rivers and associated wetlands, some seasonally and others year-round (Twedt and Loesch 1999, Stanturf et al. 2000). The region is the most important in North America as a winter refuge for migrating waterfowl and other wetland birds and as nesting habitat for neotropical migratory birds in spring and summer. The production of aquatic invertebrates is important to many

FIGURE 6.3 Mississippi River at New Orleans, Louisiana (PHOTO BY TIM PALMER).

species of these birds, connecting the riverine and terrestrial (or wetland) ecosystems.

LOWER MISSISSIPPI RIVER

The Lower Mississippi River represents the final reach of the largest river system in North America. The main stem primarily flows in a southerly direction as it traverses the Mississippi Alluvial Plain section of the Coastal Plain physiographic province from Cairo, Illinois (Rkm 1536), to Baton Rouge, Louisiana (Rkm 378) (Fig. 6.8). It then turns in a southeasterly direction as it crosses the Deltaic Plain

to Head of Passes (Rkm 0), and actually continues another 35 km to the Gulf of Mexico (Fig. 6.3). As previously mentioned, most of the flow of the LMR is due to its large tributaries that are not otherwise considered in this chapter: the Missouri, Upper Mississippi, Ohio, Arkansas, and Red rivers. Thus, the origin of the LMR at Cairo (from the Missouri, Upper Mississippi, and Ohio rivers) provides a flow that is about 80% of total flow reaching the Gulf of Mexico.

Historically, the LMR has been an extremely important provider of resources and trade routes for humans for at least 16,000 years. In 1541, Hernando de Soto found a large group of Native Americans

that were “well-provisioned and socially disciplined” on the LMR below present-day Memphis. He was met by about 200 canoes and over 7000 warriors who repeatedly attacked his small group (Wells 1994). In contrast, the French explorers Marquette and Joliet saw only two small bands of natives when they explored the river by canoes from the Ohio to the Arkansas River in 1673, 132 years later. Several ideas have been advanced to explain the dramatic decline of Native Americans in this region during that period of limited historical accounts. Some think it was due to climate change and depletion of resources. Others blame it on diseases introduced and anxieties induced by the Spanish. Some ethnographers contend that European diseases resulted in death for up to 95% of the Native Americans (Dobyns 1983). The Native Americans may have feared the return of the Spanish (with their firearms and diseases) in greater numbers to this area, so those who survived the introduced diseases moved away, largely to the Ozark and Ouachita highlands to the west. With the exception of Memphis, Tennessee, and Baton Rouge and New Orleans, Louisiana, much of the region along the LMR has lower human populations now than it did when de Soto first arrived over 460 years ago.

Physiography, Climate, and Land Use

The LMR main stem is located within the Coastal Plain (CP) physiographic province, or more specifically within a geographical subunit known as the Mississippi Embayment, an area that was inundated by the ocean during several warm interglacial periods (see Fig. 6.8). This area is popularly known as “the Delta” and is essentially a broad, rather flat, shallow trough through the center of which flows the Mississippi River. The entire area consists of fine alluvial deposits and may have formed as early as 50 to 60 million years ago when formation of the Rocky Mountains and other geological events changed the formerly westward drainage of the North American continent toward the south (Dott and Batton 1981). The LMR main stem primarily drains the Mississippi River Alluvial Plain section of the Coastal Plain, but also drains smaller areas of the East Gulf Coastal Plain and West Gulf Coastal Plain sections (Hunt 1974). Part of the East Gulf Coastal Plain is also known as the Mississippi Valley Loess Plains (Omernik 1987, Kleiss et al. 2000). The western margin of the Loess Plains, along the eastern side of the Mississippi River, consists of windblown silts that formed the Loess Hills, which are about 100 m taller

than the Mississippi River Alluvial Plain, a significant feature in this flat landscape.

Terrestrial ecoregions, as described by Ricketts et al. (1999), surrounding the LMR include the Mississippi Lowland Forests, Central U.S. Hardwood Forests, Ozark Mountain Forests, Piney Woods Forests, Southern Mixed Forests, and Western Gulf Coastal Grasslands. Other authors (e.g., Arkansas Department of Planning 1974, Bailey 1994, Omernik 1995) separate the Ozark Mountain Forests from the Ouachita Mountain Forests, as is done for freshwater ecoregions (Abell et al. 2000). In either case, both the Ozark and Ouachita mountains are included in this area. The Mississippi Lowland Forests extend for the entire length of the LMR main stem (except for the downstream end that passes through the eastern tip of the Western Gulf Coastal Grasslands) and is comprised of bottomland hardwood forests. These bottomland forests were dominated by cypress, gum, hickory, oak, and cedar trees when Europeans arrived in North America but have been extensively logged and cleared for agriculture (Sharitz and Mitsch 1993). Hydroperiod (duration of flooding) is an important environmental condition separating the different plant associations in the Mississippi Lowland Forests. Four major subdivisions of lowland forests are recognized: (1) river swamp forests that are always wet are dominated by cypress and water tupelo; (2) lowland swamp forests are more diverse and include water hickory, red maple, green ash, and river birch; (3) backwaters and flats are even richer in diversity and add sweetgum, American sycamore, laurel oak, and willow oak; and (4) upland transitional forests are an oak–hickory–pine association. Ozark and Ouachita Mountain Forests are similar in that they are both oak–hickory climax associations but are distinguished vegetationally primarily by the lesser amount of pine in the Ozarks. They differ floristically and faunistically in detail (at the species level) largely as a result of their distinct lithology and stratigraphy (i.e., edaphic factors). The Ozarks have horizontal strata of limestones, dolomites, sandstones, and shales that have been uplifted as plateaus and radially eroded. The Ouachitas have much less soluble lithology (very little limestone), with novaculites included, and were folded and uplifted, creating complex angular, often vertical, strata.

The climate of the LMR valley ranges from mild, midcontinental where it begins with the confluence of the Ohio to warm, subtropical in southern Louisiana. Over the region, mean monthly temperatures range from 6°C in January to 27°C in July (Fig. 6.9). Precipitation ranges from 7 cm during August to

over 14.5 cm in December, totaling 120 to 160 cm/yr. Rainfall is consistently high from November through July (>11.7 cm/mo) before falling below 10 cm/mo from August through October. However, it is humid year-round. In contrast, mean monthly precipitation for the entire Mississippi River basin is only about 81 cm, substantially lower than the LMR. Furthermore, precipitation peaks in May at <10 cm/mo and falls to <5 cm/mo during January and February (see Fig. 6.9).

The combination of rich soils, ample moisture, warmth, and the highest insolation on the planet during the growing season ($600 \text{ cal cm}^{-2} \text{ d}^{-1}$) give this region an extremely high potential for primary producers (Mac et al. 1998). Thus, it is not surprising that >80% of the land has been cleared of forests and is used for row-crop agriculture. Of the remainder, only 16% is forested and 4% is urbanized. Inside the levees, crop production is risky due to flooding, so silviculture is more common. Land and water inside the levees are also leased for recreational hunting and fishing.

River Geomorphology, Hydrology, and Chemistry

At their confluence at Rkm 1536, the Upper Mississippi and Ohio rivers are similar regarding discharge ($5923 \text{ m}^3/\text{s}$ and $8733 \text{ m}^3/\text{s}$, respectively) and the resulting river and its enormous volume of water ($\sim 14,600 \text{ m}^3/\text{s}$) has a substantial chemical and physical (e.g., flow, temperature, turbidity) inertia and is changed only slightly by inputs from the large western tributaries that enter the LMR. The combined White and Arkansas rivers contribute only about 10% of the proportional volume. The largest tributary rivers that enter from the east (Big Black and Yazoo) contribute only about 1% and 3%, respectively, of the volume of the LMR at their confluences. Despite the large flow near the mouth of the LMR ($>15,200 \text{ m}^3/\text{s}$, not including the Atchafalaya distributary), the cities of Baton Rouge and New Orleans and the numerous petrochemical industries near them degrade the quality of the water by depleting oxygen and lowering pH, as well as by adding toxic compounds.

The LMR traces a very sinuous path across the Mississippi Alluvial Plain to Baton Rouge, complicated by sections where the river has cut off meanders that have become too extensive and has recaptured other abandoned channels. Deep pools occur along the outside margins of bends, with exten-

sive sandbars on the inside of curves, and where the river changes directions between the pools the thalweg (deepest part of the channel) crosses over shallow bars. Huge sand dunes (up to 10 m tall) to smaller ripples occur across the bottom of the river to further complicate the form of the riverbed and flow patterns in the main channel habitat. These supply respite from the fast (up to 5 m/s) flow for invertebrates and fishes. The three-dimensional shape of the river is complex and naturally changing, but it has some elements of predictability. At base flow, the river channel is fairly incised between steep bluffs, especially in the upper portion of this reach and where it encounters the Loess Hills along the eastern bank. Although the main channel of the river certainly varies in habitat, the marginal and floodplain areas add much more variety of aquatic habitats to the total riverine ecosystem. The character of the marginal habitats is strongly influenced by both the flow in the main channel (which may be the result of rainfall and/or snowmelt in the headwaters without contributions from local rainfall) and flow conditions in the tributaries. The stage of the main channel of the Mississippi River is occasionally high enough to impound tributaries and essentially create temporary lakes upstream from the confluence of each of them. Snowmelt runoff from the Upper Mississippi River basin often causes flooding in the LMR and impoundment of its tributaries when runoff in the southern tributaries is not large.

In the LMR, habitats (e.g., pools) expand, contract, and move about with changes in conditions, especially of flow (stage). Some habitats are dry or stagnant (lentic) at low river stages but several meters deep and flowing at higher stages. Mobile (or vagile) biota move with varying conditions to remain in their preferred habitats. Baker et al. (1991) compared five different classification schemes, including the widely adopted Computerized Environmental Resources Data System (CERDS) delineation of Cobb and Williamson (1989), and proposed one of their own based on a multivariate approach that has 12 categories that “feels right” and is intellectually pleasing. Main-stem habitat types include channel, natural steep bank, revetment, lotic sandbar, lentic sandbar, and pool. Floodplain habitats are oxbow lake, borrow pit, seasonally inundated floodplain, floodplain pond, and tributary. Sloughs (contiguous and isolated) are intermediate between main-stem and floodplain habitat.

In an excellent review of aquatic habitats and biota of the LMR, Baker et al. (1991), estimated amounts of each category at low and high river stages

TABLE 6.1 Limnological characteristics of Lower Mississippi River lotic and lentic habitats during low flow conditions.

	Temperature (°C)	pH	Turbidity (NTUs)	Specific Conductance (µmhos/cm)	Suspended Solids (mg/L)	Dissolved Solids (mg/L)	Dissolved Oxygen (mg/L)	Chlorophyll <i>a</i> (mg/L)	Nutrients	Zoo- plankton
Lotic	18–29	7–8	10–65	450–500	50–75	250–300	6–7	50–70	High	Moderate
Lentic	20–34	5–9	5–15	250–675	10–35	300–450	4–20*	50–150	Low	High

Baker et al. 1991.

* Dissolved oxygen of small floodplain ponds is commonly reduced to 0.

presently and prior to human modification, then described the physical, chemical, and biotic characteristics by habitat type. The most dramatic changes resulting from modification by the U.S. Army Corps of Engineers has been reduction of all natural floodplain habitats, especially those outside the levees. Borrow pits (for levee construction) and revetments were not present naturally. Main-channel pool habitat has been increased slightly at low stages because dikes form pools, but all other habitat types have been reduced, including main-channel length and width.

Physical, chemical, and, therefore, biological, characteristics of these habitat types differ substantially (see Baker et al. 1991). Obviously, floodplain habitats have closer association with riparian vegetation and are lentic except during high flows. Sloughs are intermediate, whereas other main-channel habitats are largely isolated from riparian influence by extensive exposed sandbars and revetted banks. Most physical and chemical characteristics in flowing habitats are different from those in lentic habitats, including pools and lentic sandbar habitats connected to the main channel during low flow periods (Table 6.1). In general, the flowing habitat types are cooler, more turbid, richer in nutrients, and less variable for most parameters. During high flows all habitats tend to take on characteristics of the main channel; temperatures are lower (by 2°C to 18°C), suspended solids are higher, and chlorophyll *a* concentration is lower.

The current velocity of the LMR main channel in midstream varies from about 0.9 to 2.4 m/s during low to moderate flows but can increase up to 5 m/s during high flows, with considerable variability laterally and with depth. Large eddies (upstream flows) are common and may exceed 250 m in length and extend 150 m out from the bank. At high current velocities the water keeps large quantities of sediment in suspension (100 to 1000 mg/L). About 2×10^8

metric tons of suspended sediments are transported past Vicksburg, Mississippi, and on to the Gulf of Mexico each year (Meade 1995). The average turbidity of the water in the LMR (10 to 65 NTUs) reduces light penetration to typically less than 0.3 m, keeping primary production low even though nutrient concentrations are moderate to high in the main channel habitats. Dissolved oxygen exceeds the 75% saturation level over 90% of the time in this portion of the LMR and is typically 6 to 12 mg/L above Baton Rouge. Below Baton Rouge, dissolved oxygen commonly dips below 4 mg/L and the Atchafalaya distributary often becomes anoxic during floods, especially those induced by hurricanes, due to oxygen demand created by introduced and resuspended dissolved and particulate organic matter.

The LMR at Vicksburg, Mississippi (Rkm 704), has a mean flow of 17,075 m³/s (USGS data from 1932 to 1998) midway between Cairo and Head of Passes (Rkm 0, but actually 35 km from the Gulf). Annual runoff at Vicksburg, which drains a total area of 2.96 million km², is about 18 cm. Runoff peaks with spring snowmelt in April (2.4 cm/mo) and is lowest in September (0.7 cm/mo), apparently the result of higher evapotranspiration during the summer months (see Fig. 6.9). Downstream of Vicksburg, additional flows include contributions from the Big Black, Ouachita, and Red rivers to increase the amount that enters the Gulf of Mexico to an average 18,112 m³/s. The virgin mean annual discharge of the Mississippi River was ~18,400 m³/s (Dynesius and Nilsson 1994). Upstream of Baton Rouge, the flow becomes divided, with the principal distributary being the Atchafalaya via the Old River and associated control structures operated by the USACE. The Atchafalaya receives 19% to 50% (typically 25%) of the flow of the Mississippi River through the control structures at Old River (Rkm 480), but flows only 224 km to the Atchafalaya Bay in the Gulf of Mexico. Because the Atchafalaya River

reaches the Gulf of Mexico in less than half the distance as the main-stem Mississippi River (480 km), it is about twice as steep as the main route.

The alluvial fan across the lower delta includes several distributary rivers that were main channels at some time in the past. As the main channel deposits sediments and increases in length, at some point this creates a shorter, steeper route to the Gulf of Mexico and the river changes course. The Atchafalaya River would likely be the main channel for the Mississippi River presently if it were not for the intervention of the USACE. Natural shifts in the main channel have occurred about every 1000 years, and the present channel has been the primary one for about 1000 years (McPhee 1989).

Below Baton Rouge the river has less slope (8 cm/km) and is straighter, narrower, and more uniformly deep than the reach above Baton Rouge, where the slope is 24 cm/km. In part its character is due to natural conditions of the Deltaic Plain (less slope and finer, cohesive sediments that are less prone to erosion), but the geomorphology is also the result of maintenance of a 12 m deep channel for oceangoing vessels by the USACE. Here the habitats for biota are considerably less variable and the floodplains are almost nonexistent. Crossing the Deltaic Plain, the river is more narrowly confined by levees, and revetments line most of the banks, but dikes are not used in this section of the river. The deep, swift channel continues into the Gulf and out to the edge of the continental shelf before most of the suspended sediments are deposited. Shoreline losses in Louisiana are largely due to loss of aggradation by these sediments as the river channel has been made more narrow and swift, but also by land subsidence caused by extraction of oil, gas, and water, and by increasing sea level by glacial melt. Louisiana has no beaches, and none are likely to develop under these conditions.

Because the origin of water in the LMR is primarily from upstream tributaries, water chemistry is greatly influenced by upstream landscapes. This is exacerbated by the large volume of water, which gives it chemical as well as thermal and physical inertia. Rather than being reflective of the Coastal Plain through which it flows, the LMR water is relatively alkaline, with a pH of about 7.8 and an alkalinity ranging from 140 to 182 mg/L as CaCO₃. Water chemistry is strongly influenced by runoff from application of chemicals, including nutrients, in agricultural areas throughout the basin. Phosphate is relatively high, commonly ranging from 0.06 to 0.20 mg/L, but NO₃-N is extremely high, typically about 1.5 mg/L in the LMR. Although high, these ele-

vated NO₃-N levels are actually lower than values found in the upper Mississippi River (see Chapter 8). Baton Rouge, Louisiana, and the agrichemical and petrochemical industries nearby further enrich and degrade the water chemistry of the river as a final insult before it enters the Gulf of Mexico.

River Biodiversity and Ecology

Biodiversity of the LMR main stem is higher than would be expected for a river that flows through a single freshwater ecoregion, the Mississippi Embayment (Abell et al. 2000), perhaps because the river is very large. Tributaries within the Mississippi Embayment appear to add substantial biodiversity to that found in the main stem alone. Habitat diversity is due primarily to variations in flow and depth along its course and in its floodplain habitats (oxbows, etc).

Algae and Cyanobacteria

Information on the taxonomic composition and ecological significance of phytoplankton and periphyton in the main-stem LMR is surprisingly scarce, except for suggestions that the river, delta, and estuarine marshes are all detritus-based systems (Day et al. 1973, Mac et al. 1998). The dominant forms of phytoplankton in this general region are cyanobacteria during warmer months, changing to diatoms during winter. Some information on phytoplankton and periphyton from the Atchafalaya distributary has been summarized by Patrick (1998) and is probably similar to what would have been found in the Mississippi delta marshes before human alterations confined the lower river channel between large levees. For example, phytoplankton was dominated by diatoms, including *Melosira*, *Stephanodiscus*, and *Skeletonema*, and also included the green algae *Scenedesmus* and *Crucigenia*.

Plants

Extensive floodplain forests associated with the river are composed largely of hardwood species. Four types of bottomland hardwood forests have been identified by dominant tree associations (Smith 1996). In order of increasing period of annual inundation of the land they are as follows: willow oak and sweetgum; Nuttall's oak and green ash; overcup oak and water hickory; water tupelo and bald cypress. The river delta area that forms the extensive swamps and bayous of southern Louisiana has extensive areas of cypress and tupelo stands, but these give way to marshes dominated by aquatic macrophytes

toward the coast. The diverse and dynamic macrophytic associations have attracted several investigators (Conner et al. 1981; Mitsch and Gosselink 1993; Mac et al. 1998). The patterns of vegetation in these lush subtropical marshes are constantly changing in response to water levels, salinity, hurricanes, and invading plant and animal species. Many of the macrophytes are nonnative species that have invaded the wetlands (water hyacinth, alligatorweed, hydrilla, and Eurasian watermilfoil). Nutria, rodents introduced from South America, are very abundant, and they consume large amounts of macrophytes and young trees, including cypress (Conner 1988). As much as 70% of the deltaic marshes consist of floating-island plant associations (O'Neil 1949, Sasser et al. 1996). One of the most abundant associations is dominated by maidencane. The marsh plants that senesce produce a detritus substance, locally called "coffee grounds," that accumulates along wetland tributaries (bayous) and is eventually transported to estuaries and the Gulf by floodwaters. This detritus is refractory, but when suspended by storms and floods heterotrophic bacteria metabolize enough of it to induce hypoxia (Sabo et al. 1999).

Invertebrates

Invertebrates of the main channel include abundant caddisflies (especially *Hydropsyche orris* and *Potamyia flava*) on hard substrates and burrowing mayflies in hard clay (*Pentagenia*, *Tortopus*) and mud (*Hexagenia*). Channel habitats also have numerous scraping mayflies (*Stenonema*) on hard substrates of dikes and the articulated concrete mattresses (ACMs) installed by the USACE to control bank erosion. Chironomid midges and oligochaete worms are abundant in all habitat types of the LMR. The Asiatic clam has been abundant in sand and gravel habitats of rivers throughout this region since its colonization in the 1970s. More recently the LMR experienced an invasion of zebra mussels. Asiatic clams and zebra mussels are very efficient filter feeders that capitalize on the abundant fine particulate organic matter (FPOM) in the river. They are consumed in large quantities by catfish but are still numerous. Meiofauna have also been reported to be abundant in lotic as well as lentic habitats of the river.

Lentic habitats of abandoned channels (created naturally and by actions of the USACE) and floodplains have diverse and abundant taxa of chironomids (e.g., *Rheotanytarsus*, *Chironomus*, *Coelotanypus*, *Robackia*, *Glyptotendipes*), oligochaetes (*Limnodrilus*, *Hyodrilus*, *Nais*), and fingernail clams (*Sphaerium*). The soft sediments of these nonflowing

habitats also have numerous phantom midges (*Chaoborus*). Mayflies (especially *Hexagenia* and other burrowers) are common, but stoneflies are rare anywhere in the LMR.

Vertebrates

Freshwater fish assemblages of the LMR have been studied more than other biota, but most accounts are limited to occurrence of species, leaving ecological relationships poorly understood. Perhaps as many as 150 species of freshwater fishes once inhabited the main-stem LMR (Fremling et al. 1989), but Baker et al. (1991) reported that only 91 fish species maintain reproducing populations there, discounting recently introduced species (e.g., grass carp), strays from small tributaries, and marine species. The number of fish species in the main-stem LMR is therefore less than half that estimated for the Mississippi Embayment ecoregion as a whole (206) (Abell et al. 2000). This ecoregion includes several Mississippi tributaries, such as the lower reaches of the Arkansas and White rivers, as well as the Big Black and Tensas rivers. Some of the fish taxa in the LMR are common to abundant in nearly all habitats (e.g., channel catfish, common carp, river carpsucker, freshwater drum, gizzard shad, threadfin shad, spotted gar, short-nose gar, smallmouth buffalo, bigmouth buffalo, white crappie). Other taxa are found almost exclusively in flowing habitats, like blue catfish, blue suckers, river darters, and shovelnose sturgeon. Many more are common only in lentic habitats of pools, abandoned channels, and floodplains, including grass pickerel, chain pickerel, black bullhead, yellow bullhead, pirate perch, western mosquitofish, four top minnows (Fundulidae), nine cyprinids (Cyprinidae), and seven sunfish (Centrarchidae) species.

Many of these abundant fish species are invertivorous and/or piscivorous as adults. Gizzard and threadfin shad are planktivorous, but also feed on the bottom, as indicated by the presence of sand and detritus in their guts (Baker and Schmitz 1971). Bottom feeding may be a good way to obtain the abundant meiofauna on the surface of benthic substrates. Native phytophagous (other than algae) and detritivorous fishes are almost nonexistent in Nearctic waters. However, the grass carp has been imported from China and widely stocked by the Arkansas Game and Fish Commission to control aquatic macrophytes. Grass carp are thought to have established reproducing populations in the LMR (Robison and Buchanan 1988). The pallid sturgeon is the only LMR main-stem fish listed as endangered

by the U.S. Fish and Wildlife Service, although a few other species are listed by state agencies.

Amphibians and reptiles of the LMR are also diverse and abundant, especially toward the southern coastal zone. American alligators are abundant, along with a large variety of turtles (e.g., common snapping turtle, alligator snapping turtle, both smooth and spiny softshell turtles, red-eared turtle, Mississippi mud turtle), snakes (e.g., diamondback water snake, broad-banded water snake, western cottonmouth), and frogs (bullfrog, pig frog, spring peeper, cricket frog). Semiaquatic mammals, in addition to the nutria, include beaver, muskrat, raccoon, mink, and river otter. Wetland forests are also habitat for white-tailed deer, red and gray squirrels, swamp rabbits, black bears (subspecies classified as threatened), and endangered red wolves.

Many of the species of fishes, reptiles, mammals, and birds that occur in the LMR and its wetlands have commercial value and/or are pursued by those who hunt and fish. Populations of these animals have been studied more than others and are of particular interest to state and federal management agencies, but all species have some legal protection.

Ecosystem Processes

Ecosystem processes in the LMR may be almost as diverse as the habitat types in this large floodplain river. However, the main-channel community appears to depend primarily on species that intercept FPOM being transported downstream, in accord with the River Continuum Concept (RCC) of Vannote et al. (1980). Most invertebrates and some fishes in the main channel are collector-filterers (caddisflies, mussels, paddlefish) or collector-gatherers that exploit the rich seston of primarily allochthonous origin. The more lentic habitats are populated by burrowing collector-gatherers (mayflies, midges, oligochaetes), which use the same fine particles as they settle. Communities in the marginal habitats (sloughs, oxbows, etc.) appear to be more dependent on locally derived organic matter, whether autochthonous or allochthonous. Contribution of heterotrophic microbial production to higher trophic levels, especially via meiofauna linkages, may be very significant in the LMR. River interactions with floodplain wetlands, as would be expected in such a large lowland river according to the flood pulse concept of Junk et al. (1989), appear to be substantially reduced by the extensive engineering projects of the USACE.

There is a paucity of data for primary and secondary production, food web structure, and even habitat use by fishes, making any statements about

trophic dynamics in the LMR tenuous. Primary production (P) in flowing habitats is probably kept low by turbid, turbulent conditions, and low in lentic habitats by limited nutrient availability and shading by trees. Respiration (R) is probably high in response to temperature. Thus, the P/R ratio in most habitats most of the year is probably less than 1, in agreement with the RCC for high-order rivers. Most of the habitat types are probably allochthonous-supported, heterotrophic systems, especially if the bottomland hardwoods and other swamp vegetation are not considered part of the aquatic producers.

Ecosystem processes are largely governed by characteristics of physical habitat, and the LMR habitats have been significantly altered by the USACE. Effects of modifications to the habitat structure of the LMR by the USACE on community structure and trophic dynamics are impossible to completely assess but have been extensive. Removal of snags for the past 175 years took away much of the natural habitat that provided firm attachment sites for invertebrates, most of which are filter-feeders. This left hardened clay banks that are extensively colonized by burrowing mayflies (*Hexagenia* spp., *Tortopus incertus*, *Pentagenia vittigera*), which are collector-gatherers, and by some filtering hydroptychid caddisflies (Beckett et al. 1983, Beckett and Pennington 1986). Sand substrates in the flowing-channel habitats contain many chironomids, oligochaetes, microturbellarians, and other meiofauna, but few macroinvertebrates (Wright 1982, Baker et al. 1991). Abandoned channels (sloughs, oxbows) have high densities of phantom midges, tubificid worms, and fingernail clams (Sphaeriidae) (Mathis et al. 1981). Rocky substrates provided by dikes, ACMs, and other revetment materials (e.g., riprap) have extensively supplanted snags as suppliers of firm substrate in the LMR. These rocky substrates have the most dense macroinvertebrate assemblages of any habitat type, and they are dominated by net-spinning caddisflies (*Hydropsyche orris*, >60%) and tube-building midges (~24%), especially *Rheotanytarsus* (Mathis et al. 1982, Way et al. 1995). Revetments now cover many former hard clay substrates and soft mud habitats used by burrowing mayflies, but dike fields (materials deposited around the dikes by currents) also contain these habitats (Beckett and Pennington 1986). The GIS-based system used by the USACE (CERDS; see Cobb and Williamson 1989) has been used to estimate changes in the proportion of habitats (other than snags) before and after modifications to the LMR (Baker et al. 1991). However, there is still no way to accurately estimate the former densi-

ties of snags in the river or of invertebrates on them. It seems possible that the community structure and trophic dynamics of the system may be substantially similar to those in place before extensive alterations, as introduced rock and concrete structures have replaced snags.

It is likely that enrichment of the water with organic matter (dissolved organic matter, FPOM, bacteria) and inorganic nutrients from point and nonpoint sources of pollution have increased microbial metabolism in the main-channel habitats, but limiting contributions of these substances from the floodplain may have offset this. One thing is certain; the amount of wetland habitats in the floodplain has been extensively reduced, and flood pulses of the river are denied access to the former wetlands, many of which are now cleared agricultural cropland. The enormous anthropogenic disturbances may have changed the total amount and relative abundances of taxa in the LMR, just as they have changed the total and relative amounts of the various habitat types, without substantially altering the list of taxa (irrespective of relative abundance) and the dominant ecological processes. Decrease in the efficiency of use of resources by the community may have been the major consequence of the disturbances, and this has likely resulted in the enormous dead zone that has developed in the Gulf of Mexico. Transport of water and material from the river to the Gulf has been enormously increased, and this has substantially reduced the utilization of organic and inorganic nutrients as they enter and pass through the LMR to the Gulf.

Human Impacts and Special Features

The LMR represents the lower reach of the largest river in North America and one of the largest rivers in the world. Flowing primarily through low-relief Coastal Plain, the LMR and its alluvial plain formed one of the great river–floodplain ecosystems of the world. Unfortunately, the ecological integrity of this enormous ecosystem has been strongly challenged at the physical, chemical, and biological levels by extensive physical, chemical, and biological alterations. The major alterations are the result of (1) engineering projects to improve navigation and reduce flooding; (2) chemical contaminants from industrial, urban, and agricultural activities in >40% of the conterminous United States; and (3) the introduction of numerous nonnative species.

The need for navigation projects intensified with the advent of boats powered by steam engines, like the early paddle wheelers. Later, with more powerful

boats with diesel engines, the Mississippi River quickly became an important avenue for bulk transportation of materials from the North American heartland to the ports of Baton Rouge and New Orleans, where they could be transferred to oceanic vessels. This development was an important impetus for government intervention to “improve” the channels for navigation. Huge, devastating floods also increased the need for control of the LMR waterways. The earliest recorded large flood was in 1543 by de Soto’s expedition and the most recent was in 1993. Because of the need for cheap commercial transportation of materials and the enormous flooding potential in this region, a series of governmental actions have given extensive authorization to the USACE and other agencies to perform huge projects to enhance navigation and control flooding.

Levees were the earliest form of flood control and were first built to protect New Orleans. By 1735, levees lined the river from 48 km above to 19 km below the city. By 1844, levees were nearly continuous upstream to the confluence with the Arkansas River. Now there are nearly 3000 km of levees 9.25 m high along the LMR and very nearly another 1000 km along its tributaries. The 600,000 ha of floodplain remaining inside the LMR levees is only about 10% of the area inundated by large floods before containment (Baker et al. 1991). Levees are primarily responsible for denying the river access to its rich floodplains and disruption of the natural ecological functioning, as described by Junk et al. (1989) as the flood pulse concept.

Cutoffs are events that normally occur during floods when the river takes a shorter path downstream by either cutting across a point bar or the neck of a meander. These may become permanent features when the flood subsides. They straighten the channel and increase the slope of the reach, causing the water to flow faster. Cutoffs are desirable to the USACE because they shorten, straighten, and deepen navigation pathways, as well as allow floodwaters to subside more quickly. The USACE has artificially constructed cutoffs that have shortened the LMR channel. Natural cutoffs formerly shortened the channel also, but by a lesser extent and were offset by meandering, which is now thwarted by revetments. The exact amount of shortening of the channel by the USACE is difficult to estimate, but it has been close to 500 km, about 25% to 30% of the former length of the LMR (see Baker et al. 1991).

Floodways and control structures have been constructed to divert excess water from the main channel during only the highest flows. The Atchafalaya River

distributary has associated floodways that parallel it, within separate levees, to the Gulf of Mexico. The Atchafalaya Floodway is on the west side of the Atchafalaya River and the Morganza Floodway is on the east. Control structures at Old River can be manipulated to control flows down the Atchafalaya River and the two floodways independently of each other. When the Mississippi River discharge reaches 42,613 m³/s at Baton Rouge it can be partially diverted into the Atchafalaya River through the Morganza and West Atchafalaya floodways or into the Gulf of Mexico via the Bonnet Carre Spillway and the Rigolets (Everett 1971). In addition to the Atchafalaya, the Bonnet Carre Spillway above New Orleans can be used to discharge floodwaters from the Mississippi River to Lake Pontchartrain. The control structures have essentially dried for much of the year what were formerly wetlands by not allowing water to flow through them other than during very large floods.

Removal of snags from the Ohio and Mississippi rivers was initiated by the U.S. War Department in 1824 and is still continued in the LMR and its tributaries using special barges for this purpose (Brown and Matthews 1995). Dredging is also used to maintain deep channels at crossings (where the thalweg changes from one side of the river to the other). There are >200 crossings between Cairo, Illinois, and Baton Rouge that require periodic dredging of 32 to 81 million m³ annually to maintain a 4 m deep channel (Keown et al. 1981). Another 60 million m³/yr are dredged below Baton Rouge to maintain a 12 m deep channel to the Gulf of Mexico. Dredging introduces large volumes of fine sediments to the river water and produces a plume of turbidity downstream. It also resuspends contaminants that have become buried or adsorbed to sediment particles.

Revetments have been used extensively on the LMR to keep banks from eroding and to prevent channels from meandering. Logs, fences, gabions, rocks, tires, and automobile bodies have all been used as revetments, but since the mid-1940s ACMs have been used almost exclusively on the Mississippi River. Almost 2000 km of ACMs are in place now, and eventually nearly 50% of the banks along the LMR will be covered with them. Cypress trees several hundred years old are sometimes removed to install ACMs. Such actions diminish the natural interaction between the river and its riparian zone, as described by Thorp and Delong (1994) as the riverine productivity model (RPM).

Dikes are partial dams that also have been used throughout much of the LMR. They are used to

control the aggradation and degradation of sediments by controlling the flow of the river, thereby encouraging the river to maintain a single, straight, deep channel. They were originally made of wood from about 1880 until 1960, but now they are constructed of large limestone rocks. Dikes are usually used in parallel groupings extending nearly perpendicular to the flow. They are very large, averaging 630 m long and 10 m wide at the top. Nearly 500 km of dikes occur between Cairo and Baton Rouge.

Reservoir and lock-and-dam construction on tributaries to the Mississippi River is part of the Mississippi River and Tributaries Project plan to control floods and enhance commercial navigation. Extreme high and low flows can be moderated by operation of the dams. Many of the larger tributaries (e.g., Arkansas, White) have also been modified for navigation by barges requiring an 8 ft. (2.4 m) deep channel. Currently the USACE plans to increase the depth of the channel in the Lower White River to 9 ft. (2.7 m) to facilitate passage of larger barges. The plan required construction of a set of locks and dams near the mouth of the river (Montgomery Point), as well as extensive dredging and installation of dike fields. These alterations will disrupt natural ecological functioning of the White and Mississippi rivers, and are probably not sufficiently justified economically (Wright 2000).

In addition to physical alterations, the LMR receives inputs of municipal wastes, industrial effluents, and agricultural runoff from over 40% of the conterminous 48 states. Inputs now move quickly to the Gulf of Mexico through the shorter, steeper, deeper channel, especially during floods, by design of the USACE. This creates large problems downstream in the estuary and the Gulf. The estuary is rapidly receding because it no longer receives sediments or as much water from the river. An expansive summer dead zone of >20,000 km² resulting from oxygen depletion has developed in the Gulf. Primary production stimulated by agricultural nutrients (especially nitrogen) in runoff is thought to be the cause (McIsaac et al. 2001), but a more parsimonious explanation might be found by examining the dissolved and particulate organic carbon loading of the Gulf. The total oxygen demand of the normal LMR flow (>18,000 m³/s) to the Gulf must be immense without additional organic matter via enhanced photosynthesis. The swamps, estuaries, and bays may be predominantly heterotrophic systems with low algal primary production, but they are highly productive of aquatic macrophytes and the swamps receive large

amounts of litterfall from trees. During floods, turbidity limits aquatic photosynthesis, but accumulated organic matter in the floodplain wetlands is swept into the Gulf as the floodwaters flow out over the more dense salt water. This tremendous load of organic matter is respired by aerobic heterotrophic bacteria, reducing dissolved oxygen levels, and the refractory portion persists for many weeks, holding down oxygen concentrations. If this hypothesis is correct, even significant reduction of nitrogen will have little effect on reducing the dead zone. The dead zone may result from altered flow dynamics (controlled by the USACE) that seasonally flush enormous amounts of dissolved and particulate organic matter into the Gulf, more than from inorganic nutrient additions.

WHITE RIVER

The 1159 km long White River is a major tributary to the Lower Mississippi River, with a basin area of 72,189 km². It originates in the Boston Mountains of the Ozark Plateaus near Boston, Arkansas (35.8°N, 93.6°W), at 785 m asl and first flows west, then circles north through Missouri and southeast back into Arkansas (Fig. 6.10). The White River is strongly fragmented by dams along its main stem, but has two major tributaries (Buffalo and Current) that are protected and free flowing. Near Newport, Arkansas, the White is joined by the Black River as it leaves the Ozark Highlands and flows south across the Mississippi Alluvial Plain to its confluence with the LMR. The dendritic White River attains 5th order by its confluence with the West Fork of the White River and 7th order when joined by the Black River. The Lower White River near its confluence with the Mississippi was connected to the Arkansas River in 1969 by the USACE as part of the McClellan-Kerr Navigation Project on the Arkansas River that passes through Little Rock and on to Tulsa, Oklahoma. Several locks and dams regulate flow to facilitate navigation in both rivers.

Native Americans have occupied the Ozark Plateaus area for at least 10,000 years and the Lower White River in the Mississippi Alluvial Plain for 16,000 years. No major cultures developed in the Ozark region, but diverse cultures from other areas, including the Cahokian, Caddoan, and Mississippian cultures, were represented here (Gerlach and Wedenoja 1984). The Osage, Quapaw, and lesser numbers of other tribes were in the Ozark region of the Upper White River when Europeans arrived. The

tribes mentioned earlier for the Mississippi River were also along the Lower White, and population densities in the sixteenth century were higher than they are now. In the late eighteenth and early nineteenth centuries the U.S. government relocated many eastern tribes to the Ozarks, including the Cherokee, Delaware, Shawnee, and Kickapoo. The first European explorers were Spanish, but the first to settle in the White River basin were French, who were replaced by Scotch-Irish. Early white settlers came from Kentucky and Tennessee to exploit the abundant fishes and wildlife along the Lower White River (Keefe and Morrow 1994), as did the Native Americans who preceded them. The Ozarks provided diverse but not abundant resources to people, and this was reflected in how they lived. The river provided fishes, game, fertile floodplains for crops, and travel corridors.

Physiography, Climate, and Land Use

The headwaters and midreaches of the White River are mostly in the Ozark Plateaus (OZ) physiographic province, with a small amount in the Ouachita province (OP) (see Fig. 6.10). The headwaters of the White are in an area of karst topography where the streams have cut and dissolved deep (to 200 m) valleys through limestone and dolomite deposits. In most places, soils of the Ozarks are too thin for row-crop agricultural production and much has remained forested. The more northern part of this upper basin is primarily in the Central U. S. Mixed Hardwood Forests terrestrial ecoregion (Ricketts et al. 1999). The southern portion of the upper basin drains the more rugged mountains of the Ozark Mountains Forests ecoregion. The native forests support good stands of hardwoods dominated by oaks (red, white, black) and hickories (shagbark, bitternut). Also found are flowering dogwood, eastern red cedar, and shortleaf pine. Floodplains consist of a band of flatter, alluvial deposits whose width is proportional to the size of the streams. Most of the floodplains have been cleared of their diverse riparian vegetation and planted with fescue, a nonnative pasture grass. The fescue has extremely small seeds that are not used by native birds and other wildlife. These floodplains receive applications of large amounts of manure and litter from confined animal agricultural operations.

The White River changes almost abruptly from a mountain stream to a lowland river at Newport, Arkansas, as it moves from the Ozarks Plateaus into the Mississippi River Alluvial Plain section of the

Coastal Plain (CP) physiographic province, crossing comparatively flat, deep, transported (alluvial and windblown loess) deposits (see Fig. 6.10). As described for the Mississippi River main stem, this alluvial plain contains the Mississippi Lowland Forests, a terrestrial ecoregion from which much of the natural forests have been cleared (Ricketts et al. 1999). These forests were dominated by oak, hickory, and pine in the more upland areas and a diverse and extensive bottomland forest in the flood-prone areas.

Precipitation in the White River basin is primarily rainfall and trends from approximately 110 cm/yr in the uplands to 130 cm/yr in the lowlands. Average monthly precipitation is fairly evenly distributed through the year, but is lowest in January (7.4 cm) and highest in May (12.6 cm) (Fig. 6.11). Mean annual temperatures are 14°C (range 1°C to 26°C) in the uplands and 16.4°C (3.7°C to 27.4°C) in the lowlands. The highest mean monthly temperatures are in July (27°C) and the lowest in January (2°C).

Northwestern Arkansas in the headwaters region and Missouri in the midreaches are experiencing rapid urbanization, but most of the basin is sparsely populated (18 people/km²). Land use in the Ozark Plateaus area is dominated by silviculture and beef cattle production, but row-crop production of soybeans, cotton, and rice is characteristic of the lower basin. Forests cover about 70% in the upper and middle regions, but only about 8% in the lower region. Agriculture (excluding silviculture) is about 28% in the upper and middle regions but increases greatly to 83% in the lower region. Increasing amounts of land are being placed in the federal Crop Reserve Program in both parts of the basin. The last 95.5 km of the river flow through the 457.5 km² White River National Wildlife Refuge. This refuge was established primarily for waterfowl, but harbors many other species, including a relict population of native black bears that are genetically distinct from those that have been reintroduced from Wisconsin in the upper portion of the basin.

River Geomorphology, Hydrology, and Chemistry

The White River, like most Ozark streams, originates as an ephemeral debris-regulated channel but becomes an intermittent, gravel-bed stream with distinct pool and riffle structure while still in the 1st order reach. The floodplain also develops rapidly downstream. Within the headwaters reach (orders 1 to 3), the stream changes from a channel dominated

by bedrock outcroppings and boulders that the stream cannot move to one with more gravel whose channel shape is determined largely by flow patterns during floods. During most years the White has perennial flow in the 3rd order reach, however, the 3rd order occasionally becomes intermittent during summer (i.e., without surface flow between pools). Overall, the slope of the White River in the headwaters is about 1.5 m/km. Small reservoirs used for municipal water supplies, flood control, and recreation are common on 2nd and 3rd order tributaries, including the main stem. However, the Buffalo and Current rivers have been protected from damming so far. Large reservoirs, primarily for generation of electric power and flood control, are numerous in the White River basin on 4th and 5th order reaches. The largest of these are Beaver Lake, Table Rock Lake, Lake Taneycomo, and Bull Shoals Lake on the main stem, with Norfolk Lake on the North Fork and Greers Ferry Lake on the Little Red River (see Fig. 6.10). Thus, the midreaches of many of the streams in the White River basin are impounded by dams that release hypolimnetic water. As a result, water temperatures are cooler than normal in summer and warmer in winter in most of the Ozark Plateaus portion of the basin. The reservoirs are also a major impact on other physical and chemical characteristics of the river. There are no reservoirs below Newport, Arkansas, because the flat terrain is not as suitable for their construction. The Lower White River below Newport is a large lowland river where the riffle-pool structure has given way to a sinuous sandbed channel with extensive floodplain development. As it crosses the Mississippi Alluvial Plain it becomes more like the Lower Mississippi River in most respects, although the White is less impacted by humans.

Mean annual discharge for the White River is 979 m³/s, with an annual runoff of almost 43 cm. Mean monthly runoff shows a seasonal pattern from lowest in September (1.5 cm) and highest in March (5.6 cm) (see Fig. 6.11). The natural runoff patterns are influenced by higher precipitation in winter months and higher evapotranspiration in the summer. However, the pattern of runoff is also influenced by periods of conservation and release of water through dams for generation of hydroelectric power and flood control. Flow in the headwaters of the White is seasonal, with predictable intermittent conditions (isolated pools) developing during each summer and a period of continuous flow from about November to June in most years. The hydrograph of a typical water year for the upper portion of the river

is quite spiky because the water rises and falls rapidly, with changes of water level of 1 to 3 m fairly common. Flooding (exceeding bankfull capacity) is not predictable by month or even by season, even though average rainfall is higher during fall and spring. Flow in the Lower White River is protected by instream minimum flow regulations established by the state of Arkansas. Although the regulations are not laws, they are agreements with the management agencies to maintain minimum flows to protect water quality, navigation, and fish and wildlife resources. Proposed increases in width and depth of the barge canal and plans for withdrawal of water for an immense irrigation project seriously threaten the near-natural hydrology of the Lower White River.

Chemical water quality in the White River is of growing concern, in addition to issues regarding geomorphology (channelization, etc.) and water quantity (especially irrigation). Mean annual nutrient levels ($\text{PO}_4\text{-P} = 0.07\text{ mg/L}$, $\text{NO}_3\text{-N} = 0.39\text{ mg/L}$) are fairly high and are increasing at some monitoring sites (e.g., below Beaver Dam in northwestern Arkansas). In the Lower White at St. Charles, Arkansas, $\text{NO}_3\text{-N}$ ranges from 0.1 to 0.5 mg/L and $\text{PO}_4\text{-P}$ ranges from 0.01 to 0.15 mg/L. Water released from the reservoirs during summer and fall has very low dissolved oxygen concentrations, and this has negative impacts on downstream aquatic communities. Fish kills have been documented as a result of this, and chronic impacts on fishes are suspected. Limestone deposits in the Ozark Plateaus buffer the White River within pH extremes of 6 to 9, with an average pH of 7.65, and contribute to the average alkalinity of 110.5 mg/L as CaCO_3 . Turbidity is typically less than 10 NTUs in the headwaters and below the large reservoirs, but increases to 20 to 30 NTUs at St. Charles in the Lower White River. During periods when the river has not been flushed out recently by high flows the water has a greenish-white tinge due to fine colloids dissolved from the limestone in the basin. Overall, environmental quality of the headwaters of the White is less than that of adjacent streams in the Boston Mountains (some of which are tributaries to the White) because it has experienced more forest removal and agricultural development (Radwell 2000).

River Biodiversity and Ecology

The White River basin occurs in two freshwater ecoregions, the Ozark Highlands and the Mississippi Embayment (Abell et al. 2000). Understanding of the biological communities and ecological relationships is much more thorough for the Ozark Highlands than

for the lower half that crosses through the Mississippi Embayment. Levels and patterns (spatial and temporal) of primary and secondary production are not well known, but energetic interactions among invertebrates and fishes have received more attention, at least in the Ozark Highlands. The Lower White, being a large river in the Mississippi Embayment, shares many biota and ecological characteristics with others of that ecoregion, including the LMR. Like the LMR, it has been less thoroughly studied, probably because of the difficulty involved in sampling large rivers and its distance from major universities.

Algae and Cyanobacteria

Little is known about the algae of the White River per se, but studies of streams from the same watershed and ecoregion infer that a diverse array of periphytic diatoms are very important, especially in winter. The diatoms are limited by silica, and by early spring they exhaust the supply and other forms become more abundant. These include an extensive list of filamentous, colonial, and unicellular green algae (e.g., *Cladophora*, *Eudorina*, *Cosmarium*) and cyanobacteria (e.g., *Anabaena*, *Microcystis*, *Formidium*). The macroalga *Chara* develops extensive localized patches. Flagellated mixotrophic forms (*Euglena*, etc.) make some summer pools with limited flow emerald green, especially if the pools are frequented by cattle trying to keep cool and escape insects. Plankton are rare in free-flowing portions of the White, but are found in the large ($>30 \times 600\text{ m}$) pools in the 3rd to 5th order reaches. Periphyton and plankton have not been studied in the Lower White, but neither are likely to be abundant due to shifting sand substrates, rather turbid water conditions, and fluctuating water levels.

Plants

Water willow, an emergent macrophyte with a lanceolate leaf similar to that of willow trees, is abundant in and along all Ozark and Ouachita streams. It is found in almost all shallow areas that receive ample sunlight and escape the harshest physical disturbances (flood impacts, canoe traffic, cattle crossings). Water willow is becoming more abundant as canopy cover is removed by disturbances in the riparian forests. Smartweed, numerous sedges, and river cane are common along the White River margins and form dense stands in some areas. Numerous vines occur along the riverbanks too, including several species each of poison ivy, grapes, and greenbriers, and cucumber vine in the lower reaches. Gravel bars and stream margins are colonized by a variety of

herbaceous plants but also by willows, witchhazel, sycamore, river birch, red maple, buttonbush, and cottonwood. Adjacent floodplain forests are diverse and include many of these same woody plants and a mixture of American elm, green ash, box elder, hackberry, sweetgum, Nuttall's oak, and many others. Bald cypress and water tupelo are abundant in and along the Lower White River, but water willow is rare. Nonnative plants are not a serious problem along the main stem of the White River, although some aquatic macrophytes that are not normally seen along the river are abundant below some of the dams (e.g., elodea). Eurasian watermilfoil and coontail have created problems in shallow oxbow lakes.

Invertebrates

One striking characteristic of the White River invertebrate assemblage is the abundance and diversity of crayfishes, with 15 endemic epigeal species and 3 more in the basin that are cave-adapted (Rabeni et al. 1995, Pflieger 1996). One species, *Orconectes longidigitus*, grows to over 15 cm carapace length in the White River headwaters and in Beaver Reservoir. Another unusual characteristic is the abundance and diversity of mollusks, with about 100 known historically and 58 extant in the basin (Gordon 1982, Gordon et al. 1994). The White River was one of the main sources of mussels for the button industry during the first half of the twentieth century, and mussel shells are still harvested and shipped to Japan for seeding cultured pearls. The fat pocketbook mussel is an endangered species that occurs in the Lower White. Some of the most common mussels in the White River include threeridge, Ozark pigtoe, pimpleback, pocketbook, ladyfinger (or spike), rabbitsfoot, mucket, squawfoot, and pistolgrip.

Smaller macroinvertebrate taxa are moderately diverse and usually include large numbers of mayflies (*Stenonema*, *Hexagenia*), caddisflies (*Cheumatopsyche*, *Chimarra*), chironomid midges, beetles (*Stenelmis*, *Psephenus*), dragonflies (*Gomphus*), and damselflies (*Coenagrion*, *Argia*) (Brown et al. 1983, Rabeni et al. 1995, Doisy et al. 1997). Oligochaete worms and chironomids are locally abundant in organically rich, fine sediments. Stoneflies, especially the winter genera, are present but no longer occur in large numbers as they did 30 years ago. Meiofauna are abundant, especially rotifers and copepods, through all seven orders of the river.

Vertebrates

The entire White River basin contains at least 163 native fish species, 11 of which are endemic to the

basin (Killgore and Hoover 2003). Killgore and Hoover (2003) collected 97 species in the Lower White from 1996 to 2000. The most abundant and diverse families of fishes in the White River are Cyprinidae, Percidae (darters), Centrarchidae, Catostomidae, and Ictaluridae. Blacktail shiner, Mississippi silvery minnow, emerald shiner, mimic shiner, bullhead minnow, blue catfish, channel catfish, bluegill, spotted bass, and western sand darter are often the most abundant fishes at sites in the Lower White River. Typically, 29 to 37 fish species are collected per site in this region (Keith 1987, Buchanan 1997). The Ozark Highlands portions of the White River and its tributaries have popular sport fisheries for centrarchid species, especially smallmouth bass. The Lower White River floodplain lakes also have an exceptional centrarchid sport fishery for largemouth bass and white crappie, in addition to a very productive commercial fishery for primarily carp, suckers, gars, drum, and catfish. The pallid sturgeon is an endangered species that occurs in the Lower White but has not been collected there recently. Its congener, the shovelnose sturgeon, is fairly common. The nonnative common carp and western mosquitofish have become abundant throughout the White River system, and many other nonnative species are common there.

Amphibians and reptiles are also abundant in the White River, with numerous species of aquatic and semiaquatic snakes, turtles, frogs, and salamanders. These include the western cottonmouth and several species of water snakes, common and alligator snapping turtles, stinkpot turtles, softshell turtles, and map and false map turtles. Bullfrogs, green frogs, pickerel frogs, and southern leopard frogs are common. American alligators are abundant along the Lower White and in its floodplain waters.

Muskrats, beaver, river otters, raccoons, and mink are mammals commonly seen in or near the White River along its entire length. The White River provides winter habitat for bald eagles and numerous migratory waterbirds (double-crested cormorants, anhingas, grebes, etc.) and waterfowl (ducks and geese). Great blue herons and belted kingfishers are abundant local residents. Nearly 1219 km² of lands along the Lower White River are protected in three national wildlife refuges and seven state wildlife management areas, primarily for the protection of migratory waterfowl.

Ecosystem Processes

Plant, invertebrate, and vertebrate animal species assemblages of the White River are diverse and abun-

dant, and so are the physical and chemical environments. Therefore, ecological interactions and bioenergetics pathways are complex, but some fascinating attributes are known about them, especially for the Ozark Highlands region. Flashy hydrologic regimes remove most litterfall from rivers to the floodplains in headwaters reaches before aquatic organisms can consume it (Brown and Matthews 1995), but that remaining in the water is rapidly processed (decay rate $k = 0.01$ to 0.03 ; Brown et al. 1983). Thus, community P/R ratios are high, even in the headwaters, and shredders are rare (A. V. Brown, unpublished data). Production in shallow habitats (riffles, runs) is about twice that of respiration rates in May, June, and October, but the P/R ratio in pools is ~ 0.5 (Whitledge and Rabeni 2000). In their study of the Jack's Fork, Missouri, a tributary to the White, Whitledge and Rabeni (2000) found that primary production ranged from $749 \text{ mg O}_2 \cdot \text{m}^{-2} \cdot \text{d}^{-1}$ in a riffle during July to $30 \text{ mg O}_2 \cdot \text{m}^{-2} \cdot \text{d}^{-1}$ in a pool in October. The distinct riffle–pool structure of most of the White River and its tributaries is a physical template that overshadows the longitudinal continuum (Vannote et al. 1980, Brussock and Brown 1991, Doisy and Rabeni 2001). Distribution and movement of biota, interspecific interactions, and trophic dynamics are largely characteristic of and regulated by habitat patches of distinct flow, depth, and substrate composition (Brown and Brussock 1991, Doisy et al. 1997, Peterson and Rabeni 2001). Disturbances that impact the distribution of these physical habitat units, such as gravel mining, significantly alter the ecological functioning of gravel-bed streams like those in the Ozark Plateaus portion of the White River basin (Brown et al. 1998, Zweifel et al. 1999, Rabeni 2000).

Crayfishes are exceptionally important ecological components of the White River basin biota (Whitledge and Rabeni 1997). Half of the total benthic community production and invertebrate consumption of food in the Current and Jacks Fork rivers has been attributed to two crayfish species (golden and spot-handed; Rabeni et al. 1995). The crayfishes appear to have major impacts on algae, detritus, and invertebrates that they consume, and on several species of fishes that prey upon them (Rabeni 1992).

Ecology of the Lower White River, like other large rivers of the LMR basin, is poorly understood. The Lower White appears to be a very productive system, judging from the large harvests of fishes and mollusks that it sustains, although their harvests are much lower than they were 80 years ago (Shirley 2000, Ken

Shirley, personal communication, 2002). The Lower White also must have a very rich seston to support the exceptionally abundant filter-feeding invertebrates (hydropsychid caddisflies, Asiatic clams, zebra mussels, 58 species of other native mussels) and fishes (gizzard and threadfin shad, paddlefish, larval fish of many species).

Human Impacts and Special Features

The White is a very special North American river. It is the largest river draining the Ozark Plateaus, and two of its tributaries have been designated as National Rivers (Buffalo and Current/Jacks Fork). The human population density has been low, but it is now growing rapidly. The Lower White basin still experiences a fairly normal hydrologic flooding regime of its extensive floodplain forest despite the large main-stem reservoir system, so the flood pulse ecological rhythm (Junk et al. 1989) remains close to natural. Aquatic species diversity is high. The Lower White is also the most important winter refuge for waterfowl and neotropical migrant birds in North America and harbors a relict population of black bears. Although the White has several outstanding features, it has been substantially altered with major dams on its main stem and is now seriously threatened by additional human impacts, some of which are enormous.

Several large hydroelectric dams in midreaches of the White River have dramatically changed its ecological characteristics, making it a discontinuous system (Ward and Stanford 1983). The dams reset the river continuum so that the tailwater reaches resemble headwater reaches in several respects. On the other hand, some of the reservoirs mimic large rivers (especially Taneycomo) and others are more like lakes (Bull Shoals, Table Rock). The lentic reservoir habitats resemble lakes in some fundamental respects, but they are deepest near the dams rather than the center and have very poorly developed littoral zones. The reservoirs have an upstream–downstream nutrient gradient from eutrophic upstream to almost oligotrophic near the dams and are warm, monomictic systems (i.e., usually do not freeze over in winter). The algal communities change dramatically along this gradient. Zooplankton species assemblages are dominated by rotifers, with *Keratella cochlearis* and *Polyarthra vulgaris* often most abundant. Chironomids (midges) are the dominant benthic invertebrates in the reservoirs, joined by chaoborids (phantom midges) below the depth of the thermocline.

The reservoirs support moderately productive warmwater fisheries for a variety of centrarchids and ictalurids in the river and nonnative fishes like white bass and striped bass stocked in the reservoirs. Most native warmwater fish species (e.g., largemouth bass, spotted bass, crappie, channel catfish) flourish in the reservoirs, especially with supplemental stockings from the Arkansas Game and Fish Commission. Fisheries for walleye and sauger have been developed but are not as successful. Bluegill, redear, and green sunfish are abundant in the reservoirs also. Gizzard and threadfin shad provide additional “forage fishes” for the larger predatory sport fishes. Lake Taneycomo is small and strongly influenced by cold water released from Table Rock Lake, so it is more riverine and has a fishery that includes stocked trout. Tailwaters of the reservoirs have been stocked with several species of trout and some of the species now have largely self-sustaining populations, whereas others are primarily put-and-take fisheries. Below the dams most of the native invertebrates, including mollusks, have been extirpated, and now amphipods and isopods are abundant. Sculpins and red horse suckers are abundant native fish species.

In contrast to the dams on the Upper White River, the Lower White is dredged and snagged to maintain a 2.4 m deep barge canal to Newport. However, it lacks the revetments, dikes, cutoffs, levees, and locks characteristic of the LMR until it reaches the area subject to flooding from the Mississippi. Presently it retains access to extensive areas of its floodplains, although large areas have been cleared and drained for agriculture, and water flows swiftly to the deepened Mississippi River channel instead of flooding all of the riparian lowlands as frequently as it once did. Some of the cleared bottomland hardwood forests are now being replanted with oaks. However, current plans for deepening and widening the barge canal to 2.7 m × 76 m and for a huge irrigation system (Grand Prairie Area Demonstration Project) would lower water levels in the White and seriously diminish the flood pulse aspect of this large-river ecosystem (Sutton 2000). The proposed barge canal and irrigation project would reduce the habitat available for many of the river’s aquatic species (Chordas and Harp 1991, Gordon et al. 1994, Buchanan 1997) and devastate the remaining rich floodplain habitats (Sutton 2000, Wright 2000).

BUFFALO NATIONAL RIVER

The Buffalo National River (BNR) originates in the Boston Mountains a few kilometers east of the origin

of the White River, but it is on the other side of a large dome (Salem Plateau) and flows east-northeast to its confluence with the White (see Figs. 6.10 and 6.12). It begins at an elevation of about 701 m asl and drops 579 m during its 238 km course across the Springfield Plateau into the Salem Plateau. Although it is a relatively small river, about 190 km of the Buffalo’s length and 392 km² of its 3465 km² watershed were protected by Congress in 1972 by an act declaring it a National River and establishing the long, narrow park as a National Scenic Riverway. Furthermore, the headwaters area and last 32 km of the river are both owned by the U.S. Forest Service and have been set aside as Wilderness Areas. Thus, the entire length of the river is publicly owned and protected, a rare occurrence in the lower 48 states. Approximately 25 named tributaries enter the river and nearly all of them originate on and flow through private property before entering the narrow park along the river (Fig. 6.4).

The presence of terrace village sites and bluff shelters rich in Native American artifacts reveals that archaic tribes lived in the area as much as 10,000 years ago. More recently, tribes of Quapaw and Osage people inhabited this land, which is rich in fishes, shellfish, edible plants, medicinal plants, and wildlife resources. Presently the permanent human population (7 people/km²) in this rough terrain is probably no higher than it was thousands of years ago. However, the park campgrounds and river attract large numbers of campers, hikers, and canoers in spring and summer (Springer et al. 1977).

Physiography, Climate, and Land Use

The Buffalo National River is in the Boston Mountains section of the Ozark Plateaus (OZ) physiographic province (Hunt 1974) (see Fig. 6.12). The BNR is in an area of karst limestone topography. The limestone is soluble in water, so many fissures, collapsed dolines (sink holes), caves, and springs occur along the river course and throughout the watershed. Bluffs along the river are as high as 152 m. Diverse habitats range from xeric south-facing bluffs, open glades on high rock outcroppings with thin soils, mesic hillside forests, and riparian areas on alluvial floodplains, to damp seeps, caves, and springs along margins of the river. The limestones and associated horizontal strata of dolomites, sandstones, shales, and chert intrusions accumulated here primarily during the Ordovician and Mississippian periods under marginal and shallow marine bays, interrupted by several intervals of uplifts and erosion during the Silurian and

FIGURE 6.4 Buffalo National River, Arkansas (PHOTO BY A. C. BENKE).

Devonian. Soils are generally shallow and stony and of medium texture, but are very diverse typologically. Soil pH is patchy and variable (4.2 to 8.6) in the watershed and interacts with slope, aspect, elevation, and moisture to influence distribution of vegetational associations.

The BNR is in the Ozark Mountain Forests terrestrial ecoregion (Ricketts et al. 1999). Primary upland trees include red oak, white oak, post oak, black oak, and hickories, with eastern red cedars in areas with shallow soils and on disturbed sites. Cedar glades occur as patches, especially on south- and west-facing slopes, and harbor interesting plant associations, including diverse herbaceous species and grasses. Shortleaf pine occurs with some of the

upland hardwoods and as almost pure stands on some drier sites with thin, acid soils.

Climate of the BNR watershed is a little cooler (annual mean temperature 15°C) and less humid than that of other subbasins of the Lower Mississippi River (Fig. 6.13). July is the warmest month (26°C) and January is the coldest (2°C). Precipitation is rather evenly distributed over the year, with a low of 5.6 cm in January and a high of 12.6 cm in May, and averages just over 100 cm/yr. Most precipitation falls as rain, although several centimeters fall as snow each winter.

Land use in the BNR basin is rapidly changing due to increased timber harvests as trees have matured after intense cutting in the 1930s and due to

population increases, partly as a result of attention it received as the first National River. The BNR basin may be about 90% forested, with most of the remainder in pasture (Davis and Bell 1998). However, a study by Hofer et al. (1995) reported much less forest cover (73%) and calculated that 14.8% of the watershed that was forested in 1979 had been converted to pasture and “urban/barren” areas by 1992. There are no truly urban areas along the river now, although during a lead-mining and timber-harvesting era about a century ago as many as 5000 persons lived in Rush near the confluence with the White River. Rush is now a ghost town. Other than loss of forested area in the basin, which is the major cause of decline of environmental quality of streams in the region (Radwell 2000), the Buffalo is threatened by excessive traffic by tourists, like many other national parks.

The rough topography along the Buffalo and some of the other streams has protected them from some anthropogenic disturbances. Timber could not be harvested in the steep valleys by “snaking out” the saw logs with draft animals in the 1890 to 1930 period of intense timber harvest, or now with motorized vehicles, although some logs were cut near the rivers and floated downstream to mills during the earlier logging boom. Cable logging is not done here like it is in areas with larger stands of more valuable timber. The fact that these more pristine streams are topographically different from some others in the Ozark region (Mulberry, Illinois) may make them less suitable as good regional reference streams because their differences may be the result of their topography as much as their low level of disturbance.

Geomorphology, Hydrology, and Chemistry

The Buffalo River, although fairly steep (2.4 m/km), has abundant chert (a form of flint) gravel that was embedded in the limestone that has been dissolved away. The substrate is coarse, ranging from exposed bedrock to granule-size gravel (Wentworth 1922), with limited sands and fine sediments. The moderately steep slopes, abundant gravel, and stream power during floods (which are occasionally huge) result in distinct riffle–pool channel structure that largely conforms to the riffle interval (5 to 7 stream widths) described by Leopold et al. (1964). However, many Buffalo River meanders encounter immense limestone bluffs that do not yield to its currents and dictate the stream’s geomorphology.

Hydrologically, the BNR is quite flashy, with a mean discharge of approximately 48 m³/s at its

mouth. It has a hydrologic regime typical of streams that are dominated by surface runoff, with little groundwater storage capacity. Actually, rainfall does not travel far before finding passageways to the water table in the karst terrain, but it resurges just as rapidly as springs, often with little filtration through the thin soils of the area. Low flows of around 1.8 m³/s occur about every two years and typically last for 30 days or longer, and bankfull flows of 1275 m³/s have a similar return interval (<2.5 yr). Floods are not very predictable but do occur more commonly during January to May, when soils are nearer saturation. However, the runoff pattern is not the result of snowmelt as is typical of streams in more northern climates. Somewhat lower rainfall, rapid runoff during rainstorms, and high evapotranspiration rates during summer and early fall cause the 1st order streams in the basin to dry completely and the river to stand in isolated pools through the 3rd order reaches during this time. Thus, mean monthly runoff is highest from March through May (>6 cm/mo) and lowest during summer (<1 cm/mo) (see Fig. 6.13).

Water chemistry of the BNR is strongly influenced by the lithology of the basin. Concentrations of calcium, magnesium, and sulfate all increase downstream during base flow conditions. The calcium carbonate content of the limestone buffers the pH of the acid rain (~4.4 to 4.5) that enters the Buffalo, so pH is normally between 7 and 8 and rarely below 7 except following rainstorms. Inorganic plant nutrients are generally low (NO₃-N = 0.14 mg/L, PO₄-P = 0.06 mg/L), as are coliform bacteria, with very few exceptions (Babcock and MacDonald 1973). Coliforms and nutrients are higher downstream, which may result from increased agricultural and domestic sewage (septic systems) nonpoint-source inputs. The annual mean percentage saturation of dissolved oxygen actually exceeds 100% due to supersaturation that is frequently more than 110% in large, quiet pools (Meyer and Woomeer 1978). Dissolved organic carbon (<1 mg/L) is generally low and the stream is exceptionally clear (<5 NTU).

River Biodiversity and Ecology

The BNR is probably the least disturbed major tributary within the Ozark Highlands freshwater ecoregion (Abell et al. 2000). Since designation of the Buffalo as a National River and establishment of the national park there have been many surveys of its physical, chemical, and biological properties but very few of the results are published in peer-reviewed scientific journals (but contact the Arkansas Water

Resources Center at the University of Arkansas, Fayetteville). Few studies have been performed in the Buffalo that address ecological interactions and processes (trophic dynamics, energetics, nutrient cycling), but these can be inferred from studies of other streams in the region. Recent unpublished studies have focused on impacts of summer intermittent conditions on ecological interactions in the isolated pools and how they affect fish and meiofauna species assemblages.

Algae, Cyanobacteria, and Protists

Over 270 algal taxa are recorded from the BNR (Springer et al. 1977). Diatoms are the major algae, with various species of *Cymbella*, *Achnanthes*, *Navicula*, *Coconeis*, and *Nitzschia* most abundant. However, diatoms peak in late winter to early spring as silica levels are depleted, and they are replaced in summer by a broad spectrum of algae, especially greens and cyanobacteria. *Cladophora*, *Spirogyra*, and the macroalga *Chara* form extensive patches in summer and autumn, with cyanobacteria (*Anabeana*, *Lyngbya*, *Oscillatoria*, *Synechococcus*) becoming principal components of epilithic biofilms (Rippey and Meyer 1975). Flagellates including *Euglena*, *Dinobryon*, *Synura*, *Pandorina*, and *Trachelomonas* are abundant in languid pools, especially those rich with organic matter. Periodic spates reset or interrupt this seasonal succession. Plankton are rare in the Buffalo, but include *Pediastrum*, *Staurastrum*, *Ceratium*, *Stephanodiscus*, and *Pandorina*. Desmids (e.g., *Cosmarium*, *Closterium*) are also common, as are epiphytes (e.g., *Gomphonema*, *Coconeis*) of water willow and some of the larger filamentous algae (e.g., *Cladophora*).

Plants

Water willow is an abundant aquatic macrophyte in the Buffalo River. Although it does not appear to be grazed by terrestrial or aquatic herbivores, it is ecologically significant in other ways. For example, it provides surface for attachment of epiphytic algae that are grazed by aquatic snails, including *Elimia potosiensis*. The rhizomes and roots stabilize substrates. The physical structure of the plants, which occur in dense stands, provide preferred habitat for many macroinvertebrate and fish taxa, both predators and prey. The dead shoots and leaves of water willow contribute detritus.

Riparian forests are not as distinct and extensive along the Buffalo as they are along streams with less slope and more extensive floodplain development. The ephemeral to intermittent flow patterns of head-

water reaches indicate the dry conditions that occur along the Buffalo, especially on steep south-facing slopes. Gravel bars are colonized by black willow, Ward's willow, witchhazel, and, nearer the water, smartweed, water willow, and rushes. Stream sides are lined with sycamore, river birch, silver maple, cottonwood, and buttonbush (Dale 1973). Large stands of giant river cane dominate the herb layer in some places. Floodplains may have some of these same plants but also green ash, box elder, and sweetgum. Nonnative plants include Japanese honeysuckle, multiflora rose, loblolly pine, mimosa, and fescue, but none are very abundant near the river.

Invertebrates

Macroinvertebrates are not very abundant in the BNR but are just as diverse as other tributaries of the White River. Mayflies are the most abundant and diverse insect taxon throughout the length of the Buffalo. Common genera of mayflies include *Isonychia*, *Baetis*, *Heptagenia*, *Centroptilum*, *Stenonema*, *Caenis*, *Ephemerella*, and *Ephoron*. Stoneflies (e.g., *Acroneuria*, *Neoperla*, *Perlesta*, *Taeniopteryx*) and caddisflies (especially *Cheumatopsyche*, but also *Hydropsyche*, *Polycentropus*, *Chimarra*) are well represented. Beetles, especially genera like *Lutrochus*, *Psephenus*, *Stenelmis*, and *Helicus*, are common and occasionally codominant with the mayflies at a site. True flies such as chironomid midges do not appear as abundant in the BNR as in other rivers. Dragonflies (*Hagenius*, *Macromia*, *Neurocordulia*, *Gomphus*) and damselflies (*Enallagma*, *Hetaerina*, *Argia*, *Lestes*) are diverse but not numerous. Hellgrammites (especially *Corydalus* and *Chauliodes*) are common but in low densities.

Crayfish species (*Orconectes* spp.) are an important invertebrate in the Buffalo, as they are in other Ozark streams (Rabeni et al. 1995). In general, Ozark Highlands streams are remarkable for the diversity and uniqueness of their crayfishes (Abell et al. 2000). Crayfishes are opportunistic feeders that generally prefer macroinvertebrates for food. Mollusca are also common in the Buffalo but are not as numerous as in the Lower White (Gordon 1982). Snails (*Elimia*, *Physella*) are important grazers. The nonnative Asiatic clam has become abundant in the BNR, as in other rivers of the LMR region. Standing crop biomass of all benthic macroinvertebrates is generally low, but to our knowledge no estimates of invertebrate secondary production have been performed in the BNR.

The meiofauna species assemblage of the BNR is composed primarily of copepods, cladocerans, ostra-

cods, and mites (Hydrachnidia). In other streams of the region the dominant meiofauna are rotifers and tiny chironomids, but in the BNR they are minor components. When the headwater pools cease to flow and become isolated, resulting in lentic habitats during summer and fall, two meiofauna species, *Bosmina longirostris* and *Keratella cochlearis*, rapidly proliferate. These two species commonly account for ~90% of the density of planktonic meiofauna in isolated BNR pools.

Vertebrates

Over 66 species of fishes occur in the Buffalo National River (Becker and Kilambi 1975, Kilambi and Becker 1977). The most diverse and abundant are Percidae (mostly darters) and Cyprinidae (minnows), with the darters more numerous in riffles and minnows more abundant in pools. Centrarchids (e.g., longear sunfish, smallmouth bass, Ozark bass) and ictalurids (Ozark madtom and slender madtom) are also common. The Buffalo is an excellent smallmouth bass stream, but fishermen who use small lures or baits must catch far more of the colorful longear sunfish than smallmouth bass because they outnumber them more than 10 to 1. The most abundant cyprinids are the dusky stripe shiner, telescope shiner, rosyface shiner, and central and largescale stonerollers. Abundant darters include the yoke darter, rainbow darter, Arkansas saddled darter, and banded darter. Banded sculpin are also fairly abundant.

The Buffalo River has a moderate diversity of amphibians and reptiles, with several snakes (western cottonmouth, midland water snake), turtles (softshell turtle, map turtle, snapping turtle), and frogs, but none are very abundant. Common mammals include beaver, muskrat, raccoon, and mink. River otters are present but not abundant. Great blue herons and belted kingfishers are common year-round, and a few bald eagles can be seen there in winter, as is true of all Ozark rivers.

Ecosystem Processes

Although the physical, chemical, and biological elements of the Buffalo National River have been fairly extensively surveyed and reported in governmental agency reports and publications, almost no studies of ecosystem processes (primary/secondary production, metabolism, food web analyses, trophic dynamics, etc.) have been performed. These can only be inferred from the survey data, studies in the other tributaries of the White River, and studies of other

streams in the Ozark Plateaus. Large woody debris is scarce in the Buffalo, as in most Ozark streams. Several factors cause this: removal of snags by canoe rental agencies and government employees, rapid decay of wood in this area, and removal to the floodplains by large floods. Flashy hydrology and lack of retention result in most litterfall being flushed out of the stream channel to the floodplains. Dissolved organic matter is also low (<1 mg/L). Primary production is limited by low nutrient concentrations. Thus, low organic matter resources limit secondary production. From perusal of invertebrate species abundances, very few shredders are present and grazers are most abundant. Grazing fishes (central and largescale stonerollers) are also numerous, but most fishes are invertivorous (darters and small cyprinids) or piscivorous (bass). Thus the river is probably an autotrophic system despite being in a forested area. The clear water and clean gravel of the river are indicative of its trophic status.

Human Impacts and Special Features

The Buffalo National River is one of only 42 natural free-flowing rivers >200 km long in the conterminous 48 United States (Benke 1990). Water quality in the Buffalo has been studied fairly extensively and is exceptionally good. The Buffalo and several of the other streams flow down the sides of the Ozark dome from which they originate (Salem Plateau) in a radial pattern (Big Piney Creek, Mulberry River, Crooked Creek, Illinois Bayou, War Eagle Creek). They are considered to be among the best examples in the United States of high-quality reference streams (Omernik 1995, Radwell 2000). Water quality of rivers in this region is closely tied to the percentage of forested area in the watershed (Radwell 2000). This is of particular concern to managers of the BNR, as most of the watershed is in private ownership despite the fact that the full length of the waterway and riparian zone of the main-stem river is in public ownership. Several studies of land use in the basin have been performed (Scott and Smith 1994, Hofer et al. 1995, Davis and Bell 1998), and although they do not agree on the details it is apparent that the watershed is being converted from forest to pasture. The current outbreak of red oak borers resulting from several very dry summers that stressed the trees is adding to the problem.

Although the BNR is an uncommon river in a scenic and relatively undeveloped watershed ecosystem, development of the basin is occurring fairly rapidly. People who live in the watershed do not want

to leave it, yet require income for their families. Thus, many cut trees, clear pastures for livestock, build cabins to rent to tourists, rent canoes, or live and work in the basin as employees of the National Park Service. All of this contributes to declining environmental quality in the basin. Ironically, part of the environmental degradation is the result of actions taken to protect it. However, the Buffalo would have been dammed by the USACE, like most other tributaries to the White River, at Gilbert and/or Lone Rock 40 to 50 years ago except for strong opposition from the National Park Service, Ozark Society, Arkansas Audubon Society, and The Nature Conservancy (Albright 1957–1993). A recent controversy concerns a proposed reservoir on Bear Creek, one of the major tributaries to the BNR. In August 2002 the USACE granted a permit to build a drinking-water reservoir on Bear Creek, one of the major tributaries of the Buffalo, in spite of opposition from the National Park Service, U.S. Fish and Wildlife Service, and many conservation organizations, in apparent violation of federal law.

BIG BLACK RIVER

The Big Black River is the least disturbed river in the Delta region of western Mississippi and is a prime candidate for inclusion in Mississippi's natural and scenic waterways system (Mareska and Jackson 2002). It originates in the hills of north-central Mississippi, flows southwesterly across the state for 434 km, and discharges directly into the Mississippi River 43 km downstream from Vicksburg, draining a watershed area of approximately 8770 km² (Fig. 6.14). There are no dams on the main stem of the river, but there are small impoundments on some of the tributary streams. Channel modification for navigation and flood control has been minimal, and there has been virtually no maintenance on these public works projects since 1955 (U.S. Army Corps of Engineers 1964). Recovery processes (Jackson 2000) are advanced for the Big Black River.

During the Civil War, gunboat battles raged on the Big Black River. It is still possible to find artifacts from the period following flood-induced scouring of the stream channel. As a consequence of logjams, fallen trees, and snags (large woody debris), boat navigation now is restricted to small craft, and often even these (excepting canoes) cannot travel along the system unless a path is cleared through debris with a chain saw.

Physiology, Climate, and Land Use

The Big Black River drops 152 m as it courses through the Coastal Plain (CP) physiographic province, beginning in the Eastern Gulf Coastal Plain section and then moving into the Mississippi River Alluvial Plain section near its mouth (see Fig. 6.14). It drains an area representing the westernmost portion of the Southeastern Mixed Forests terrestrial ecoregion, whose natural vegetation is characterized by oak–hickory–pine forests (Ricketts et al. 1999). Higher elevations within the watershed are mixtures of longleaf pine, oaks, hickories, elms, Eastern red cedar, and herbaceous vegetation. Pastureland in the watershed typically is a mixture of broomsedge, non-native fescue, and Dallas grass. Terrestrial ecotones in the watershed support Osage orange, black locust, honey locust, persimmon, blackberry, honey suckle, and the nonnative privet and kudzu.

Rainfall in the Big Black River watershed averages around 135 cm/yr, with highest rainfall typically 12 to 14 cm/mo during winter/spring and 8 to 10 cm/mo during summer (Fig. 6.15). Mean annual air temperature is approximately 18°C, with temperatures frequently exceeding 30°C during summer and occasionally falling below –5°C during winter. The wet temperate climate coupled with a long growing season encourages rapid regeneration of forests (typically <20 years) along upper sandbar terraces of riparian zones and throughout the watershed.

The watershed of the Big Black River is sparsely populated (<25 people/km²) and is a mixture of forest (~54%), row-crop agriculture (~35%), and pastureland (~11%) (Insaurralde 1992). Most forested lands are natural mixes of hardwoods and pines, but planted pine forests are common. These landscape characteristics have changed little since the 1960s (Holman et al. 1993).

Geomorphology, Hydrology, and Chemistry

The Big Black River is a low-gradient stream with a slope ranging from approximately 50 cm/km in its upper reaches to approximately 20 cm/km in downstream reaches. Channel width in the upper reaches near Kilmichael, Mississippi, is approximately 30 m, whereas in the lower reaches near Bovina, Mississippi, the width increases to around 80 m (Holman et al. 1993). The river is a mosaic of shallow runs, deep holes, steep cut banks, and expansive sand bars, lined by riparian forest comprised primarily of bottomland hardwood assemblages (Fig. 6.5). Highly erodible soils comprised primarily of sand, silt, and

FIGURE 6.5 Big Black River, Mississippi (PHOTO BY D. JACKSON).

clays dominate the Big Black River watershed. Hard rock features are rare or absent, and when present are typically in the form of gravel deposits. Scour and fill processes result in lateral channel movements that locally can exceed several meters a year.

Mean discharge in the Big Black River is $107 \text{ m}^3/\text{s}$ based on a 66-yr record (1936 to 2002) at the USGS gaging site near Bovina, Mississippi. However, extremes in local and regional weather conditions can lead to extensive flooding as well as severely reduced streamflows. For example, maximum and minimum flows recorded for the Bovina station are approximately $2600 \text{ m}^3/\text{s}$ and $1.5 \text{ m}^3/\text{s}$, respectively (Mississippi Department of Environmental Quality 1992). Holman et al. (1993) reported that highest discharges occur from February through April ($>200 \text{ m}^3/\text{s}$), and that lowest discharges are from August through October (15 to $41 \text{ m}^3/\text{s}$). Monthly runoff ranges from an average of $0.61 \text{ cm}/\text{mo}$ in September to $8.07 \text{ cm}/\text{mo}$ in March (see Fig. 6.15) and is influenced by seasonal differences in evapotranspiration and rainfall patterns.

Water quality (U.S. Geological Survey 2000b, 2001) for the Big Black River is considered good.

Suspended sediment varies seasonally but averages around $135 \text{ mg}/\text{L}$. Dissolved oxygen concentration typically exceeds $5.0 \text{ mg}/\text{L}$ regardless of season, and pH is fairly stable, ranging between 6.8 and 7.2. Total alkalinity and hardness both are around $50 \text{ mg}/\text{L}$ as CaCO_3 . Nitrate-nitrogen typically is $<0.3 \text{ mg}/\text{L}$ and reflects a watershed primarily devoted to forestry and wildlife management rather than intensive agriculture. Mean concentrations for $\text{PO}_4\text{-P}$ are somewhat elevated, ranging from $0.18 \text{ mg}/\text{L}$ during the dry period to $0.31 \text{ mg}/\text{L}$ during the wet season (Holman et al. 1993).

River Biodiversity and Ecology

The Big Black River is a relatively intact, functional floodplain river ecosystem within the Mississippi Embayment freshwater ecoregion (Abell et al. 2000). Although there has been research on invertebrates and fishes, the river has not been intensively studied, particularly for ecosystem processes.

Plants

As a result of variable flow regimes and fairly high turbidity, aquatic vegetation is not common in littoral

zones and lower elevations of sand and mud bars along the Big Black River. In the higher elevations of riparian zones on the inside of meanders there are assemblages of American sycamore, red maple, river birch, black willow, green ash, and cottonwood. Beyond these zones, where the bars make the transition to *terra firma*, and along the outside of channel meanders, where current erodes the stream bank, there are hardwood forests dominated by aggregates of various oaks, bald cypress, and, on floodplain terrace ridges, black walnut.

Invertebrates

Invertebrates in the Big Black River are best known from drift net studies by Insaurrealde (1992). Major taxa were the mayflies *Baetis*, *Cinygmula*, and *Tricorythodes*; the dragonfly *Gomphus*; the caddisflies *Hydropsyche*, *Cheumatopsyche*, and *Nectopsyche*; the beetles *Ancyronyx* and *Stenelmis*; the hellgrammites *Corydalus* and *Chauliodes*; various chironomid midges; and the blackfly *Prosimulium*. Collectively these insects contributed nearly 60% by weight to the overall drift net catches. Caddisflies originated mostly from snags, whereas the chironomids originated mostly from stream bottom substrates (Insaurrealde 1992). Hartfield and Rummel (1985) documented 34 species of mussels from the Big Black River but in 2002, 38 species were noted (Mississippi Department of Wildlife, Fisheries, and Parks 2002). Some common mussels are the mucket, rock pocketbook, butterfly, southern pocketbook, and southern mapleleaf. The Big Black River has two species of mussels that are on Mississippi's endangered species list: the pyramid pigtoe and the rabbitsfoot. Archaeological remains of sheepnose and western fanshell exist in the river, but currently there are none known to be alive in the system (Mississippi Department of Wildlife, Fisheries, and Parks 2002).

Vertebrates

Ross (2001) provides a comprehensive list of 112 fish species from the Big Black River. Principal larger fishes are flathead catfish, blue catfish, channel catfish, smallmouth buffalo, bigmouth buffalo, black buffalo, freshwater drum, white crappie, black crappie, largemouth bass, gizzard shad, bluegill, longnose gar, spotted gar, blue sucker, and paddlefish (Holman et al. 1993). Flathead catfish is the most important fishery resource in the river, although productive fisheries also exist for blue catfish, channel catfish, and, to a lesser extent, sunfishes (Centrarchidae). Principal smaller fishes are blacktail shiner, emerald shiner, striped shiner, creek chubsucker,

freckled madtom, blackspotted topminnow, central stoneroller, scaly sand darter, slough darter, logperch, and dusky darter (Holman et al. 1993).

Other vertebrates associated with aquatic environments of the Big Black River include mammals (beaver, river otter, raccoon, mink), reptiles (western cottonmouth, common snapping turtle, alligator snapping turtle, slider, Mississippi map turtle), and birds (great blue heron, kingfisher, wood duck, and, seasonally, various species of migrating waterfowl, particularly mallard). Beaver, otter, raccoon, and mink support local trapping, with a major fur buyer and distributor located in nearby Kosciusko, Mississippi. Migratory waterfowl provide the foundation for seasonal hunting in the numerous hunting clubs that are operative along the river. Riparian zones and floodplains harbor high densities of whitetail deer, wild turkey, gray squirrel, fox squirrel, gray fox, coyote, armadillo, cottontail, swamp rabbit, and numerous raptors and neotropical migrant birds.

Ecosystem Processes

Little research has been done on ecosystem processes in the Big Black River, and the description here is based to a large extent on field observations and the literature from other river-floodplain systems, including studies in the Mississippi River basin. Heterotrophic processes are the principal bioenergetic driving forces for floodplain river ecosystems in Mississippi. Allochthonous organic materials can enter the stream directly from riparian zones or can blow or wash in from more remote locations in the watershed. Floods set into motion incorporation of extrachannel allochthonous organic materials (Junk et al. 1989, Bayley 1995, Thorp and Delong 1994, Sparks 1995). Along the transitional front separating the aquatic environment from the terrestrial environment, rapid nutrient exchange occurs (Bayley 1989). These nutrients leach from allochthonous organic materials and organic components of soils and are utilized by microbes (Fisher and Likens 1973, Anderson and Sedell 1979). These processes, in conjunction with the (seasonally) warmer, clearer, shallow water of the floodplain relative to main-stream channels, encourage production of plankton and other microflora and microfauna on the floodplain that are used as forage by benthic macroinvertebrates and early life history stages of fishes. Coarse particulate organic matter (CPOM) remaining after nutrient leaching can serve as invertebrate habitat (Brown and Matthews 1995). As this CPOM is further colonized by microbes and broken into smaller particles, it is consumed by macroinver-

tebrates (Cummins 1974, Marzolf 1978) that in turn become potential forage items for fishes. Ultimately, the dynamics of this secondary production are expressed most vividly in terms of the river's excellent fisheries, and particularly those targeting catfishes (Ictaluridae) (Jackson and Francis 1993). Low flow periods during summer and autumn concentrate aquatic biota within the stream channel and in backwater seasonal lentic environments (e.g., ephemeral pools, sloughs, oxbow lakes).

Flooding also introduces snags (large woody debris) into the main channel of a floodplain river ecosystem. In streams such as the Big Black River that have fine-grained substrates, snags provide important habitat and refuge for fishes and attachment sites for macroinvertebrates (Gorman and Karr 1978, Benke et al. 1985, Insaurrealde 1992, Skains 1992, Brown and Matthews 1995).

The general well-being of the Big Black River as a floodplain river ecosystem fishery is best reflected by the stock structure and population dynamics of flathead catfish, the top predator within the Big Black River fish assemblage (Jackson 1999). Using low-altitude (300m) aerial photography, Insaurrealde (1992) characterized Big Black River riparian zones and estimated the abundance of snags in the stream channel. Then he related these environmental characteristics to flathead catfish biology. He found that the abundance of flathead catfish in the Big Black River was directly related to the proportion of the riparian zone in mature forest ($R^2 = 0.77$), and the proportion of the flathead catfish population >41 cm was related to the number of snags/km ($R^2 = 0.61$).

Human Impacts and Special Features

Like the Buffalo National River, the Big Black River is one of only 42 natural free-flowing rivers >200 km in length in the lower 48 states (Benke 1990). Its significance is further highlighted in this regard in that it is a functioning floodplain river ecosystem in a fairly stable, primarily forested watershed. Most floodplain rivers in the United States have been ravaged by flood-control programs, including channelization, dredging, clearing of riparian zones, removal of large woody debris, damming, or combinations of these impacts. With the exception of the river's lowermost reaches near Vicksburg, Mississippi, the Big Black River has been spared these insults and subsequently deserves recognition as a state and national treasure. It is replete with aesthetic beauty as it meanders through its floodplain and associated bottomland forests. Its natural state

encourages fisheries and wildlife resources, and subsequently human interactions with the river and these resources. As of 2003 there were no fish consumption human health advisories for the Big Black River.

During low flow periods (May to October) the Big Black River is an extremely popular fishing destination. Recreational anglers, particularly those targeting catfishes, invest considerable effort in fishing the system, primarily with multihook longlines baited and deployed in deeper pools and left to fish passively overnight. In addition, during May, June, and July there is a special season for recreational hand fishing. The Big Black River is noted by hand fishers for its exceptionally large flathead catfish (commonly >25 kg). In this fishery, the fisher enters the water, feels under the water with hands or feet for cavities under the stream bank or within logjams or root wads, and upon encountering a fish grabs it by the jaw (often the fish grabs the fisher) and attempts to wrestle it either into a waiting boat or onto the stream bank (Francis 1993).

Wildlife considered game species are subject to hunting by local human populations. This hunting is generally within the constraints of established clubs with exclusive access to private property. Current trends in land purchase and development throughout the watershed, primarily for forestry, wildlife management, and hunting purposes, should maintain the integrity of the Big Black River ecosystem and its various tangible and intangible resources.

YAZOO RIVER

The Yazoo River is a large floodplain river ecosystem that encompasses approximately $35,000$ km² in north-central and northwestern Mississippi (Fig. 6.16). It has six principal tributary rivers: the Coldwater, Sunflower, Tallahatchie (including the Little Tallahatchie), Yocona, Skuna, and Yalobusha rivers. All but the Sunflower River originate in the hill country of northern Mississippi and flow generally west and southwest, converging in the Mississippi River Alluvial Plain (or Delta) to form the main stem of the Yazoo River near Greenwood, Mississippi. The Sunflower River originates within the Delta, west of Greenwood, courses primarily north to south, and enters the Yazoo River approximately 50 km from the Yazoo River's confluence with the Mississippi River near Vicksburg.

For the last 3500 years the Yazoo River system has been used by at least four cultures. Mound Builders were the first known inhabitants of the

region, arriving around 3500 years ago (Smith 1954). By the late seventeenth century they were decimated by diseases transported into the region by the exploration party of Hernando de Soto in 1541. Choctaw and Chickasaw tribes settled the region during the eighteenth century and engaged in agriculture, hunting, and fishing. Native American tribes were driven out of the region by European-American settlers via several U.S. government treaties during the early nineteenth century. These settlers converted large tracts of land from bottomland hardwood forest to agricultural land conducive for row-crop production of cotton but had to contend with expansive regionwide flooding for nearly half of each year. Some built private levees to protect their lands from flooding, but this tended to generate problems with neighbors downstream and frequently stimulated hostility.

After the great flood of 1927 the U.S. Congress authorized massive flood-control projects throughout the Yazoo River system. Subsequently, during the middle of the twentieth century all of the principal tributaries of the Yazoo River with the exception of the Sunflower River (Coldwater, Little Tallahatchie, Yocona, Yalobusha) were dredged, cleared, snagged, and/or channelized and had upstream flood-control dams constructed, generally near the boundary separating the eastern hill country from the Delta (Jackson and Jackson 1989, Jackson et al. 1993).

Physiography, Climate, and Land Use

The Yazoo River system is contained entirely within the state of Mississippi and is positioned in the Coastal Plain (CP) physiographic province (see Fig. 6.16). The upper reaches of principal tributary streams are in uplands of the Eastern Gulf Coastal Plain section of the province. The lower reaches of the system extend into and across the Mississippi Alluvial Plain section. Upper and eastern tributaries drain portions of the Central U.S. Hardwood Forests (native oak and hickory) and Southeastern Mixed Forests (native oak, hickory, and pine) terrestrial ecoregions, respectively (Ricketts et al. 1999). However, most of the main stem, including the main stem of the Tallahatchie, and all of the western tributaries drain from the Mississippi Lowlands Forests ecoregion. Natural vegetation of the Mississippi lowlands once also included oak–hickory–pine forests and various other bottomland hardwood species, but only remnants of native forest remain, most having been converted to agriculture.

The prevailing climate is one of hot, humid summers and cool, moist winters (Ye 1996). Heaviest rainfall typically occurs during winter and spring, with average precipitation from December through June of approximately 12.5 cm/mo (Fig. 6.17). The driest period is August through October, with average precipitation of approximately 7.6 cm/mo. Normal summer temperatures can exceed 27°C and normal winter temperatures can be below 7°C.

Land use in the upper reaches of tributary streams is primarily forestry (including U.S. National Forests) and diversified agriculture (including livestock grazing). In the lower reaches, row-crop agriculture prevails, although throughout the system there are still large tracts devoted to timber production and wildlife management. Insaurralde (1992) utilized satellite imagery (LANDSAT) and high-altitude aerial photography (NAP) to characterize the landscape of the Tallahatchie River's lower reaches (typical of the Yazoo River basin) and reported that approximately 80% was in row-crop agriculture (primarily cotton and soybeans) and approximately 15% was bottomland hardwood forest. The remainder was pasture and small tracts of pine or mixed pine–hardwood forestland. Overall, approximately 60% of the Yazoo River basin is devoted to agriculture (U.S. Geological Survey 2002).

The entire Yazoo River basin is a major wintering area for migrating waterfowl. The international significance of the region in this regard has resulted in the establishment of numerous state wildlife management areas and federal wildlife refuges throughout the Yazoo River basin, primarily dedicated to waterfowl. Large tracts of private lands also are being converted to these purposes (Zekor and Kaminski 1987, Uihlein 2000).

Geomorphology, Hydrology, and Chemistry

Stream reaches upstream from Yazoo's flood-control reservoirs course through relatively soft substrates comprised of clay, sand, and silt mixed with occasional gravel deposits. Deforestation coupled with poor agriculture practices during the 1800s and 1900s resulted in massive regionwide land erosion that ultimately forced large numbers of people to leave the area. In addition to rendering much of the land uninhabitable and unsuitable for farming, this erosion filled the tributary streams and main channels of the rivers with sediment. Through reforestation programs (including establishment and development of national forests throughout northern Mississippi) and implementation of soil conservation

FIGURE 6.6 Yazoo River, Mississippi (PHOTO BY D. JACKSON).

practices these destructive fluvial processes were substantially reduced by the 1980s. In this last regard, the USDA Sedimentation Laboratory (Oxford, Mississippi) has been particularly instrumental through development and implementation of stream rehabilitation programs throughout the region (e.g., Shields et al. 1998). Rehabilitated streams in these upper reaches of the Yazoo River basin have relatively stable stream banks, heterogeneous instream habitat, clear water (relative to most streams in Mississippi), and recovering fish assemblages, as evidenced by development of local recreational fisheries targeting spotted bass. These upland tributaries typically have bankfull widths of <20m and, at minimum flows, average depths of <2m.

Jackson et al. (1993) described the riverine environments in the lower reaches of the Yazoo River's principal tributary streams downstream from the flood-control dams. Generally, at bankfull flows (common in winter and spring) the main channels are <50m wide, with depths of <10m. Under low flow conditions (summer and autumn) widths and depths can be considerably less. The Yazoo River itself (Fig. 6.6) has somewhat greater bankfull widths (75 to

175 m), with depths occasionally >20 m. Even under low flow regimes, the main channel of the Yazoo River typically can accommodate shallow draft barge navigation as far upstream as Greenwood, Mississippi. Historically, however, steamboats traveled upstream as far as the current Sardis Dam (near Oxford, Mississippi) on the Little Tallahatchie River, and as far as Avalon, Mississippi, on the Yalobusha River.

The rivers in the Yazoo River system are usually very turbid, particularly in their lower reaches, with Secchi transparencies commonly <10cm. Substrates are comprised of sand, loamy silt, and clay, with occasional patches of small gravel. Large woody debris originating from riparian zones is common as isolated snags or more complex logjams. Most stream reaches are lined by riparian forest, but these forests can be reduced to narrow strips of trees as a result of land clearing for agricultural purposes. Under high flow regimes this practice commonly results in bank collapse, channel meandering, loss of cropland, and introductions of sediment, pesticides, and large woody debris into the river channels.

The design discharge from the region's flood-control projects was established at 566 m³/s for the Yazoo River at Greenwood, Mississippi. The USGS gaging site at Greenwood provides a long-term mean annual discharge of 296 m³/s. In order to protect farmland from flooding, the dams are operated to ensure that the discharge does not exceed 312 m³/s during the crop season (U.S. Army Corps of Engineers 1991). Mean monthly runoff and flooding are highest in winter and spring and are typically minimal during summer and autumn, as would be expected without dam regulation (see Fig. 6.17). However, the dams reduce peak flooding. Discharge from the flood-control dams is determined by rule curves regulating reservoir pool levels to ensure ample flood storage capacity while maintaining secondary socioeconomic benefits associated with recreational uses of the reservoirs (e.g., fishing and boating). Instream flow management for purposes other than flood control have for all practical purposes been ignored, although Ye (1996), Cloutman (1997), Cloutman et al. (1999), and Jackson and Ye (2000) have clearly demonstrated relationships between stream hydrology and principal fishery resources (catfishes and buffalo fishes) and angling in the lower reaches of the Yazoo's principal tributary streams. Additional relationships (impacts) are probable with regard to aquatic fauna throughout the ecosystem, because under current management flood pulses are dampened (but prolonged) during winter and spring and stream flows downstream from the dams during summer and autumn often are greater than during these seasons prior to the dams.

In the extreme lower reaches of the Yazoo River, at its junction with Steele Bayou just upstream from Vicksburg, Mississippi, the USGS (2002) reported mean monthly discharge ranged from 294 to 869 m³/s from 1996 to 2000, with an annual mean discharge of 522 m³/s. During this period discharge from the Yazoo River represented 2.8% of the Mississippi River flow at Vicksburg.

Water-quality data for the Yazoo River system (U.S. Geological Survey 2000b, 2001, 2002) reflect land use patterns (primarily agricultural enterprise) coupled with the dynamics of scour and fill processes through deep alluvial deposits. These deposits are nutrient rich and typically slightly acidic to somewhat basic (pH 6.7 to 7.7). Application of agricultural fertilizer is considered the primary source for elevated levels of NO₃-N (range 0.05 to 1.2 mg/L; mean 0.20 mg/L) and PO₄-P (range 0.11 to 0.94 mg/L; mean 0.29 mg/L) in the rivers. Suspended sediments can be high seasonally (range 52 to 468 mg/L;

mean 168.4 mg/L), and usually can be traced to sheet flow across unprotected agricultural lands. Dissolved oxygen typically is sufficient for warmwater stream fishes (range 4.2 to 11.3 mg/L; mean 7.7 mg/L). Water temperature averages 21.5°C but can range from 0°C during winter to nearly 30°C during summer.

River Biodiversity and Ecology

The Yazoo River is a highly modified floodplain river ecosystem (Jackson and Ye 2000) located within the Mississippi Embayment freshwater ecoregion. Broad-scale ecological studies of the river are sparse, but the fish community is well described, and there have been several studies of the fisheries in the basin.

Plants

Most of the floodplains of the Yazoo River system are converted agricultural lands. Remnant bottomland hardwood forests are dominated by various oaks, bald cypress, black walnut, and pecan. Along recovering riparian corridors, black willow, cottonwood, American sycamore, green ash, red maple, and river birch prevail. Mature riparian zones are dominated by oaks, water tupelo, and bald cypress. Aquatic vegetation within and along main-stream channels is absent or rare as a result of variable flow regimes. However, during drought conditions when low stream flows are maintained for extended periods, exposed mud bars can develop thick stands of herbaceous vegetation. Backwater environments (e.g., sloughs, swamps, oxbow lakes) with low turbidity frequently develop assemblages of aquatic vegetation comprised of various combinations of water primrose, spikerush, alligatorweed, water shield, cattail, American lotus, pondweed, and chara.

Invertebrates

Large woody debris in the Yazoo River system provides important attachment sites for benthic macroinvertebrates, primarily caddisflies and mayflies, whereas other macroinvertebrates, such as chironomid midges, tend to be associated with bottom sediments (Insaurralde 1992). Major taxa were the caddisflies *Hydropsyche*, *Cheumatopsyche*, and *Nectopsyche*; the mayflies *Baetis*, *Caenis*, *Cinygmula*, *Stenonema*, and *Tricorythodes*; the true flies *Choborus*, *Prosimulium*, and *Simulium*; and the hellgrammites *Corydalus* and *Chauliodes*.

Collectively, throughout the Yazoo River system there are 44 species of mussels of which 13 species are imperiled (threatened or endangered), primarily as a result of flood-control programs coupled with

poor agricultural practices (Mississippi Department of Wildlife, Fisheries, and Parks 2002). The Sunflower River has the only known populations of the sheepnose and the mucket in Mississippi (Mississippi Department of Wildlife, Fisheries, and Parks 2002). Other common mussels in the Yazoo River system are the rabbitsfoot and the pyramid pigtoe.

Vertebrates

The Yazoo River and its principal tributaries are inhabited primarily by fishes best described as fluvial habitat generalists (Cloutman 1997). A comprehensive list of 119 fish species in the Yazoo is provided by Ross (2001). Catfishes (Ictaluridae), suckers (Catostomidae), and gars (Lepisosteidae) are the dominant large species in lotic environments of the Yazoo River system. Sunfishes (Centrarchidae), gars, and suckers dominate the system's backwater lentic environments. Minnows (Cyprinidae), small centrarchid sunfishes, topminnows (Cyprinodontidae), madtoms (Ictaluridae), mosquitofishes (Poeciliidae), and darters (Percidae) dominate the small species assemblages.

Dominant catfishes are channel catfish, flathead catfish, and blue catfish, all of which support important recreational, subsistence, and small-scale commercial fisheries. Smallmouth buffalo, bigmouth buffalo, longnose gar, and spotted gar also contribute to small-scale commercial fisheries. Principal smaller fishes are blacktail shiner, emerald shiner, bluntface shiner, bullhead minnow, freckled madtom, and orangespotted sunfish (Cloutman et al. 1999).

Common aquatic/semiaquatic mammals are beaver, river otter, mink, and raccoon. Principal amphibians and reptiles are bullfrog, leopard frog, western cottonmouth, diamondback water snake, redbellied water snake, slider, common snapping turtle, alligator snapping turtle, and Mississippi map turtle. The American alligator is present but not common. Common resident aquatic birds are great blue heron, little blue heron, green heron, and wood duck. The rivers and associated floodplains (including croplands) seasonally are used by migratory waterfowl, such as snow goose, white-fronted goose, mallard, gadwall, scaup, American widgeon, pintail, and double-crested cormorant.

Ecosystem Processes

There has been little in the way of ecosystem studies of the Yazoo River system, either before or after the dams in the upper reaches or channelization in the lower reaches of the basin. Being a Coastal

Plain river, this river historically would have experienced important connections with its naturally broad floodplain during floods that normally occurred in the winter and spring. Although still subject to flood pulses (Junk et al. 1989) that inundate adjacent floodplains (including agricultural lands), the river is disconnected from many sections of its floodplain by an extensive levee system. This restricts incorporation of organic materials into the aquatic component of the ecosystem, secondary production of benthic macroinvertebrates, and access to these floodplain resources by aquatic fauna in the river channels.

Dams produce their own unique environmental processes in the reservoirs and in tailwaters immediately downstream from the impoundments (see review by Jackson and Marmulla 2000). The semilentic environments of the reservoirs are driven primarily by autotrophic processes of various seasonal phytoplankton assemblages but suspended materials (primarily colloidal clay particles) attenuate the euphotic zone, resulting in a restricted trophogenic zone that is most extreme during summer. Thermal and associated chemical stratification are abrupt, with strong gradients that persist until late September or October. Early autumn fronts with brisk winds can create internal seiches that bring deoxygenated, low pH waters into littoral trophogenic zones. This can cause massive kills of lacustrine benthic macroinvertebrates. In addition, cool, cloudy days during late summer and early autumn, coupled with cooling rains, can break down thermoclines and result in complete lake turnovers (mixing of epilimnetic and hypolimnetic waters). These can result in deoxygenated water throughout the reservoirs and corresponding fish kills.

Tailwaters below the flood-control dams typically receive epilimnetic water from their respective reservoirs throughout the year, flushing plankton and other organic seston through the system throughout the entire year. This greatly alters the natural food resources, but they are used by an abundance of filter-feeding benthic macroinvertebrates (e.g., caddisflies, blackflies, bivalve mollusks) below dams that are themselves utilized as the foundation for extremely productive, albeit localized, fisheries. White bass, white crappie, blue catfish, and paddlefish are principal fisheries resources in the tailwaters. Well-developed facilities and access for anglers exploiting these fisheries resources are provided through cooperative arrangements between the U.S. Army Corps of Engineers (Vicksburg District) and the Mississippi Department of Wildlife, Fisheries, and Parks.

Downstream from the tailwaters, stream channels are periodically subject to channel dredging, removal of large woody debris, clearing of riparian forests, and, in some cases, have been channelized and leveed (see review by Hubbard et al. 1993). These impacts can be devastating to floodplain river ecosystems because they result in homogeneous channel environments and remove the principal substrate (i.e., large woody debris) used as attachment sites by most benthic macroinvertebrates. This undoubtedly reduces secondary production, reduces contributions of allochthonous materials from riparian zones, and tends to reduce overbank flooding. The normal incorporation of allochthonous organic materials into biological production processes and fish and invertebrate access to seasonally (winter) warmer, clearer floodplain water is greatly diminished compared to natural processes. However, throughout the Yazoo River system dredging schedules have been neglected. This has allowed the rivers to recover substantially, even to the point where many stream reaches, floodplains, and their associated hydrologic regimes have characteristics not unlike those of unaltered lowland stream reaches elsewhere in the region. Corresponding to this neglect are increased benefits to human society, in consumptive (e.g., fisheries) and nonconsumptive dimensions (e.g., aesthetics and existence values).

Human Impacts and Special Features

As described, the Yazoo River basin is a highly modified ecosystem, primarily from construction of dams on the upstream tributaries and channelization, dredging, floodplain clearing, and other abuses in the lower river. Before these alterations the river was highly dynamic, depending on extensive floodplain forests, highly variable river–floodplain interactions, and accumulations of wood in channels as essential habitats for river animals. The altered hydrology from dams and channel maintenance continues to have negative impacts on aquatic fauna that have evolved in more variable environments.

Although terribly abused during the past century, the Yazoo River ecosystem has shown some degree of recovery thanks to a mild temperate climate, substantial rainfall, deep, nutrient-rich soils, and, most of all, an evolving sense of natural resources stewardship and stream conservation throughout the region. The traditional advocates for river ecosystem destruction are losing voice and political influence throughout the region as a result of changing demographics. Throughout Mississippi there is growing

sentiment that people must learn to live with the rivers rather than be pitted against them. However, constant vigilance is required in order to keep those who would abuse the river ecosystems in check (Jackson and Jackson 1989). To this end, river conservation educational efforts have been initiated that emphasize fisheries and sociological/cultural connections to the rivers and their natural resources, and keep the issues alive and active in public forums.

Through public school education programs, civic and religious group involvement, legislative initiatives, and support from nonprofit conservation organizations and professional societies, the public is learning that the flood-control dams throughout the Yazoo River basin have negative impacts from river fishery perspectives, but these have been ameliorated to a certain extent by development of the reservoir and tailwater fisheries (Jackson and Marmulla 2000). In addition, and in spite of flood-control programs, the public is becoming aware that flooding is good because it maintains lateral connectivity between the rivers and their respective floodplains (Junk et al. 1989, Flotemersch et al. 1999) and enhances overall system productivity and floodplain river fisheries (Cloutman 1997, Jackson et al. 1993, Jackson and Ye 2000).

ADDITIONAL RIVERS

The Atchafalaya River is a 224 km long distributary that receives 20% to 50% of the LMR's annual flow and all of the flow from the Red River (Fig. 6.18). Removal of a 30 km long logjam in the Atchafalaya near the former confluence of the Mississippi and Red rivers in 1855 allowed both rivers to begin flowing down the Atchafalaya. Numerous subsequent actions of the USACE (dredging, levee construction, etc.) culminating with construction of the Old River Control Structure in 1963 shaped the Atchafalaya into a deep (24 to 55 m) river with the 6th largest average flow in North America (5178 m³/s). The Atchafalaya Basin Floodway (2129 km²) contains the largest bottomland hardwood forest (>1500 km²) in North America. The floodway, which is confined by levees (see Fig. 6.18), consists of a natural maze of distributary channels, bayous, lakes, and cypress–tupelo gum swamps that is now crisscrossed with canals dug to facilitate oil and gas extraction. During high water the floodway becomes a 24 to 32 km wide sheet of water flowing to the Gulf of Mexico. Physical and chemical conditions (shade, turbidity, low nutrients) do not support

high levels of aquatic primary production (Bryan et al. 1975). However, the trees and macrophytes are very productive and provide high levels of particulate and dissolved organic matter to the system.

The Cache River, paralleled by a major tributary, Bayou De View, flows southward 229 km along the western edge of the Coastal Plain in northeastern Arkansas (Fig. 6.20). The long narrow (<29 km) basin covers 5240 km² of nearly flat alluvial deposits of clay, silts, and sand. Natural vegetation in the basin consists of cypress–tupelo gum swamps and seasonally flooded (March to May), diverse bottomland hardwood forests that include overcup oak, Nuttall's oak, water hickory, green ash, cottonwoods, willows, and buttonbush (Smith 1996). These wetlands constitute one of the largest and least-disturbed tracts of this habitat type (~60,000 ha) remaining in the LMR basin. Hydrology of the system is also fairly natural, with low flow in early to midsummer, elevated in late summer and fall (Fig. 6.21). Some impacts are associated with irrigating rice in the basin (Wilber et al. 1996) and with removal of about 65% of the forest cover for production of cotton, rice, and soybeans (Kress et al. 1996). The Cache River and associated wetlands are an intact flood-pulse ecosystem (Junk et al. 1989), with production of fishes significantly enhanced by their exploitation of the seasonally flooded forests (Killgore and Baker 1996).

The Ouachita River basin significantly enhances the habitat diversity and biotic diversity found in the Lower Mississippi River basin. Approximately the first 400 km of the 974 km long river flows east across the steep (1.64 m/km), rocky terrain of the Ouachita province. Near Hot Springs, Arkansas, the river turns to the south-southeast to cross the flatter (0.17 m/km), fine alluvium of the Coastal Plain to its confluence with the Tensas River, which together become the Black River in northern Louisiana (Fig. 6.22). The Black River soon thereafter joins the Red River just before it empties into the Atchafalaya River distributary of the Mississippi River. The Ouachita is naturally different in these two distinct physiographic provinces, but the differences are increased by three hydroelectric and flood-control reservoirs along the main stem just before it enters the Coastal Plain (see Fig. 6.22). Two other main-channel locks and dams facilitate the small amount of barge traffic up to Camden, Arkansas. The large watershed (64,206 km²) is less impacted by land use, with 84% forested and only 9% cleared for pasture. However, silviculture (Brown et al. 1997, Smith et al. 2001), mining (barite, sand, rocks, gravel), and petroleum extraction/refining have impacted the biota. A special

feature is the 263 km² Felsenthal National Wildlife Refuge centered around a 60 km² natural lake in the Ouachita River just north of the Louisiana border.

The Saline River (from its source as the Alum Fork) is a 328 km long gravel-bed stream whose watershed drains the eastern Ouachita province. Near Benton, Arkansas, it enters the Coastal Plain and continues about 186 km to its confluence with the Ouachita River in the Felsenthal National Wildlife Refuge (Fig. 6.24). The headwater streams (Alum Fork, North Fork, Middle Fork, and South Fork) are listed by the Arkansas Department of Environmental Quality as Extraordinary Resource Waters for their exceptional water quality and the presence of an endangered mussel, the Arkansas fatmucket; an endangered fish, the Ouachita madtom; and several other species of special concern (e.g., taillight shiner, peppered shiner, and southern pocketbook mussel). There are numerous small reservoirs in the headwaters tributaries, including the 555 ha Lake Winona on Alum Fork and 167 ha Lake Norrell on North Fork. However, downstream from these the Saline is the only river in the Ouachita province that flows >200 km without being impounded (Fig. 6.7). Water quality remains good to excellent in lower reaches of the Saline and it is an excellent smallmouth bass stream.

The Current River flows southeasterly from its source in Missouri for 215 km to its confluence with the Black River in Arkansas (Fig. 6.26). This river and its chief tributary, the Jack's Fork, are spring fed with substantial flow all year (mean discharge 77 m³/s; Fig. 6.27), unlike most other Ozark streams that experience seasonal low flows. The Current and Jack's Fork were protected from reservoir construction by the Ozark National Scenic Riverways Act in 1964, and the riverway is now managed by the National Park Service. The Current is one of the few remaining natural, free-flowing rivers in the lower 48 conterminous United States (Fig. 6.1). Both streams have gradients of about 1 m/km, have cherty limestone gravel-cobble substrates, and distinct riffle–pool geomorphology. The clean, cool waters of the Current and Jack's Fork rivers and the scenic Ozark Plateaus landscape attract numerous visitors, most of whom traverse the rivers by float tubes, canoes, rafts, john boats, or jet skis during the summer. The macroinvertebrate assemblage is moderately diverse and productive (Rabeni et al. 1995), and crayfishes account for half of invertebrate production. Smallmouth bass, rock bass, and longear sunfish are the most abundant sportfishes among the approximately 117 fish species.

ACKNOWLEDGMENTS

We are indebted to John (Sonny) Hall and his wife Carolyn Hall for several guided tours by numerous means of travel (hiking, boats, ATVs, auto) in the region where the Arkansas and White rivers flow into the Mississippi River. We appreciate Jack Kilgore and Jan Hoover and Ken Shirley for sharing unpublished data with us. Lists of endangered species for the Atchafalaya and Mississippi rivers in Louisiana were supplied by the Louisiana Natural Heritage Program. Assistance with lists of endangered species in Arkansas was provided by the Arkansas Game and Fish Commission. The USGS Nonindigenous Aquatic Species Database was very useful for identifying nonnative species in several of the rivers.

FIGURE 6.9 Mean monthly air temperature, precipitation, and runoff for the Lower Mississippi River basin.

LOWER MISSISSIPPI RIVER

Relief: 826 m (LMR only), 4141 m (entire basin)

Basin area: $3.27 \times 10^6 \text{ km}^2$

Mean discharge: $18,400 \text{ m}^3/\text{s}$

River order: 10

Mean annual precipitation: 140 cm (LMR only),
94 cm (entire basin)

Mean air temperature: 17°C (LMR only)

Mean water temperature: 16°C

Physiographic provinces: Coastal Plain (CP), Ouachita Province (OP), Ozark Plateaus (OZ)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Mississippi Embayment, Ozark Highlands, Ouachita Highlands

Terrestrial ecoregions: Mississippi Lowland Forests, Central U.S. Hardwood Forests, Ozark Mountain Forests, Piney Woods Forests, Southeastern Mixed Forests

Number of fish species: 375 (entire Mississippi basin)

Number of endangered species: 3 fishes, 2 mussels,
1 bird (main stem only)

Major fishes: longnose gar, shortnose gar, shovelnose sturgeon, bowfin, gizzard shad, threadfin shad, central silvery minnow, speckled chub, silver chub, emerald shiner, river shiner, silverband shiner, mimic shiner, river carpsucker, blue sucker, smallmouth buffalo, blue catfish, channel catfish, flathead catfish, inland silverside, white bass, sauger, freshwater drum

Major other aquatic vertebrates: American alligator, western cottonmouth, snapping turtles, softshell turtles, Mississippi mud turtle, red-eared turtle, bullfrog, pigfrog, southern leopard frog, beaver, muskrat, river otter, nutria, great blue heron, cormorant, cattle egret, ibis, belted kingfisher

Major benthic invertebrates: mayflies (*Pentagenia*, *Tortopus*, *Stenonema*, *Baetis*), caddisflies (*Hydropsyche*, *Potamyia*), true flies (*Chaoborus*, *Rheotanytarsus*), crustaceans (*Procambarus*, *amphipods*), mollusks (*Sphaerium*), oligochaete worms (*Limnodrilus*, *Branchiura*, *Nais*), hydrozoans (*Cordylophora*, *Hydra*), turbellarian flatworms (*Dugesia*)

Nonnative species: Asian clam, zebra mussel, common carp, grass carp, silver carp, bighead carp, striped bass, rainbow smelt, rainbow trout, chinook salmon, American shad, greenhouse frog, nutria, alligatorweed, wild taro, water hyacinth, Peruvian water grass, Eurasian watermilfoil, water lettuce, curly pondweed, water spangles, dotted duckweed

Major riparian plants: willow, bald cypress, water tupelo, Nuttall's oak, swamp chestnut oak, overcup oak, sweetgum, ash, river birch, cottonwood, Eastern hophornbeam, water hickory, pecan, buttonbush, drummond maple, dwarf palmetto, palmettos, greenbriers, poison ivy, giant river cane, maidencane, alligatorweed

Special features: third largest river basin in world, with extensive floodplain habitats

Fragmentation: no dams on LMR main stem but highly modified for navigation and flood control

Water quality: $\text{pH} = 7.7$, alkalinity = 161 mg/L as CaCO_3 , $\text{NO}_3\text{-N} = 1.4 \text{ mg/L}$, $\text{PO}_4\text{-P} = 0.13 \text{ mg/L}$

Land use: 80% agriculture, 16% forest, 4% urban/other (LMR); 57% agriculture, 28% forest/shrub, 14% urban (entire basin)

Population density: 10 people/km^2 (LMR only)

Major information sources: Baker et al. 1991, Rutherford et al. 1995

FIGURE 6.8 Map of the Lower Mississippi River basin. Physiographic provinces are separated by yellow lines.

FIGURE 6.11 Mean monthly air temperature, precipitation, and runoff for the White River basin.

WHITE RIVER

Relief: 731 m

Basin area: 72,189 km²

Mean discharge: 979 m³/s

River order: 7

Mean annual precipitation: 117 cm

Mean air temperature: 15°C

Mean water temperature: 19°C

Physiographic provinces: Ozark Plateaus (OZ),
Ouachita Province (OP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Ozark Highlands, Mississippi Embayment

Terrestrial ecoregions: Ozark Mountain Forests,
Central U.S. Hardwood Forests, Mississippi Lowland Forests

Number of fish species: 163

Number of endangered species: 5 mussels, 10 fishes

Major fishes: longnose gar, gizzard shad, central stoneroller, Mississippi silvery minnow, Ozark minnow, bullhead minnow, emerald shiner, bigeye shiner, duskystripe shiner, blacktail shiner, mimic shiner, northern hogsucker, black redhorse, channel catfish, blue catfish, Ozark bass, longear sunfish, smallmouth bass, white crappie, rainbow darter, orangethroat darter, banded sculpin

Major other aquatic vertebrates: American alligator, snapping turtle, Mississippi mud turtle, map turtle, slider, softshell turtles, cottonmouth, midland water snake, yellow-bellied water snake, cricket frog, bullfrog, green frog, southern leopard frog, pickerel frog, muskrat, beaver, river otter, raccoon, mink, great blue heron, belted kingfisher

Major benthic invertebrates: mayflies (*Tortopus*, *Pentagenia*, *Baetis*, *Stenonema*, *Caenis*), stoneflies (*Acronuria*), caddisflies (*Chimarra*, *Hydropsyche*, *Agapetus*), hellgrammites (*Corydalus*), beetles (*Stenelmis*, *Psephenus*, *Optioseruus*), crustaceans (*Orconectes*), mollusks (threeidge, rabbitsfoot, pimpleback, pocketbook, and pistolgrip mussels; *Elimia*)

Nonnative species: Asian clam, zebra mussel, grass carp, common carp, silver carp, bighead carp, yellow perch, sauger, walleye, redeye bass, striped bass, white bass, American shad, threadfin shad, northern pike, muskellunge, chain pickerel, brown bullhead, cutthroat trout, rainbow trout, brown trout, brook trout, lake trout, Eurasian watermilfoil, water hyacinth, duck lettuce

Major riparian plants: willows, witchhazel, American sycamore, river birch, red maple, buttonbush, cottonwood, American elm, green ash, box elder, sugarberry, sweetgum, Nuttall's oak, bald cypress, water tupelo, hickories, river cane, poison ivy, greenbrier, cucumber vine, smartweed

Special features: karst topography in headwaters, extensive bottomland hardwood forest floodplains; two tributaries are National Rivers

Fragmentation: 4 large dams on main stem, 3 large dams on tributaries

Water quality: pH = 7.65, alkalinity = 110.5 mg/L as CaCO₃, NO₃-N = 0.39 mg/L, PO₄-P = 0.07 mg/L

Land use: 28% agriculture, 70% forest, 1% urban (upper/middle region); 83% agriculture, 8% forest, 1% urban (lower region)

Population density: 18 people/km²

Major information sources: Arkansas Department of Environmental Quality 2000, Bayless and Vitello 2001, U.S. Geological Survey 2000a, Ken Shirley (personal communication)

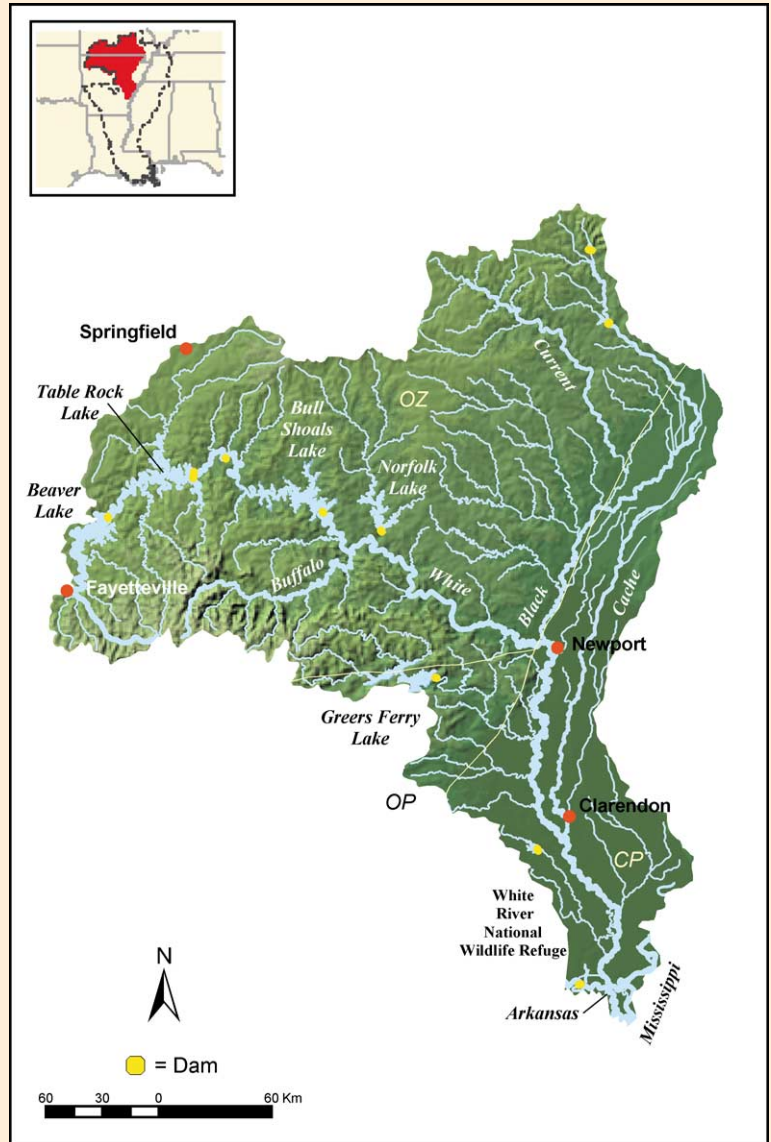

FIGURE 6.10 Map of the White River basin. Physiographic provinces are separated by yellow lines.

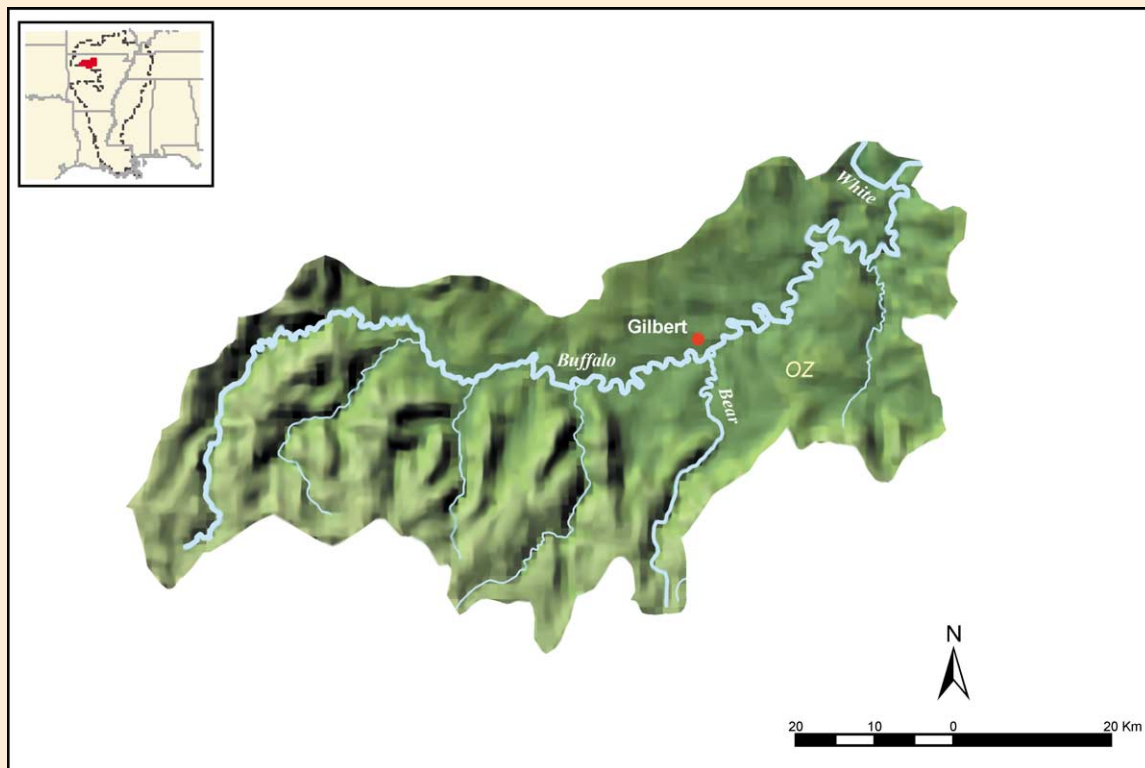

FIGURE 6.12 Map of the Buffalo National River basin.

BUFFALO NATIONAL RIVER

Relief: 666 m

Basin area: 3465 km²

Mean discharge: 48 m³/s

River order: 4

Mean annual precipitation: 107 cm

Mean air temperature: 15°C

Mean water temperature: 13°C

Physiographic province: Ozark Plateaus (OZ)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Ozark Highlands

Terrestrial ecoregion: Ozark Mountain Forests

Number of fish species: >66

Number of endangered species: 9 riparian vascular plants, 1 mussel

Major fishes: longear sunfish, smallmouth bass, largemouth bass, spotted bass, Ozark bass, largescale stoneroller, dusky stripe shiner, rosyface shiner, telescope shiner, bigeye shiner, Ozark madtom, slender madtom, channel catfish, banded sculpin, greenside darter, rainbow darter, Arkansas saddled darter, yoke darter, banded darter, gilt darter, Ozark minnow, bigeye chub, northern hogsucker

Major other aquatic vertebrates: beaver, river otter, mink, common snapping turtle, map turtle, slider, midland smooth softshell turtle, western cottonmouth, midland water snake, yellow-bellied water snake, red river waterdog, cricket frog, bullfrog, green frog, southern leopard frog, pickerel frog, great blue heron, belted kingfisher

Major benthic invertebrates: mayflies (*Pseudocloeon*, *Heptagenia*, *Stenonema*, *Ephemerella*, *Isonychia*, *Baetis*, *Ephoron*), stoneflies (*Perlesta*), beetles (*Lutrochus*), caddisflies (*Agapetus*, *Cheumatopsyche*), crayfishes (*Orconectes*) mollusks (mucket, spike, plain pocketbook, Ozark broken-ray, Ozark pigtoe, and bleedingtooth mussels; *Elimia potosiensis*, *Pleurocera acuta*)

Nonnative species: freshwater jellyfish, Asian clam, common carp, fathead minnow, western mosquitofish, largemouth bass, smallmouth bass, walleye, rainbow trout

Major riparian plants: American elm, green ash, silver maple, box elder, American sycamore, river birch, black willow, Ward's willow, sandbar willow, cottonwood, sweetgum, witchhazel, buttonbush, giant river cane, sea oats, sedges, water willow

Special features: almost pristine main stem protected as National River; one of few natural free-flowing rivers in conterminous 48 states

Fragmentation: none

Water quality: pH = 7.6, alkalinity = 102.3 mg/L as CaCO₃, NO₃-N = 0.14 mg/L, PO₄-P = 0.06 mg/L

Land use: 9.5% agriculture, 90% forest, 0.5% urban/other

Population density: 7 people/km²

Major information sources: Arkansas Department of Environmental Quality 2000, U.S. Geological Survey 2000a

FIGURE 6.13 Mean monthly air temperature, precipitation, and runoff for the Buffalo National River basin.

FIGURE 6.15 Mean monthly air temperature, precipitation, and runoff for the Big Black River basin.

BIG BLACK RIVER

Relief: 152 m

Basin area: 8770 km²

Mean discharge: 107 m³/s

River order: 4

Mean annual precipitation: 135 cm

Mean air temperature: 17.7°C

Mean water temperature: 17.2°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi Embayment

Terrestrial ecoregions: Southeastern Mixed Forests, Central U.S. Hardwood Forests, Mississippi Lowland Forests

Number of fish species: 112 (native)

Number of endangered species: 1 fish, 1 reptile, 2 mussels

Major fishes: flathead catfish, blue catfish, channel catfish, smallmouth buffalo, bigmouth buffalo, black buffalo, freshwater drum, white crappie, black crappie, largemouth bass, gizzard shad, bluegill, longnose gar, spotted gar, blue sucker, paddlefish, blacktail shiner, emerald shiner, striped shiner, creek chubsucker, freckled madtom, blackspotted topminnow, central stoneroller, scaly sand darter, slough darter, logperch darter, dusky darter

Major other aquatic vertebrates: beaver, river otter, cottonmouth, red-bellied water snake, common snapping turtle, alligator snapping turtle, slider, Mississippi map turtle, great blue heron, green heron, little blue heron, wood duck, mallard, kingfisher

Major benthic invertebrates: mayflies (*Baetis*, *Cinygmula*, *Tricorythodes*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Nectopsyche*), hellgrammites (*Corydalus*, *Chauliodes*), beetles (*Ancyronyx*, *Stenelmis*), dragonflies (*Gomphus*), black flies (*Prosimulium*), mussels (mucket, rock pocketbook, butterfly, mapleleaf)

Nonnative species: Asian clam, common carp, grass carp, goldfish, striped bass, bluespotted sunfish, dotted duckweed, parrot feather, sacred lotus, water lettuce

Major riparian plants: American sycamore, red maple, river birch, black willow, green ash, cottonwood, water oak, willow oak, water tupelo, bald cypress, honey suckle, American lotus, waterlily, water shield, pondweed, cattail, water primrose, alligatorweed

Special features: only free-flowing river in Mississippi that flows directly into Mississippi River; intact forested floodplain; numerous Civil War relics (sunken gunboats)

Fragmentation: no dams; only portions of lowermost reaches impacted by channel modification

Water quality: suspended sediment varies seasonally, with average of 134.8 mg/L, pH = 7.0, alkalinity = 48.4 mg/L as CaCO₃, hardness = 49.8 mg/L as CaCO₃, NO₃-N = 0.24 mg/L, PO₄-P = 0.25 mg/L

Land use: 35% agriculture, 11% pastureland, 54% forest

Population density: 25 people/km²

Major information sources: Holman et al. 1993, Insaurralde 1992

FIGURE 6.14 Map of the Big Black River basin.

FIGURE 6.17 Mean monthly air temperature, precipitation, and runoff for the Yazoo River basin.

YAZOO RIVER

Relief: 195 m

Basin area: 35,000 km²

Mean discharge: 523 m³/s

River order: 6

Mean annual precipitation: 134 cm

Mean air temperature: 17.6°C

Mean water temperature: 21.5°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi Embayment

Terrestrial ecoregions: Mississippi Lowland Forests

Number of fish species: 119 (native)

Number of endangered species: 1 threatened reptile (federal); 2 endangered fishes (state), 13 endangered mussels (federal)

Major fishes: flathead catfish, blue catfish, channel catfish, smallmouth buffalo, bigmouth buffalo, freshwater drum, white crappie, black crappie, largemouth bass, gizzard shad, bluegill, longnose gar, spotted gar, blue sucker, paddlefish, black buffalo, striped bass

Major other aquatic vertebrates: beaver, river otter, cottonmouth, bullfrog, common snapping turtle, alligator snapping turtle, Mississippi map turtle, slider, great blue heron, wood duck

Major benthic invertebrates: mayflies (*Baetis*, *Caenis*, *Cinygmula*, *Stenonema*, *Potamanthus*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Nectopsyche*), hellgrammites (*Chauliodes*, *Corydalus*), beetles (*Peltodytes*, *Berosus*, *Atrichopogon*), true flies (*Chaoborus*, *Simulium*, *Prosimulium*, *Hemerodromia*)

Nonnative species: freshwater jellyfish, Asian clam, common carp, grass carp, bighead carp, goldfish, white bass, striped bass, yellow perch, walleye, fathead minnow, American shad, tilapia, alligatorweed, water hyacinth, dotted duckweed, parrot feather, water lettuce

Major riparian plants: American sycamore, red maple, river birch, black willow, green ash, cottonwood, water oak, willow oak, water tupelo, bald cypress, honey suckle, water primrose, spikerush, alligatorweed, water shield, cattail, American lotus, waterlily, pondweed

Special features: tremendously productive recreational and “artisanal” fisheries for catfish; floodplains internationally important overwintering areas for migratory waterfowl

Fragmentation: major dams on tributaries (Coldwater, Little Tallahatchie, Yocona, Yalobusha–Skuna); extensive channelization

Water quality: suspended sediments = 168.4 mg/L, pH = 7.0, alkalinity = 45 mg/L as CaCO₃, NO₃-N = 0.20 mg/L, PO₄-P = 0.29 mg/L

Land use: 60% to 80 % agriculture, 15% to 30% forest, 5% to 10% other

Population density: 16 people/km²

Major information sources: www.mdwfp.state.ms.us/museum/html/research, www.msstate.edu/Dept/GeoSciences/climate, Runner et al. 2002, Mississippi Department of Environmental Quality 1992, Wiseman 1982, Jackson et al. 1993, Insaurralde 1992, Jackson and Ye 2000

FIGURE 6.16 Map of the Yazoo River basin.

FIGURE 6.19 Mean monthly air temperature, precipitation, and runoff for the Atchafalaya River basin.

ATCHAFALAYA RIVER

Relief: 15 m

Basin area: 8345 km²

Mean discharge: 5178 m³/s

River order: not applicable

Mean annual precipitation: 153 cm

Mean air temperature: 20°C

Mean water temperature: 22°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi Embayment

Terrestrial ecoregion: Mississippi Lowland Forests

Number of fish species: 181

Number of endangered species: 1 mammal, 3 fishes, 1 reptile, 3 birds, 1 riparian plant

Major fishes: redear sunfish, bluegill, smallmouth buffalo, white crappie, black crappie, largemouth bass, warmouth, white bass, spotted gar, alligator gar, channel catfish, blue catfish, gizzard shad, threadfin shad, freshwater drum, bowfin, common carp, emerald shiner, silverband shiner, mimic shiner, golden shiner, mosquitofish, inland silverside

Major other aquatic vertebrates: American alligator, western cottonmouth, yellow-bellied water snake, bullfrog, pigfrog, southern leopard frog, beaver, muskrat, river otter, mink, nutria, great blue heron, green heron, cormorant, belted kingfisher, egrets, ibis, anhinga, wood duck

Major benthic invertebrates: mayflies (*Tortopus*, *Pentagenia*), caddisflies (*Hydropsyche*), true flies (*Coelotanypus*, *Polypedilum*, *Chaoborus*), crustaceans (White River crawfish, red swamp crayfish, *Palaemonetes kadiakensis*, *Lirceus*, *Gammarus*, *Hyalella*), mollusks (*Sphaerium*, mapleleaf mussel, *Anodonta*, *Physa*), oligochaete worms (*Limnodrilus*)

Nonnative species: Asian clam, zebra mussel, grass carp, silver carp, bighead carp, common carp, nutria, water hyacinth, Eurasian watermilfoil, hydrilla, alligatorweed, wild taro, horsefly's eye, Brazilian water weed, dotted duck weed, marshweed, Uruguay seedbox, parrot feather, brittle naiad, watercress, rice, duck lettuce, torpedo grass, water lettuce, water spangles

Major riparian plants: bald cypress, black willow, water tupelo, drummond maple, cottonwood, river birch, American sycamore, sweetgum, sugarberry, buttonbush, ash, smartweed, fanwort, coontail, Eurasian watermilfoil, pondweed, duckweed, frogbite, bladderwort, maidencane, cattails, dwarf spikerush, purple ammania, palmetto

Special features: 3rd largest continuous wetland area in United States, with about 30% of all bottomland hardwood forests in Mississippi Alluvial Plain; Mississippi River distributary that captured Red River

Fragmentation: no dams, but extensive levees; discharge determined by control structures (dams and floodgates) linking Atchafalaya to Mississippi and Red rivers

Water quality: pH = 7.4, alkalinity = 105 mg/L as CaCO₃, NO₃-N = 1.2 mg/L, PO₄-P = 0.22 mg/L, becomes anoxic during summer low flow

Land use: 33.5% forest/wetland, 63% agriculture, 3.5% urban/other

Population density: 18 people/km²

Major information sources: Patrick 1998, Rutherford et al. 2001, Sabo et al. 1999, U.S. Geological Survey 2000a

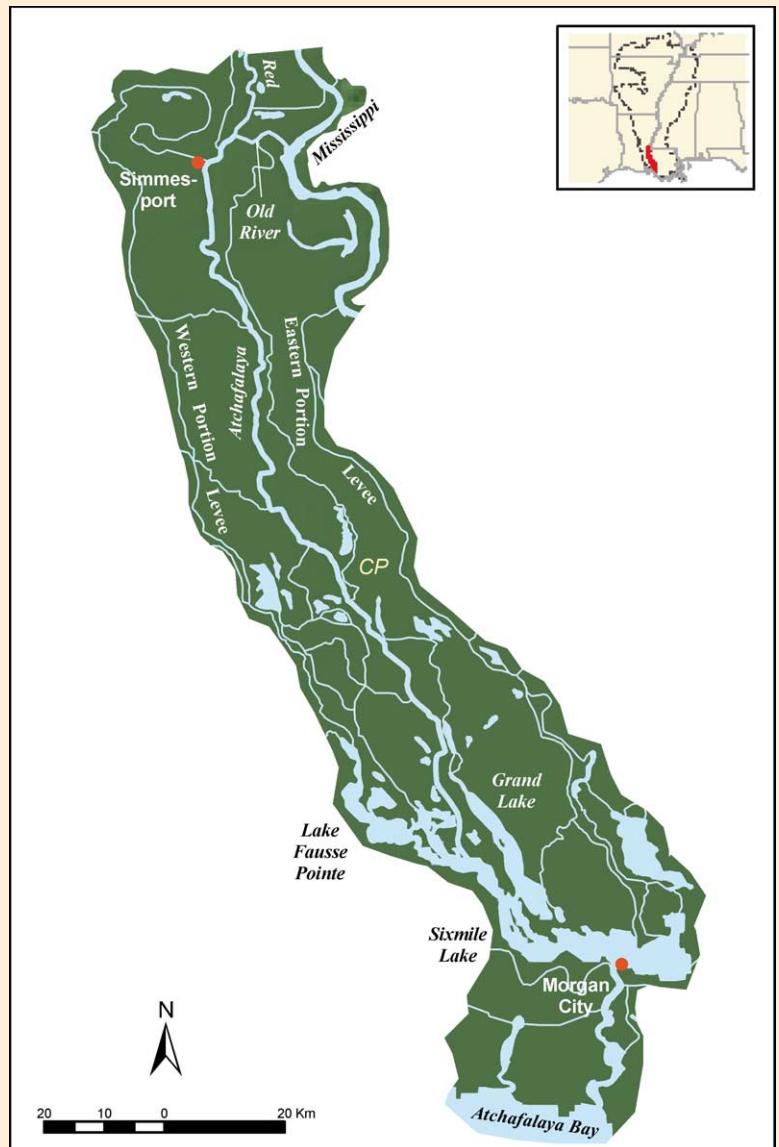

FIGURE 6.18 Map of the Atchafalaya River basin.

FIGURE 6.21 Mean monthly air temperature, precipitation, and runoff for the Cache River basin.

CACHE RIVER

Relief: 50 m

Basin area: 5227 km²

Mean discharge: 68 m³/s

River order: 4

Mean annual precipitation: 126 cm

Mean air temperature: 16°C

Mean water temperature: 17°C

Physiographic province: Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Ozark Highlands

Terrestrial ecoregion: Mississippi Lowland Forests

Number of fish species: 32

Number of endangered species: 1 mussel

Major fishes: gizzard shad, pugnose minnow, bullhead minnow, spotted sucker, channel catfish, tadpole madtom, blackspotted topminnow, flier, black crappie, blacktail shiner, mud darter, bluntnose darter, slough darter, cypress darter, speckled darter, river darter, logperch, spotted gar, shortnose gar, smallmouth buffalo, mosquitofish, longear sunfish, orangespotted sunfish, bluegill

Major other aquatic vertebrates: beaver, muskrat, river otter, mink, great blue heron, alligator snapping turtle, snapping turtle, stinkpot turtle, map turtle, Mississippi map turtle, slider, midland smooth softshell turtle, spiny softshell turtle, western cottonmouth, yellow-bellied water snake, midland water snake, green water snake, broad-banded water snake, bullfrog, green frog, southern leopard frog, marbled salamander

Major benthic invertebrates: mayflies (*Baetis*, *Caenis*, *Stenacron*), caddisflies (*Cheumatopsyche*, *Pycnopsyche*), alderflies (*Sialis*), beetles (*Berosus*, *Macronychus*), midges (*Tribelos*), damselflies (*Argia*), crustaceans (*Orconectes*, *Gammarus*, *Palaemonetes*), mussels (threeridge, bankclimber, pimpleback, mapleleaf), oligochaete worms (*Dero*)

Nonnative species: Asian clam, common carp, grass carp, bighead carp, chain pickerel, grass pickerel, sauger, Eurasian watermilfoil

Major riparian plants: overcup oak, Nuttall's oak, water oak, willow oak, red maple, water hickory, American elm, water elm, persimmon, bald cypress, pumpkin ash, honey locust, sweetgum, stiff dogwood, American hornbeam, swamp privet, buttonbush, Virginia sweetspire

Special features: contains Black Swamp, one of largest contiguous bottomland forests in Lower Mississippi Valley; one of few natural free-flowing rivers in conterminous 48 states

Fragmentation: no dams but extensive channelization in upper and middle reaches

Water quality: pH = 7.5, alkalinity = 81.6 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₃-P = 0.25 mg/L

Land use: 81% agriculture, 17% forest, 1.5% urban/other

Population density: 23 people/km²

Major information sources: Arkansas Department of Environmental Quality 2000, U.S. Geological Survey 2000a

FIGURE 6.20 Map of the Cache River basin.

FIGURE 6.23 Mean monthly air temperature, precipitation, and runoff for the Ouachita River basin.

OUACHITA RIVER

Relief: 810 m

Basin area: 64,454 km²

Mean discharge: 843 m³/s

River order: 6

Mean annual precipitation: 130 cm

Mean air temperature: 17°C

Mean water temperature: 16°C

Physiographic provinces: Ouachita Province (OP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Ouachita Highlands, Mississippi Embayment

Terrestrial ecoregions: Piney Woods Forests, Ozark Mountain Forests, Mississippi Lowland Forests

Number of fish species: 80

Number of endangered species: 10 mussels, 2 fishes

Major fishes: spotted gar, longnose gar, northern hog sucker, spotted sucker, black redhorse, golden redhorse, central stoneroller, bigeye shiner, rosyface shiner, redbfin shiner, steelcolor shiner, bluntnose minnow, blackspotted topminnow, channel catfish, freckled madtom, brook silverside, green sunfish, spotted bass, orangebelly darter, greenside darter, channel darter

Major other aquatic vertebrates: snapping turtle, stinkpot turtle, Mississippi mud turtle, Ouachita map turtle, southern painted turtle, midland smooth softshell turtle, western spiny softshell turtle, western cottonmouth, broad-banded water snake, yellow-bellied water snake, diamondback water snake, green water snake, bullfrog, green frog, southern leopard frog, great blue heron, belted kingfisher, river otter, mink

Major benthic invertebrates: stoneflies (*Amphinemura*), mayflies (*Isonychia*, *Caenis*, *Stenonema*), caddisflies (*Hydroptila*, *Agapetus*, *Chimarra*), hellgrammites (*Corydalus*), beetles (*Stenelmis*), crustaceans (*Orconectes*, *Caecidotea*, *Lirceus*), mollusks (Wabash pigtoe, mucket, flutedshell, threeridge, giant floater, and Louisiana fatmucket mussels, *Physa*)

Nonnative species: Asian clam, threadfin shad, grass carp, common carp, silver carp, bighead carp, northern pike, muskellunge, chain pickerel, blue catfish, white catfish, striped bass, sauger, walleye, rainbow trout, brown trout, brook trout, alligatorweed, wild taro, water hyacinth, yellow iris, parrot feather, water lettuce, hydrilla, Eurasian watermilfoil

Major riparian plants: American sycamore, sweetgum, shortleaf pine, loblolly pine, American hornbeam, eastern hophornbeam, red oak, beech, American holly, Ozark witchhazel, water tupelo, poison ivy, greenbrier, smartweed

Special features: geothermal hot springs in basin; natural reservoir formed by Felsenthal basin

Fragmentation: 5 impoundments on main stem; 1 large impoundment on each of two major tributaries

Water quality: pH = 7.1, alkalinity = 22.5 mg/L as CaCO₃, NO₃-N = 0.19 mg/L, PO₄-P = 0.05 mg/L; mercury levels have resulted in a fish consumption advisory; thermal impacts of reservoirs

Land use: 13% agriculture, 81% forest, 6% urban/other

Population density: 16 people/km²

Major information sources: Arkansas Department of Environmental Quality 2000, U.S. Geological Survey 2000a

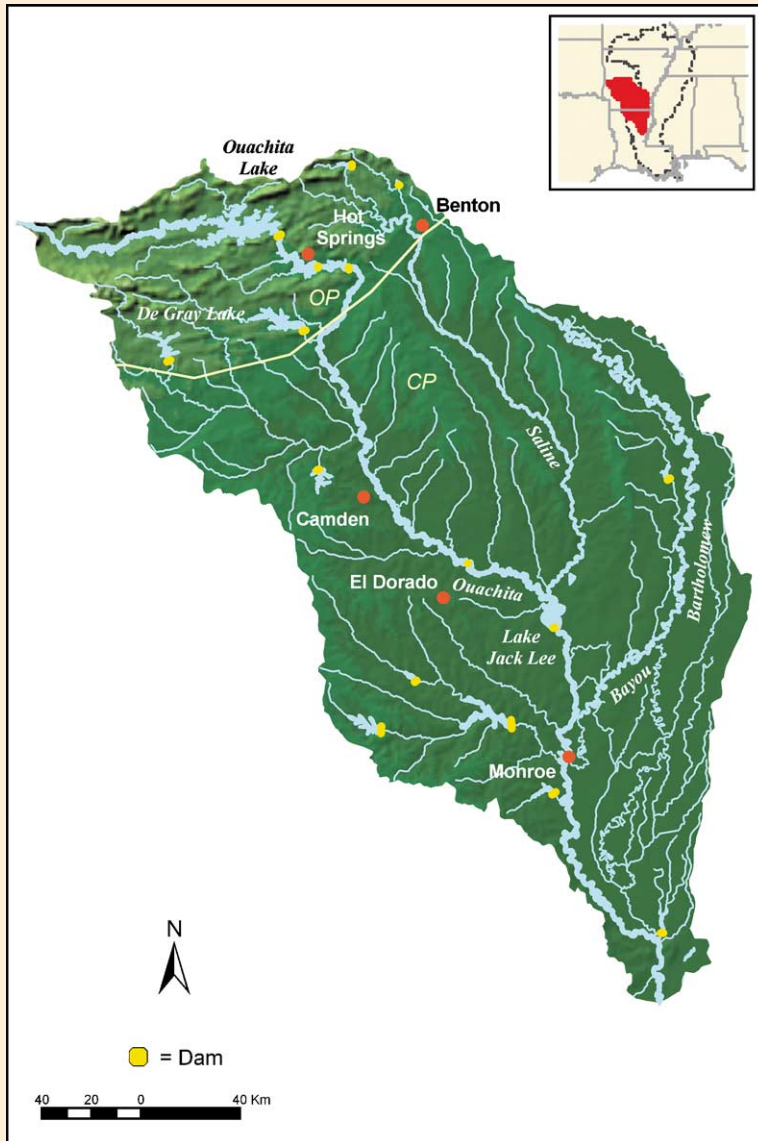

FIGURE 6.22 Map of the Ouachita River basin. Physiographic provinces are separated by a yellow line.

FIGURE 6.25 Mean monthly air temperature, precipitation, and runoff for the Saline River basin.

SALINE RIVER

Relief: 532 m

Basin area: 5465 km²

Mean discharge: 89 m³/s

River order: 5

Mean annual precipitation: 130 cm

Mean air temperature: 17°C

Mean water temperature: 17°C

Physiographic provinces: Ouachita Province (OP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Ouachita Highlands

Terrestrial ecoregion: Piney Woods Forests

Number of fish species: 85

Number of endangered species: 3 mussels, 1 fish

Major fishes: smallmouth bass, largemouth bass, spotted bass, warmouth, shadow bass, longear sunfish, bluegill, green sunfish, banded pygmy sunfish, black crappie, channel catfish, Ouachita madtom, cypress darter, taillight shiner, peppered shiner, redbfin shiner, big eye shiner, striped shiner, steelcolor shiner

Major other aquatic vertebrates: snapping turtle, Ouachita map turtle, midland smooth softshell turtle, midland water snake, yellow-bellied water snake, diamondback water snake, green water snake, western cottonmouth, red river waterdog, green frog, bullfrog, southern leopard frog, pickerel frog, belted kingfisher, great blue heron, muskrat, beaver, mink, river otter

Major benthic invertebrates: mayflies (*Stenonema*, *Isonychia*), stoneflies (*Neoperla*, *Amphinemura*), caddisflies (*Chimarra*, *Cheumatopsyche*), hellgrammites (*Corydalus*), beetles (*Psephenus*), crustaceans (*Orconectes*), mussels (ladyfinger, fluted shell, Ouachita kidneyshell, black sandshell, Wabash pigtoe, Louisiana fatmucket, squawfoot)

Nonnative species: freshwater jellyfish, Asian clam, grass carp, common carp, goldfish, walleye, chain pickerel, blue catfish, threadfin shad, fathead minnow

Major riparian plants: water oak, willow oak, red oak, sweetgum, American sycamore, black willow, river birch, buttonbush, smooth alder, eastern hophornbeam, American hornbeam, common winterberry, haws, water willow, smartweed

Special features: one of the few natural free-flowing rivers in conterminous 48 states (last in Ouachita Mountain area); excellent float and fishing river

Fragmentation: no major dams, 2 small ones in headwaters

Water quality: pH = 7.0, alkalinity = 39.9 mg/L as CaCO₃, NO₃-N = 0.1 mg/L, PO₄-P = 0.05 mg/L

Land use: headwaters >90% forest, remainder >50% agricultural

Population density: 17 people/km²

CURRENT RIVER

Relief: 372 m
 Basin area: 6776 km²
 Mean discharge: 77 m³/s
 River order: 6
 Mean annual precipitation: 123 cm
 Mean air temperature: 15°C
 Mean water temperature: 17°C
 Physiographic provinces: Ozark Plateaus (OZ), Coastal Plain (CP)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: Ozark Highlands
 Terrestrial ecoregion: Central U.S. Hardwood Forests
 Number of fish species: 117
 Number of endangered species: 5 mussels, 1 snail, 2 fishes, 1 hellbender

Major fishes: smallmouth bass, rock bass, longear sunfish, northern hog sucker, central stoneroller, rosyface shiner, telescope shiner, Arkansas saddled darter, greenside darter, rainbow darter, fantail darter, stargazing darter, mountain madtom, blackspotted topminnow

Major other aquatic vertebrates: snapping turtle, softshell turtle, Mississippi map turtle, midland water snake, western cottonmouth, green frog, beaver, river otter, muskrat, raccoon, mink, great blue heron, belted kingfisher, green-backed heron

Major benthic invertebrates: mayflies (*Stenonema*, *Baetis*), stoneflies (*Neoperla*, *Leuctra*), caddisflies (*Hydropsyche*, *Ceratopsyche*), hellgrammites (*Corydalus*), beetles (*Stenelmis*), crustaceans (*Orconectes luteus*, *O. punctimanus*), mollusks (Ozark pigtoe, Ozark broken-ray, round pigtoe, rainbow mussels; *Ammicola*, *Physa*, *Elimia*)

Nonnative species: Asian clam, common carp, chain pickerel, grass pickerel, white bass, walleye, rainbow trout, brown trout

Major riparian plants: American sycamore, box elder, American elm, winged elm, slippery elm, black willow, river birch, hackberry, silver maple, sugar maple, bur oak, green ash, white ash, common witchhazel, spicebush, pawpaw, American hornbeam, flowering dogwood, hawthorns, poison ivy, water willow, smartweed

Special features: 161 km protected as Ozark National Scenic Riverways; numerous large springs provide 60% of base flow; one of few natural free-flowing rivers in conterminous 48 states

Fragmentation: none

Water quality: pH = 7.8, alkalinity = 145 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.05 mg/L

Land use: 17% agriculture, 83% forest, <1% urban

Population density: 6 people/km²

INTRODUCTION

Two large, separate river basins, the Arkansas and the Red, drain the southern Great Plains region of the United States south of the Kansas River and north of the Texas–Gulf coastal drainages (Fig. 7.2). All major rivers in the region drain generally from northwest to southeast and are tributaries of the Mississippi River. The Southern Plains region includes all of Oklahoma, much of western and central Arkansas, and parts of eastern New Mexico, Colorado, Kansas, north Texas, and western and central Louisiana. The region is characterized by shortgrass prairie in the west, mixed or tallgrass prairie in the midsection, and forests in the east. A general description of rivers in the southern Great Plains is in Matthews (1988), Matthews and Zimmerman (1990), and Brown and Matthews (1995).

The largest rivers (Arkansas, Canadian, Red, Washita, Cimarron) all have upper main stems that lack flow at times and mid- and downstream reaches that are wide, shallow, and sand or mud bottomed. They are some of the hottest and harshest aquatic habitats on Earth, with water temperatures reaching near 40°C when exposed to full sun under low flow conditions. Hefley (1937), describing the South Canadian River near Norman, Oklahoma, wrote,

“Probably no more ecologically dynamic region exists: the seasonal, diurnal, and yearly fluctuations of meteorological factors are great and sudden; the course of the river changes with each succeeding rain and the shifting sand . . . is constantly being moved by wind and water.” Adding to this the intense summer heat and winter cold of the region, organisms of these rivers are challenged by harsh, rapidly changing environmental conditions (Matthews and Hill 1979, Matthews 1987, Matthews and Zimmerman 1990).

People occupied the Arkansas and Red basins 11,500 to 10,000 years ago as hunters of the last ice age large animals (mammoths, mastodons, and big horned bison), roaming from central Texas, where they apparently spent winters fashioning and refurbishing tools from cherts of the region. By 10,500 years ago, the Ouachita Mountain parts of the Arkansas and Red basins were primarily grasslands, with sparse, riparian woodlands of oak and pine. Hunter-gatherers there and in the Ozarks focused on deer, turkey, small game, and wild plant foods. By 7500 years ago the Ozarks and Ouachitas were denuded of most woodlands, as a hot, dry Altithermal climate prevailed until about 4500 years ago. Recovery from the adverse effects of the Altithermal climatic regime was slow. Substantial numbers of

FIGURE 7.2 Southern Plains rivers covered in this chapter.

hunter-gatherers came to occupy the eastern parts of the Arkansas and Red basins, and by 2000 years ago they were adopting the bow and arrow and manufacturing pottery. By 1500 years ago these people were becoming farmers of corn, beans, and squash, and by 900 years ago major populations of these people occupied the fertile valleys along the Grand, Arkansas, Poteau, Little, and Red rivers in eastern Oklahoma and adjacent Arkansas. Meanwhile, to the west, sizeable societies of part-time bison hunters and farmers were spreading along the Washita River in Oklahoma, the South Canadian River in the Texas panhandle, and the Beaver (North Canadian) River in the Oklahoma panhandle (D. Wyckoff, personal communication).

By 500 years ago these people were undertaking major migrations and social change as climatic fluc-

tuations adversely affected farming and other native societies moved into the plains from the Mississippi Valley and the Great Basin. It was during this transitional period that French and Spanish explorers began recording native inhabitants and lifeways in the basins of the Red and Arkansas rivers (D. Wyckoff, personal communication). The Arkansas and Red basins first came under European control under the claims of Spanish explorers like Coronado and de Soto. By the early 1700s many French explorers, trappers, and traders came into the region, making contact with and in many cases marrying native people. Spain was recognized by other European nations as the owner of the region in treaties of 1762–1763 (Morris et al. 1986), but transferred ownership of “Louisiana” to France in negotiations in 1800–1802. The United States purchased

“Louisiana” for \$15,000,000 in 1803, by which most of the Red and Arkansas river basins, along with the Missouri and western Mississippi basins, became permanently owned by the United States. Following this purchase, numerous military expeditions throughout the West provided the first records of natural history of the region, and the stage was set for European dominance of the Red and Arkansas river basins.

In spite of similarities among the larger rivers, the streams of the region are so diverse overall that they represent many of the types of rivers in North America, ranging from shallow, unstable sand-bed rivers, to tumultuous montaine headwaters, to small rivers in upland valleys of modest gradient. We selected four focus rivers in the region, including the Arkansas, Canadian, Red, and Little rivers. The Canadian and Little river systems are substantial tributaries of the Arkansas and Red rivers, respectively, but their dominance of the landscape or their unique faunas cause us to give them special attention. Of the many lesser rivers in the southern Great Plains, seven best represent the wide range of diverse physical, hydraulic, and floral–faunal characteristics of streams of the southern Great Plains: the Cimarron, Neosho (Grand), Illinois, and Poteau in the Arkansas River basin and the Washita, Blue, and Kiamichi in the Red River basin. Some of these smaller rivers differ substantially from most other streams in the region (e.g., the calcareous, marl-depositing Blue River), and we included them for their unique features.

Physiography and Climate

Physiographic provinces included in the region are Southern Rocky Mountains, Great Plains, Osage Plains section of the Central Lowland province, Coastal Plain, Ozark Plateaus, and Ouachita Province (Hunt 1974). The latter two provinces are known collectively as the “Interior Highlands” in many treatments of fauna, particularly fishes. The region is quite diverse (Brown and Matthews 1995) and includes some of the highest mountains in the conterminous United States, vast expanses of flat plains, parts of the Gulf Coastal Plain, the highly eroded Ozark Mountains, the ridge and valley structures of the Ouachita Mountains, and numerous smaller but important uplifted areas, including the Flint Hills in Kansas and the Wichita and Arbuckle mountains in Oklahoma. Outside the mountainous areas the landscape of the region appears relatively flat, but the plains drop from an elevation exceeding

1200 m at the base of the Rocky Mountains to 50 m asl or less in the east. A major feature of the western part of the region is the Llano Estacado or “Staked Plain,” which rises abruptly along a long north–south line in the Texas and Oklahoma panhandles, forming a high level plain of immense proportions.

Geologically, the region is complex (Hunt 1974). It was not glaciated in the Pleistocene, but glaciation to the north had strong influence on river courses and connectivity in the southern plains (Cross et al. 1986) and likely on distributions of aquatic organisms. The Arkansas and Canadian rivers arise in granitic-volcanic terrain as high-gradient, turbulent streams over boulder-strewn channels, with the upper Arkansas River sufficiently large and high gradient to support a white-water rafting industry.

Thus, at the extreme western edge of the region are mixed volcanic and metamorphic rock and Tertiary or Mesozoic sedimentary deposits, mostly of marine origin. Dominance of marine sedimentary deposits continues east onto the Great Plains, with streambeds also characterized by outwash from the Rocky Mountains (Hunt 1974, Brown and Matthews 1995). Much of the region in eastern Kansas, most of Oklahoma, and western Arkansas includes marine and continental sediments of Mississippian, Pennsylvanian, and Permian age, with sedimentary Cretaceous formations in southeast Oklahoma and southwest Arkansas. The Red River from south-central Oklahoma through Louisiana passes mostly over Quaternary sedimentary deposits of fluvial origins, as does the Arkansas River after it drops off the Fall Line onto the Mississippi Delta of the Coastal Plain (Hunt 1974). As a consequence of geologic diversity between and within the river drainages, the physical structure of rivers in the southern Great Plains ranges from high-gradient riffle–pool headwaters to wide, shallow, sandy river main stems, with substrates varying from boulder and bedrock to fine river sands.

Extensive geological and podological research near the Great Bend of the Arkansas River documents soil development and surface stability about 36,000 years ago, followed by wind and water erosion until some 22,000 years ago. The region was a C₄ dominated grassland, where horses, camels, and mammoths were the prevalent large herbivores. By 21,000 years ago the Wisconsinan glaciation was nearing its maximum. Silt from the glacial front was deposited in the Arkansas basin, and macrofossil finds indicate that at least scattered stands of spruce woodlands were present along the middle Arkansas River during full glacial times. To the east, in the

Grand (Neosho) watershed, spruce and pine woodlands persisted until at least 12,000 years ago. During full glacial times the High Plains and their eroded eastern margins in the Red and Arkansas basins were lush grasslands where mammoth, camel, and big horned bison were common (D. Wyckoff, personal communication).

Total rainfall and its temporal distribution has long been the bane of settlers in the western parts of the region. Thornthwaite (1941) noted about the Great Plains, “Men have been badly fooled by the semiarid regions because they are sometimes humid, sometimes desert, and sometimes a cross between the two.” The Llano Estacado of eastern New Mexico and west Texas, through which the Red River, Canadian River, and southern tributaries of the Arkansas River pass, is so lacking in surface water that a patrol of “Buffalo Soldiers” of the 10th Cavalry, somewhere near the headwaters of the Red River in 1877, drank the blood and urine of their horses in an attempt to survive (Leckie 1967).

Climate differs markedly from southeast to northwest. Louisiana and eastern Arkansas are in a region of hot summers (daily average temperature about 28°C in July) and moderate winters. In the western part of these river basins, summers are also hot, but winters can have extended periods of cold and true blizzard conditions. Snow cover is not persistent, however, except at high elevations in the mountainous westernmost parts of the Arkansas and Canadian rivers. Air temperatures in the headwaters of the Canadian and Arkansas rivers in Colorado–New Mexico are cold, influenced by elevation, but even on the lower-altitude western plains in the upper parts of these basins mean air temperature in January is below freezing. Mean annual precipitation decreases from >120cm in Arkansas or Louisiana to about 20cm in the west, in the rain shadow of the Rocky Mountains (Brown and Matthews 1995). Because of its central location in the North American continent, air masses from the Pacific Ocean, Gulf of Mexico, and Canada converge in the region, resulting in some of the most violent weather on Earth (e.g., central Oklahoma averages more tornados per year than any other location, and the most powerful tornado ever recorded hit Oklahoma City on May 3, 1999).

Basin Landscape and Land Use

Biomes within the southern Great Plains region include Temperate Mountain Forest, Temperate Grasslands, and Temperate Deciduous Forest. Terrestrial ecore-

gions in the southern Great Plains include, roughly from west to east, the Colorado Rockies Forests, Western Short Grasslands, Central and Southern Mixed Grasslands, Flint Hills Tall Grasslands, Central Forest/Grassland Transition Zone, Ozark Mountain Forests, Piney Woods Forests, and Mississippi Lowland Forests (Ricketts et al. 1999). Major rivers like the Red, Canadian, and Arkansas flow through and cut across the terrestrially defined ecoregions but have such distinctive faunas that some states (e.g., Oklahoma) have officially recognized an additional “Big Rivers Ecoregion” that represents these unique large rivers and their associated riparian zones. A prominent feature within the Central Forest/Grassland Transition Zone is the “Crosstimbers,” a mosaic of forest, woodland, savanna, and prairie vegetation dominated by post oak and blackjack oak (Hoagland et al. 1999) about 100km wide east to west and extending from southern Kansas to north Texas.

Before European settlement many river main stems in the east flowed through vast forests, and even in the western part of the region riparian forests of cottonwood, willow, or chinaberry existed before they fell to the axes of early settlers in need of timber and firewood. One enormous cottonwood near the Canadian River in present-day north Texas was reported by Capt. Randolph Marcy as being 19.5 feet (almost 6m) in circumference. Historically, vast forests covered the Interior Highlands and unbroken grasslands extended to the west. Forests of the Ozark Mountains remain relatively like the original oak–hickory forest and probably have had the least cultural modification overall. The Ouachita Mountains in south Arkansas and eastern Oklahoma were dominated in presettlement times by relatively open parkland of large pine trees interspersed with grasses.

Beyond the immediate proximity of the rivers, much of the western part of the region was covered in presettlement times by seemingly endless plains of short grasses. Near the headwaters of the Red and Canadian rivers, Marcy described “the elevated plateau of the Staked Plain, where the eye rests upon no object of relief within the scope of vision,” and that “the grass upon the Staked Plain is generally a very short variety of misquite [*sic*], called buffalo-grass, from one to two inches in length, and gives the plains the appearance of an interminable meadow that has been recently mown very close to the earth” (Foreman 1937).

Rivers have played major roles in the European human history of the region. In 1806, Capt. Zebulon Pike’s expedition followed the Arkansas River from Great Bend west to the Rocky Mountains, but a

detachment under Lt. James Wilkerson turned downstream at Great Bend to follow the Arkansas past the present site of Webbers Falls, Oklahoma, thence to New Orleans. These explorations provided some of the earliest accounts of the landscape and natural history of the Arkansas River region. Other pre-Civil War explorations of the Arkansas River region in Kansas–Colorado were by parties under command of or including Maj. Stephen Long, Thomas Say, Jacob Fowler, Jedediah Smith, John C. Fremont, and Washington Irving. Further south, substantial explorations and descriptions of natural history were by Col. George Sibley (Chikaskia River and Salt Fork of the Arkansas), Maj. Stephen Long (Red River, Kiamichi River, Mountain Fork, Poteau River), Thomas Nuttall (botanical descriptions of streams and mountains in southeast Oklahoma, then the Arkansas, Grand, Verdigris, Canadian, North Canadian, Deep Fork, and Cimarron rivers, and native peoples encountered therein), and a variety of other military or trading expeditions (Morris et al. 1986). Highly significant in knowledge of natural history of the region were the “Pacific Railroad Surveys” westward across the region under the command of Whipple, Marcy, and others, completed by the War Department in the 1850s.

In the mid-1800s, military expeditions under Marcy and Whipple followed the major east–west rivers like the Canadian and Red to seek routes for railroads, trade and commerce, or westward settlement. Steamboats navigated the Arkansas and Red rivers upstream to eastern Oklahoma by the early 1800s, and rivers became corridors along which movements of settlers and military were common. Throughout the 1800s, native peoples from elsewhere in the United States were displaced from their homelands and moved to the region that would become Oklahoma. The major original native people in the Red and Arkansas basins prior to the European-mediated displacements of the 1800s were the Kichai and Caddo in Louisiana, eastern Oklahoma, and southwest Arkansas; the Quapaw and Osage in southern Oklahoma, northeast Oklahoma, Arkansas, and Kansas; the Wichita along the Red River; and the Comanche, Kiowa-Apache, and Apache on the high plains to the west. Arapaho and Cheyenne lands were generally north of the Arkansas River basin (Socolofsky and Self 1988), but these nomadic peoples of the high plains no doubt were also present in the Southern Plains region at times.

European settlement of the Arkansas or Red River basin was advanced by establishment of military forts throughout the region from about 1820

onward, by the existence of federal wagon roads after 1849, by stage routes through the region after 1850, by cattle trails from Texas that crisscrossed the region from about 1840 to 1897, by sheep trails up the Arkansas River from the 1870s to 1900, and by establishment of railroads with access to commerce in western Kansas and eastern Colorado after 1865, followed by rail lines throughout the region by the 1870s and 1880s. Statehood promoted settlement by the establishment of permanent governments, with the states in the Southern Plains region granted statehood as follows: Louisiana (1812), Arkansas (1836), Texas (1845), Kansas (1861), Colorado (1876), and Oklahoma (1907).

Europeans dramatically changed the region by plowing the prairies, cutting forests, mining, altering patterns of stream flow, and extracting oil and natural gas. The region is now a mosaic of private timber production, large areas of forest under federal ownership and management, row-crop production, and cattle ranching, with only a few large cities and very limited heavy manufacturing. In recent decades, large-scale swine and poultry production has sharply increased, threatening water quality. Feedlots for cattle also cause local water-quality problems. Plowing of native prairie caused increases in silt and associated losses of some fish species in streams (Cross and Moss 1987). Fire suppression on former prairies allowed encroachment of trees, and the introduced cattle imposed grazing patterns very different from those of the wide-ranging native bison they replaced. The last “virgin forest” in the central United States (in the Ouachita Mountains) was harvested for timber before 1950 (Smith 1986) and replaced by pine monoculture, now cut mostly for pulp, particle board, and similar products.

As the vast southern bison herd was annihilated in the late 1800s, open ranging of cattle began, followed by huge privately owned cattle ranches hundreds of square kilometers in size or larger (e.g., in the upper Red River region). Where water was available, row crops of wheat, corn, sorghum, milo, cotton, and, more recently, peanuts came to dominate the landscape. Center-pivot irrigation allowed extension of row crops farther west than formerly possible, but decimated important aquifers like the Ogallalah, which formerly recharged many prairie streams but now is reduced and imperiled. A dramatic example of irrigation and aquifer depletion is in the Oklahoma Panhandle. There, a sharp increase in numbers of high-capacity irrigation wells (since about 1960) coincided with a dramatic increase in the number of “no-flow” days per year in the Beaver

(upper North Canadian) River. No-flow days increased from fewer than 20 before 1960 to almost 100 in many of the years from 1980 to the present (<http://nwis.waterdata.usgs.gov/ok/nwis/discharge>).

Discovery of oil and gas resulted in further changes to the landscape in the 1900s, with negative impacts on some streams from salt water and other byproducts of drilling. In some areas, mining for zinc, lead, or other minerals contaminated large terrestrial areas and polluted streams like Tar Creek in northeast Oklahoma. Limited coal mining in the east and some gold mining in the west has had local impacts on streams. However, the region largely lacks raw materials, such as iron, copper, or coal, that support heavy manufacturing, so rivers here escaped some of the pollution problems. An increasing lack of water relative to demands, siltation from agriculture, local sewage or agricultural pollution due to large agribusinesses, impacts of impoundments, and generally poor water quality or physical conditions for biota in western parts of the region remain the most serious challenges to streams in the region. Rivers to the east, including the Little, Kiamichi, Neosho (Grand), and Illinois, may be some of the “best” in North America in retaining much of their original presettlement biodiversity and aesthetic quality. However, some, like the Blue River, are under increasing user pressure and erosion of overall quality.

Ultimately, the largest cities in the region grew on or near major rivers, including Little Rock and Fort Smith, Arkansas; Shreveport, Louisiana; Tulsa and Oklahoma City, Oklahoma; and Wichita, Kansas. With construction of the Kerr-McClellan navigation system from 1957 to 1970 widening and modifying the Arkansas and Verdigris rivers, Tulsa, Muskogee, and Little Rock became major barge ports, linking those inland cities to overseas commerce. The construction of numerous locks and dams along that system, in addition to the large dams and reservoirs on most river systems in the region, have changed irreversibly the channel configurations and flow schedules of these systems (although not necessarily altering overall annual discharge for river basins).

The Rivers

Rivers of the region flow through the Southern Plains, Central Prairie, Ozark Highlands, Ouachita Highlands, and Mississippi Embayment “freshwater ecoregions” (Abell et al. 2000). However, these freshwater ecoregions are very large and therefore generalized, and there is great diversity of streams

within any one ecoregion. The rivers included in this chapter fall into two rather different groups on the basis of their upland versus lowland characteristics. The group including the Arkansas, Canadian, Red, Washita, and Cimarron rivers represents typical large to medium-size low-gradient prairie main stems with wide, shallow, braided, unstable sand-bed channels, often carrying heavy loads of large wood snags washed in by floods. These form massive brush piles around bridge abutments, requiring regular removal in some rivers (e.g., Washita River in southern Oklahoma). These rivers are highly distinctive as habitats or “ecoregions” within the region, containing animals and plants (e.g., some fishes and riparian vegetation) not found elsewhere. The other rivers, including the Little, Kiamichi, Blue, Illinois, Neosho (Grand), and Poteau, arise in upland areas as stony-bottomed streams and are typified in their upper reaches by relatively clear water, differentiation into swift riffles and deep pools, and relatively diverse and stable structural features. As streams of this latter group leave the uplands they become more turbid, sluggish, and incised but lack the braided sand-bed channels that typify rivers of the other group.

However, even within these groups each river has unique features of topography and biota, hence their inclusion here to provide a cross-section of rivers typical of the southern Great Plains region. The main-stem Red River arises in the Texas Panhandle near Amarillo, Texas, and lacks any montaine snowmelt influence. The Arkansas River and the Canadian River originate in the Rocky Mountains, and thus are influenced by snowmelt in their upper reaches. However, as they emerge from the mountains onto the dry western plains they lose water from evaporation or agricultural withdrawals and become small streams in western Oklahoma and Kansas.

In sharp contrast to low-gradient rivers flowing eastward across the prairies and grasslands, other rivers in the region arise in heavily forested, uplifted areas like the Ozark and Ouachita mountains in Oklahoma–Arkansas, the Arbuckle Mountains of Oklahoma, and the Flint Hills of Kansas. The Neosho (Grand), Illinois, Blue, Kiamichi, and Little rivers are strongly influenced in physiognomy by the uplifted areas where they arise and through which they flow for much of their length. Streams originating in these uplands typically have high-gradient headwaters with strong base flow (in spite of some dramatic drought conditions in recent years), more benign environmental conditions, clear water, and stony bottoms with much more well-defined riffle–pool configurations than for prairie streams.

Large to modest-size springs dominate base flow in the Ozarks and Arbuckles, whereas the Ouachita uplands have fewer large springs and their streams arise from runoff and more gradual influx of sub-surface water. Rivers in the eastern mesic part of the region generally have more reliable flow, complex physical structure, and diverse faunas than rivers further west.

Late-summer drying of streams in the region is a function of both evapotranspiration and lowered rainfall. Shallow river main stems in the midportion of the region can enter winter under drought conditions if autumn rains are lacking, and under those conditions icing can be substantial in main channels. To the southeast, icing of river main stems typically does not occur. In most of the region spates can occur in any month of the year, and flow patterns are unpredictable (Resh et al. 1988, Brown and Matthews 1995). The rivers influenced by snowmelt may have more predictable seasonal patterns, but their flow also becomes erratic after entering the plains.

Extreme rainfall events result in annual or more frequent bankfull spates and streambed scouring in many of the smaller tributaries to the main rivers. For example, in October 1981, approximately 43 cm of rain fell in a two-day period in parts of south Oklahoma, resulting in massive flooding of small streams and alteration and complete scouring and reshaping of their physical structure. Such events also cause widespread flooding of main rivers, rearrangement of their sand-bed substrates and braided flow patterns, and extreme water-level fluctuations in main-stem reservoirs. Conversely, severe drought years have occurred in the region in recent decades (e.g., 1977–1979, 1981, 1991, 1998, and 2000), with long reaches of streams dewatered or reduced to small, isolated pools and reservoirs reaching very low levels. Under such conditions temperature and oxygen stress can be extreme, and animals crowded into shrinking habitats may experience density-dependent as well as density-independent constraints on their growth, survival, or population sizes (Matthews et al. 2001). Although the fauna is largely resistant to or adapted for physical stress, some evidence now suggests that recurrent drought may be having impacts on stream fishes (W. J. Matthews, unpublished data) and mussels (D. Spooner and C. C. Vaughn, unpublished data).

The rivers that originate in the Rocky Mountains (Canadian, Arkansas) arise as retentive, debris-regulated channels that become alluvial gravel beds with fluvially formed riffle–pool structure farther

downstream and wide, braided sandbed channels after entering the plains (Brown and Matthews 1995). Other streams originating in the region arise as alluvial gravel riffle–pool channels or sand-bed or mud-bottomed streams. In the prairie portions of rivers like the upper Arkansas, Red, Canadian, Cimarron, and Washita, harsh physical conditions owing to solar heating, extreme and extended winter cold, and unpredictable drought or flooding limit development of the biota and may disrupt the transitions in flora and fauna hypothesized for more stable systems. Rivers in the prairie may be characterized by local patchiness of habitat and physico-chemical conditions (e.g., local refugia formed at mouths of creeks entering river main stems). There, deeper shaded refugia, compared to the shallow exposed main stems, may provide less harsh thermal, oxygen, or other physical conditions (Matthews and Hill 1979). Sources of energy for streams in the western and central parts of the southern Great Plains likely differ from those in mesic forested regions in that headwaters of many systems lack riparian forest, and energy may come directly from autochthonous production (periphyton, biofilms) or from prairie grasses as allochthonous inputs.

In rivers arising in the mesic uplands to the east (including the Little, Kiamichi, Blue, Illinois, Neosho [Grand], and Poteau rivers) base flow (often spring fed) is more reliable, harsh physical conditions are less common, and a more predictable longitudinal zonation or continuum of biota and ecosystem processes may exist. However, most of these rivers are interrupted by dams, ranging from very large flood-control/hydropower structures to local low-head dams for municipal water supply or other uses, all potentially disrupting natural transitions of organisms and processes from headwaters to lower rivers. Finally, modern distribution of some aquatic organisms may be influenced by a large “Pre-Glacial Plains Stream” (Metcalf 1966, Cross et al. 1986) that hypothetically cut across present-day east–west river systems, draining into the lower Mississippi River or Gulf of Mexico, thus providing an avenue of north–south movement for stream fishes in the Pleistocene.

All large rivers and most small ones in the region have been dammed, resulting in reaches below dams in which physical conditions are markedly altered (e.g., increased water clarity due to trapping of silt in the reservoir; increased stony substrates in some cases). Rivers have been altered by clearing and snagging rivers for boat passage, contamination by salt water from oil production, and interbasin water

transfers (Red to Trinity river basins). However, many physical features of main stems in the central part of the region remain similar to presettlement/first explorer reports (Matthews 1988).

ARKANSAS RIVER

The Arkansas River basin is the largest in the lower Great Plains, draining the western Mississippi River basin south of the Missouri River basin (Fig. 7.7). It originates in central Colorado near some of the tallest peaks in North America. Denver may be the “Mile High” City, but the Arkansas River could claim the title of “two mile” river because it drops almost exactly two miles in elevation from its headwaters to its confluence with the Mississippi River. In its course it passes through highly changing terrain, climate, and land use. It has strong flow in the Rocky Mountains, loses water to evaporation and withdrawal in eastern Colorado and western Kansas (Ferrington 1993), then recharges to be a major plains river through the rest of its path to the Mississippi River. In Oklahoma, the main-stem Arkansas River is joined by the Salt Fork, Cimarron, Verdigris, Neosho (Grand), Illinois, and Canadian rivers. The Arkansas becomes a 7th order river at the confluence of the Verdigris, at which it remains to its confluence with the Mississippi River. Some old maps show the large White River of north Arkansas and southern Missouri as joining the Arkansas River before the latter enters the Mississippi River, but at present the White River flows directly into the Mississippi River and there is no direct connection of the White and Arkansas rivers (except perhaps during periods of major flooding).

The lower Arkansas River basin was occupied from 10,000 to 2000 years ago by Paleo-Indians similar to those of known bluff-dwelling sites in the Ozarks and Ouachita mountains, who produced characteristic projectile points and stone tools (Hanson and Moneyhon 1989). In the “formative period” of Paleo-Indian culture in the lower Arkansas basin, permanent villages appeared, and major mound-building cities arose. For example, the Spiro Mound, near the Arkansas River in eastern Oklahoma, produced a rich treasure of detailed and intricate artifacts, making clear that this was a major center of prehistoric culture. By the mid 1500s the Spanish explorer de Soto reported large native populations along the Arkansas River, with substantial fortified villages (Hanson and Moneyhon 1989). In the western Arkansas basin nomadic peoples like the

Kiowa, Comanche, Arapaho, and Cheyenne roamed the plains, with their mobility vastly increased and lifeways highly altered by dispersion of European horse onto the plains in the 1600s to early 1700s (Beck and Haase 1989). The upper Arkansas River basin was first explored with an eye toward permanent settlement beginning in about 1806, after the Louisiana Purchase, and during the next 50 years a substantial number of military and private expeditions used the upper Arkansas River as a conduit to the west.

Physiography, Climate, and Land Use

The Arkansas River basin flows primarily in an east-southeasterly direction, from latitude 39°N to latitude 34°N, passing through six physiographic provinces, including Southern Rocky Mountains (SR), Great Plains (GP), Central Lowland (CL), Ozark Plateaus (OZ), Ouachita Province (OP), and Coastal Plain (CP). This area includes the Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone, Ozark Mountain Forests, and Mississippi Lowland Forests terrestrial ecoregions (Ricketts et al. 1999). There is a wide range of vegetation, including coniferous uplands in the Rocky Mountains, short native grasses in the west, mixed to tallgrass prairie in the east, slopes covered with deciduous forests in the Ozarks, and dense Coastal Plain forest downstream in eastern Arkansas.

Climate varies greatly along the Arkansas River from central Colorado to eastern Arkansas. Near its headwaters in Colorado, mean monthly air temperatures typically range from -8°C in January to 13°C in July, with average annual rainfall about 51 cm. Overall, precipitation is greatest in May or June and lowest from December to February (Fig. 7.8). Mean temperatures are hottest in July and August and lowest in January. To the east, the climate is warm-subtropical, with generally hot, humid summers and mild winters and only occasional extreme cold events. At Pine Bluff, Arkansas, near the far eastern end of the basin, mean January temperature is 7°C, mean July temperature is 29°C, and rainfall exceeds 100 cm per year. In much of Colorado and western Kansas, January daily average temperatures are below freezing, but in eastern Oklahoma and Arkansas, January temperatures average well above freezing. From Colorado through western Kansas there is too little rainfall (<50 cm/yr) for farming without irrigation. As the river passes through Kansas and Oklahoma it traverses sharp increases in

rainfall, passing the 100 cm/yr isopleth in northeast Oklahoma.

Land use in the Arkansas basin varies with climate. In arid lands to the west, rangelands and grazing of cattle dominate, with row-crop agriculture, particularly wheat, increasing with rainfall to dominate the landscape through much of Kansas. In Oklahoma and Arkansas, row crops and livestock dominate the immediate river valleys, but the surrounding hills and mountains are heavily wooded. The entire region, with the exception of major cities like Pine Bluff, Little Rock, Fort Smith, Muskogee, Tulsa, and Wichita, is predominantly rural; oil and gas production is a major industry. There is little heavy manufacturing in the region; hard-mineral extraction is limited or localized and has no substantial impact on the river. Estimated percentages of land use outside of cities are, from U.S. Department of Agriculture maps, 50% rangeland and 50% cropland in the western parts of the basin, compared to 50% forest, 15% cropland, and 25% pasture further to the east.

River Geomorphology, Hydrology, and Chemistry

The Arkansas River is formed by creeks near Leadville, Colorado, at 3010 m asl, 30 km north of Mt. Elbert, the highest mountain in the state (and in the Arkansas River basin) at 4370 m asl. The Rocky Mountains in central Colorado are volcanic and metamorphic rock interspersed with sedimentary marine deposits; thus, the upper Arkansas River main stem flows through steep and rugged terrain en route to the plains. Near Canyon City, Colorado, it flows through the Royal Gorge, where one of the highest suspension bridges in the world passes over the turbulent main stem 320 meters below.

Downstream, it leaves the Rocky Mountains and flows near Pueblo, Colorado, onto the plains of east-central Colorado, becoming a low-gradient river through grazing and agricultural lands. Crossing Kansas, Oklahoma, and western Arkansas, the river traverses marine and continental sediments of Mississippian, Pennsylvanian, and Permian age, bisecting the formerly continuous Interior Highland (Ozark and Ouachita mountains) and finally reaching Quaternary sediments of the Mississippi Embayment. Before leaving Colorado the Arkansas is joined by the Purgatoire River, which drains very arid lands of southeastern Colorado, and forms John Martin Reservoir, the first large reservoir on the main stem.

Eastward in Kansas, it passes Garden City and Dodge City, losing water to become ephemeral upriver of Great Bend. The most severe dewatering has been in a reach from Syracuse to Great Bend, Kansas, where complete loss of surface flow has occurred in several places for as much as a year (Ferrington 1993). Serious declines in surface flow coincided with increases in groundwater withdrawal in the early 1970s (Ferrington 1993). Near Great Bend it receives water from the Pawnee River and passes near the famous Cheyenne Bottoms Wildlife Area, which is a critical wetland for waterfowl and a wide variety of birds in the Central Flyway. Downstream from Great Bend the Arkansas thus is again a “river,” about 20 m to more than 100 m wide in places, with moderate to swift current over coarse gravel and cobble in riffles and sand-bottomed pools to nearly a meter deep. Flowing through Wichita, Kansas, it has a braided, sandy channel, and beyond Wichita it is joined by the sandy Ninnescah River and the turbid Walnut River and is a sizeable stream as it crosses into Oklahoma. Immediately below the Kansas–Oklahoma border it becomes Kaw Lake, gains the Salt Fork of the Arkansas, and flows into Keystone Lake, impounded at the juncture of the Cimarron and Arkansas rivers.

Below Keystone Lake the Arkansas River flows through downtown Tulsa, Oklahoma, where it has a sand-bottomed, braided channel hundreds of meters wide, with flow strongly controlled by releases from the reservoir. Near Muskogee, Oklahoma, it is joined by the channelized Verdigris River and becomes the Kerr-McClellan Navigation System. The river passes through locks and dams and the Robert S. Kerr reservoir, exiting Oklahoma near Ft. Smith, Arkansas. At Ft. Smith the stream is a large, deep river several hundred meters wide, with mostly sand banks, and the channel is controlled by wing dikes and other navigational developments. Near Russellville, Arkansas, the river enters Dardanelle Reservoir, the last large man-made impoundment on the river. In central Arkansas the river gains more barge traffic at the port of Little Rock, then flows southeast through the large forests and rich farmlands of the Mississippi Delta to its confluence with the Mississippi River. From Little Rock downstream the river is low gradient, with broad meanders, backwater bays and sloughs, and flooded riparian forests, but is frequently interrupted by locks and dams of the Kerr-McClellan Navigation System. In its total course from headwaters in the Rocky Mountains to its confluence with the Mississippi River the Arkansas River has a mean overall slope of 185 cm/km.

Virgin discharge (1928 to 1939, before large dams) averaged 1004 m³/s downstream in the basin at Little Rock, Arkansas. For the entire period of record at Little Rock the mean annual discharge “prior to regulation” (1928 to 1969) was 1118 m³/s, whereas after upstream regulation by locks and dams, the mean annual discharge from 1970 to 2000 was 1389 m³/s (ranging from 360 to 2711 m³/s). Thus, overall flow statistics show that in spite of water withdrawal in Colorado and west Kansas and the highly regulated nature of the system, as much water is delivered downstream at Little Rock as during virgin flow conditions. Slightly upstream, near Van Buren, Arkansas, mean annual discharge only decreased from 885 to 826 m³/s after regulation by Lake Eufaula (on the Canadian River, a large tributary), further evidence of only modest changes in discharge relative to virgin flow conditions. Runoff (0.3 to 1.5 cm/mo) is low in the Arkansas River basin because it includes arid lands, with most of the precipitation lost as evapotranspiration before it ever reaches the mouth (see Fig. 7.8).

The headwaters near Leadville, Colorado, are cold even in summer (e.g., 10°C) and low in ion concentrations. Typical values at three USGS headwater sites include conductivity of 85 to 150 μS/cm, pH of 6.3, hardness of 30 to 50 mg/L as CaCO₃, and calcium, magnesium, sodium, and chloride all <10 mg/L. Crossing the plains, the river changes chemically so that below Great Bend, Kansas, the main stem is characterized by pH typically >8.0, conductivity of 1000 to 3000 μS/cm, total hardness of 300 to 500 mg/L as CaCO₃, alkalinity of 150 to 300 mg/L as CaCO₃, and ions dominated by sodium (300 to 500 mg/L) and chloride (200 to 800 mg/L), but with substantial magnesium (20 to 40 mg/L), calcium (100 to 130 mg/L), and sulfate (150 to 250 mg/L). From Ft. Smith downstream the main stem typically has pH of 7.5 to 8.3, conductivity of about 400 to 900 μS/cm, total hardness of 100 to 200 mg/L as CaCO₃, alkalinity of 80 to 130 mg/L as CaCO₃, sodium of 30 to 80 mg/L, chloride of 40 to 150 mg/L, magnesium of 10 to 15 mg/L, calcium of 30 to 50 mg/L, and sulfate of 40 to 90 mg/L. In the lower river in east Arkansas, where there is much row-crop agriculture, nutrients are high: Total organic nitrogen is typically 0.5 to 2.0 mg/L and sometimes as high as 4.0 mg/L, and total phosphorus is about 0.05 to 0.20 mg/L. Water temperatures of the main river in eastern Arkansas have reached 32°C in some summers and as low as 4°C in winter. Average year-round water temperature for the basin is estimated at about 18°C.

River Biodiversity and Ecology

As mentioned, the Arkansas changes greatly along its course, and in so doing passes through four freshwater ecoregions: Southern Plains, Central Prairie, Ozark Highlands, and Mississippi Embayment (Abell et al. 2000). The Ozark Highlands ecoregion is largely defined by its high-gradient tributaries that drain into the Arkansas River; the main stem remains a low-gradient river that does not itself pass through the Ozark Mountains before entering the Mississippi Embayment. There are no comprehensive, basinwide studies of the flora and fauna of the Arkansas River. Sections of the river are treated in appropriate “state” floral and faunal guides, and there have been substantial studies of fishes in Kansas and Colorado by the University of Kansas, Fort Hays State University, and Colorado State University.

Algae

Relatively little is known about algal communities of the Arkansas River. Wilhm et al. (1978), however, reported that phytoplankton was dominated by diatoms (109 of 128 taxa), with *Cyclotella* and *Melosira* the most abundant genera. Benthic diatoms included *Navicula*, *Surirella*, *Nitzschia*, *Synedra*, *Cocconeis*, *Amphiprora*, and *Gomphonema*.

Plants

Riparian areas are dominated by silver maple, box elder, bur oak, and red oak. Sugarberry is common. Cottonwood–willow woodlands are common on floodplains throughout the watershed. Cattails and American bulrush occur in temporarily flooded sloughs. Within-channel macrophytes are not a noteworthy feature of the main-stem Arkansas River.

Invertebrates

The Arkansas River supports a diverse array of macroinvertebrates. Hard substrates (clear, rocky areas of the upper river and woody snags throughout) support grazing mayflies such as *Stenonema* and *Heptagenia*, filtering caddisflies such as *Cheumatopsyche* and *Hydropsyche*, the stonefly *Neoperla*, and black flies (*Simulium*). Further downstream the mayflies *Caenis* and *Hexagenia* (a burrower) become more common. Chironomid midges associated with hard substrates include *Polypedilum*, *Rheotanytarsus*, and *Glyptotendipes* (Wilhm et al. 1978). Crayfishes include *Orconectes palmeri*,

O. virilis, *O. nais*, *Procambarus simulans*, and *P. acutus* (Reimer 1969, E. A. Bergey, personal communication). Goldhammer and Ferrington (1992) demonstrated the importance of “epirheic” zones of capillary water fringe habitats as sources of secondary production of aquatic invertebrates in the Cimarron River, a tributary of the Arkansas River.

Lower reaches of the Arkansas River contain a diverse “big-river” mussel assemblage dominated by the commercially important washboard mussel, threeridge, and mapleleaf. Other common mussels include pink papershell, bleufer, plain pocketbook, fluted shell, fragile papershell, pimpleback, fawns-foot, and pondhorn (Branson 1982, 1983, 1984, C. C. Vaughn, unpublished data). Two nonnative bivalves have invaded the Arkansas River: the Asian clam and the zebra mussel. Zebra mussels were introduced via barges in the early 1990s and are common in several main-stem impoundments, particularly Kerr Reservoir.

Vertebrates

The Arkansas River basin has 141 known species of native fishes and about 30 nonnative species. The number of native species occurring in the lower, middle, and upper river are 117, 111, and 64, respectively (Cross et al. 1986), with the fewest species in the far western reaches. Some species like longear sunfish occur widely in habitats from main stem to small tributaries, but others, like the river shiner or river darter, are mostly in the main channel. Native trout occur in the Arkansas River headwaters. The Arkansas River shiner, a federally threatened species, occurs in the main channel of the lower Arkansas River. Other main-stem-limited taxa of special interest are small minnows of the speckled chub complex, with the peppered chub (now rare or extinct) known from middle and upper portions of the system, and the shoal chub present in middle and lower parts of the drainage (Eisenhour 1999). The speckled chubs and Arkansas River shiner thus are unique faunal elements of the main stem. Collections made with small-meshed seines produced 7 and 9 species at a single site in the main stem of the upper Arkansas River at Great Bend, Kansas, compared to 16 and 17 species with about the same effort in shallow edges at a middle main-stem site at Webers Falls, Oklahoma. Below Ft. Smith in western Arkansas, T. M. Buchanan (personal communication) typically finds 18 to 20 species in similar seining samples in the main stem. The Arkansas River main stem in the lower parts of the basin is occupied by game fish like large-

mouth bass and spotted bass and the introduced striped bass, whereas upriver, where the main stem is smaller and shallower, white bass are more common piscivores. Channel catfish and blue catfish are also common in the main river. Formerly present anadromous species like American eel may persist lower in the basin, but their upstream passage through high dams is unlikely, so they would now be rare in the system upstream. Gars of the genus *Lepisosteus* are common in the lower main channel and associated backwaters or oxbow lakes.

Major aquatic amphibians or reptiles of the upper Arkansas River main stem and associated habitats (Colorado or Kansas) include plains leopard frog, American bullfrog (introduced in Colorado), snapping turtle, yellow mud turtle, common slider, midland smooth softshell turtle, western spiny softshell turtle, and northern water snake. Farther downstream (Oklahoma or Arkansas) are common snapping turtle, false map turtle, red-eared turtles, and several species or subspecies of water snakes. Cottonmouth are found from east Oklahoma downstream through Arkansas. Major riparian birds and mammals include white pelican (which sometimes overwinters), great blue heron, green heron, belted kingfisher, beaver (which are broadly increasing), and muskrat. River otter is an Oklahoma state species of special concern in the Arkansas River system, whose populations may be increasing due to stocking programs. River otter are increasing in Arkansas (Sealander and Heidt 1990), as are the nonnative nutria. Nonvegetated beaches and sandbars of the Arkansas River support breeding populations of the federally endangered interior least tern, including a protected population within the city of Tulsa.

Ecosystem Processes

The structure and function of Arkansas River ecosystems, from montaine headwaters to confluence with the Mississippi River, have not been studied comprehensively. Productivity in the headwaters is probably dominated by availability of coarse rock substrates and relatively clear water and perhaps nutrient limited, whereas far downstream the main river is sufficiently large and turbid that photosynthesis is probably restricted to upper parts of the water column and hard substrate processes are probably of minimal importance. The river downstream in Arkansas and Oklahoma is too deep in midchannel for substantial development of large snag piles, although wood is probably biologically important in backwaters or side channels. Comprehensive studies

of such processes for the lower main stem are lacking. Capillary fringe habitats (Goldhammer and Ferrington 1992), which have become scarcer since European settlement, may nonetheless be important sites of secondary production.

Many upland tributaries are stony bottomed, with algal communities forming thick coatings on substrates. In these tributaries, large standing crops of central stonerollers, other algae-eating minnows (Ozark minnow, southern redbelly dace), crayfishes, and snails likely have a strong influence on benthic algae and autochthonous primary productivity. In contrast, tributaries in prairie regions are typically muddy, with shifting mud-sand bottoms and a poorly developed benthic algal flora.

Human Impacts and Special Features

Within the southern Great Plains the Arkansas River is unique as the river most likely influenced by snowmelt from the Rocky Mountains and probably crossing more diverse landscapes than any other in the region. Its headwaters are high in the Rocky Mountains, followed by its passage as substantial rapids through rock-bound canyons, thence out onto the plains, where its loss and gain of water is dramatic. Crossing Kansas, what was a brawling mountain river is reduced to such a small size that one can literally step across it in places; then, to the east it again gains water to become a major river and a watercourse famous in European history, now dotted with large dams and their associated reservoirs.

Military posts were present on the Arkansas River by the early 1800s, and steamboats traveled upriver to Muskogee by that time. Throughout most of the history of European settlement the main Arkansas River remained largely unaltered, but the latter half of the 1900s saw marked changes, with modification by the Kerr-McClellan Navigation System upstream to Tulsa, addition of numerous large dams, and withdrawal of water in the western half of the basin. As previously noted, loss of water from the main channel of the river in western Kansas is extreme, owing to depletion of aquifers and removal of water for irrigation. This devastation of the main river channel must have had tremendous, albeit unknowable, impacts on the animals and plants that depended on the river in that reach of the plains in pre-European times. In addition, the channel has been modified by wing dikes and other navigation-control structures. Major impacts in the middle and lower river are locks and dams for boat passage, conversion of much of the midreach into the

Kerr-McClellan Navigation Channel, and construction of major on-channel reservoirs (Lake Dardanelle, Arkansas; Keystone Lake, Oklahoma). Major cities on the main-stem river include Wichita, Kansas, and Tulsa, Oklahoma, where major oil refineries are alongside the river. Zebra mussels have invaded the river via barges in the navigation channel.

CANADIAN RIVER

The Canadian River, with the North Canadian River (Beaver River in the Oklahoma Panhandle), is the longest tributary of the Arkansas River (Fig. 7.9). The main stem of the Canadian River is the “south” Canadian River, which flows eastward between 37°N and 35°N latitude and is joined by the North Canadian River and the Deep Fork River in Lake Eufaula in eastern Oklahoma just before the system joins the Arkansas River. We focus on the “south” Canadian River in this description. The Canadian, like the Arkansas, originates as a high-gradient stream in the southern Rocky Mountains, crosses vast, arid plains, where it courses through earthen-walled canyons or past steep bluffs, and then becomes a wide, sand-bed river through western and central Oklahoma. Through much of its midreach the river is shallow, flowing over mobile sand-bed substrates and exposed to intense solar heating in summer (Fig. 7.3). It is possible that no large river on Earth has a harsher or more rapidly changing thermal environment to challenge the existence of fishes and aquatic invertebrates (Hefley 1937, Matthews and Hill 1979).

Human history in the Canadian River basin is similar in many ways to that of the geographically parallel Arkansas and Red rivers. The same Paleo-Indians that roamed the upper Arkansas and Red rivers no doubt also included the Canadian in their journeys, as did many early European explorers. In recent presettlement history, the Kiowa, Kiowa-Apache, and Comanche dominated the upper Canadian basin. As some of the original native peoples were displaced by tribes from the east, nations like the Sac and Fox, Shawnee, Seminole, Creek, Choctaw, Kickapoo, and Iowa were established in the eastern Canadian basin, and the western Canadian basin became territory of the Wichita, Caddo, Cheyenne, and Arapaho. Important early forts in the Canadian basin were Fort Holmes and Camp Arbuckle on the Canadian River and Fort Reno and Camp Supply on the North Canadian River. Military roads connecting these forts helped promote movement of people and goods. The

FIGURE 7.3 South Canadian River, Oklahoma (PHOTO BY W. J. MATTHEWS).

California Road, from Fort Smith on the Arkansas–Oklahoma border, followed the Canadian River through Oklahoma and westward, retracing the route initially followed by Whipple’s expedition as part of the Pacific Railroad Surveys. The western Canadian River basin became permanently settled as open-range cattle herding gave way to farming and fencing of the plains in the late 1800s.

Physiography, Climate, and Land Use

The Canadian River passes through four physiographic provinces (Southern Rocky Mountains [SR], Great Plains [GP], Central Lowland [CL], Ouachita Province [OP]) and three terrestrial ecoregions (Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone) (see Fig. 7.9). The Canadian River basin originates in northeastern New Mexico and southern Colorado in a region of mixed Cretaceous sedimentary deposits and rocks of volcanic origin. It crosses a broad belt of Tertiary sedimentary rock in the Oklahoma–Texas panhandle region, Quaternary sedimentary deposits in western Oklahoma, a broad region

of Upper Paleozoic unmetamorphosed sedimentary deposits in central Oklahoma, and then metamorphic rock related to the Ouachita uplift en route to its confluence with the Arkansas River (Hunt 1974). Soils in the western half of the Canadian basin are mostly alkaline red or red-brown prairie soils, whereas the eastern part of the basin flows through a region of neutral prairie soils (Hunt 1974). Original vegetation varied from short grasses in the west to mixed and tallgrass prairie in central Oklahoma, intermixed with the Crosstimbers region, which is dominated by low-growth form oak forests.

Like the upper Arkansas River, the Canadian River initially flows through a very arid region, with rainfall less than 40 cm/yr and high rates of evaporation. Summers are hot, with low humidity, and winters cold, with snow and blizzard conditions common. In eastern Oklahoma the Canadian River flows through more mesic country, with annual rainfall averaging 100 to 120 cm/yr. On average for the entire basin, rainfall is greatest in May, declining through the summer and autumn to winter low precipitation in December and January (Fig. 7.10). The upper Canadian system averages only about 175

to 180 frost-free days per year, whereas in east Oklahoma 210 to 220 days per year are without killing frost. Air temperatures in most of the Canadian River basin average about 2°C in January and 27°C in August (see Fig. 7.10).

Land use in the upper Canadian (New Mexico and Texas) is dominated by grazing and short grasslands, with Amarillo, Texas, the only major city near the river. Its course through Oklahoma is mostly rural, in landscapes dominated by cattle ranching, some oil production, and wooded bluffs or terraces. From central Oklahoma eastward, farms and ranches are common, with grazing land, wheat, cotton, milo, and substantial wooded areas. Land use overall is about 50% rangeland or pasture and 30% cropland but can be up to 55% forested in the eastern part of the basin.

River Geomorphology, Hydrology, and Chemistry

The Canadian River arises at about 1970m asl near Raton, New Mexico, and is joined within the mountains by the Mora River, which arises south of Taos, New Mexico. The average slope of the entire Canadian River main stem from the headwaters to its confluence is 2.8m/km. After exiting the mountains it crosses an arid, short-grass region and flows into Conchas Reservoir, a relatively small impoundment. Below Conchas Reservoir the river runs through steep-walled canyons, and Revuelto Creek adds water from the south before the river enters the Texas Panhandle. Crossing the Texas Panhandle north of Amarillo, it flows within about 50km of the headwaters of the Red River, and early explorers were sometimes confused about which river they were on. Lake Meredith, near Borger, Texas, regulates flow of the river, which becomes a modestly wide, shallow, sand-bed river downstream through Texas and into western Oklahoma. In west Oklahoma the river makes three major loops, passing the Antelope Hills and the Black Kettle national grasslands, then flowing almost directly southeast for about 250km past Norman, Oklahoma. In west Oklahoma it is a widening, sand-bedded river, with steep earthen-bluff banks that are 20 to 30 meters high in places. In central Oklahoma the Canadian flows through a riverbed several kilometers wide, with an actual sand bed half a kilometer or more wide in places and with flow highly variable and braided.

This is the area described by Helfley (1937) and the site of studies on fish habitat selection and

tolerance as a function of physical stressors (Matthews and Hill 1979, 1980, Matthews 1987). Helfley (1937) described flood formation of terraces of the Canadian River and the physical dynamics of the unstable floodplain. This condition remains in spite of upstream dams built since Helfley's writing. The main-channel Canadian River in central Oklahoma still shrinks in hot summers to be so narrow that a child can step across, but occasional rains convert the Canadian at the same locality into a raging river with standing waves of a meter high or more, running "full" from bank to bank. The same aeolian processes described by Helfley dominate the architecture of the sand bed outside the wetted channel, leaving wide expanses of sand bars sculpted by the wind.

Near Ada, Oklahoma, the Canadian turns to flow slightly northeast to its confluence with the Arkansas River. En route it remains a wide, shallow, sand-bed river, characterized by an unstable and shifting sand bed, with relatively steep, incised bluffs on the outside of bends in the river and wide expanses of sand bars and flat floodplain with willow and small cottonwoods on the inside of bends. It is joined from the north by the Little River, which originates in Norman, Oklahoma (a different "Little River" than the one in southeast Oklahoma), then joins the North Canadian River and Deep Fork River in forming Lake Eufaula, the largest man-made impoundment in Oklahoma. After leaving Lake Eufaula, the Canadian, now carrying water from all its major tributaries, flows a few kilometers across the Arkansas River floodplain and joins that main stem in Robert S. Kerr Lake, near Webbers Falls, Oklahoma.

The system is fed by snowmelt in New Mexico, with flow controlled by Conchas Lake, New Mexico, and Lake Meredith, Texas, and, in its lowest reaches in east Oklahoma, by Lake Eufaula. Flow is highly variable through most of Oklahoma because of the occurrence of extreme rainfall events, at any time of year, that create river flooding, and summer desiccation, which in some years reduces the main stem to not more than a meter wide (W. J. Matthews, personal observation). In its headwaters near Logan, New Mexico, the Canadian River has a recent (since dam construction upriver) 30-year (1970 to 1999) mean discharge of about 1.3 m³/s, with a few high discharge years (four years in the series had average discharge >2.8 m³/s). In sharp contrast, virgin flow in that reach from 1927 to 1947 had annual mean stream flow an order of magnitude higher, averaging 12.1 m³/s (<http://waterdata.usgs.gov/nwis/sw>). Downstream, near Whitefield, Oklahoma, mean

annual discharge of the Canadian River before regulation by Eufaula Lake (1939 to 1963) averaged $174\text{ m}^3/\text{s}$, compared to $120\text{ m}^3/\text{s}$ from 1964 to 1984, after the lake was built. Basinwide runoff in this mostly arid area is extremely low, ranging from only $0.15\text{ cm}/\text{mo}$ in August to $1.04\text{ cm}/\text{mo}$ in May (see Fig. 7.10), due to high evapotranspiration.

With the exception of its headwaters in the Rocky Mountains, the Canadian River flows mostly over very unstable sand and mud substrates with a braided channel that changes continually. Each stage rise changes the patterns of flow and sandbars in the river bed, and stable habitats are largely nonexistent (Matthews and Hill 1980). The Canadian River has a highly shifting channel in its lower portions, often eroding away or depositing new farmlands. Oklahoma law allows a landowner with “new” land deposited by the river to use it, but the landowner on the other side, whose land is washed away, is merely “out of luck.” The main stem in central Oklahoma has a bed several hundred meters wide, but flow over these sandy beds is often reduced to a few meters wide by late summer (Hefley 1937, Matthews and Hill 1979), with flow as little as 1 to $2\text{ m}^3/\text{s}$. During extreme drought in the early 1950s, many kilometers of the main stem in central Oklahoma were reported by local residents to be completely dewatered. After rains the channel can run full, with swift and turbulent waters bank to bank over the sand bed, but by late summer the Canadian River near Norman is often reduced to a series of pools connected by scant flow in shallow channels 1 to 2 m wide. Under those conditions, solar heating is extreme, and the biota is impacted by high water temperatures and low oxygen alternating with supersaturation in backwaters. These conditions apparently have strong influence on the distribution of fishes, which sometimes are concentrated in huge numbers in microhabitats that offer slight survival advantages (Matthews and Hill 1979, 1980).

At Logan, New Mexico, the Canadian has occasional high specific conductance (1200 to $>9000\text{ }\mu\text{S}/\text{cm}$, depending on flow), pH ranging from 8.0 to 8.3 , and is dominated chemically by sodium and chloride (150 to $1900\text{ mg}/\text{L}$ and 60 to $2800\text{ mg}/\text{L}$, respectively) but with high concentrations of sulfate (300 to $500\text{ mg}/\text{L}$). Hardness ranges from about 300 to $600\text{ mg}/\text{L}$ as CaCO_3 , and alkalinity is about 200 to $330\text{ mg}/\text{L}$ as CaCO_3 . By Amarillo, Texas, values remain approximately in those ranges. Alkalinity remains high and the river is well-buffered through central Oklahoma, with values at Calvin, Oklahoma, approximating specific conductance of 600 to $1200\text{ }\mu\text{S}/\text{cm}$, pH 8.2 to 8.5 , total

hardness about $300\text{ mg}/\text{L}$ as CaCO_3 , alkalinity about $200\text{ mg}/\text{L}$ as CaCO_3 , and ions like calcium, magnesium, sodium, and chloride ranging from 20 to $150\text{ mg}/\text{L}$. At this site nutrients in recent years have ranged from 0.1 to $0.5\text{ mg}/\text{L}$ total nitrogen and 0.04 to as high as $0.49\text{ mg}/\text{L}$ total phosphorus. In central Oklahoma, water temperature in the main channel regularly reaches or exceeds 36°C on summer afternoons, when direct sunlight strongly heats the shallow waters (less than 1 m deep) of the exposed sand-bed channel. The river in central Oklahoma ices along the shore in some winters, with main-channel water temperatures measured at 0°C to 1°C (W. J. Matthews, unpublished data).

River Biodiversity and Ecology

Unlike the Arkansas River, which traverses four freshwater ecoregions, the Canadian River passes only through the Southern Plains freshwater ecoregion (Abell et al. 2000), and, not surprisingly, its overall biological diversity is substantially less than the main river. Not only is its western portion even harsher than the main-stem Arkansas, but it does not flow as far into the more mesic east. Ecological studies of the Canadian are limited, with the most information available on the fish community.

Plants

The Canadian River basin has a distinct vegetation gradient from east to west. To the east, patches of silver maple and box elder occur on stream banks. An elm–hackberry–ash association is common in lower reaches of the river in Oklahoma. From the central to the western parts of the basin mixed grasses are common along the rivers edge, with cottonwood–willow woodlands common on floodplains, as well as patches of salt-cedar and sandbar willow. Salt-cedar, a major invader upstream, becomes limited downstream. Oak forest occurs on the upper terraces.

Invertebrates

The sand and clay sediments of the Canadian River support a limited invertebrate fauna, and most invertebrates are associated with snag habitats. Oligochaetes worms (*Limnodrilus*) and midges (e.g., *Bezzia*, *Chironomus*, *Cryptochironomus*, *Paratendipes*) are abundant. The most common mayflies are *Tricorythodes* and *Caenis*. The caddisfly fauna is dominated by filter-feeding *Cheumatopsyche* and *Hydropsyche* (Bass and Walker 1992, Wilhm et al. 1978). Crayfishes include *Orconectes nais*, *Procam-*

barus simulans, and *P. acutus* (Reimer 1969, E. A. Bergey, personal communication). Mollusks include *Physa* and the fingernail clams *Sphaerium* and *Pisidium*. At least 11 unionid species are known from the river, including pink papershell, fragile papershell, yellow sandshell, and white heelsplitter (Branson 1982, 1983, 1984). The introduced Asian clam is common.

Vertebrates

Cross et al. (1986) considered about 63 species of fishes to be native to the Canadian River system. Fish distribution in this system changes more gradually from west to east than in the Red River, with its salt gradients. One federally threatened fish species (the Arkansas River shiner) in the South Canadian River is now much reduced from its former range, but it was common in 1978 at least as far upstream as Revulito Creek, New Mexico (W. J. Matthews, personal observations). Marked differences exist in distribution of some fish species between North and “south” Canadian rivers (e.g., no Arkansas River shiners in the North Canadian). Like the Red and Arkansas rivers, there is a main-stem “big-river” fish fauna in the wide, shallow, sandy main-channel Canadian River that differs from that in tributary creeks (Matthews and Hill 1979, 1980). Typical and abundant (at least formerly) main-stem species include red shiners (also common in creeks), Arkansas River shiner, plains minnow, bullhead minnow, and emerald shiner.

Fish habitat use is strongly influenced by high temperatures and other physical stressors in summer, as temperatures in the main channel approach lethal limits for all species (Matthews and Hill 1979, Matthews 1987, Matthews and Zimmerman 1990). Important fish habitat is found at or near creek inflows, where pools typically are deeper and more stable than in the shallow main stem. These edge habitats also support fathead minnows in backwaters, longear and green sunfishes, and a limited number of channel catfish, largemouth bass, and gizzard shad. The Red River pupfish, formerly restricted in Oklahoma to the Red River basin, was introduced to the Canadian River in central Oklahoma. However, numbers of species at any site reflect the lower number of species in this basin compared to other main rivers, with typically only about a dozen species taken at any one seining site.

River otter, an Oklahoma state species of special concern, is found in eastern parts of the Canadian River. Nonvegetated beaches and sandbars of the Canadian River support breeding populations of the

federally endangered interior least tern (Byre 2000). Smooth softshell turtles are commonly found burrowing into the sand bed, and snapping turtle, common slider, yellow mud turtle, and stinkpot turtle are found. Water snakes are common. Beavers are common in tributary creeks near their confluence with the main river channel, and beaver cuttings are commonly seen along the main stem as well. Great blue herons (sometimes in large numbers), green herons, and little blue herons occur along the river. Nesting colonies of great blue herons occur in large trees on upper terraces of the river at Norman, Oklahoma.

Ecosystem Processes

There are no comprehensive studies of ecosystem processes in the Canadian River or its large tributaries. However, in that much of this river flows through grasslands or former prairie, we would suspect that ecosystem processes are dominated by inputs of grasses or smaller amounts of tree-derived vegetation, combined with periodic high primary productivity within the streambed. For example, in autumn of some years, major portions of the streambed can become encrusted with a thick layer of algae that appears to be highly productive and is, in fact, directly eaten by some of the common fishes (W. J. Matthews, personal observations). An additional important organic input to the river itself is probably derived from the encroachment of seedlings of cottonwood and other woody plants, which rapidly grow on the dried portions of the streambed at low water. Upon the next flooding, this material is uprooted and washed into the river, where it no doubt provides substantial nutrients by its decomposition (W. J. Matthews, personal observations). However, retention of particulate carbon is probably low, in that stage rises substantially move the easily shifted sand bed.

Human Impacts and Special Features

The Canadian River was described by Hefley (1937) as one of the harshest environments on Earth, and heating of water can be extreme in summer (W. J. Matthews, unpublished data). The Canadian is probably one of the most dynamic and variable river environments anywhere in the world, ranging from a mere trickle in late summer to a boldly flooding river following rains. This natural flow cycle apparently was important as a stimulus to reproduction by some of the common fishes, which are now substantially

reduced in number as a result of flow moderation by upstream dams.

Two dams influence flow, and there is a strong influence of agriculture and oil production on the river. Near Norman the riverbed is extensively disturbed by commercial sand mining, but it also is protected in numerous places by private landowners and The Nature Conservancy, with nesting refuges on sandbars for the federally endangered interior least tern. No major cities are on the primary main stem, but the North Canadian River flows through Oklahoma City, where it recently has been dammed in several places to provide water for a new tourist canal system in the refurbished downtown. Lake Overholser is an “off-channel” impoundment on the North Canadian River near Oklahoma City, and an artificially heated power plant lake northeast of Oklahoma City apparently allowed establishment of a population of nonnative blue tilapia (Pigg 1978), which reproduce and invade the North Canadian River in large numbers in some years, as far as 50 to 75 km downstream to near Seminole (Matthews and Gelwick 1990). The Canadian River and its drainage generate controversy between the states of Texas and Oklahoma, with Oklahoma officials alleging that Texas is wrongfully storing water in a reservoir on a Canadian basin tributary in the Texas Panhandle (*Daily Oklahoman*, August 26, 2002).

RED RIVER

The Red River is the 2nd largest river basin in the southern Great Plains (169,890 km²), arising at about 1050 m asl as mostly dry or ephemeral creeks converging in Palo Duro Canyon in the Texas Panhandle, and joining the Mississippi River (and/or the Atchafalaya River) in eastern Louisiana at about 25 m asl (Fig. 7.11). The Red River drains some of the driest areas of the Southern Plains, consisting of the western portion of the Texas Panhandle, where surface water is scarce, playa lakes appear and disappear, and permanent water in streams is rare. It is in or near this area that troopers of the U.S. 10th Cavalry died of thirst in the 1870s. From Eastern Oklahoma through Arkansas and Louisiana, the Red enters a more mesic climate and is joined by a large tributary, the Ouachita River (see Chapter 6), just before it reaches the Mississippi River.

There has been considerable debate over whether North Fork or Prairie Dog Town Fork in western Oklahoma is the true main stem of the Red River. Prairie Dog Town Fork was followed by Marcy’s

military expedition of 1852 to find the source of the Red River, and, on the basis of lengthy congressional and judicial findings (Tyson 1981), is considered the main fork of the Red River. On the other hand, North Fork is nearly as long and typically carries more water (9.6 m³/s for North Fork at Headrick; 3.2 m³/s for Prairie Dog Town Fork near Childress), but legal decisions have agreed with Marcy’s determination that the Prairie Dog Town Fork is “the river.”

Native peoples along the Red River basin had sharply differing cultures even before Europeans entered the region. To the east were cultures of the eastern Piney Woods, dominated by tribes of the Caddoan Confederacy and characterized by a sedentary lifestyle in an area of plentiful game and favorable conditions for growing crops. In the middle Red River region, the Wichita and Tonkawa tribes roamed the prairies, living in skin tepees or pole and brush structures, with seasonal hunting and limited farming. In the western Red River basin, the Lipan Apache were the originally dominant native peoples but were displaced by the Comanche from the north in the 1700s, after which the upper Red basin was dominated by the Comanche until Europeans took control of the region in the late 1800s.

During European settlement after the American Civil War the upper Red River area in Oklahoma and the Texas Panhandle was a region of war or lawlessness involving Comanches, the U.S. Cavalry “Buffalo Soldiers” of Fort Sill and other frontier forts, infamous outlaws and outlaw towns, cattle barons with huge holdings, and lawmen of legendary proportions. Perhaps no other region in the southern Great Plains so epitomizes the “Wild West” in all its inglorious forms. It has been immortalized in popular historical novels by Larry McMurtry (*Lonesome Dove*) and Elmer Kelton (*The Far Canyon*), in songs (“Panhandle Wind” by Bill Staines), and in films (*Red River*, starring John Wayne). However, despite wishes to the contrary by some residents, the plaintive love song “Red River Valley” was actually written about a cowboy at the “Red River of the North” in Minnesota.

The Red River forms the long-debated boundary between Oklahoma and Texas, with a long history of legislative and judicial arguments, a U.S. Supreme Court judgment to legally identify the main fork, and a recent agreement by the states setting the southern border of Oklahoma at the vegetated edge of the water line on the south bank. The focus of this debate was also on Greer County, Oklahoma, between the two main forks of the Red River in southwest Oklahoma, whose ownership was bitterly contested

by Texas versus “the United States” for decades, and which was known as the “Empire of Greer” in some early documents and now is referred to locally as “Old Greer County.” As recently as 1931, National Guard units of the two states risked armed hostilities over ownership of the river and its oil-bearing riverbed, culminating in the peacefully ended “Red River Bridge War” (Fugate and Fugate 1991) over the right to establish toll fees for crossing.

Physiography, Climate, and Land Use

The Red River passes through four physiographic provinces (Great Plains [GP], Central Lowland [CL], Ouachita Province [OP], and Coastal Plain [CP]) and four terrestrial ecoregions (Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone, Piney Woods Forests) (see Fig. 7.11). The upper Red River originates at about 35°N latitude on the elevated plain known as the Llano Estacado in the Texas Panhandle at the eastern edge of primarily Tertiary deposits of sedimentary and mostly marine origin (Hunt 1974). In the eastern Texas Panhandle and western Oklahoma to about Lake Texoma, the Red River passes mostly through nonmetamorphosed marine and continental sedimentary deposits of Mississippian, Pennsylvanian, and Permian age. In western and central Oklahoma, the basin also drains streams from large granitic uplifted areas in the Wichita Mountains and other smaller and isolated granitic areas such as the locally important Tishomingo Granite. East of Lake Texoma, the Red River drains Cretaceous formations that abound in ammonites and “sea biscuit” echinoderm fossils, but the river main stem soon enters Quaternary sedimentary deposits, through which it flows to its mouth in eastern Louisiana at about 31°N (Hunt 1974).

The Red River basin in Texas and western Oklahoma is characterized by generally red to red-brown alkaline soils (Hunt 1974). In central Oklahoma and north Texas the basin drains generally neutral prairie soils, then drains mostly acidic red or yellow podzol soils in east Oklahoma and much of Louisiana and crosses alluvial soil in extreme eastern Louisiana. Vegetation generally reflects the major terrestrial ecoregions drained by the basin, with short and mixed grasses in the west, a transitional zone of short deciduous oak forest (“Cross-timbers”) and taller native grasses, and the heavily forested mixed coniferous and deciduous regions of eastern Oklahoma and Louisiana.

Climatologically, the Red River flows from arid grasslands in the Texas Panhandle, receiving less than 50 cm/yr of rainfall on average with frequent blizzard conditions in winter, to areas in Louisiana that receive more than 140 cm/yr of rain and average about 250 frost-free days per year, with snow a rarity. The region as a whole has generally mild to cold continental winters, but summers are very hot, with July and August monthly means near 30°C (Fig. 7.12). In the upper Red River basin, average daily temperatures in January are about 2°C, in contrast to about 8°C in the lower basin in Louisiana. From April through autumn the middle and eastern Red River basin often has massive rain fronts coming in from the Gulf of Mexico or near daily afternoon thunderstorms, some of which reach violent mesocyclone proportions. Greatest average monthly precipitation is in the month of May (see Fig. 7.12).

The Red River now flows mostly through cattle ranching or row-crop farming areas, with Shreveport, Louisiana, and Alexandria, Louisiana, the only large cities directly on the river. Oil and gas production are prominent features of land use near the river, with some large oil fields in southwest Oklahoma. The region is mostly rural, with many small municipalities in counties adjoining the river, plus the moderately sized cities of Wichita Falls and Sherman-Denison, Texas, and Texarkana, Arkansas–Texas. In the west, land use is about 40% to 60% rangeland and 30% cropland, whereas to the east it is about 50% forested, 20% cropland, and 10% pasture.

River Geomorphology, Hydrology, and Chemistry

Originating outside the Rocky Mountains, the Red River has no substantial influence of snowmelt and lacks montane outwash in its sandy riverbed. The channel form throughout essentially all of the basin is a gently sloping floodplain a kilometer or more wide, bordered in some reaches by moderately sloping, rounded bluffs 20 to 30 m in height (Fig. 7.1). The exception is the steep-walled Palo Duro Canyon, through which the headwaters of the Prairie Dog Town Fork of the river flows. Beyond Palo Duro the river is essentially low gradient for its entire course, lacking waterfalls or any steep drops in elevation.

The main-stem Red River (Prairie Dog Town Fork) originates in Palo Duro Canyon in the Llano Estacado (High Plains) south of Amarillo, Texas,

flows eastward through the relatively arid Texas Panhandle to the western border of Oklahoma, then forms the southern border of Oklahoma with Texas. The river flows almost entirely through terrain of relatively low relief, resulting in a mean slope for the entire main stem of only 65 cm/km. In the Oklahoma–Texas reach it is joined by the North Fork and Salt Fork from Oklahoma and the Wichita River from Texas. Flow in even the largest of these forks remains uncertain in dry years, “pooling up” in some summers as far downstream as Burkburnett, Texas. Further downstream, where at least some flow persists in most years, it remains a sandy-muddy river, the crossing of which has vexed Europeans since Marcy’s expedition in the 1850s and the first cattle drives. The Red becomes a substantial river from about Wichita Falls, Texas, downstream to Lake Texoma, a major on-channel impoundment at the junction of the Washita and Red rivers (see Fig. 7.11). Only below Lake Texoma, in the mesic region from eastern Oklahoma through Louisiana, does the river take on a more consistent flow in a defined channel, bordered by large deciduous forests and, in some places, oxbow lakes and overflow swamps. Below Lake Texoma the river is joined by the Blue, Boggy, and Kiamichi rivers from the north in Oklahoma, by the Little River in Arkansas, and by the Sulfur River and Cypress Bayou–Caddo Lake systems that originate in Texas. En route east, the main-stem Red River flows from arid grasslands to increasingly mesic forests, but throughout most of its length it has a sand-bed channel with massive bars and navigation hazards. The Cypress Bayou system, a substantial tributary in northeast Texas, has one of the largest remaining cypress forests in the region, with huge old trees in vast, winding river channels and overflow fringing swamps.

The Red River in eastern Oklahoma–north Texas and deep into Louisiana was the location of the incredible “Great Raft” or “Red River Raft” of drift logs and mud that existed before European settlement and was reported by early explorers (1806) to be as much as 240 km long and 30 km wide, blocking the channel and causing the river to spill over into countless oxbow and side-channel shallow lakes. A channel through the Great Raft as far as present-day Shreveport was first opened between 1833 and 1836 by the “snag steamboat” invented by Capt. Henry Shreve, but by 1839 the river had rebuilt and closed the raft. The Great Raft defied all attempts to remove it until intensive efforts were resumed in 1872 employing snag boats, “saw boats,” “crane boats,” and nitroglycerin. The Great Raft finally was cleared

by about 1900, and the river remained permanently open thereafter (Tyson 1981).

Mean virgin discharge of the Red River (1928 to 1944) was 852 m³/s, with basinwide runoff varying from very low in late summer (about 0.3 cm/mo) to about 2.5 cm/mo in late spring (see Fig. 7.12). A relatively high fraction of precipitation is lost as evapotranspiration. For the Red River downstream of Lake Texoma, in east Oklahoma, mean annual discharge was about 260 m³/s before regulation by the dam, but from 1945 to 2000, mean annual discharge was identical, at 260 m³/s. Drastic variation has, however, been observed in that period, from a low of 77 m³/s in 1964 to a maximum of 652 m³/s in 1990.

Upper portions of all forks have unpredictable flow. The main stem as far downstream as Wichita Falls, Texas, is subject to extended periods of “no-flow” and pooling up. Downstream of the forks it is a perennial, wide, shallow, sand–mud bed river, with discharge that varies greatly. The most likely months for storm-induced spates in tributaries are April, May, and midautumn. The Red River main stem can rise rapidly after heavy rains in the basin and can produce extreme flooding and turbidity in Lake Texoma, with strong effects on fishes and zooplankton.

Water chemistry reflects the harsh arid country through which the river flows. Marcy’s 1852 expedition to the headwaters in Palo Duro Canyon was forced to endure bad water conditions, with the chemically charged Prairie Dog Town Fork causing severe gastrointestinal distress for army troopers who attempted to drink it. In the eastern Texas Panhandle, north Texas west of Wichita Falls, and extreme southwest Oklahoma, this river has (for “freshwater”) extremely high salinity, approaching or exceeding that of seawater, because of a dozen or more brine springs from Permian strata. Downstream in Oklahoma, tributaries of the Red River flow through a large gypsum region, resulting in inputs of sulfates to the river.

Typical chemical values in the Prairie Dog Town Fork near Childress, Texas, include pH 7.7 to 8.2, alkalinity 75 to 110 mg/L as CaCO₃, total hardness 1800 to 5200 mg/L as CaCO₃, specific conductance 16,000 to 72,000 μS/cm, sodium 12,000 to 17,000 mg/L and chloride 17,000 to 28,000 mg/L (greater, overall, than for seawater), and calcium 600 to 1500 mg/L and magnesium 100 to 360 mg/L, suggesting the laxative properties of the water discovered by Marcy’s army troops. In contrast, below Lake Texoma the main-stem Red River near DeKalb, Texas, has calcium and magnesium ranging around only about 25 to 70 mg/L and 5 to 25 mg/L,

respectively, sodium and chloride values of only 10 to 100 mg/L and 10 to 140 mg/L, respectively, and specific conductance about 200 to 950 $\mu\text{S}/\text{cm}$, depending on flow and discharge. The Red River near DeKalb, Texas, has typical nutrient concentrations ranging 0.1 to 0.3 mg/L total nitrogen, and 0.03 to 0.13 mg/L total phosphorus. Water temperatures in the main channel of the Red River regularly exceed 36°C in late summer and have been recorded as high as 39°C, making it one of the hottest large rivers on Earth, because of intense solar heating of the shallow water in the unshaded channel (Matthews and Zimmerman 1990).

River Biodiversity and Ecology

The Red River flows primarily through three freshwater ecoregions, the Southern Plains, the Ouachita Highlands, and the Mississippi Embayment (Abell et al. 2000). The Red River does not actually pass through the Ouachita Highlands, but several of its tributaries drain the highlands before entering the Coastal Plain and subsequently joining the main stem. Thus, the main stem remains a low-gradient river throughout its length as it enters the Mississippi Embayment ecoregion before joining with the Atchafalaya–Mississippi rivers. The overriding ecological feature of the upper Red River (in the Southern Plains above Lake Texoma) is strong structuring of biota by salinity gradients produced in the Permian Redbeds, with high fish diversity downstream reduced to as few as only two very hardy and salt-tolerant fish species in some of the headwaters (Echelle et al. 1972). Below Lake Texoma the river has relatively consistent flow, essentially never pools up or goes dry, and salinity gradients that would structure biota are lacking.

Plants

The basin as a whole has a gradient from high plains vegetation in the west to southern bottomland hardwood in the east. Cottonwood–willow woodlands are common on floodplains throughout the watershed. Stream banks contain patches of box elder and silver maple. Second growth slippery elm, sweetgum, black oak, and post oak are common. Eastern oxbows support swamp oak. Second growth loblolly pine, both naturally occurring and in plantations, occurs in the lower watershed.

Invertebrates

The shifting clay and sand sediments of the main-stem Red River, coupled with the high conductivities,

create a harsh environment for many benthic invertebrates, and there have been few comprehensive studies of the benthic fauna. Oligochaetes, burrowing mayflies (*Hexagenia*), and chironomid midges (*Chironomus*) are common in sediments. Most other invertebrates are associated with snag habitats, including the chironomids *Glyptotendipes*, *Dicotendipes*, and *Rheotanytarsus* (Sublette 1953, Vaughn 1982). Mayflies include *Caenis* and *Stenonema*, and the caddisflies *Chimarra*, *Cyrnellus*, *Hydropsyche*, *Cheumatopsyche*, *Oecetis*, *Hydroptila*, and *Triaenodes* are common (Resh et al. 1978). Crayfishes include *Orconectes palmeri*, *O. nais*, *O. virilis*, and *Procambarus simulans* (Reimer 1969, E. A. Bergey, personal communication). The Red River contains a large population of the Mississippi grass shrimp (Cheper 1988), an omnivore that thrives in the high-conductivity water. Upper reaches of the Red River are fed by hypersaline (43 ppm) springs that contain grapsoid crabs, *Hemigrapsus estellinensis* (Creel 1964).

The mussel fauna of the main-stem Red River is depauperate for a river of its size, largely because many species do not fare well in the shifting sediments. The fauna is dominated by pink papershell, fragile papershell, and bleufer. Other mussel species known from the main-stem Red River include white heelsplitter, yellow sandshell, threehorn wartyback, giant floater, maple leaf, pimpleback, lilliput, pistol-grip, and paper pondshell (Branson 1982, 1983, 1984; W. J. Matthews et al. unpublished data; Valentine and Stansbery 1971; Vaughn 2000). The nonnative Asian clam occurs throughout the river. In contrast to the main-stem Red River, tributaries to the river contain a diverse mussel fauna that has been well studied (Isely 1924, Valentine and Stansbery 1971, Vaughn 1997). The easternmost tributaries arising in the Ouachita uplands are particularly diverse. For example, 31 species of mussels are known from the Little River (Vaughn and Taylor 1999) and 29 from the Kiamichi River (Vaughn et al. 1996). Two federally endangered mussels, the Ouachita rock pocketbook and the scaleshell mussel, occur in Red River tributaries (Vaughn and Pyron 1995, ONHI 2001).

Vertebrates

A total of 171 fish species, 152 of them native, was reported by Cross et al. (1986), and additional introduced species are now present. A sharp contrast exists between the 133 native fish species in the lower Red River and the 56 in the upper Red River above Lake Texoma (Cross et al. 1986). The upper reaches that dry often or have very high salt loads have

environmental conditions so harsh that only two species (Red River pupfish and plains killifish) occur in some headwater reaches. Farther downstream, as salt concentrations are diluted by tributaries, a more speciose fish assemblage develops, with upstream limits to many species set by salinity gradients (Echelle et al. 1972). Below the highest salinity, upper reaches of the Red River are dominated by a recognizable “big-river” fish fauna, notably minnows like red shiner, chub shiner, plains minnow, silver chub, and the endemic Red River shiner. Main-channel members of the speckled chub complex include the prairie chub in the upper river and the shoal chub in the lower river, with the species sympatric near Wichita Falls (D. Eisenhour, personal communication). Nearing Lake Texoma additional minnow species like bullhead minnow and emerald shiner become more common, as do gizzard shad, channel catfish, introduced inland silversides, various sunfish species, white crappie, largemouth bass, white bass, and the introduced striped bass. In addition, gars are common above Lake Texoma, and paddlefish have been reintroduced above the reservoir.

Lake Texoma has a relatively stable fish assemblage (Gido et al. 2000) dominated both by native species like red shiners, blacktail shiners, gizzard shad, blue catfish, channel catfish, black bass, and various sunfishes, and abundant introduced species like striped bass, threadfin shad, and inland silversides. Lake Texoma and Keystone Reservoir on the Arkansas–Cimarron rivers are two of very few artificial impoundments with reproducing populations of the prized striped bass. Here, for unknown reasons likely related to salinity, striped bass exhibit spawning runs, resulting for Lake Texoma in a strong, naturally reproducing striped bass fishery with an economic value to the local economy estimated at \$26 million per year.

Downstream from Lake Texoma the river remains dominated by unstable sand substrates and fishes tolerant of those conditions, with shads, catfishes, minnows, sunfishes, gars, and suckers (Catostomidae) common. The majority of the habitat is shifting sand-bottom, which supports numerous minnows (red shiner, blacktail shiner, speckled chub, emerald shiner, ghost shiner, and bullhead minnow), inland silversides, western mosquitofish, longear sunfish, bluegill, largemouth bass, and several darter species like western sand darter, Johnny darter, and bigscale logperch. Larger-bodied fishes that occur in the deeper portions of the main channel include shovelnose sturgeon, blue sucker, river carpsucker, and golden redhorse. In addition, there are low-velocity

backwater or deep pool habitats that contain several gar species (shortnose, longnose, spotted), gizzard and threadfin shad, smallmouth and bigmouth buffalo, and common carp. After passing the Arkansas–Louisiana border, the river winds southeast through Louisiana, with a fish fauna typical of lowland streams of the Gulf Coastal Plain but still dominated by many of the same groups. The separation of the river into an upper and lower reach by Cross et al. (1986) not only reflects the general geography of the river, but the features of its native fish communities as well.

Lake Texoma is home to numerous visitors, such as gulls and shorebirds from the Gulf Coast, and bald eagles are very common during winter. Osprey are seen year-round at this impoundment. White pelicans are common in autumn, as they use Lake Texoma as a stopover, and sometimes overwinter. Many great blue herons and green herons, and an increasing number of cormorants, occur at Lake Texoma. Beaver are becoming very abundant around Lake Texoma, and nutria and muskrat are commonly associated with the river in Louisiana. Amphibians and reptiles associated with Red River in Oklahoma and eastward include snapping turtles, occasional alligator snapping turtles (from Lake Texoma eastward), plain-bellied water snake, false map turtle, yellow mud turtle, and cottonmouth from below Lake Texoma and eastward. We have never observed a cottonmouth in Lake Texoma, but they are common in the Blue River, the first substantial tributary east of the reservoir.

Ecosystem Processes

Relatively little is known about ecosystem processes in the main-stem Red River. However, in the Little Washita River (tributary to Washita River, thence to Red River) of south-central Oklahoma, riparian cover upstream was directly related to availability of whole leaves in the stream, and long reach lengths served as sources of detrital input at a given point (Johnson and Covich 1997). Johnson and Covich (1997) also found that organic content of benthic materials declined from headwaters to lower in the Little Washita River, and that floods reduced coarse POM in headwaters and increased the amount of fine organic material (10 to 360 μm) that were in suspension downstream.

Ecosystem factors like amounts and kinds of periphyton, primary productivity, ash-free dry mass (AFDM) and percentage of organic material in the substrate, size fractions of particulate organic matter, bacteria, and invertebrate standing crops, and

carbon–nitrogen ratios in Brier Creek, Marshall County, Oklahoma, a tributary of the Red River (in Lake Texoma), are strongly influenced by presence of the algae-grazing stoneroller minnows (Power et al. 1985, Matthews et al. 1987, Gelwick and Matthews 1992). A trophic cascade involving piscivorous black bass, central stoneroller minnows, and algal density and composition has been shown to influence primary productivity in pools (Power et al. 1985). Red shiners from the Washita River enhanced benthic primary productivity in experimental streams (Gido and Matthews 2001). In addition, another dozen fish species from several trophic or functional groups from Red River tributaries have been found to alter benthic primary productivity (C. Hargrave, K. Gido, W. Matthews, unpublished data.). Gido (1999) found in experimental pens in Lake Texoma that large-bodied, benthic-feeding fishes like river carpsucker and gizzard shad changed densities of chironomid larvae in benthic substrates, and that excretion by these fishes can be in sufficient amounts to account for substantial nutrient inputs to the reservoir.

Human Impacts and Special Features

Notable human impacts include the influence of agriculture (wheat, cattle) and of oil production in headwaters, and the construction of Lake Texoma, a 36,000 ha reservoir, at the juncture of the Washita and Red rivers. Interbasin water transfer from Lake Texoma to a reservoir of the upper Trinity River, Texas, is possible via a conveyance system completed in 1993. The largest city on the main stem is Shreveport, Louisiana, but the growing cities of Sherman-Denison and Wichita Falls, Texas, have a growing desire for Red River water for municipal uses. The Dallas–Ft. Worth metropolis also has increasing potential to use Red River water via interbasin transfer.

The mussel fauna of the Red River drainage has been significantly impacted by human activity. Vaughn (2000) resampled 19 sites in the drainage in Oklahoma and Texas that had been sampled in the 1910s and in some cases in the 1960s. Species richness declined at 89% of the sites. Local extinction rates were significantly greater than local colonization rates, indicating that mortality of mussels is significantly exceeding recruitment in the region.

In spite of all the human-induced changes, the Red River still retains many of its characteristics from presettlement times. The upper river, in its wide, shallow, and sandy nature, still reflects conditions first described by Marcy in the 1850s, although many

small creeks and tributaries no longer flow freely or as clear as Marcy found them. Downriver, Lake Texoma blocks upstream migration of anadromous fish like American eel and traps huge loads of silt and woody debris borne by the upper river on flood flows. Further downstream, in spite of removal of the Great Raft, which formerly blocked human passage on the river, the river remains relatively unstable, and navigation of the river for commercial purposes is impractical along the Oklahoma–Texas border. From Lake Texoma onward, the river flows almost entirely through rural regions with small populations (with the exception of Shreveport and Alexandria, Louisiana), and it still overflows into oxbows and swamps throughout much of its lower course. Some of the remaining largest cypress forests and swamps in Texas remain along the Cypress Bayou system, which is a major tributary of the Red basin in northeast Texas. The Red River has thus resisted most efforts of humans to tame its unruly nature. Lake Texoma minimizes flood losses downstream when massive hurricane-derived rain fronts stall over the basin, but otherwise much of the river remains much as it was as seen by the first explorers—a relatively “wild” place where human impacts seem rather small. However, the Army Corps of Engineers has begun a massive program to reduce chlorides in the upper basin, which, if ever completed, will threaten the existing, natural salinity gradient that is the template for much of the distribution of flora and fauna in the upper river. In addition, if the waters of the upper Red River were lower in salinity such that they could be directly used for irrigation, water withdrawals would no doubt increase, and hydrological estimates suggest that “no flow” days in the upper basin might be tripled annually.

LITTLE RIVER

The Little River, a major tributary of the Red River, drains 10,720 km² in southeastern Oklahoma and southwestern Arkansas (Fig. 7.13). This system is the antithesis of many of the other rivers in the region, with the upper main stem or larger tributaries representing mostly high-quality habitat flowing from rocky uplands of the southern slopes of the Ouachita Mountains. Outside the uplands the Little River becomes a low-gradient stream, with large gravel riffles interspersed with long, deep pools. Biodiversity of this system is some of the highest in the southern Great Plains, and in some reaches it contains highly diverse local aquatic faunas at the ecotone

between upland and lowlands. Highly diverse fish, benthic invertebrate, and mussel faunas exist, and numerous species (e.g., about 15 fish species) reach their westward range limits in the Little River basin. The Little River and some of its tributaries are noteworthy for their remaining native mussel fauna, including some federally endangered species and several fish species of concern or with federal protection are in these streams.

Early human history of the region was dominated in prehistoric times by groups of woodlands cultures, with a mixture of hunting and gathering and planting of crops like corn, squash, beans, pumpkins, and sunflowers. The Kichai, Caddo, and Kadohadacho peoples dominated recent prehistory, when as many as 8000 Caddo, many in permanent settlements, lived in the region. As native peoples from the east were displaced, the Little River basin was eventually dominated by the Choctaw Nation, with establishment of early settlements like Eagletown and a prosperous culture dominated by farming and ownership of plantation-style homes and lifeways. During the 1900s native forest gave way to major pine plantations, and the Little River basin has a later history dominated more by the major land-holding timber companies, as well as national forests maintained by the federal government.

Physiography, Climate, and Land Use

The Little River passes through two physiographic provinces (Ouachita Province [OP], Coastal Plain [CP]) and three terrestrial ecoregions (Ozark Mountain Forests, Central Forest Grassland Transition Zone, Piney Woods Forests), flowing between about 35°N and 34°N (see Fig. 7.13). Geology of the region is dominated by the Ouachita uplift, in which all major tributaries (Glover, Mountain Fork, Rolling Fork, Cossatot, and Saline rivers), as well as the Little River proper, originate. The Ouachita Mountains exhibit “ridge and valley” structure, with long (as much as 50 km), steep, but narrow (only a few kilometers wide in most places) mountain ridges, with rivers flowing through the valley floors between the ridges. Rock is mostly sedimentary, of marine origin, but much is metamorphosed to form shales, quartzites, and similar noncalcareous bedrock. After flowing generally southward out of the Ouachita uplift, the Little River crosses Cretaceous sedimentary deposits and then enters Quaternary sedimentary deposits in the lowlands before flowing into the Red River. Soils of the basin are typically acidic red or yellow podzol (Hunt 1974). Dominant vegetation of the Ouachita Mountain uplands is

conifer forest, apparently mixed in presettlement times with tall grasses in relatively open parkland. Downstream in the lowland parts of the basin, Coastal Plain deciduous forests mixed with conifer dominate the landscape.

Climate in the Little River basin is hot and humid in summer, with influence from Gulf Coastal weather patterns, and winters are milder than in most of the Great Plains. In the Little River basin, rainfall averages in excess of 100 cm/yr, and there are about 220 to 240 frost-free days per year. Mean monthly precipitation is highest in May (16 cm), with lows in January and August (7 cm) (Fig. 7.14). Air temperature in the Little River basin averages about 4°C in January and 26°C in August.

Land use in the uplands is almost entirely commercial timber, National Forest, or cattle ranching, and there are extensive cattle ranching, small farms, and some timber in the lowlands. Commercial poultry houses have increased in recent decades, and there is a major processing plant near the Little River south of Broken Bow, Oklahoma, that has locally polluted the Little River at times. There are few row crops, and the region largely lacks impacts of oil production. The lower main-stem Little River in Oklahoma is in the Little River Wildlife Refuge (U.S. Fish and Wildlife Service), but threats to the system continue from plans to transfer water out of state or to channelize some main-stem reaches. There are no large cities in the Little River basin; the region remains almost completely rural or in commercial timber, and the streams are prized by fishermen, hunters, and recreationists. Land use in the Little River basin is about 75% forest, 10% cropland, and 15% pasture, with no large urban areas.

River Geomorphology, Hydrology, and Chemistry

All major tributaries and the main-stem Little River originate in steep uplands of the Ouachita Mountains of Oklahoma or Arkansas, with typically rocky (boulder/bedrock) riffles and large pools with boulder-strewn bottoms. Here, the water is sufficiently clear that underwater observation of fishes is a useful study method. Upon exiting the uplands, the Little River flows onto the Coastal Plain, where it becomes deeply incised into sandy or clay soils, with highly developed floodplain/riparian forests and long, wide riffles separating pools often as much as a kilometer or more long. Overflow ponds or oxbow lakes, as well as fringing swamps, formerly

dominated the landscape of the lower Little River, although vast, large swamps are now drowned under Millwood Reservoir (see Fig. 7.13).

The main-stem Little River originates on the southern slopes of the Kiamichi and Winding Stair mountains at about 460m asl in remote, rugged uplands in southeast Oklahoma near Honobia, then flows southwest and eventually eastward in a wide arc (see Fig. 7.13). Its headwaters are boulder-cobble and gravel, with well-developed pools and swift rapids until the main stem forms Pine Creek Reservoir. Below the reservoir the river retains pool-riffle structure over a mostly gravel bed, with water willow a common structural feature in the shallows. The Little River then turns eastward, widening and deepening, flowing through cypress riparian forest, and entering the Little River Wildlife Refuge near Idabel, Oklahoma. It flows parallel to and north of the Red River to the Arkansas border and gains major tributaries, including (west to east) the Glover, Mountain Fork, Rolling Fork, Cossatot, and Saline rivers (see Fig. 7.13). The entire system flows into and forms Millwood Reservoir northeast of Ashdown, Arkansas, inundating formerly huge swamplands. Below Millwood Reservoir the Little River enters the Red River about 2km west of Fulton, Arkansas, at an elevation of 70m. Mean slope for the entire Little River main stem is 2.1m/km.

Although arising in uplands, headwaters are not fed by any large springs; thus, flows in upper reaches can be tenuous in late summer. In spite of this, the location of these streams in a relatively mesic area makes the Little River a large tributary of the Red River. Mean annual virgin discharge at Idabel, Oklahoma, from 1930 to 1968 (before closure of the upstream Pine Creek Reservoir) was about 45 m³/s. Average annual discharge at Idabel from 1971 to 2000 was 53 m³/s, suggesting no major change of discharge as a result of regulation. The highest annual mean discharge at Idabel was 89 m³/s, whereas the lowest, during the worst drought on record in 2000, was only 18 m³/s. Average annual discharge for the entire basin, measured at Millwood Dam, Arkansas, is 183 m³/s. Monthly runoff for the entire basin ranges from only 0.8cm/mo in late summer (apparently due to high summer evapotranspiration) to more than 8 cm/mo in spring (see Fig. 7.14).

Water chemistry at one site on the main-stem Little River included pH 7.2, alkalinity 24 mg/L as CaCO₃, and NO₃-N 0.33 mg/L. Total phosphorus can be as high as 0.36 mg/L, but typically ranges from 0.06 to 0.09 mg/L. The lower pH and alkalinity of the Little River or its major tributaries compared to

other rivers of the Southern Plains is due to its origin in noncalcareous uplands, with subsequent passage through conifer forest and the Coastal Plain. For example, a large tributary, the Cossatot River, has pH values as low as 5.9, hardness ranging from 9 to 16 mg/L as CaCO₃, and low concentrations of ions like calcium, magnesium, sodium, and chloride, with specific conductance only 48 μS/cm. Measured water temperatures in the main channel near Idabel, Oklahoma, have ranged in recent decades from 0°C to 33°C, so this is clearly a “warmwater” river despite its origins in the Ouachita Mountains.

River Biodiversity and Ecology

The Little River is part of the Ouachita Highlands freshwater ecoregion (Abell et al. 2000). The river is known for its high aquatic biodiversity and was identified by The Nature Conservancy as a critical watershed for protecting freshwater biodiversity based on its diverse and healthy fish and mussel fauna (Master et al. 1998). It is one of the better-known river ecosystems in the Southern Plains, with extensive surveys of fishes, mussels, and other invertebrates by C. C. Vaughn and collaborators.

Plants

Common riparian corridor species include river birch, sycamore, smooth alder, sugar maple, and box elder (Hoagland 2000). Lower portions of the river flow through bottomland hardwood forest characterized by willow oak and blue beech (Hoagland et al. 1996). Sloughs and swamps along the river contain bald cypress. Extensive growths of water willow develop in shallow areas of low flow throughout the river.

Invertebrates

The Little River harbors 31 species of mussels, including regional endemics such as the Ouachita kidneyshell and the Ouachita creekshell and nationally declining species such as the rabbitsfoot and butterfly (Vaughn and Taylor 1999). Comparisons of historical mussel distributions (Isely 1924, Valentine and Stansbery 1971) with current distributions reveal no species extirpations from the river (Vaughn 2000), although populations below impoundments have been severely impacted (see the Human Impacts and Special Features section for this river). A small population of the federally endangered Ouachita rock pocketbook mussel occurs in the river (C. C. Vaughn, unpublished data).

Upper portions of the Little River are rocky, and cobble–gravel riffles occur throughout the river, so snags are not as important a habitat for invertebrates as in sandy-bottomed southern plains rivers. Limpets (*Ferrissia*) and snails (*Physa*, *Elimia*, *Helisoma*) are common throughout the river. Crayfishes include *Orconectes palmeri* and *Procambarus acutus* (Reimer 1969, E. A. Bergey, personal communication). The Little River contains an abundant and diverse insect fauna, including beetles (*Stenelmis*, *Psephenus*), mayflies (*Pseudocleon*, *Ephemerella*, *Hep- tagenia*, *Leucocuta*, *Stenacron*, *Stenonema*, *Paralep- tophlebia*, *Isonychia*), damselflies (*Argia*), stoneflies (*Neoperla*, *Acroneuria*), and caddisflies (*Cheumatop- syche*, *Helicopsyche*, *Chimarra*, and *Polycentropus*). (C. C. Vaughn, unpublished data).

Vertebrates

The fish fauna of the Little River is quite diverse for a system of such small size, with many small-bodied insectivore–omnivore species. Jenkins (1956) reported 87 species from the preimpounded basin, and a count of species from the “Fish Atlas” (Lee et al. 1980) and our own collections shows about 110 native species in the drainage. This unusually high number of fish species for such a small drainage reflects its geographic position, with headwaters in high-gradient stony streams of the Ouachita Moun- tains, its passage onto the low-gradient, soft- bottomed substrates, and eventual entry to the Gulf Coastal Plain. Thus, the headwaters have typical high-gradient upland fish species such as Ouachita Mountain shiner, steelcolor shiner, and orangebelly darter. In the midreach of the Little River, redbfin shiner, harlequin darter, and numerous other darters were formerly common. The dominant game fish of the uplands is native smallmouth bass. After entering the Coastal Plain, upland species drop out and a largely different suite of species occurs, including, in the river or its swampy backwaters, taxa such as the rare bluehead shiner, pirate perch, pygmy sunfish, Blair’s starheaded topminnow, redhorse suckers of the genus *Moxostoma*, grass pickerel, flier, bantam sunfish, and dollar sunfish. Downstream, dominant predaceous or game fishes include largemouth bass and gars. However, some species, like steelcolor shiner and orangebelly darter, are common through- out most of the system. In some off-channel habitats like overflow ponds, pirate perch and pygmy sunfish dominate and are extremely abundant. The main channel can yield very diverse local assemblages. Eight darter (*Etheostoma*, *Percina*) species were taken in a single gravel riffle, and as many as 29

species were in some individual seining collections (W. J. Matthews and C. C. Vaughn, personal observations).

One federally threatened fish species (leopard darter) is endemic to this system, as is the Ouachita Mountain shiner. Several other fish species, such as peppered shiner and orangebelly darter, although not endemic, are of very limited ranges geographically, with strongholds in this drainage. The crystal darter, now becoming uncommon throughout its range, has a substantial population in the Little River near Idabel. Other species of particular interest known from the Little River drainage include the southern brook lamprey, taillight shiner, and blackside darter, all state species of special concern in Oklahoma.

Aquatic and riparian areas of the Little River also support alligator snapping turtle and mole sala- mander, considered species of special concern in Oklahoma. Swamp rabbits are present in the riparian zone. Snapping turtle, common slider, razor-backed musk turtle, diamondback and northern water snakes, and cottonmouth, occur in the river proper. As else- where in the southern Great Plains, beaver are common, and American alligator could occur in the easternmost parts of Little River. Herons and king- fisher can be expected. Large vulture roosts are found on gravel bar islands in the river from below Pine Creek Reservoir to the Arkansas state line.

Ecosystem Processes

Ecosystem processes in the main-stem Little River have not been studied. In some tributaries, mussel beds (Spooner 2002, C. C. Vaughn et al. unpublished data) and abundant central stoneroller minnows may alter nutrients, primary productivity, standing crops of invertebrates, or ecosystem processes, but studies of those effects have not been made in this system. Headwaters in this river system are typically clear, and where riparian canopy is open, stones are coated with a rich algal covering, and autochthonous primary productivity appears high. Farther down- stream, outside the uplands, the Little River becomes an incised, more turbid stream, with less potential for autochthonous primary productivity.

Human Impacts and Special Features

The Little River system, including the main stem and its array of large tributaries, collectively represent one of the most diverse riverscapes in North America relative to their short length. All major branches of the system arise on steep slopes of the Ouachita uplands, then drain long valley floors until they

emerge from the mountains to flow across the low-gradient, historically swampy Coastal Plain. Thus, in their relatively short distances, the branches of the Little River system mimic the headwater to lower river differences that are often seen in river systems over distances of thousands of miles, and also show clearly the biological phenomenon of a sharp ecotone between uplands and lowlands. As a result, these rivers, including the Little River main stem, depict strong longitudinal differentiation of taxa very well. In addition, they harbor rare or at-risk species, including some federally threatened and endangered fishes or invertebrates, and are marked by very high diversity of some groups, like darters.

The greatest human impacts in the region include dams on the main stem and all main tributaries except the Glover River (which remains one of the few free-flowing rivers in the region) and effects of the timber industry. Following final clearing of the last major old-growth forest in the central United States early in the twentieth century, vast tracts of the region were converted under timber company ownership to pine monoculture, replacing the original large pine-savannah and mixed deciduous forest with grow-and-cut forests. In some of the streams where timber is harvested, there has been a noticeable increase in silt on streambed surfaces in the last three decades (W. J. Matthews, personal observations). Large areas also are managed by the USDA Forest Service, and there have been recent land trades between private holders and the Forest Service that now place more of the rivers under federal authority. In some reaches, forest industries create pollutants, such as an outfall from a large mill near Wright City, Oklahoma, that apparently reduced native fish assemblages between the 1970s and 1990s (W. J. Matthews, personal observations). Additional pollutants can come from poultry processing effluents.

The Little River basin is most influenced by the three largest impoundments (see Fig. 7.13). The main stem of the river is impounded by 1644 km² Pine Creek Reservoir, used for flood control, water supply, and recreation. A major tributary of the Little River, the Mountain Fork River, is impounded by 1952 km² Broken Bow Reservoir, used for generation of hydropower, flood control, water supply, and recreation. Outflow from Broken Bow Reservoir enters the Little River via the Mountain Fork River, 64 km downstream of Pine Creek dam. Vaughn and Taylor (1999) examined the distribution and abundance of mussels at 37 sites along a 240 km length of the river. They observed an extinction gradient downstream from the two impoundments, with a gradual, linear

increase in mussel species richness and abundance with increasing distance from the reservoirs. Mussel species distributions were significantly nested, with only sites furthest from the reservoirs containing rare species. The extreme downstream portion of the basin is now impounded by Millwood Reservoir, which drowned vast shallow swamplands of southwest Arkansas. This chapter's senior author vividly recalls as a child crossing those "spooky" swamps late at night on the old highway from Nashville to Ashdown, Arkansas, across what seemed like interminable wooden bridges, while his parents talked in hushed tones in the front seat of the old Nash Rambler station wagon and glanced nervously about, probably hoping the tubes in the tires wouldn't fail.

ADDITIONAL RIVERS

The Cimarron River is a large, shallow, low-gradient prairie tributary to the Arkansas River, interesting for its harsh physical conditions and desiccation of substantial reaches in the upper river in most summers. It arises in the Great Plains and flows through the Central Lowland before terminating in Keystone Lake (Fig. 7.15). It is representative of medium-size southern plains rivers, with an unstable, braided sand bed and highly fluctuating physical conditions. The Cimarron River has low basinwide runoff (<1 cm/mo year-round) due to very high evapotranspiration (Fig. 7.16). There has been widespread introduction of the Red River shiner from outside the drainage, coincident with dramatic loss of the native Arkansas River shiner. Red River pupfish has become abundant in at least one tributary to the Cimarron (D. McNeely, personal communication).

The Neosho (Grand) system also is a large tributary of the Arkansas River, arising in the Flint Hills of Kansas (Fig. 7.17). Endemic fish species and isolated or relict populations of other formerly widespread species exist in the drainage, such as the Topeka shiner, isolated populations of cardinal shiner and southern redbelly dace, and the endemic and federally threatened Neosho madtom. The lower main stem of the Neosho (Grand) system is dominated by three large tailwater-to-headwater reservoirs, with little free-flowing river remaining.

The Illinois River, with its major tributary, the Baron Fork, is a large Ozark river system in the Arkansas River basin (Fig. 7.19). It arises in karst topography, with many spring-fed tributaries, caves, and gravel-bottomed riffle-pool reaches. The Illinois River contains some of the highest-quality stream

FIGURE 7.4 Illinois River, Oklahoma (PHOTO BY C. C. VAUGHN).

habitat in the region and is the only major tributary flowing into the Arkansas River that represents an Ozark uplift, calcareous stream type (Fig. 7.4). Tenkiller Reservoir is a major on-river impoundment on the lower Illinois River. There is a particularly diverse (101 species) fish fauna (Moore and Paden 1950) for such a small basin, with many Ozark-limited fish species like the Ozark minnow, cardinal shiner, banded sculpin, slender madtom, greenside darter, and banded darter as prominent members of the fauna.

The Poteau River is a substantial southern tributary to the Arkansas River in east Oklahoma and west Arkansas. It arises in the steep Ouachita Mountains and feeds, along with other large upland tributaries, into the impounded Lake Wister, after which there is a long portion of low-gradient river and densely wooded riparian habitat before it enters the Arkansas River (Fig. 7.21). Numerous locally restricted fish species exist, like the relatively rare blackside darter and longnose darter. The Poteau River exhibits extremes of seasonal runoff, from an average as low as 0.25 cm/mo in August to more than 6 cm/mo in winter (Fig. 7.22).

The Washita River is the largest low-gradient, western tributary of the Red River that flows into Lake Texoma (Fig. 7.23). An unstable mud-sand riverbed and steeply incised, erosive red earth banks makes this one of the most turbid, silt-laden streams in North America (Fig. 7.5). The Washita River basin is heavily affected by agriculture, with cattle farming and row crops dominating the landscape, along with oil and gas operations. The native fish fauna historically was somewhat limited even before human impacts, with gaps in distribution of some minnow species. However, it has an excellent sports fishery for native flathead catfish and channel catfish.

The Blue River is a relatively short but faunally important tributary of the Red River, fed by large springs in south-central Oklahoma (Fig. 7.25). The upper portion of the river is strongly marl-depositing, and marl dikes form pools and small waterfalls throughout much of the upper main stem. There are no major dams on this system. Two locally unique forms of fishes (orangebelly darter and striped shiner) are distinctive morphologically or genetically from those taxa elsewhere in their range and warrant species-level recognition. Also, the redspot

FIGURE 7.5 Washita River, Oklahoma (PHOTO BY W. J. MATTHEWS).

chub is found only here and in the Ozarks. A reach of several kilometers is owned by the state conservation department for public access, particularly a stocked trout fishery. The latter results in heavy vehicle traffic in and near this part of the river. Mussels (24 species) have been extirpated from 75% of the Blue River over the last 30 years, probably primarily due to siltation from riparian clearing and agriculture (Vaughn 1997).

The Kiamichi River is an upland tributary of the Red River. It arises just east of the Arkansas–Oklahoma border, flows westward into Oklahoma, then south to join the Red River near Antlers, Oklahoma (Fig. 7.27, Fig. 7.6). It flows through a narrow river valley floor, bordered on both sides by steep slopes of long ridge-and-valley mountains. Its flow is altered about halfway down the main stem by the off-channel Sardis Reservoir, which controls inflow from a large tributary creek, and the lower main stem is altered by Hugo Reservoir. The Kiamichi River arises as a clear stream with riffles and long wide pools flowing over stony cobble–boulder substrate or well-developed gravel bars. Water willow is a prominent feature of shallow riffles and pool edges throughout

the upper two-thirds of the river. It possesses an important native fish and mussel fauna, with two federally protected mussel species. The Kiamichi River has been particularly hard hit by drought in recent summers, with long reaches of typically flowing headwaters badly dewatered, which has had impacts on native mussel beds.

ACKNOWLEDGMENTS

We thank Don Wyckoff, associate curator of archaeology at the Sam Noble Oklahoma Museum of Natural History (SNOMNH), for advice on prehistory of native peoples and climates in the region. We also thank David Edds (Emporia State University) for information on the Neosho River, Elizabeth Bergey (Oklahoma Biological Survey) and the Oklahoma Conservation Commission for unpublished data, Oklahoma Natural Heritage Inventory for information on endangered species, Donna Cobb (OU Biological Station) for assistance in searching databases, Jason B. Jackson (assistant curator of ethnology, SNOMNH) for reviewing our sections on contemporary and recent native peoples, Bruce Hoagland (Oklahoma Biological Survey) for information and verification of riparian plant species, and

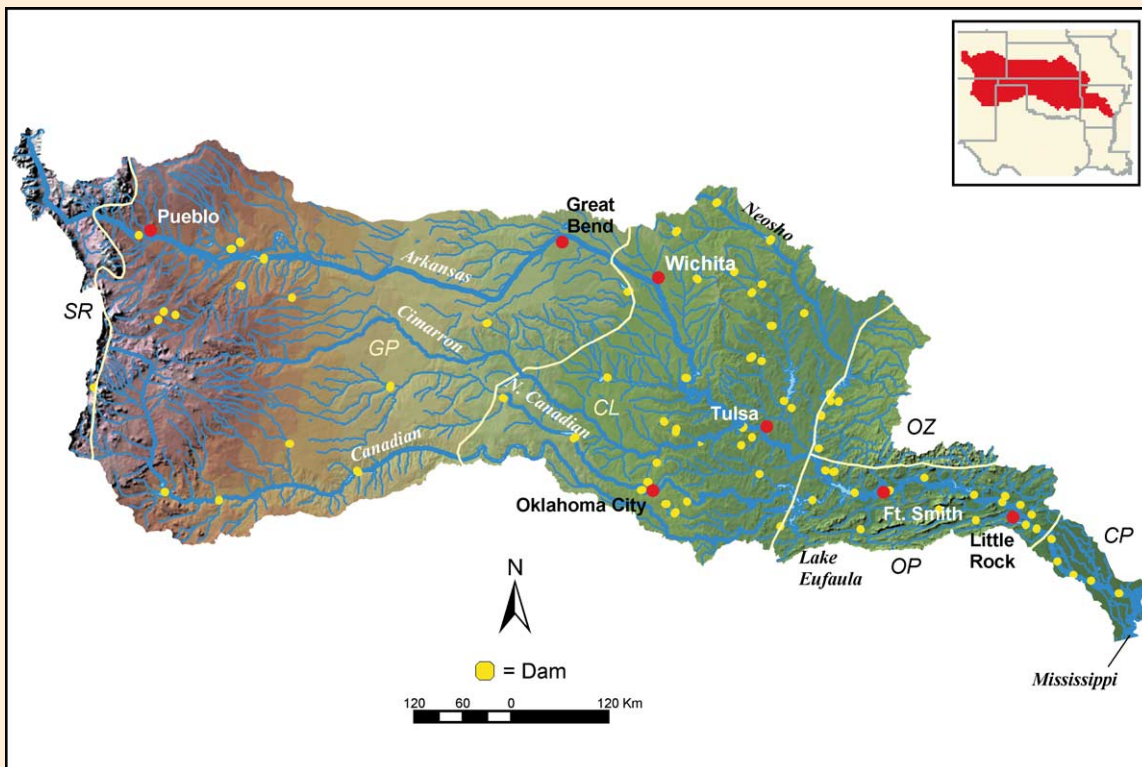

FIGURE 7.7 Map of the Arkansas River basin. Physiographic provinces are separated by yellow lines.

ARKANSAS RIVER

Relief: 4340 m
Basin area: 414,910 km²
Mean discharge: 1004 m³/s
River order: 7
Mean annual precipitation: 70.8 cm
Mean air temperature: 15°C
Mean water temperature: 17.9°C
Physiographic provinces: Southern Rocky Mountains (SR), Great Plains (GP), Central Lowland (CL), Ozark Plateaus (OZ), Ouachita Province (OP), Coastal Plain (CP)
Biomes: Temperate Mountain Forest, Temperate Grasslands, Temperate Deciduous Forest
Freshwater ecoregions: Southern Plains, Central Prairie, Ozark Highlands, Mississippi Embayment
Terrestrial ecoregions: 6 ecoregions (see text)
Number of fish species: 171 (141 native)
Number of endangered species: 1 fish, 1 bird
Major fishes: paddlefish, gars, gizzard shad, red shiner, river shiner, emerald shiner, plains minnow, smallmouth buffalo, bigmouth buffalo, river carpsucker, channel catfish, flathead catfish, plains killifish, western mosquitofish, white bass, largemouth bass, spotted bass, sunfishes, river darter
Major other aquatic vertebrates: plains leopard frog, American bullfrog, Blanchard's cricket frog, snapping turtle, spiny softshell turtle, smooth softshell turtle, yellow mud turtle, common slider, false map turtle, painted turtle, northern water snake, diamondback water snake, American white pelican, great blue heron, belted kingfisher, beaver, muskrat
Major benthic invertebrates: mayflies (*Caenis*, *Hexagenia*, *Stenonema*), caddisflies (*Cheumatopsyche*, *Hydropsyche*), chironomid midges (*Polypedilum*, *Glyptotendipes*), crayfishes (*Orconectes palmeri*, *Procambarus simulans*), mussels (washboard, threeridge, mapleleaf, pink papershell)
Nonnative species: Asian clam, zebra mussel, ~30 fish species (common carp, grass carp, striped bass), nutria in Arkansas
Major riparian plants: silver maple, box elder, hackberry, cottonwood, willow, cattails, American bulrush
Special features: arises as strongly flowing mountain river, almost disappears in western Kansas due to water withdrawal and evaporation; recharged near Great Bend, Kansas
Fragmentation: five major reservoirs on main stem, plus 17 locks and dams; part of the Kerr-McClellan Navigation System
Water quality: pH = 7.4, alkalinity = 52 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.02 mg/L, but with wide range of values from headwaters to lower main river
Land use: western basin: mining, oil and gas production, 50% rangeland, 50% cropland; eastern basin: 50% forest, 15% cropland, 25% pasture; urban in Wichita, Tulsa, Little Rock
Population density: 14.6 people/km²
Major information sources: Branson 1982, 1983, 1984; Cross et al. 1986; Reimer 1969; Sealander and Heidt 1990; Solley et al. 1998

FIGURE 7.8 Mean monthly air temperature, precipitation, and runoff for the Arkansas River basin.

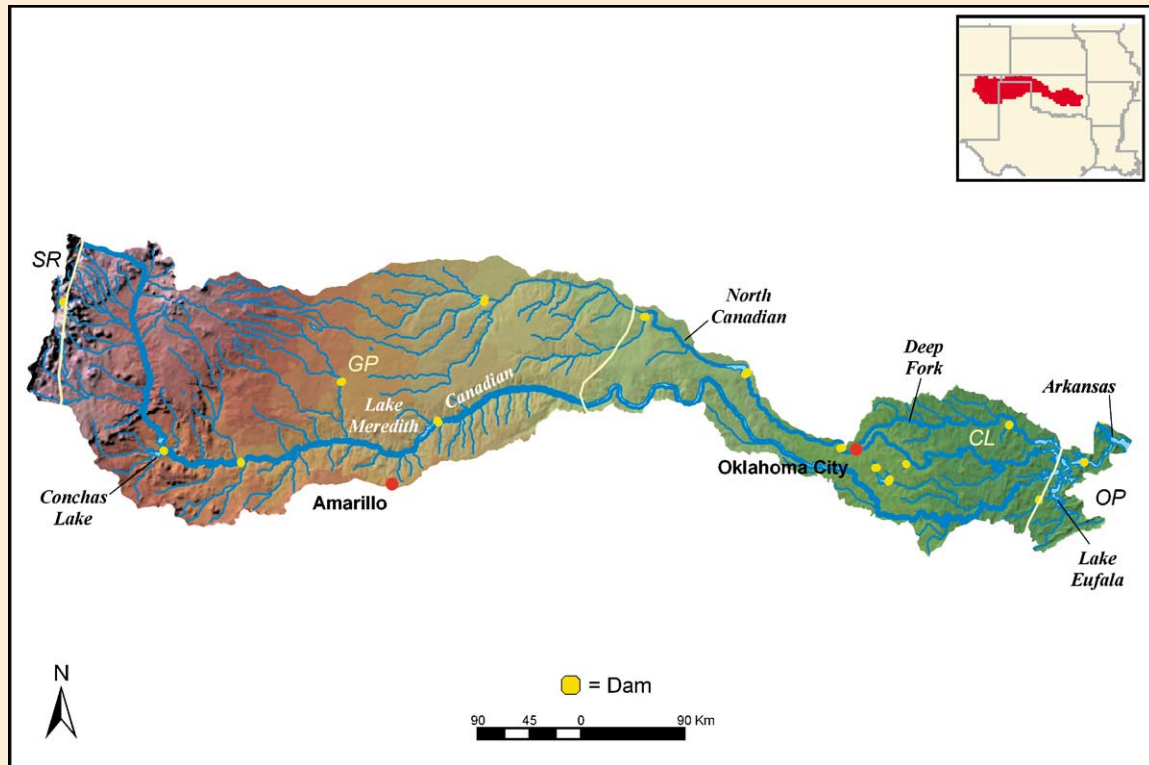

FIGURE 7.9 Map of the Canadian River basin. Physiographic provinces are separated by yellow lines.

CANADIAN RIVER

Relief: 4132 m

Basin area: 122,070 km²

Mean discharge: 174 m³/s

River order: 6

Mean annual precipitation: 52.5 cm

Mean air temperature: 15°C

Mean water temperature: 18°C

Physiographic provinces: Southern Rocky Mountains (SR), Great Plains (GP), Central Lowland (SL), Ouachita Province (OP)

Biomes: Temperate Mountain Forest, Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: Southern Plains

Terrestrial ecoregions: Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone

Number of fish species: 63 (native)

Number of endangered species: 1 fish, 1 bird

Major fishes: gizzard shad, red shiner, Arkansas River shiner, emerald shiner, plains minnow, bluntnose minnow, fathead minnow, plains killifish, western mosquitofish, river carpsucker, channel catfish, white bass, largemouth bass, longear sunfish, green sunfish

Major other aquatic vertebrates: snapping turtle, yellow mud turtle, stinkpot turtle, smooth softshell turtle, beaver

Major benthic invertebrates: oligochaetes, midges (*Bezzia*, *Chironomus*, *Cryptochironomus*), mayflies (*Tricorythodes*, *Caenis*), caddisflies (*Cheumatopsyche*), crayfish (*Orconectes nais*), fingernail clams (*Sphaerium*, *Pisidium*), mussels (pink papershell, fragile papershell, yellow sandshell, white heelsplitter)

Nonnative species: Asian clam, Red River pupfish, inland silversides, common carp, blue tilapia, saltcedar

Major riparian plants: silver maple, box elder, American elm, hackberry, sandbar willow, ash, cottonwood, saltcedar

Special features: crosses arid grasslands in west, sometimes desiccating, mesic forest in east; shallow, shifting "sand bed" rivers create harsh environments, limiting richness and persistence of fauna

Fragmentation: four impoundments on main stem

Water quality: pH = 8.2, alkalinity = 156 mg/L as CaCO₃, NO₃-N = 0.46 mg/L, total phosphorus = 0.32 mg/L

Land use: 50% rangeland or pasture, 30% cropland; up to 55% forested in east

Population density: 9.1 people/km²

Major information sources: Branson 1982, 1983, 1984, Byre 2000, Cross et al. 1986, Matthews and Hill 1979, 1980, Solley et al. 1998, Reimer 1969

FIGURE 7.10 Mean monthly air temperature, precipitation, and runoff for the Canadian River basin.

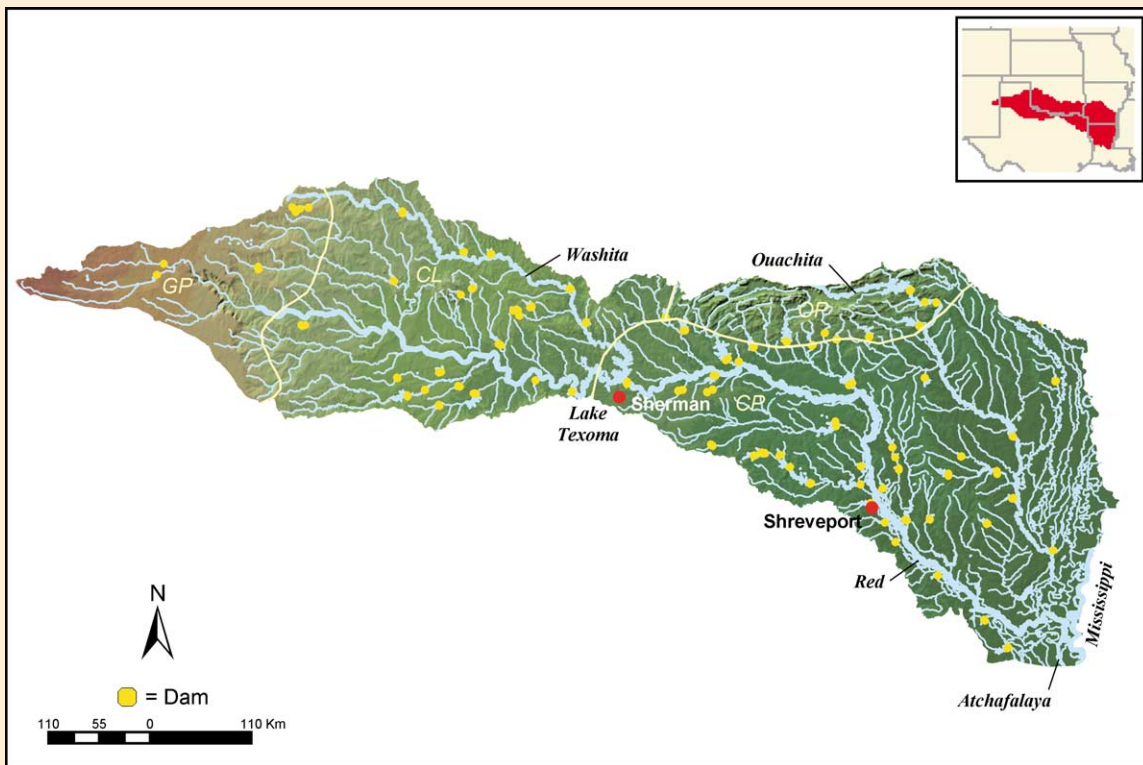

FIGURE 7.11 Map of the Red River basin. Physiographic provinces are separated by yellow lines.

RED RIVER

Relief: 1347 m

Basin area: 169,890 km²

Mean discharge: 852 m³/s

River order: 7

Mean annual precipitation: 82 cm

Mean air temperature: 18°C

Mean water temperature: 19.3°C

Physiographic provinces: Great Plains (GP), Central Lowland (CL),
Ouachita Province (OP), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregions: Southern Plains, Ouachita Highlands,
Mississippi Embayment

Terrestrial ecoregions: Western Short Grasslands, Central and Southern
Mixed Grasslands, Central Forest Grassland Transition Zone,
Piney Woods Forests

Number of fish species: 171 (152 native)

Number of endangered species: 1 bird

Major fishes: alligator gar, longnose gar, gizzard shad, red shiner,
emerald shiner, Red River shiner, chub shiner, emerald shiner, blacktail shiner, bluntnose minnow, plains minnow, blue
sucker, smallmouth buffalo, river carpsucker, channel catfish, blue catfish, plains killifish, Red River pupfish, sunfishes, white
bass, largemouth bass, bigscale logperch

Major other aquatic vertebrates: alligator snapping turtle, common slider, spiny softshell turtle, false map turtle, yellow mud
turtle, plain-bellied water snake, cottonmouth, American alligator, great blue heron, beaver, muskrat, nutria

Major benthic invertebrates: Chironomid midges (*Glyptotendipes*, *Dicrotendipes*, *Chironomus*), mayflies (*Hexagenia*, *Caenis*,
Stenonema), caddisflies (*Cynnellus*, *Hydropsyche*), crayfishes (*Orconectes palmeri*, *O. nais*, *Procambarus simulans*), mussels
(pink papershell, fragile papershell, bleufer)

Nonnative species: Asian clam, nutria, striped bass, walleye, threadfin shad, inland silversides, common carp, grass carp

Major riparian plants: cottonwood, willows, box elder, silver maple, slippery elm, sweetgum, post oak

Special features: spans gradient from driest to some of wettest climatic conditions in North America; high salinity in headwaters,
frequently drying; Great Raft, once a logjam of gigantic proportions upstream from Shreveport

Fragmentation: one major impoundment (Lake Texoma) on main stem; four locks and dams in Louisiana

Water quality: pH = 8.0, alkalinity = 131 mg/L as CaCO₃, NO₃-N = 0.18 mg/L, PO₄-P = 0.11 mg/L, total phosphorus =
0.12 mg/L; chloride extremely high in headwaters, conductivity to 35 μS/cm, decreasing to about 2 μS/cm near Lake Texoma

Land use: 40% to 60% rangeland and 30% cropland in west; 50% forest, 20% cropland, and 10% pasture in east

Population density: 9.1 people/km²

Major information sources: Branson 1982, 1983, 1984, Creel 1964, Cross et al. 1986, Echelle et al. 1972, Hoagland 2000,
Valentine and Stansbery 1971

FIGURE 7.12 Mean monthly air temperature, precipitation, and runoff for the Red River basin.

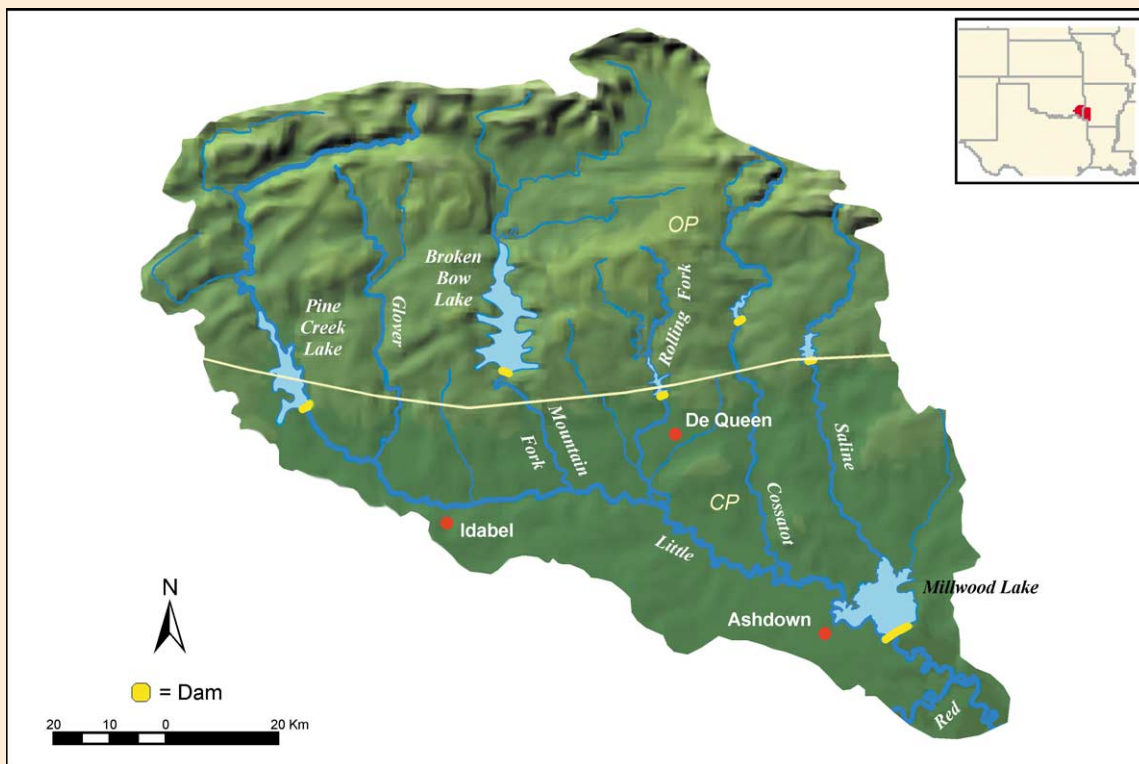

FIGURE 7.13 Map of the Little River basin. Physiographic provinces are separated by a yellow line.

LITTLE RIVER

Relief: 741 m
Basin area: 10,720 km²
Mean discharge: 183 m³/s
River order: 6
Mean annual precipitation: 123 cm
Mean air temperature: 16°C
Mean water temperature: 16.5°C
Physiographic provinces: Ouachita Province (OP), Coastal Plain (CP)
Biome: Temperate Deciduous Forest
Freshwater ecoregion: Ouachita Highlands
Terrestrial ecoregions: Ozark Mountain Forests, Central Forest
 Grassland Transition Zone, Piney Woods Forests
Number of fish species: 110
Number of endangered species: 2 mussels, 1 fish
Major fishes: gars, rocky shiner, blacktail shiner, central stoneroller, river redhorse, golden redhorse, blackstriped topminnow, grass pickerel, flier, bantam sunfish, pirate perch, dusky darter, crystal darter, orangethroat darter, orangebelly darter, largemouth bass, spotted bass, sunfishes, leopard darter
Major other aquatic vertebrates: snapping turtle, common slider, razor-backed musk turtle, diamondback water snake, northern water snake, cottonmouth, swamp rabbit, beaver, river otter, mink
Major benthic invertebrates: mussels (threeedge, mucket, pimpleback), limpets (*Ferrissia*), snails (*Elimia*, *Heliosoma*), crayfishes (*Orconectes palmeri*, *Procambarus acutus*), mayflies (*Stenonema*, *Ephemerella*, *Heptagenia*, *Isonychia*), beetles (*Stenelmis*, *Psophenus*), stoneflies (*Acroneuria*, *Neoperla*), caddisflies (*Cheumatopsyche*, *Helicopsyche*, *Chimarra*)
Nonnative species: Asian clam, brown trout, rainbow trout, common carp; grass carp and striped bass likely
Major riparian plants: river birch, sycamore, smooth alder, sugar maple, box elder, willow oak, blue beech, bald cypress
Special features: some of last well-preserved upland rivers in central United States; regional “hot spot” of biodiversity
Fragmentation: two reservoirs on main stem (Pine Creek and Millwood); four large reservoirs on main tributaries
Water quality: pH = 7.2, alkalinity = 24 mg/L as CaCO₃, NO₃-N = 0.33 mg/L, PO₄-P = 0.06 to 0.09 mg/L
Land use: 75% forest, 10% cropland, 15% pasture; no urban areas
Population density: 3.2 people/km²
Major information sources: Hoagland 2000, Hoagland et al. 1996, Jenkins 1956, Reimer 1969, Shackelford and Whitaker 1997, Solley et al. 1998, Vaughn 2000, Vaughn and Taylor 1999

FIGURE 7.14 Mean monthly air temperature, precipitation, and runoff for the Little River basin.

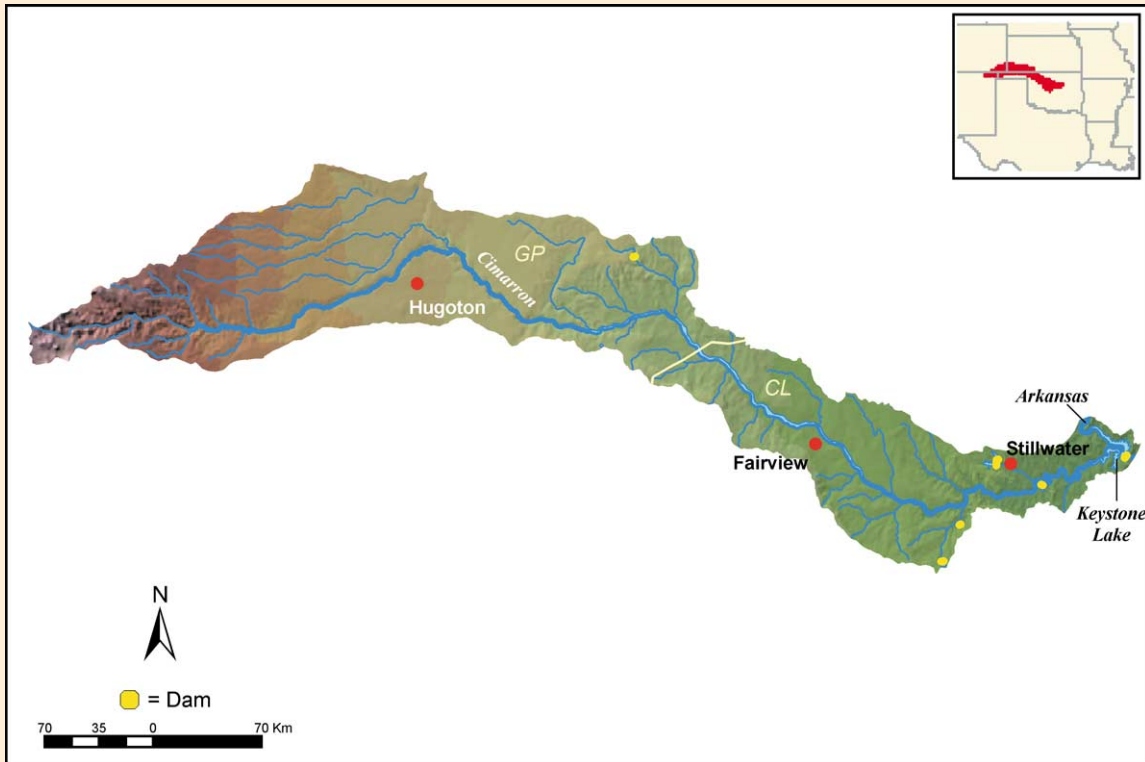

FIGURE 7.15 Map of the Cimarron River basin. Physiographic provinces are separated by a yellow line.

CIMARRON RIVER

Relief: 2036 m
 Basin area: 50,540 km²
 Mean discharge: 42 m³/s
 River order: 4
 Mean annual precipitation: 55.3 cm
 Mean air temperature: 15°C
 Mean water temperature: 18.4°C
 Physiographic provinces: Great Plains (GP), Central Lowland (CL)
 Biomes: Temperate Grasslands, Temperate Deciduous Forest
 Freshwater ecoregion: Southern Plains
 Terrestrial ecoregions: Western Short Grasslands, Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone
 Number of fish species: 48
 Number of endangered species: 1 fish, 1 bird
 Major fishes: red shiner, plains minnow, plains killifish, gizzard shad, white bass, channel catfish, western mosquitofish; Arkansas River shiner now much reduced in abundance
 Major other aquatic vertebrates: snapping turtle, beaver
 Major benthic invertebrates: mollusks (fingernail clam), crayfish (*Orconectes nais*), oligochaete worms (*Chaetogaster*, *Limnodrilus*), mayflies (*Caenis*, *Baetis*), caddisflies (*Cheumatopsyche*, *Hydropsyche*), beetles (*Stenelmis*)
 Nonnative species: Asian clam, Red River shiner, striped bass, saltcedar
 Major riparian plants: silver maple, box elder, ash, hackberry, cottonwood, sandbar willow, black willow, saltcedar, American elm
 Special features: drains some of most arid lands of southern Great Plains; long reaches of western main stem intermittent; harsh conditions, but relatively diverse fish fauna
 Fragmentation: two large reservoirs on main stem; other fragmentation by natural or human-enhanced desiccation of main-stem reaches
 Water quality: pH = 8.1, alkalinity = 169 mg/L as CaCO₃, NO₃-N = 1.32 mg/L, total phosphorus = 0.84 mg/L
 Land use: 50% rangeland or pasture, 35% cropland, up to 30% forest in east; no large cities
 Population density: 6.7 people/km²
 Major information sources: Hoagland 2000, ONHI 2001, Solley et al. 1998

FIGURE 7.16 Mean monthly air temperature, precipitation, and runoff for the Cimarron River basin.

FIGURE 7.18 Mean monthly air temperature, precipitation, and runoff for the Neosho River basin.

NEOSHO (GRAND) RIVER

Relief: 325 m

Basin area: 54,550 km²

Mean discharge: 254 m³/s

River order: 6

Mean annual precipitation: 91 cm

Mean air temperature: 12°C

Mean water temperature: 15.4°C

Physiographic provinces: Central Lowland (CL), Ozark Plateaus (OZ)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: Central Prairie

Terrestrial ecoregion: Central Forest Grassland Transition Zone

Number of fish species: 94 native

Number of endangered species: 1 fish, 1 bird, 1 mussel

Major fishes: upstream: Topeka shiner, orangethroat darter, cardinal shiner, southern redbelly dace, endemic Neosho madtom; downstream: paddlefish, gizzard shad, numerous native minnows, smallmouth buffalo, river carpsucker, white bass, largemouth bass, sunfishes

Major other aquatic vertebrates: hellbender (threatened in Kansas), mudpuppy, snapping turtle, spiny softshell turtle, smooth softshell turtle, common slider, false map turtle, Ouachita map turtle, painted turtle, diamondback water snake

Major benthic invertebrates: 33 species of mussels (three-ridge, monkeyface, Neosho mucket), caddisflies (*Hydropsyche*, *Potamyia*), crayfishes (*Orconectes virilis*, *O. neglectus*), chironomid midges (*Glyptotendipes*)

Nonnative species: Asian clam, common carp, rainbow trout

Major riparian plants: silver maple, box elder, red maple, river birch, hackberry, pecan, eastern swamp privet, ash, blackgum, sycamore, cottonwood, pin oak, American elm

Special features: drains unique uplifted region of Kansas known as “Flint Hills”; streams comprising clear water “outposts” disjunct from and containing species common to Ozark Plateaus

Fragmentation: four impoundments on main stem

Water quality: pH = 7.4, alkalinity = 52 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.02 mg/L

Land use: upper basin: 60% rangeland and pasture, 20% crops; lower basin: 75% forest, 20% pasture, 5% crops; no large cities

Population density: 13.5 people/km²

Major information sources: Covich et al. 1978, Hoagland 2000, Obermeyer et al. 1997, Nulty 1980, Reimer 1969, Solley et al. 1998, Vaughn 1998

FIGURE 7.20 Mean monthly air temperature, precipitation, and runoff for the Illinois River basin.

ILLINOIS RIVER

Relief: 390 m

Basin area: 4260 km²

Mean discharge: 54 m³/s

River order: 5

Mean annual precipitation: 103 cm

Mean air temperature: 14°C

Mean water temperature: 16.5°C

Physiographic province: Ozark Plateaus (OZ), Ouachita Province (OP)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Ozark Highlands, Central Prairie

Terrestrial ecoregion: Ozark Mountain Forests

Number of fish species: 101

Number of endangered species: 1 bird and 1 mussel federally threatened

Major fishes: southern brook lamprey, longnose gar, central stoneroller, bigeye shiner, Ozark minnow, rosyface shiner, cardinal shiner, redspot chub, golden redbreast, slender madtom, blackspotted topminnow, brook silverside, smallmouth bass, spotted bass, longear sunfish, green sunfish, white bass, stippled darter, orangethroat darter, greenside darter, banded darter, banded sculpin

Major other aquatic vertebrates: American bullfrog, common slider, spiny softshell turtle, false map turtle, water snakes, cottonmouth

Major benthic invertebrates: 22 species of mussels (elktoe, threeridge, pigtoe), fingernail clams (*Sphaerium*, *Pisidium*), snails (*Elimia*, *Physa*), crayfish (*Orconectes meeki*), mayflies (*Baetis*, *Pseudocleon*), caddisflies (*Helicopsyche*, *Cheumatopsyche*)

Nonnative species: Asian clam, striped bass, rainbow trout

Major riparian plants: silver maple, box elder, red maple, river birch, pecan, eastern swamp privet, possum haw, sycamore, black gum, cottonwood, pin oak, American elm

Special features: state Scenic River (Oklahoma); generally a clear upland river, but water quality deterioration (municipal wastes) in headwaters (Arkansas); heavily used for recreation

Fragmentation: one major impoundment (Tenkiller); old spillway (former Lake Frances) at Arkansas–Oklahoma border impedes upstream movement of fishes

Water quality: pH = 7.4, alkalinity = 52 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.02 mg/L

Land use: 70% forest, 20% pasture, 10% cropland; no large cities

Population density: 18.3 people/km²

Major information sources: Gordon et al. 1979, Hoagland 2000, ONHI 2001, Moore and Paden 1950, Reimer 1969

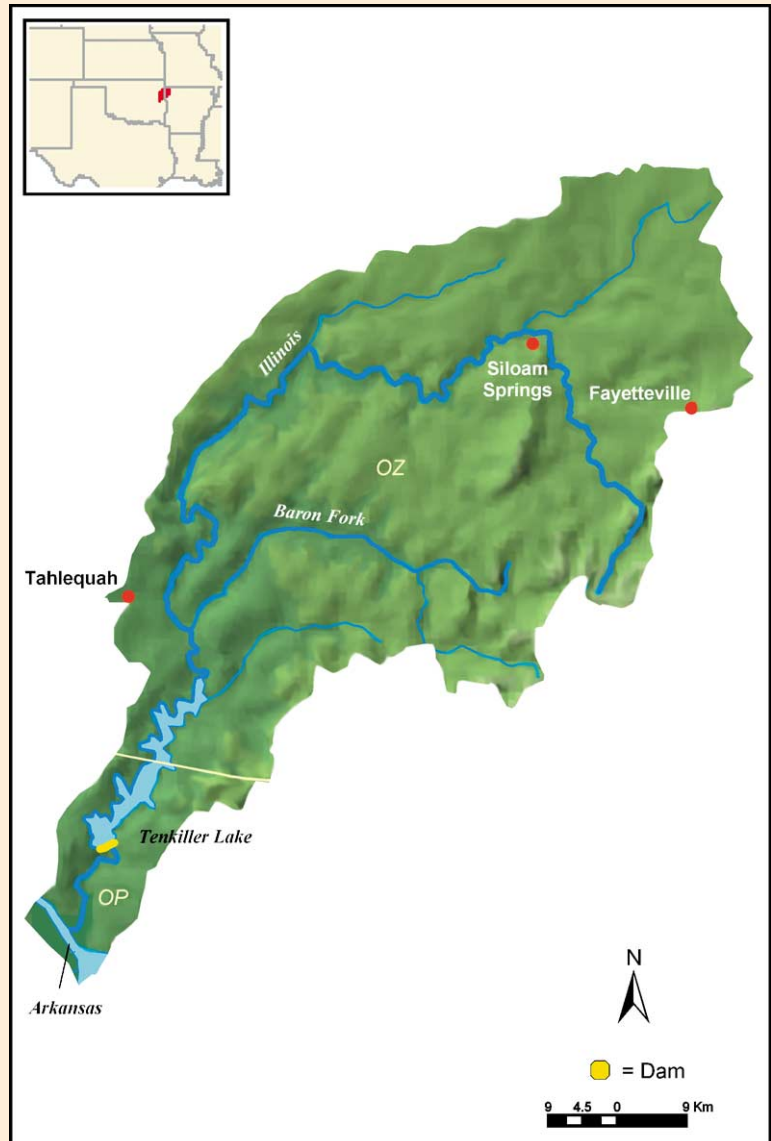

FIGURE 7.19 Map of the Illinois River basin. Physiographic provinces are separated by a yellow line.

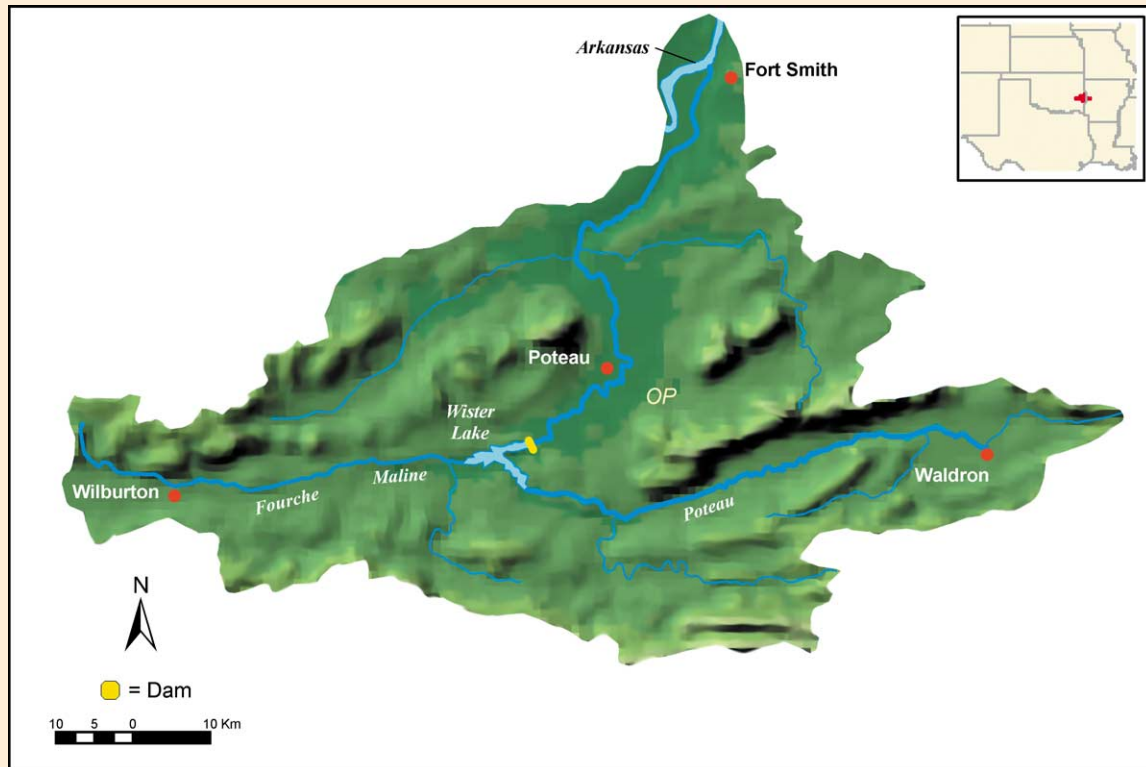

FIGURE 7.21 Map of the Poteau River basin.

POTEAU RIVER

Relief: 680 m

Basin area: 4840 km²

Mean discharge: 68 m³/s

River order: 4

Mean annual precipitation: 112 cm

Mean air temperature: 16°C

Mean water temperature: 17°C

Physiographic province: Ouachita Province (OP)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Ouachita Highlands, Central Prairie

Terrestrial ecoregion: Ozark Mountain Forests

Number of fish species: 95

Number of endangered species: none

Major fishes: spotted gar, grass pickerel, pugnose minnow, steelcolor shiner, redbfin shiner, bluntnosed minnow, central stoneroller, smallmouth buffalo, river carpsucker, creek chubsucker, channel catfish, blackstriped topminnow, western mosquitofish, largemouth bass, spotted bass, longear sunfish, white crappie, logperch, redbfin darter, orangethroat darter

Major other aquatic vertebrates: mudpuppy, common slider, snapping turtle, beaver, river otter

Major benthic invertebrates: 32 species of mussels (three-ridge, washboard, fluted shell), freshwater shrimp (*Palaemonetes kadiakensis*), mayflies (*Pseudocleon*, *Choroterpes*), caddisflies (*Cheumatopsyche*, *Hydroptila*), beetles (*Microcylloepus*, *Stenelmis*, *Dubiraphia*)

Nonnative species: Asian clam, common carp, striped bass, inland silversides

Major riparian plants: silver maple, box elder, red maple, smooth alder, blue beech, ash, black gum, cottonwood, willow oak, American elm, slippery elm

Special features: arises in steep upland slopes of Ouachita Mountain “Ridge and Valley” structural features but makes abrupt transition to low-gradient, turbid conditions before flowing into Arkansas River; commercially harvested for mussels

Fragmentation: one large impoundment (Lake Wister)

Water quality: pH = 7.1, alkalinity = 19 mg/L as CaCO₃, NO₃-N = 1.11 mg/L, total phosphorus = 0.15 mg/L

Land use: 65% forest, 20% pasture, 5% to 10% cropland; no large cities

Population density: 9.4 people/km²

Major information sources: Cross and Moore 1952, Hoagland 2000, Lindsay et al. 1983, Solley et al. 1998

FIGURE 7.22 Mean monthly air temperature, precipitation, and runoff for the Poteau River basin.

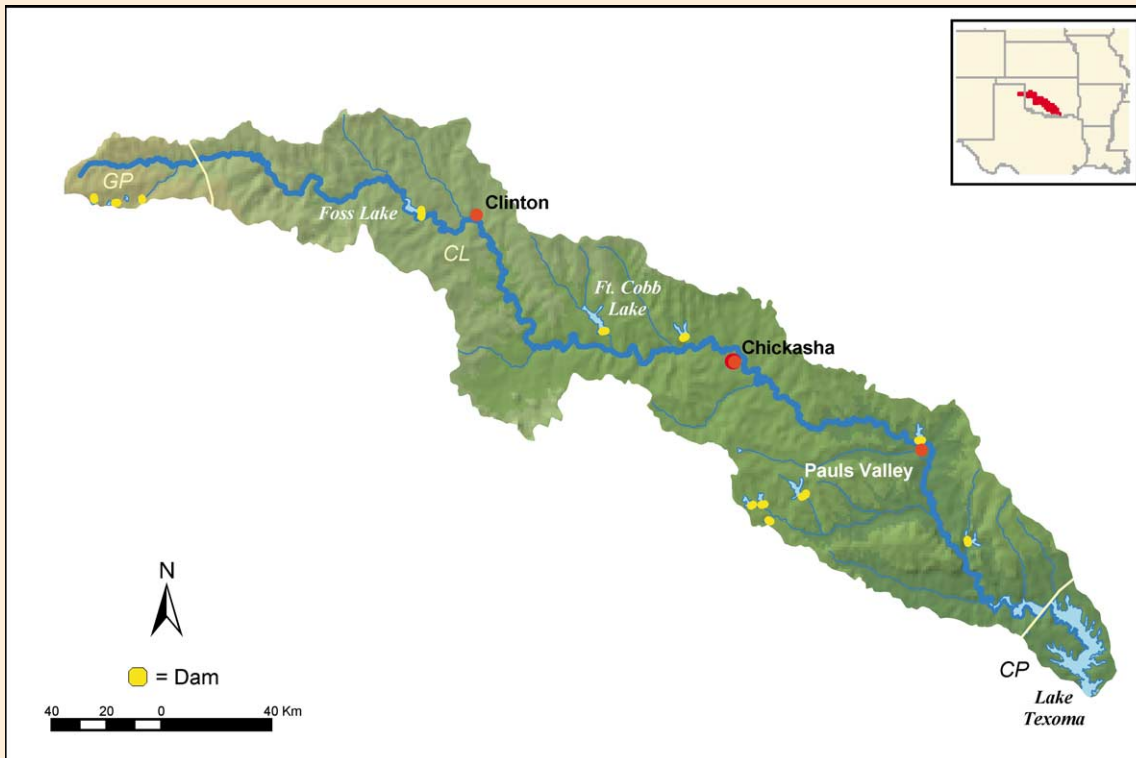

FIGURE 7.23 Map of the Washita River basin. Physiographic provinces are separated by yellow lines.

WASHITA RIVER

Relief: 714 m

Basin area: 20,230 km²

Mean discharge: 44 m³/s

River order: 4

Mean annual precipitation: 76 cm

Mean air temperature: 16°C

Mean water temperature: 18.4°C

Physiographic provinces: Great Plains (GP), Central Lowland (CL), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: Southern Plains

Terrestrial ecoregions: Central and Southern Mixed Grasslands, Central Forest Grassland Transition Zone

Number of fish species: 51

Number of endangered species: none

Major fishes: gizzard shad, speckled chub, channel catfish, longear sunfish, green sunfish, bluegill, red shiner; carpsuckers common in lower river

Major other aquatic vertebrates: common slider, false map turtle, plain-bellied water snake, beaver

Major benthic invertebrates: At least 10 mussels (bleufer, white heelsplitter, yellow sandshell), chironomid midges (31 genera), mayflies (*Baetis*, *Choroterpes*), caddisflies (*Hydropsyche*, *Hydroptila*), beetles (*Dubiraphia*, *Heterelmis*)

Nonnative species: Asian clam, striped bass, threadfin shad, inland silversides, common carp, saltcedar

Major riparian plants: silver maple, box elder, ash, hackberry, cottonwood, bur oak, sandbar willow, black willow, saltcedar, American elm

Special features: lower main stem one of most turbid rivers in North America, extremely heavy load of silt or clay; very muddy bottoms; large snag piles common, likely to be major habitat

Fragmentation: two impoundments on main stem

Water quality: pH = 8.0, alkalinity = 170 mg/L as CaCO₃, NO₃-N = 2.53 mg/L, PO₄-P = 0.051 mg/L

Land use: 55% rangeland or pasture, 30% crops, 5% to 10% forest; no large cities

Population density: 8.7 people/km²

Major information sources: Branson 1982, 1983, 1984, Hoagland 2000, Johnson and Vaughn 1995, Magdych 1984, Morris and Madden 1978, ONHI 2001, Solley et al. 1998

BLUE RIVER

Relief: 330 m

Basin area: 1650 km²

Mean discharge: 9 m³/s

River order: 4

Mean annual precipitation: 100 cm

Mean air temperature: 17°C

Mean water temperature: 17°C

Physiographic provinces: Central Lowland (CL), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregions: Ouachita Highlands, Southern Plains

Terrestrial ecoregion: Central Forest Grassland Transition Zone

Number of fish species: 85

Number of endangered species: none

Major fishes: redbot chub, central stoneroller, bigeye shiner, blacktail shiner, rocky shiner, spotted sucker, golden redbot, largemouth bass, longear sunfish, channel darter, orangethroat darter, smallmouth buffalo, river carpsucker, blue sucker; unique forms of the orangebelly darter and striped shiner are distinct from those found elsewhere in their range

Major other aquatic vertebrates: westernmost tributary of Red River with razor-backed musk turtle, cottonmouth

Major benthic invertebrates: 24 species of mussels (threeidge, pigtoe, pistolgrip), amphipod crustaceans (*Hyalella azteca*), crayfish (*Orconectes virilis*), mayflies (*Stenonema*, *Tricorythodes*), beetles (*Dubiraphia*, *Helichus*), caddisflies (*Cheumatopsyche*, *Hydropsyche*)

Nonnative species: Asian clam, common carp, rainbow trout, possibly rudd

Major riparian plants: silver maple, box elder, hackberry, pecan, ash, American elm, sycamore, desert false indigo

Special features: upper portion strongly marl-depositing; marl dikes a prominent feature forming pools and small waterfalls; disjunct populations of seaside alder and redbot chub

Fragmentation: no large impoundments

Water quality: pH = 8.2, alkalinity = 186 mg/L as CaCO₃, NO₃-N = 1.65 mg/L, total phosphorus = 0.43 mg/L

Land use: 50% pasture, 20% cropland, 30% forest; no large cities

Population density: 18.9 people/km²

Major information sources: Hoagland 2000, ONHI 2001, Reimer 1969, Vaughn 1997

KIAMICHI RIVER

Relief: 701 m

Basin area: 4650 km²

Mean discharge: 48 m³/s

River order: 5

Mean annual precipitation: 110 cm

Mean air temperature: 17°C

Mean water temperature: 16.7°C

Physiographic provinces: Ouachita Province (OP), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Ouachita Highlands

Terrestrial ecoregions: Ozark Forests (although not in Ozark

Mountains proper), Central Forest Grassland Transition Zone

Number of fish species: 86

Number of endangered species: 2 mussels

Major fishes: orangebelly darter, Johnny darter, dusky darter, central stoneroller, bigeye shiner, redfin shiner, rocky shiner, steelcolor shiner, spotted sucker, flathead catfish, smallmouth bass, spotted bass, largemouth bass, blackstriped topminnow, red shiner, gizzard shad, gars, blue sucker, river carpsucker

Major other aquatic vertebrates: snapping turtle, false map turtle, stinkpot turtle, spiny softshell turtle, plain-bellied water snake, cottonmouth, beaver

Major benthic invertebrates: 29 mussel species (threeridge, mucket, pigtoe, pimpleback) freshwater shrimp (*Palaemonetes kadiakensis*), crayfish (*Octonectes menae*), mayflies (*Stenonema*, *Caenis*), caddisflies (*Oecetis*, *Nectopsyche*), beetles (*Stenelmis*, *Microcylloepus*)

Nonnative species: Asian clam, common carp, striped bass in lower main stem, threadfin shad

Major riparian plants: silver maple, box elder, red maple, smooth elder, river birch, blue beech, ash, sweetgum, swamp tupelo, black gum, sycamore, cottonwood, willow oak, American elm, slippery elm

Special features: identified by The Nature Conservancy as one of most critical watersheds in United States for protecting freshwater biodiversity; population of endangered Ouachita rock pocketbook mussel; reintroduction of river otters

Fragmentation: one major impoundment on main stem; one major impoundment on tributary

Water quality: pH = 7.3, alkalinity = 120 mg/L as CaCO₃, NO₃-N = 0.31 mg/L, total phosphorus = 0.71 mg/L

Land use: 75% forest, 15% pasture, 10% crops; no large cities

Population density: 5.6 people/km²

INTRODUCTION

The Upper Mississippi River basin, which represents 10% of the 3rd largest drainage basin in the world, begins as a 1st order stream draining Lake Itasca in the bog and spruce swamps of northern Minnesota and flows south to join the Ohio River as a 10th order alluvial river to form the largest river in North America (Fig. 8.2). The progression of the river from lake outlet to great river creates an impressive range of physical, chemical, and biological diversity throughout the basin. The Upper Mississippi River basin includes areas within Minnesota, South Dakota, Wisconsin, Illinois, Indiana, Iowa, and Missouri, ranging in latitude from 47°N to 37°N. Because of its generally north–south flow across the temperate zone of North America, climatic conditions vary considerably from its source to the confluence with the Ohio River. Describing the Upper Mississippi River as beginning at Lake Itasca and ending at the confluence of the Ohio River would include the Missouri River basin; however, details on the Missouri River basin are given elsewhere and all information provided for the Upper Mississippi River excludes the Missouri (see Chapter 10). The basin encompasses five terrestrial ecoregions, three biomes,

and three physiographic provinces. Despite the variability created by climate and geology, commonalities are evident among rivers at the physiographic province and terrestrial ecoregion levels.

Archaeological finds suggest that human history in the upper Mississippi River basin dates back 9000 or more years. Ceremonial and community mounds and other signs of man-made structures found throughout the basin hint at the cultural diversity present in the basin prior to European settlement. The first Europeans credited with exploring the Upper Mississippi, Louis Joliett and Father Jacques Marquette, arrived in 1673. Settlement of the basin began slowly, with a few isolated groups in Missouri and Illinois in the early eighteenth century and in the northern reaches of the basin in the early nineteenth century. Expansion of settlements came with the advent of the paddle wheeler, which opened the fertile soils of the basin to immigrants seeking to farm their own land. The river today maintains its significant role as a center of commerce for the transportation of goods by barge.

The rivers described in this chapter were selected as representative within each region and to reflect both the common threads among rivers in the Upper Mississippi River basin and their unique attributes.

FIGURE 8.2 Rivers of the Upper Mississippi River basin covered in the chapter.

Five rivers are discussed in detail: Upper Mississippi, Minnesota, St. Croix, Wisconsin, and Illinois. Abbreviated descriptions of physical, chemical, and biological attributes are included for six additional rivers: Chippewa, Root, Wapsipinicon, Rock, Des Moines, and Kaskaskia.

Physiography and Climate

The Upper Mississippi River basin lies within three physiographic provinces: Superior Upland, Central Lowland, and Ozark Plateau. The dominant physiographic feature, representing almost 85% of the basin, is the Central Lowland physiographic province (Fig. 8.11). The features of the northern part of the province, which includes the Upper Mississippi basin,

are a result of glacial processes, as evidenced by its low altitude (<620 m asl) and limited local relief (Hunt 1967). Although the Central Lowland appears to be relatively homogeneous and creates some common physical features among rivers (i.e., low stream gradient), glacial and other geological processes have provided some measure of variation in the landscape. The Central Lowland is divided into six physiographic sections, five of which lie within the Upper Mississippi River basin.

The drainage basin begins in the Western Lakes physiographic section, characterized by deep glacial drift left by the Wisconsin glaciation, which created abundant kettle and moraine lakes as well as wetlands and bogs. The drift lies over a bed of Precambrian igneous and metamorphic rock extending from

the Superior Upland physiographic province, which is replaced in the southern limit of the Western Lakes section of the Central Lowland Province by Paleozoic sandstones. The Eastern Lakes section includes eastern Wisconsin and is also covered by Wisconsin Drift, under which lies Paleozoic limestones and shales (Nielsen et al. 1984). The Driftless Area of southeastern Minnesota and central-southwestern Wisconsin lies between the Eastern and Western Lakes sections. The major glaciations passed around this area, leaving outcroppings consisting of alternating layers of limestone and sandstone rather than the low-relief terrain typical of the areas over which the glaciers moved. Actions of rivers and streams in the Driftless Area have created a rolling bluff topography, with some bluffs extending 100 to 200 m above the floor of the plain. Although not touched directly by glaciation, the area was repeatedly filled with debris from glacial outwash from the glacial River Warren, the predecessor of the Upper Mississippi.

The part of the basin that encompasses Iowa, Illinois, Missouri, and Indiana is divided into the two sections of the Central Lowland province: the Till Plain section to the east of the Upper Mississippi River proper and the Dissected Till Plain section to the west. Both are covered by highly weathered Illinoian and Kansan Drift and loess deposits. Loess in the Dissected Till Plain is commonly more than 10 m thick and gradually thins eastward into the Till Plain. Paleozoic limestones and shales lie deep beneath the overlying drift and loess. Glaciation of the Dissected Till Plain occurred earlier than in the Till Plain, which was also partly covered by the Wisconsin glaciation. Although the Till Plain still retains plains features with little relief, the area to the west of the Upper Mississippi has been dissected by streams and rivers (Hunt 1967).

The Upper Mississippi flows from the Central Lowland province into the Ozark Plateau province near St. Louis, Missouri, before emptying into the Coastal Plain province, through which the Lower Mississippi River flows (Chapter 6). Only about 5% of the basin lies within the Ozark Plateau province, which is a transition into the broader floodplain of the Lower Mississippi River below the confluence of the Upper Mississippi and Ohio rivers.

Although the main-stem Upper Mississippi begins in the Central Lowland province, the northeastern corner, or about 10%, of the basin lies within the Superior Upland physiographic province. The Superior Upland is an extension of the Precambrian Shield of Canada created by an upwarp of Precambrian

rock (Hunt 1967). The result is a gently rolling landscape with limited erosion by the streams and rivers flowing through this region, which creates river systems very different from the rest of those found in the drainage. As described earlier, the geological features of the Superior Upland province influence the geology of the Western and Eastern Lakes sections of the Central Lowland physiographic province.

Climatic conditions change considerably from the northern extreme of the basin to its southern boundary at the confluence with the Ohio River. The average annual air temperature ranges from 3°C in the north to 15°C in the southern portion of the basin. Precipitation demonstrates a similar gradient, increasing from 60 cm/yr in the north to 81 cm/yr in the middle of the basin to 122 cm/yr in the south. Precipitation is usually highest from April to June in the northern basin and from April to July in the southern part of the basin. January and February are the driest months throughout the basin, but precipitation above 42°N latitude is low November through March and is primarily in the form of snow. Average runoff yield is 24% throughout the basin but varies from 5% to 40% as a function of location (Nielsen et al. 1984).

Basin Landscape and Land Use

The Upper Mississippi River basin covers three biomes: Boreal Forest, Temperate Deciduous Forest, and Temperate Grassland. The basin is further divided into five terrestrial ecoregions (Ricketts et al. 1999) that reflect attributes of the biomes and transitional gradations between biomes. The Western Great Lakes Forest ecoregion overlaps the Boreal Forest and Temperate Deciduous Forest biomes and is typified by a forest composition that includes paper birch, black spruce, jack pine, white pine, sugar maple, red maple, and balsam fir. The Upper Midwest Forest/Savanna Transition ecoregion lies to the south of the Western Great Lakes ecoregion. It is an ecotonal unit separating the Great Plains from the eastern forests (Ricketts et al. 1999). The region was heavily forested with oak, maple, and basswood, with oak savannas present throughout the forested areas.

The Upper Midwest Forest/Savanna Transition gives way to the Central Tall Grasslands to the southwest (southern Minnesota and most of Iowa) and the Central Forest/Grassland Transition Zone ecoregion to the southeast (most of Illinois and northern Missouri). The Central Forest/Grassland Transition is also an ecotonal unit, separating the

eastern deciduous forests from tallgrass and mixed-grass prairies. The Central Tall Grasslands ecoregion supported the greatest diversity of tallgrasses—big bluestem, switchgrass, and Indian grass—due largely to the high levels of rainfall (100 cm/yr; Ricketts et al. 1999). The southernmost part of the basin extends into the Central U.S. Mixed Hardwood Forests ecoregion. Although primarily viewed as an oak–hickory forest, the ecoregion once retained the savanna-prairie mosaic characteristic of the Central Forest/Grassland Transition Zone and is, therefore, reminiscent of that ecoregion (Ricketts et al. 1999). Tree species diversity is low in this ecoregion, but it once possessed the richest diversity of shrub and herbaceous vegetation in North America.

The landscape of the Upper Mississippi River, although once diverse, is drastically different from the presettlement period. The Great Lakes Forest ecoregion could be considered the most pristine of the ecoregions, but only 20% of the forest remains (Ricketts et al. 1999). Intensive logging has eliminated most old-growth stands of white pine and red pine, which have been replaced by younger stands of birch and aspen or have been converted to agriculture or urban and recreational developments. The Upper Midwest Forest/Savanna has fared even less well, with less than 5% of the ecoregion considered intact. Conversion of land for crop agriculture and overgrazing has been the primary causes of habitat loss. The Central Tall Grasslands and the Central Forest/Grassland Transition Zone ecoregions are now the Corn Belt, with over 80% of the available land used for agriculture. Streams and rivers in these ecoregions have among the highest nitrate concentrations in the country and have been identified as a likely source of much of the nitrogen loading contributing to the formation of a biological “dead zone” in the Gulf of Mexico to the west of the Mississippi River alluvial fan.

The Rivers

The entire Upper Mississippi River basin represents the Mississippi freshwater ecoregion (Abell et al. 2000). If viewed from this larger scale of representing a single freshwater ecoregion and almost entirely in a single physiographic province (Central Lowland), it might be concluded that there is little variability among the rivers of the Upper Mississippi River system. Certainly, commonalities in the physical, chemical, and biological attributes of these rivers do exist, but there are also obvious differences. These differences stem from the influence of glaciation,

specifically the movement of ice sheets over the surface of the Upper Mississippi River basin on several occasions. The most logical approach to identify unique features and common threads between rivers in the Upper Mississippi River system is based on the physiographic sections through which they flow and climatic differences resulting from the 10-degree range of latitude in the basin.

One grouping of rivers includes those flowing through the Superior Upland and the Western Lakes section of the Central Lowland province (Fig. 8.2, Fig. 8.11). This includes the Mississippi headwaters as well as the St. Croix, Chippewa, and Wisconsin rivers. The upper ends of all of these systems are relatively high gradient, with beds of gravel, cobble, boulder, and bedrock. Of these, however, only the St. Croix retains these features for most of its length. The Chippewa and Wisconsin rivers decrease in stream gradient farther downstream as they flow into the Driftless Area, where substrata change from gravel to sand-dominated beds. Most of the St. Croix River is afforded the protection of being in the St. Croix National Scenic Riverway. This is in sharp contrast to the Chippewa and Wisconsin rivers, which have been heavily dammed for hydroelectric production and flood control. Only the lower portions of both rivers are free of dams. The northern rivers are influenced by snow pack, with discharge highest in the spring (April to May) as spring rains fall on the melting snow. Discharge decreases rather abruptly following peak discharge. Minimum discharges occur in the winter as the rivers and the surrounding drainage basin freeze. These systems also exhibit a hydrological feature not evident in other rivers within the Upper Mississippi River system (with the exception of the Upper Mississippi River proper). All three rivers have a slight increase in discharge in the autumn due to increased surface runoff following leaf fall and a reduction in evapotranspiration as air temperature declines. Although not as substantial as the spring peak, this rise appears to be a critical component in the population dynamics of some benthic invertebrates.

The Minnesota River is the first major tributary to join the Mississippi headwaters and flows primarily through the Western Lakes section of the Central Lowland province. Glacial processes created a channel morphology that causes the Minnesota to stand out from the other rivers of the basin. Bottom sediments are similar to those of the other northern rivers—gravel, cobble, and sand—but large quantities of silt are also present in the river channel, originating from the erosion of the large amount of loess

present. The Minnesota is also hydrological similar to the northern rivers. Peak flows are in the spring, resulting from snowmelt and spring rains over the snow, and lowest flows are in the winter. There is, however, no autumn increase in discharge, making the hydrograph resemble those of the rivers in the Dissected Till Plain.

The rivers of the Driftless Area, represented by the Root River, stand out from the other rivers of the basin in that they flow through a region that escaped the direct effects of glaciation. Rivers flowing through the Driftless Area have carved out deep valleys, or coulees, as they flow to the Upper Mississippi River. Geology influences both the physical and chemical characteristics, causing high alkalinity (>200 mg/L as CaCO₃) and a basic pH (8 to 9). The tributaries are coldwater, owing to their groundwater sources, and the main rivers are coolwater systems. Bottom sediments are gravel, cobble, and sand, some of which includes glacial outwash. Rivers on the Minnesota side of the Driftless Area originate in the Dissected Till Plain, which explains the presence of silt deposits in and along the river channels of this region. Natural erosion from the Dissected Till Plains did occur in these systems, but agriculture has exacerbated the problem, making suspended sediment transport a critical water-quality concern. Hydrologically, rivers in the Driftless Area reach peak flows from March to April as spring rains fall on the snow pack, and reach their minimum over the winter. They are susceptible to flash flooding because of their steep-banked valleys and geology. These rivers are largely free flowing, with no major impoundments.

Downriver are the rivers flowing through the Dissected Till Plains and the Till Plains. Although these rivers share many common features, they are best viewed as two separate groups. Rivers flowing through northern Iowa (Wapsipinicon and Des Moines rivers) and northern Illinois (Rock River) begin in areas with surface geology comprised of Wisconsin Drift and thin loess. Bottom sediments in the upper reaches consist of cobble, sand, sand-gravel, and silt. As they work their way into the more weathered Illinoian and Kansan Drift, bottom substrates change to predominantly silt and sand-silt. The hydrology of the Wapsipinicon and Rock rivers more closely resembles rivers in the northern part of the basin. Annual discharge for the Des Moines, which flows into the Upper Mississippi River much farther to the south, more closely resembles the southern rivers, with a protracted peak flow period (March to July) and minimum flows in the fall

(September to October) as evapotranspiration becomes the controlling factor.

The last group of rivers includes the Illinois and Kaskaskia rivers, both of which flow almost entirely through the Till Plains. Rivers in this region exhibit low gradients and bottom substrata consisting of sand, sand-gravel, and silt. Some cobble and gravel areas are found in the upper Illinois River and its tributaries to the north. Rivers in the southern portion of the basin exhibit a more protracted falling limb in their annual hydrograph, probably attributable to subsurface and groundwater inputs and because snowmelt and thawing ground are not part of their hydrological cycle. A trend for rivers of this region is to shift from peak discharges in the spring (Illinois River) to maximum flows in the winter (Kaskaskia) farther south. Minimum discharge occurs in September and October.

The biological distinctiveness of the Upper Mississippi River is rated as only bioregionally outstanding (Abell et al. 2000). This is partly due to the fact that there is only one species of fish, one species of crayfish, and one freshwater mussel that are endemic to the region. Another reason is that the Upper Mississippi, along with the Lower Mississippi, has served as a faunal refugium and has been the source for fauna now inhabiting adjacent ecoregions. The value of the Upper Mississippi River as a faunal refugium is evident by the presence of ancestral species, such as the paddlefish and alligator gar, and because the northernmost biogeographical range of many species occurs only along the Upper Mississippi River (Abell et al. 2000). The conservation status of the basin is endangered, owing to the extensive conversion of the prairie and forest landscape to agriculture and alteration of the rivers for navigation and flood control. The major environmental threats are channelization, flood-control and navigation impoundment, and the still lingering effects of point-source pollution. Introduction of nonnative species, particularly following the linkage of the Upper Mississippi to the Great Lakes, is another serious threat to the diversity and productivity of the basin.

UPPER MISSISSIPPI RIVER

The Upper Mississippi River proper refers exclusively to the main channel of the river and all habitats encompassed within the boundaries of its floodplain (see Fig. 8.11). The main-stem Upper Mississippi River begins at Lake Itasca in northern Minnesota and flows 2008 km, receiving water from tributaries

FIGURE 8.3 Upper Mississippi River above Little Falls, Minnesota (PHOTO BY TIM PALMER).

draining a 444,185 km² area before joining with the Missouri River to form a 10th order stream (Fig. 8.3). The waters of the Missouri increase the flow of the Upper Mississippi by one-third and add another 1,331,810 km² to the total area drained by the Upper Mississippi–Missouri river system. The river flows another 312 km, drawing water from an additional 45,325 km² (not including the Missouri), before joining the Ohio River to form the Lower Mississippi River (see Fig. 8.11). Representing over half of the total length of the Mississippi River, the Upper Mississippi drains some of the most unique landscape found in the Mississippi River basin, including boreal forest, glacial lakes, and bog and spruce swamps.

The importance of the Upper Mississippi River as a center of commerce and community extends well before the arrival of Europeans. Shards of pottery, skeletal remains, and spear tips suggest that humans were in the Upper Mississippi River Valley as early as 8000 years ago, but the best known ancient peoples date back 3000 years. Predominant among these was the Mississippian culture and their settlement, Cahokia, near St. Louis. Cahokia is believed to have been home to 5000 or more people. Both burial and ceremonial mounds are evident throughout the Upper Mississippi basin, including effigy mounds in Iowa and lizard mounds in Wisconsin. Early cultures were later replaced by the Ojibwas, Mesquakie,

Sauk, Dakota, Iowa, and Winnebago Indian nations. The first Europeans credited with seeing the Upper Mississippi River were Louis Joliett and Father Jacques Marquette, who led an expedition from Quebec in 1673 to find a route to China. They arrived at the Upper Mississippi near present-day Prairie du Chien, Wisconsin, and continued down to the Lower Mississippi River near the mouth of the Arkansas River (Waters 1977). The first steamboat reached St. Anthony Falls in St. Paul, Minnesota, in 1828, opening the basin to agriculture, timber harvest, and urbanization.

Physiography, Climate, and Land Use

The Upper Mississippi River proper flows almost entirely through the Central Lowland (CL) physiographic province, with the last 300 km flowing along the Ozark Plateau (OZ) province (see Fig 8.11). Soils in the basin and bottom sediments in the river, however, change considerably as the river flows through areas impacted differently by glaciation. These differences are evident when it is considered that the channel winds through five different terrestrial ecoregions: Western Great Lakes Forests, Upper Midwest Forest/Savanna Transition, Central Tall Grasslands, Central Forest/Grassland Transition, and Central U.S. Hardwood Forests (Ricketts et al. 1999). Many of the characteristics of these ecoregions are determined by whether they were influenced by glaciation and the timing of the last glacial event. The upland vegetation reflects the influence of glaciation on the basin as well as the transition from north temperate to south temperate climates. Upland vegetation in the upper reaches of the river basin includes balsam fir, black spruce, and white pine. Upland vegetation then shifts to oak–maple forest before transitioning into oak-savannas. The middle of the basin was dominated by grasses of the Central Tall Grasslands prior to conversion for agriculture. The lower basin returns to an oak–hickory forest as the river meets the Central U.S. Hardwood Forests as it nears the confluence with the Ohio River.

Climatic conditions change considerably from the northern end of the river to the confluence with the Ohio River. Because of this range, the values shown for temperature and precipitation in Figure 8.12 reflect averages for the length of the river. Precipitation is usually highest from April to July in the northern basin and from April to September in the southern part of the basin. January and February are the driest months throughout the basin, but precipitation above 42°N latitude is low from November

through March and is primarily in the form of snow.

The human population density in the basin is 45 people/km². There are 18 metropolitan areas with populations >100,000 people, with three of these (Minneapolis–St. Paul, Minnesota; the Quad Cities of Iowa and Illinois; and St. Louis, Missouri) occurring on the Upper Mississippi River proper. Despite this, only 5% of the basin has been converted to urban areas. Nearly 70% of the basin has been converted to agriculture, with the most intense activities in the Corn Belt. Corn and soybeans are the most common row crops. Livestock (hogs, cattle) production is also common in this portion of the basin. The concentration of livestock in small feedlots has become a growing environmental issue on smaller tributaries. Approximately 25% of the basin is forested, with the majority of the remaining forested areas in the Mississippi headwaters, the upper ends of the Chippewa and Wisconsin rivers, and the Driftless Area.

River Geomorphology, Hydrology, and Chemistry

The entire Upper Mississippi River, including all tributaries, is within its own freshwater ecoregion, the Mississippi (Abell et al. 2000). The Upper Mississippi River flows from Lake Itasca, Minnesota, at an elevation of 440 m asl. The headwaters flow through bogs, spruce swamps, sand plains, glacial lake beds, and moraine (Fremling et al. 1989). Subsequently, it alternates between low-gradient and high-gradient reaches. At the end of the headwaters is St. Anthony Falls, formed by erosion of the glacial River Warren and now largely obscured by higher water levels created by the nearby lock and dam. St. Anthony Falls served as a barrier to fishes and was the end point for navigation on the Upper Mississippi prior to construction of the lock and dam system.

The Upper Mississippi is believed to flow along its preglacial course from Minneapolis to Davenport, Iowa (also known as the Quad Cities area; Patrick 1998). As the late Wisconsin glacier retreated 14,000 years ago, it cut off river drainage to Hudson Bay, forming glacial Lake Agassiz and glacial Lake Duluth. The overflow of these lakes was carried by the Minnesota and St. Croix rivers, respectively. The massive flows of both rivers carved deeply, as much as 90 m, into the Mississippi River valley (Fremling et al. 1989). As flow from the glaciers diminished, the river valley became partly filled with glacial outwash,

leaving bottom sediments of sand and gravel. From the confluence of the Minnesota downstream to the Driftless Area, the channel is highly braided due to inputs of sand. Channel morphology is most complex near the inflow of tributaries (Nielsen et al. 1984). Braiding diminishes below the Driftless Area, where sediments transported by tributaries in Iowa, Illinois, and Missouri are dominated by silt (Patrick 1998).

Mean annual discharge near Thebes, Illinois (77 Rkm upstream of the confluence of the Ohio River) is 5923 m³/s. Once the contribution of the Missouri River is deducted, average annual discharge for the Upper Mississippi and its tributaries is 3576 m³/s. The annual discharge pattern of the river remains consistent from headwaters to the confluence with the Ohio. Discharge is highest in the spring (April and May) in response to snowmelt and spring rains (Fig. 8.12). Spring peak flows remain at flood stage or higher for 6 to 8 wk before receding. Evapotranspiration increases from late May to June, causing discharge to decline through the summer. Discharge increases slightly in September or October as the effects of evapotranspiration diminish with cooling air temperatures and increased surface runoff following leaf fall (Patrick 1998). The river maintains an annual pattern of discharge comparable to pre-navigation dam conditions, except that minimum discharge levels increased following dam construction. In addition, the peak in the annual hydrograph diminishes as the river approaches a navigation dam to the point that it is almost an inverse of the hydrograph prior to dam construction (Sparks 1995).

The Upper Mississippi is a hardwater system, with slightly alkaline pH. Alkalinity decreases from an average of 184 mg/L as CaCO₃ at Lake Itasca to 156 mg/L as CaCO₃ at St. Louis (Fremling et al. 1989). The pH remains around 8 throughout the length of the river but is more basic between St. Paul and Rock Island, Illinois, where limestone is more abundant. Hardness follows a similar pattern. Nitrate-N and total phosphorus concentrations are low in the headwaters, ranging from 0.11 to 0.33 mg/L and from 0.03 to 0.15 mg/L, respectively (Fremling et al. 1989). Nitrate-N concentrations increase in the Driftless Area, reaching concentrations of 1.58 mg/L, and are as high as 5.70 mg/L in the Corn Belt. Nitrate-N concentrations decline slightly at St. Louis (1.2 to 4 mg/L), but remain high. Total phosphorus concentrations approach 0.5 mg/L by the time the river reaches Keokuk, Iowa, and increase further by the time the river reaches St. Louis (0.18 to 0.8 mg/L). Suspended sediment concentrations are low (<20 mg/L)

from the headwaters down to the confluence with the Missouri River (Patrick 1998). Below the Missouri, suspended sediment concentrations average 340 mg/L (Fremling et al. 1989). Specific conductance also increases dramatically as higher quantities of dissolved solids, particularly sulfates and chlorides, enter the Upper Mississippi via the Missouri River.

Average annual water temperature above Minneapolis–St. Paul is 10°C (range 0°C to 25°C) at Royalton, Minnesota, the northernmost gaging station with long-term physical data. Average water temperature increases to 15.6°C, with a range from 0°C to 29°C, at Clinton, Iowa. Average water temperature at Thebes, Illinois, the last gaging station with long-term data, is 16.6°C, with a range from 0°C to 31.5°C. Water temperatures reach maximum levels from late July to early August, but only remain at these levels for short periods (2 to 3 wk).

River Biodiversity and Ecology

Algae and Cyanobacteria

Benthic algae are largely limited to nearshore areas of the main channel, side channels, and backwaters. Epiphytic algae are particularly abundant, as is algal growth on snags. Diatoms are the predominant taxa among the microalgae, with *Gomphonema*, *Synedra*, *Navicula*, and *Diatoma* among the most abundant. Green algae become slightly more abundant in the periphyton during the summer months. The filamentous green algae *Cladophora* is also common and produces dense mats on rocks in wing dams and rip-rap. Diatoms are also the most abundant of the phytoplankton, in some cases representing as much as 85% of the community (Patrick 1998). The diatoms *Melosira*, *Asterionella*, *Stephanodiscus*, and *Cyclotella* are among the most abundant phytoplankton in the main river. Diatoms are the most abundant of the phytoplankton in backwaters early in the year (February to April), but diversity increases from June to August, with increased abundance of green algae and, to a lesser extent, cyanobacteria (Patrick 1998).

Plants

The greatest complexity in the riparian and floodplain vegetative communities can be found in the headwaters, where the river flows through sedge meadow, willow–alder shrub swamp, conifer swamps, lowland hardwood forest, and maple–basswood forest. Riparian and floodplain vegetation

downstream of the confluence with the Minnesota River is relatively uniform, with only the relative abundance of the representative species changing. This may not have been the case historically, as studies have indicated that wide tracts of prairie and savanna may once have been an integral part of the terrestrial floodplain community (Nelson and Sparks 1997). Urban development, agriculture, and, probably most important, fire suppression have led to the replacement of prairie and savanna habitats by flood-tolerant and fire-intolerant species. Throughout the Upper Mississippi River floodplain the predominant trees are silver maple, cottonwood, and black willow. River birch is present in the floodplain in Minnesota and Wisconsin, but diminishes downstream.

The numerous backwaters and shallow border habitats along main and side channels provide ample habitat for aquatic macrophytes. Macrophyte abundance in these areas often exceeds the upper range of biomass reported in the literature (Patrick 1998), but the occurrence of macrophytes generally declines farther downriver as the abundance of backwaters and shallow margins declines in response to natural and anthropogenic changes in channel morphology. The abundance of macrophytes in navigation reaches 5 to 8 results in dense mats floating downriver and collecting in snags and on shore as macrophytes senesce from late August through October. Arrowheads are among the most abundant emergent macrophytes, typically occurring in monotypic stands. Several species of submergent vegetation are common, with coontail, waterweed, and wild celery among the most widespread. Coontail and waterweed are limited to backwaters, whereas wild celery prefers higher-current areas along the channel borders. American lotus and American waterlily are the most common floating-leaved plants and are often found in association with arrowheads. Duckweed is common in quiet habitats throughout the year, but often forms dense mats in late summer through fall that drift into the main channel to collect along the shoreline.

Invertebrates

The diversity of benthic invertebrates reflects the tremendous habitat diversity of the Upper Mississippi River. A compilation of past studies estimated that almost 430 invertebrate taxa are found in the Upper Mississippi (Patrick 1998), but even this is an underestimate, as many of the insect taxa are not identified to species. Invertebrate studies in the headwaters

have been limited, but taxa found here are more representative of a small lotic system, with black flies and net-spinning caddisflies representing the most abundant groups.

Taxa composition for the river below the headwaters is typical of a large river system, with distribution influenced primarily by current velocity and substrate type. Although species represented do change longitudinally, the generic makeup of invertebrate communities remains fairly consistent. Taxa richness in soft substrates is relatively low (Seagle et al. 1982). Taxa richness and organismal abundance are much greater on hard substrates. Most rocky substrate in the river is artificial, consisting of wing dams and rip-rap, rocks placed along erosional banks to increase stability. Submerged wood, or snags, found in the nearshore areas of channels, backwaters, and floodplain lakes are the most important natural hard substrate. Taxa on snags in nearshore areas of channels possess a greater diversity of caddisflies, including filterers (*Hydropsyche*, *Cheumatopsyche*, *Potamyia*), herbivores (*Hydroptila*, *Nectopsyche*), and predators (*Oecetis*). Mayflies are also abundant and are represented primarily by the grazers *Stenonema*, *Stenacron*, *Caenis*, and *Heptagenia*. Beetles are represented primarily by the riffle beetles *Stenelmis*, *Macronychus*, and *Dubiraphia*. Common chironomid midges include *Rheotanytarsus*, *Dicrotendipes*, *Polypedilum*, *Ablabesmyia*, and *Cryptochironomus*. Other invertebrate groups well represented on snags in nearshore channel habitats include snails (*Physella*, *Gyraulus*, *Pleurocera*, *Ferrissia*), leeches (*Placobdella*, *Erpobdella*), stoneflies (*Acroneuria*, *Perlesta*), and odonates (*Enallagma*, *Macromia*).

Invertebrate fauna on snags in the lentic habitats (backwaters and floodplain lakes) are quite different from the channel fauna, although some overlap occurs. For example, the midges *Dicrotendipes*, *Polypedilum*, and *Cricotopus* are abundant but represented by different species. Other midges in the lentic habitats include *Glyptotendipes* and *Chironomus*. Caddisflies are represented by the filterer *Polycentropus* and gatherer/scrapers like *Nectopsyche*, *Orthotrichia*, and *Ceraclea*. Snails are well represented, including *Physella*, *Campeloma*, and *Heliosoma*. The Odonata are abundant in lentic habitats, particularly *Enallagma*, *Argia*, and *Dromogomphus*.

There are 51 documented species of freshwater mussels in the Upper Mississippi, but only 44 species have been found in the last 35 years (Havlik and Sauer 2000). There are three species on the federally endangered list: winged mapleleaf, Higgin's eye, and

fat pocketbook. Thirteen species are listed as endangered by one or more of the states along the river.

Vertebrates

Habitat heterogeneity also greatly influences the diversity of fishes in the Upper Mississippi River. Approximately 145 species have been identified in the Upper Mississippi River, including 44 species of Cyprinidae (carp and minnows), 19 species of Catostomidae (suckers), 11 species of Centrarchidae (sunfishes), and 10 species of Ictaluridae (Burr and Page 1986, Fremling et al. 1989). Like the invertebrates, there are considerable differences in the species and their distribution longitudinally and in response to habitat heterogeneity. There are 67 species in the headwaters, some of which did not occur above St. Anthony Falls until the falls were bypassed with the completion of a lock in 1963. Common fishes in the headwaters include goldeye, northern pike, common shiner, bluegill, and yellow perch (Fremling et al. 1989). Gizzard shad, common carp, and emerald shiners are found in abundance throughout the Upper Mississippi River in both lentic and lotic habitats.

The most abundant species inhabiting lotic habitats (including nearshore areas with slower flow) from Lake Pepin to Keokuk, Iowa, include river shiner, spotfin shiner, shorthead redhorse, channel catfish, white bass, and sauger. Fishes common to backwaters or floodplain lakes are bullhead minnow, smallmouth buffalo, bluegill, largemouth bass, and black crappie. Silver redhorse and freshwater drum are found in both lentic and lotic habitats (Patrick 1998, Burkhardt et al. 1998). Farther downriver to the confluence with the Missouri River, distinctions between lotic and lentic species diminishes, with shortnose gar, threadfin shad, river carpsucker, smallmouth buffalo, channel catfish, white bass, bluegill, freshwater drum, common carp, gizzard shad, and emerald shiners representing the most abundant fishes to occur in both lentic and lotic habitats (Burkhardt et al. 1998). Fishes present in abundance in backwaters of this region include bullhead minnow, river shiner, golden shiner, black crappie, and white crappie. The pallid sturgeon and Topeka shiner are the only federally endangered fish species on the Upper Mississippi. Each state maintains a list of locally threatened and endangered species. A total of five fishes are listed as endangered in at least one state and seven fishes are listed as threatened. Common among state lists is the skipjack herring, as the construction of the lock and dam system is believed to have cut off their migratory path.

Based on available lists, there are 11 species of salamanders, 14 species of turtles, 14 species of frogs, 6 species of snakes, and 3 species of mammals in the Upper Mississippi River. No vertebrate species are listed as federally endangered, but each state lists several reptiles and amphibians as locally threatened or endangered. Most of the aquatic vertebrates found on the Upper Mississippi primarily use side channels, backwaters, and floodplain lakes, but some species, especially among the turtles, can be found in slow-flow nearshore areas where cover (snags and rock-covered wing dams) is abundant. The most common turtles include the painted turtle, spiny and smooth softshells, and the common map turtle. The choruses of treefrogs can be heard throughout the floodplain, as can the calls of leopard frogs and bullfrogs. Some herpetofauna appear to be extending their range north using the Upper Mississippi as a corridor. For example, the range of the lesser siren extends north of Tennessee only along the Upper Mississippi (Abell et al. 2000). Beaver and muskrat are common in floodplain lakes, with the macrophyte and mud dens of muskrats looking like small towns as winter approaches.

Ecosystem Processes

As a floodplain river, the predictable flood cycle is of critical importance in shaping physical and chemical processes of the Upper Mississippi River. The annual spring flood inundates the 1 to 10 km wide floodplain, eroding and redepositing sediments and changing the physical features of the floodplain, islands, and channels (Sparks 1995). Nutrient exchanges between the river and floodplain provide benefits to both terrestrial and aquatic organisms, with the river depositing nutrient-laden sediments when the floodplain is inundated during the spring flood and aquatic autotrophs increasing rates of primary production in the shallow and rapidly warming waters. The annual flood cycle is also critical for the reproduction of fishes dependent on floodplain spawning habitats. Floodplain spawners enter the floodplain as the river overflows its banks in the spring; however, construction of levees cuts off the river from the floodplain, reducing the amount of reproductive habitat available for floodplain spawners. This is particularly true where the river flows along the heavily agricultural areas of Illinois, Iowa, and Missouri.

Quantification of organic matter and trophic processes has focused on the origins of organic matter transported in the water column. Organic matter inputs into Reach 19, near Keokuk, Iowa, have

been estimated to consist of almost 86% materials transported from upstream sources, 7% from tributaries, 6% from floodplain vegetation, 0.15% from aquatic macrophytes, and 0.15% from phytoplankton (Patrick 1998). Phytoplankton contributions to organic matter inputs are highly variable along the length of the river and appear to be related to the abundance of main-channel and side-channel slackwater habitats as well as frequency of backwaters (e.g., Fremling et al. 1989). Grubaugh and Anderson (1989) noted that organic matter inputs are seasonal, with floodplain contributions highest during autumn leaf fall and the spring flood.

Missing from estimates of the amount of organic matter present has been attempts to link potential food sources to consumers. A study using stable isotope ratios of carbon and nitrogen identified a linkage between fine transported organic matter (FTOM) and invertebrate consumers (Delong et al. 2001). The association between FTOM and consumers continued through to insectivorous and piscivorous fishes. Based on stable isotope and C/N ratios it was hypothesized that FTOM consisted primarily of phytoplankton and other autotrophic organic matter produced within the river rather than organic matter from the floodplain, although the latter was more abundant. A separate study, which looked at seasonal patterns of stable isotope ratios of transported organic matter, also concluded that organic matter in transport was composed primarily of matter that was riverine in origin (Kendall et al. 2001).

Human Impacts and Special Features

The location of the Upper Mississippi River places it at the crossroads for transition from the eastern deciduous forests and the Great Plain as well as from the boreal forests of the north to the temperate forests of the south. This transition, coupled with gradations in the landscape formed by various glacial events, creates a diverse landscape that, in turn, influences the many rivers found within the basin. The river's location, however, has also influenced its use and subsequent development. As a center of commerce and civilization from prehistoric times through today, the river has been impacted by human activities intended to alter the river for navigation and to make the surrounding floodplain available for agricultural and urban development. Despite these changes, the Upper Mississippi River still retains much of its natural condition, with >80% of the floodplain still connected to the river and a hydro-

logical pattern that, at least regionally, still closely resembles natural conditions. It is apparent, however, that human activity in and along the river has adversely impacted the ecological integrity of the upper half of the mighty Mississippi.

The most obvious human impact on the Upper Mississippi River is the 26 locks and dams located between St. Paul and the confluence with the Missouri River (see Fig. 8.11). Two dams were in place prior to 1920, with the other dams built in the 1930s following authorization by the U.S. Congress of a 2.75 m navigation channel. In contrast to the large flood-control dams associated with many rivers, dams on the Upper Mississippi are low-head navigation dams, designed to maintain a 2.75 m deep navigation channel during periods of low flow but not altering peak flows. Many hydrological and physical features of the river remain despite the presence of the dams, but there are obvious impacts. Regulation of the river has decreased river–floodplain interaction on the upstream side of the dams through the inundation of the floodplain (Sparks 1995). Dams have also increased the rate of sedimentation in backwaters and side channels, decreasing the quality of these critical habitats. The primary function of navigation dams is to keep water in the channel during periods of low flow. The result has been a reduction in the amount of slackwater habitats, zones of increased primary production, in the upper portion of the navigation reaches, and the formation of a large slow-flow area as the river approaches the next dam. Dam construction is not limited to the river south of Minneapolis–St. Paul. There are 11 dams in the Mississippi headwaters, functioning for either flood control, hydroelectric production, or as navigation aids. Changes in the river for navigation did not begin with the construction of the lock and dam system. Snag removal (removing woody debris to prevent it from interfering with boat traffic) dates back to 1824. Wing dams, structures composed of rock debris and willow, were laid perpendicular to the shoreline and at the upstream ends of side channels beginning in the 1870s to divert water to the main channel and force sediment deposition to the shoreline rather than in the channel.

Agriculture is probably the single greatest water-quality concern in the river today. The effect of agriculture is evident in the nitrogen and phosphorus concentrations described previously, with the amount of both increasing downstream to the confluence with the Ohio River. Agriculture has also contributed to decreased connectivity between the river and floodplain through the construction of levees. Levees

above the confluence of the Rock River are limited to urban areas, so that about 95% of the floodplain is still inundated by the river. Large protective levees become more abundant downriver, where they are built near the river channel to prevent inundation of bottomland converted to farmland.

Point-source pollution issues have been greatly diminished since the enactment of the Clean Water Act. Large zones depauperate of life were common in the river below large urban areas, but better industrial waste management (with the exception of occasional spills) and sewage treatment limit point-source impacts to highly localized areas.

Several nonnative species are present in the river, with some causing ecological concerns. Introductions have come primarily through the flooding of ponds in areas adjacent to the river (e.g., grass carp, bighead carp, silver carp) or via the Illinois River and its connection to the Great Lakes (e.g., zebra mussel). The Chicago Sanitary and Ship Canal linking the Great Lakes to the Upper Mississippi system will continue to expose the river to additional introductions. Common carp, intentionally introduced as a potential forage fish, is among the most common fish, by biomass, in the Upper Mississippi. Feeding and spawning activity by common and grass carp tears out vegetation in slackwater areas, decreasing water clarity. Bighead and silver carp, which are largely limited to the river around and below the confluence with the Illinois River, are both zooplanktivores. Capable of rapid growth, both species may outcompete larvae of native fishes that are dependent on zooplankton as a food source. Zebra mussels, present in the Upper Mississippi River since 1992, consume phytoplankton and have the potential to be a major disruption to the food web through their removal of this important resource. By attaching to hard substrate, rocks, and snags, zebra mussels may outcompete some invertebrate taxa for space, thus changing invertebrate community structure and reducing the resources available for invertivorous fishes.

Water quality has improved considerably in the Upper Mississippi River since the 1970s, but it is apparent that new concerns about water quality have arisen. Nonpoint-source pollution compounded with changes in hydrological processes and physical attributes of the river threaten the health and sustainability of this great river–floodplain system. Despite this, the Upper Mississippi River retains more of its natural attributes than perhaps any other large river–floodplain ecosystem in the eastern United States and should be considered the starting point for gaining a better understanding of the dynamics of

great rivers and the role model for river–floodplain restoration.

MINNESOTA RIVER

The Minnesota River, the first major tributary of the Upper Mississippi River, increases the Mississippi's discharge by almost 50% (Fig. 8.13). Draining about one-fifth of Minnesota, plus a small part of South Dakota and northern Iowa, the Minnesota River is the first tributary to drain primarily agricultural land and the first tributary from the Central Tall Grasslands. The Upper Mississippi does not receive tributaries that flow through the Central Tall Grasslands again for 500 Rkm downstream. The Minnesota is also a river of contrasts. Although possessing some of the most scenic falls and river corridors in Minnesota, it is also heavily impacted by human activity, with the lower Minnesota receiving a U.S. Environmental Protection Agency watershed indicator index of 6—more serious problems and high vulnerability—due to the potential for future degradation of water quality.

The river played an important role in Minnesota history and in the settling of the northern plains. It was a point of navigation for goods and supplies into the Dakotas in the nineteenth century and was the route that many immigrants took in the 1850s after treaties were arranged with the upper and lower bands of the Sioux nations along the Minnesota River. The Minnesota River basin was also the site of one of the worst conflicts between Native Americans and settlers during the Sioux Uprising of 1862 (Waters 1977). Like other parts of the Upper Mississippi River basin, evidence of human settlement dates back at least 8000 years.

Physiography, Climate, and Land Use

The Minnesota River lies entirely within the Central Lowland (CL) physiographic province and almost entirely within the Central Tall Grasslands terrestrial ecoregion. A small portion near the confluence with the Upper Mississippi lies within the Upper Midwest Forest/Savanna Transition zone (Ricketts et al. 1999). The basin has been greatly influenced by glaciation, as demonstrated by the identification of 27 different geomorphic sections based on glacially formed features. Soils in the basin are primarily Wisconsin Drift overlying igneous and metamorphic rock or poorly consolidated shales and sandstones. The poor drainage of soils in some regions, especially the upper end of the river, historically created broad

areas of wetlands and lakes. Characteristic of the mesic conditions of the Central Tall Grasslands, dominant vegetation in much of the basin prior to settlement were tallgrasses, primarily big bluestem, switchgrass, and Indian grass. Vegetation in the eastern one-third of the basin consisted of oak–prairie mix and forests of oak, maple, basswood, ash, and elm. Only remnants of presettlement vegetation can be found today, with much of this limited to the river valley.

Average annual precipitation varies from 60 cm/yr in the west to 76 cm/yr near the mouth. Precipitation is primarily rain, occurring in the greatest amount during the summer (Fig. 8.14). Precipitation is lowest in the winter, falling as snow. The major climatic event in the basin is in the spring, when rain falls over the melting snow and thawing ground. Average snowfall in the basin is 117 cm/yr (as snow). Mean annual temperature is about 7.5°C, with an average monthly range of –11°C to 23°C (see Fig. 8.14).

About 95% of the basin is used for agriculture, with corn and soybeans as the major crops. Wheat production is also important in the basin, as is hog and cattle production. Less than 1% of the basin is urban, with Mankato and part of the Minneapolis–St. Paul metropolitan area as the major urban areas on the river. The remainder of the basin is an agriculture/forest mix, although a few areas of wetland, prairie, oak forest, and prairie-woodland persist, largely in the river valley and riparian zone.

River Geomorphology, Hydrology, and Chemistry

The Minnesota River has been described as a small stream in an oversized valley (Hunt 1967). The geological term for this is an underfit river. This designation is because the Minnesota River flows through a valley as much as 80 m deep and 8 km wide (Waters 1977). The valley was cut by the glacial River Warren during the Wisconsin Glaciation. The glacier cut off drainage of Lake Agassiz to Hudson Bay. A natural dam on the southern end of the lake ruptured and a torrent of water was released. The glacial River Warren followed a path to the southeast, then turned to the northeast, a path dictated by the southern edge of the ice sheet and moraine. The massive flows of the River Warren continued for as much as 9000 to 12,000 years before eventually subsiding after the glacier had retreated sufficiently to reopen flow from Lake Agassiz to Hudson Bay. Although the Minnesota River flows as a small river through an

immense valley, the valley itself creates impressive scenery as many of the tributaries flow into the valley over falls or through gorges and rapids as they descend from the plains (Waters 1977).

The Minnesota River begins as Big Stone Lake, a channel lake formed as the sediments carried by the Whetstone River formed a fan in the channel of the Minnesota River (see Fig. 8.13). The river does not originate from mountains or plateau, but from a depression, specifically a glacial river valley where a slightly higher area within the depression serves as a watershed divide (Waters 1977). Two other channel lakes, Marsh Lake and Lac qui Parle, are in the upper Minnesota River and are formed by suspended sediment deposits from the Pomme de Terre and Lac qui Parle rivers, respectively. The river, at least historically, ran through and by many bogs and marshes formed by the poor drainage of soils in the basin, especially in the upper Minnesota. The river meanders from bluff to bluff as it moves along the valley floor (Fig. 8.4). These meanders have created many oxbow lakes. Additional floodplain lakes formed by the deposition of natural levees are also present. Most of the river flows over glacial drift, moraine, and outwashes that include sand, gravel, and some boulders. Bedrock is exposed in some areas, a remnant of the erosive force of the River Warren. Sediment composition shifts in the middle Minnesota River, near Mankato, as the river begins to flow over younger sedimentary rock, including limestones, sandstones, and dolomite (Waters 1977). The river meanders over these deposits in response to their varying thickness, often behaving like a typical low-gradient (15 cm/km) plains river.

Average annual discharge is 125 m³/s (1935 to 1999), with peak flows in April in response to snowmelt, ground thawing, and spring rains (see Fig. 8.14). Discharge declines through the rest of the year as evapotranspiration increases. Discharge reaches its lowest levels in January and February, when soils freeze deeply and lock up most of the subsurface runoff. Hydrological processes can be very erratic, with rapid rises and falls throughout the basin because the tiling of fields increases the rate of water removal from soils. There are 12 major subbasins, which can be divided into three groups. The first are the tributaries flowing from the northern part of the basin—Pomme de Terre River, Chippewa River, and Hawk Creek—which supply the Minnesota with 10% of its total discharge (Waters 1977). The Lac qui Parle, Yellow Medicine, Redwood, and Cottonwood rivers flow across the southwest low plains of the basin. Last is the Blue Earth River, the

FIGURE 8.4 Minnesota River at flood stage, Minnesota (PHOTO BY TIM PALMER).

largest and last major tributary, joining the river as it changes to a northeasterly path. The Blue Earth River provides 25% of the Minnesota's discharge.

The Minnesota River is best described as a hard-water, turbid river. Alkalinity exceeds 200 mg/L as CaCO_3 but varies along the gradient of the river in response to changing geology. Before shifting its course to the northeast over sedimentary rock, the relatively high total dissolved solids concentrations are from NaCl and CaSO_4 (gypsum). The concentrations of sulfates, sulfides, and chlorides decline after the river passes Mankato, and bicarbonate concentrations increase (Downing et al. 1999). Other aspects of water chemistry do not change appreciably longitudinally, but do reflect the high dissolved solids and limestone/dolomite topography of the area. Conductivity is high (865 $\mu\text{S}/\text{cm}$), as is hardness (435 mg/L as CaCO_3), and pH is slightly basic (8.0). Nutrient concentrations are consistently high throughout the length of the river. Total phosphorus ranges from 0.04 to 0.48 mg/L and $\text{NO}_3\text{-N}$ concentrations frequently exceed 20 mg/L (Payne 1994).

Suspended sediment concentrations also change longitudinally, but this is due to a combination of natural landscape and human activities. Suspended sediment concentrations were high prior to agriculture, particularly below tributaries such as the Blue Earth River, which drain areas with more weathered soils. Suspended sediment concentrations are lower in the upper reaches of the river (approximately 40 mg/L), but this is probably due primarily to settling in upstream reservoirs (Payne 1994). Concentrations increase continually downstream until reaching their maximum (sometimes >300 mg/L) approximately 125 Rkm from the mouth. A substantial increase occurs as the Blue Earth River, which contributes about 55% of the total suspended sediment load, empties into the Minnesota. Concentrations begin to decline as the river approaches the Minneapolis–St. Paul Metropolitan area. Much of the sediment load in the lower river enters the Upper Mississippi River, as there is very little long-term deposition in the mainstem Minnesota River (Downing et al. 1999). Average annual water temperature is 10.5°C, with a range of 0°C (January) to 29°C (July) near Mankato.

River Biodiversity and Ecology

Algae and Cyanobacteria

The diatoms *Nitzschia amphibia*, *Gomphonema parvulum*, *Navicula radiosa*, and *Achnanthes lanceolata* are the major members of the benthic algal community and are found nearly throughout the Minnesota River. Other taxa found include *Surirella*, *Cymbella*, and *Cyclotella*. Cyanobacteria and filamentous algae are less common and are typically found in slower-flowing waters. There are no known studies on the phytoplankton taxa of the Minnesota River.

Plants

The riparian zone is considerably degraded in many areas, but there are still many natural areas of scenic value (Waters 1977). When present, cottonwood, green ash, black willow, and sandbar willow are in the riparian zone. Intense agricultural activity has resulted in corn and soybeans displacing natural vegetation in many areas. Aquatic macrophytes are common in the lakes and wetlands in the upper Minnesota River. Cattails and sedge grasses are the predominant emergent plants, with submerged pondweeds being the most common submerged plants. Macrophytes appear to be limited in abundance throughout much of the main stem, owing to the high turbidity of the system, but are found in the marshes and oxbow lakes.

Invertebrates

Studies of benthic invertebrates on the Minnesota River have largely been for assessing pollution impacts and for developing an index of biotic indicators (Zischke et al. 1994). Approximately 100 invertebrate taxa have been identified and are largely representative of large-river fauna. Chironomid midges (22 genera) are the most diverse group, with *Glyptotendipes*, *Polypedilum*, and *Tanytarsus* typically having the greatest numbers of individuals. Mayflies, of which 14 genera have been identified, are represented primarily by the scrapers *Stenonema* and *Stenacron*, the filterer *Potamanthus*, and the collector-gatherer *Tricorythodes*. The filterers *Hydropsyche*, *Cheumatopsyche*, and *Cyrmellus* are the most abundant of the nine genera of caddisflies identified. Zischke et al. (1994) examined benthic invertebrate community structure from below Lac qui Parle Lake to Jordan, Minnesota (Rkm 80). They found that amphipods were the most abundant invertebrates immediately below Lac qui Parle Lake, whereas caddisflies were most abundant at all other sites, with

midges as the second most abundant group. All sites received a macroinvertebrate biotic index pollution rating of poor. Substrate consisted of gravel, sand, silt, and woody debris at all locations, but no quantification of these is given.

The status of benthic invertebrates is best exemplified by freshwater mussels. Historical accounts note the presence of 40 species of freshwater mussels. Bright et al. (1990) found only 20 species living in the Minnesota River, with only 14 species abundant enough to be considered healthy populations. Many of the other species are present in low densities and appear to no longer be reproducing. Possible causes for the decline of freshwater mussels include unstable substrates, excessive siltation, and chemical pollution (Bright et al. 1990).

Vertebrates

The fish community consists of 87 species, including 29 species of Cyprinidae (minnows and carp), 14 species of Percidae (perches), 10 species of Centrarchidae (sunfishes), and 8 species of Catostomidae (suckers). The most abundant fishes from below Lac qui Parle Lake downstream to Jordan, Minnesota, are fairly consistent throughout this portion of the river: shorthead redhorse, quillback, common carp, freshwater drum, emerald shiner, spotfin shiner, sand shiner, channel catfish, and gizzard shad (Bailey et al. 1994). There is a slight increase in the number of species and an increase in fish abundance as the geology of the river valley changes from drift and igneous/metamorphic rock to limestones, sandstones, and shale, but increased abundance is primarily from greater numbers of emerald shiners and gizzard shad. Channel catfish also decline considerably in the lower river (Bailey et al. 1992c).

Although the most common fishes, the Cyprinidae, are trophic generalists, many of the other fishes are small insectivorous species. It is likely that they are focusing on benthic invertebrates, particularly the abundant caddisflies and midges. The most abundant piscivorous fish, walleye, is present in low numbers, and smallmouth bass and largemouth bass are rare (Bailey et al. 1994). Four fishes are listed as extirpated from the Minnesota, including three Catostomidae (Burr and Page 1986): skipjack herring, bigmouth buffalo, spotted sucker, and river redhorse. Paddlefish is listed as threatened by the state of Minnesota. Five other fish species designated statewide as a special concern are found in the Minnesota River.

Three species of salamanders, six species of frogs, five species of turtles, and two species of snakes are

recorded in the Minnesota River valley. Herpetofauna in the Minnesota River are consistent with other rivers of the region, with painted turtles, common snapping turtles, northern water snakes, treefrogs, northern leopard frogs, and mudpuppies among the species found. No reports on the status of aquatic vertebrates in the Minnesota River were located. Habitat surveys indicate that snag abundance and instream cover is low (Bailey et al. 1994, Kischke et al. 1994). This, combined with drainage of wetlands, has probably been detrimental to aquatic vertebrates. Muskrat and beaver are present primarily in the upper Minnesota.

Ecosystem Processes

No comprehensive studies of ecosystem processes have been conducted in the Minnesota River. Historical accounts of the Minnesota River indicate that it was a turbid system prior to conversion of agricultural fields. Despite this, instream primary producers are abundant in some areas, even where suspended sediment concentrations are high. Phytoplankton biovolume approaches $30 \text{ mm}^3/\text{L}$ at Jordan, compared to $<1 \text{ mm}^3/\text{L}$ in the Mississippi headwaters above the Minneapolis–St. Paul metropolitan area (Stark et al. 2001). Abundance of phytoplankton could be sufficient to support the invertebrate community that appears to consist primarily of filter feeders such as caddisflies and midges (Tanytarsini). Reliance on instream primary production may also be a necessity in light of the degradation of riparian vegetation. This could result in low availability of particulate organic matter from terrestrial sources, contributing further to the environmental stresses placed on this agriculturally impacted river. High chlorophyll concentrations ($>15 \mu\text{g}/\text{L}$) relative to the Mississippi headwaters and St. Croix River may, however, be entirely an artifact of high nutrient inputs generating low food-quality phytoplankton and benthic algae, the abundance of which may create problems stemming from high biological oxygen demand during algal decomposition (Payne 1994, Downing et al. 1999).

Human Impacts and Special Features

The Minnesota River, representing the first river draining the central grasslands to empty into the Upper Mississippi, stands out as a small river flowing through an oversized river valley. The river valley, formed by the glacial River Warren, is just one of many remnants of glacial processes that characterize this river. The valley has also been a blessing ecolog-

ically, for it is within the river valley that much of the vegetation and wildlife that was once characteristic of the entire basin can still be found. Although most of the basin has been converted for agricultural use, the river valley still provides many areas of scenic beauty and recreational opportunities (Waters 1977).

Suspended sediments are the primary water-quality concern for the Minnesota River. Sediment load during summer rain events can range between 2 and 500 tons/d below Lac qui Parle Lake (465 Rkm above the mouth) to approximately 40 to 4000 tons/d at Henderson. Most sediment delivery is through tributaries, with the major contributors being tributaries draining the southern and eastern part of the basin (Watonwan, Blue Earth, and Le Sueur rivers), where soils consist of finer particle sizes and precipitation is slightly higher in summer (Payne 1994).

Agriculture has also created concern because of high nutrient and pesticide concentrations. The longitudinal pattern for $\text{NO}_3\text{-N}$ closely reflects that of suspended sediments, with the inflow of the Watonwan, Le Sueur, and Blue Earth rivers each progressively increasing concentrations within the main-stem Minnesota River. Nitrate-N concentrations exceeded the national standard of $10 \text{ mg}/\text{L}$ in 11% of samples collected at Jordan (Stark et al. 2001). The Minnesota basin is included in the Upper Mississippi River basin National Water Quality Assessment (NAWQA) program, along with the Upper Mississippi River down to Lake Pepin and the St. Croix River. Of the three rivers, the Minnesota has by far the greatest occurrence of pesticides, especially atrazine, deethylatrazine, metolachlor, acetochlor, and alachlor (Stark et al. 2001). Many of these pesticides are also found in the Prairie du Chien–Jordan aquifer, which serves as a major water source for the Minneapolis–St. Paul metropolitan area.

The major change in agricultural practices in the basin was the tiling of the land, which dates back to the 1880s. The poor drainage of the soils in the basin made it difficult to grow crops in the rich soils, and tiling systems were placed below the soil surface to rapidly move water from fields into ditches that would drain into nearby streams. Tiling also allowed for marshy areas to be drained and plowed and changed the hydrology of the basin. Prior to tiling, much of the precipitation percolated through the soils and was stored in aquifers. Delivery to surface waters has gone from a long-term process to being almost immediate. Discharge has become very erratic, reflecting shortened delivery time that creates a rapid increase in discharge followed by a rapid decline without subsurface and groundwater flow to

dampen the falling limb of the hydrograph. Tiling has also increased the delivery rate of contaminants to the river.

Hydrology is further impacted by dams and water diversions. There are 63 dams on the Minnesota and its tributaries. The greatest number of dams, most of which are small diversion dams, is on the upper Minnesota and Chippewa rivers. Dams have been placed at the outlets of the three large natural lakes, Big Stone, Marsh, and Lac qui Parle, for flood control and to control lake levels. In addition, flow from the Chippewa River basin is diverted to Lac qui Parle Lake. All flow in excess of 28 m³/s is diverted during spring and summer floods and about one half of the flow is diverted when <28 m³/s (Payne 1994). Ironically, dams on some parts of the Minnesota actually improve fish abundance immediately downstream relative to unimpounded portions of the river (Bailey et al. 1994). The dams and diversions, combined with extensive tiling, have contributed to the rapid rises and falls seen in the hydrograph of the Minnesota River.

It is clear that human activities have adversely impacted the ecology and ecosystem dynamics of the Minnesota River. Bailey et al. (1994) collected only 54 species of fishes, although 87 species are supposed to be in the Minnesota River (Burr and Page 1986). The relatively low diversity of invertebrate taxa and apparent extirpation of 17 species of freshwater mussels further suggest ecosystem degradation. Increasing nutrient delivery, while increasing phytoplankton abundance, is enhancing the production of mostly undesirable taxa. Conversely, increased rates of soil erosion and pesticide delivery from the tiling system degrade habitat quality and enhance exposure to higher concentrations of contaminants. Declines in organismal diversity, coupled with changes to the landscape, clearly demonstrate that the Minnesota River, overall, is an ecosystem in peril.

ST. CROIX RIVER

The St. Croix River was one of the original eight rivers protected under the National Wild and Scenic River Act of 1968 and is viewed as one of the best recreational rivers in the Midwest (Waters 1977). It is the second major tributary of the Upper Mississippi, joining the river 53 Rkm downstream of the Minnesota River (see Fig. 8.2). The St. Croix flows from the north, beginning in the northern highlands of Wisconsin and continuing south for 276 km through rapids, pools, and gorges before flowing into

Lake St. Croix and the Upper Mississippi River (Fig. 8.15).

Prior to the presence of Europeans, the Dakota nation was the primary occupant of the basin until the 1500s. At this time, the Chippewa nation began to move from the east into the basin and the two nations battled continuously before the Chippewa eventually drove the Dakota out of the St. Croix valley. The St. Croix was important as a point of passage early in the exploration of the upper Midwest because of the proximity of its headwaters to Lake Superior. It became a route, first found by Sieur du Luth in 1680, for the fur trade, first by the French and later by the British (Waters 1977). The river later became one of the busiest logging rivers in the Midwest (Fago and Hatch 1993).

Physiography, Climate, and Land Use

Roughly two-thirds of the river flows through the Superior Upland (SU) physiographic province, in which most of the Western Great Lakes ecoregion lies (see Fig. 8.15). The lower one-third flows through the Central Lowland (CL) as the river approaches the Upper Mississippi. The Superior Upland is an extension of the Canadian Shield, composed of Precambrian igneous and metamorphic rock exposed by the movement of glaciers. The St. Croix region was on the edge of the last ice sheet, which left moraine and drift (up to 70 m deep in some areas) over much of the landscape (Hunt 1967). The materials overlaying bedrock are not extensively weathered, which, when combined with the underlying bedrock, leaves the headwaters poorly drained, with almost 40% of the headwaters area covered in lakes and marshes. Bedrock in the lower St. Croix is Cambrian sandstones and dolomite, in addition to some basaltic bedrock. The basin is divided into the upper and lower St. Croix at Taylor Falls Dam (Rkm 85), the former site of the St. Croix Falls.

The St. Croix begins in the Western Great Lakes Forest terrestrial ecoregion before entering the Upper Midwest Forest/Savanna Transition ecoregion (Ricketts et al. 1999). Vegetation present on the St. Croix today is similar to what was present prior to settlement, although it is mostly second-growth forest. The portion of the basin within the Western Great Lakes ecoregion has a northern hardwood-conifer mixed forest, with sugar maple, basswood, and yellow birch as the dominant hardwoods. White pine, balsam fir, and white spruce are the representative conifers (National Park Service 1997). Also common in the upper St. Croix are conifer swamps

and bogs, with black spruce, tamarack, and white cedar. In the lower basin the forest contains red oak, basswood, black ash, green ash, and yellow birch. Oak barrens and tallgrass prairie are also present because the lower St. Croix basin includes the northern limit of the Forest/Savanna Transition zone.

Average annual air temperature is 6.3°C at St. Croix Falls, Wisconsin (Fig. 8.16). Air temperature is lowest in January (−12°C) and highest in July (22°C). Average annual precipitation is 78 cm/yr and is highest during summer months (>9 cm/mo), dropping to only 2 cm/mo in January and February (see Fig. 8.16). Snowfall is also important in the basin, with average snow accumulation of 107 cm/yr over the entire basin and snowfall approaching 130 cm/yr in the headwaters.

Land use is 27% agriculture, mostly in the lower St. Croix, 50% forest, and around 2% urban, most of which is near the confluence with the Upper Mississippi. Most of the remainder of the basin is wetland and open lake. Corn and dairy production are the predominant forms of agriculture in the basin, with a number of other activities creating a diverse, if limited, agriculture (Waters 1977). Timber harvesting was important in the basin in the nineteenth century but is limited today with the designation of the St. Croix as a protected National Wild and Scenic River. Most of the urban development is in the lower basin as the river approaches the Minneapolis–St. Paul metropolitan area.

River Geomorphology, Hydrology, and Chemistry

As with the St. Croix basin, the features of the channel were shaped by glaciation. Runoff from glacial Lake Duluth drained to the south through the present St. Croix River valley. The torrent eroded through the igneous and metamorphic bedrock as it flowed south toward the glacial River Warren. As lake levels receded, the middle reaches of the glacial river dried, leaving one river flowing to the south that drained the glacial melt and precipitation falling on the side of the divide and another river flowing to the north (Bois Brule) into what would become Lake Superior (Hunt 1967). The modern St. Croix River begins in the northern highlands of Wisconsin as an outflow of Upper St. Croix Lake. The river changes considerably at the confluence with the Namekagon River, a tributary actually larger than the St. Croix when they join. The channel widens and current velocity decreases, except when rapids are encoun-

FIGURE 8.5 St. Croix River above Grantsburg, Wisconsin (PHOTO BY TIM PALMER).

tered (Fig. 8.5). The river slows again as it approaches Taylors Falls Dam (Waters 1977). The remaining 84 km provide some of the best scenery on the river. Glacial meltwaters cut deeply into lava rock, creating deep vertical channels, palisades, and large rock formations that jut out over the river (Waters 1977). There are also many islands throughout this section of the river. The river ends in Lake St. Croix, a 26.4 km channel lake formed by the deposition of sand and silt across the mouth of the St. Croix by the Upper Mississippi (Fago and Hatch 1993). Stream gradient is 47 cm/km in the upper river but has a gradient of 105 cm/km in the 13 km Kettle River Rapids, located on the St. Croix above and below its confluence with the Kettle River (Waters 1977). Gradient averages 15 cm/km in the lower river (Fago and Hatch 1993).

There are six major tributaries in the St. Croix system, the most noteworthy of which are the Namekagon, Kettle, and Snake rivers. The Kettle and

Snake offer some of the most spectacular and treacherous rapids in the St. Croix system (see Fig. 24.1), with each having a gradient approaching 100 cm/km (Waters 1977). Average annual discharge near Taylors Falls Dam is 122 m³/s. The Apple River, the only major tributary below this site, has an annual discharge of 8.5 m³/s. Other smaller tributaries probably only add slightly to discharge before the river enters the Upper Mississippi. Discharge in the St. Croix reaches a peak in midspring (April) in conjunction with snowmelt and spring rains (see Fig. 8.16). Average discharge then decreases with decreasing snowmelt and increasing rates of evapotranspiration until reaching low flows in late summer (August). High retention of water in the numerous lakes and bogs also contributes to lower discharge, even during periods of heavy rain. Lowest annual flows occur from December through February, when parts of the river and the surrounding drainage basin are frozen.

The St. Croix River is best described as a soft-water, brown-water river (Waters 1977). Staining of the water reflects the drainage of bogs and marshes in the upper reaches and from tributaries such as the Kettle River. Turbidity is low, averaging less than 5 NTU throughout much of the year. Nutrient concentrations are also low, with total nitrogen averaging <1 mg/L and total phosphorus averaging <0.09 mg/L throughout the length of the river. Low suspended sediment and nutrient concentrations of the St. Croix serve to benefit the Upper Mississippi by diluting the elevated concentrations of suspended sediments and nutrients entering the Upper Mississippi River from the Minnesota River (Stark et al. 2001). Conductivity is also low (150 μ S/cm) and pH is close to neutral, averaging around 7.5. Alkalinity (59 mg/L as CaCO₃) and hardness (65 mg/L as CaCO₃) are also low and reflect the limited presence of limestone in the basin. Water chemistry remains relatively consistent along the length of the river. Average annual water temperature is 10.4°C, with a range of 0°C to 27°C. The water temperature has never exceeded 26°C in the upper St. Croix for the period of record (1976 to 2000).

River Biodiversity and Ecology

Algae and Cyanobacteria

Studies of phytoplankton have been limited to quantification of chlorophyll concentrations and have not addressed taxonomic composition. Diatoms are the predominant representatives of the benthic

algal community, but no taxonomic breakdown is available.

Plants

An important feature of the riparian vegetation of the upper St. Croix are conifer swamps, with black spruce, tamarack, and white cedar as the dominant trees. Lowland hardwood forests, where basswood, black ash, green ash, red oak, and yellow birch are the dominant trees, are interspersed with the conifer swamps. Hardwood swamps composed of red maple, paper birch, and black ash are also common through the middle reaches. The floodplain forest of the lower river consists primarily of silver maple and green ash (National Park Service 1997). Aquatic macrophytes in the upper basin are associated primarily with bogs and swamps.

Invertebrates

Surveys have identified 332 species of invertebrates throughout the St. Croix, including 71 species of Diptera, 54 species of mayflies, 37 species of caddisflies, and 19 species of beetles. The invertebrate community changes longitudinally, with 218 species identified in the upper river and 167 species in the lower (Fago and Hatch 1993). Major faunal differences are in the numbers of mayflies, caddisflies, and stoneflies, with 46 species from these orders known in the lower river versus 113 species in the upper. Although many invertebrates are representative of large-river fauna, there are also species not seen in other large rivers in the Upper Mississippi system owing to the unique features of the St. Croix, particularly in the upper reaches.

Many of the abundant invertebrates in the upper St. Croix are described functionally as being collector-gatherers/grazers, with the choice of diet probably dictated by resource availability. Most abundant among these are mayflies, particularly *Baetis*, *Siphonurus*, and *Ephemerella* (Lillie 1995). The riffle beetle *Dubiraphia* is another common genus that falls into this category. The mayflies *Brachycercus* and *Cercobrachys* are characterized as collector-gatherers, whereas the mayflies *Heptagenia* and *Stenonema* and the caddisfly *Helicopsyche* are considered almost exclusively algal scrapers. The riffle beetle *Stenelmis* is another abundant scraping invertebrate in the upper St. Croix. One of the more abundant filterers is the mayfly *Anthopotamus*. The caddisflies *Hydropsyche* and *Ceratopsyche* represent the other abundant filterers (Lillie 1995). Shredding invertebrates include the caddisflies *Nectopsyche* and *Lepidostoma*, the stonefly *Pteronarcys*, and the beetle

Peltodytes. Predaceous invertebrates are represented by 45 different species of dragonflies and damselflies (most of which occur in tributaries), seven species of perlid stoneflies, and the beetle *Gyrinus*. A breakdown of invertebrates to genus was not found for the lower St. Croix, but family lists indicate that many of the common large-river invertebrates are represented. Principal among these is the mayfly family Heptageniidae, the caddisfly family Hydropsychidae, and 24 genera of midges (Fago and Hatch 1993).

The St. Croix hosts a diverse and abundant community of 40 species of freshwater mussels. In some locations, 20 to 30 species might be found together, with many locations having densities of >20 mussels/m² and some areas even approaching 200 mussels/m² (Hornbach 2001). Mussels are abundant throughout the river, but the species composition does shift, probably due to the cutoff of fish migration by Taylors Falls Dam (Fago and Hatch 1993, Hornbach 2001). The most common mussels in the river are threeridge, deertoe, spike, and Wabash pigtoe. Two federally endangered species are present, the Higgin's eye and winged mapleleaf. There are seven mussels listed as endangered and three listed as threatened by Wisconsin. Minnesota lists three endangered and six threatened species of mussels for the St. Croix.

Vertebrates

There are 110 species of fishes recorded in the St. Croix basin, including 43 species of Cyprinidae (minnows and carp), 16 species of Percidae (perches), 12 species of Catostomidae (suckers), and 9 species of Centrarchidae (sunfishes). Seven species have not been reported since 1974 and are believed to be extirpated, but it is believed that the St. Croix was a marginal habitat for these species (Fago and Hatch 1993). Another six species are nonnative, including common carp, rainbow trout, brown trout, and lake trout. There are 22 species found in the lower St. Croix, but not the upper St. Croix, and 18 species found only in the upper river (Fago and Hatch 1993). St. Croix Falls and, later, Taylors Falls Dam are believed to have been a barrier to fish migration from lower to upper river. Of the 18 species of fishes listed by the State of Wisconsin as threatened or endangered, 8 are in the St. Croix and have healthy populations (National Park Service 1997). Of note on this list is the river redhorse, which is reported to have declined in numbers in many of the other tributaries of the Upper Mississippi River.

The majority of riverine fishes found throughout the St. Croix River (Gordan Dam to mouth) are

characterized as insectivores. Examples include golden redhorse, shorthead redhorse, river redhorse, spottail shiner, mimic shiner, quillback, and Johnny darter. Common carp, an omnivore, are also found throughout the length of the river. The major carnivores, smallmouth bass and walleye, are found throughout the river, although walleye are more abundant in the upper St. Croix than the lower. Bluegill and yellow perch, both insectivores, are common in more lentic habitats throughout the river. Planktivorous gizzard shad and emerald shiner, an insectivore, are among the most abundant fishes found exclusively in the lower St. Croix. Five species of darters are also found exclusively in the lower river. Many of the fishes found only in the upper St. Croix, such as longnose dace, brassy minnow, and hornyhead chub, are also benthic insectivores. There are several specialists, including the algivorous central stoneroller, found only in the upper St. Croix. The bigmouth shiner is among the most abundant omnivores found exclusively in the upper St. Croix.

Eighteen species of amphibians and 14 reptile species are known to occur in the St. Croix. Very little is known about their numbers and current status (National Park Service 1997), except that the seven turtle species present are more abundant in the lower river. Turtles known to occur in the region include painted turtles, common map turtles, wood turtle, and spiny softshell turtles. A number of treefrogs are known to the area, including spring peepers. Tiger salamanders are also known to occur in the basin. Mammals known to be associated with the river include muskrat, beaver, mink, river otter, and moose.

Ecosystem Processes

There have been no comprehensive ecosystem studies of the St. Croix River. Water quality and the diversity of trophic specialists among the invertebrates and fishes suggest, however, that the river has a healthy and diverse trophic structure. The description of the St. Croix as a brown-water river infers that terrestrial inputs from riparian vegetation and connected swamps and bogs are important to system dynamics. Terrestrial inputs are, mostly likely, a result of direct litterfall and from transported organic matter delivered by tributaries considering that the often-incised nature of the channel valley creates a floodplain of limited size throughout much of the river. Phytoplankton abundance is low, only about 10% of that seen in the Upper Mississippi at the confluence of these two rivers, but seasonal algal blooms develop in slackwater and backwater habitats

(National Park Service 1997). Benthic algae are reported in both lentic and lotic habitats, and the presence of several algivorous invertebrates and fishes (e.g., central stoneroller) suggests it is available in quantities to support part of the food web. Abundant rock substrate and snags throughout the river create structural heterogeneity that might otherwise be lacking given the generally constrained nature of the river channel. Emergent and submergent aquatic vegetation is present in both lentic and lotic habitats and could contribute to energy flow, particularly as detritus.

Human Impacts and Special Features

The upper St. Croix from Gordon Dam (Rkm 247) downstream to Taylors Falls Dam (Rkm 85) and all of the Namekagon River were among the first eight rivers afforded protection under the Wild and Scenic Rivers Act of 1968. The lower St. Croix was added in 1972. Together, they form the St. Croix National Scenic Riverway, managed by the National Park Service. Thus, the river and a narrow terrestrial corridor on each side of the river are protected from further development. The primary human impact on the river today is through recreation, particularly camping, hiking, and canoeing. Lake St. Croix is designated as recreational, allowing for the use of motorized boats. Water quality and the physical structure of the river remain intact through the protection afforded by the scenic river designation, giving it a physical and chemical stability not seen in any of the other large tributaries of the Upper Mississippi River.

The designation of the St. Croix as a scenic river, however, does not mean that it has not been influenced by human activity. As is the case with other rivers extending into the Superior Upland, the basin was logged heavily in the nineteenth century and into the early twentieth century. White and red pines, in particular, were cut throughout most of the basin, leaving very little old-growth forest in the basin. The river served for transport of huge log rafts downstream to the many sawmills built along the lower St. Croix (Waters 1977). Natural features of the river actually aided in the delivery of logs to the mills. The many channels created by islands above Lake St. Croix were used to sort logs prior to their arrival at the mills. Timber harvesting declined into the early twentieth century, leaving most of the basin relatively undisturbed after 1920 and allowing for the regrowth of native vegetation. Agriculture is limited primarily to the lower St. Croix, and impacts

appear minimal, based on low nutrient and suspended sediment concentrations throughout the length of the river. Lake St. Croix has a history of industrial development that is still evident today through the issuance of fish consumption advisories. Consumption advisories are primarily due to the presence of PCBs in lake sediments. A navigation channel is maintained in the lake, but barge traffic, which was once as high as 120 tows/yr, is minimal today, with most materials transported by rail (Fago and Hatch 1993).

In addition to the nonnative fishes already mentioned, zebra mussels and the Asiatic clam have been reported in Lake St. Croix. Asiatic clams have only been reported in proximity to outflows from a power plant and do not appear abundant. Federal and state agencies worked throughout the early 1990s through educational programs and boat inspections to prevent the migration of zebra mussels from the Upper Mississippi into the St. Croix. Zebra mussels, however, have been reported in the lower St. Croix in very low numbers since 1994.

The St. Croix River is almost an anomaly in the Upper Mississippi basin. Although, like all other rivers in the basin, it has been impacted by human activity, the St. Croix River maintains more of its natural condition than perhaps any other system in the Upper Mississippi basin. With its designation as a National Wild and Scenic River and the protection afforded by its inclusion in the National Park System, the river will continue to retain its beauty and splendor, thus remaining a jewel at the top of the Upper Mississippi River.

WISCONSIN RIVER

The Wisconsin River is the largest and longest river system in Wisconsin, draining approximately 22% of the state and totaling 692 km in length. The river begins in the northern highlands of Wisconsin, winding south into the glacial drift left behind by the Wisconsin glaciation, then turning west toward the Upper Mississippi River (Fig. 8.17). The Wisconsin River is heavily dammed for hydroelectric production and flood control. Most of the dams occur in the upper and middle river, with the headwaters and the last 133 km of the river flowing freely. It is important locally for recreation, including boating, canoeing, fishing, and hunting. Despite its size and importance within the state, however, comprehensive studies of the ecology of the river are limited, with most studies focusing on the “large river” lower Wisconsin.

Human presence in the Wisconsin River basin dates back to the end of the last ice age (9000 to 12,000 years ago), but their presence is known only from a few spear points and tools (Nichols 1984). The Woodland cultures (2100 to 400 years ago) included the mound builders found throughout the Upper Mississippi valley. Only three Native American tribes are definitively known to have been in the basin before the late seventeenth century: the Menominee, Winnebago, and Santee Sioux. Other tribes, including the Mascoutan, Potawatomi, Kickapoo, Fox, and Huron, moved into the area by the late seventeenth century as European settlement of the east pushed tribal nations to the west (Nichols 1984). The first Europeans on the Wisconsin River were Father Marquette and Louis Jolliet during their search for a water route to China. After canoeing down the Fox River, they portaged to the Wisconsin and took it to the confluence with the Upper Mississippi River near Prairie du Chien. Although they did not find their route to China, the French would later establish a lucrative fur trade with the Indian nations along the Wisconsin River. Settlers moved into the basin in greater numbers beginning in the 1830s, drawn by the lead mines of southern Wisconsin. The river served as a means of transporting people and trade goods, in addition to log rafts from the pine forests to the north.

Physiography, Climate, and Land Use

The Wisconsin River begins in the Superior Upland (SU) physiographic province, with the remainder of the basin in the Central Lowland (CL) province (see Fig. 8.17). The terminal moraine of the late Wisconsin glaciation forms an approximate boundary between the two provinces near Merrill, Wisconsin (Martin 1932). The basin within the Superior Upland is characterized by numerous lakes and muskegs (open marshes) owing to the poor drainage of the soils. The drainage basin changes markedly in the Central Lowland, where the basin alternates between glaciated areas with older, more weathered drift overlying Cambrian sandstones and the Driftless Area. The Driftless Area, a region of extensive topographic relief near the terminus of the drainage basin, was bypassed by the glaciers, leaving an area of extensive topographic relief formed by erosion from the numerous streams and small rivers flowing through the region. The only natural lakes in the Driftless Area are fluvial in origin.

The Wisconsin River begins in the Western Great Lakes Forest terrestrial ecoregion, but much of the

basin lies within the Upper Midwest Forest/Savanna Transition ecoregion (Ricketts et al. 1999). The Western Great Lakes region corresponds roughly with the Superior Upland physiographic province. The forest of the upper Wisconsin historically was a mixed conifer–hardwood forest. Conifers were represented by white pine and red pine and the hardwoods were primarily sugar maple, birch, and ash. Timber harvest, especially for pines, was intense in this area, but stands of the original vegetation are still present, largely as second growth. Aspen is also abundant in clear-cut areas. Forest vegetation in the lower Wisconsin basin is represented primarily by sugar maple, red oak, white oak, burr oak, basswood, and elm. Prairies are also present, particularly along the south-facing slopes of the bluffs of the Driftless Area. Prairie vegetation includes big bluestem, northern dropseed, Indiangrass, pasqueflower, coneflowers, columbine, and blackeyed Susan (Nichols 1984).

Average annual air temperature in the headwaters is 4°C, compared to 9°C near the mouth of the Wisconsin. Average monthly temperatures range from a maximum of 19°C and a minimum of –13°C in the north to 23.5°C and –8°C in the south (Fig. 8.18). Precipitation is similar in both regions, averaging 85 cm/yr, with precipitation heaviest (8 to 11cm/mo) from April through September (see Fig. 8.18). Snowfall, as would be expected, does differ considerably. Average annual snowfall is 252 cm/yr in the headwaters, with snow occurring during all seasons except summer. Snowfall in the south totals only 92 cm/yr, with most falling in winter.

Land cover in the basin is 27% agriculture, 54% forest, and 3% urban. The remainder is mostly open water and wetland. Agriculture is predominantly dairy production, corn, hops, and oats. Cranberries are an important crop in the bog regions in the upper Wisconsin River basin. Wausau, located on the upper Wisconsin River, is the major metropolitan area. The area around Wisconsin Dells, Portage, and Baraboo is a major summer recreational area, with activities on and around the river.

River Geomorphology, Hydrology, and Chemistry

The Wisconsin River begins in the northern highlands of Wisconsin as an outlet to Lac Vieux Desert. As the upper Wisconsin River flows south, it traverses drift and moraine. Rapids are common throughout the glaciated areas through which the

FIGURE 8.6 Wisconsin River at Prairie du Sac, Wisconsin (PHOTO BY TIM PALMER).

river flows because of areas with steeper than average gradient and the cobble–boulder substrate. The upper river drops from an elevation of 510 m asl to 285 m asl, a gradient of 67 cm/km. Below Merrill the middle Wisconsin River forms a broad, shallow valley across sandstones that were only lightly marked by glaciation. The river flows through this area as a low-gradient system with few tributaries. Bottom substrate consists primarily of gravel and sand, with some cobble in this region. The channel narrows to a steep-walled canyon known as the Wisconsin Dells. The river flows for 11 km by sandstone cliffs as high as 31 m. The channel widens once it has passed through the Dells. The river turns to the west as it enters the Driftless Area, just downstream from Prairie du Sac Dam, the last dam on the river (Fig. 8.6). The landscape changes from a relatively broad plain to limestone and sandstone bluffs approaching 125 m high on both sides of the river. The lower Wisconsin River is free-flowing for 133 km from the Prairie du Sac Dam to the confluence with the Upper

Mississippi. The lower river has a low gradient, 28 cm/km, as it flows through an incised river valley. Islands and sand bars are abundant, creating backwaters and side channels as the river flows over glacial outwash.

Annual discharge in the headwaters is 19 m³/s. This increases to 76 m³/s at Merrill, where the river moves from the Superior Upland to the Central Lowland. By the time the river reaches Muscoda, the last gaging station on the river (Rkm 72), annual discharge increases to 247 m³/s. Discharge begins rising in February at Muscoda as the snow melts and spring rains begin, reaching annual peak discharge in April (see Fig. 8.18). Discharge decreases to near annual minimum flows in the summer as evapotranspiration increases and runoff rates decline following development of canopy and ground cover foliage. Unlike other rivers in the northern Upper Mississippi basin, summer and winter minimum discharges are nearly identical on the lower Wisconsin. The annual peak discharge in the spring is reduced in magnitude by the retention of water in lakes and muskegs of the headwaters (Martin 1932). A sustained increase in discharge from September through November following the minimum low flow in August is probably a combination of late summer–early fall rains and reduced evapotranspiration and leaf fall.

Water chemistry from the headwaters to Merrill suggests that pH is acidic (6.6 to 6.9) and hardness is low (25 to 35 mg/L as CaCO₃). The headwaters receive substantial inflow from the numerous lakes and muskegs of the region, which typically contain large quantities of decomposing organic matter. The limited amount of limestone in the soils of the Superior Upland would have a low buffering capacity. These conditions are further supported by the description of the lower Wisconsin as a brown-water system containing large quantities of particulate and dissolved organic matter transported from upstream (Lillie and Hilsenhoff 1992).

Despite the brown coloration from natural and anthropogenic organic inputs, turbidity in the lower Wisconsin is low, averaging 5 NTU. Suspended sediment concentrations, averaging 21 mg/L, are low relative to other rivers flowing through the same physiographic provinces as the Wisconsin (e.g., Chippewa River, Black River). Suspended sediment concentrations generally remain <100 mg/L, largely due to sediment retention by dams farther upstream (Rose 1992). Hardness is higher than in the headwaters (100 mg/L as CaCO₃) and pH is more basic (7.9). Alkalinity is not as high in the lower Wisconsin as in other rivers flowing through the Driftless

Area, averaging 89 mg/L as CaCO₃. Concentrations of inorganic nitrogen are <0.6 mg N/L in the lower Wisconsin and dissolved phosphorus concentrations are <0.02 mg P/L (Lillie and Hilsenhoff 1992).

Average annual water temperature in the lower Wisconsin River is 11.8°C, with a range of 0°C to 28°C. The thermal regime is influenced by tributaries, groundwater inputs, and impoundments at Wisconsin Dells and Prairie du Sac (Lillie and Hilsenhoff 1992). Water temperatures in the spring and fall can fluctuate 2°C within 24 hours. Thermal gradients with a range as great as 7°C have been observed in the summer as much as 300 m downstream of cold-water tributaries (Lillie and Hilsenhoff 1992).

River Biodiversity and Ecology

Plants

The upper Wisconsin River floodplain includes hardwoods of the region, principally birch, aspen, and alder. Conifer swamps and muskegs are also a common feature of the upper river. The lower Wisconsin River has diverse floodplain forests composed of silver maple, river birch, swamp white oak, green ash, cottonwood, and black willow. Dry and wet prairies are also still found along the lower Wisconsin (Nichols 1984). These grass-dominated communities contain species such as big bluestem, Indiangrass, northern dropseed, and switchgrass. Aquatic vegetation is found primarily in sloughs, backwaters, and oxbow lakes off the main river (Nichols 1984). The predominant emergent vegetation includes cattails and arrowhead, whereas American lotus and American white waterlily are the most common floating-leaved plants. Submerged pondweed, coontail, northern watermilfoil, spatterdock, and bladderwort are common submerged plants found in deeper water.

Invertebrates

A total of 232 species of benthic invertebrates have been identified in the lower Wisconsin River (Lillie and Hilsenhoff 1992). Invertebrates are broadly represented, as indicated by the 53 species of beetles, 49 species of true flies, 42 species of mayflies, and 38 species of true bugs. Some of the most common taxa found were the true bug *Sigara*, a piercing herbivore, and *Trichocorixa*, a predator. Other common invertebrate predators were the beetles *Gyrinus* and *Dineutus*, the stonefly *Isoperla*, and the damselfly *Enallagma*. Common filter-feeders included the caddisflies *Hydropsyche*, *Cheumatopsyche*, and *Potamyia*, the black fly *Simulium*, and the mayfly *Isonychia*.

The most abundant of the invertebrates are characterized as grazers/collector-gatherers. Most of these are mayflies (*Baetis*, *Baetisca*, *Procladius*, *Stenonema*, *Stenacron*, and *Caenis*). The most abundant shredder was the caddisfly *Nectopsyche* (Lillie and Hilsenhoff 1992).

Substrate and habitat type appear to be the greatest influence on invertebrate diversity and abundance in the lower Wisconsin (Lillie and Hilsenhoff 1992). Sand is the predominant substrate, found in 90% to 95% of the total available habitat, but only 16% of the invertebrates are found exclusively in sand. Another 30% of the fauna are found in areas with some sand. Snags, rock, and gravel beds are much less abundant but account for a substantially greater number of invertebrate species and total numbers of individuals than sand. Among habitats, invertebrates were most abundant in nearshore areas, followed by rocky runs. Backwaters were moderately productive, with 12% of the species found. The deeper main channel and sandy runs have the lowest diversity.

Thirty-six species of freshwater mussels are known for the Wisconsin River, including five listed as endangered and five listed as threatened by the state of Wisconsin. Higgin's eye, a federally endangered mussel, is in the lower Wisconsin River. Another endangered species, the winged mapleleaf, was extirpated in the Wisconsin by the 1930s. The most common mussels are threeridge, Wabash pigtoe, pocketbook, and pimpleback. Some species are known to have been extirpated from the middle Wisconsin and several others have declined due to industrial discharges into the 1980s (David Heath, personal communication). Water quality has improved, but mussels have failed to recover, partly due to the inability of downstream populations to restock upstream stocks. The dams on this section of the river are believed to prevent or limit upstream movement of fish hosts, thereby restricting mussel dispersal.

Vertebrates

Historically, 119 species of fishes were found in the Wisconsin River (Burr and Page 1986); however, more recent surveys have identified 100 species, including 30 species of Cyprinidae (carp and minnows), 16 species of Percidae (perches), 17 species of Catostomidae (suckers), 10 species of Centrarchidae (sunfishes), and 7 species of Ictaluridae (catfishes) (Fago 1992, Lyons et al. 2000). No federally endangered fishes are found in the Wisconsin

River. The state lists five species as endangered, six as threatened, and six as of special concern.

Four fishes are common throughout the length of the river: shorthead redhorse, Johnny darter, logperch, and walleye, although the status of walleye in the headwaters is uncertain (John Lyons, unpublished data). Thirty-nine species of fishes have been associated with the headwaters, with 12 species occurring either exclusively in the headwaters or occurring rarely below Otter Rapids Dam, approximately 60 Rkm upstream of Rhinelander, Wisconsin. Common species limited to the headwaters are the southern brook lamprey and mottled sculpin. Below Otter Rapids Dam, largemouth bass, smallmouth bass, bluegill, and yellow perch are common throughout the remaining length of the river.

The upper and middle Wisconsin are the most heavily impounded segments of the river and were historically most heavily impacted by pollution from pulp and paper mills and municipal sewage from small communities. The most heavily impacted section of the river is between Rhinelander (Rkm 550) and Petenwell (Rkm 275). Portions of river that still retain flow and riverine habitat are >16 km in length between dams on the upper river, but are usually <2 km long in the middle Wisconsin, where dam effects are more pronounced. Sixty species have been collected through the 352 km length of the upper and middle Wisconsin (excluding the headwaters), with 20 species considered common. In addition to broadly common species already mentioned, species common in this section include white sucker, silver redhorse, black bullhead, and black crappie.

The lower Wisconsin consists of the 133 km free-flowing portion of the river below Prairie du Sac Dam downstream to the Upper Mississippi. With 95 species known to occur in the lower Wisconsin and 40 species considered abundant, this portion of the river by far contains the greatest diversity of fishes. Common large-river fishes include paddlefish (threatened in Wisconsin), mooneye, river shiner, river carp-sucker, smallmouth buffalo, gizzard shad, quillback, and freshwater drum.

Information on other aquatic vertebrates is limited to curator lists, which show that seven species of frogs, 11 species of turtles, and one species of snake are found in the Wisconsin River (G. Casper, personal communication). Turtles frequently seen in and along the river include painted turtle, common map turtle, common snapping turtle, and smooth and spiny softshells. Green frogs, mink frogs, and spring peepers are common, and the northern water snake is the lone snake found in proximity to the river. The

wood turtle and Blanding's turtle are listed as threatened in Wisconsin. Muskrat and beaver are also common throughout the Wisconsin River, particularly in quiet waters of sloughs, backwaters, and oxbow lakes.

Ecosystem Processes

Despite being the largest river in Wisconsin and one of the longest tributaries of the Upper Mississippi, there have been no ecosystem-level studies of the Wisconsin. The invertebrate and fish communities both contain representatives of a wide range of trophic guilds, including many generalists. Although filter-feeding invertebrates such as net-spinning caddisflies and black flies are abundant in the lower river, their presence only implies feeding on transported organic matter and not a specific form of organic matter. Algal grazing/scraping invertebrates are also well represented (e.g., heptageniid mayflies), implying, at least for hard substrates, that algal periphyton is available for consumption. No data are available on amounts of particulate organic matter transported in the water column, but it is likely that high concentrations of fine particulate organic matter and dissolved organic matter are transported from upstream sources. Limited data indicate that both periphyton (14.2 mg/m²) and phytoplankton (30 to 59 µg/L; Lillie and Hilsenhoff 1992) are present in quantities that could support consumers.

Human Impacts and Special Features

At nearly 700 km in length, the Wisconsin River is the longest tributary of the Upper Mississippi River, excluding the Missouri River. It is also the last tributary entering the Upper Mississippi that originates in the Superior Uplands. Although the river has been markedly influenced by human activities, it is still a focal point for recreation and still retains natural features in the floodplain in many areas. It also retains many of the physical and biological features of a large river in its lower reaches, thus making it an important point for comparison in understanding the effects of human activities on large-river ecosystems.

One of the first major impacts on the Wisconsin River was timber harvest. Like the other river basins of the Superior Uplands, the stands of white and red pines were cut throughout the nineteenth century. Mills were built to rough cut timber before it was floated downriver in huge log rafts to finishing mills on the Mississippi River, primarily in St. Louis (Nichols 1984). The amount of timber coming out of the Wisconsin valley was impressive. The largest

logjam in Wisconsin history occurred at Grandfather Falls when 2.5×10^7 m of timber created a jam of logs over 6 m high. Low discharge periods slowed the movement of logs downstream; therefore dams with weirs wide enough to allow passage of log rafts were constructed in the upper Wisconsin so that logs could be floated over rapids (Nichols 1984). The timber harvest continued to dwindle into the 1890s, when there was not enough pine left to make it profitable.

The basin has a history of agriculture, beginning with wheat production in the 1850s. Despite this, the effects of agriculture impacts are not dealt with extensively for the Wisconsin River, largely because agriculture is viewed as having less of an impact on the river than flow regulation, municipal sewage, and industrial (pulp mill) effluent. Low nitrogen and phosphorus concentrations found throughout the river suggest that agricultural inputs are low, supporting efforts by managers to focus on other human impacts.

The pulp and paper mill industry and inputs from municipal sewage have had perhaps the greatest impact. This is particularly true for the upper and middle Wisconsin down to Rkm 275, where 16 pulp and paper mills and 14 municipal waste treatment plants were present prior to 1980. Water quality was poor throughout this part of the river, as is evident from comparison of fish and invertebrate studies immediately following enactment of the Clean Water Act to studies performed in later years. The number of fish species has increased, as has abundance over this period (John Lyons, personal communication). Benthic invertebrate diversity and abundance increased from 1972 to 1980, particularly among net-spinning caddisflies and *Hexagenia*. Improvement in water quality is also evident in the diversity of mayflies found in the Wisconsin River (Lillie and Hilsenhoff 1992). Effects of past and present pulp milling, however, are still evident. Mercury present in pulp effluent into the 1960s is still present in bottom sediments and mercury contamination of fishes (common carp and walleye) in the 1980s was similar to levels observed in the early 1970s (Rada et al. 1986).

Forty-seven storage reservoirs for flood control and 27 hydroelectric dams fragment the upper and middle Wisconsin River and its tributaries. In some areas the only riverine habitat is the tailwaters immediately below a dam. Changes in the physical structure are apparent in the diversity of fishes described earlier. Many lentic species are most abundant in the heavily impounded areas, whereas large-river species are not found in abundance until below the Prairie

du Sac Dam (marking the beginning of the free-flowing lower Wisconsin). Water levels in riverine sections fluctuate dramatically, particularly below dams where hydropower peaking is practiced. A bright spot to this is that there have been efforts to remove dams in tributaries. The last dam on the Baraboo River was removed in 2001, letting the river flow freely throughout its 185 km length for the first time in 150 years.

The Wisconsin River is a system that has been profoundly impacted by alteration of hydrological dynamics throughout much of its length as well as within many of its tributaries. In many instances within the upper and middle Wisconsin, lacustrine fauna have replaced lotic species. The Wisconsin also retains the legacy of heavy nonpoint-source pollution from paper mills and municipal sewage, which still has an effect of native fauna even though effluent releases have been drastically reduced over the last 20 years (e.g., Lyons et al. 2000). Still, the headwaters and lower river retain relatively natural conditions that have allowed for the retention of fauna that would be expected to occur within the region, thus serving to maintain some of the ecological integrity of this large river.

ILLINOIS RIVER

The Illinois River, at 439 km in length and draining 44% of the state, is the largest river in Illinois. Formed by the confluence of the Des Plaines and Kankakee rivers 77 km southwest of Chicago, then flowing to the southwest, the Illinois formerly drained 73,038 km² that also included part of Wisconsin and Indiana (Fig. 8.19). The drainage area increased to 75,136 km² when the Chicago Sanitary and Shipping Canal opened in 1900, reversing the flow of the Chicago and Calumet rivers, thus diverting water from Lake Michigan to the Illinois and pushing the boundaries of the basin even closer to Lake Michigan (Starrett 1971a). The Illinois is typically divided into two sections. The upper Illinois runs from the origin downstream to a section of the river known as the Great Bend (Rkm 338) and includes the Fox, Des Plaines, Kankakee, and Vermillion rivers. The remainder of the river is the lower Illinois and includes, in downstream order, the Mackinaw, Spoon, Sangamon, and La Moine rivers, until it finally reaches the Mississippi (Fig. 8.7).

Like other areas of the Upper Mississippi basin, humans were present in the Illinois valley as early as 8000 to 9000 years ago (Starrett 1971a). Evidence of

FIGURE 8.7 Illinois River (right) and Mississippi River (left) just upstream of their confluence west of Alton, Illinois (PHOTO BY TIM PALMER).

the presence of the Black Sand culture, a group that practiced agriculture, dates from 4500 to 2500 years ago. The Late Woodland Culture (1300 to 700 years ago), as evidenced by their ceremonial mounds, was also present. Immigration by Europeans and Americans into the Illinois country was slow, with settlements not growing appreciably until navigation of the Illinois River began in 1828. Population growth exploded in the late nineteenth century, going from 180,000 people in 1840 to 3.3 million in the Illinois River basin by 1900 as Chicago, Peoria, and other cities in the basin grew.

The natural history of the Illinois River has been studied extensively through the efforts of the Illinois Natural History Survey. Stephen A. Forbes established a biological station near Havana, Illinois, in 1894 that would become a center for the study of the river. Since then, detailed studies of the natural history of many of the biota inhabiting the river have

been conducted. The Survey has also monitored the impacts of pollution on the river and today tracks the Illinois River's recovery through the Illinois River Biological Station in Havana.

Physiography, Climate, and Land Use

The Illinois River lies within the Tilled Plains section of the Central Lowland (CL) physiographic province (see Fig. 8.19). Included within this area is the Central Forest/Grassland Transition terrestrial ecoregion (Ricketts et al. 1999). Impacted by later glacial periods (Illinoian and Wisconsin), the area has low relief and river valleys are not extensively incised. Glacial drift is more weathered than glaciated areas to the north. Loess is also found throughout the basin, with the thickness of this layer diminishing progressively east of the Upper Mississippi River (Martin 1932). Underlying the loess and drift are Paleozoic shales and limestones (Nielsen et al. 1984). Coal deposits are also present near the surface, primarily where loess deposits are thin.

The upper Illinois basin historically was tallgrass prairie with big bluestem, Indiangrass, and switchgrass as the dominant vegetation. Although prairie areas were found sporadically in the lower basin, areas along waterways and river and stream valleys were primarily oak, hickory, and maple forests. Some forest areas remain within the basin, as do protected prairies; however, much of the basin has been converted to agriculture.

Climate in the region is described as humid continental. Average annual air temperature varies from 12.4°C near the confluence with the Upper Mississippi to 10.3°C near the origin. Air temperature basinwide ranges from a daily average of -5.8°C in January to 24°C in July (Fig. 8.20). Precipitation ranges from 91.5 cm/yr to 97.9 cm/yr throughout the Illinois basin. Snow is not as significant as in the northern tributaries of the Upper Mississippi, with 65 cm/yr in the upper Illinois basin and 35.6 cm/yr to the southwest. Precipitation exceeds 6 cm/mo during every month except January and February but is highest from April through September (see Fig. 8.20).

Agriculture covers approximately 87% of the basin, with corn and soybeans the primary commercial crops. Approximately 7% is forested, mostly in and along the river and stream valleys, and 5% of the basin is urbanized. With five urban areas with populations >100,000 people (Chicago, Peoria, Bloomington–Normal, Springfield, and Decatur), the population density is 97 people/km².

River Geomorphology, Hydrology, and Chemistry

Like the Upper Mississippi's tributaries to the north, the channel features of the Illinois were shaped by glacial processes. The upper Illinois is geologically younger than the lower river and does not flow through a preglacial channel. About 4500 years ago the moraine holding back lakes to the north and east gave way, releasing a flood of water known as the Kankakee Torrent, carving a channel to the present lower Illinois. The upper Illinois has carved a channel as much as 2 km wide through the younger glacial drift. In some areas the river has cut down to rock (Martin 1932). Gradient in the upper Illinois is 20 cm/km. The lower river from Hennepin, Illinois, downstream to the mouth, flows through a preglacial channel previously occupied by the Upper Mississippi River. The Upper Mississippi River flowed through this channel until one of the Wisconsin glacial advances pushed the Mississippi west into its present valley (Martin 1932). Flow in the Illinois decreased following the final retreat of the Wisconsin glacier and the valley was partially filled with sand and gravel glacial outwash. The river carved a trench through the outwash 45 to 77 m deep and, in many places, 8 to 11 km wide. The gradient of the lower Illinois is extremely low, only 2 cm/km.

The Illinois River is an aggrading system, depositing silt and sand along the shoreline, building low natural levees, and creating a broad marshy plain, at least under natural conditions (Martin 1932, Sparks 1984). Substrates in the lower Illinois are primarily sand, silt, and some gravel. The river receives considerable sediment inputs from tributaries draining the Till Plains. Alluvial fans are often evident at a tributary mouth, causing the channel of the Illinois to migrate away from the fan. Peoria Lake is a channel lake created by tributary deposition in the Illinois River channel.

The Kankakee River contributes an annual discharge of 126.8 m³/s to the upper Illinois. The Des Plaines, through inputs from the Chicago Sanitary and Ship Canal, contributes an annual average of 100 m³/s. Annual discharge is 306 m³/s when the Illinois reaches Marseilles, 51 Rkm downstream. The Illinois better than doubles in size to 649 m³/s by the time it reaches Valley City, approximately 90 Rkm upstream of the confluence with the Upper Mississippi River. Discharge is measured at Valley City because the water level of the Upper Mississippi sometimes affects flow in the Illinois River downstream of Valley City (Groschen et al. 2000).

Discharge is typically lowest in September, as precipitation is low in August and evapotranspiration remains high into September (see Fig. 8.20). Discharge increases through the fall and winter as rates of evapotranspiration decrease. Discharge within a given year can be highly variable and is dependent on the release of water through the low-head dams, particularly the Peoria Lock and Dam (Rkm 254) and the La Grange Lock and Dam (Rkm 129) in the lower Illinois. The lack of coordination between the locks and dams creates pronounced fluctuations in discharge locally to the extent that hydrographs have different shapes from one gaging station to the next.

Most physicochemical characteristics are similar throughout the Illinois. Average annual water temperature is around 16°C, with a minimum of 0°C and a maximum of 32°C. Alkalinity averages near 275 mg/L as CaCO₃ and pH averages 7.8. Conductivity is high, averaging around 740 μS/cm, and hardness averages around 280 mg/L as CaCO₃ in both sections of the river. Nitrate-N and total phosphorus concentrations are high throughout the river, ranging from 0.24 to 9.3 mg/L and 0.04 to 0.86 mg/L, respectively. Suspended sediment concentrations differ substantially, averaging 82 mg/L in the upper river compared to 337 mg/L in the lower river. This is most likely a reflection of geology, with the lower river receiving waters from a basin with more weathered drift and abundant fine loess.

River Biodiversity and Ecology

Algae

There have been no recent assessments of the phytoplankton assemblage for the entire Illinois, and benthic algae have only been reviewed in the upper Illinois, where community composition suggests mesoeutrophic or eutrophic conditions (Leland and Porter 2000). Common taxa among the green algae included *Cladophora*, *Sphaerocystis*, and *Oocystis*. *Navicula*, *Achnanthes*, and *Nitzschia* were the diatoms found at the greatest number of sample sites in the upper Illinois.

Plants

Presettlement floodplain vegetation in the upper Illinois consisted of oak–hickory forest with patches of bluestem prairie. Only remnants of the prairie remain, as the fertile soils of the prairie were converted to agriculture beginning in the mid-nineteenth century (Arnold et al. 1999). Floodplain vegetation prior to settlement in the lower Illinois was a mixture

of codominant species represented by hackberry, pecan, American elm, silver maple, and oaks. Prairies and savannas were also present (Nelson and Sparks 1997). Diversion through the Chicago Canal in 1900 and the opening of the lock and dam system each raised water levels, inundating wide tracts of floodplain and eliminating many species from the floodplain. Fire control and agriculture had a profound impact on grassland vegetation in both the floodplain and the river basin (Nelson and Sparks 1997). Typical floodplain vegetation today is dominated by silver maple, in addition to ash, hackberry, box elder, and willow.

Sporadic water fluctuations of up to 1 m from dam regulation limit the abundance of aquatic plants in the main channel of the Illinois River, but patches of submergent sago and horny pondweed, wild celery, and coontail can be found in stable areas of the main channel. Aquatic plants are considerably more abundant in backwaters and floodplain lakes, particularly in the upper Illinois, where 11 species of submerged plants have been observed. The most common submerged aquatic plants are coontail, curly-leaved pondweed, the nonnative Eurasian watermilfoil, and longleaf pondweed. Bulrush is among the most common of the emergent aquatic plants, and American waterlily is a common floating-leaved plant. Another floating-leaved plant, the nonnative water hyacinth, appears to be increasing in abundance in the upper Illinois (T. Cook, personal communication). Duckweed is also common to backwaters and floodplain lakes.

Invertebrates

Published accounts of benthic invertebrates in the upper Illinois River consist primarily of freshwater mussel surveys. Surveys of the Illinois from the confluence of the Des Plaines and Kankakee rivers to Rkm 372 between 1870 and 1900 found 38 species of mussels. A survey in 1912 found only two species, whereas a survey conducted in 1966 to 1969 found no living mussels (Starrett 1971b). Sphaeriidae, which are often used as a water-quality indicator in large rivers, are also absent from the area (Sparks 1984) even though water quality has improved. Fortunately, the Kankakee River contains a diverse and healthy assemblage of mussels (Page et al. 1992); therefore there is a potential for recruitment. Long-term pollution of bottom sediments, however, may limit the ability of invertebrates to recolonize the area (Sparks 1984).

Benthic invertebrates in the lower Illinois are representative of typical large-river fauna. Filter-feeding

caddisflies (*Potamyia*, *Hydropsyche*, *Cyrnellus*) are present on hard substrates (Seagle et al. 1982). Oligochaetes and midges can also be found on hard substrates, although they are typically more abundant in nearshore areas. Main-channel midge (*Robackia* and *Rheosmittia*) and oligochaete (*Barbidrilus*) sand specialists can be abundant in the main channel (Dettmars et al. 2001). Sand-silt is the predominant substrate in the lower Illinois, with snags serving as the only natural hard substrate. Water-level fluctuations created by the dams, however, appear to clear woody debris or leave it above the water level. Siltation of hard substrates also reduces invertebrate abundance and diversity (Seagle et al. 1982). Collection records indicate that other large river mayflies (e.g., *Stenonema*, *Stenacron*, *Caenis*, *Hexagenia*) are found in the lower Illinois River (Burks 1953).

The fate of freshwater mussels in the lower Illinois River was no better than their counterparts in the main-stem upper Illinois. Pollution and habitat alteration through modification of flow are thought to be the primary reasons for their decline. Thirty-eight species were found in the lower river in 1870. This number dropped to 14 species by 1966 (Cummings 1991). The current outlook for freshwater mussels throughout the length of the Illinois River is poor (Cummings 1991, Page et al. 1992). Only 23 of the 47 species known to occur in the Illinois River were found in 1967. All of these species found in the 1967 survey were common to other rivers, and no state or federally endangered species were found living. The state of Illinois lists four species as threatened, eight as endangered (including two federally listed endangered species, Higgin's eye and fat pocketbook) that were historically found in the Illinois River.

Vertebrates

Fishes in the upper river were dealt a similar fate to that of mussels following the opening of the Chicago Canal. Increasing sewage waste caused oxygen levels to fall to near zero, and fishes were practically eliminated in the upper Illinois (Arnold et al. 1999). The river gradually improved to the point where nonnative common carp and goldfish were abundant and, still later, native fishes returned. Recent surveys identified 74 species of fishes in the upper Illinois, including 24 species of Cyprinidae (minnows and carp), 11 species of Catostomidae (suckers), 10 species of Centrarchidae (sunfishes), and 8 Percidae (perches). Green sunfish, bluntnose minnow, common carp, and white sucker were the

most abundant fishes (Arnold et al. 1999). Although native fishes have returned to the Illinois, the low number of pollution-intolerant fishes, such as the Percidae, and the types of abundant fishes present suggest that water-quality problems still persist.

There are 131 species of fishes known for the lower Illinois, including 37 species of Cyprinidae, 17 species of Catostomidae, 15 species of Centrarchidae, and 14 species of Percidae. Large-river specialists are well represented in the lower Illinois, but there also appears to be more overlap into habitats with lower current velocities than is seen in the Upper Mississippi. Side channels, as is the case in the Upper Mississippi, harbor several species that are typically viewed as specialized for lotic or lentic habitats. White bass and channel catfish are common in all three habitats (Burkhardt et al. 1998). Gizzard shad, emerald shiners, and freshwater drum are common fish species in nearshore areas of the main channel. Another fish abundant in the main channel is the skipjack herring, which is rare or considered extirpated in the Upper Mississippi and tributaries above the Illinois River. The deep main channel is viewed as an area used by fishes only to move from one habitat to another, with no more time spent in the high current velocity than necessary. Trawl samples of the lower Illinois show that over 50% of the fishes collected in the main channel are present throughout much of the year, suggesting they are spending more time in the main flow and are feeding there (Dettmers et al. 2001). Common fishes in trawls of the main flow are freshwater drum, gizzard shad, and channel catfish. Fishes abundant in backwater habitats include bluegill, largemouth bass, common carp, smallmouth buffalo, and western mosquitofish (Burkhardt et al. 1998). Many of these fishes are also associated with nearshore areas of the side channel.

No federally endangered fishes are found in the Illinois River, but there are 11 fishes listed as threatened and 5 listed as endangered by the state of Illinois. Of these, 13 species are thought to be extirpated from the Illinois River (Page et al. 1992). The pallid shiner, river redhorse, and greater redhorse have been found in the river.

Collection lists indicate there are nine species of frogs, six species of turtles, seven species of salamanders, and two species of snakes in the upper Illinois. Amphibian and reptile diversity drops almost immediately below the confluence of the Des Plaines and Kankakee rivers and remains low into the upper sections of the lower Illinois. As few as three species of frogs, three species of turtles, and only one species of salamander are shown on county species lists from

Rkm 436 downstream to the vicinity of Rkm 305. The number of species begins to increase slightly downstream, but an appreciable change is not seen until the river reaches Rkm 216. Additional species reappear downstream or appear for the first time to the point that 12 species of frogs, 11 species of turtles, 5 species of salamanders, and 4 species of snakes can be found throughout the lower Illinois River. Common among these are the common map turtle, painted turtle, smooth softshell turtle, slider, treefrogs, southern leopard frog, and northern water snake. The alligator snapping turtle is listed as state endangered and Blanding's turtle is listed as threatened.

Ecosystem Processes

As a river–floodplain ecosystem, functional processes within the Illinois River were dependent on periodic and prolonged inundation of the floodplain and the creation of aquatic linkages of the main river to backwaters and floodplain lakes. Historically, floodplain inundation and aquatic habitat connectivity would last as long as 6 months (Sparks 1995). This prolonged period would allow riverine organisms, including benthic invertebrates and zooplankton, access to high levels of primary productivity in shallow floodplain lakes and backwaters. These areas also served as spawning grounds and nurseries for several species of fishes. Inundated areas also provided food resources for migrating waterfowl, shorebirds, and bald eagles. Later in the year, after water withdrew from the floodplain, moist soil vegetation would grow in the newly deposited nutrient-rich sediments, creating resources for waterfowl and shorebirds as they migrated south in the fall. Much of this dynamic, as discussed later, has been lost due to disruption of annual hydrological patterns and the construction of levees that cut the river off from the floodplain.

Although most recent studies have dealt with assessing the current status of the ecological condition of the Illinois River and life histories of flora and fauna, some studies have examined trophic dynamics in the Illinois and provide an indication of current ecosystem dynamics. A study focusing on the main channel of the lower Illinois noted that 14 of 26 fish species collected were omnivorous and 11 species were insectivores (Dettmers et al. 2001). Only one primarily piscivorous species was found. Gut contents of channel catfish and freshwater drum consisted primarily of larval and pupal Chironomidae and Hydropsychidae. Zooplankton are abundant in both backwaters and the main channel, with main-

channel densities averaging around 80 individuals/L. The abundant zooplankton provide an ample food source for larval and adult planktivorous fishes such as gizzard shad. Dettmers et al. (2001) concluded that both riverine primary production and organic matter from terrestrial sources are probably important to the food web of the lower Illinois. The most abundant benthic invertebrates, midges and oligochaetes, are viewed as primarily detritivorous in nature, feeding on detritus deposited in the bottom sediments. Filter-feeding caddisflies are considered omnivorous, consuming nearly all materials caught in their nets. It is assumed, therefore, that terrestrial organic matter derived from the floodplain is important for benthic-based trophic processes and instream production would be important to trophic groups associated with the phytoplankton-zooplankton assemblages. Phytoplankton counts averaging 21,100 cells/mL, with some samples as high as 150,000 cells/mL, indicate that phytoplankton are abundant, thus accounting, at least, for the abundance of zooplankton.

Human Impacts and Special Features

The Illinois River, prior to settlement, discharged about the same amount of water into the Upper Mississippi River as the Rock River located to the north (Richard Sparks, personal communication). Annual flow patterns, however, were much more like those of a large floodplain river because of the nature of the river valley of the lower Illinois. The river valley carved out by the ancestral Mississippi River is 8 to 11 km wide in some areas and the floodplain is very flat. The combination of a broad, flat floodplain and low slope of the river resulted in water remaining on the floodplain for much longer than would be expected for a river of this size. Prolonged inundation of the floodplain also allowed the river to scour out backwaters and floodplain lakes, where many species of fishes could be found feeding and spawning. These conditions resulted in the Illinois River having a commercial fishery that consistently ranked at or near the top nationally. This structural diversity also contributed to the presence of a diverse assemblage of fishes, including lotic and lentic specialists, and a high diversity of freshwater mussels. Much of this has changed, however, due to the changes inflicted on the system by humans.

The effects of population growth were probably the first human impacts to be felt in the Illinois River. The Chicago Sanitary and Ship Canal was opened in 1900 to divert flow from the Chicago River into the

Des Plaines River to protect Chicago's water supply (Starrett 1971a). This wedge of pollution continued downstream over the years and was compounded by population growth on the Illinois River proper and a major tributary, the Sangamon River. The effects throughout the river are evident from the demise of freshwater mussels described earlier. Although the river is significantly cleaner than before through improved waste treatment practices, problems do linger, partly from unknown, and possibly irreversible, effects of earlier pollution (Sparks 1984) and because of continued population growth. There are still 196 wastewater treatment plants in the upper Illinois, including the Kankakee and Des Plaines basins (Arnold et al. 1999).

Current nutrient concerns relate more to agricultural activities. Approximately 54% of the nutrient load to the Illinois River in the 1980s was from nonpoint sources, whereas 46% came from point sources. More recent studies illustrate that nutrient inputs from agriculture are a continuing concern. All of the study sites in the lower Illinois NAWQA study were in the highest 10% nationally for $\text{NO}_3\text{-N}$, whereas total phosphorus concentrations ranked in the top 25% nationally at seven of eight sites on the lower Illinois River (Groschen et al. 2000). Pesticides are also a major water-quality concern. Concentrations of atrazine and cyanazine sometimes exceed U.S. Environmental Protection Agency guidelines (Groschen et al. 2000). Increased suspended sediment transport is contributing to habitat loss by filling backwaters and floodplain lakes and increasing turbidity in these highly productive habitats.

Hydrological alterations and flood control have also played a part in reducing habitat and species diversity. The opening of the Chicago Canal raised water levels throughout the length of the river, eliminating some aquatic habitats. Water levels were raised further when five navigation dams were opened in the 1930s to maintain a 2.75 m navigation channel. The effects of the dams compounded the habitat loss already begun by the opening of the Chicago Canal. Water levels fluctuate unpredictably throughout the year as a result of current management of releases through the dams. Many areas of the river are still connected to the floodplain, but levees have been built throughout the river valley and the land behind the levees has been drained for farming. A consequence of this is that the river can no longer deposit sediments across the breadth of the floodplain. Sediment deposition between the levees and in the channel has raised the level of the river to the point that, in some areas, the river is perched above

the surrounding floodplain. Many efforts have been initiated to restore some of the natural qualities of the Illinois River, particularly in the floodplain. Over 20 state and federal areas have been established as fish and wildlife refuges or as management areas to improve the quality of fish and wildlife habitat. The Nature Conservancy of Illinois has purchased areas from private landowners with plans to restore connectivity between these former floodplain habitats and the river.

The opening of the Chicago Canal has made the Illinois and the rest of the Mississippi River susceptible to invasion by nonnative species established in the Great Lakes. This is the path through which zebra mussels entered the Illinois and moved throughout the entire Mississippi system. Several nonnative species have moved into the Illinois from the Mississippi River, including common carp, grass carp, bighead carp, silver carp, and the cladoceran zooplankton *Daphnia lumholtzi*.

Despite the extensive effects of human activity in the Illinois River, there are efforts to restore this river–floodplain system. The Illinois Natural History Survey, largely through the Illinois River Biological Station in Havana, continues to study the dynamics of the river. The Survey has an extensive history on the Illinois River, making it possible to compare the current status of the river to past conditions and identify positive and negative attributes. This is bolstered by the Survey's affiliation with the Long Term Resource Monitoring Program (LTRMP), a monitoring program established in the Upper Mississippi and Illinois rivers to assess the health and stability of the ecosystem. There are also efforts to restore river–floodplain connectivity. This has been primarily through the efforts of The Nature Conservancy, which has purchased two areas formerly used for crop production with plans to reestablish linkages between these lands and the Illinois River. The goal is to recreate some of the structural diversity that once contributed to the tremendous productivity of this river–floodplain ecosystem.

ADDITIONAL RIVERS

The Chippewa River of Wisconsin, like the St. Croix and Wisconsin rivers, begins in the Superior Upland physiographic province and ends in the Central Lowland (Fig. 8.21, Fig. 8.1). The Chippewa River transports a tremendous volume of sand from the deposits left behind by the Wisconsin glaciation. Deposition of sand at the mouth of the Chippewa

River as it empties into the Upper Mississippi River led to the formation of Lake Pepin, which marks one of the widest areas of the entire Mississippi River. Common to many rivers in the upper Midwest, the Chippewa has been dammed extensively for hydroelectric production. Many of these facilities practice hydropower peaking, where water is held back for most of the day and is then released in large volumes. Discharge during the summer at the Dells Dam in Eau Claire is held at 14 m³/s, then raised to as high as 142 m³/s in less than 2 hours when electricity is needed. Over 125 dams are identified on the Chippewa and its tributaries, although many of these are for small storage reservoirs.

The Root River is a small system with a drainage basin of only 4325 km² in southeastern Minnesota (Fig. 8.23), but it is an important representative of the rivers entering the Upper Mississippi from the Driftless Area. The Driftless Area was bypassed during the glacial events of the ice age, leaving behind a terrain highlighted by bluffs where the streams have carved out deep valleys known as coulees. The geology of this region creates numerous pockets of groundwater, and it is these groundwater seeps that feed the many streams and small rivers of the region to create a complex of coldwater and coolwater streams. The Root is also typical of other rivers flowing through this limestone-dominated terrain in that it is a hardwater system with alkalinity >200 mg/L as CaCO₃ and pH >8. Registered on the National River Inventory as a scenic river, the river is impacted by corn and soybean production and the presence of livestock concentrated into small feedlots.

The Wapsipinicon River, the first river after the Minnesota that flows almost entirely through the Central Tall Grasslands terrestrial ecoregion, has a narrow drainage basin that extends from its confluence with the Upper Mississippi River in central Iowa up into southern Minnesota (Fig. 8.25). One of the first of the larger streams to flow through the Corn Belt, it is distinct from other rivers draining this region, such as the Iowa–Skunk River system and the Des Moines River, in that it does not carry as high a nutrient load (NO₃-N average concentration is <5 mg/L). It also is one of the few rivers in Iowa that still possesses mature stands of riparian and floodplain forest (Fig. 8.8). The main-stem Wapsipinicon is free-flowing, with the only impoundments in the upper tributaries.

The basin of the Rock River traverses the Central Forest/Grassland and Upper Midwest Forest Savanna Transition Zone terrestrial ecoregions as it flows

FIGURE 8.8 Wapsipinicon River north of Tripoli, Iowa (PHOTO BY S. PORTER, U.S. GEOLOGICAL SURVEY).

FIGURE 8.9 Rock River north of Watertown, Dodge County, Wisconsin (PHOTO BY S. WADE).

south from central Wisconsin (Fig. 8.9) through northern Illinois to its confluence with the Upper Mississippi (Fig. 8.27). The diversity of the terrain it covers is reflected in its biological diversity, with 115 species of fishes, ranging from coldwater to warm-

water species. The Rock River has been extensively impounded, with 19 hydroelectric dams on the main stem and over 250 small dams, primarily for water storage, on its tributaries. Urbanization is a concern for the Rock River, as the metropolitan areas

FIGURE 8.10 Des Moines River near Des Moines, Iowa (PHOTO BY TIM PALMER).

of Madison, Wisconsin, and Rockford, Illinois, lie within the basin.

The Des Moines River is the largest of the rivers draining the Central Tall Grasslands terrestrial ecoregion to empty into the Upper Mississippi River (Fig. 8.29, Fig. 8.10). Characteristic of rivers draining the Corn Belt, nonpoint-source pollution is a major concern in the basin. Concentrations of $\text{NO}_3\text{-N}$ average around 6 mg/L throughout the basin. Pesticide concentrations in fish tissues are low but are still considered a point of concern. Sediment loads are also high, with 6.3 million kg/d delivered to Red Rock Lake, one of two large reservoirs on the Des Moines River. Gas supersaturation-induced gas bubble trauma has been blamed for 16 fish kills below Red Rock Dam since 1983. Habitat loss due primarily to the impoundments has caused declines in the abundance of aquatic vertebrates, especially turtles.

The Kaskaskia River is the last major tributary to empty into the Upper Mississippi River before the confluence of the Ohio River (Fig. 8.31). Flowing south through central and southwestern Illinois, the river's basin lies entirely within the Temperate Decid-

uous Forest biome. The largest contiguous tract of forest, including bottomland, remaining in Illinois lies within the Kaskaskia River basin. The forest includes pecan, sugar maple, bur oak, pin oak, and shellbark hickory. Nearly 40% of the vascular plants known in Illinois can be found in the Kaskaskia River basin. There are 107 dams in the basin, located primarily on the tributaries. Two large reservoirs are on the main-stem Kaskaskia, including Lake Shelbyville, a 4452 ha reservoir that receives heavy recreational use, particularly from Champaign, located in the northern end of the basin. There is a lock and dam near the mouth that forms a 21 km long pool. The last 58 km of the river have been channelized for navigation. Primary pollution concerns in the basin are nutrients and siltation from urban and agricultural runoff.

ACKNOWLEDGMENTS

I would like to thank the following people for their assistance and expertise: Terry Balding, Heath Benike, Michael Bohn, Gary Casper, Thad Cook, Kevin Cummings, Cal

Fremling, Marian Havlik, David Heath, Randolph Hoffman, Daryl Howell, Robert Hrabik, Dan Kelner, Maria Lemke, Paul La Liberte, David Lonzarich, Gregory Milton, Gary Montz, Neal Mundahl, Dan North, Mark Pegg, Clay Pierce, Robin Richardson, Joseph Rohrer, Steven Russell, Konrad Schmidt, Trent Thomas, and Scott Whitney. I am especially grateful to John Lyons and Dick Lillie for the wealth of information provided for the Wisconsin River and Don Fago and Byron Karns for information on the St. Croix.

UPPER MISSISSIPPI RIVER

Relief: 337 m

Basin area (excluding Missouri River): 489,510 km²

Mean discharge (excluding Missouri River): 3576 m³/s

River order: 10

Mean annual precipitation: 96 cm

Mean air temperature: 10.5°C

Mean water temperature: 14.3°C

Physiographic provinces: Central Lowland (CL), Superior Upland (SU), Ozark Plateau (OZ)

Biomes: Boreal Forest, Temperate Deciduous Forest, Temperate Grassland

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Western Great Lakes Forests, Upper Midwest Forest/Savanna Transition, Central Tall Grasslands, Central Forest/Grassland Transition, Central U.S. Hardwood Forests

Number of fish species: 145

Number of endangered species: 7 fishes, 3 mussels

Major fishes: carp, smallmouth buffalo, shorthead redhorse, river redhorse, gizzard shad, emerald shiner, bluntnose minnow, smallmouth bass, largemouth bass, bluegill, walleye, sauger, channel catfish, flathead catfish, carpsucker, quillback, drum, logperch, paddlefish

Major other aquatic vertebrates: painted turtle, common snapping turtle, smooth softshell turtle, spiny softshell turtle, common map turtle, false map turtle, bullfrog, northern leopard frog, southern leopard frog, pickerel frog, mink frog, treefrogs, common mudpuppy, northern water snake, muskrat, beaver, river otter

Major benthic invertebrates: Caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Potamyia*, *Cynellus*, *Oecetis*, *Hydroptila*, *Nectopsyche*), mayflies (*Hexagenia*, *Stenonema*, *Tricorythodes*, *Baetisca*, *Baetis*, *Caenis*), chironomid midges (*Dicoretendipes*, *Rheotanytarsus*, *Cricotopus*), stoneflies (*Perlesta*), damselflies (*Ischnura*, *Enallagma*), dragonflies (*Dromogomphus*), crustaceans (*Asellus*, *Gammarus*), snails (*Physella*, *Fossaria*, *Ferrissia*), bivalves (*Sphaerium*, *Pisidium*)

Nonnative species: rainbow trout, rainbow smelt, common carp, grass carp, bighead carp, silver carp, white catfish, ninespine stickleback, striped bass, zebra mussel, Asiatic clam, *Daphnia lumholzi*, Eurasian watermilfoil

Major riparian plants: cottonwood, silver maple, river birch, black willow, sandbar willow, box elder, green ash

Special features: large floodplain river that still retains >80% of river-floodplain connectivity; close to natural hydrograph

Fragmentation: 11 dams in headwaters; 26 locks and low-head dams on main stem

Water quality: pH = 8, alkalinity = 170 mg/L as CaCO₃, NO₃-N = 3.2 mg/L, total phosphorus = 0.19 mg/L; nutrient inputs from fertilizers; sedimentation

Land use: 70% agriculture, 25% forest, 5% urban

Population density: 54 people/km²

Major information sources: Fremling et al. 1989, Patrick 1998

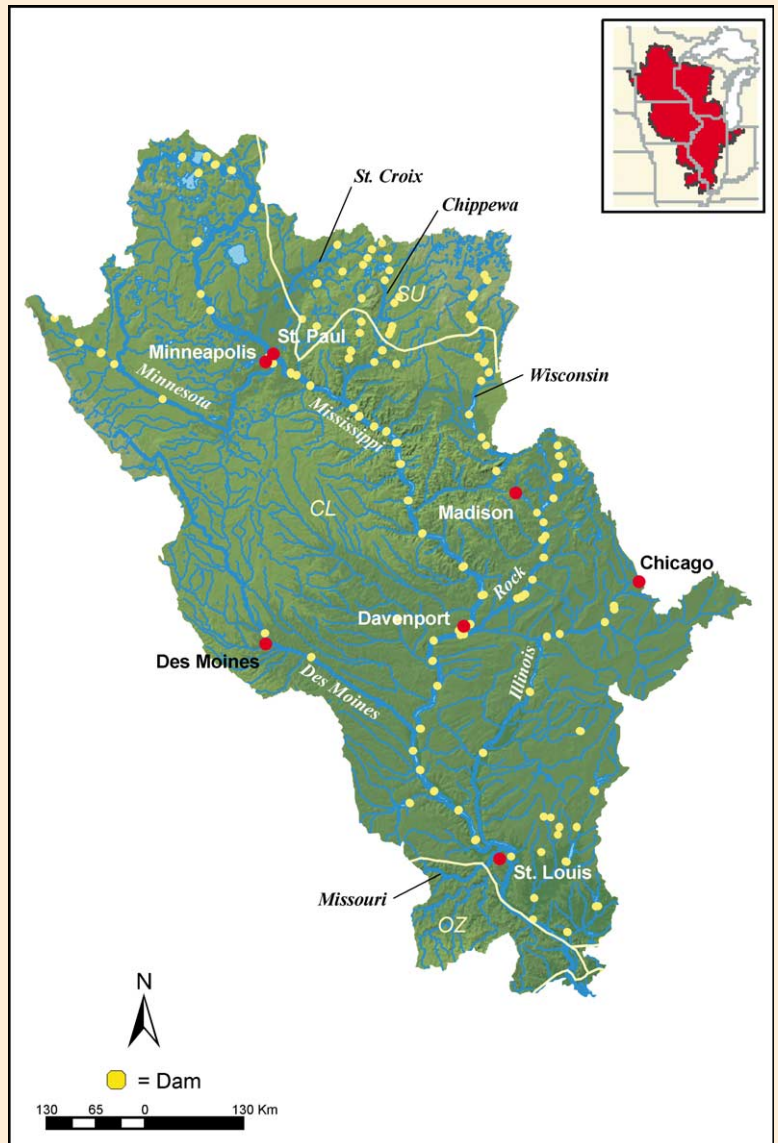

FIGURE 8.11 Map of the Upper Mississippi River basin. Physiographic provinces are separated by yellow lines.

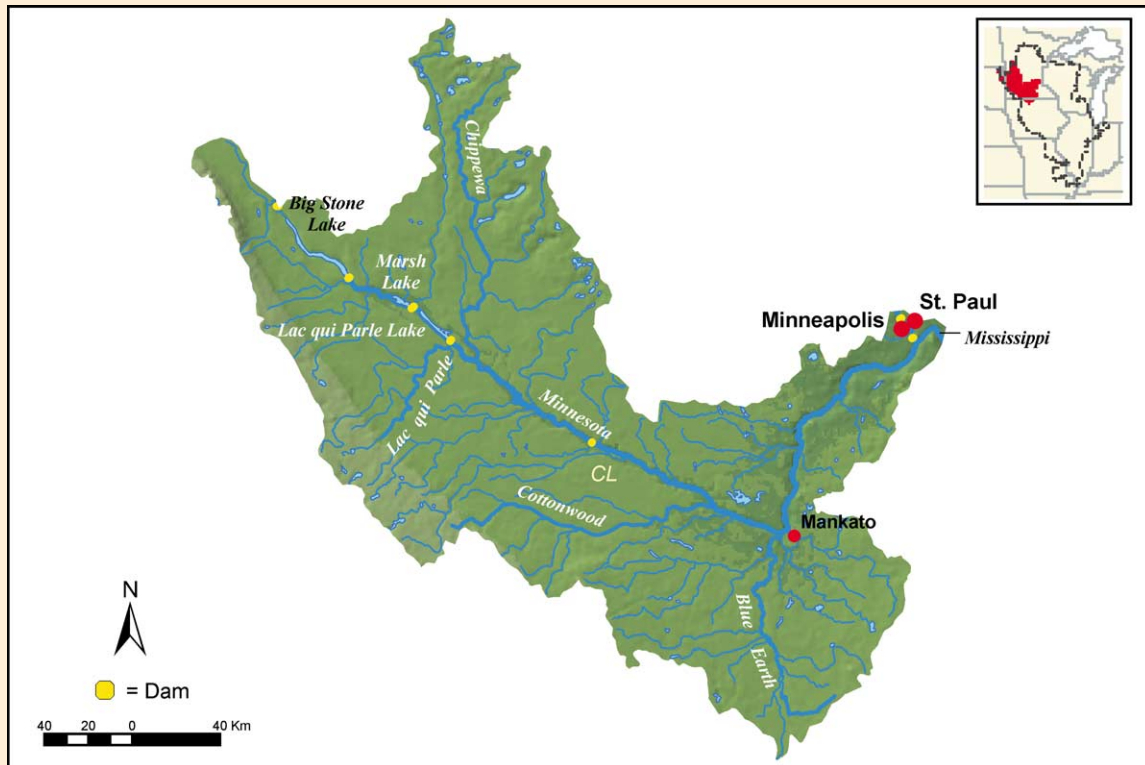

FIGURE 8.13 Map of the Minnesota River basin.

MINNESOTA RIVER

Relief: 85 m

Basin area: 27,030 km²

Mean discharge: 125 m³/s

River order: 7

Mean annual precipitation: 66 cm

Mean air temperature: 7.5°C

Mean water temperature: 10.5°C

Physiographic province: Central Lowland (CL)

Biomes: Temperate Grassland, Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Central Tall Grasslands, Upper Midwest Forest/Savanna Transition

Number of fish species: 87

Number of endangered species: 2 mussels (extirpated)

Major fishes: shorthead redhorse, quillback, carp, emerald shiner, spotfin shiner, sand shiner, channel catfish, freshwater drum, gizzard shad, bluntnose minnow, smallmouth buffalo, bigmouth buffalo, walleye, fathead minnow, quillback, fathead minnow

Major other aquatic vertebrates: northern leopard frog, mink frog, wood frog, treefrogs, mudpuppy, tiger salamander, painted turtle, common snapping turtle, false map turtle, common map turtle, northern water snake

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Cyrnellus*), mayflies (*Stenonema*, *Stenacron*, *Potamanthus*, *Tricorythodes*), damselflies (*Enallagma*, *Argia*), dragonflies (*Dromogomphus*), stoneflies (*Isoperla*), chironomid midges (*Glyptotendipes*, *Polypedilum*, *Tanytarsus*), crustaceans (*Gammarus*, *Hyaella*), snails (*Physella*)

Nonnative species: brown trout, brook trout, goldfish, common carp, longear sunfish, Asiatic clam

Major riparian plants: cottonwood, green ash, black willow, sandbar willow

Special features: small river in a 1 to 10km wide channel formed by glacial River Warren

Fragmentation: six dams on main stem, including outlets of three natural channel lakes

Water quality: highly impaired; high sediments, fertilizer, and pesticides from agriculture; pH = 8, alkalinity = 252 mg/L as CaCO₃, NO₃-N = 4.09 mg/L, PO₄-P = 0.08 mg/L

Land use: 95% agriculture, 1% urban, 1% forest

Population density: 6 people/km²

Major information sources: Bailey et al. 1994, Zischke et al. 1994, Downing et al. 1999

FIGURE 8.14 Mean monthly air temperature, precipitation, and runoff for the Minnesota River basin.

FIGURE 8.16 Mean monthly air temperature, precipitation, and runoff for the St. Croix River basin.

ST. CROIX RIVER

- Relief:** 319 m
Basin area: 20,018 km²
Mean discharge: 131 m³/s
River order: 6
Mean annual precipitation: 78 cm
Mean air temperature: 6.3°C
Mean water temperature: 10.4°C
Physiographic provinces: Superior Upland (SU), Central Lowland (CL)
Biome: Temperate Deciduous Forest
Freshwater ecoregion: Mississippi
Terrestrial ecoregions: Western Great Lakes Forest, Upper Midwest Forest/Savanna Transition
Number of fish species: 110
Number of endangered species: 2 mussels
Major fishes: emerald shiner, golden redbhorse, shorthead redbhorse, common carp, gizzard shad, smallmouth bass, bluegill, yellow perch, Johnny darter, spottail shiner, common shiner, spotfin shiner, bluntnose minnow, mimic shiner, brassy minnow, central stoneroller
Major other aquatic vertebrates: painted turtle, common snapping turtle, wood turtle, common map turtle, false map turtle, spiny softshell turtle, northern leopard frog, green frog, spring peeper, treefrogs, tiger salamander, muskrat, beaver, mink
Major benthic invertebrates: caddisflies (*Hydropsyche*, *Ceratopsyche*, *Nectopsyche*, *Lepidostoma*), mayflies (*Baetis*, *Stenonema*, *Stenacron*, *Heptagenia*, *Anthopotamus*, *Siphonurus*, *Ephemerella*), stoneflies (*Pteronarcys*), beetles (*Gyrinus*, *Peltodytes*)
Nonnative species: rainbow trout, brown trout, brook trout, lake trout, rainbow smelt, common carp, zebra mussel, Asiatic clam
Major riparian plants: paper birch, slippery elm, black ash, tamarack, black spruce, white cedar, basswood, red maple, yellow birch
Special features: one of first eight rivers protected as National Wild and Scenic Rivers; spectacular gorges and rapids; most pristine river in Upper Mississippi basin
Fragmentation: two dams on main stem, but mostly free flowing; 134 small dams on tributaries
Water quality: high; pH = 7.5, alkalinity = 59 mg/L as CaCO₃, total nitrogen = 0.4 mg/L, total phosphorus = 0.05 mg/L
Land use: 27% agriculture, 65% forest, 2% urban
Population density: 13 people/km²
Major information sources: Fago and Hatch 1993, National Park Service 1997

FIGURE 8.15 Map of the St. Croix River basin. Physiographic provinces are separated by a yellow line.

FIGURE 8.18 Mean monthly air temperature, precipitation, and runoff for the Wisconsin River basin.

WISCONSIN RIVER

Relief: 300 m

Basin area: 30,000 km²

Mean discharge: 261 m³/s

River order: 8

Mean annual precipitation: 85 cm

Mean air temperature: 7.5°C

Mean water temperature: 11.8°C

Physiographic provinces: Central Lowland (CL), Superior Upland (SU)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Western Great Lakes Forest, Upper Midwest Forest/Savanna Transition

Number of fish species: 119

Number of endangered species: 2 mussels

Major fishes: shorthead redhorse, Johnny darter, logperch, walleye, largemouth bass, smallmouth bass, bluegill, yellow perch, river carpsucker, smallmouth buffalo, common carp, gizzard shad, quillback, freshwater drum

Major other aquatic vertebrates: northern water snake, common snapping turtle, common musk turtle, wood turtle, painted turtle, common map turtle, false map turtle, Ouachita map turtle, smooth softshell turtle, spiny softshell turtle, green frog, mink frog, spring peeper, treefrogs, muskrat, beaver

Major benthic invertebrates: hemiptera (*Sigara*, *Trichocorixa*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Potamyia*, *Nectopsyche*), mayflies (*Stenonema*, *Baetisca*, *Baetis*, *Caenis*, *Stenacron*, *Proclleon*, *Isonychia*), beetles (*Stenelmis*, *Macronychus*, *Peltodytes*, *Gyrinus*), stoneflies (*Isoperla*), damselflies (*Enallagma*), dragonflies (*Gomphurus*)

Nonnative species: rainbow trout, brown trout, common carp, grass pickerel

Major riparian plants: silver maple, river birch, swamp white oak, green ash, cottonwood, black willow

Special features: largest river in Wisconsin, draining 22% of state; Grandfather Falls rapids descend 28 m over 2.4 km

Fragmentation: heavily impounded in middle and upper reaches; 47 storage reservoirs and 27 hydroelectric dams on main stem and major tributaries

Water quality: point-source discharges from paper mills and municipal sewage; pH = 7.9, alkalinity = 89 mg/L as CaCO₃, NO₃-N = 0.52 mg/L, PO₄-P = 0.08 mg/L

Land use: 27% agriculture, 54% forest, 12% open water, 3% urban

Population density: 46 people/km²

Major information sources: Fago 1992, Lillie and Hilsenhoff 1992, Lyons et al. 2000

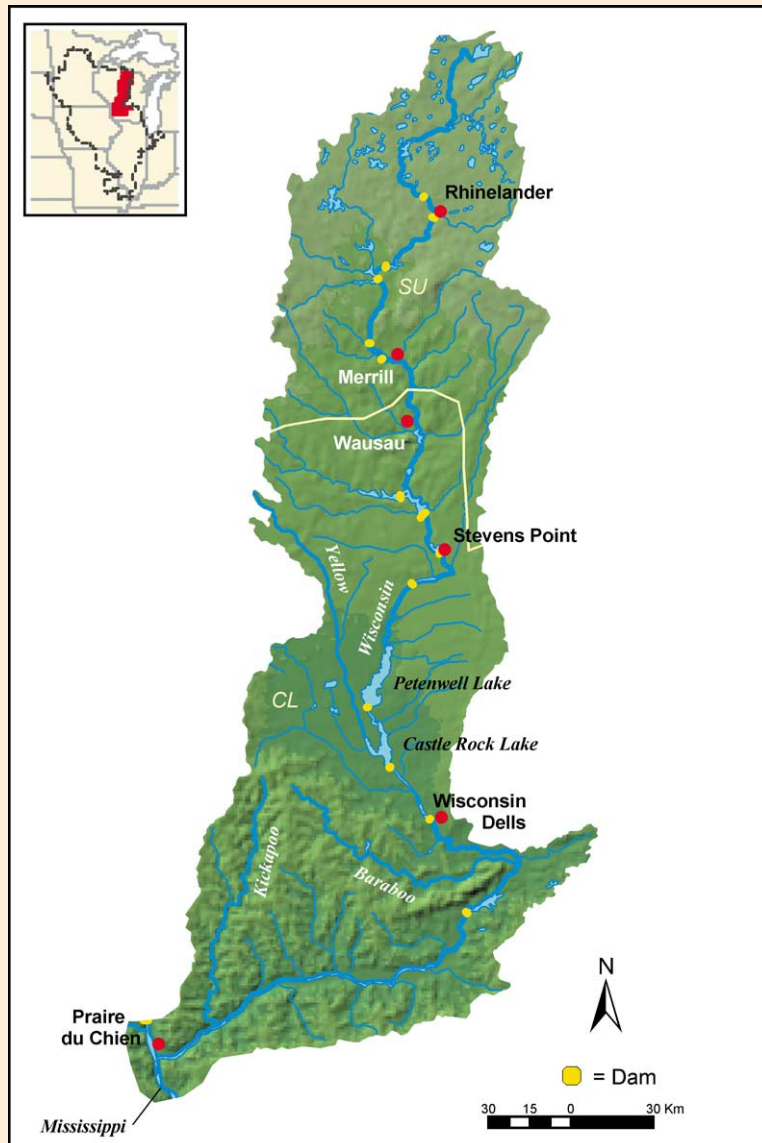

FIGURE 8.17 Map of the Wisconsin River basin. Physiographic provinces are separated by a yellow line.

FIGURE 8.20 Mean monthly air temperature, precipitation, and runoff for the Illinois River basin.

ILLINOIS RIVER

Relief: 45 m

Basin area: 75,136 km²

Mean discharge: 649 m³/s

River order: 9

Mean annual precipitation: 92 cm

Mean air temperature: 10.4°C

Mean water temperature: 16°C

Physiographic province: Central Lowland (CL)

Biomes: Temperate Grassland, Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregion: Central Forest/Grassland Transition

Number of fish species: 127

Number of endangered species: 2 mussels

Major fishes: gizzard shad, emerald shiner, freshwater drum, white bass, bluegill, green sunfish, largemouth bass, common carp, smallmouth buffalo, white sucker, bluntnose minnow, channel catfish, flathead catfish, bowfin, shortnose gar, grass pickerel, quillback, carpsucker

Major other aquatic vertebrates: common snapping turtle, smooth softshell turtle, common map turtle, false map turtle, slider, treefrogs, southern leopard frog, tiger salamander, northern water snake

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Potamyia*, *Cyrtellus*), mayflies (*Stenonema*, *Baetis*, *Hexagenia*, *Heptagenia*), crustaceans (*Gammarus*, *Asellus*), bivalves (*Pisidium*), beetles (*Stenelmis*), chironomid midges (*Robackia*, *Rheosmittia*), flies (*Hemerodromia*), damselflies (*Argia*), oligochaete worms (*Barbidrilus*)

Nonnative species: rainbow trout, rainbow smelt, common carp, grass carp, bighead carp, silver carp, zebra mussel, Asiatic clam, round goby, *Daphnia lumholtzi*

Major riparian plants: silver maple, ash, box elder, black willow, hackberry

Special features: lower river flows through channel abandoned by Upper Mississippi; broad low-gradient floodplain results in protracted spring flood

Fragmentation: five low-head navigation dams on main stem

Water quality: pH = 7.8, alkalinity = 180 mg/L as CaCO₃, NO₃-N = 0.41 mg/L, PO₄-P = 0.18 mg/L; municipal sewage (upper river); nutrients, pesticides, soil erosion from agriculture throughout

Land use: 87% agriculture, 7% forest, 5% urban

Population density: 97 people/km²

Major information sources: Starrett 1971a, Page et al. 1992, Arnold et al. 1999

FIGURE 8.22 Mean monthly air temperature, precipitation, and runoff for the Chippewa River basin.

CHIPPEWA RIVER

Relief: 290 m

Basin area: 24,827 km²

Mean discharge: 218 m³/s

River order: 6

Mean annual precipitation: 80 cm

Mean air temperature: 6°C

Mean water temperature: 11°C

Physiographic provinces: Central Lowland (CL), Superior Upland (SU)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Western Great Lakes Forest, Upper Midwest Forest/Savannah Transition

Number of fish species: 110

Number of endangered species: 3 fishes, 2 mussels

Major fishes: shorthead redhorse, golden redhorse, smallmouth buffalo, carpsucker, common carp, mooneye, gizzard shad, shovelnose sturgeon, smallmouth bass, northern pike, channel catfish, walleye, sauger, muskellunge, emerald shiner, paddlefish

Major other aquatic vertebrates: muskrat, beaver, river otter, snapping turtle, common map turtle, false map turtle, spiny softshell turtle, leopard frog, green frog, treefrogs, northern water snake

Major benthic invertebrates: mayflies (*Pseudocloeon*, *Stenonema*, *Hexagenia*), alderflies (*Sialis*), dragonflies (*Dromogomphus*), stoneflies (*Allocaenia*), beetles (*Stenelmis*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Agraylea*, *Cyrnellus*), biting midges (*Dasyhelia*), chironomid midges (*Cladotanytarsus*, *Dicrotendipes*, *Orthocladius*, *Robackia*), black flies (*Simulium*), bivalves (*Pisidium*)

Nonnative species: rainbow trout, brown trout, rainbow smelt, common carp, curly-leaved pondweed, Eurasian watermilfoil

Major riparian plants: cottonwood, silver maple, black willow, green ash, American elm, river birch, white swamp oak

Special features: sand carried by Chippewa River led to formation of Lake Pepin on Upper Mississippi River

Fragmentation: over 125 dams, including 16 impoundments >12 km²; hydrology extensively altered by hydropower

Water quality: pH = 7.6, alkalinity = 49 mg/L as CaCO₃, NO₃-N = 0.68 mg/L, PO₄-P = 0.05 mg/L; fertilizer, pesticide, and soil runoff from agriculture and urbanization

Land use: 36% agriculture, 54% forest, 2% urban, remainder primarily open water

Population density: 12 people/km²

Major information source: Voss and Beaster 2001

FIGURE 8.21 Map of the Chippewa River basin. Physiographic provinces are separated by a yellow line.

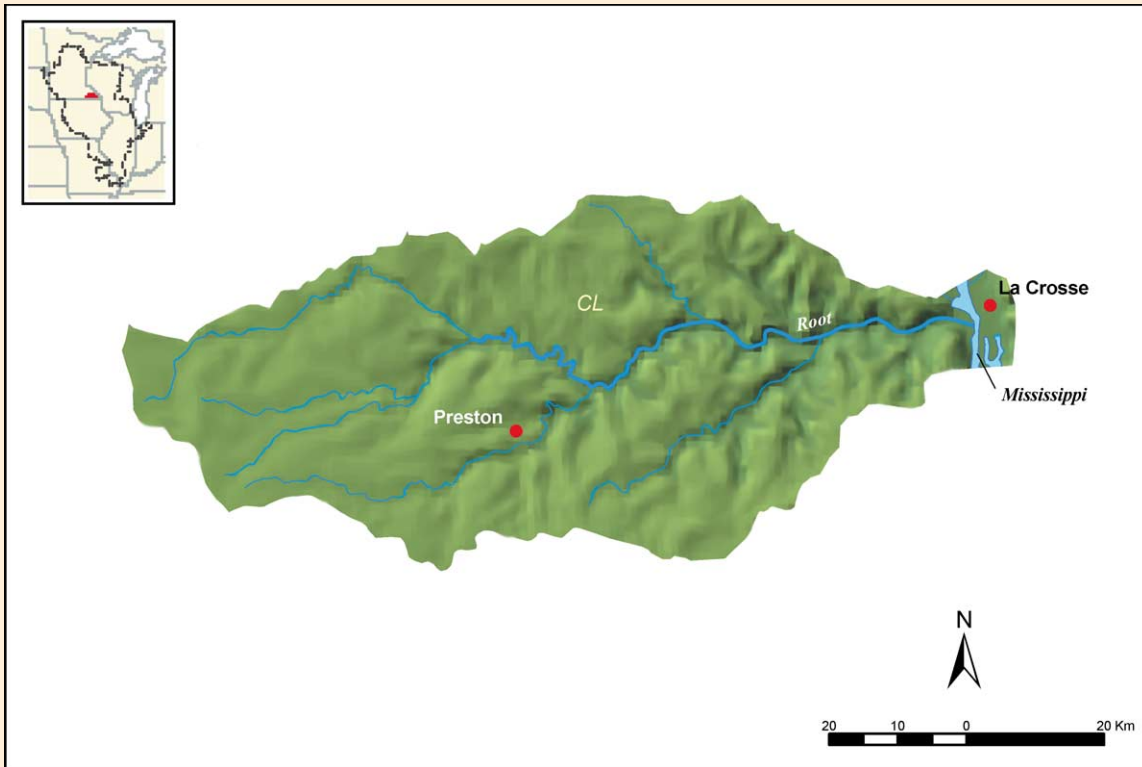

FIGURE 8.23 Map of the Root River basin.

ROOT RIVER

Relief: 170 m

Basin area: 4325 km²

Mean discharge: 21 m³/s

River order: 5

Mean annual precipitation: 82 cm

Mean air temperature: 6.4°C

Mean water temperature: 11°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregion: Upper Midwest Forest/Savanna Transition

Number of fish species: 97

Number of endangered species: unknown

Major fishes: brown trout, brook trout, slimy sculpin, white sucker, longnose dace, blacknose dace, brook stickleback, American brook lamprey, northern hog sucker, shorthead redhorse, smallmouth bass, common shiner, southern redbelly dace, longnose dace, central stoneroller, fantail darter

Major other aquatic vertebrates: muskrat, beaver, river otter, snapping turtle, common map turtle, false map turtle, spiny softshell turtle, leopard frog, green frog, treefrogs, northern water snake

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Brachycentrus*), mayflies (*Stenonema*, *Baetis*, *Isonychia*), stoneflies (*Neoperla*, *Pteronarcys*), beetles (*Stenelmis*, *Optioservus*), flies (*Atherix*, *Simulium*, *Tipula*), crustaceans (*Hyalella*), snails (*Physella*)

Nonnative species: brown trout, rainbow trout, common carp

Major riparian plants: cottonwood, silver maple, box elder, black willow, red oak, American elm

Special features: representative of the coolwater–coldwater rivers of Driftless Area; registered on the national scenic river inventory with heavy recreational use

Fragmentation: mostly free-flowing, with a few small dams in headwaters

Water quality: pH = 8.2, alkalinity = 221 mg/L as CaCO₃, NO₃-N = 3 mg/L, PO₄-P = 0.18 mg/L, turbidity often >50 NTU; fertilizers, pesticides, and livestock runoff (fecal coliform often >200/mL)

Land use: approximately 60% agriculture, 22% forest, 2.5% urban, 15% pasture/grassland

Population density: 9 people/km²

Major information sources: N. Mundahl (unpublished data), K. Schmidt (unpublished data), Waters 1977

WAPSIPINICON RIVER

Relief: 195 m
Basin area: 6050 km²
Mean discharge: 47 m³/s
River order: 5
Mean annual precipitation: 88 cm
Mean air temperature: 9°C
Mean water temperature: 12°C
Physiographic province: Central Lowland (CL)
Biomes: Temperate Grassland, Temperate Deciduous Forest
Freshwater ecoregion: Mississippi
Terrestrial ecoregion: Central Tall Grasslands
Number of fish species: 74
Number of endangered species: 1 fish
Major fishes: American brook lamprey, spotfin shiner, Mississippi silvery minnow, bigmouth shiner, sand shiner, bluntnose minnow, bullhead minnow, river carpsucker, shorthead redhorse, Johnny darter
Major other aquatic vertebrates: muskrat, beaver, river otter, snapping turtle, western painted turtle, common map turtle, false map turtle, mudpuppy, spiny softshell turtle, treefrogs, leopard frog
Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Ceratopsyche*, *Nectopsyche*), mayflies (*Tricorythodes*, *Heptagenia*, *Baetis*, *Caenis*, *Stenonema*), stoneflies (*Paragnetina*, *Pteronarcys*), beetles (*Macronychus*, *Dubiraphia*), chironomid midges (*Ablabesmyia*, *Cricotopus/Orthocladius*), flies (*Simulium*, *Atherix*), crustaceans (*Orconectes*), snails (*Physella*)
Nonnative species: common carp, rainbow trout, brown trout
Major riparian plants: silver maple, cottonwood, black willow, sandbar willow
Special features: one of few Iowa rivers that retains mature stands of riparian and floodplain vegetation; very narrow basin
Fragmentation: 21 dams, mostly small impoundments on tributaries of upper basin
Water quality: pH = 8.1, alkalinity = 137 mg/L as CaCO₃, NO₃-N = 6.2 mg/L, PO₄-P = 0.06 mg/L, Atrazine = 1.68 µg/L, Cyanazine = 0.18 µg/L, Carbofuran = 0.06 µg/L; pollution primarily from row-crop agriculture
Land use: 88% agriculture, 10% forest, 2% urban
Population density: 14 people/km²
Major information sources: Sullivan 2000, Brigham and Sadorf 2001

ROCK RIVER

Relief: 155 m

Basin area: 28,101 km²

Mean discharge: 184 m³/s

River order: 7

Mean annual precipitation: 99 cm

Mean air temperature: 10°C

Mean water temperature: 12°C

Physiographic province: Central Lowland (CL)

Biomes: Temperate Grassland, Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Central Forest/Grassland Transition, Upper Midwest Forest/Savanna Transition

Number of fish species: 115

Number of endangered species: 1 mussel

Major fishes: gizzard shad, carp, spotfin shiner, smallmouth buffalo, largemouth buffalo, channel catfish, white bass, smallmouth bass, walleye, northern pike, freshwater drum, white sucker, green sunfish, Johnny darter, central stoneroller

Major other aquatic vertebrates: tiger salamander, common mudpuppy, bullfrog, green frog, northern leopard frog, pickerel frog, treefrogs, common snapping turtle, common map turtle, painted turtle, slider, common musk turtle, northern water snake

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Nectopsyche*), mayflies (*Stenonema*, *Stenacron*, *Baetis*), crustaceans (*Gammarus*, *Crangonyx*, *Hyaella*, *Caecidotea*), black flies (*Simulium*)

Nonnative species: rainbow trout, brown trout, lake trout, common carp, grass carp, goldfish, rusty crayfish, zebra mussel, Eurasian watermilfoil

Major riparian plants: cottonwood, silver maple, box elder, black willow, sandbar willow

Special features: upper river drains unique glacial formations, creating constrained channels for many tributaries

Fragmentation: 19 hydroelectric dams on main stem and 272 dams throughout the basin

Water quality: pH = 8.3, alkalinity = 220 mg/L as CaCO₃, NO₃-N = 3.2 mg/L, PO₄-P = 0.13 mg/L; pollution from municipal wastewater treatment and agriculture

Land use: 71% agriculture, 14% urban, 12% forest, 2% wetland

Population density: 52 people/km²

Major information sources: Page et al. 1992, U.S. Army Corps of Engineers (unpublished data)

DES MOINES RIVER

Relief: 290 m

Basin area: 31,127 km²

Mean discharge: 182 m³/s

River order: 6

Mean annual precipitation: 96 cm

Mean air temperature: 11°C

Mean water temperature: 11.6°C

Physiographic province: Central Lowland (CL)

Biomes: Temperate Grassland, Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregions: Central Tall Grasslands, Central Forest/Grassland Transition

Number of fish species: 84

Number of endangered species: 3 fishes

Major fishes: shorthead redhorse, common carp, smallmouth buffalo, emerald shiner, bluntnose minnow, bluegill, largemouth bass

Major other aquatic vertebrates: snapping turtle, painted turtle, spiny softshell turtle, smooth softshell turtle, red-eared slider, treefrogs, mudpuppy, leopard frog, pickerel frog, green frog, muskrat

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Ceratopsyche*, *Nectopsyche*), mayflies (*Tricorythodes*, *Heptagenia*, *Baetis*, *Caenis*, *Stenonema*), stoneflies (*Paragnetina*, *Pteronarcys*), beetles (*Macronychus*, *Dubiraphia*), chironomid midges (*Ablabesmyia*, *Cricotopus/Orthocladius*), black flies (*Simulium*), snails (*Physella*)

Nonnative species: common carp, grass carp, bighead carp, striped bass

Major riparian plants: cottonwood, ash, black willow, sandbar willow

Special features: largest river in Iowa, with drainage basin covering 23% of state

Fragmentation: two major impoundments (>12 km³) and 58 small to medium-size impoundments on main stem and tributaries

Water quality: pH = 8, alkalinity = 190 mg/L as CaCO₃, NO₃-N = 5.36 mg/L, PO₄-P = 0.72 mg/L; pollution primarily from agriculture

Land use: 86% agriculture, 5% urban, 3% forest

Population density: 22 people/km²

Major information sources: Keeny and DeLuca 1993, Lutz et al. 2001

KASKASKIA RIVER

Relief: 100m

Basin area: 15,025 km²

Mean discharge: 107 m³/s

River order: 6

Mean annual precipitation: 99 cm

Mean air temperature: 11°C

Mean water temperature: 15.2°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Mississippi

Terrestrial ecoregion: Central Forest/Grassland Transition

Number of fish species: 112

Number of endangered species: 1 mussel

Major fishes: common carp, shorthead redhorse, channel catfish, freshwater drum, bluegill, largemouth bass, flathead catfish, white crappie, yellow bass, white bass, gizzard shad, sand shiner, bigmouth buffalo, western mosquitofish

Major other aquatic vertebrates: smooth softshell turtle, painted turtle, false map turtle, river cooter, smooth softshell turtle, slider, southern leopard frog, pickerel frog, green frog, treefrogs, tiger salamander, smallmouth salamander, northern water snake, diamondback water snake

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*), mayflies (*Stenonema*, *Caenis*, *Tricorythodes*), stoneflies (*Taeniopteryx*), beetles (*Stenelmis*, *Macronychus*), flies (*Atherix*), crustaceans (*Gammarus*, *Crangonyx*, *Hyalella*, *Procambarus*, *Orconectes*, *Lirceus*, *Caecidotea*)

Nonnative species: bighead carp, common carp, silver carp, goldfish, white catfish, redear sunfish, zebra mussel

Major riparian plants: silver maple, box elder, black willow, cottonwood

Special features: southernmost large tributary of upper Mississippi; largest contiguous tracts of forest, including bottomland, in Illinois

Fragmentation: 107 dams on the main stem and tributaries, including four impoundments >12 km²; lock and dam near mouth creates 21 km long pool

Water quality: primary impacts from fertilizer, pesticide and soil runoff, increased urbanization; pH = 7.5, hardness = 46 mg/L as CaCO₃, NO₃-N = 2.94 mg/L, PO₄-P = 0.08 mg/L

Land use: 80% agriculture, 13% forest, 4% wetland, 3% urban

Population density: 30 people/km²

Major information source: Page et al. 1992

LITERATURE CITED

INTRODUCTION

The word “Ohio” comes from Iroquois, meaning “beautiful river.” Early French explorers also called it “La Belle Rivière.” The Ohio basin is the third largest by discharge (8733 m³/s) in the United States, accounting for more than 40% of the discharge of the Mississippi River but making up only 16% of its drainage area. The basin lies between 34°N and 41°N latitude and 77°W and 89°W longitude and drains major portions of eight states and minor parts of six additional states (529,000 km²), from New York in the northeast to Georgia and Alabama in the south to Illinois in the west (Fig. 9.2). The eastern portion of the basin has its tributary origins in the Appalachian Mountains, and the northern tributaries border on Laurentian Great Lakes drainages. Climate is continental, with abundant rainfall, cool moist winters, and warm summers. With the exception of some prairie in the north and west, the region historically was heavily forested, but today agriculture is a major feature along with many large urban areas. Patterns of glaciation, mountains, and varied geology have resulted in a highly diverse biological environment.

At the time of the first French explorers the basin was home to a wide variety of Native Americans, including Shawnee, Mosopelea, Erie–Iroquois, Cherokee, and Miami–Pottawatomie cultures. French and British traders competed with each other for the lucrative fur trade for more than a century until first the French and then the British gave up claims to territories. In the 1780s, following the American Revolutionary War, European settlers poured in from the south through Georgia, east through the Cumberland Gap, and down the Ohio River. Within 30 years they had completely displaced Native Americans and had begun to permanently alter the landscape. Development was very rapid; all the states in the Ohio basin had been admitted to the Union by 1818, and almost all of the major cities had been established.

In this chapter, we first discuss the Ohio River main stem and then four of the major rivers that reflect the basin’s diversity in an upstream progression from the Tennessee River to the Cumberland River, Wabash River, and Kanawha River (see Fig. 9.2). Abbreviated descriptions of physical and biological features are provided for the Green, Kentucky, Great Miami, Scioto, Licking, Monongahela, and

FIGURE 9.2 Rivers of the Ohio River basin covered in the chapter.

Allegheny rivers. Because of space limitations, several other large tributaries to the Ohio River are not covered here, but their major contributions to the system are recognized (e.g., the Salt River, the Little Miami River, the Big Sandy River, and the Muskingum River).

Physiography and Climate

The Ohio River basin slopes generally east to west, spanning six physiographic provinces (Hunt 1967). The eastern portions of the basin begin in the Blue Ridge, Valley and Ridge, and Appalachian Plateaus provinces of the Appalachian Highlands. The central and northern parts of the basin drain the Interior Low Plateaus province and the glaciated topography

of the Central Lowland province. At its western end the basin just touches on the Coastal Plain province.

The eastern extent of the basin is in the Blue Ridge and Valley and Ridge provinces, which run parallel to each other and contain some of the highest mountain peaks in the eastern United States. The closely spaced ridges of the Blue Ridge are made up of metamorphic Precambrian granites and gneiss along with sandstones and conglomerates. The folded mountains of the geologically younger Valley and Ridge province are primarily Paleozoic limestones, shale, and sandstones and contain heavily mined anthracite coal beds. Contiguous with the Valley and Ridge province to the west is the much larger Appalachian Plateaus province with its varied landscape of Ordovician, Silurian, and Devonian

limestone, sandstone, shale, and bituminous coal formations. The western part of the Appalachian Plateaus province extends into eastern Tennessee, Kentucky, and Ohio and contains eroded low hills of Mississippian and Pennsylvanian limestone. Soils range from thin and easily eroded mountain soils to deeper podzols in the valleys. Together the three provinces contain the richest diversity of plants and animals in the United States.

The Interior Low Plateaus province slopes gently from southeast to northwest and is composed of dissected and highly eroded Ordovician limestone plateaus and domes. Notable for its high biodiversity is the Highland Rim that separates the Appalachian Plateaus province from the deeply eroded Nashville Basin in middle Tennessee. Much of the topography from northern Alabama to central Indiana is karst with extensive cave formations (e.g., Mammoth Cave, Crystal Cave). There are comparatively few small surface streams, as the landscape is dotted with sinkholes. The northwestern section contains extensive near-surface deposits of bituminous coal and has been heavily strip mined. Soils are primarily red and yellow podzols.

The northwestern part of the basin from Ohio to central Illinois lies in the Central Lowland physiographic province. The topography and surface geology were shaped and reshaped by Pleistocene glaciation, and the province was not completely ice free until 15,000 to 20,000 years ago. The landscape varies from gently rolling to extremely flat, with a mantle of glacial tills and till plains, deeply entrenched rivers, and occasional Pennsylvanian limestone outcroppings. Soils are rich neutral to basic loams, resulting in generally high-alkalinity surface waters. A few pothole lakes occur in the northern extent of the Wabash River basin, but the remainder of the province, and indeed the entire Ohio River basin, is lake free.

The climate is continental temperate with cool moist winters and warm humid summers. Monthly mean temperatures range from -7°C to 10°C in winter and 24°C to 28°C in summer. Average monthly precipitation is fairly uniform throughout the year, with significant accumulations of snow in the north and Appalachians. Annual precipitation ranges from 94 to 112 cm and is only slightly greater in higher elevations.

Basin Landscape and Land Use

The Ohio River basin covers two biomes (Temperate Grasslands and Temperate Deciduous Forest) and

eight terrestrial ecoregions (Ricketts et al. 1999). The eastern part of the basin contains the Appalachian/Blue Ridge Forests, which combine the mountainous Blue Ridge and Valley and Ridge physiographic provinces of Hunt (1967). Much of this ecoregion remains forested, with evergreen spruce–fir forests dominating higher elevations and deciduous oaks and hickories lower elevations. Running from southwest to northeast and paralleling the Appalachian/Blue Ridge Forests are the mountainous Allegheny Highlands Forests and the Appalachian Mixed Mesophytic Forests ecoregions that roughly correspond with the Appalachian Plateaus physiographic province (Hunt 1967). Beech–hemlock forests that included white pine and sugar maple originally dominated the more northern Allegheny Highland Forests. The rolling hills of the Appalachian Plateaus contain extremely rich and diverse broadleaf forests of oaks, hickories, maples, and poplars in the valleys and birch–maple–hemlock forests higher up, with relict bogs.

Most of the lower part of the basin is in the Southern Great Lakes Forests and Central United States Hardwoods Forests ecoregions. Hardwood forests of oaks, maples, and hickories mark both ecoregions, differing primarily in their species composition and understories. Three additional ecoregions just touch on the Ohio Basin. Prairies of the Central Forest Grassland Transitional Zone (Temperate Grasslands biome) occur in the northwest, Mississippi Lowland Forests swamps with bald cypress and black gum are present at the confluence with the Mississippi River, and the piney Southern Mixed Forests range into northern Alabama and southern Tennessee.

The largest single land classification in the basin is forestland, which accounts for up to 80% of land use in Pennsylvania and in river basins flowing northward from Kentucky. The proportion of agricultural lands increases from 12% to 14% in the east to 64% to 73% in western Ohio, Indiana, and eastern Illinois. Although the eastern part of the basin remains extensively forested, logging and fires in the late nineteenth century greatly reduced hardwood and pine stands and increased the distribution of aspen and other softwoods. All of the forest in once glaciated parts of Ohio, Indiana, and Illinois was removed and is now in agriculture with patches of second-growth forest. Much of the forest of central and western Kentucky and Tennessee suffered a similar fate, but the soils were less fertile and more highly erosive, and more of it has reverted to second-growth forest.

The Rivers

Past the confluence of the Allegheny and Monongahela rivers the largest tributaries to the Ohio River enter around Cincinnati (Little Miami, Great Miami, Kentucky, and Licking rivers from Rkm 740 to 870) and around Paducah (Green, Wabash, Cumberland, and Tennessee rivers from Rkm 1365 to 1503). Collectively the 12 major tributaries contribute 84% of the entire basin drainage. Most of the other 57 named tributary basins are rather small, with basins <1000 km².

Major differences in ecology, geochemistry, and present-day land use of rivers in the Ohio basin reflect two differing geologic histories. Rivers entering the Ohio from the north and much of the Ohio main stem itself are geologically young, having been greatly affected by Pleistocene glaciation. Rivers entering from the south and east, including the Tennessee, Cumberland, Green, Kentucky, Kanawha, Monongahela, and Allegheny, are geologically much older, allowing for development of a wide array of endemic species. Indeed, the Tennessee and Cumberland have the greatest richness of aquatic invertebrates and vertebrates of any rivers in North America. Based on the differences in geomorphology and species richness, including endemics, Abell et al. (2000) divided the Ohio basin into two distinct aquatic ecoregions, the Teays–Old Ohio and the Tennessee–Cumberland.

The Teays–Old Ohio rivers can be roughly divided into three types based on slope and physiography. The first group includes the Monongahela, Allegheny, Kanawha, Licking, and Kentucky rivers that drain the Appalachian Mountains. The river slopes are high, particularly in the headwaters, and the bottoms can be rocky. The greater relief of these areas has led to extensive impoundment for hydroelectric power generation, shipping, and flood control. Alkalinity, PO₄-P, and NO₃-N are naturally low. Even though these rivers are geologically old, with the New River the oldest in the United States, there are surprisingly few endemic fishes. These rivers also have had similar human impacts from coal mining.

The second group includes the Green River (along with the Salt River), which lies entirely within the Interior Low Plateaus physiographic province. These rivers have moderately high gradients in the headwaters. Stream bottoms are sandy with chert cobble, and surface waters are generally low in alkalinity, PO₄-P, and NO₃-N. These rivers have rich and diverse fishes and benthic invertebrate faunas, and the Green

River supports the highest number of endemic fishes in the ecoregion.

The Wabash, Great Miami, and Scioto rivers (along with several others) of Illinois, Indiana, and Ohio form a third group. All three begin in the glacial till plains of west-central Ohio and flow generally southward, becoming moderately to deeply entrenched in the gently sloping landscape. River bottoms are generally sandy with larger glacial till. These rivers have not been heavily dammed. Except below major cities, water-quality problems generally can be traced to land use. Alkalinity, pH, PO₄-P, and NO₃-N are naturally high compared with other rivers in the Ohio basin, and most are augmented with additional PO₄-P and NO₃-N from agricultural runoff. The rivers have high plant and animal diversity but no endemics because of the recent glaciation.

The Tennessee–Cumberland aquatic ecoregion consists of those two rivers. Both are high gradient in their Appalachian Mountain headwater tributaries and then parallel each other through a variety of lower gradient physiographic provinces and substrate types to their mouths on the Ohio River. Although not historically connected except via the Ohio River, both rivers have very high diversity and share many endemic species. Endemism of fishes and invertebrates is the highest of any aquatic ecoregion in North America. Much of the endemism occurs in the headwaters and also at the transitions between physiographic provinces. Both also share the dubious distinction of being among the most impounded of any of the major rivers in the United States. In these rivers, human impact has been much more complex, reflecting not only agricultural, industrial, and urban inputs but also acid mine drainage in the tributaries and lakelike conditions in the main-stem impoundments.

The Ohio River basin, in particular the Tennessee–Cumberland aquatic ecoregion, is considered to be globally outstanding by virtue of its high fish and invertebrate diversity (Abell et al. 2000). More species of fishes, freshwater mussels, and crayfishes occur here than in any other basin in the United States, and more are endangered than anywhere else. Although better agricultural practices have reduced runoff throughout the basin, soil erosion along with fertilizer and pesticide pollution continue to be major problems, as do impoundment, urbanization, industry, and coal mining.

OHIO RIVER MAIN STEM

The Ohio River main stem is a 9th order river that begins at the confluence of the Allegheny and

FIGURE 9.3 Ohio River at Paducah, Kentucky (PHOTO BY G. HARRIS).

Monongahela rivers in the Appalachian Mountains at Pittsburgh, Pennsylvania, and runs generally southwest for approximately 1575 km through the agricultural Midwest to the Mississippi River near Cairo, Illinois (Fig. 9.14). It is the only North American river with navigation miles numbered from the origin rather than from the mouth (Resh et al. 1976). Major tributaries include the Tennessee, Cumberland, Wabash, Green, Salt, Kentucky, Little Miami, Great Miami, Licking, Scioto, Muskingum, Kanawha, Allegheny, and Monongahela rivers. The present-day Ohio is a highly managed industrial river, with more tonnage and industrial use per kilometer

than any river of comparable length in the United States. The 20 low-water river locks and dams maintain a 3 m minimum pool depth throughout the river's length (Fig. 9.3).

Humans have lived along the river for at least the past 12,000 years. Paleo-Indian foraging cultures were present from 11,500 to 10,000 years ago, Archaic cultures followed from 10,000 to 3000 years ago, and then Woodland cultures (Adena, Hopewell) between 3000 and 1000 years ago. From 1000 years ago to the mid 1600s, extensive cities, trade, and warfare became common throughout the basin, and agriculture surpassed hunting and gathering (Lewis

1996). At the time the first French explorers visited (La Salle in 1669, Marquette and Joliet in 1674), the Ohio, Shawnee, Mosopelea, and Erie-Iroquois tribes occupied much of the main stem. The French and British vied for control of the basin and the fur trade throughout much of the seventeenth and eighteenth centuries until the Treaty of Paris (1763) ended France's claim to lands east of the Mississippi. George Rogers Clark's defeat of the British at Vincennes in 1779 transferred control of the basin to the United States. A number of battles and treaties in the interim had effectively ended most tribal rights to lands east of the Mississippi River, and the Indians moved westward (Hyde 1962, Williams 1993).

The history of the Ohio River was the history of the West in the late eighteenth and early nineteenth centuries. Europeans, led by Daniel Boone and Simon Kenton, came up the Wilderness Road through the Shenandoah Valley to settle Harrodsburg, Boonesboro, Louisville, and Limestone. The first settlers at the Falls of the Ohio (Louisville) were led by George Rogers Clark, who built blockhouses and a fort in 1778 with 20 families and 150 volunteers (Simon 1939). In the summer of 1788, 4500 people rode flatboats down the river past Marietta in the western expansion into what were once Indian lands. The first commercial packet boat passenger service between Pittsburgh and Cincinnati began in October 1793. The first steam ship, *Orleans*, came down the Ohio from Pittsburgh to Cincinnati and Louisville in 1811 and was stopped by the Falls of the Ohio. There were 35 steamboats on the river by 1818, and 400 by 1829 (WPA 1943).

Physiography, Climate, and Land Use

The main stem of the Ohio River flows through three physiographic provinces (see Fig. 9.14): the Appalachian Plateaus (AP), underlain by Pennsylvanian and Mississippian limestones, shale, and coal beds; the Central Lowland (CL), covered with glacial tills; and the Interior Low Plateaus (IL), underlain by Mississippian limestone sand and chert, just entering the sedimentary deposits and loess of the Coastal Plain (CP) at its juncture with the Mississippi River (Hunt 1967).

The main stem passes through four terrestrial ecoregions (Ricketts et al. 1999). It begins in the Appalachian Mixed Mesophytic Forests in the upper reaches, dominated by oaks, hickories, ashes, maples, pines, and elms. Central U.S. Hardwood Forests occur in much of the lower reaches and are primarily white oak, red oak, hickories, American elm,

tulip tree, and sweetgum. Through portions of Indiana and Ohio, the Ohio River forms the southern boundary of the Southern Great Lakes Forests, with sugar maple, American beech, basswood, oaks, elms, hickories, and ashes. At its confluence with the Mississippi River, the Ohio touches on the bald cypress-black gum swamps of the Mississippi Lowland Forests.

Precipitation for the basin is fairly evenly distributed throughout the year (Fig. 9.15) and ranges from 91.5 to 114 cm/yr (mean of 104). The basin is generally drier in the northern portions and wetter in the southern portions. The 40 to 59 days of thunderstorms per year add an element of violent weather during spring and summer. Average temperatures range from January daily lows of -6.7°C in the eastern mountains to daily highs in July of 27°C along the main stem. Snowfall ranges from 2.5 to 30 cm in the southwest to 30 to 91 cm the east, reaching >152 cm in the mountains. The average percentage of sunshine decreases from 60% to 70% in the southwest to $<50\%$ in the eastern part of the drainage (Williams 1994).

The majority of the basin's 26 million residents live in close proximity to the major rivers, including ten major cities ranging from 250,000 to 2,300,000 people. The average population density for the entire basin is approximately 49 people/ km^2 ; however, just considering counties that border the Ohio River itself the population density would be greater than 200 people/ km^2 . Basinwide, urban areas compose 4% of land use, 47% is agricultural, 47% is forested, and 1% is water. Importantly, 1% of the basin has been disturbed by mining, amounting to $>2\%$ of the land area of the Allegheny, Monongahela, Muskingum, and Big Sandy river basins.

River Geomorphology, Hydrology, and Chemistry

The upper Ohio River valley (the Teays River) was formed prior to the Illinoian glaciation about 2 million years ago and included the Kanawha-New rivers that flowed northward through the Scioto River valley (Fig. 9.2) to a now obliterated major westerly river northwest of Springfield, Illinois, which presumably ran to the Mississippi drainage. The Illinoian glacial advance blocked northern drainage at Hamilton, Ohio, creating 18,000 km^2 Lake Tight upriver of Cincinnati, which covered parts of southern Ohio, West Virginia, and Kentucky and reached an elevation of nearly 275 m asl. When

the water breached divides at Cincinnati (about 400,000 years ago), it flowed southwest, forming the present channel of the Ohio River. The valley deepened by almost 46 m at Wheelersburg, Ohio, to its present level (Pohana 1992). Although not directly altering the main stem, Wisconsin glaciers changed drainage patterns in the Wabash River and other south-flowing rivers (Hough 1958).

Much of the river bottom was sand prior to impoundment and continues to be so today. Glacial gravel and cobble form 40 named islands in the river above Cincinnati. Of these, 21 constitute the Ohio River Island National Wildlife Refuge. In the lower portion of the river, there are 57 sand bar islands. Very few islands occur in the middle third of the river, but limestone outcroppings at Louisville created the Falls of the Ohio.

In 1824 the U.S. Congress allotted \$75,000 for improving the Ohio River, and the U.S. Army Corps of Engineers built its first dam on the river at Henderson, Kentucky. By 1830 a set of three locks could raise small steamboats up 9 m (30 ft) over the Falls at Louisville. The first wicket lock and dam was opened in 1885 at Davis Island, and in 1929, canalization was completed, with 53 locks and a 2 m minimum pool. Modernization began in 1955 with replacement of 14 dams and reinforcement of five more, creating a 3 m deep channel at low water. Today there are 20 run-of-the-river locks and dams, with only the original wicket locks 52 and 53 remaining, which will be consolidated in a new dam by 2005 (Reid 1991).

At the convergence of the Monongahela and Allegheny rivers at Pittsburgh, elevation is 217 m asl and drops to 88 m at Rkm 1578 at Cairo, Illinois, an average slope of only 8 cm/km. The slope is higher near Pittsburgh, dropping rapidly from 50 cm/km to 10 cm/km in the first 250 km. Through the remaining distance, there is little change in slope.

Mean discharge at the Mississippi River (including the Tennessee and Cumberland rivers) is 8733 m³/s. Discharge is highest in March, during snowmelt, decreasing to lows in August and September (see Fig. 9.15). Higher evapotranspiration during summer months appears to account for much of the difference between runoff and precipitation (Patrick 1995). Floods have been a common occurrence on the Ohio River. Following the huge flood of 1937, 78 tributary flood-control dams were built, the last completed in 1990. The coordinated use of these reservoirs is alleged to take 3 m off flood crests and provide up to half the flow of the river during droughts (Reid 1991). The major flood-control reservoirs in the basin (excluding the Tennessee River) col-

lectively can hold about 26.4 km³ of water, more than six times the volume of the river (ORSANCO 1994).

Main-stem water quality has generally improved since the mid 1970s, particularly downstream from urban areas, but cities remain point sources for nutrients and industrial waste and account for much of the BOD load to the river. The main stem remains degraded by power plant thermal inputs, and industrial spills occur at least once a decade. Agriculture runoff dominates most tributary inputs, but orphaned mines still exude acid. Average pH is 7.2, increasing slightly in a downriver direction. Alkalinity averages about 70 mg/L as CaCO₃. Not considering reaches immediately below major cities, NO₃-N averages 1.6 mg/L and PO₄-P averages <0.2 mg/L. Both nutrients tend to increase in a downstream direction. Mean annual water temperature is 14°C, but the temperature at summer low flows can reach 35°C, aided by power plant thermal discharges.

River Biodiversity and Ecology

With the exception of the Tennessee and Cumberland rivers, the Ohio River and its tributaries compose the Teays–Old Ohio freshwater ecoregion (Abell et al. 2000). The diversity of aquatic plants and animals in this ecoregion is globally high, but the number of endemic species is comparatively low.

Algae and Cyanobacteria

Even though high turbidity and a strong current keep the Ohio River light limited throughout most of its length, there are significant numbers of phytoplankton, particularly during summer low flow. Wehr and Thorp (1997) identified 134 taxa of cyanobacteria, chlorophytes, euglenophytes, chrysophytes, pyrophytes-cryptophytes, and diatoms in a survey conducted in 1992 along a 361 km stretch from Cincinnati to Evansville, Indiana. Dominant summer cyanobacteria were *Aphanothece saxicola*, *Merismopedia punctata*, *Microcystis aeruginosa*, and *Synechococcus*. Of their 82 diatom species, the primary spring taxon was *Cyclotella*, followed by *Melosira jurgensii* and *Melosira distans* in summer. *M. aeruginosa* apparently became numerically dominant in 1997 and 1998 when zebra mussels reached peak abundance, but densities were reduced in 2000 when zebra mussels declined (M. Kannan, unpublished data).

Plants

Increased turbidity from agricultural runoff, along with impoundment, has all but eliminated submersed

aquatic macrophytes. There is still extensive floodplain and riparian forest along most of the river, except in urban areas. Trees are typical in much of the basin and include red maple, cottonwood, black willow, black gum, and American sycamore. Bald cypress occurs as far upstream as southwestern Indiana (Deam 1953). Buttonbush is common along the banks in many places. Nonnatives include purple loosestrife, brittle naiad, curly pondweed, and Eurasian watermilfoil.

Invertebrates

As with phytoplankton, the Ohio River supports a diverse zooplankton assemblage, with highest densities from May through November (Thorp et al. 1994). Rotifers dominate in all months, with *Polyarthra* most abundant, followed by copepod nauplii, the cladoceran *Bosmina longirostris*, calanoid copepods, and the rotifers *Branchionus calyciflorus* and *Keratella* spp. Density is directly related to temperature and inversely related to velocity and turbidity (Thorp et al. 1994). With the potential exception of copepod nauplii, zooplankton does not appear to affect algal densities (Wehr and Thorp 1997). The nonnative *Daphnia lumholtzi* is present, but its relation to other cladoceran species remains unknown. The effects of fishes upon the zooplankton community have been documented by Jack and Thorp (2002).

Benthic invertebrate surveys of the main stem have been made by the U.S. Environmental Protection Agency (USEPA), the Ohio River Valley Water Sanitation Commission (ORSANCO), and power plants since the early 1960s, primarily using grabs, rock baskets, or Hester-Dendy plate samplers. In the 1960s, numbers of taxa collected increased in a downstream direction, ranging from 13 to 22 at Pittsburgh to 45 to 58 near Evansville (ORSANCO 1978). Upriver sites contained primarily worms and chironomids, often dominated by pollution-tolerant *Nanocladius distinctus* and *Cricotopus intersectus*. Numbers of individuals and diversity appear to have dramatically increased since the enactment of the National Environmental Policy Act (NEPA) in 1969. Recent ORSANCO unpublished data lists 222 invertebrate taxa for the Ohio main stem, exclusive of mussels, snails, and zooplankton. Nearly 90 of the taxa are dipterans, primarily Chironomidae (*Chironomus*, *Coelotanypus*, *Dicrotendipes*, *Stenochironomus*, *Pentatanytus*); however, there are a variety of mayflies (*Hexagenia*, *Stenonema*, *Ephemerella*, *Caenis*, *Stenacron*), stoneflies (*Perlesta*, *Isoperla*), caddisflies (*Hydroptila*, *Cheumatopsyche*, *Hydropsyche*, *Symphitopsyche*, *Ceraclea*, *Cyrnellus*, *Polycen-*

tropus, *Potamyia*, *Chimarra*), dragonflies/damselflies (*Stylurus*, *Argia*), and worms (*Limnodrilus*, *Branchiura*, *Nais*). Other common taxa include amphipods (*Gammarus*) and fingernail clams (*Pisidium*, *Sphaerium*). Although some of the increase may be due to cleaner water conditions, the greater number of taxa also may reflect more intensive sampling efforts and greater taxonomic resolution.

The Ohio River main stem is now habitat for approximately 50 species of unionid mussels, down from perhaps 80 species in pre-European times. Taylor (1989) documented 33 species from the upper Ohio River. More exhaustive recent surveys have added 9 more species, and 15 of those present from 1880 to 1920 have disappeared. Two species are extirpated from the Ohio River (leafshell and round combshell) and eight are federally listed as threatened and endangered. Common species include threehorn wartyback, Wabash pigtoe, maple leaf, white heel-splitter, three ridge, and fat mucket. The nonnative Asiatic clam and zebra mussel are common in the river today. The Asiatic clam arrived in the Ohio River by 1957 and quickly expanded into most of its tributary rivers, but it does not appear to compete with native unionids for optimum habitat.

The zebra mussel arrived in 1993, carried by barges coming down the Illinois River from the Great Lakes, and continues to move upriver as a crest of reproductive colonization. Highest densities in 2001 were near Pittsburgh (J. Hageman, unpublished data). Based on ORSANCO Hester-Dendy plate sampler studies, the periods for massive reproduction in the middle section of the river were the summers of 1997 and 1998. One-third of their samplers in 1997 had >10,000 colonists (Rkm 768 to 1460). A drought during late summer 1998 and all year in 1999 aided by once-through cooling plants created very high temperatures that may have been the proximal cause of the decline of zebra mussels in that section in subsequent years. The densities in the Ohio River have been shown to be capable of altering the phytoplankton community and rotifer densities (Jack and Thorp 2000). Predators such as common carp, channel catfish, redhorse, and smallmouth buffalo may be adapting to consume zebra mussels (Thorp et al. 1998). Zebra mussels have been responsible for the death of more than 80% of native mussel populations at some of the downriver sites in the late 1990s (J. Sickel, personal communication).

Vertebrates

Historically, the Ohio River main stem has contained 160 to 170 fish species in 25 families (Lachner

1956, Trautman 1981, Pearson and Krumholz 1984, Reash and van Hassel 1988). Constantine Samuel Rafinesque originally described many of the species in the early 1800s, including 10 that were drawn by James J. Audubon as a practical joke on Rafinesque. The joke species remained in the literature for decades (Everman 1918). Today 28 species (18%) are rare, another 21 species (13%) are of “special concern” as lost from one state or in recent decline, and only 27 species are common to the length of the Ohio River. Although species composition changes, the number of species is relatively evenly distributed from one end to the other: 122 species between Rkm 0 to 526, 132 between Rkm 527 to 1052, and 119 between Rkm 1053 to 1578. Nineteen fish species reported before 1970 have not been reported since, including lake sturgeon, Alabama shad, and the sand darter.

Fourteen species have been introduced through human activity. Rainbow trout, brown trout, and brook trout are or have been stocked. Common carp were introduced from the 1870s through the mid 1880s, when they were one of the largest fisheries in the river. Goldfish have done well, and goldfish/common carp hybrids are common. The banded killifish and mummichog were introduced as bait or forage fishes. White catfish, white bass, yellow perch, and several centrarchids are being stocked in tributary streams and even in the river. Striped bass are being released into the river as a game fish. At least five species have been added through river connections since 1984, including smelt, fathead chub, and rosefin shiner (Pearson and Pearson 1989).

Power companies and ORSANCO have documented historic trends in fish populations since 1957 (Lachner 1956, Mason et al. 1971, USEPA 1978, Pearson and Pearson 1989, EA Environmental 2001). In general, fish abundance and richness have increased since 1969. Most notable is the increase in many species in the middle and upper thirds of the river. White bass, most of the catostomids, river darter, logperch, sauger, and freshwater drum have clearly responded. Gizzard shad has once again replaced the emerald shiner as the numerically dominant species. Pollution-tolerant species have declined in the upper third of the river, namely bullheads, white sucker, and common carp. In the past 20 years, several large-river species have moved upstream: paddlefish, spotted gar, mooneye, and highfin carpsucker. Other common species throughout the main stem include skipjack herring, smallmouth buffalo, flathead catfish, sauger, largemouth bass, bluegill, silver chub, golden redhorse, and smallmouth bass.

Turtles and water snakes are plentiful along the river. Common species include the snapping turtle, stinkpot, mud turtle, common map turtle, midland painted turtle, spiny softshell, slider, Florida cooter, common water snake, and queen snake. The cottonmouth is not common but is present in the lower portion of the river. Common frogs include pickerel frog, green frog, southern leopard frog, and bullfrog (Barbour 1971). Both the bald eagle and osprey are now nesting in protected areas. A wide variety of waterfowl can be seen along the river during spring and fall migrations, and 36 species are known to nest along the river. Beaver, muskrat, and river otter are common in the basin and occasionally seen along the main stem.

Ecosystem Processes

Ecosystem processes in the Ohio River main stem have been examined in much greater detail than in any of the large tributary rivers. Primary physical controls are current velocity, light penetration, and temperature. Run-of-the-river navigation dams appear to be less important to processes than the flood storage/hydroelectric impoundments of tributaries, such as in the Tennessee and Cumberland. Summer densities of algae are high (>100,000 cells/mL) and positively correlate with temperature and negatively correlate with turbidity and velocity (Wehr and Thorp 1997). Wehr and Thorp (1997) noted that decreased velocities near dam sites did contain greater algal biomass and larger cell sizes. Algae only moderately deplete N and P, which may be amended or diluted by tributary inputs (Bukaveckas et al. 2000). Bukaveckas et al. (2000) found a summer downstream depletion of Si, which could limit phytoplankton growth. Zooplankton average >21/L from May through November, and copepod nauplii densities have been correlated with a loss of picoplankton in the pools (Wehr and Thorp 1997).

Koch (2001) estimated summer primary production at 115 and 114 g C m⁻² yr⁻¹ at the mid and lower river sections, respectively, and respiration at 780 and 562 g C m⁻² yr⁻¹, with P/R ratios ranging from 0.15 to 0.20. Bacterial production was only 4% and 3% of the primary production. Thorp and DeLong (2002) point out that although allochthonous inputs (riparian and downstream transport) are important initial sources of organic matter and large rivers are heterotrophic on an annual basis, there is strong evidence that overall metazoan production in most large rivers ≥4th order is driven by autochthonous production that enters through algal-grazer and decomposer

pathways. Their riverine productivity model (RPM) may be very important to understanding ecosystem processes throughout the basin, particularly in low-gradient tributaries.

Human Impacts and Special Features

Prior to European contact the river was clear and constantly flowing and contained lush growths of aquatic plant life and clean beds of gravel, rock, and sand (described by the Lewis and Clark expedition of 1803, Reid 1981). Despite impoundment and heavy industrial, urban, and agricultural use, the river remains remarkably biodiverse.

Today the entire river is impounded and a 3 m deep navigation channel is maintained. There are several large urban areas and numerous industrial facilities. To maintain the navigational channel, the U.S. Army Corps of Engineers dredges an average 500,000 m³ of silt, sand, and gravel each year (1991 to 2000). Barge transportation amounts to 263 metric tons worth \$45 billion, dominated by coal and aggregates. There are 67 power plants on the Ohio River and in adjacent counties. Once-through cooling for electrical power generation in summer can push thermal plumes from one power plant to the next. There are 28 major petroleum facilities, 12 grain elevators and terminals, and 29 chemical plants and terminals on the Ohio's main stem or tributary mouths.

Main-stem water quality has generally improved since the mid 1970s, particularly downstream from urban areas, but city wastewater treatment plants and combined sewer overflows remain point sources for nutrients, intestinal microbes, and pathogens. Pollution from steel mills in and around Pittsburgh and coke plants in Huntington has been reduced, but sediment contamination from industrial releases continues to be of concern, prompting fish consumption advisories. Industrial spills still occur at least once a decade. Agriculture erosion and runoff of nutrients and pesticides continue to dominate tributary inputs.

Nonnative plant invasions have not been much of a problem to date, but zebra mussels have had major effects on native species and ecosystem processes. The effects of nonnative fish species are more difficult to determine, as native fishes are still responding to water-quality mitigation.

TENNESSEE RIVER

Measured by average discharge (2000 m³/s), the 8th order Tennessee River is the largest tributary to the

Ohio River (Fig. 9.16). The Tennessee basin covers approximately 105,000 km² of the states of Tennessee, Kentucky, Virginia, North Carolina, Georgia, Alabama, and Mississippi. Headwaters drain portions of the southern Appalachian Mountains, flowing generally westward across four physiographic provinces. The Tennessee River itself begins at the confluence of the French Broad and Holston rivers just east of the city of Knoxville, Tennessee. From Knoxville the river runs southwest into northern Alabama before turning north through Tennessee and Kentucky and emptying into the Ohio River at Rkm 1504 just above the city of Paducah, Kentucky, a distance of about 1050 km (Fig. 9.4). Major tributaries include the French Broad, Holston, Little Tennessee, Clinch, Hiwassee, Paint Rock, Duck, and Big Sandy rivers. Additional outflow from the Tennessee occurs in the Tennessee–Tombigbee waterway, completed in 1984. The “Tenn–Tom” now directly links the Tennessee River with the Black Warrior/Tombigbee River system in Alabama. When Lake Barkley was impounded in 1966 on the Cumberland River just to the east, a shipping canal was dug between that reservoir and Kentucky Lake on the Tennessee River and water now may flow freely in either direction between the two rivers.

The history of human influence dates back at least 12,000 years to the entrance of Paleo-Indian groups that followed the warming climate. By at least 5000 years ago there was limited agriculture along the river valleys. The Woodland period from about 3100 to 1200 years ago saw the development of extensive agriculture, pottery, and trade routes. By the Mississippian period (1200 to 500 years ago) cities with temples were developed, new varieties of corn and beans were being used, and there was well-organized warfare among neighboring tribes. In 1540, Hernando de Soto was the first European explorer to see the river. Choctaw, Cherokee, Shawnee, and Chickasaw were the primary inhabitants of the Tennessee Valley in the late 1600s. European traders followed, bringing guns and disease, and the Cherokee, who became quite dependent on European goods, eventually replaced the other existing cultures. The name “Tennessee” is thought to be from the Cherokee. Its true meaning is unknown but may refer to “the place where the river bends.” There were no permanent European settlements until 1769, when William Bean built a cabin on the Watauga River. Jonesborough, Tennessee, was the first chartered town in the basin (1779). By the end of the eighteenth century several more towns had been established along the Tennessee River, including Knoxville and

FIGURE 9.4 Tennessee River near Reidland, Kentucky (PHOTO BY G. HARRIS).

Chattanooga. Colonization of the basin was rapid during the first half of the nineteenth century, and by the end of the nineteenth century much of the farmland was in poor condition and there was little in the way of manufacturing.

Physiography, Climate, and Land Use

The headwaters of the Tennessee basin begin primarily in the incised Blue Ridge (BL) and Valley and Ridge (VR) physiographic provinces of western Virginia, North Carolina, and eastern Tennessee (Hunt 1967) (see Fig. 9.16). The Blue Ridge geology is primarily Precambrian gneiss, granite, sandstone, conglomerates, and siltstone, whereas the Valley and Ridge is composed more of Paleozoic limestones, sandstones, and shale. The Tennessee River proper begins near Knoxville, Tennessee, and flows southward to Chattanooga, crossing into the Cumberland Plateau section of the Appalachian Plateaus (AP) province, which is underlain by Pennsylvanian and Mississippian limestones, shale, and coal beds. The river then continues southward through the

Sequatchie Valley into northern Alabama, where it turns westward across the Highland Rim of the Interior Low Plateaus (IL) province. The river then runs northward through the Western Valley, which separates the Highland Rim of the Interior Low Plateaus from the Coastal Plain (CP) physiographic province. The Interior Low Plateaus is underlain by Mississippian limestone, sand, and chert, and the Coastal Plain geology is primarily alluvium, sedimentary deposits, and loess (Hunt 1967).

The Tennessee River basin lies in four terrestrial ecoregions (Ricketts et al. 1999). Much of the headwaters are in the Appalachian/Blue Ridge Forests. Higher elevations are dominated by red spruce, balsam fir, and Frazer fir, and lower elevations are principally deciduous, including red oak, black oak, hickories, birches, and black locust. The main stem begins in Appalachian Mixed Mesophytic Forests, with American beech, sugar maple, eastern hemlock, mountain laurel, mountain maple, and rhododendrons at higher elevations and oaks, hickories, ashes, maples, pines, elms, sweetgum, black locust, and black cherry at lower elevations. Most of the lower

part of the basin flows through Central United States Hardwood Forests, primarily white oak, post oak, southern red oak, hickories, American elm, tulip tree, and sweetgum, with understories of winged elm, flowering dogwood, and sassafras. A very short section of the river, primarily in northeastern Mississippi, enters the Southeastern Mixed Forests terrestrial ecoregion, which is primarily oak–hickory but also contains stands of shortleaf, loblolly, and longleaf pines.

The climate is continental temperate. Monthly mean temperatures range from about 2°C in January to about 23°C in July (Fig. 9.17). Temperatures are generally cooler in the Appalachian headwaters and warmer throughout the Interior Plateau. Winter temperatures are regularly below 0°C, particularly at night, and often exceed 38°C in July, August, and September. Annual precipitation ranges from about 80 to 130 cm (average 105 cm) and is fairly uniform throughout the year but lowest in October (see Fig. 9.17).

Human population density for the basin averages 19 people/km² and is concentrated primarily in two large cities, Knoxville at 600,000 and Chattanooga at 430,000. The Knoxville and Pigeon Forge areas have had rapid development over the past decade and are the fastest-growing areas of the basin. The upper basin contains more than 64% forest, and agriculture accounts for 27% of land use (primarily pasture). Approximately 6% is urban and the remainder is either barren, water, or in mining. There are extensive coal reserves in the Appalachian Plateau, and mining has had strong effects on water quality and biota. Approximately 55% of the lower part of the basin is forested. Row crops and pasture cover 41%, wetlands and water 3%, and urban 1% (TVA, unpublished data). Much of the lower basin has been in agriculture for the past 150 years. By 1900 agricultural land was in poor condition, but better farming practices put in place after the Great Depression have decreased erosion and increased crop yields. The primary crops are corn, soybeans, cotton, and winter wheat. Tobacco remains a cash crop throughout the basin. In the western part of the basin, pine plantations are becoming a more important crop.

River Geomorphology, Hydrology, and Chemistry

Geological evidence suggests that the upper two-thirds of the Tennessee River once drained directly

into the Gulf of Mexico during the Tertiary. At some time the Tennessee merged with the ancestral Duck River, resulting in a northward flow to where it now empties into the Ohio River (Starnes and Etnier 1986). The elevation at the confluence of the French Broad and Holston is approximately 269 m asl and falls to 90 m asl at the confluence with the Ohio River. This average gradient of 17 cm/km does not mean much, however, as most of the river is now impounded, creating a stair-step gradient (Table 9.1). The present history of the Tennessee basin is directly related to the vast river modifications created by the Tennessee Valley Authority (TVA). Congress created TVA on May 18, 1933, as part of the New Deal to provide relatively inexpensive electricity to a region of the country that was agriculturally and industrially poor and had been hard hit by the Great Depression. Initially, TVA purchased a number of existing hydroelectric dams from the Tennessee Electric Power Co. The first TVA-constructed hydroelectric dam was Norris on the Clinch River in northeastern Tennessee, filled in 1937. TVA now operates 48 multipurpose dams in the basin (TVA 1980). Additional dams and reservoirs are operated by private companies and by the Army Corps of Engineers, including the lock and dam system for the Tenn–Tom Waterway located in northeast Mississippi and west-central Alabama. The Tennessee River main stem consists of nine reservoirs managed for hydroelectric power generation, flood control, and navigation, and very little would be considered free flowing except between its origin and the upper reaches of Ft. Loudoun Reservoir (see Table 9.1).

Hydrologically and limnologically, the reservoirs can be divided into three functional zones, each with its own chemical and biological characteristics: riverine, transitional, and lacustrine (Thornton et al. 1990). The locations and sizes of the three functional zones may shift depending on dam operations and rainfall patterns. Riverine zones tend to resemble the original river geomorphology and generally are within the original riverbanks. Flows, however, are quite variable and depend on release cycles from upstream dams. In the Tennessee River, riverine zones tend to have relatively high velocity (>1 m/s is common), river bottoms contain much sand and cherty gravel, and the water is usually turbid. In transitional zones, water velocity slows and larger organic and inorganic particulates drop out. Bottom substrates are often mixed sands, cherty gravel, and pockets of organic deposition. The lacustrine zones are most lakelike but retain strong longitudinal flow patterns. Lacustrine zones in the Tennessee main-

TABLE 9.1 Physical features of the Tennessee River TVA main-stem reservoirs.

Reservoir	Landscape position rank	Tailwater elevation m asl	Mean discharge m ³ /s	Mean retention in days	Drainage basin km ²
Ft. Loudoun	1	224	396.4	10	24,734
Watts Bar	2	206	792.8	14	44,833
Chickamauga	3	193	991.1	5.6	53,846

Kentucky	9	91	1,912.0	16.7	104,117

Data from TVA 1980.

stem reservoirs occupy the entire floodplain, thus the average water depth (6 to 8 m) is quite shallow compared with many of the upstream tributary reservoirs (e.g., Norris Lake). Lacustrine zone bottom substrates are usually fine, clayey deposits of low organic content (generally <1% carbon in the main channel). All of the main-stem reservoirs have seasonally regulated pools designed to accommodate spring runoff. In Kentucky Lake, the furthest downstream in the system, winter pool (late August to March) is approximately 2 m lower than summer pool (April to early August). Tributary reservoirs such as Norris can have as much as a 20 m difference in water level between winter and summer pools (TVA 1980).

Mean discharge is 2000 m³/s. Although the system is highly regulated, long-term monthly runoff patterns are related to evapotranspiration (see Fig. 9.17). Discharge is highest in the winter months and lowest in September. Superimposed on Tennessee River discharge patterns is flood storage and release that can occur anytime during the year. Effects of a flood anywhere in the Mississippi River system can be lessened by holding back the Tennessee River until the flood crest has passed or by emptying the Tennessee reservoirs prior to a flood crest. To this end, discharge from Kentucky Lake has approached 10,000 m³/s on several occasions. Further, the discharges of the Tennessee and Cumberland rivers are often commingled through the canal linking Kentucky Lake and Lake Barkley.

Water chemistry is dependent on seasonal patterns and characteristics of water retention, dam manipulation, and landscape position (Soranno et al. 1999). NO₃-N averages 0.2 mg/L, PO₄-P averages <0.01 mg/L, pH averages 7.2, and alkalinity averages 40 mg/L as CaCO₃. With the exception of NO₃-N values, which decrease, most chemical concentrations increase in a downriver direction, including alkalinity,

Ca, SO₄, Si, and total P. Secchi depth transparency also tends to decrease as more and more fine particles are entrained in the flow. As turbidity and velocity decrease in the transitional zones, productivity may be quite high if NO₃-N and PO₄-P are present in sufficient quantities; therefore, pH can range from 7.2 to 9.5 within hours on a warm, sunny day in May. Because of the water velocity, main-stem reservoirs rarely thermally stratify, but oxygen deficits may occur in summer when discharges are low. Increased water retention coupled with constant mixing often results in the entire water mass of the Tennessee River reaching 30°C or warmer in August. With their much longer retention times, tributary impoundments such as Norris Reservoir do thermally stratify, and cool hypolimnetic releases are capable of supporting salmonid fishes.

River Biodiversity and Ecology

The Tennessee River and its sister river, the Cumberland, form the Tennessee–Cumberland freshwater ecoregion (Abell et al. 2000). The diversity of this ecoregion may be the highest of all temperate ecoregions (Starnes and Etnier 1986, Abell et al. 2000), with the greatest number of endemic species of any ecoregion in the United States. This is one of the few areas of the United States where new species of both invertebrates and fishes are still being described in tributary rivers. Although not historically connected except by the Ohio River, the two rivers share many of the same endemic species, with the Tennessee slightly more diverse.

Algae and Cyanobacteria

Because of extensive impoundment, the greatest source of autochthonous production is now phyto-

plankton (Yurista et al. 2001). A spring diatom peak (primarily *Melosira*) occurs in the main-stem reservoirs from late March to early April, with chlorophyll values often reaching 40 µg/L. The dominant midsummer phytoplankton are green algae (*Scenedesmus*, *Pediastrum*), diatoms (*Asterionella*, *Fragilaria*, *Melosira*, *Synedra*, *Cymbella*), and various cyanobacteria (*Anabaena*, *Oscillatoria*) (Tabor 2000).

Plants

Much of the floodplain riparian vegetation has been lost or significantly altered because of impoundment and seasonally fluctuating water levels. Except in the embayments, typical upland hardwood forests grow right to the river or reservoir edges (Luken and Spaeth 2002). There is little documentation of macrophyte beds prior to impoundment, but water willow beds most likely would have been prominent in shallow river runs. Water willow appears to be resistant to reservoir level fluctuations and is one of the few native aquatic plants established in backwaters and embayments. Nonnative macrophytes have done well in embayments (parrot-feather, alligatorweed, brittle naiad, curly pondweed, Nepal grass). Eurasian watermilfoil remains common in embayments despite extensive TVA control measures in the 1980s (Kobraei and White 1996). Other common embayment taxa include red maple, buttonbush, black gum, black willow, and sweetgum. Bald cypress has been extensively planted.

Invertebrates

Phytoplankton–zooplankton interactions are an important ecological feature of the system. The spring diatom peak is quickly grazed by *Bosmina longirostris* and then by *Daphnia retrocurva*. *Leptodora kindti* is the major invertebrate predator on *Bosmina* and *D. retrocurva*, and all three cladocerans, along with a number of copepods, are a primary source of food for larval fishes (Schram and Marzolf 1993, Yurista et al. 2001). Until the 1990s, *Diaphanosoma birgei* was the primary midsummer grazing zooplankton and a major food source for larval fishes. Since then, the nonnative *Daphnia lumholtzi*, which feeds heavily on desmids, has pushed *D. birgei* populations later into the summer.

There have been no comprehensive surveys of the benthic invertebrates of the Tennessee River since its impoundment, and, with the exception of the unionids, there is not much information available on preimpoundment conditions. Most data are in reports to either the TVA or state agencies. Penning-

ton and Associates (1994) found that longitudinal benthic trends within the impoundments were consistent with riverine, transitional, and lacustrine zone reservoir bottom conditions. Riverine zones tend to be dominated by filter-feeding bivalves (Unionidae, Corbiculidae, and Sphaeriidae). Among the predominant insects are the mayflies *Stenonema* and *Tricorythodes* and the caddisfly *Cheumatopsyche*. Transitional zones have the greatest diversity and density of benthic invertebrates and are dominated by subsurface deposit-feeding worms (*Limnodrilus* spp.), with the mayflies *Stenonema*, *Tricorythodes*, and *Caenis*, the caddisfly *Hydroptila*, and more than 200 species of Chironomidae the primary insects.

Lacustrine zone sediments are often poor in organic matter, and deposit-feeding tubificid worms average <100/m² in Kentucky Lake. Benthic invertebrates are primarily sediment deposit gatherers and surface filterers. The mayfly *Hexagenia limbata* is common, as are surface-deposit-gathering Chironomidae. Including littoral areas, more than 100 Chironomidae species (e.g., *Chironomus*, *Parachironomus*, *Polypedilum*, *Tanytarsus*, *Cricotopus*) have been identified from Kentucky Lake. The most spectacular is *Chironomus major*, which has larvae up to 50 mm long in the 4th instar. The majority of lacustrine zone surface filterers are unionids (24 species), fingernail clams, and the Asiatic clam. The predaceous larva of the dipteran *Chaoborus punctipennis* is abundant throughout the lacustrine zones, and the opossum shrimp is becoming abundant (Brooks et al. 1998). Sixty-five species of crayfishes (*Cambarus*, *Procambarus*, *Orconectes*) are present in the basin, but most occur only in the smaller tributaries. Forty species are endemic and have very limited distributions (Hobbs 1988).

The Tennessee River drainage has the highest diversity of freshwater mussels (Unionidae and Margaritiferidae) of any river in North America. Approximately 100 species have been recorded, of which 5 are now extinct, 22 are listed as endangered, and an additional 14 are being considered for endangered status under the Endangered Species Act (Parmalee and Bogan 1998). More than 40 species are found in the fast-flowing headwater streams of the Holston, Powell, and Clinch rivers of Virginia and North Carolina. Impoundment has greatly reduced the density and diversity of the main-stem mussel populations through habitat loss, pollution, and possibly through loss of host fish species for the parasitic glochidia stage. A number of species, however, have done very well in the reservoirs (e.g., threeridge, mapleleaf, washboard), with annual com-

mercial mussel harvests in Kentucky Lake exceeding \$1 million/yr in the mid-1990s. Asiatic clam densities have decreased slowly over the past 20 years, which may be due to an increase in predators such as carps, catfishes, and freshwater drum. The zebra mussel has localized colonies throughout the main stem as far upstream as Ft. Loudoun, and populations may be on the increase. Zebra mussel populations in the Tennessee River are not as great as in the Ohio River, making the Tennessee a potential refuge for freshwater mussels.

Vertebrates

Depending on the level of taxonomic resolution, between 225 and 240 species of fishes occur in the Tennessee River drainage (Etnier and Starnes 1993), including at least 20 nonnative forms. Percidae (primarily darters) and Cyprinidae (minnows) are the two most diverse families, followed by Ictaluridae (catfishes), Catostomidae (suckers), and Centrarchidae (sunfishes). Much of the diversity occurs in the Highland Rim interface of the Interior Low Plateaus and Valley and Ridge physiographic provinces, which is home to a large number of endemic darters. Including several species that occur in the Cumberland River, 67 species are endemic to the ecoregion, including 5 catostomids, 16 cyprinids, and 41 darters. The number of darters probably will increase as new species are described from the headwaters. Three species are listed as federally endangered: the boulder darter, the smoky madtom, and the pygmy madtom.

The fishes of the Tennessee River proper have been greatly altered by impoundment, pollution, and introductions through stocking. The principle forage fishes are now gizzard shad and threadfin shad, which are dependent on the abundant plankton in the system. Major piscivores include channel catfish, small cyprinids, largemouth bass, smallmouth bass, white bass, and striped bass. The freshwater drum feeds heavily on mollusks, particularly the Asiatic clam. Major species feeding on benthic invertebrates include the common carp, paddlefish, and 18 species of Catostomidae. Commercial species include channel catfish and paddlefish, which is sought for its caviar. Seven different nonnative salmonids have been introduced into the reservoirs and cooler tail waters of tributary dams. Rainbow trout, Ohrid trout, and brown trout have proven successful, whereas introductions of cisco, cutthroat trout, and coho and sockeye salmon have not (Etnier and Starnes 1993). Other nonnative species include

bighead carp, common carp, goldfish, grass carp, tench, golden shiner, rainbow smelt, yellow perch, and striped bass.

Reservoir backwaters and embayments provide excellent habitat for turtles, and more than a dozen species have been recorded. The common snapping turtle, stinkpot, mud turtle, common map turtle, midland painted turtle, and spiny and smooth soft-shell turtles are present almost everywhere in the basin. The alligator snapping turtle, Ouachita false map turtle, slider, and Florida cooter are present in the main-stem reservoirs. The red-eared slider occurs in the lower half of the drainage and is replaced by the Cumberland slider in the upper half. Four water snakes occur in the lower reservoirs, but only the common water snake and the queen snake are abundant throughout the drainage. The cottonmouth is present but not common in Kentucky Lake. A dozen species of frogs, including green frog, pickerel frog, and bullfrog, occur in the Tennessee basin and are common in the reservoirs (Barbour 1971).

Once rare, bald eagles and ospreys have become common sights, and both have breeding populations along the lower Tennessee. Great blue herons, gulls, terns, Canada geese, and a variety of ducks are common throughout the year. The Tennessee National Wildlife Refuge units have increased the winter abundance of waterfowl throughout the lower part of the basin. Beaver are once again common throughout the basin and considered a nuisance. River otters and muskrats also are abundant.

Ecosystem Processes

With the exception of headwater tributaries, processes occurring in the extensive series of impoundments dominate the ecosystem. Shallow shoals, large snags, and accumulations of woody debris have all but disappeared; thus, benthic processes appear to be much less important than they were prior to impoundment. Although the reservoirs are net heterotrophic and the principal organic matter supply may still be allochthonous, autochthonous primary production probably fuels most water-column processes (Thornton et al. 1990, Kimmel et al. 1990, also see Thorp and DeLong 2002). The chemistry of riverine zones is dependent on what is released from the upstream river; however, productivity is usually low because of the high turbidities. As turbidity and velocity decrease in the transitional zones, productivity may be quite high if $\text{NO}_3\text{-N}$ and $\text{PO}_4\text{-P}$ are present in sufficient quantities. Lacustrine zone $\text{NO}_3\text{-N}$, $\text{PO}_4\text{-P}$, and Si reach maximum water-column concentrations in March, producing chloro-

phyll peaks in early April (D. White, unpublished data), and productivity rates of $1400 \text{ mg C m}^{-2} \text{ day}^{-1}$ are common (Taylor 1971). By early June $\text{NO}_3\text{-N}$ and $\text{PO}_4\text{-P}$ concentrations often are too low to measure. Very little primary or secondary production accumulates in bottom sediments, as they typically contain <1% organic carbon. Much of the fixed carbon probably is flushed through the dams or metabolized in the water column (Yurista et al. 2001); thus, water retention time is likely the controlling factor for productivity (Kimmel et al. 1990).

Because reservoirs create ecosystem conditions that did not exist previously in the basin, conceptually these are “new” ecosystems. Reservoir ecosystems do not reach the longitudinal and temporal equilibriums of the parent river (Thornton et al. 1990), producing conditions ripe for invasion of true nonnative plants and animals that are highly adaptable. Although most species occurred in the system prior to impoundment, the dominant species now are those adapted to the new set of environmental conditions. Understanding ecosystem processes in the Tennessee River requires a much better knowledge of the sources and fates of carbon and nutrients, as well as a knowledge of the aging processes that occur as the reservoirs fill in.

Human Impacts and Special Features

The species diversity and richness of the Tennessee River prior to European settlement was equal to any basin in North America. Despite extensive impoundment and a myriad of other human influences, a number of smaller rivers and sections of rivers have retained high biodiversity (Abell et al. 2000). The Clinch, Holston, North Fork, and Powell rivers have high diversities of fishes, freshwater mussels, invertebrates, and amphibians, although there are continued threats from strip mining and forest practices. Similar high diversities occur in portions of the Hiwassee and Little Tennessee rivers that drain parts of Georgia and North Carolina. The Duck and Buffalo rivers of central Tennessee are cool, clear streams in the Highland Rim that have retained a diverse aquatic insect fauna and macrophyte flora, including extensive beds of hornleaf riverweed. The small Obed River basin contains 73 km of river that are part of the National Wild and Scenic River system. The Tennessee River from the Kentucky Lake Dam to the Ohio River is an important site for a number of large-river freshwater mussel species because it is free flowing and has not yet been heavily colonized by the zebra mussel. Enlargement of the lock and construction of

new bridges is expected to lead to mussel habitat loss mitigation and relocation of about 70,000 individual mussels (J. Sickle, personal communication).

Many extensive impacts of the reservoirs have already been described. In addition to impoundment, the Tennessee River has been affected by siltation and turbidity, deforestation, dredging and canalization, industrial and domestic pollution and enrichment, herbicides and pesticides, acid mine drainage, diversions, thermal modifications, and nonnative species. Several hundred kilometers in the basin are considered nonsupporting of aquatic life due to industrial and domestic waste pollution. Strip mining and resulting siltation and acid mine drainage continue to be a problem in the Appalachians, particularly in the Clinch and Sequatchie rivers (Burr and Warren 1986, Etnier and Starnes 1993).

The Tenn–Tom Waterway has permitted migration of both fishes and invertebrates between two very different ecoregions, and the long-term effects remain to be seen. The Tennessee National Wildlife Refuge operates three diked and seasonally flooded waterfowl habitat units in the Kentucky Lake portion of the river. When water is drained into tributary embayments, excess nutrients result in anoxia in the bottom waters. Apatite mining that once occurred in the Duck River may still be releasing particulate phosphorus into the lower Tennessee system. As noted by Burr and Warren (1986), the specific causes for the demise of most species are often difficult to attribute to particular sources. Cumulative effects from multiple stressors may cause much longer lasting damage to a basin, and the effects on species are more difficult to detect than those from any single source alone.

CUMBERLAND RIVER

The Cumberland basin covers $46,430 \text{ km}^2$ of southeastern and western Kentucky and the north-central part of Tennessee (Fig. 9.18). The Cumberland begins at the confluence of the Poor, Martin’s, and Clover forks at the town of Harlan in southeastern Kentucky. From Harlan, the river runs generally southwest into northern Tennessee through the city of Nashville, where it turns northwest until it nears the Tennessee River. The Tennessee and Cumberland rivers then parallel each other, flowing northward to the Ohio River. The Cumberland empties into the Ohio River at Rkm 1481 as a 7th order river near the town of Smithland, Kentucky, after covering a distance of about 1120 km (Fig. 9.5). In general the

FIGURE 9.5 Cumberland River near Smithland, Kentucky (PHOTO BY G. HARRIS).

upper portion of the river's landscape is low mountains with quite a bit of forest, whereas the landscape of the lower half is more rolling and agricultural. Major tributaries include the relatively pristine Rockcastle River, the Big South Fork, the Caney Fork River, the Obey River, the Harpeth River, the Red River, and the Little River. The Barkley Canal between Lake Barkley (Cumberland River) and Kentucky Lake (Tennessee River) allows water to flow freely between both rivers. Local residents quip that the Tennessee River is now the largest tributary to the Cumberland River.

Human influence began at least 12,000 years ago with the Paleo-Indian cultures that entered as the climate warmed. The limited agriculture within the central Cumberland Valley 5000 years ago grew considerably in the Woodland period from about 3100 to 1200 years ago, along with pottery and extensive trade routes. The Mississippian period (1200 to 500 years ago) saw development of cities with temples, improvements in agriculture, and warfare among neighboring tribes. It is not known who the first Europeans were to see the basin, but the original

name, "Rivière des Chauouanons" (Shawnee River), is attributed to Jacques Marquette and Louis Joliet, who visited the river in 1674. The primary cultures at that time were the Choctaw, Cherokee, Shawnee, and Chickasaw. The river received its present name after William Augustus, Duke of Cumberland in 1750, by Dr. Thomas Walker, one of the first English explorers and settlers (McCague 1973). Disease and firearms brought in by traders and rapid European settlement in the late 1700s all combined to displace the native cultures. The Cumberland Valley was settled by Europeans coming from the east through the Cumberland Gap and from the south through the Tennessee River valley. Several towns were established, including what would become Nashville, the largest city on the river. By the end of the nineteenth century much of the land in the lower part of the basin had been cleared for farming and was in poor condition. Coal mining, which had begun a hundred years earlier in the Kentucky Eastern Coal Fields of the Appalachian Mountains, was greatly expanded by a number of competing railroad lines. Thus, two very different environments and cultures, mining and

agriculture, were established and persist to the present (McCague 1973).

Physiography, Climate, and Land Use

The headwaters of the Cumberland begin in the Appalachian Plateaus (AP) and Valley and Ridge (VR) physiographic provinces (see Fig. 9.18). The Valley and Ridge is composed of Paleozoic limestones, sandstones, and shale, whereas low-nutrient Pennsylvanian limestone, sandstone, coal beds, and shale underlie the Appalachian Plateaus. The river then passes through the Highland Rim and Nashville Basin sections of the Interior Low Plateaus (IL) province, with Ordovician and Mississippian age limestones. The Highland Rim is rich in caves, many of which feed into the Cumberland River, raising the generally low productivity. The Nashville basin represents the remnants of the highly eroded Nashville Dome, marked by chert and soluble Ordovician limestones (Hunt 1967). The lower Cumberland River is again very cherty and underlain by Mississippian limestones.

The headwaters lie in the highly diverse Appalachian Mixed Mesophytic Forests terrestrial ecoregion, with American beech, sugar maple, eastern hemlock, mountain laurel, mountain maple, and rhododendrons at higher elevations and oaks, hickories, ashes, maples, pines, and elms at lower elevations. The lower portion is in the Central United States Hardwood Forests terrestrial ecoregion and is comprised of white oak, southern red oak, hickories, American elm, tulip tree, and sweetgum, with understories of winged elm and flowering dogwood (Ricketts et al. 1999).

The climate is continental temperate. Monthly mean temperatures range from about 2°C in January to 25°C in July (Fig. 9.19). Temperatures are generally cooler in the Appalachian Mountains and warmer throughout the Highland Rim. Temperatures in winter regularly fall below 0°C and often exceed 38°C in the summer. Annual precipitation ranges from about 90 to 175 cm (average 127 cm). It is quite evenly distributed throughout the year, with highest amounts usually in March, April, and May (11 to 13 cm) and lowest in October (about 8 cm) (see Fig. 9.19).

The basin is approximately 51% forest, agriculture accounts for about 40% of land use, about 5% is urban, about 3% is water, and the remainder is fallow or in mining (TVA, unpublished data). The principal industries in the Appalachian Plateaus region are coal mining and tourism, and both have had a decided effect on the ecosystem. The Interior

Low Plateaus areas have been in agriculture for more than 150 years. Better farming practices put in place after the Great Depression have decreased erosion and increased crop yields. Primary crops are corn, soybeans, cotton, winter wheat, and Kentucky Colonels (Hunt 1967), and tobacco remains a cash crop throughout the basin. Human population density for the basin is about 16 people/km² and is concentrated primarily within the Nashville metropolitan area (about 1,200,000 people).

River Geomorphology, Hydrology, and Chemistry

The elevation of the Cumberland at the confluence of the Poor, Martin's, and Clover forks is approximately 355 m asl, and it is 90 m asl at the mouth with an overall mean slope of 23.5 cm/km. The Cumberland's headwater streams are deeply incised but relatively low gradient, with sand and shale bottoms. Waterfalls are common, the largest of which is Cumberland Falls, which drops 20 m. Further downstream the larger tributaries cut deeply into Mississippian limestones, whereas side tributaries often are still in sandstones and cherts, giving the region a natural mosaic of substrate types. From the Highland Rim to the Ohio River, stream gradients are moderate, and where the river is free flowing, stream bottoms are generally sandy with chert cobble (Starnes and Etnier 1986, Etnier and Starnes 1993).

There are nine major impoundments in the basin, five of which are on the main stem, and there are several smaller impoundments on the tributaries. Other than for some short sections, the Cumberland River itself is no longer a free-flowing river. With the exception of the Great Falls Reservoir on the Caney Fork River (built in 1916), which is now owned and operated by TVA (TVA 1980), the reservoirs are managed by the U.S. Army Corps of Engineers for a variety of purposes, including flood control, power generation, navigation, and public water supply. The oldest reservoir is Dale Hollow Lake on the Obey River, built in 1943, and the newest is Cordell Hull Lake on the Cumberland River, built in 1973. Barges and other large traffic can lock through to Nashville, approximately 300 km upriver, and boats with less than 1 m draft can navigate as far as Burnside, Kentucky, about 825 km upriver. The largest reservoir is Lake Barkley, with the dam at Rkm 40. Cheatham Lake begins at Rkm 230, Old Hickory Lake at Rkm 346, and Cordell Hull Lake at Rkm 502. Together the four reservoirs create one nearly continuous 600 km long main-stem impoundment.

The fifth main-stem impoundment is Lake Cumberland at Rkm 738. Lake Cumberland is the 2nd largest reservoir in surface area, but unlike the other impoundments it is clear and relatively deep and is classified more as a tributary impoundment (Thornton et al. 1990).

The hydrology and chemistry of the Cumberland River are now dominated by the reservoirs, as little remains free flowing. As with the Tennessee River, the four lower main-stem reservoirs can be divided into riverine, transitional, and lacustrine functional zones, each with its distinct hydrologic, chemical, and biological characteristics (Thornton et al. 1990). Average depth of these reservoirs is shallow (<4m), except in the old river channels. Riverine zones follow the original river geomorphology and generally occupy the original riverbanks, but the original sequences of shoals and pools no longer exist. Flow in the riverine zones depends on release cycles from the upstream dams and usually is kept at levels that provide sufficient depth for transportation. The riverine zone bottoms are primarily sand and cherty gravel. Water velocity slows and larger organic and inorganic particulates drop out in the transitional zones. Bottom substrates are often mixed sands, cherty gravel, and pockets of organic deposition. Bottom substrates in the lacustrine zones are usually composed of fine, clayey deposits of low organic content (generally <1% carbon).

The mean discharge at the mouth of the Cumberland is 862m³/s; however, all of the main-stem reservoirs are highly regulated to hold back floods and spring rain runoff and to provide a guaranteed year-round shipping channel depth. Runoff is highest from January through March and decreases with evapotranspiration to lows during fall months (see Fig. 9.19). In Lake Barkley, the farthest downstream in the system, winter pool (August to March) is approximately 2 m lower than summer pool (April through early August). Summer and winter pool elevation differences are much more pronounced in the tributary reservoirs and Lake Cumberland, allowing them greater storage capacity.

The chemistry of the upper portion of the Cumberland River represents a mosaic of low-nutrient, low-alkalinity tributaries flowing through shale and sandstone, which empty into a main river that has cut into more productive limestones (Etnier and Starnes 1993). Alkalinity of the upper tributaries ranges from 9 to 30 mg/L as CaCO₃. Alkalinity at Nashville averages 60 mg/L as CaCO₃ and then nearly 80 mg/L as CaCO₃ as it empties into the Ohio River. Calcium, SO₄, Si, and total P also tend to

increase in a downstream direction, but their concentrations are highly dependent on annual cycles within the reservoirs. Average NO₃-N values again are dependent on reservoir processes but tend to decrease from Nashville downstream.

Beginning with Cordell Hull Lake, the chemistry of riverine zones reflects what is released from the upstream reservoir, but productivity is usually low because of the high turbidities. As turbidity and velocity decrease in the transitional and lacustrine zones, productivity may be quite high. Nitrate-nitrogen, PO₄-P, and Si reach maximum water-column concentrations in March, producing chlorophyll peaks in early April, and productivity rates of 1000 mg C m⁻² day⁻¹ are common (D. White, unpublished data). Nitrate-nitrogen and PO₄-P concentrations in early June are often less than 1 µg/L. Much of the fixed carbon of each reservoir probably is flushed through the dams or metabolized in the water column, as very little accumulates in the sediments. pH is generally at or above 7.2 but can increase from 7.2 to 9.5 within a matter of hours on warm, sunny days in April and May. Even in the lacustrine zones water velocity remains high, preventing thermal stratification, but oxygen deficits may occur in late summer when discharges are low.

River Biodiversity and Ecology

The Cumberland River is part of the Tennessee-Cumberland freshwater ecoregion, which contains the greatest diversity of aquatic biota in the United States (Abell et al. 2000). Both rivers have very similar fauna and share many endemic species, with the Tennessee River having only slightly greater diversity.

Algae and Cyanobacteria

Following impoundment, phytoplankton became an important part of primary production. The spring diatom peak in the reservoirs (primarily *Melosira*) occurs from late March to early April, and chlorophyll values often exceed 30 µg/L. A wide variety of diatoms (*Navicula*, *Asterionella*, *Fragelaria*, *Melosira*, *Synedra*), green algae (*Scenedesmus*, *Pediastrum*), and cyanobacteria (*Anabaena*, *Oscillatoria*) are the dominant midsummer phytoplankton.

Plants

Because of impoundment and agriculture, most of the original floodplain riparian vegetation has been lost or significantly altered along the main stem. Typical upland hardwood forests (maples, oaks,

hickories, etc.) are primarily present. There are no significant macrophyte beds in the main stem, but the native water willow has become established in the backwaters and embayments, along with several non-natives (brittle naiad, curly pondweed, alligatorweed, parrot feather). Nonnative Eurasian watermilfoil is common in reservoir embayments despite extensive control measures, and hydrilla occurs sporadically. Other native aquatic macrophytes occurring primarily in backwaters include coontails and pondweeds.

Invertebrates

Primary phytoplankton grazers are the cladoceran zooplankton *Bosmina longirostris* and *Daphnia retrocurva*. The major invertebrate predators on *B. longirostris* and *D. retrocurva* are the cladoceran *Leptodora kindti* and phantom midge (*Chaoborus punctipennis*), both of which are abundant throughout the lacustrine zones. Cladocerans along with copepods and larger rotifers (e.g., *Keratella*) are a primary source of food for larval fishes. *Diaphanosoma birgei* was the primary midsummer grazing zooplankton until the 1990s, when the nonnative *Daphnia lumholtzi* displaced it until later in summer.

There are few published surveys of the benthic invertebrates in the main stem of the Cumberland River, either before or since its impoundment, but some data are available in U.S. Army Corps and state agency reports. The longitudinal benthic trends within the impoundments appear to be consistent with riverine, transitional, and lacustrine zone bottom conditions. Filter-feeding bivalves (Unionidae, Sphaeriidae, Asiatic clams, zebra mussels) dominate the riverine zones. The mayfly *Stenonema*, the caddisflies *Cheumatopsyche* and *Ceraclea*, and a variety of Chironomidae are the dominant insects on consolidated substrates. The greatest diversity and density of benthic invertebrates occurs in transitional zones that contain both consolidated and unconsolidated substrates. Primary taxa include surface deposit-feeding tubificid worms (*Limnodrilus*, *Branchiura*), the mayflies *Stenonema*, *Tricorythodes*, and *Caenis*, the caddisflies *Hydroptila* and *Ceraclea*, and numerous Chironomidae, particularly the genera *Ablabesmyia*, *Procladius*, *Cryptochironomus*, *Polypedilum*, *Pseudochironomus*, *Tanytarsus*, and *Chironomus* (D. White, unpublished data).

Lacustrine-zone sediments have generally low organic content even in backwaters and sidearm tributaries. Subsurface deposit feeding tubificid worms (*Limnodrilus*, *Branchiura*) are present but not abundant. The mayfly *Hexagenia limbata* is a common

surface deposit gatherer, as are several genera of Chironomidae. The majority of the surface filter feeders are unionids, fingernail clams, and the nonnative Asiatic clams and zebra mussels.

Next to the Tennessee, the Cumberland River drainage has the 2nd highest diversity of mussels in North America. Eighty-seven species and subspecies once occurred, of which only 55 are now presumed to exist (Parmalee and Bogan 1998). Federally listed endangered species include Cumberland bean mussel, Cumberland elktoe, little wing pearly mussel, Cumberlandian combshell, northern riffleshell, tan riffleshell, oyster mussel, purple cat's paw, pink mucket, fanshell, ring pink, orangefoot pimpleback, clubshell, and rough pigtoe. Much of the present diversity exists in the headwater streams in the Daniel Boone National Forest, notably the Rock Castle River and its tributaries (e.g., Horse Lick Creek). Logging, mining, and off-road vehicle use pose threats to mussel populations. Throughout the lower Cumberland River, impoundment has altered mussel populations through habitat loss and loss of glochidia host fish species. Lake-adapted mussels (e.g., threeridge, washboard, floater, mapleleaf, fragile papershell) have become well established in the reservoirs and are now the most common species.

More than 60 species of *Orconectes*, *Cambarus*, and *Procambarus* crayfishes exist in the Cumberland basin, of which about two-thirds are endemic to the Tennessee–Cumberland ecoregion and have very limited distributions (Hobbs 1988). Notable among these is the endangered Nashville crayfish, which is now found only in Mill and Sevenmile creeks in the metropolitan Nashville area. Despite concerns, the distribution of this species continues to decline with increased urban development.

Vertebrates

Between 172 and 186 species of fishes occur in the Cumberland River drainage, including at least 11 nonnative species (Etnier and Starnes 1993). Nine species are endemic: the blackside dace and eight darters (Burr and Warren 1986). Much of the fish diversity occurs in the transition between the Appalachian Plateaus physiographic province and the Highland Rim section of the Interior Low Plateaus physiographic province, which are home to numerous darters, many of which are endemic. Cyprinidae (44 species, primarily minnows, shiners, chubs, and daces) and Percidae (43 species, primarily darters) are the two most diverse families, followed by suckers (17 species), sunfishes (13 species), and catfishes (11 species). Several species are now thought

to be extinct in the drainage, including the speckled chub, stargazing minnow, hairlip sucker, crystal darter, and longhead darter. The only native salmonid is the brook trout, but rainbow trout, brown trout, and lake trout were introduced successfully into the upstream reservoirs and some of the tributaries. An unsuccessful attempt was made to introduce cutthroat trout into Center Hill and Dale Hollow reservoirs in the mid-1950s (Etnier and Starnes 1993).

The native fish populations of the basin have been greatly altered by impoundment and introductions (Etnier and Starnes 1993). The principle reservoir forage fishes are now the planktivorous gizzard shad and threadfin shad. The planktivorous alewife was introduced into Dale Hollow Reservoir in 1976 and may be spreading throughout the system. Major piscivores now include channel catfish, gars, small cyprinids, largemouth bass, smallmouth bass, and the introduced white bass and striped bass. Species feeding primarily on aquatic invertebrates include the common carp, paddlefish, suckers, sculpins, catfishes, and a vast array of darters, sunfishes, and minnows. The freshwater drum feeds heavily on mollusks, particularly Asiatic clams, and may find an additional food source in the zebra mussel. Channel catfish and paddlefish are the primary commercial species.

Most of the Midwestern species of turtles and water snakes are found in the drainage (Barbour 1971). Much additional habitat for turtles now occurs in the reservoir backwaters and embayments. The most abundant turtles throughout are common snapping turtle, stinkpot, mud turtle, common map turtle, midland painted turtle, spiny softshell, and smooth softshell. Several more western or southern species are found in the lower portion of the river through Lake Barkley: alligator snapping turtle, Ouachita false map turtle, and slider. The red-eared slider is common in the lower half of the drainage and replaced by the Cumberland slider in the upper half. Four species of *Nerodia* water snakes are present in the lower portion of the drainage on snags and fallen trees along the riverbanks and reservoir embayments. Only the common water snake and the queen snake are widespread throughout the drainage. The cottonmouth is present in the lower part of the river, including Lake Barkley, but is not common. At least 11 species of frogs occur in the Cumberland basin, and many are common in the river and reservoirs (e.g., pickerel frog, green frog, bullfrog, leopard frog).

Bald eagles and ospreys are now a common site in the lower half of the basin. Common waterfowl include blue herons, terns, gulls, mallards, coots, and Canada geese. Loons are present in the winter and

spring months. Beaver, muskrat, and river otter also are common, particularly in the tributaries and embayments.

Ecosystem Processes

The ecosystem of the main-stem Cumberland River is now almost completely dominated by impoundments. The once common shoals, large snags, and accumulations of woody debris are gone except along the shorelines and around islands, and benthic processes probably are much less important than they were prior to impoundment. Allochthonous inputs may still provide the greatest amount of organic matter, creating net heterotrophy; however, autochthonous primary production probably drives most water-column metazoan production (Thornton et al. 1990, Kimmel et al. 1990, also see Thorp and DeLong 2002). Reservoir riverine zones are dependent on upstream releases, but productivity is usually low because of the high turbidities. Turbidity and velocity decreases in the transitional and lacustrine zones promote chlorophyll peaks when $\text{NO}_3\text{-N}$, $\text{PO}_4\text{-P}$, and Si concentrations are high, particularly in March and April (D. White, unpublished data). Mid-summer $\text{NO}_3\text{-N}$ and $\text{PO}_4\text{-P}$ concentrations often are too low to measure. Very little primary or secondary production accumulates in bottom sediments, as it most likely is flushed through the dams or metabolized in the water column. Even under low nutrient conditions, water retention time may be the overriding factor for productivity (Kimmel et al. 1990). For example, the average hydraulic retention time for Lake Barkley is about 12 days. If hydraulic retention time is increased to greater than about 20 days, plankton blooms occur (U.S. Army Corps of Engineers, unpublished data).

Many of the species that existed in the lotic conditions prior to impoundment have been displaced or are now limited to tributaries. The lack of longitudinal and temporal equilibriums in manipulated reservoirs favors plants and animals that are highly adaptable and increases the potential for invasion of nonnatives. Understanding ecosystem processes now occurring in the lower Cumberland River requires a much better knowledge of reservoir processes, including hydraulic retention, sediment biogeochemistry, and reservoir aging.

Human Impacts and Special Features

A major special feature of the Cumberland is its biodiversity, of which several pockets remain in the headwater reaches, particularly in the Daniel Boone

National Forest. Outstanding among these is the Rockcastle River, which is home to many endangered fishes and freshwater mussels and a high diversity of darters. Headwater rivers have been geologically isolated by Cumberland Falls, producing considerable endemism. More than two dozen nature preserves, some as large as 2500 ha, are providing some additional protection. Seven streams have been designated as Wild Rivers by the state of Kentucky, including portions of the Big South Fork, Martins Fork, and the Rock Castle River. Protected lands in the lower portion of the basin include the Land-Between-the-Lakes National Recreation Area (U.S. Forest Service) and the Cross Creeks National Wildlife Refuge.

The Cumberland River and its basin have two sets of impacts that are related to differences in geology and culture: pollution and dams. The lower Cumberland has been affected by municipal and industrial discharges in the Nashville metropolitan area and receives considerable agricultural runoff further downstream; for example, NO₃-N levels in the Little River (Kentucky) result in chlorophyll levels of up to 100 µg/L (D. White, unpublished data). The lower portion of the Cumberland basin also contains extensive karst flow systems that are showing signs of water-quality degradation from nutrients and pesticides. Siltation, deforestation, domestic pollution, herbicides and pesticides, diversions, and off-road vehicle use affect the upper portion of the Cumberland River basin, which contains much of the high diversity of fishes and invertebrates. Several hundred kilometers of the basin, including the main stem, have been classified as nonsupporting of aquatic life due to industrial and domestic pollution. Strip mining and resulting siltation and acid mine drainage continue to be a problem throughout the Appalachians (Burr and Warren 1986, Etnier and Starnes 1993).

As mentioned, a primary human impact on the main stem is the series of large multipurpose reservoirs that are managed for hydroelectric power generation, flood control, and navigation. The reservoirs have dramatically altered not only the river but also the surrounding landscape. Natural riverine processes have been completely altered, and the native plant, fish, and invertebrate species largely have been displaced or their functions have been supplanted by nonnative or once uncommon species.

Asiatic clam densities have generally decreased over the past 20 years, but the zebra mussel is now present and may be breeding as far upstream as Nashville. The effects of zebra mussels on the river

ecology and native unionids are unknown. Identifying the effects of nonnative fishes is problematic because so much of the Cumberland has been drastically altered by impoundment.

WABASH RIVER

The name “Wabash” comes from the Miami phrase “wah-bah-shik-ki,” meaning “pure white” in reference to the limestone bedrock that could be seen through the clear water in pre-European times. The Wabash is an 8th order river and the 2nd largest tributary in area to the Ohio River (85,340 km²). It originates in the rolling agricultural countryside of western central Ohio that also contains the headwaters of the Maumee, Great Miami, and Scioto rivers. From there the Wabash flows west through Indiana, then south, eventually forming the border between Indiana and Illinois until it empties into the Ohio River (Fig. 9.20) at Ohio River Rkm 1365. The Tippecanoe River is the 2nd largest tributary to the Wabash in Indiana and is one of few larger rivers that is unimpounded throughout much of its length (Benke 1990, Abell et al. 2000). The major Wabash River tributaries draining Illinois are the Little Wabash and Embarras rivers. The Wabash, Tippecanoe, Little Wabash, and Embarras rivers flow through a large expanse of relatively flat agricultural landscape (Fig. 9.6). The tributary White River flows through Indiana’s largest city, Indianapolis, and through the more hilly regions of southern Indiana. The Wabash and White rivers are of approximately equal discharge at their confluence downstream from Vincennes (Gammon 1991).

Archaic hunter-gatherer tribes existed in the basin from approximately 10,000 to 3000 years ago, when agriculture was introduced throughout most of eastern North America (Hyde 1962). One of the early cultures was the Adena, who built permanent settlements and the first of the burial mounds in the area. By 2200 years ago the Hopewell culture appeared and even larger settlements and more elaborate burial mounds were produced. By 1500 years ago the Hopewell culture was replaced by temple- and fortress-building Mississippian cultures. Mississippian cultures dominated through the 1500s until the first Europeans arrived in the region. In the 1600s the Iroquois, armed with European weapons, increased their raids from Canada into the Ohio Valley, eventually displacing most other Indian tribes until the late 1700s, when tribes such as the Miami, Wea, Piankashaw, Potawatomi, and Kickapoo

FIGURE 9.6 Wabash River near Montezuma, Indiana (PHOTO BY T. HARRIS).

returned to the Wabash Valley. The Potawatomi were defeated in 1811 by William Henry Harrison at the battle of Tippecanoe, losing their rights to land in Indiana, and eventually all tribes were moved westward as European settlement increased (Hyde 1962).

The first Europeans were Spanish explorers in the 1500s; however, it was not until the late 1600s that the French and English began to actively vie for trade and trading routes. By the early 1700s the French had built a major fort at what now is Vincennes, but in 1765 the British took control of the region. George Rogers Clark defeated the British at Vincennes in 1779, giving control of the Northwest Territory to the United States (Gammon 1991). With fertile farmland and ample water transportation routes, the European population quickly expanded to nearly 150,000 by 1820. In 1828 the decision was made to construct an extensive network of shipping canals throughout the state that would permit easy transport of goods to ready markets in the east and south. The most extensive of these was the Wabash and Erie Canal, which began at Fort Wayne, running to Lafayette and then southward to Terre Haute and

eventually ending near the town of Washington, east of Vincennes. Floods, drought, and competition from the developing railroad system continually plagued operation of the canals, and eventually they were abandoned in the late 1850s, but the building and operation of the canals had greatly increased agriculture, lumber production, quarrying, and manufacturing throughout the basin (Gammon 1991).

Physiography, Climate, and Land Use

The entire Wabash River valley lies in glacial tills of various ages and depths. The upper quarter of the Wabash is in the relatively steep Bluffton Till Plain section of the Central Lowland (CL) physiographic province. Between the towns of Logansport and Clinton (north of Terre Haute), the river flattens out, passing through the Entrenched Valley section of the Central Lowland and then through the Interior Low Plateaus (IL) province at its mouth (Hunt 1967). Glacial deposits with occasional limestone outcrops largely cover this region of the Central Lowland.

Pennsylvanian and Mississippian limestones, sand, and chert underlie the Interior Low Plateaus.

The northern and eastern portions of the basin lie in the Southern Great Lakes Forests terrestrial ecoregion, which is dominated by sugar maple, American beech, basswood, oak, elm, hickory, and ash. The middle section of the river drains a small portion of the Central Forest/Grassland Transitional Zone, with both tallgrass prairies and scattered woodlands. The lower portion lies within the Central United States Mixed Hardwood Forests ecoregion (Ricketts et al. 1999). Forests in this ecoregion are primarily white oak, red oak, hickory, American elm, tulip tree, and sweetgum, with understories of winged elm, flowering dogwood, and sassafras.

The climate is continental temperate, and the northern parts of the basin receive an average snowfall of 152 cm/yr. Average rainfall in the basin is 96 cm/yr, with the upper portion of the basin receiving about 91 cm/yr and the lower portion about 112 cm/yr. Rainfall is relatively evenly distributed throughout the year, although April through July may be slightly wetter than fall months (Fig. 9.21). January temperatures average -4°C and July temperatures average about 24°C (see Fig. 9.21). Long periods of winter temperatures below 0°C are common in the north, as are long periods greater than 35°C in the south during summer.

The mean population density as of 2000 was 62.7 people/km². Approximately 5% of the Wabash River basin is urban. The largest city by population in the basin is Indianapolis (731,000) on the White River portion of the Wabash drainage. Major cities through which the Wabash main stem runs include Lafayette (70,000), Terre Haute (58,000), and Vincennes (20,000). With the construction of the canals and the concurrent draining of the land, much of the basin was converted to agriculture by the mid-1800s and remains some of the richest farmland in the Midwest. Major crops are corn and soybeans; however, the basin south of Terre Haute is a prime area for peaches, melons, and vegetables. About 65.2% of the Wabash basin is in agriculture and an additional 8.2% is pasture. Only about 21.6% is forested lands, primarily second growth, and most forested lands occur in the southern portion of the basin (ORSANCO 1990).

River Geomorphology, Hydrology, and Chemistry

The Wabash flows through an ancient valley dating to the Devonian (350 million years ago) that is now

filled with till left by Illinoian and Wisconsin glaciers. The entire valley was ice covered as late as 20,000 years ago (Gammon 1991). Portions of the Wabash were once part of the Teays River system, draining west through present-day Indiana and Illinois. About 14,000 years ago the Wabash drained glacial Lake Maumee through the Maumee River but was cut off by uplifting (Hough 1958). The total length of the present main stem is 772 km. The present origin is near Fort Recovery, Ohio, at an elevation of approximately 267 m asl. Between the origin and Logansport, Indiana, the gradient is 45 cm/km. The gradient abruptly changes below Logansport and averages only 12 cm/km, entering the Ohio River at 97 m asl (Gammon 1991). Prior to the 1820s the Wabash was described as a clear river with relatively constant discharge and numerous sandbars and long cobble riffles (Gammon 1991). Although the river remains free flowing for much of its length, the long history of agriculture and canal building has changed the river to quite turbid and highly variable in discharge, and the amounts of silts and clays on the bottom have greatly increased.

Mean discharge for the entire Wabash system is 1001 m³/s at its mouth on the Ohio. At their confluence the Wabash River contributes 341.5 m³/s and the White River contributes 335.6 m³/s, with most of the remainder coming from the Little Wabash River and other tributaries draining southeastern Illinois. The high amounts of evapotranspiration in late summer (see Fig. 9.21) are in part due to agricultural practices that drained marshy and swampy areas (Gammon 1991). Mean monthly discharge is nearly four times greater in March and April than in September and October (see Fig. 9.21). The mean annual discharge is approximately doubled in the wettest years compared with dry years; however, because of the incised channel the river rarely leaves its banks.

Water temperatures as measured at Lafayette, Indiana, are typically at or just above 0°C in January and reach 25°C to 30°C in July and August. Although the river was historically clear, suspended solids now average greater than 60 mg/L in the upstream reaches to greater than 150 mg/L near the mouth at New Harmony. Conductivity generally decreases in a downriver direction (565 $\mu\text{S}/\text{cm}$ in upper reaches to 488 $\mu\text{S}/\text{cm}$ at New Harmony), as do $\text{NO}_3\text{-N}$ (3.57 to 2.17 mg/L), $\text{NH}_3\text{-N}$ (0.195 to 0.145 mg/L), and $\text{SO}_4\text{-S}$ (64.7 to 60.1 mg/L) (ORSANCO 1990). As with most large rivers, $\text{PO}_4\text{-P}$ increases in a downriver direction from an average of 0.185 mg/L at Peru to 0.300 mg/L at New Harmony. Both phosphate and nitrate loadings were

greatly reduced in the 1970s through improved sewage treatment, the ban on phosphate detergents, and better farming practices. Agriculture remains the major loading contributor (Gammon 1991). Dissolved oxygen concentrations are generally near saturation at midday but may drop to near 50% of saturation during warm summer nights. pH averages 7.2 but may range from 6.8 to 7.8 over a 24-hour period. Alkalinity ranges from 160 to 250 and averages about 200 mg/L as CaCO₃ (Gammon 1991).

River Biodiversity and Ecology

The Wabash lies in the Teays–Old Ohio freshwater ecoregion (Abell et al. 2000). As with other rivers in this ecoregion, the diversity of aquatic plants and animals is high. Because the entire basin was ice covered during the Illinoian glaciation, there are no endemic species.

Algae and Cyanobacteria

Although the Wabash has notably high chlorophyll concentrations (Bukaveckas et al. 2000), the taxonomic distribution of phytoplankton is not well documented. Benthic diatoms of some of the tributaries (e.g., Embarras River) include species of *Achnanthes*, *Cocconeis*, *Gomphonema*, *Navicula*, *Nitzschia*, and *Surirella* (Vaultonburg and Pederson 1994).

Plants

Although much of the floodplain forest along the Wabash was removed in the 1800s and converted to agriculture, some forest does remain along most of the banks. Floodplain forests in the Wabash valley above Terre Haute are typical of the Great Plains and include red maple, cottonwood, black willow, black gum, and American sycamore. Below Terra Haute are the Lower Wabash valley woodland floodplains, which contain these species and the northern extensions of sugar hackberry, waterlocust, and bald cypress (Deam 1953). The contributions of the floodplain forests to the ecology of the river remain unstudied; however, it is assumed that snags and fallen trees provide significant habitat and cover along the banks and a source of organic matter. Non-native aquatic species include purple loosestrife and Eurasian watermilfoil.

Invertebrates

As once occurred in the rivers in this part of the Midwestern United States, freshwater unionid mussels were very abundant in the Wabash prior to

European settlement and about 75 species historically have occurred in the basin (Cummings and Mayer 1992). Indian tribes once used the mussels as a source of food, and early settlers used the shells as a source of lime. Until the early twentieth century the shells were made into buttons. Cummings and Mayer (1994) collected 68 species in the late 1980s, but only 51 were alive. Eleven species are either now extinct or extirpated from the river. Three species are federally listed as endangered: clubshell, fat pocketbook, and eastern fanshell. Although populations of fragile papershell, mapleleaf, and hickorynut are still common, the density and diversity of unionids have been greatly reduced through loss of habitat and water-quality changes in the river. The nonnative Asiatic clam and zebra mussel are common throughout the basin, but their effects on native species have not been examined.

Little has been published on the other benthic invertebrate groups in the Wabash. Based on unpublished drift and artificial substrate studies (D. White, unpublished data), the main stem of the Wabash contains a diverse array of aquatic insects. Bottom sands and silts contain sediment-dwelling mayflies such as *Hexagenia*, *Caenis*, *Tricorythodes*, *Anepeorus* (Wallace's mayfly), and numerous chironomid midge genera. The greatest diversity appears to be associated with logs and woody debris. The mayflies *Stenonema* and *Heptagenia* are abundant, along with the caddisflies *Cheumatopsyche*, *Hydropsyche*, *Ceraclea*, *Hydroptila*, and *Ceratopsyche*, and additional genera of Chironomidae. *Allocapnia* and other winter stoneflies are present, as well as *Acroneturia*, *Isoperla*, *Pellesta*, and *Neoperla*. The megalopterans *Corydalus* and *Sialis* are common, as are the true flies *Simulium* and *Tipula*. Common aquatic beetles include *Tropisternus*, *Berosus*, *Gyrinus*, and *Stenelmis*.

Vertebrates

In the early 1800s the Wabash was known for its abundant fish resources, particularly black bass, pickerels, sunfishes, and catfishes. Gammon (1991) recorded 76 species of fishes in the Wabash proper, which did not include several darters, small cyprinids, and other small species that are common in smaller tributaries or not often collected by electrofishing. The total number of species in the basin is probably greater than 100. The most abundant main-stem species recorded by Gammon (1991) were gizzard shad, common carp, channel catfish, longnose gar, shorthead redhorse, silver redhorse, golden redhorse, and freshwater drum. Other abundant species include steelcolor shiner, emerald shiner, and

quillback, particularly in the lower half of the river. Besides common carp, nonnative species include goldfish, bighead carp, yellow perch, brook trout, and rainbow trout.

Gizzard shad along with skipjack herring are the primary main-stem planktivores. At least 17 species of minnows are present, along with 12 species of sunfishes, most of which are insectivorous. The dominant piscivores are longnose gar, shortnose gar, channel catfish, flathead catfish, white bass, largemouth bass, smallmouth bass, spotted bass, white crappie, and sauger. Bottom-feeding fishes include a diverse array of suckers (15 species), common carp, stoneroller, bullheads and catfishes, paddlefish, and shovelnose sturgeon. Paddlefish are not common but are consistently collected in the lower half of the river. Shovelnose sturgeon is fairly common in the upper half of the Wabash, and numbers may be increasing (Gammon 1991). Other species occasionally found in the river include lampreys, bowfin, mooneye, goldeye, American eel, grass pickerel, and burbot.

The amphibians and reptiles of the Wabash River are typical species of the Midwest (Barbour 1971). Snapping turtle, stinkpot, map turtle, midland painted turtle, and spiny softshell are common throughout the drainage. The Wabash below Terre Haute contains several additional turtle species with primarily southern or western distributions, including false and Ouachita subspecies of the map turtle, mud turtle, red-eared slider, Florida cooter, and smooth softshell. The alligator snapping turtle is rare but present in the extreme lower portion of the river. Four species of water snakes occur, with the common water snake the most abundant on snags and fallen trees along the riverbanks. Queen snake, red-bellied water snake, and Kirtland's water snake are also present. The cottonmouth occurs along the Ohio River and may be present in the extreme southern part of the Wabash. At least 10 species of frogs occur in the basin and many are common in the river (e.g., leopard frog, green frog, bullfrog). Several species of salamander also are found in the river and tributaries, including hellbender, red spotted newt, and mudpuppy. Bald eagle, osprey, and belted kingfisher have become common in the lower basin, along with beaver, muskrat, and river otter.

Ecosystem Processes

As with most other aspects of the Wabash River, there are few published studies on ecosystem-level processes. It can be assumed that the river is heterotrophic throughout and relies on tributary

allochthonous inputs for the organic matter base. This probably is particularly true in the upper portions of the river, as extensive macrophyte beds now occur only in the relatively pristine Tippecanoe River tributary. Agricultural development, along with the creation of the canal system, removed most of the original wetlands and organic inputs that may have occurred there. A significant source of organic matter still appears to be riparian vegetation and downed trees along the main-stem banks. Phytoplankton appears to be an important source of primary production in the lower portion of the river (Lafayette southward), even though turbidity is high (Gammon 1991). Primary production most likely is fueled by nitrogen inputs from agricultural runoff, which can result in dramatic day–night swings in dissolved oxygen concentrations.

Human Impacts and Special Features

Because of the low gradient, there are relatively few dams on the main stem or major tributaries. There is a single impoundment on the Wabash itself, Huntington Lake, at Rkm 662, and from there it flows uninterrupted to the Ohio. Benke (1990, also see Abell et al. 2000) includes the Tippecanoe River in his list of major free-flowing rivers in the United States. The Tippecanoe River is 267 km long and drains 5240 km² of northeastern Indiana. It originates as the outflow of some 80 glacial lakes, including Tippecanoe Lake, which is the deepest lake in the state. Discharge remains fairly constant throughout the year and the water is clear except after heavy rains. Water quality has remained quite high and fishes and invertebrates are abundant and diverse despite considerable agriculture in the area. Aquatic macrophyte beds are extensive in the upper portion of the river, which has a much gentler slope than the lower half.

Human impacts throughout the basin are primarily related to agricultural activities, including soil erosion and runoff of nutrients and pesticides. Groundwater nitrate levels in heavily agricultural areas often exceed the 10 mg/L maximum contaminant level for drinking water. Pesticide levels, sewage, and industrial spills have led to occasional notable fish kills (e.g., the White River near Anderson, Indiana, in 1999) and fish consumption advisories. Urban releases (sewage, toxic organic contaminants, metals) have caused localized concerns, particularly around Indianapolis, but few basinwide problems. Several coal-fired power plants are on the Wabash and White rivers. Through the early 1970s, cooling

waters were taken directly from the river and returned without regulating temperatures, and differences of more than 20°C above and below cooling water outfalls were common.

The limnology and contamination of the White River basin, which occupies 29,400 km² or about half the Wabash basin, have been detailed by NAWQA studies in the early 1990s (USGS, unpublished data). The primary focuses were on surface and groundwater quality, and extensive data are available through the U.S. Geological Survey on pesticide concentrations. The White River differs from the remainder of the Wabash basin in having the influences of a larger urban area (Indianapolis at 772 people/km²), in containing a higher percentage of forested watersheds, and in having its lower to middle reaches in areas of high-relief limestone outcroppings.

KANAWHA RIVER

The name “Kanawha” comes from the Native American word for “place of white rocks,” which presumably referred to the natural salt licks that occur in the basin. The Kanawha is a 6th order river and the 4th largest tributary in both area (31,690 km²) and discharge (537 m³/s) to the Ohio River. Most of the Kanawha River lies within the heavily forested mountains of West Virginia, with the exception of the New River, which also drains mountainous portions of western Virginia and North Carolina (Fig. 9.22). The basin generally flows in a northwesterly direction, emptying into the Ohio River at Rkm 427. The largest tributaries in order are the New, Greenbrier, Elk, and Gauley rivers. Together they compose more than 60% of the basin area and discharge (Kanawha River Basin Coordinating Committee 1971, unpublished data).

Paleo-Indian hunters were present before 11,000 years ago following retreat of the glaciers. As the large game disappeared, archaic hunter-gatherer tribes developed more permanent settlements throughout most of eastern North America (Hyde 1962). By 2200 years ago the Adena culture had appeared, with settlements, agriculture, and burial mounds. The Adena were followed by the Hopewell, but the Hopewell had all but disappeared by 1500 years ago. By the 1600s the Delaware and Shawnee were the dominant organized tribes, but in the late 1600s the Iroquois Confederacy armed with European weapons controlled most of the trade in the basin. Throughout much of the seventeenth and eighteenth centuries the French and British vied for control of the basin and

fur trade with the prevailing tribes. The Treaty of Paris (1763) ended France’s claim to lands east of the Mississippi, giving control to the British. Native Americans, in particular the Shawnee, continued their fights against the British, leading King George III to prohibit settlement in Virginia west of the Allegheny Mountains. In 1768 the Indian Nations (except for the Shawnee) signed a treaty with the British relinquishing rights to land between the Ohio River and the Alleghenies. The Shawnee suffered final defeat in 1774 at the mouth of the Kanawha River. George Rogers Clark’s defeat of the British at Vincennes in 1779 transferred control to the United States and effectively ended most tribal rights to lands east of the Mississippi River (Hyde 1962, Williams 1993).

The treaty of 1768 produced the first influx of settlers, who came up the Kanawha River or across the Alleghenies. The end of the Revolutionary War in 1783 saw an even greater influx of settlers (Williams 1993). Except in some of the larger river valleys, much of the rugged landscape was not conducive to agriculture, but timber and coal were plentiful. Coal mining, tourism, forestry, and chemical manufacturing remain among the top economic concerns today and have been responsible for many of the past water-quality problems.

Physiography, Climate, and Land Use

The Kanawha River and its principal tributaries drain portions of the Blue Ridge (BL), Valley and Ridge (VR), and Appalachian Plateaus (AP) physiographic provinces (Hunt 1967) (see Fig. 9.22). The geology of the Blue Ridge is largely Precambrian gneiss, granite, sandstone, conglomerates, and siltstone. The Valley and Ridge is composed more of Paleozoic limestones, sandstones, and shale, whereas the Appalachian Plateaus are primarily low-nutrient Pennsylvanian limestone, coal beds, sandstone, and shale. Landscape gradients are generally steep (often >20%) throughout the basin, limiting accumulation of soils and unconsolidated sediments and allowing high potential soil loss on disturbed sites.

The terrestrial ecoregions are the Appalachian/Blue Ridge Forests and the Appalachian Mixed Mesophytic Forests (Ricketts et al. 1999). The higher elevations of the Appalachian/Blue Ridge Forests are dominated by red spruce, balsam fir, and Frazer fir, whereas lower elevations are principally deciduous, including red oak, black oak, hickories, birches, and black locust. American beech, sugar maple, eastern hemlock, mountain laurel, mountain maple, and rho-

dodendrons dominate Appalachian Mixed Mesophytic Forests at higher elevations. Lower elevations are rich in a variety of oaks, hickories, ashes, maples, pines, elms, sweetgum, black locust, and black cherry (Ricketts et al. 1999).

The climate is continental temperate, and the northeastern and southern higher elevations may receive considerable amounts of snow in winter. Average precipitation in the basin is 94 cm/yr and is distributed evenly throughout the year, although May is slightly wetter than fall and winter months (Fig. 9.23). The mean basin air temperature is 13°C, with a monthly minimum average of 1.8°C in January and maximum of 23.5°C in July (see Fig. 9.23). The northeastern portion of the basin may be considerably cooler in winter, averaging only -6°C. In the summer months, temperatures greater than 35°C are common.

The mean population density as of 2000 was 29 people/km², with about a quarter of the population in Charleston (200,000). Other cities are small, with only five having populations as great as 10,000. The primary land use is forest, at about 70%. Because of the slope, agriculture (23% of land use) is limited to larger river valleys and some ridge tops. Agriculture is primarily row crops (soybeans, corn) or pasturelands. Approximately 3% is urban/industrial, and about 1% is water. The remaining 2% to 3% of land use is coal mining or barren from past mining activities.

River Geomorphology, Hydrology, and Chemistry

Contrary to its name, the Kanawha–New River system is often described as the oldest basin in North America (although see Chapter 4, Mobile River) and represents the upper portion and headwaters of the ancient Teays River system. The age of the basin, and in particular the New River, has been the subject of considerable debate, with estimates ranging from 30 to more than 300 million years. The Kanawha River begins at the confluence of the Gauley and New rivers, approximately 145 km upstream from the Ohio River (Fig. 9.7). About 2 km downstream from the confluence is the Great Kanawha Falls. The total relief is more than 1500 m, with most occurring above the falls; thus, slopes of all the major tributaries are quite steep. Tributary valleys are V-shaped, and some are quite deep, particularly in the New River basin. Streambeds and riverbeds are rocky, with some accumulations of sand.

Mean discharge for the Kanawha system is 537 m³/s at its mouth on the Ohio. Of this volume, the New River contributes nearly 70%. The Elk, Gauley, and Greenbrier rivers contribute another 20%. Monthly mean runoff is greatest in March with snowmelt and lowest in September (see Fig. 9.23) when evapotranspiration is high. Even though the slope is quite steep, flooding is not common. There are four major flood-control dams, one on the Gauley River, one on the Elk River, and two on the New River. Three locks and dams on the main-stem Kanawha allow for barge traffic, hydroelectric power, and some flood control.

Water-quality conditions in the Kanawha River have greatly improved since the 1970s; however, acid mine drainage, agricultural, and industrial/urban inputs throughout the basin still cause some problems. Mean water temperature in the Kanawha main stem is 14°C, but mean temperatures in the higher-elevation tributaries may be much cooler. Winter water temperatures commonly are at or less than 1°C, whereas summer temperatures may exceed 25°C. Main-stem mean pH is 7.3, and mean alkalinity is generally low (38 mg/L as CaCO₃). Improvements in sewage treatment and better agricultural practices have lowered nutrient levels. Nitrate-nitrogen in the main stem averages 1.2 mg/L, and PO₄-P averages 0.08 mg/L.

River Biodiversity and Ecology

The Kanawha River is part of the Teays–Old Ohio freshwater ecoregion (Abell et al. 2000). Although the Kanawha–New River basin is quite old, endemism and the diversity of aquatic organisms are much less than in the contiguous Tennessee–Cumberland freshwater ecoregion. The Great Kanawha Falls provides a natural barrier to invasion by Ohio River fishes and invertebrates. Beneath the falls the river is free flowing and undisturbed for only about 8 km. This short section, however, has good water quality and supports a high diversity of fishes and freshwater mussels, including two endangered species.

Plants

With 70% of the basin in forests, snags and fallen trees provide habitat and cover along riverbanks and act as a primary source of organic matter. Typical floodplain forests include river birch, red maple, cottonwood, black willow, American sycamore, and tag and speckled alders. Aquatic macrophytes in the main stem are not particularly abundant. Tributaries

such as the Greenbrier and New rivers, however, do contain periphyton and submerged and emergent macrophyte beds that have been shown to significantly contribute to the organic matter budget (Hill and Webster 1983). Typical macrophyte species are water willow, hornleaf riverweed, common cattail, elodea, and various pondweeds. Nonnative species throughout the basin include Eurasian watermilfoil, purple loosestrife, parrotfeather, alligatorweed, brittle naiad, curly pondweed, yellow iris, and watercress.

Invertebrates

Many of the >40 species of freshwater mussels occur below the Great Kanawha Falls (e.g., three-ridge, washboard, giant floater, mapleleaf, pistolgrip, and fragile papershell). Above the falls, fanshell, pink mucket, northern riffleshell, and clubshell are listed as endangered species. Some species that are common elsewhere in the Ohio River basin, such as pistolgrip and purple wartyback, are present above the falls,

but there is concern because populations are small. The same is true for the seep mudalia snail. The non-native Asiatic clam occurs above and below the falls (Rodgers et al. 1977), and zebra mussels are present below the falls and may occur in some of the tributaries. It is not known if they are affecting native species populations.

Because of the rocky bottoms and amounts of woody debris, the benthos is quite diverse above the falls and in other major tributaries. Major benthic insect taxa include the mayflies *Baetis*, *Stenonema*, *Isonychia*, *Baetisca*, *Ephemerella*, and *Leptophlebia*, the stoneflies *Taeniopteryx*, *Nemoura*, *Peltoperla*, and *Isoperla*, the hellgrammite *Corydalus*, the alderfly *Sialis*, the caddisflies *Cheumatopsyche*, *Hydropsyche*, *Neureclipsis*, *Macronema*, and *Brachycentrus*, black flies, chironomid midges, and the crane fly *Tipula*. Water pennies and riffle beetles are common and diverse throughout the headwaters and some of the larger streams. Common genera are *Psephenus*, *Stenelmis*, *Optioservus*, *Promoresia*, *Macronychus*,

FIGURE 9.7 Kanawha River northeast of Charleston, West Virginia (PHOTO BY J. BOYNTON).

and *Ancyronyx*. Gammon's riffle beetle (*Stenelmis gammoni*) is listed as a species of concern in the New River, as are the mayfly *Ephemerella floripara*, the stonefly *Attaneuria ruralis*, the caddisflies *Ceraclea mentiea* and *C. slossonaei*, and the dragonflies *Ophiogomphus mainensis*, *O. asperses*, *O. mainensis*, and *Stylurus scudderi* (North Carolina Division of Water Quality, unpublished reports). Several crayfishes are present, including the New River crayfish.

Vertebrates

About 126 species of fishes occur in the Kanawha River basin. Only 46 native species occur above the Great Kanawha Falls (see Fig. 9.22), of which eight are endemic. Of special concern because of limited distributions are sharpnose darter, Kanawha darter, Appalachia darter, Kanawha minnow, New River shiner, and bigmouth chub (North Carolina Division of Water Quality, unpublished data). Several species endemic downstream of the falls have been introduced above the falls, and their ranges are increasing, causing concerns about natural populations. Margined madtoms now occur in the Greenbrier River, and telescope shiner and least brook lamprey are present in the Gauley River. At least 118 large-river species occur in the Kanawha main stem and tributaries below the falls. All of these are common to the Ohio River basin and include gizzard shad, emerald shiner, common carp, channel catfish, longnose gar, golden redhorse, flathead catfish, white bass, smallmouth bass, sunfishes, spotted bass, white crappie, and sauger. A variety of nonnative fish species are present, many of which have been introduced both above and below the falls and may become problematic. In addition to common carp, they include bighead carp, goldfish, grass carp, tench, coho salmon, golden shiner, rainbow smelt, Ohrid trout, rainbow trout, brown trout, yellow perch, striped bass, bighead carp, and brook stickleback.

The amphibians and reptiles of the Kanawha River are typical species of those in the upper Ohio River basin (Barbour 1971), including snapping turtle, stinkpot, midland painted turtle, hieroglyphic river cooter, and spiny softshell. The primary water snakes are common water snake and queen snake. Common frogs in the basin are green frog, pickerel frog, and bullfrog. Numerous species of plethodontid salamander are found in the surrounding Appalachians. River salamanders include hellbender, newt, and mudpuppy. Belted kingfisher, osprey, coot, and a number of ducks are common, along with beaver, muskrat, and river otter.

Ecosystem Processes

Along with portions of the headwaters of the Cumberland and Tennessee rivers, the headwater tributaries of the New and Greenbrier rivers remain comparatively undisturbed. With the exception of the upper New River, however, little has been published on ecosystem-level processes. Hill and Webster (1983) and others have examined macrophyte production, decomposition, and subsequent contributions to the organic matter budget. Macrophytes accounted for about 13% of the total particulate organic matter input and 28% of the POM generated within their study reach. It can be assumed that macrophyte decomposition provides much more labile organic matter than does allochthonous leaf fall. Further, it provides an organic matter source that comes between summer periphyton production and winter allochthonous-based food production. The underlying geology is not particularly rich in nutrients or as a source of alkalinity; however, agricultural runoff and domestic wastes may contribute to autochthonous production. The benthos is rich in filterers, scrapers, and other deposit-feeding aquatic insects. Although the fish fauna is not diverse above the falls, the majority of the species are insectivores.

Human Impacts and Special Features

Two of the primary tributaries above the Great Kanawha Falls are worth special mention. The 266 km long Greenbrier River is listed by Benke (1990) as one of the few relatively natural and unimpounded rivers in this part of the United States. The river flows generally south-southwest in the Valley and Ridge physiographic province, emptying into the New River just downstream from the Bluestone Reservoir. Most of the basin is forested, there is very little mining, and water clarity and quality are generally very good. Benthos, fish, and aquatic macrophyte diversity are among the highest in the Kanawha Basin (NAWQA 2000b; West Virginia Department of Natural Resources, unpublished data). The New River is 510 km long, beginning in the Blue Ridge Mountains of North Carolina, where it flows northeast through Virginia and into West Virginia. This very old river is generally wide and shallow without a well-developed floodplain. The gradient is steep and averages >2 m/km. The 85 km long New River Gorge National River, located between the falls and Bluestone Reservoir (see Fig. 9.22), was created in 1978 by the National Park Service. The New River

Bridge, built across the Gorge, is the largest steel-arch bridge in the United States. Portions of the upper New River (43 km) and the Bluestone River (16 km), a tributary of the New, have been designated National Wild and Scenic Rivers.

Human impacts throughout the basin are related primarily to coal mining, chemical manufacturing, and agricultural activities (NAWQA 2000b). Mined areas greater than 10% occur in some of the Appalachian Plateau physiographic province tributary watersheds. Because much of the coal has low sulfur content, mining, including mountain-top removal, has increased since 1990, and many of the coal seams have been mined repeatedly with new technologies. The Kanawha basin provides about 7% of the coal used in the United States (NAWQA 2000b). The effects of coal mining on water quality have improved since implementation of the Surface Mining Control and Reclamation Act of 1977. Although iron and manganese concentrations in surface water have decreased and acidity is not a major problem, high levels of sulfate continue to be of concern to human health. Siltation from mining activities continues to result in the loss of mayflies (e.g., *Epeorus*), caddisflies (e.g., *Dolophilodes*, *Rhyacophila*), and riffle beetles (Elmidae).

Soil erosion and runoff of nutrients and pesticides from agriculture pose some problems throughout the entire basin but generally fewer than in most other Ohio Basin rivers (NAWQA 2000b). Bacterial concentrations often exceed human contact guidelines in the major tributaries because of poor or nonexistent treatment and allowing cattle to wander in streams. Perhaps more important are contaminants resulting in part from mining but primarily from main-stem industrial inputs in the Charleston and Elkton areas. Even though discharges have been greatly reduced since the 1970s, volatile organic compounds and heavy metals (e.g., dioxin, benzene, PCB, PAH, Ni, Zn, Pb) continue to be found in the sediments and in fish tissues (NAWQA 2000b).

There are three major locks and dams on the Kanawha between the Ohio River and the confluence with the New River, and several impoundments on the tributary rivers. The dams create barriers to movement of fish populations and alter natural runoff patterns by holding back spring rains and snowmelt. More than 50 nonnative species of crayfishes, fishes, and plants have been recorded for the Kanawha River basin (U.S. Geological Survey, unpublished reports), but their effects on native species remain largely unknown.

ADDITIONAL RIVERS

The Green River was named for Revolutionary War hero General Nathaniel Greene. The Green flows west through the Interior Low Plateaus (IL) physiographic province of central Kentucky (Fig. 9.24). The upper Green begins in the heavily agricultural rolling karst area and then flows through Mammoth Cave National Park. Most rainfall enters the system through sinkholes and is discharged from large cave springs (e.g., Mammoth Cave). Biodiversity is high (151 fish species, 71 mussel species) and there are many endemics, including fishes, mussels, and crustaceans. A portion of the Red River tributary (31 km), including that flowing through the Red River Gorge, has been designated a National Wild and Scenic River. The lower Green River flows through the western coalfield region of Kentucky (Fig. 9.8), which continues to be heavily strip mined. The lower river has seven navigation locks and dams that are used to transport coal. Another six dams create recreational and flood-control reservoirs on the major tributaries. Lock and Dam #6 in Mammoth Cave National Park is scheduled to be removed in the next few years.

The Kentucky River begins in the Appalachian Plateaus (AP) province area known as the Eastern Kentucky Coal Fields and flows northwest through the Interior Low Plateaus (Fig. 9.26). The name Kentucky comes from an Indian word meaning “at the head of the river.” Acid mine drainage continues to be a serious water-quality problem throughout much of the headwaters. The middle portion of the river passes through parts of the Daniel Boone National Forest, where invertebrate and fish diversity are high but not as high as in the Green River to the west or the Cumberland River to the south. There are 14 navigation locks and dams on the main stem that are used largely for coal transportation. The lower part of the river lies in the agricultural Blue Grass region of the Interior Low Plateaus and is deeply incised into the landscape, with many steep bluffs (Fig. 9.9). The U.S. Geological Survey collected water-quality data from the Kentucky Basin from 1987 through 1990 as part of its NAWQA program, but little has been published to date.

The Great Miami River begins in the Till Plains section of the Central Lowland (CL) province and flows in a southerly direction (Fig. 9.28). Although most of the landscape is gently rolling, the river has cut deeply into the glacial till, leaving very steep-sided valley walls. Nearer the Ohio River the till is thinner

FIGURE 9.8 Green River near Rockport, Kentucky (PHOTO BY J. BOYNTON).

FIGURE 9.9 Kentucky River near Tyrone, Kentucky (PHOTO BY J. BOYNTON).

FIGURE 9.10 Great Miami River at Miamitown, Ohio (PHOTO BY K. WILHELM).

and the landscape much hillier (Fig. 9.10). The great Miami Buried Valley aquifer, which follows the pathway of the river from Dayton to the Ohio River, not only supplies base flow but also drinking water to more than 1.5 million people in the basin. Miami and Erie Canal was completed in the 1830s and extended 400 km, linking Toledo with Cincinnati, Ohio, using 103 lift locks. Railroads took the place of the canal in the 1850s, and today the river is not highly fragmented (one major main-stem dam). The Stillwater River has been designated an exceptional warmwater habitat.

The Licking River received its name from the numerous mineral springs that attracted buffalo, deer, and other wildlife. The Licking, as with the Kentucky River to which it runs parallel, begins in the rolling farmlands and Eastern Kentucky Coal Fields of the Appalachian Plateaus province, then passes through the biologically diverse Daniel Boone National Forest (Fig. 9.30). Most of the lower 500 km traverses the agricultural Blue Grass region of the Interior Low Plateaus as it flows northwest to the

Ohio River (Fig. 9.11). Surface coal mines and acid and brine drainage still influence biodiversity in the headwaters. Near the Ohio it receives industrial and domestic inputs from the northern Kentucky portion of the greater Cincinnati metropolitan area. Unlike other rivers flowing northward to the Ohio River, much of the main stem is free flowing. The Licking has only one major dam, which is located at Rkm 287 and forms the 61 km long Cave Run Lake. Biodiversity of fishes, mussels, and aquatic insects is high but generally less than in surrounding river basins.

The Scioto River begins in the agriculturally rich Till Plains section of the Central Lowland (CL) physiographic province and flows southeast across west-central Ohio (Fig. 9.32). The name “Scioto” comes from an Indian word meaning “hairy.” The reference apparently is to the amount of hair that would be in the river when the deer were shedding. Headwater aquifers in the glacial tills are geochemically rich, and pH (7.9), alkalinity (183 mg/L as CaCO_3), $\text{NO}_3\text{-N}$ (2.14 mg/L), and $\text{PO}_4\text{-P}$ (0.33 mg/L) are all among the highest in the Ohio River basin. The main stem and

FIGURE 9.11 Licking River near Midland, Kentucky (PHOTO BY J. BOYNTON).

most of the larger tributaries are deeply incised into the till, often with steep-sided valleys. A major portion of Big and Little Darby creeks (73 km) are designated as National Wild and Scenic Rivers. Fragmentation from dams on the main stem is low, but the middle portion of the basin, including the Olentangy River, continues to show impacts from increased agriculture and urbanization (Fig. 9.12). The river from Chillicothe downstream is in the heavily forested Appalachian Plateaus (AP) province.

The Allegheny River begins in the Appalachian Mountains of north-central Pennsylvania, then flows in a broad “U” shape northwest into New York and then southwest to its confluence with the Monongahela River at Pittsburgh to form the Ohio River (Fig. 9.34). Allegheny is Indian for “fair river.” The upper portion of the basin is primarily oak–hickory and beech–maple forests and quite scenic, with little urban development. About 139 km of the upper Allegheny River and 83 km of the Clarion River tributary have been designated as National Wild and Scenic Rivers. There are at least 100 undeveloped islands on the upper Allegheny main stem. The lower

part of the basin is fragmented, with eight navigation locks and dams on the main stem. The last 35 km is highly urbanized, and acid mine drainage, agricultural, and industrial/urban inputs still cause water-quality problems (Fig. 9.13).

The Monongahela River derives its name from an Indian word meaning “river without islands,” probably in reference to the steep banks throughout much of the basin (see Fig. 9.1). The Monongahela begins at the confluence of the Cheat and Tygart Valley rivers and flows north to Pittsburgh, meeting the Allegheny River to form the Ohio River (Fig. 9.36). The headwaters of the Cheat and Tygart Valley rivers begin in the Monongahela National Forest of southern West Virginia. Many of the tributary streams, however, are heavily impacted by coal mining and acid mine drainage. The main stem is fragmented by nine navigation locks and dams in the lower 150 km, and the entire basin is regulated for flow and navigation. Agriculture is limited in the basin, primarily in the lower half. The last 30 km flow through urban areas near Pittsburgh, with industrial and urban inputs.

FIGURE 9.15 Mean monthly air temperature, precipitation, and runoff for the Ohio River basin.

OHIO RIVER

Relief: 2300 m

Basin area: 529,000 km²

Mean discharge: 8733 m³/s

River order: 9

Mean annual precipitation: 104 cm

Mean air temperature: 12°C

Mean water temperature: 14°C

Physiographic provinces: Blue Ridge (BL), Valley and Ridge (VR), Appalachian Plateaus (AP), Central Lowland (CL), Interior Low Plateaus (IL), Coastal Plain (CP)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregions: Teays–Old Ohio, Tennessee–Cumberland

Terrestrial ecoregions: 8 ecoregions (see text)

Number of fish species: 240 to 250

Endangered species: 8 mussels

Major fishes: gizzard shad, skipjack herring, emerald shiner, white sucker, golden redhorse, black buffalo, river carpsucker, channel catfish, flathead catfish, longnose gar, shortnose gar, largemouth bass, smallmouth bass, bluegill, white crappie, freshwater drum

Major other aquatic vertebrates: snapping turtle, stinkpot, common map turtle, spiny softshell turtle, slider, common water snake, queen snake, green frog, bullfrog, pickerel frog, bald eagle, osprey, great blue heron, Canada goose, coot, mallard, beaver, muskrat, river otter

Major benthic invertebrates: bivalves (threehorn wartyback, Wabash pigtoe, white heelsplitter, fat mucket), worms (*Branchiura*), crustaceans (*Gammarus*, *Cambarus*, *Procambarus*, *Orconectes*), mayflies (*Hexagenia*, *Ephemerella*, *Caenis*, *Stenacron*), stoneflies (*Isoptera*), dragonflies (*Stylurus*), damselflies (*Argia*), caddisflies (*Hydroptila*, *Hydropsyche*, *Ceraclea*, *Cynnellus*, *Polycentropus*, *Potamyia*, *Chimarra*), true flies (*Tipula*)

Nonnative species: *Daphnia lumholtzi*, zebra mussel, Asiatic clam, yellow perch, common carp, goldfish, rainbow smelt, fathead chub, rosefin shiner, bighead carp, grass carp, striped bass, silver carp, brown trout, brittle naiad, curly pondweed, Eurasian watermilfoil, purple loosestrife

Major riparian plants: red maple, cottonwood, black willow, sycamore, black gum, sugar hackberry, water willow, buttonbush

Special features: high biodiversity, especially fishes, freshwater mussels, crayfishes, and aquatic insects; >40% of Mississippi River discharge

Fragmentation: 20 low-water locks and dams on main stem; >700 major dams in basin

Water quality: generally improved since 1970s, agriculture runoff, power plant thermal inputs, urban/industrial discharges still cause problems; pH = 7.2, alkalinity = 70 mg/L as CaCO₃, NO₃-N = 1.6 mg/L, PO₄-P = <0.17 mg/L

Land use: 48% agriculture, 47% forest, 4% urban or barren, 1% water

Population density: 49 people/km²

Major information sources: ORSANCO 1994, 2000, Pearson and Pearson 1989, EA Environmental 2001, Patrick 1995

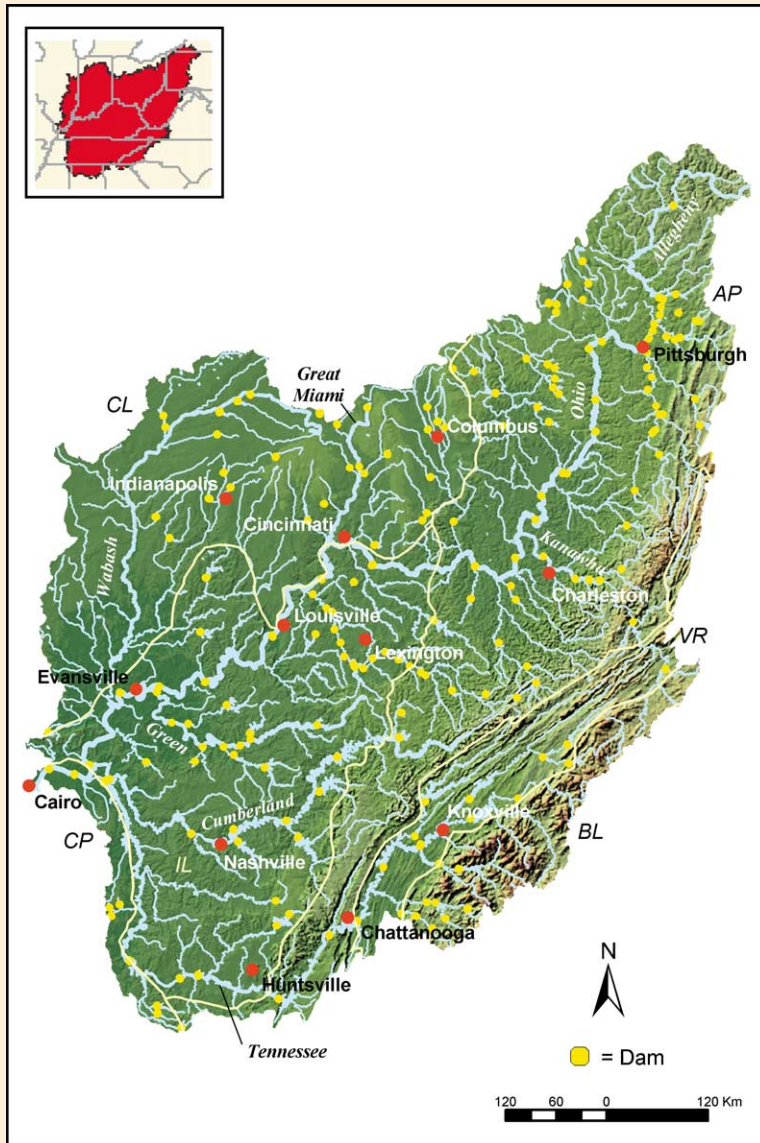

FIGURE 9.14 Map of the Ohio River basin. Physiographic provinces are separated by yellow lines.

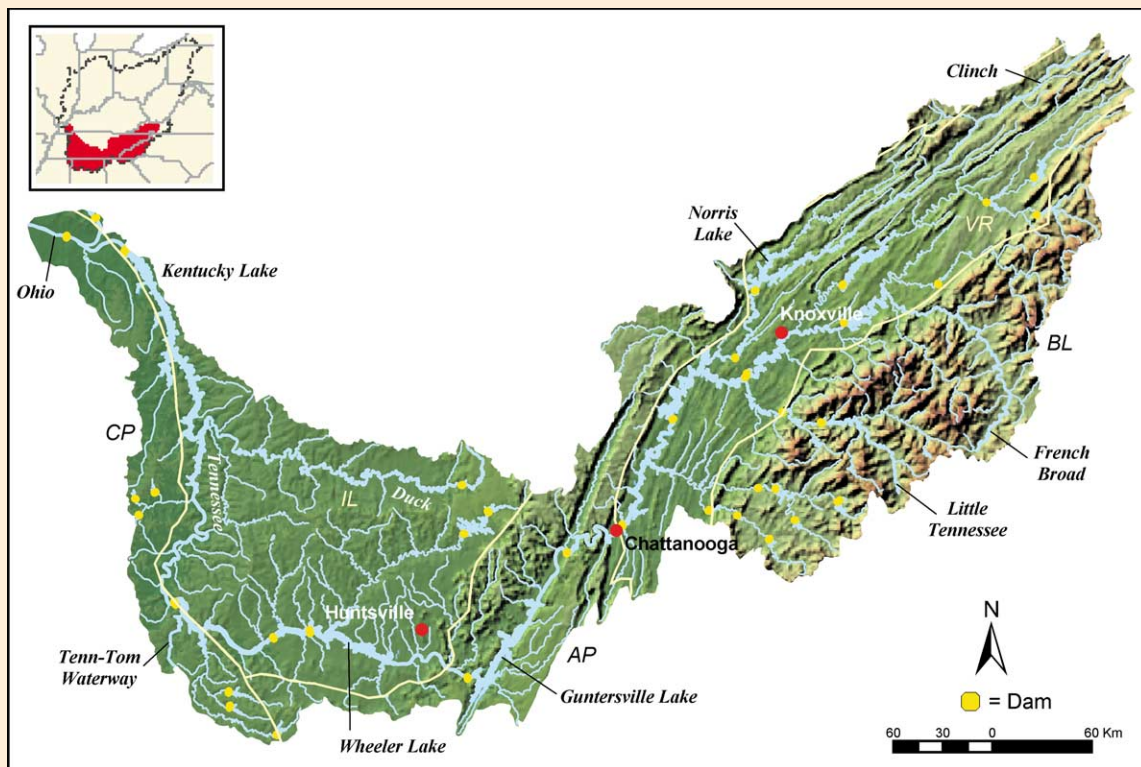

FIGURE 9.16 Map of the Tennessee River basin. Physiographic provinces are separated by yellow lines.

TENNESSEE RIVER

Relief: 1910 m

Basin area: 105,870 km²

Mean discharge: 2000 m³/s

River order: 8

Mean annual precipitation: 105 cm

Mean air temperature: 13°C

Mean water temperature: 19°C

Physiographic provinces: Valley and Ridge (VR), Blue Ridge (BL), Appalachian Plateaus (AP), Interior Low Plateaus (IL), Coastal Plain (CP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Tennessee–Cumberland

Terrestrial ecoregions: Appalachian Mixed Mesophytic Forests, Central U.S. Hardwood Forests, Appalachian/Blue Ridge Forests, Southeastern Mixed Forests

Number of fish species: 225 to 240

Endangered species: 22 mussels, 9 fishes

Major fishes: gizzard shad, threadfin shad, largemouth bass, channel catfish, white bass, striped bass, smallmouth bass, freshwater drum, paddlefish, white crappie, bluegill, flathead catfish, white sucker, spotfin shiner, striped shiner, emerald shiner, orangethroat darter, fantail darter, sauger

Major other aquatic vertebrates: snapping turtle, stinkpot, mud turtle, common map turtle, midland painted turtle, spiny softshell turtle, sliders, common water snake, queen snake, green frog, bullfrog, cottonmouth, bald eagle, osprey, great blue heron, coot, mallard, common loon, ring-billed gull, American white pelican, beaver, river otter, muskrat

Major benthic invertebrates: bivalves (threeridge, washboard, giant floater, mapleleaf, pistolgrip, fragile papershell), crustaceans (*Procambarus*, *Cambarus*, *Orconectes*), mayflies (*Hexagenia*, *Caenis*), stoneflies (*Acroneuria*), alderflies (*Sialis*), caddisflies (*Hydroptila*, *Cheumatopsyche*, *Ceraclea*, *Brachycentrus*), beetles (*Gyrinus*, *Tropisternus*, *Berosus*)

Nonnative species: *Daphnia lumholzi*, Asiatic clam, zebra mussel, goldfish, grass carp, tench, golden shiner, rainbow smelt, Ohrid trout, rainbow trout, brown trout, yellow perch, bighead carp, brook stickleback, Eurasian watermilfoil, purple loosestrife, parrot-feather, alligatorweed, brittle naiad, curly pondweed, watercress, Nepal grass

Major riparian plants: water willow, red maple, buttonbush, cottonwood, black gum, American sycamore, black willow

Special features: most endemic fishes, mussels, and crayfishes of any river in North America; Holston, Clinch, North Fork, Duck, and Powel tributaries have retained much diversity; Obed is National Wild and Scenic River

Fragmentation: 48 multipurpose dams on main stem and major tributaries

Water quality: relatively free of major pollutants; areas of urban and industrial wastes; upper tributaries affected by acid mine drainage and logging; pH = 7.2, alkalinity = 40 mg/L as CaCO₃, NO₃-N = 0.2 mg/L, PO₄-P = <0.01 mg/L

Land use: 58% forest, 36% agriculture, 4% urban or barren, 2% water

Population density: 19 people/km²

Major information sources: TVA 1980, Starnes and Etnier 1986, Burr and Warren 1986, Etnier and Starnes 1993

FIGURE 9.17 Mean monthly air temperature, precipitation, and runoff for the Tennessee River basin.

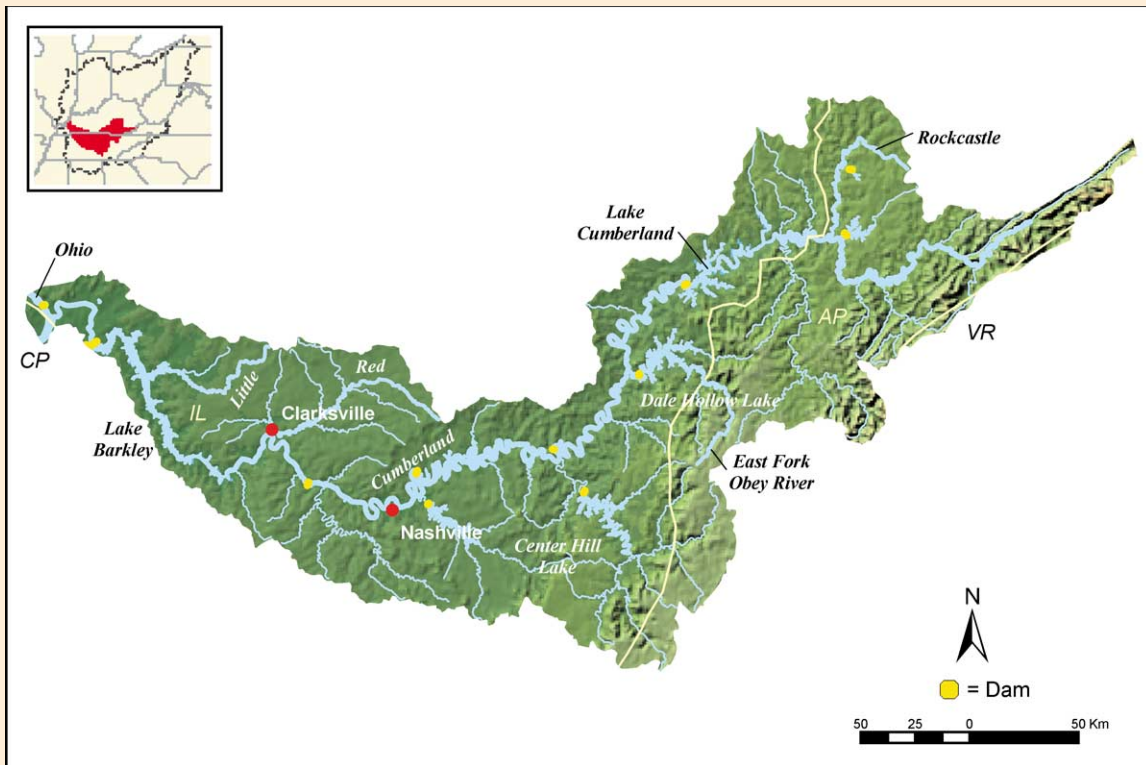

FIGURE 9.18 Map of the Cumberland River basin. Physiographic provinces are separated by yellow lines.

CUMBERLAND RIVER

Relief: 1160 m
 Basin area: 46,430 km²
 Mean discharge: 862 m³/s
 River order: 7
 Mean annual precipitation: 127 cm
 Mean air temperature: 14°C
 Mean water temperature: 16°C
 Physiographic provinces: Valley and Ridge (VR), Interior Low Plateaus (IL), Appalachian Plateaus (AP)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: Tennessee–Cumberland
 Terrestrial ecoregions: Appalachian Mixed Mesophytic Forests, Central U.S. Hardwood Forests

Number of fish species: 172 to 186

Endangered species: 14 mussels, 1 crayfish, 1 snail, 3 fishes

Major fishes: gizzard shad, threadfin shad, channel catfish, largemouth bass, smallmouth bass, spotted bass, white bass, striped bass, common carp, white sucker, freshwater drum, shortnose gar, longnose gar, bluegill, green sunfish, white crappie, paddlefish

Major other aquatic vertebrates: common snapping turtle, stinkpot, mud turtle, common map turtle, midland painted turtle, spiny softshell turtle, common water snake, queen snake, mudpuppy, plethodontid salamanders, bullfrog, green frog, bald eagle, osprey, great blue heron, coot, mallard, ring-billed gull, beaver, muskrat, river otter

Major benthic invertebrates: bivalves (three-ridge, giant floater, washboard, mapleleaf, pink heelsplitter, threehorn wartyback, fingernail clams), crustaceans (*Nashville crayfish*, *Orconectes*, *Cambarus*), mayflies (*Stenonema*, *Caenis*, *Tricorythodes*, *Hexagenia*), alderflies (*Sialis*), caddisflies (*Cheumatopsyche*, *Ceraclea*, *Hydroptila*), beetles (*Gyrinus*, *Tropisternus*, *Stenelmis*)

Nonnative species: Asiatic clam, zebra mussel, *Daphnia lumholtzi*, common carp, goldfish, striped bass, rainbow trout, brown trout, yellow perch, bighead carp, grass carp, tench, grass carp, golden shiner, alewife, Eurasian watermilfoil, hydrilla, brittle naiad, watercress, curly pondweed, alligatorweed, yellow iris, Uruguay seedbox, parrot-feather

Major riparian plants: water willow, buttonbush, red maple, cottonwood, American sycamore, black willow, black gum

Special features: Cumberland Falls; Rockcastle River with many endemic fishes and mussels; caves and karst flow in midregion

Fragmentation: 10 major dams and many tributary dams

Water quality: acid mine drainage in upper tributaries, high levels of nonpoint nitrogen in lower tributaries; pH = 7.2, alkalinity = 60 mg/L as CaCO₃, NO₃-N = <0.4 mg/L, PO₄-P = <0.02 mg/L

Land use: 51% forest, 40% agriculture, 5% urban, 3% water, 1% mining and barren

Population density: 16 people/km²

Major information sources: McCague 1973, Starnes and Etnier 1986, Etnier and Starnes 1993, Parmalee and Bogan 1998

FIGURE 9.19 Mean monthly air temperature, precipitation, and runoff for the Cumberland River basin.

FIGURE 9.21 Mean monthly air temperature, precipitation, and runoff for the Wabash River basin.

WABASH RIVER

Relief: 275 m

Basin area: 85,340 km²

Mean discharge: 1001 m³/s

River order: 7

Mean annual precipitation: 96 cm

Mean air temperature: 11°C

Mean water temperature: 15°C

Physiographic provinces: Central Lowland (CL),
Interior Low Plateaus (IL)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregions: Central Forest/Grassland
Transitional Zone, Central U.S. Hardwood Forests,
Southern Great Lakes Forests

Number of fish species: >95

Endangered species: 3 mussels

Major fishes: gizzard shad, common carp, steelcolor shiner, spotfin shiner, channel catfish, longnose gar, shortnose gar, quillback, river carpsucker, shorthead redhorse, silver redhorse, golden redhorse, freshwater drum, emerald shiner, longear sunfish, white crappie, sauger, white bass, shovelnose sturgeon

Major other aquatic vertebrates: snapping turtle, stinkpot, midland painted turtle, spiny softshell turtle, common water snake, red-bellied water snake, Kirtland's water snake, queen snake, newt, mudpuppy, leopard frog, bullfrog, green frog, bald eagle, osprey, belted kingfisher, mallard, coot, beaver, muskrat, river otter

Major benthic invertebrates: crustaceans (*Orconectes*), bivalves (fingernail clams, fragile papershell, mapleleaf, hickorynut, black sandshell, wartyback), mayflies (*Hexagenia*, *Caenis*, *Brachycerus*, *Tricorythodes*, *Stenonema*, *Heptagenia*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Ceraclea*), stoneflies (*Taeniopteryx*, *Allocapnia*, *Isoperla*, *Perlesta*), damselflies (*Calopteryx*), beetles (*Tropisternus*), alderflies (*Sialis*)

Nonnative species: Asiatic clam, zebra mussel, common carp, goldfish, bighead carp, yellow perch, brook trout, rainbow trout, purple loosestrife, Eurasian watermilfoil

Major riparian plants: red maple, cottonwood, American sycamore, black willow, black gum, sugar hackberry, buttonbush

Special features: 267km long Tippecanoe River remains relatively pristine, drains several northern glacial pothole lakes, and has extensive aquatic macrophytes beds

Fragmentation: one major dam at Rkm 662; free flowing from there to confluence with Ohio River

Water quality: relatively free of major pollutants, primarily agricultural runoff; pH = 7.2, alkalinity = 200 mg/L as CaCO₃, NO₃-N = 2.8 mg/L, PO₄-P = 0.24 mg/L

Land use: 65% agriculture, 8% pasture or open lands, 22% forest, 5% urban

Population density: 62.7 people/km²

Major information sources: ORSANCO 1990, Gammon 1991, Cummings and Mayer 1994

FIGURE 9.20 Map of the Wabash River basin. Physiographic provinces are separated by a yellow line.

FIGURE 9.23 Mean monthly air temperature, precipitation, and runoff for the Kanawha River basin.

KANAWHA RIVER

Relief: 1545 m

Basin area: 31,690 km²

Mean discharge: 537 m³/s

River order: 6

Mean annual precipitation: 94 cm

Mean air temperature: 13°C

Mean water temperature: 14°C

Physiographic provinces: Blue Ridge (BL), Valley and Ridge (VR), Appalachian Plateaus (AP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregions: Appalachian/Blue Ridge Forests, Appalachian Mixed Mesophytic Forests

Number of fish species: 126

Endangered species: 3 mussels

Major fishes: emerald shiner, spotfin shiner, white sucker, river herring, golden redbreast, channel catfish, flathead catfish, longnose gar, white bass, smallmouth bass, green sunfish, longear sunfish, spotted bass, white crappie, sauger, sharpnose darter, Kanawha darter, Appalachia darter, Kanawha minnow, New River shiner, bigmouth chub

Major other aquatic vertebrates: snapping turtle, stinkpot, midland painted turtle, hieroglyphic river cooter, spiny softshell turtle, common water snake, queen snake, bullfrog, green frog, hellbender, newt, mudpuppy, osprey, bald eagle, mallard, coot, great blue heron, beaver, muskrat

Major benthic invertebrates: bivalves (three-ridge, kidneyshell, round hickorynut, black sandshell, elephantear), crustaceans (*Orconectes*), mayflies (*Stenonema*, *Isonychia*, *Leptophlebia*), stoneflies (*Allocapnia*, *Taeniopteryx*, *Isoperla*, *Peltoperla*), hellgrammites (*Corydalus*), caddisflies (*Hydropsyche*, *Ceraclea*, *Hydroptila*, *Brachycentrus*), flies (*Tipula*), beetles (*Psephenus*, *Stenelmis*, *Optioservus*, *Promoesia*)

Nonnative species: Asiatic clam, zebra mussel, rusty crayfish, alewife, common carp, goldfish, golden shiner, striped bass, fathead minnow, tench, purple loosestrife, brittle naiad, curly pondweed, yellow iris

Major riparian plants: red maple, cottonwood, black willow, American sycamore, speckled alder, tulip poplar

Special features: Great Kanawha Falls limits species migration; New is oldest North American river; Greenbrier is unimpounded; New and Greenbrier have generally good water quality and significant free-flowing stretches

Fragmentation: four locks and dams on Kanawha main stem, one dam on Elk and Gurley rivers, two dams on New River

Water quality: improved since 1970s; acid mine drainage, agricultural/forest practices, and industrial/urban inputs near Charlestown still degrade water quality; pH = 7.3, alkalinity = 38 mg/L as CaCO₃, NO₃-N = 1.2 mg/L, PO₄-P = 0.08 mg/L

Land use: 70% forest, 23% agriculture, 3% urban/industrial, 3% mined/barren, 1% water

Population density: 29 people/km²

Major information sources: North Carolina Division of Water Quality, unpublished data; Kanawha River Basin Coordinating Committee 1971; NAQWA 2000b

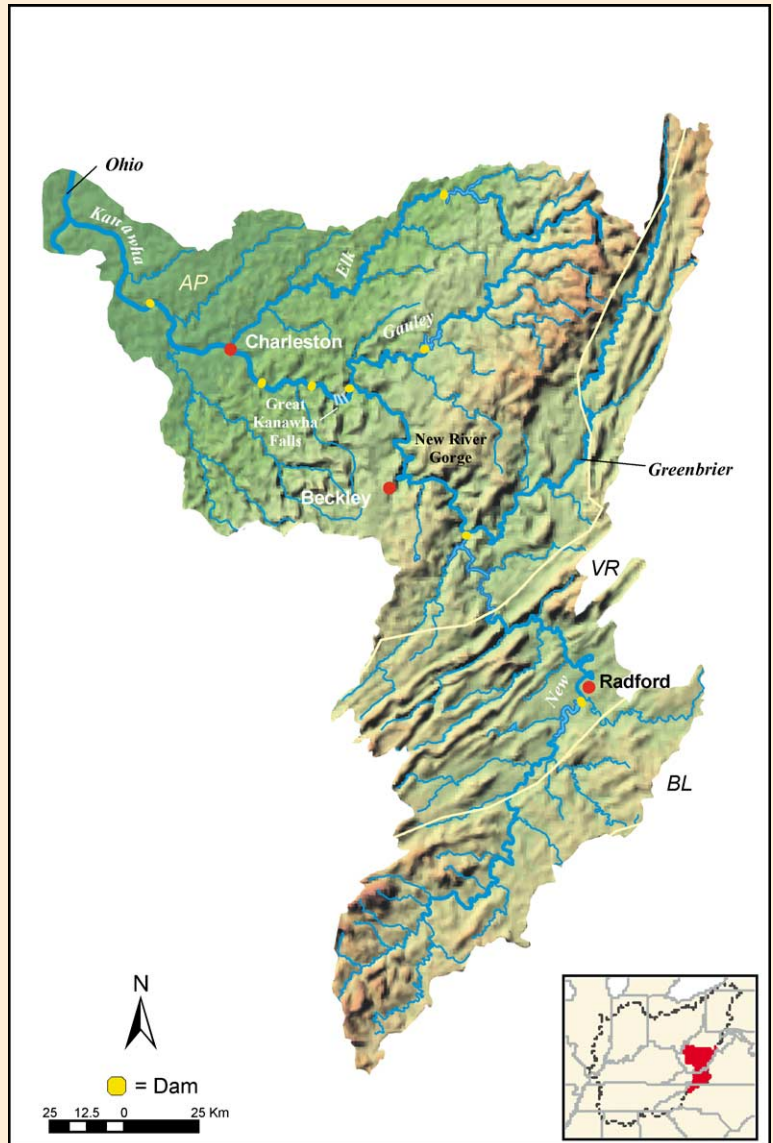

FIGURE 9.22 Map of the Kanawha River basin. Physiographic provinces are separated by yellow lines.

FIGURE 9.24 Map of the Green River basin.

GREEN RIVER

Relief: 385 m

Basin area: 23,850 km²

Mean discharge: 420 m³/s

River order: 7

Mean annual precipitation: 110 to 125 cm

Mean air temperature: 14°C

Mean water temperature: 16°C

Physiographic province: Interior Low Plateaus (IL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregions: Appalachian Mixed Mesophytic Forests,
Central U.S. Hardwood Forests

Number of fish species: 151

Endangered species: 1 fish, 1 cave shrimp, 9 mussels; >20 mussel
species may be extinct

Major fishes: white sucker, gizzard shad, bluegill, rock bass,
largemouth bass, spotted bass, splendid darter, orangefin darter,
teardrop darter, Kentucky snubnose darter, blackfin sucker, channel catfish, cavefish, spotted sunfish, flier

Major other aquatic vertebrates: banded water snake, slider, false map turtle, stinkpot, spiny softshell turtle, mudpuppy,
hellbender, bald eagle, osprey, great blue heron, beaver, muskrat, river otter

Major benthic invertebrates: bivalves (washboard, threeridge, white heelsplitter, giant floater, mapleleaf), crustaceans
(*Orconectes*, *Cambarus*, *Procambarus*), mayflies (*Hexagenia*, *Caenis*, *Ephemerella*, *Isonychia*, *Stenonema*), stoneflies
(*Allocaenia*, *Acroneturia*, *Isoperla*, *Taeniopteryx*, *Neoperla*), hellgrammites (*Corydalus*), alderflies (*Sialis*), caddisflies
(*Ceraclea*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*), beetles (*Tropisternus*)

Nonnative species: Asiatic clam, zebra mussel, common carp, goldfish, striped bass, yellow perch, fathead minnow, brown trout,
rainbow trout, yellow iris, parrot-feather, brittle naiad, watercress, Eurasian watermilfoil, purple loosestrife

Major riparian plants: red maple, buttonbush, black willow, cottonwood, sycamore, water willow, cattails

Special features: upper portion of river lies in karst topography with numerous sinkholes and caves, including Mammoth Cave

Fragmentation: 13 major dams, 7 of which have navigation locks for barge traffic

Water quality: relatively free of major pollutants; acid mine drainage occurs throughout mid-reaches; pH = 7.1, alkalinity =
62 mg/L as CaCO₃, NO₃-N = 0.7 mg/L, PO₄-P = <0.1 mg/L

Land use: 55% agriculture, 39% forest, 3% urban, 2% water, and 1% barren land

Population density: 34 people/km²

Major information sources: Kentucky Division of Water, unpublished data; U.S. Army Corps of Engineers, unpublished data;
Burr and Warren 1986

FIGURE 9.25 Mean monthly air temperature, precipitation, and runoff for the Green River basin.

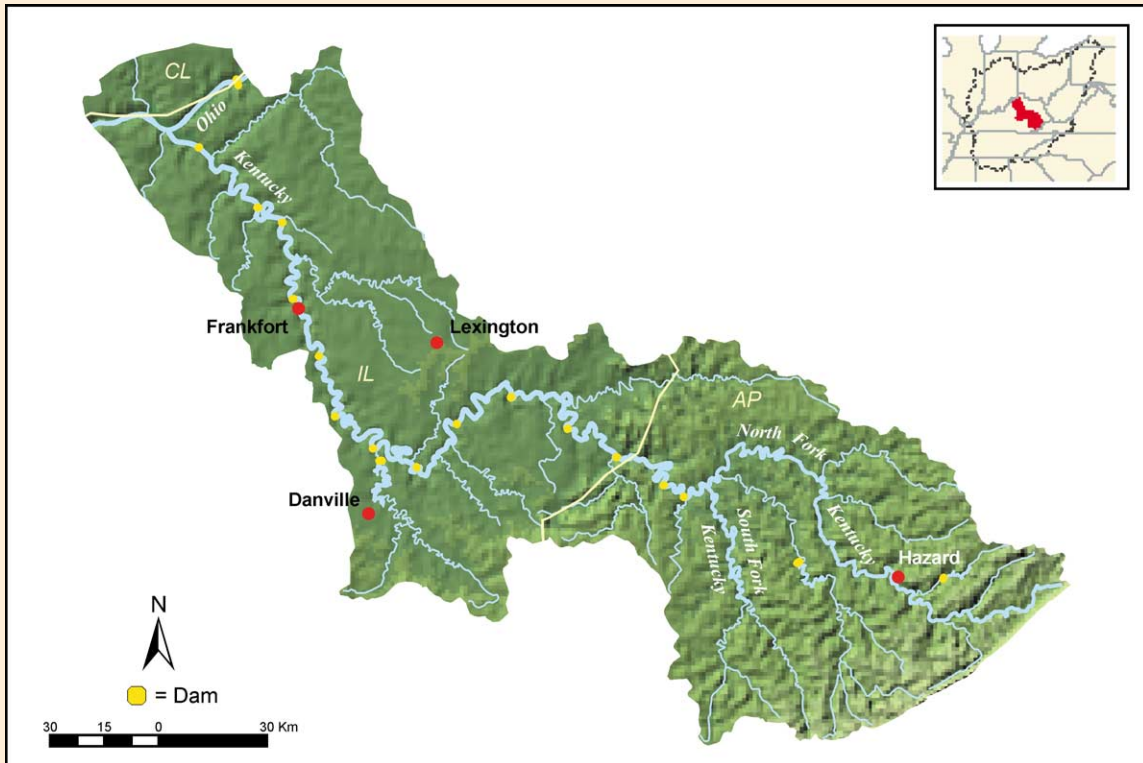

FIGURE 9.26 Map of the Kentucky River basin. Physiographic provinces are separated by yellow lines.

KENTUCKY RIVER

Relief: 840 m

Basin area: 18,025 km²

Mean discharge: 285 m³/s

River order: 6

Mean annual precipitation: 111 cm

Mean air temperature: 13°C

Mean water temperature: 15°C

Physiographic provinces: Appalachian Plateaus (AP), Interior Low Plateaus (IL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregions: Appalachian Mixed Mesophytic Forests, Central U.S. Hardwood Forests

Number of fish species: 110 to 115

Number of endangered species: 1 fish, 1 salamander, 11 mussels

Major fishes: gizzard shad, bluegill, rock bass, largemouth bass, spotted bass, redbreast sunfish, mimic shiner, eastern sand darter, slender chub, sharpnose darter, channel catfish, spotted sucker, golden redhorse, shorthead redhorse, silver redhorse, striped shiner, longnose gar, rainbow darter, greenside darter, sauger

Major other aquatic vertebrates: banded water snake, midland painted turtle, stinkpot, spiny softshell turtle, mudpuppy, hellbender, bullfrog, green frog, bald eagle, great blue heron, beaver, muskrat

Major benthic invertebrates: bivalves (washboard, pink heelsplitter, white heelsplitter), crustaceans (*Procambarus*, *Orconectes*), mayflies (*Ephemera*, *Isonychia*), stoneflies (*Allocaptnia*, *Acroneturia*, *Isoperla*, *Taeniopteryx*, *Perlesta*), hellgrammites (*Corydalus*), caddisflies (*Ceraclea*, *Cheumatopsyche*, *Hydropsyche*), beetles (*Stenelmis*, *Psephenus*)

Nonnative species: Asiatic clam, zebra mussel, common carp, goldfish, striped bass, yellow perch, brook stickleback, rainbow trout, brown trout, purple loosestrife, brittle naiad, curly pondweed

Major riparian plants: speckled alder, red maple, buttonbush, black willow, water willow, cottonwood, American sycamore

Special features: middle portion of river passes through Daniel Boone National Forest, where invertebrate and fish diversity are high; portions of Red tributary, including Red River Gorge, are in National Wild and Scenic River system

Fragmentation: 14 navigation dams on main stem

Water quality: relatively free of major pollutants; acid mine drainage in headwaters; pH = 7.2, alkalinity = 58 mg/L as CaCO₃, NO₃-N = 0.4 mg/L, PO₄-P < 0.01 mg/L

Land use: 42% agriculture, 54% forest, 4% mining, urban, and built up

Population density: 39 people/km²

Major information sources: Kentucky Division of Water, unpublished data; U.S. Army Corps of Engineers, unpublished data; Burr and Warren 1986

FIGURE 9.29 Mean monthly air temperature, precipitation, and runoff for the Great Miami River basin.

GREAT MIAMI RIVER

Relief: 305 m

Basin area: 13,915 km²

Mean discharge: 152 m³/s

River order: 6

Mean annual precipitation: 102 cm

Mean air temperature: 11°C

Mean water temperature: 15°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregion: Southern Great Lakes Forests

Number of fish species: 120 to 125

Endangered species: 1 crayfish

Major fishes: gizzard shad, stoneroller, white sucker, hog sucker, rock bass, largemouth bass, spotted bass, smallmouth bass, mimic shiner, creek chub, sharpnose darter, channel catfish, bullhead, golden redbreast, rainbow darter, black crappie, sauger, green sunfish, spotted sucker, striped shiner, spotfin shiner, black buffalo, striped bass

Major other aquatic vertebrates: common water snake, queen snake, midland painted turtle, stinkpot, spiny softshell turtle, mudpuppy, green frog, pickerel frog, bullfrog, wood duck, great blue heron, mallard, beaver, muskrat

Major benthic invertebrates: bivalves (threeidge, washboard, pistolgrip, fragile papershell), crustaceans (*Orconectes*), mayflies (*Isonychia*, *Stenacron*, *Ephemerella*, *Stenonema*), stoneflies (*Allocapnia*, *Isoperla*, *Acroneuria*), true bugs (*Aquarius*), damselflies (*Argia*), alderflies (*Sialis*), caddisflies (*Hydroptila*, *Hydropsyche*, *Cheumatopsyche*, *Ceratopsyche*, *Ceraclea*), beetles (*Tropisternus*, *Stenelmis*, *Dubiraphia*), true flies (*Tipula*)

Nonnative species: Asiatic clam, zebra mussel, common carp, goldfish, striped bass, rainbow smelt, tench, brown trout, rainbow trout, purple loosestrife, Eurasian watermilfoil, European brooklime

Major riparian plants: red maple, cottonwood, sycamore, black willow, water willow

Special features: Great Miami Buried Valley aquifer extends from Dayton to Ohio River and roughly follows pathway of river; Stillwater River designated as exceptional warmwater habitat

Fragmentation: minor; Taylorsville dam north of Dayton

Water quality: water-quality problems primarily related to agricultural runoff, some urban/industrial inputs; pH = 8.1; alkalinity = 227 mg/L as CaCO₃, NO₃-N = 4.5 mg/L, PO₄-P = 0.27 mg/L

Land use: 80% agriculture, 13% forest, 5% urban or barren, 2% water

Population density: 134 people/km²

Major information sources: Trautman 1981, ORSANCO 1994, 2000, Ohio Environmental Protection Agency, unpublished data

LICKING RIVER

Relief: 345 m
 Basin area: 9600 km²
 Mean discharge: 145 m³/s
 River order: 6
 Mean annual precipitation: 112 cm
 Mean air temperature: 12°C
 Mean water temperature: 14°C
 Physiographic provinces: Appalachian Plateaus (AP), Interior Low Plateaus (IL)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: Teays–Old Ohio
 Terrestrial ecoregions: Appalachian Mixed Mesophytic Forests, Central U.S. Hardwood Forests
 Number of fish species: 110
 Number of endangered species: 1 fish, 1 salamander, 11 mussels
 Major fishes: rock bass, largemouth bass, spotted bass, redbreast sunfish, mimic shiner, eastern sand darter, slender chub, sharpnose darter, channel catfish, white sucker, spotted sucker, golden redhorse, striped shiner, longnose gar, fantail darter, rainbow darter, greenside darter, Johnny darter, sauger, white crappie, black crappie, longear sunfish
 Major other aquatic vertebrates: banded water snake, midland painted turtle, stinkpot, spiny softshell turtle, mudpuppy, hellbender, newt, bullfrog, green frog, bald eagle, great blue heron, belted kingfisher, beaver, river otter, muskrat
 Major benthic invertebrates: bivalves (three-ridge, mapleleaf, white heelsplitter, pink heelsplitter, black threehorn wartyback, elephantear), crustaceans (*Procambarus*, *Orconectes*), mayflies (*Baetis*, *Caenis*, *Ephemerella*, *Isonychia*), stoneflies (*Allocaptnia*, *Acroneturia*, *Isoperla*, *Taeniopteryx*, *Perlesta*), true bugs (*Aquarius*), hellgrammites (*Corydalus*), caddisflies (*Ceraclea*, *Hydropsyche*, *Hydroptila*), beetles (*Stenelmis*, *Psephenus*), true flies (*Tipula*)
 Nonnative species: Asiatic clam, zebra mussel, grass carp, common carp, goldfish, rainbow trout, striped bass, brook stickleback, brittle naiad
 Major riparian plants: speckled alder, red maple, buttonbush, black willow, water willow, American sycamore, cottonwood
 Special features: middle portion passes through Daniel Boone National Forest, where invertebrate and fish diversity is high
 Fragmentation: one major dam at Rkm 278, low-water dams on several tributaries
 Water quality: relatively free of major pollutants; acid mine drainage in headwaters; pH = 7.2, alkalinity = 58 mg/L as CaCO₃, NO₃-N = 0.4 mg/L, PO₄-P = <0.01 mg/L
 Land use: 42% agriculture, 54% forest, 4% mining, urban, and built up
 Population density: 36 people/km²
 Major information sources: Kentucky Division of Water, unpublished data; U.S. Army Corps of Engineers, unpublished data; Burr and Warren 1986

SCIOTO RIVER

Relief: 307 m

Basin area: 16,882 km²

Mean discharge: 189 m³/s

River order: 6

Mean annual precipitation: 98 cm

Mean air temperature: 11°C

Mean water temperature: 15°C

Physiographic provinces: Central Lowland (CL), Appalachian Plateaus (AP), Interior Low Plateaus (IL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays--Old Ohio

Terrestrial ecoregions: Southern Great Lakes Forests, Appalachian Mixed Mesophytic Forests

Number of fish species: 120 to 130

Endangered species: 2 mussels, 1 fish

Major fishes: sand shiner, silver redhorse, green sunfish, rock bass, smallmouth bass, gizzard shad, mottled sculpin, flathead catfish, rock bass, spotted bass, reidside dace, mimic shiner, eastern sand darter, slender chub, sharpnose darter, spotted sucker, hog sucker, golden redhorse, spotfin shiner, striped shiner, longnose gar, rainbow darter, greenside darter, Johnny darter, sauger, black crappie

Major other aquatic vertebrates: snapping turtle, stinkpot, midland painted turtle, spiny softshell turtle, common water snake, queen snake, bullfrog, green frog, pickerel frog, bald eagle, great blue heron, osprey, beaver, river otter, common loon, mallard, coot, muskrat

Major benthic invertebrates: bivalves (three-ridge, washboard, giant floater, mapleleaf, pistolgrip, fragile papershell), crustaceans (*Orconectes*), mayflies (*Acerpenna*, *Stenacron*, *Isonychia*, *Hexagenia*), stoneflies (*Allocapnia*, *Isoperla*, *Perlesta*, *Acroneturia*), alderflies (*Sialis*), caddisflies (*Hydroptila*, *Hydropsyche*, *Cheumatopsyche*), beetles (*Tropisternus*, *Berosus*, *Stenelmis*, *Dubiraphia*, *Macronychus*, *Optioservus*), flies (*Tipula*), black flies (*Simulium*)

Nonnative species: Asiatic clam, zebra mussel, tench, white bass, common carp, goldfish, yellow iris, purple loosestrife, Eurasian watermilfoil, brittle naiad, curly pondweed, European brooklime

Major riparian plants: red maple, cottonwood, American sycamore, black willow, black gum, buttonbush, water willow

Special features: river from Chillicothe downstream in Appalachian Plateaus is heavily forested; Big and Little Darby creeks are National Wild and Scenic Rivers

Fragmentation: one major dam on main stem, several tributary dams

Water quality: relatively free of major pollutants except below urban areas; primarily agricultural runoff, dredging, and point-source problems; pH = 7.9; alkalinity = 183 mg/L as CaCO₃, NO₃-N = 2.14 mg/L, PO₄-P = 0.33 mg/L

Land use: 69% agriculture, 21% forest, 9% urban, 1% water

Population density: 108 people/km²

Major information sources: Trautman 1981, ORSANCO 1994, 2000, Ohio Environmental Protection Agency, unpublished data

ALLEGHENY RIVER

Relief: 690 m

Basin area: 30,300 km²

Mean discharge: 600 m³/s

River order: 7

Mean annual precipitation: 104 cm

Mean air temperature: 9°C

Mean water temperature: 11°C

Physiographic province: Appalachian Plateaus (AP)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Teays–Old Ohio

Terrestrial ecoregions: Allegheny Highlands Forests, Appalachian Mixed Mesophytic Forests

Number of fish species: 114 to 120

Endangered species: 1 sedge, 2 fishes, 2 mussels

Major fishes: gizzard shad, common carp, bluegill, largemouth bass, spotted bass, channel catfish, walleye, sauger, emerald shiner, white crappie, gravel chub, blackchin shiner, river herring, black redhorse, longhead darter

Major other aquatic vertebrates: snapping turtle, stinkpot, midland painted turtle, spiny softshell turtle, common water snake, queen snake, bullfrog, green frog, hellbender, mudpuppy, osprey, great blue heron, mallard, beaver, muskrat

Major benthic invertebrates: bivalves (three-ridge, elephant ear, white heelsplitter, giant floater, black sand shell), crustaceans (*Procambarus*, *Orconectes*), mayflies (*Hexagenia*, *Ephemerella*, *Isonychia*), stoneflies (*Allocaenia*, *Isoperla*, *Acroneuria*), hellgrammites (*Corydalus*), alderflies (*Sialis*), caddisflies (*Hydroptila*, *Hydropsyche*, *Cheumatopsyche*, *Ceraclea*), beetles (*Berosus*, *Stenelmis*, *Dubiraphia*, *Optioservus*), true flies (*Tipula*)

Nonnative species: Asiatic clam, zebra mussel, common carp, goldfish, striped bass, yellow perch, brown trout, watercress, curly pondweed, brittle naiad, Eurasian watermilfoil, yellow iris, purple loosestrife

Major riparian plants: river birch, red maple, cottonwood, black willow, American sycamore, speckled alder

Special features: Upper Allegheny and Clarion rivers designated as National Wild and Scenic Rivers; upper Allegheny has >100 undeveloped islands

Fragmentation: eight navigation locks and dams on lower main stem, twelve major tributary dams

Water quality: conditions improved since 1970s; acid mine drainage, agricultural, and industrial/urban inputs cause problems in lower basin; pH = 7.0, alkalinity = 29 mg/L as CaCO₃, NO₃-N = 1.2 mg/L, PO₄-P = 0.07 mg/L

Land use: 64% forest, 30% agriculture, 4% urban, 1% barren/mined, 1% surface water

Population density: 39 people/km²

Major information sources: ORSANCO 1994, 2000, NAWQA 2000a

MISSOURI RIVER BASIN

DAVID L. GALAT CHARLES R. BERRY JR. EDWARD J. PETERS ROBERT G. WHITE

INTRODUCTION

MISSOURI RIVER MAIN STEM

YELLOWSTONE RIVER

WHITE RIVER

PLATTE RIVER

GASCONADE RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The Missouri River basin is the second largest in the United States, surpassed in area only by the Mississippi River basin of which it is a part. It drains about one-sixth of the conterminous United States (1,371,017 km²) and about 25,100 km² in Canada. The Missouri basin trends in a northwest to southeast direction across the north-central United States (Fig. 10.2) and includes all or parts of 10 states, 2 Canadian provinces, and 25 Native American Tribal Reservations or Lands (74,500 km²). Latitude of the basin ranges from 49.7°N in southwest Saskatchewan to 37.0°N in southwest Missouri.

About 20 Native American tribes belonging to four linguistic groups (Algonkian, Siouian, Caddoan, Shoshonean) lived in the Missouri River basin around 1500. After the Louisiana Purchase in 1803 put the entire Missouri River basin into federal ownership and significant Euro-American expansion into the basin began in 1848, well-documented conflicts with Native Americans ensued. Today, private interests, counties, states, or Native American tribes own about 86% of the basin.

Twelve rivers are discussed in this chapter. In addition to the Missouri main stem, we describe four

tributaries in detail: the Yellowstone, White, Platte, and Gasconade rivers. These rivers extend over 56% of the Missouri River's total length and represent all three physiographic divisions in the basin. None of these tributaries have main-stem impoundments, and tributary regulation is minimal except for the North Platte and South Platte. Abbreviated physical and biological information are also provided for the Madison, Milk, Cheyenne, Niobrara, Big Sioux, Kansas, and Grand rivers. All but the Madison and Gasconade rivers rank in the top 15 of the Missouri basin by drainage basin area.

Physiography and Climate

A wide range of climatic conditions, geologic complexity, and topographic relief exist within the three physiographic divisions that contribute to the Missouri River basin. From west to east, these divisions and the number of physiographic provinces within each (in parentheses) are as follows: Rocky Mountain System (4), Interior Plains (2), and Interior Highlands (1). Basin climate is governed by interactions of four major air masses: warm, moist air originating in the Gulf of Mexico; cool, moist air from the north Pacific Ocean; cold, dry air from the north

FIGURE 10.2 Missouri River basin showing major tributaries, most of which are covered in this chapter.

polar regions; and hot, dry air from plateaus in north-central Mexico. Convergence of these air masses and the midcontinent location of the basin produce extreme seasonal variability in weather. Daily fluctuations can also be sudden and severe. Winters are relatively long and cold; spring is cool, moist, and windy; summers are fair and hot; and autumn is cool, dry, and windy.

The basin is largely semiarid. About one-half receives <41 cm/yr of precipitation, with 70% of this occurring as rainfall during the growing season. Length of the freeze-free period is about 30 days at higher elevations in the Rocky Mountains, about 140 days on the Interior Plains, and about 180 days in the Interior Highlands (Missouri River Basin Commission 1977).

Rocky Mountain System

About 10.7% (~142,400 km²) of the Missouri River's U.S. drainage basin is within this division. The Rocky Mountains are characterized by great topographic relief, with mountain summits typically >1500 m above their bases. Missouri River headwaters originate along the eastern slope of the Rocky Mountain system from Alberta south to Colorado. Climate is typical of highlands, with atmospheric conditions changing markedly over short distances in response to altitude, orientation, and slope. Annual precipitation in the mountains averages >80 cm and can exceed 127 cm, in contrast to 25 cm in some intermountain valleys. Precipitation often arrives as snowfall, and accumulations of >4 m/yr are common.

January is normally the coldest month, with mean daily minimum temperatures as low as -40°C . July is the warmest month, with daily maximum air temperatures average about 22°C .

Parts of all four physiographic provinces within the Rocky Mountain system are contained within the Missouri River basin: Northern Rocky Mountains (NR), Middle Rocky Mountains (MR), Wyoming Basin (WB), and Southern Rocky Mountains (SR) (Fig. 10.15). Geology, topography, and soils vary widely among these provinces and help define the physiochemistry of the headwater rivers to the Missouri. Elevations of the Northern Rocky Mountains range between 1200 and 3000 m asl but reach 3443 m asl at the Missouri River headwaters in the upper Madison River subbasin, Montana. Most of the Montana portion of the Northern Rockies is semiarid, receiving precipitation of $<50\text{ cm/yr}$, and only about one-fifth of the province drains to the east in Canada and the United States. Important tributaries to the Missouri originating in the Northern Rockies include the Milk, Marias, Big Hole, Jefferson, Madison, Gallatin, and Yellowstone rivers.

Mountains within the Middle Rocky Mountains trend in many directions and altitudes range from 1500 to about 3700 m asl. The Yellowstone subbasin is a remnant dissected volcanic plateau and thermal springs are common. Annual precipitation in the Middle Rocky Mountains ranges between 25 and 64 cm. The Bighorn and Yellowstone rivers have their origins here.

The Wyoming Basin is a series of semiarid subbasins separated by isolated low mountain ridges and knobs whose elevations range from 1800 to 2400 m asl. Extensive alluvial deposits occur in floodplains of streams and in fans at the base of mountains. Precipitation (25 to 51 cm/yr) averages lower than in the Rocky Mountain provinces and weathering is slight. The Wind, Laramie, and North Platte rivers are tributaries of the Missouri originating in the Wyoming Basin. About one-half of the Middle Rocky Mountain and Wyoming Basin drain to the Missouri River basin.

The Southern Rocky Mountains consist of a series of high-elevation ranges and intervening basins. The tallest and most rugged mountains within the division occur here, including the highest point within the Missouri River basin, Mt. Elbert, Colorado (4399 m asl), at the headwaters of the Platte River subbasin. About 50% of annual runoff from the Southern Rocky Mountains results from thunderstorms, in contrast to about 30% in the Middle Rockies and only 15% in the Northern Rockies.

Two-thirds of the Southern Rocky Mountains drain eastward into the Missouri, Arkansas, or Rio Grande basins. The North and South Platte rivers are tributaries to the Missouri River having part or all of their origins in the Southern Rocky Mountains.

Interior Plains

The largest portion of the Missouri River basin in the United States, 70.3% ($\sim 932,400\text{ km}^2$), is within the semiarid Great Plains (GP) province of the Interior Plains division (see Fig. 10.15). It includes parts of Alberta, Saskatchewan, Montana, North Dakota, South Dakota, Colorado, Nebraska, and Kansas. Harsh winter climate, a short growing season, and periodic severe droughts characterize the climate of much of this province. Annual precipitation averages only 36 cm and ranges from <28 to $>60\text{ cm}$. Minimum January air temperature averages -19°C and mean maximum July temperature is about 30°C . The Great Plains slope eastward from about 1670 m asl at their contact with the Rocky Mountain System to about 608 m asl along their eastern boundary. This province experienced at least three cycles of marine transgression and regression, resulting in deposition of extensive layers of sandstone, shale, limestone, conglomerate, and lignite. Silts, sands, and gravels deposited by eastern flowing streams from the Rocky Mountains overlie these rocks. The most northern section of the Great Plains province within the Missouri River basin is the Missouri Plateau. Surficial deposits in northern parts of this section in Alberta, Saskatchewan, Montana, North Dakota, and South Dakota are highly erodible glacial till with a gently rolling topography and belts of glacial moraines. The Missouri River and its tributaries are entrenched tens of meters into these sediments. The largest of these glacial deposits is a 745 m elevation plateaulike highland, the Missouri Coteau, located east of the Missouri River in southern Saskatchewan and northern North Dakota. Other topographic features of the Missouri Plateau are several small domed mountain groups, including the Black Hills of western South Dakota and eastern Wyoming. South of the Missouri Plateau is the High Plains section of the Great Plains province, which contains thick alluvial sediments eroded from the Rocky Mountains. Included here is the sand hills area between the Niobrara and Platte rivers.

The north portion of the lower Missouri River basin is contained within the Central Lowland province of the Interior Plains division and includes parts of North Dakota, South Dakota, Iowa, Nebraska, Kansas, and Missouri. Its western boundary with the Great Plains province approximates the

608 m asl contour and ~50 cm precipitation line. It contributes about 17.1% (~227,400 km²) to Missouri River basin's area and exhibits a relatively flat relief, with elevations ranging from 300 to 600 m asl. Most of the Central Lowland was glaciated during the Pleistocene, and glacial deposits of sands, gravels, and till dominate its contemporary surficial topography. Sections of this province within the Missouri River basin are distinguished primarily by differences in glacial histories. Portions of the Dissected Till Plains section in eastern Nebraska, southern Iowa, and northern Missouri are mantled with >9 m of highly erodible loess deposits derived from the post-glacial Missouri River. About 6% of the Missouri River basin is eroded (Revenga et al. 1998), and estimated sediment yield during the 1960s was highest (>2 million kg km⁻²yr⁻¹) from the Central Lowland between the Big Sioux and Kansas rivers (Missouri Basin Inter-agency Committee 1969).

Average annual precipitation within the Central Lowland province ranges from about 40 cm in the northwest to 102 cm in the southeast. Air temperatures range from -17°C in January to 32°C in July.

Interior Highlands

The smallest area of the Missouri River basin, about 2.0% (~28,300 km²), is located in the south lower basin within the unglaciated Ozark Plateaus (OZ) province of the Interior Highlands division (see Fig. 10.15). The Ozark Plateaus are structurally and topographically a low symmetrical dome of predominately dolomites and limestones with lesser quantities of shales, cherts, and sandstones. Highest elevations within this portion of the Missouri River basin range from 444 to 532 m asl. The Ozarks have karst topography; springs and losing streams (i.e., streams where discharge decreases due to groundwater losses) are common. This province has the most mesic climate within the basin, with annual precipitation averaging >100 cm. Mean monthly air temperature ranges from about -6°C in January to about 32°C in July.

Basin Landscape and Land Use

Thirteen terrestrial ecoregions are represented in the Missouri River basin (Ricketts et al. 1999), reflecting its altitudinal, latitudinal, and climatic gradients. From west to east these ecoregions grade from Rocky Mountain coniferous forests, to shrub steppe, then short, mixed, and tall grasslands, and finally to mixed hardwood forests.

Douglas fir, Engelman spruce, sub-alpine fir, lodgepole pine, and ponderosa pine are the dominant

conifers in the North Central, South Central, and Colorado Rockies Forests terrestrial ecoregions. Mountain meadows, foothill grasslands, riparian woodlands, and upper treeline-alpine tundra are other major vegetation communities within the Rockies Forests ecoregions. Northwestern Mixed Grasslands is the largest ecoregion within the Interior Plains, with grama-needlegrass and wheatgrass the principal native grass communities. Sagebrush is the dominant shrub and prickly pear is present on drier sites. Shrubby aspen, willow, cottonwood, and box elder are found on shaded valley slopes and river terraces. Typical grasses of the Northern Mixed Grasslands include grama, little bluestem, needle-and-thread grass, wheatgrass, and junegrass, whereas native grasses of the Central Tall Grasslands ecoregion are predominately big bluestem, switchgrass, and Indian grass. The Central Mixed Hardwoods ecoregion is one of the richest in North America for plants and shrubs, with over 2500 species (Ricketts et al. 1999). Widespread trees are white, red, and black oaks and bitternut and shagbark hickories. Flowering dogwood, sassafras, and hornbeams are important understory trees. Riparian areas and wetter sites favor cottonwood, American elm, sycamore, green ash, and silver maple.

The basin is 37% cropland, 30% grassland, 13% shrub, 11% forested, and 9% developed (Revenga et al. 1998). Major land-surface resources within the basin from northwest to southeast are Rocky Mountain range and forest, western range and irrigated agriculture, northern Great Plains spring wheat, western Great Plains range and irrigated agriculture, central Great Plains winter wheat and range, central feed grains and livestock, and east and central general farming and forest (Slizeski et al. 1982).

Metallic minerals (gold, silver, copper, zinc, molybdenum) are important subsurface resources in the Rocky Mountains, and nonmetallics such as flourspar, feldspar, phosphate, lime, mica, bentonite, and construction aggregate are also mined within the basin. Energy fuels are the largest and most valuable resource commodity, contributing about 55% of U.S. recoverable coal reserves and 8% of petroleum output during the early 1970s (Missouri River Basin Commission 1977).

The Rivers

Three freshwater ecoregions (Upper Missouri, Middle Missouri, and Central Prairie; Abell et al. 2000) containing 47 rivers with drainage basins >1000 km² contribute to the Missouri River. Its three

TABLE 10.1 Features of the six major earth-filled dams and reservoirs on the Missouri River. Location of dam is kilometers upstream from Missouri River mouth (see Fig. 10.15).

Feature	Lake					
	Fort Peck	Sakakawea	Oahe	Sharpe	Francis Case	Lewis & Clark

largest tributaries, the Platte, Yellowstone, and Kansas (see Fig. 10.2), are ranked from 13th to 15th in descending order of drainage basin area in the United States, respectively (van der Leeden et al. 1990).

The southern limit of continental glaciation largely defines the present course of the Missouri River. Both the Upper and Middle Missouri ecoregions experienced heavy glaciation as recently as 10,000 to 15,000 years ago and harbor no known endemic fishes, mussels, crayfishes, or aquatic herpetofauna (Abell et al. 2000). Tributaries to the main stem within the Great Plains show unequal development (see Fig. 10.2). Tributaries on the west (only lightly glaciated) of the Missouri are larger and represent well-developed drainage systems dating to the early Tertiary (e.g., Knife, Cheyenne, White rivers). The Missouri River floodplain is wide where the river cuts across these preexisting alluvial valleys. Tributaries to the east (glaciated) side are small and have developed since melting of the Wisconsin ice (Johnson et al. 1976).

Thirty-seven tributaries with drainage areas >3000 km² enter the Missouri River, and those we discuss further (see Fig. 10.2) are italicized here. Ten tributaries have their origins within the Rocky Mountain Division, including, from upriver to downriver, the *Milk*, *Marias*, *Sun*, *Jefferson*, *Madison*, *Gallatin*, *Judith*, *Musselshell*, *Yellowstone*, and *Platte* rivers. Rivers of similar minimum basin area that originate in the Great Plains include the *Dry*, *Redwater*, *Popular*, *Big Muddy*, *Little Missouri*, *Knife*, *Heart*, *Cannonball*, *Grand*, *Moreau*, *Cheyenne*, *Bad*, *White*, *Niobrara*, and *Kansas*. The *James*, *Vermillion*, *Big Sioux*, *Little Sioux*, *Nishnabotna*, *Platte* (Mis-

souri), *Grand* (Missouri), *Chariton*, *Lamine*, and *Osage* rivers originate entirely or partially within the Central Lowland Province. Four rivers—the *Lamine*, *Moreau* (Missouri), *Osage*, and *Gasconade*—have part or all of their headwaters in the Ozark Plateaus.

Although few endemic aquatic vertebrates occur within the three Missouri River ecoregions, several fishes adapted to large, turbid, main-stem environments (i.e., “big river” fishes) are found through the main stem. These include the pallid and shovelnose sturgeons, blue sucker, and sicklefin and sturgeon chubs.

Approximately 100 multipurpose and over 1200 single-purpose reservoirs have been constructed in the basin, with a total multipurpose storage capacity of about 130.7 km³ (U.S. Army Corps of Engineers 2001). The most prominent water development project is the six reservoirs on the main-stem Missouri (Fig. 10.15, Table 10.1). This system accounts for 69% of the basin’s total multipurpose storage capacity and will be discussed further in the Missouri River section.

MISSOURI RIVER MAIN STEM

An unpredictable river in an unpredictable landscape best describes the historical Missouri River. It is the longest river in the United States (4180 km) from its headwaters in Hell Roaring Creek, Montana (its longest named source stream), and the second-longest river in North America following the Mackenzie–Slave–Peace rivers (4241 km) (van der

Leeden et al. 1990). Total length of the named Missouri River from the confluence of the Jefferson, Madison, and Gallatin rivers near Three Forks, Montana, to its junction with the Mississippi River about 24 km north of St. Louis, Missouri, is generally reported as 3768 km (Hesse et al. 1989), making it the longest named river in North America. The northernmost extent of its main channel is located near Tioga, North Dakota, at 48.17°N latitude and its southernmost extent is between Washington and Augusta, Missouri, at 38.53°N latitude (see Fig. 10.15). Elevation of the named Missouri River ranges from about 1226 m at Three Forks, Montana, to about 122 m at the mouth.

The Missouri River valley supplied abundant resources to Native Americans living along its course, including an unfailing supply of water, game, and wood. River bottom forests gave shelter from summer heat and winter wind and cold. Use of the river for travel by Native Americans was not substantial; small buffalo-skin “bull boats” were their primary craft. Major tribal groups living along the river around 1800 from its mouth northwestward included the Oto, Missouri, Omaha, Ponca, Brule, Teton Sioux, Yankton Sioux, Yanktonai Sioux, Arikara, Hidatsa (Minitari), Mandan, Assiniboin, Atsina, and Piegan Blackfoot. Two major centers of aboriginal trade within the northern plains existed along the Missouri River: the Arikara villages near the mouth of the Grand River in South Dakota and the Mandan and Hidatsa villages near the mouth of the Knife River in North Dakota.

The Lewis and Clark expedition (1804 to 1806) gave us unprecedented detail of the unaltered Missouri’s geography, natural history, and ethnography of its native peoples. Today their journals are revered as classics in the American literature of discovery and exploration (Cutright 1969). Moreover, Lewis and Clark’s systematic approach to exploration of the Missouri set the pattern for future scientific expeditions throughout the Americas.

Following Lewis and Clark’s “Corps of Discovery,” the Missouri became the “original highway west” for Euro-American development of the United States (Thorson 1994). Keelboats were an early (~1815) mode of conveyance for explorers, trappers, immigrants, and their supplies upriver and furs and agricultural produce downriver. The glory days of Missouri River transport came during the steamboat era (1820s to 1880s), first servicing fur traders and then gold seekers and settlers.

The steamboat also played a crucial role in transformation of Native American culture. It brought

the early traders with their welcome merchandise, but also their liquor and smallpox. It transported the commissioners to make treaties, and the Indian agent with the annuities those treaties guaranteed. It brought the artists George Catlin and Karl Bodmer to glorify the American frontier through portraits and scenes of their culture. It delivered the hunters who exterminated their buffalo, and finally it brought the military to pacify them.

Steamboating on the Missouri was terribly hazardous. Shifting channels, shallow sandbars, ice, countless snags, and boiler explosions sank hundreds of steamboats. Railroads began to displace river travel when rail service reached St. Joseph, Missouri, in 1859, and long-distance steamboat navigation ended by 1887.

Physiography, Climate, and Land Use

The Missouri River begins in the Northern Rocky Mountain (NR) physiographic province, then flows for most of its length through highly erodible soils of the Great Plains (GP) and Central Lowland (CL) provinces (see Fig. 10.15). It traverses six of the thirteen terrestrial ecoregions within its basin: North Central Rockies Forests, Montana Valley and Foothill Grasslands, Northwestern Mixed Grasslands, Northern Mixed Grasslands, Central Tall Grasslands, and Central Forest/Grassland Transition Zone.

Climatic ranges of the main stem reflect those described previously for the Great Plains and Central Lowlands provinces, with mean annual precipitation ranging from about 36 to 104 cm/yr. Using mean values for the entire basin, it is clear that there is a very seasonal pattern of precipitation (Fig. 10.16). Lowest precipitation occurs from January to February (~1.7 cm) and highest in June (~8 cm). January is the coldest month (−7°C to −2°C) and July the warmest (20°C to 26°C).

Land use within 5 km of the river is primarily cropland (33%) and grassland (26%), with about 17% of the area developed (Revenga et al. 1998). Basinwide land-use percentages are similar to those presented in the general introduction, except that development is higher near the river.

River Geomorphology, Hydrology, and Chemistry

The Missouri River historically was braided, shifted frequently, and contained numerous sandbars, islands, and unstable banks. Overbank floods were

FIGURE 10.3 Illustrations of Missouri River zones discussed in text. (a) upper or least-altered zone in central Montana showing the Cow Island area (~RM 1942) where the river channel lies 150 to 300 m below the 3 to 16 km wide alluvial valley and highly eroded river bluffs (PHOTO BY C. BERRY). (b) Garrison Dam (left center), the fifth-largest earthen dam in the world, and Lake Sakakawea, nearly 300 km long in central North Dakota, is located in the interreservoir zone (PHOTO BY NASA EARTH SCIENCES; IMAGE COURTESY OF EARTH SCIENCES AND IMAGE ANALYSIS LABORATORY, NASA JOHNSON SPACE CENTER). Lake Sakakawea has the largest volume (29.3 km^3) of the six U.S. Army Corps of Engineers main-stem reservoirs. (c) Middle or interreservoir zone near Bismarck, North Dakota, showing the 1.6 to 11.0 km wide alluvial valley, complex riverine and floodplain habitats, and remnant cottonwood forest (PHOTO BY NORTH DAKOTA GAME AND FISH DEPARTMENT). (d) Lower or channelized zone in Missouri, where the formerly braided channel has been engineered into a smoothly curved, self-scouring, single channel to facilitate navigation (PHOTO BY J. ROBINSON). Alluvial valley width here ranges from 2.4 to 27.4 km and averages 8.1 km.

common, turbidity high, and sediment transport enormous, giving it the nickname “Big Muddy.” It is most conveniently divided into upper, middle, and lower zones based on contemporary geomorphology and hydrology (Fig. 10.3).

The upper zone is unchannelized and extends about 739 km from the origin of the named Missouri River to the first of the six major main-stem impoundments, Fort Peck Lake, Montana (see Fig. 10.15). A National Wild and Scenic River section

occurs over 240km between Fort Benton and Fort Peck Lake, representing the last largely free-flowing portion of the Missouri River that retains most of its primitive characteristics. The alluvial valley is a picturesque gorge of badlands and breaks (see Fig. 10.3a). Gradient averages 60 cm/km and ranges from <40 to >190 cm/km.

The middle or “interreservoir” zone also remains unchannelized, but it was impounded between 1937 and 1963 (see Table 10.1, Fig. 10.3b and c). It runs from the upper end of Fort Peck Lake (Rkm 3029) to Gavins Point Dam (Lewis and Clark Lake, Rkm 1305) and extends an additional 127km to Sioux City, Iowa (Rkm 1178), where channelization begins (see Fig. 10.15). Riverbanks have been stabilized in a 44km reach above Sioux City.

Surficial deposits within the middle zone (Great Plains province) near Bismarck, North Dakota, are a mixture of glacial till, loess, and alluvial sediments with an average depth of 30 to 35 m. Soils are predominately clays, silts, sands, and gravels. Bedrock is generally composed of shales and sandstones. These features result in highly erodible banklines and river bottoms. Slope from the top of the multiple-use pool at Fort Peck Lake to Lewis and Clark Lake is 18 cm/km. Only 547 km (3.2%) of fragmented river segments currently remain in the 1724 km between Fort Peck Lake and Gavins Point Dam (see Fig. 10.15). These remnant riverine reaches exhibit relatively sinuous to semibraided channels and retain many of the islands, backwaters, side channels, and floodplain wetlands characteristic of predam geomorphology (see Fig. 10.3c). Two sections, a 58 km reach between Fort Randall Dam and the delta of Lewis and Clark Lake and a 93 km reach below Lewis and Clark Lake, are designated as National Recreational Rivers. The latter reach is the only unchannelized segment remaining in the lower 1300 km of river; here channel widths average 720 m.

The 1178 km of the Missouri River below Sioux City to its confluence with the Mississippi River is referred to as the lower or “channelized” zone (see Fig. 10.15). This zone is now altered by channelization, bank stabilization, and floodplain levees (Fig. 10.3d). The floodplain area is about 7690 km² or 6.5 km²/km of river (U.S. Fish and Wildlife Service 1980). Alluvium consists largely of clay and silt overlying sand and gravel to a depth of about 30 m. Channel width before channelization ranged from 610 to 1829 m between Rkm 1297 and Rkm 589, and channel migration was dynamic.

Gravel composes about 39% of bed materials in upper Missouri River outside bends, inside bends,

and channel crossovers (where the thalweg crosses the midchannel between two bends) and decreases to 5% in these habitats within middle and lower zones. Sand is the dominant substrate throughout the main channel. Mean percentage of sand is highest in the middle zone (86%) compared with the upper (45%) and lower (81%) zones. Percentage of silt averages <10% of bed materials in main-channel habitats but is the predominate substrate in nonconnected secondary channels and tributary confluences (Galat et al. 2001).

Spatiotemporal patterns in runoff and hydrology of the Missouri River reflect the great climatic variability among physiographic provinces within its basin. From 1967 to 1996 runoff ranged from 11.2 cm/yr for the basin above Fort Benton, Montana, decreased to 3.2 cm/yr for the area between Fort Benton and Omaha, Nebraska, and was highest in the mesic lower subbasin between Kansas City and Hermann, Missouri (29.9 cm/yr). Overall, runoff to the Missouri is relatively low, reflecting dominance of the semiarid Great Plains. For example, mean annual runoff is about four times less for the 3610 km long Missouri River at Hermann (4.6 cm/year) than for the nearby 1111 km long Upper Mississippi River at Alton, Illinois (Galat and Lipkin 2000). Such a low basin runoff reflects a combination of low precipitation and losses from evapotranspiration throughout the Great Plains, where annual evaporation from all six main-stem reservoirs is about 5% of average annual river discharge (see Fig. 10.16).

Mean annual discharge between 1929 and 1996 ranged from 204 m³/s at Fort Benton (Rkm 3336), to 883 m³/s at Omaha (Rkm 991), to 2256 m³/s at Hermann (Rkm 158). Increases in flow are gradual in the semiarid Great Plains of the upper and middle Missouri River zones, but below Omaha flow increases more steeply and interannual flow variability is higher due to the more mesic climate and numerous large tributaries originating in the Central Lowland and Ozark Plateaus. Although the Missouri River from Omaha to its mouth drains only about 38% of the total basin, it contributed about 61% of the 1929 to 1996 mean annual discharge.

The seasonal increase in runoff and discharge begins in March with ice-out and runoff from prairie snowmelt. It peaks in June, corresponding to Rocky Mountain snowmelt and late spring precipitation in the lower basin, then declines in July (see Fig. 10.16). Basinwide drought in the 1930s and flooding in the 1990s resulted in 34% higher mean annual discharge and runoff after flow regulation (1967 to 1996) than before (1929 to 1948) (see Fig. 10.16). Despite this

climatic effect, flow regulation now depresses the flood pulse, except in the lowermost river, and increases flows from August until navigation ceases in December. Tributary discharge ameliorates flow-reduction effects of upriver impoundments in the lowermost river, where catastrophic flooding occurred in 1993 and again in 1995. The 21,240 m³/s discharge at Boonville, Missouri (Rkm 317), on July 29, 1993 is the highest on record, and over 500 levees were overtopped or breached. Mean current velocity in the main-channel Missouri River is highest in the lower zone (1.03 m/s) and similar within the upper (0.74 m/s) and middle (0.75 m/s) zones.

Most of the Missouri is a warmwater river. Mean July to October water temperature increases about 5.5°C between upper (21.5°C) and lower (27.0°C) zones, but is affected in the middle zone by hypolimnetic water releases from reservoirs. Temperature depressions from mid July to early October average 8.5°C and 6.0°C between river segments above and below Fort Peck and Garrison dams, respectively. The farthest downriver reservoir, Lewis and Clark Lake, has little effect on water temperatures because of its shallow depth and short residence time (see Table 10.1).

Turbidity was historically high over much of the Missouri River due to the erosive landscape but is now reduced by sedimentation in reservoirs. For example, turbidity is only 16 NTUs below Fort Peck Lake in the upper Missouri but increases to >150 NTUs after the confluence with the Yellowstone River. Turbidity again decreases below Lake Sakakawea and remains <20 NTU through the remainder of the interreservoir zone (Galat et al. 2001). It then increases to >200 NTUs in the channelized river of central Missouri. Areal sediment yield of the Missouri is about 159 tons km⁻²yr⁻¹, second in the United States only to the Colorado River (212 tons km⁻²yr⁻¹).

Throughout its length the Missouri is a hard- to very hard-water river (~140 to 250 mg/L as CaCO₃ total hardness; Patrick 1998). It is alkaline (145 to 162 mg/L as CaCO₃, pH 8.0 to 8.3), high in conductivity (370 to 800 µS/cm), and high in total dissolved solids (230 to 500 mg/L). Longitudinal patterns of dissolved constituents are somewhat variable, reflecting interactions between geology, physiography, reservoir evaporation, and tributary influx.

Macronutrient concentrations of the Madison and Gallatin tributaries to the upper Missouri are naturally high (NO₃ + NO₂-N = <0.1 to 0.33 mg/L, PO₄-P = <0.01 to 0.05 mg/L) because of hydrothermal geology in the greater Yellowstone ecosystem

(Hauer et al. 1991) but decrease downstream in central Montana (Patrick 1998). Concentrations of NO₃-N + NO₂-N above Lewis and Clark Lake (Rkm 1363) range from <0.05 to 0.36 mg/L and dissolved PO₄-P from <0.01 to 0.025 mg/L (1990 to 1999). In the lower Missouri at Hermann, NO₃-N + NO₂-N ranges between 0.02 and 3.2 mg/L and dissolved PO₄-P between 0.01 and 0.23 mg/L (1980 to 1998) due to the urbanization, intensive agriculture, and livestock operations.

Concentrations of arsenic and selenium in the middle Missouri River are naturally high and may exceed state water-quality standards. Past gold mining in the Cheyenne River basin yielded high discharges of mercury, arsenic, and other contaminants to Lake Oahe and the Missouri River. Bioaccumulation of methylmercury has resulted in consumption advisories for reservoir sport fishes. Additional consumption advisories for fishes in Nebraska and Missouri are due to polychlorinated biphenyls and dieldrin.

River Biodiversity and Ecology

The Missouri is one of the few large river basins in North America that encompasses more than one freshwater ecoregion (Upper Missouri, Middle Missouri, and Central Prairie; Abell et al. 2000), reflecting its variability in physical and biological diversity. Many studies of its biology and ecology have been conducted from the upper to the lower river zones.

Algae and Cyanobacteria

High turbidity, high current velocity, and lack of adjoining lentic habitats contributed to low phytoplankton abundance prior to completion of the mainstem dams. Phytoplankton densities in the lower Missouri River before impoundment averaged 67 cells/L (Berner 1951) and diatoms (e.g., *Fragilaria*) and chlorophytes (e.g., *Pediastrum*) were dominant groups. Abundance increased markedly after impoundment, when Reetz (1982) reported phytoplankton densities in the channelized river below Lewis and Clark Lake (Rkm 1039 to 857) ranging from <1000 and >25,000 units/L, with 98% of values <10,000 units/L. Diatoms (e.g., *Asterionella*, *Stephanodiscus*) remained the dominant family, with chlorophytes (e.g., *Actinastrum*, *Ankistrodesmus*, *Scenedesmus*) becoming more abundant in summer. Cyanobacteria (e.g., *Merismopedia*) were generally <10% of total phytoplankton. Mean chlorophyll *a* concentrations ranged from 4.2 to 42 mg/m³ and showed little seasonal pattern. Increased phyto-

plankton densities are primarily a result of their discharge from main-stem impoundments, with numbers decreasing with increasing distance downstream from dams (Hesse et al. 1989, Patrick 1998). Primary substrates for periphyton colonization in the lower river have changed from silt, sand, and wood to rock rip-rap used for bank stabilization and channel maintenance structures. Diatoms composed 78% to 94% of periphyton taxa collected from the Missouri River above and below the Platte River, Nebraska (Farrell and Tesar 1982).

Plants

Aquatic macrophytes are nearly absent from the main-stem Missouri River due to its high turbidity, unstable substrates, and variable discharge. Perennial vegetation is sparse on sandbars and composed largely of young cottonwoods and willows. Contemporary vegetation in the Missouri River floodplain is a mosaic dominated by agriculture interspersed with remnant patches of forest, shrub/scrub, mesic prairies, and wetlands. Dominant overstory forest trees along the upper and middle Missouri River valley include plains cottonwood, green ash, box elder, and American elm. Peach-leaved willow and burr oak are subdominants (Keammerer et al. 1975, Johnson et al. 1976). Nonnative Russian olive is becoming a more common riparian plant here. Sandbar willow and black willow replace peach-leaved willow in the lower Missouri River, and hackberry, American sycamore, silver maple, red mulberry, and black walnut are added to the floodplain forest community (Bragg and Tatschl 1977). Tree species typically associate along a gradient of decreasing flood disturbance and increasing height above the channel. Willows and cottonwoods are nearest the channel, followed by sycamore, green ash, mulberry, silver maple, and box elder on intermediate sites. Burr oak, hackberry, and walnut are at higher, more protected locations.

Invertebrates

Abundance, seasonality, and taxonomic composition of contemporary Missouri River zooplankton are largely determined by discharges of reservoir assemblages. Zooplankton density and biomass generally decline with increasing distance downstream from dams. Repsys and Rogers (1982) reported 27 species of rotifers, 22 species of copepods, and 40 species of cladocerans from the main stem in central Nebraska. Dominant taxa included Rotifera (*Branchedionus* spp., *Conochiloides* spp., *Conochilus* spp., *Polyarthra* spp., *Synchaeta* spp.), Copepoda (*Cyclops*

bicuspidatus, *C. vernalis*, *Diaptomus clavipes*, *D. forbesi*, *Mesocyclops edax*), and Cladocera (*Daphnia galeata*, *D. retrocurva*, and *D. leuchtenbergianum*).

Zooplankton abundance differs between unchannelized and channelized river segments and among riverine habitats. Kallemeyn and Novotny (1977) reported mean total densities of zooplankton in the unchannelized river below Gavins Point Dam (Rkm 1286 to 1253) were generally higher in the main channel (12,980 to 13,234/m³) and chutes (i.e., secondary channels, 8248 to 11,796/m³) than along the main-channel border (9326 to 9577/m³), whereas the main-channel border of the channelized reach had higher mean total densities (10,041/m³) than did the main channel (6084/m³). Recently created floodplain scours also have a rich zooplankton fauna, containing 39 species of Cladocera and 13 species of Copepoda (Havel et al. 2000).

Shifting substrates and high sediment loads in the preregulation main channel likely limited macroinvertebrates, which were most abundant on channel snags, in backwaters, and in floodplain wetlands. A rich and abundant macroinvertebrate fauna still exists in the upper Missouri River, where habitat loss is minimal and larger, more stable channel substrates occur. Hauer et al. (1991) reported mayflies (24 taxa, particularly *Baetis tricaudatus*, *Ephemerella inermis*, and *Tricorythodes minutus*) and caddisflies (13 taxa, particularly *Arctopsyche grandis*, *Hydropsyche* spp., *Cheumatopsyche* sp., *Glossosoma* sp., and *Brachycentrus* sp.) as abundant in the uppermost Missouri River from near Fort Benton to Three Forks, Montana. Densities were typically high (>1000/m²) but variable among sites, being greatest below reservoirs. Dipterans such as chironomid midges and black fly larvae were also abundant, reaching densities of >3000 and 6000/m², respectively. Dipterans (37%), mayflies (32%), and caddisflies (18%) were also the major macroinvertebrates downstream from Hauer et al.'s sites in the Wild and Scenic Missouri River, Montana (Berg 1981).

In the unchannelized Missouri River below Gavins Point Dam and in the channelized lower river, macroinvertebrate abundance is lowest in main channel and unvegetated secondary channels, intermediate on submerged sandbars and along sandy banks, higher along muddy banks and silty backwaters (secondary channel connected at downstream end), and highest in *Typha* marshes (Patrick 1998). Densities increase with increases in substrate stability, reduced current velocity, and increasing silt and organic matter. Highest densities and biomasses occur on hard substrates (originally snags, now

largely rock dikes) rather than in shifting sand substrates.

Generalizations on relative density or biomass patterns among taxa are difficult for the lower Missouri River because of differences in collection methods and habitats sampled. Collector-gatherer taxa like the mayfly *Baetis* and collector-filterers like black flies and the caddisfly *Hydropsyche* are abundant on stable substrates in the fast-water main channel. The mayflies *Caenis* and *Hexagenia*, the caddisfly *Neureclipsis*, the dragonflies *Gomphus* and *Libellula*, the chironomids *Demicryptochironomus* and *Polypedium*, and oligochaetes are major taxa in slow-water channel, chute, and backup marsh habitats. Densities in drift are high and major differences occur in composition and abundance between macroinvertebrates collected in benthic and drift samples. A moderately rich unionid mussel fauna of 12 species is present in the lower Missouri River despite its turbidity and unstable substrates (Hoke 1983).

Vertebrates

The Mississippi River basin, including the Missouri River, supports the richest freshwater fish fauna in North America, about 260 species (Robison 1986). There are about 183 species present in the Missouri River basin and about 136 reside in the main channel (Galat et al. in press). No fishes are endemic to the main stem and only two species (Niangua darter and bluestripe darter) are endemic to the basin. Seventy-eight percent of the river's fishes are native; two species, American eel and Alabama shad, are diadromous.

Sixty-eight percent of main-stem fishes belong to six families: Cyprinidae (46 species), Catostomidae (13), Salmonidae (12), Centrarchidae (12), and Ictaluridae (9). Species representing the archaic families Acipenseridae, Polyodontidae, Lepisosteidae, and Hiodontidae also occur in the Missouri River. About one-half of the Missouri's fishes are considered big-river species, residing primarily in the main channel.

Numerous big-river fishes share an array of ecomorphological adaptations to high turbidity, high velocity main-channel environments that make them one of the most distinctive faunas in North America. Some species are turbid-water benthic specialists, exhibiting an inferior mouth position, dorsoventral flattening of the head, streamlined or deep hump-backed body shape, sickle-shaped or enlarged pectoral fins, reduced eyes, and diverse and well-developed chemosensory organs (e.g., sturgeons, chubs, buffaloes, carsuckers, blue suckers, catfishes,

burbot, and freshwater drum). Similar adaptations occur in fishes of the turbid Colorado River (see Chapter 11).

The pallid sturgeon is the only Missouri River fish listed as federally endangered by the U.S. Fish and Wildlife Service. Habitat and hydrologic alterations are the primary factors responsible for population declines of this obligate large-river species. Four other fishes are listed as globally vulnerable (G3; NatureServe 2002 <http://www.natureserve.org/explorer/servlet/NatureServe?init=Species>): lake sturgeon, Alabama shad, sicklefin chub, and sturgeon chub. Significant declines in native fishes have been reported from the middle and lower river, including paddlefish, burbot, silver chub, plains minnow, western silvery minnow, blue catfish, and sauger. Most are listed as imperiled (S1 to S3) in two or more states within the basin (NatureServe 2002 <http://www.natureserve.org/explorer/servlet/NatureServe?init=Species>) and all are big-river species (Cross et al. 1986). Nonnative species compose 21% of the entire river's fishes but increase to 43% in the upper river (Galat et al. 2004). Many were intentionally stocked into main-stem reservoirs for recreation or as forage for sport fishes (e.g., salmonids [10 species], centrarchids [8 species], rainbow smelt).

Approximately 78 species of reptiles and amphibians live within the Missouri River and floodplain ecosystem, although scant information is available on their distribution and ecology. Smith (1996) listed the following species richness by major group: aquatic salamanders (2) terrestrial salamanders (7), toads (6), treefrogs (2), chorus frogs (2), frogs (7), aquatic turtles (8), terrestrial turtles (2), lizards (9), aquatic snakes (5), semiaquatic snakes (6), and terrestrial snakes (22). Relative to the Mississippi River, the Missouri is characterized by western elements in the herpetofauna, with a moderately large number of snakes and lizards.

The river corridor is a migration and wintering habitat for millions of waterbirds. Most use is from spring and late summer through autumn. Shorebirds and dabbling ducks rest on islands and sandbars and forage in mudflats (shorebirds), wetlands, and grain fields (waterfowl) during migration. Seventeen species of ducks, three species of geese, and one swan species occur along the river. Common waterbirds along the lower Missouri River are American white pelican, American coot, snow goose, Canada goose, blue-winged teal, green-winged teal, northern shoveler, gadwall, mallard, wood duck, and great blue heron. Killdeer, lesser yellowlegs, pectoral, Baird's, least, spotted, and semipalmated sandpipers are

common shorebird migrants. Eight species of terns and gulls occur along the lower Missouri River.

The Missouri River provides breeding habitat for interior populations of the endangered least tern, northern Great Plains populations of the threatened piping plover, and the threatened bald eagle. Presently, about 12% of the known population of interior least terns and 22% of the northern Great Plains population of piping plovers nest along the Missouri River main stem and its major tributaries (Smith 1996). Migration and wintering habitat are also used by the bald eagle and endangered whooping crane. Large numbers of bald eagles winter near open water below Missouri River main-stem dams and in the lowermost river, which seldom freezes.

Principal aquatic mammals along the Missouri River include mink, river otter, beaver, muskrat, and raccoon. Federally endangered gray and Indiana bats are reported to use lower Missouri River bluff caves for hibernation and the riparian corridor for foraging.

Ecosystem Processes

Information on ecosystem processes of the Missouri River is incomplete, but patchy data exist on production and food web structure. Seasonal mean primary production for phytoplankton has been measured only in the channelized river, Nebraska, and ranges from $7.4 \text{ mg C m}^{-3} \text{ h}^{-1}$ in winter to $203 \text{ mg C m}^{-3} \text{ h}^{-1}$ in autumn (Reetz 1982). Mean periphyton production ranged from 135 to $310 \text{ mg m}^{-2} \text{ d}^{-1}$ AFDM in the same reach (Farrell and Tesar 1982).

Light, rather than nutrients, limits algal growth in the lower Missouri River. Knowlton and Jones (2000) reported photic depths averaged 0.78 m and ranged from 0.12 to 2.4 m and mixed depth/photic depth ratios averaged 10.2 (range 1.2 to 55). Despite high turbidity, they suggested algal production was considerable in the lower Missouri River, Missouri, from 1994 to 1998. Flux of algal biomass for this area was estimated from chlorophyll concentrations as 270,000 kg/d.

High suspended sediment concentrations in the Missouri River transport the bulk of its organic carbon. Concentrations of dissolved organic carbon (DOC) and suspended sediment organic carbon (SSOC) in 1969–1970 averaged 4.6 mg/L and 20 mg/L, respectively (Malcolm and Durum 1976). Over 80% of the annual organic load is transported in the suspended fraction. Almost one-third of the SSOC load of the Mississippi River is contributed by the Missouri, which accounts for <10% of water inflow

to the Mississippi. Carbon/nitrogen ratios for the Missouri are slightly higher (8.9) than Malcolm and Durum (1976) recorded from five other U.S. rivers (mean range, excluding Missouri, of 6.9 to 8.7).

Benthic insect production in the unchannelized Missouri River below Gavins Point Dam declined by 61% from 1963 to 1980 (Mestl and Hesse 1993). Secondary-channel and backwater habitats contributed 37% of this production in 1973, but their contribution declined to only 19% by 1980. Main-channel degradation draining these habitats was proposed as the cause. Insect production on woody habitats in the main channel contributed the highest amount to total production (69%, 42.4 g/m^2) in 1963 compared with mud and sand substrates and backwaters (Mestl and Hesse 1993).

No information exists on fish production, but there have been increases in the number of species collected and considerable changes in their relative abundances based on surveys made at approximately 20 yr intervals in Missouri (Pflieger and Grace 1987). Species reported to have become more abundant due to decreased turbidity are largely pelagic planktivores and sight-feeding carnivores: skipjack herring, gizzard shad, white bass, bluegill, white crappie, emerald shiner, and red shiner. Introduced fishes pose another potential threat to the native fish community structure, although their impacts have not been evaluated.

Human Impacts and Special Features

The Missouri is the longest river in North America and America's first highway to the west. Its flow patterns and braided channel geometry were once described as "uncertain as the actions of a jury or the state of a woman's mind" (*Sioux City Register*, March 28, 1868). This once highly dynamic river is today one of the most regulated rivers in the United States, containing the largest series of impoundments and >1100 km of largely flow-regulated, stable, uniform channel.

The earliest human impacts on the Missouri River were largely snag removal and deforestation. Snag removal to facilitate navigation was authorized by Congress in 1832, and between 1843 and 1846 over 60,000 channel snags were removed. A steamboat consumed >20 cords of wood per day on an upstream journey and consequently forests were nearly eliminated along the riverbanks.

Alterations of the Missouri began in earnest with passage of the Reclamation Act of 1902, "to turn the

Missouri River on itself” from Sioux City, Iowa, to St. Louis, Missouri (Ferrell 1996). A system of wooden pile dikes created a single self-scouring navigation channel (1.8 m deep, 61 m wide), and great masses of woven-willow and lumber revetments stabilized the banks of outside bends of the channel from St. Louis to Kansas City, Missouri. The first of the main-stem reservoirs, Fort Peck, was constructed in 1937 in central Montana to provide minimum flows for downriver navigation (see Fig. 10.15). The navigation channel was subsequently expanded and extended upriver to Sioux City, Iowa, with more sophisticated engineering designs replacing wooden structures. The collective effort, referred to as the Missouri River Bank Stabilization and Navigation Project, was completed by 1981.

Flooding was historically an essential process maintaining the natural character of the river-floodplain complex but an impediment to development. Construction of federal flood-control levees began in 1947 and fostered farming the floodplain. As the societal cost of flooding increased, the Pick-Sloan Plan (1944) resulted in the construction of the five remaining main-stem Missouri River dams between 1946 and 1963 (see Table 10.1). The total storage capacity of the six reservoirs is the largest of any river in the United States (90.5 km³).

Major geomorphic changes between 1879 and 1972 occurred in the channelized river from Rkm 801 to the mouth (Funk and Robinson 1974). There was an 8% reduction in channel length, a 50% reduction in channel water surface area, a 98% reduction in island area, and an 89% reduction in the number of islands (see Fig. 10.3d).

Impoundment and flow regulation have nearly eliminated overbank flooding and sediment deposition on the floodplain in the middle and lower zones. Channel degradation and reduced rates of sandbar and island formation also occurred. For example, up to 1.8 m of bed degradation has occurred over the 32 km below Fort Randall Dam, and 3.1 m immediately below Gavins Point Dam, as substrate size has increased downstream (to gravel and cobble) since dam closure. Sediment deposition in the six main-stem reservoirs averages 113.5 km³/yr, and large deltas have built up in the upper ends of Fort Peck (42 km long), Sakakawea (61 km), Oahe (103 km), and Lewis and Clark (23 km) lakes and at the mouths of major tributaries.

Commercial navigation on the Missouri River was projected in 1939 to transport about 10.9 million metric tons of freight per year (MMt/yr), but freight actually shipped from 1954 to 1996

averaged only 1.9 MMt/yr (U.S. Army Corps of Engineers 2001). The U.S. Army Corps of Engineers (cited in National Research Council 2002) estimated that annual net benefits of full-service commercial navigation in 1995 were <\$3 million. In contrast, annual recreation benefits for 1994 from Fort Peck Lake to the mouth were estimated at \$87.1 million, with about 78% generated largely from water-based recreation *within* the interreservoir zone.

Over 1600 intakes withdraw water from the Missouri River for irrigation, domestic, municipal, and industrial uses. Twenty-five thermal electric generating stations use cooling water from main-stem reservoirs and the lower river. Collectively these plants have a gross generation capacity of about 15,000 MW (U.S. Army Corps of Engineers 2001). Hydropower at the six main-stem dams adds 2435 MW of combined capacity, producing about 10.2 million MWh/yr (see Table 10.1).

Recent events have directed national attention to the Missouri River. Declines in populations of archetypical Missouri River fishes and birds resulted in multiple listings under the Endangered Species Act (ESA) and American Rivers designated the Missouri the nation’s most endangered river in 1997 and again in 2001. Basinwide drought in the late 1980s and catastrophic flooding in the 1990s highlighted conflicts over water allocation. Socioeconomic values for the river and floodplain are shifting from agriculture and transportation to reservoir- and river-based recreation. There is a recognized need for more balance among all of the river’s designated beneficial uses. Natural resource efforts along the river are moving away from chronicling human impacts toward designing and implementing restoration programs.

Several steps have been proposed by the National Research Council (2002) to guide Missouri River recovery within a framework of multiple uses. Recovery programs are now largely directed at acquiring floodplain lands in the lower zone and reconnecting them to the river during high flows; increasing main-channel habitat complexity, particularly the amount of shallow, low-velocity water (Fig. 10.4); and modifying reservoir water management to improve recreation and restore more natural river flows while sustaining other authorized uses. The philosophy behind these recommendations and actions is that both flow and habitat restorations are needed to benefit ecological services and broaden societal benefits of the Missouri River.

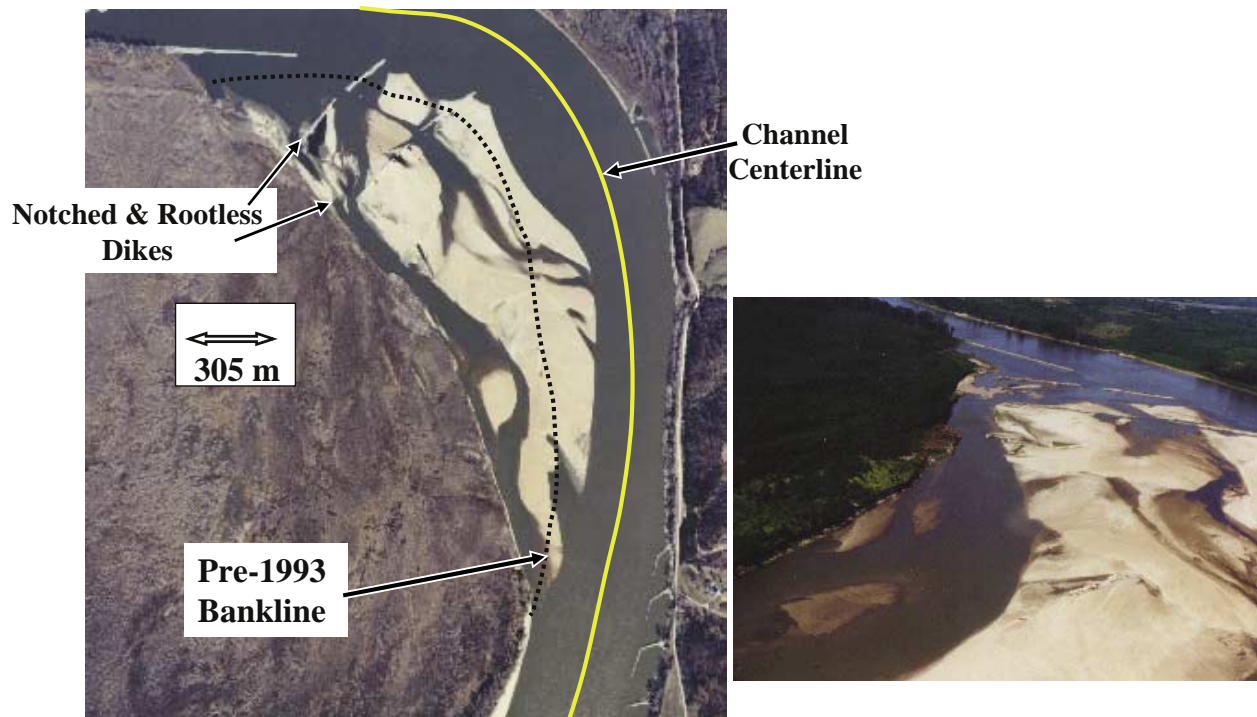

FIGURE 10.4 Notched and rootless rock dikes are used to re-create and maintain shallow-water sandbar complexes where Missouri River channel width was increased by the 1993 flood. Navigation remains along the channel centerline. Plan view (left) and oblique view (right) (From Jameson Island Unit, Big Muddy National Fish and Wildlife Refuge, Missouri, Rkm 342.7, February 2000; M. Chapman, U.S. Army Corps of Engineers, Kansas City District).

YELLOWSTONE RIVER

The Yellowstone River is the longest free-flowing river in the conterminous United States (1091 km), making it a rare model of the structure and function of large western rivers. It originates in the Absaroka Mountains in northwestern Wyoming near the southeast border of Yellowstone National Park and flows into Yellowstone Lake. From the outflow of the lake the river flows through the scenic Grand Canyon of the Yellowstone, then north and northeasterly through a drainage basin of 182,336 km² to its confluence with the Missouri River in extreme western North Dakota (Fig. 10.17). The Yellowstone has nine major tributaries, seven of which enter from the south, including the Bighorn and Powder rivers.

The origin of the name “Yellowstone,” or the explorer who first called the river Roche Jaune—yellow rock—is unknown. Some Indian tribes called it Mitsiadaz, loosely translated as Yellow Rock River (Silverman and Tomlinsen 1984). The Yellowstone Valley has a rich history. Although many Native American tribes inhabited the valley for about 12,000 years, those first encountered by explorers

were mainly nomadic Crow tribes. Captain William Clark led the first extensive exploration of the Yellowstone in 1806 during the return trip of the famous Lewis and Clark expedition. Clark described the vast abundance and diversity of wildlife and extensive cottonwood forests along the river. Although a variety of perturbations, including introduced species, water withdrawals, agricultural and energy developments, mining, and logging, have affected the Yellowstone, it retains much of the character it had in Clark’s day (White and Bramblett 1993).

Physiography, Climate, and Land Use

The Yellowstone basin includes four physiographic provinces (Wyoming Basin [WB], Northern Rocky Mountains [NR], Middle Rocky Mountains [MR], and Great Plains [GP]) that are distinctly different in structure and stratigraphy, as well as hydrology and geomorphology (see Fig. 10.17). The landscape encompasses four terrestrial ecoregions: Wyoming Basin Shrub Steppe, South Central Rockies Forests,

Montana Valley and Foothill Grasslands, and North-western Mixed Grasslands. Vegetation varies along the river corridor, from Douglas fir in the wetter upper river, to Rocky Mountain juniper in mid-reaches, to a grassland community of blue grama or western wheatgrass in east-central Montana, to green ash and bur oak in extreme eastern Montana and western North Dakota (Silverman and Tomlinsen 1984).

Elevations of the basin range from 3660m asl in alpine headwaters to less than 660m asl at the mouth, resulting in large climatic differences between headwater areas and the semiarid plains. Precipitation ranges from more than 210cm/yr in the mountains to less than 30cm/yr in the plains. Most mountain precipitation is in the form of late-winter and early-spring snow, whereas on the plains it comes primarily as early-summer rain (Fig. 10.18). Air temperatures are extremely variable. Average air temperature varies longitudinally and through time, ranging from -7°C in January to 22°C in July. The river freezes during winter and large ice jams are common.

The Yellowstone River flows through a largely rural landscape, with only one major urban area (Billings). Human population density is 10 people/km²; only 1% of lands adjoining the river are urbanized. Principal land uses are range (47%), forestry (28%), and agriculture (20%). Agricultural use includes dry-land farming and irrigated cropland along alluvial valleys and benches. About 30 active mines remove coal by strip mining in the Powder River Basin. Oil and gas production also occurs here as well as in the Big Horn basin.

River Geomorphology, Hydrology, and Chemistry

From its origin in northwest Wyoming, the Yellowstone flows into Yellowstone National Park and into a caldera created 600,000 years ago by the most recent major volcanic eruption that formed Yellowstone Lake. The river then flows through deep canyons (Grand Canyon of the Yellowstone, see Fig. 1.1) of erodible volcanic ash and forms large waterfalls in areas of more resistant lava rock (Silverman and Tomlinsen 1984). As the river leaves the mountains it flows over mainly Quaternary alluvial deposits, which are also the primary source of groundwater in the upper river (Fig. 10.1). Farther downstream on the plains the basin is underlain by Cretaceous and Tertiary sediments of alternating sandstone, shale, coal, and red klinker beds of the Fort Union Formation, which

contains the enormous coal reserves of Montana (Silverman and Tomlinsen 1984).

The general morphological character of the Yellowstone remains the same as described by Clark in 1806. Channel pattern varies from sinuous, to braided, to irregular meanders. The channel is often braided or split, particularly in the lower river, and long side channels are common. Islands and bars range from large stable islands with mature vegetation to unvegetated point and midchannel sand and gravel bars. Bed material is largely gravel and cobble in upstream reaches, grading to sand in the lower 50 km (Bramblett and White 2001, Koch et al. 1977). Slope ranges from 8.9m/km in the upper river, to 1.4m/km in the middle Yellowstone, to 46cm/km near its mouth at the North Dakota border (Koch et al. 1977).

Characteristics of the Yellowstone River that retain any of their pristine character (hydrology, geomorphology, water quality, and biotic communities) do so because the main stem is not dammed. However, 31% of the drainage basin (mostly in the Bighorn River basin) is upstream of storage reservoirs (Koch et al. 1977). Damming of the Bighorn River, the largest tributary of the Yellowstone (see Fig. 10.17) in 1966 caused an 80% reduction in annual sediment yield (over 5 million metric tons) from that basin. Koch et al. (1977) report that the Yellowstone did not show any reduction in sediment transport at the gaging station near the mouth, indicating that it may have been out of equilibrium below the Bighorn and was degrading its bed and banks to produce extra sediment. Recent evaluation of channel changes revealed that reduction in average peak flow of 255 m³/s and of channel maintenance flow of 57 m³/s (5%) have resulted in channel thread stabilization, reduction in open-bar area, and vegetation encroachment downstream of the Bighorn River confluence (Womack and Associates 2001).

The undammed Yellowstone River retains a near natural hydrograph, with a small spring rise in March in downstream areas as snow melts on the plains, followed by peak flows in June from mountain runoff and precipitation (see Fig. 10.18). The difference between runoff pattern and precipitation is due to winter storage of snow in the Rocky Mountains and the subsequent spring thaw. High spring flows are important in maintaining natural channel function. Although localized flooding occurs in winter because of ice-dam formation and breakages, spring flooding is most important in determining channel form. Average annual discharge near the mouth for the 87 years of record is 362 m³/s. The largest flow recorded

was 4500 m³/s and the smallest 13.3 m³/s. The largest mean annual flow of 560 m³/s occurred in 1997. Humans have had some impact on channel morphology, largely through bank armoring, closing side channels, and clearing bank vegetation. Following two consecutive floods in 1996 and 1997, channel training (dikes and armoring) increased substantially around population centers. For example, near Billings, channel training increased from approximately 21% in 1957 to 41% in 1999, resulting in a decrease in channel length of about 5% in this area (Aquoneering and Womack and Associates 2000).

Although water quality shows a general deterioration from source to mouth, it is generally good and free from major pollution inputs. Total suspended solids, total dissolved solids, turbidity, sulfates, and water temperature increase in the lower river. Average alkalinity is 45 mg/L as CaCO₃, pH is 7.5, NO₃-N is 0.08 mg/L, and PO₄-P is 0.03 mg/L. Dissolved oxygen levels are usually near saturation, biological oxygen demand levels indicate no major organic pollution, and fecal coliform levels are low. Dissolved metals only rarely exceed water-use criteria (Klarich and Thomas 1977; USEPA 2001 <http://www.epa.gov/storet/>). Nitrogen is the major limiting nutrient in the river; sequential inputs from tributaries and wastewater discharges had relatively high levels of total soluble inorganic nitrogen, resulting in a 6- to 17-fold increase in primary production. However, neither the productivity rates nor nitrogen and phosphorus concentrations were characteristic of eutrophication; overall, the river is best characterized as mesotrophic (Klarich 1976) or oligo-mesotrophic (Peterson et al. 2001). Nuisance algae conditions have been documented in several sections of the river, possibly indicating eutrophic conditions. Levels of organochlorine insecticides in fish tissue collected throughout the river are low compared to other sites in the Rocky Mountain area and to national statistics. The concentrations of DDT and its metabolites were highest from sites in and near Yellowstone National Park, probably due to historical DDT spraying programs for spruce budworm.

River Biodiversity and Ecology

The Yellowstone River is in the Upper Missouri freshwater ecoregion. No comprehensive studies of the ecology of the Yellowstone have been completed.

Algae

Bahls (1974) identified 28 genera of algae in three samples taken from the upper, middle, and lower Yel-

lowstone River in April. *Cladophora* was the most abundant alga by volume at all sites. As a group, diatoms were the most abundant and diverse, with 75 varieties and 23 genera identified. Further analyses of samples taken in the mid 1970s at 11 sites along the river revealed well over 100 taxa of diatoms. Relative abundance of common species changed going downstream from benthic species, including nitrogen fixers in the montane zone, to a middle-river transition mix of benthic species, including some species associated with eutrophic conditions, to a zone of more planktonic species in the lower river (David Peterson, personal communication). The algal flora at the intersection of the Bighorn River is intermediate between that of a high mountain stream and a lowland plains river, coinciding with the transition between a coldwater and warmwater environment.

Plants

Composition of riparian plant communities of the Yellowstone varies longitudinally with climate, proximity, and elevation of the site to the river channel, and disturbance caused by flooding. Pioneer plant communities on disturbed sites or newly deposited bars are typically willow, followed by cottonwood. Midsere vegetation consists of mature cottonwood forests, which persist for about 100 years. Cottonwoods form extensive forests on islands and banks of the lower Yellowstone River. River-associated wetlands support many of the globally significant plants in the watershed, notably Tweedy's rush and Rolland's scirpus (Jean and Crispin 2001).

Invertebrates

The most complete survey of macroinvertebrate communities is that of Newell (1977), who sampled 20 sites from just below Yellowstone National Park to the mouth. Newell documented a rich macroinvertebrate fauna dominated by mayflies, caddisflies, and true flies; 154 taxa of benthic macroinvertebrates were collected, although more recent collections have added to Newell's list (D. Gustafson, personal communication). Densities ranged from 12,000/m² to less than 100/m². Species richness and density declined downstream. Mayfly assemblages exhibited a gradual change from a mountain fauna in the upper river (*Baetis*, *Ephemerella*, *Epeorus*, *Ephemera*) to a prairie fauna more adapted to the slower current velocities, warmer temperatures, and finer substrates in the lower river (*Ametropus*, *Lachlania*, *Ephoron*, *Caenis*, *Centroptilum*, and *Isonychia*). Mayfly species richness ranged from 19 species upstream to 10

species in the lower river, with a total of 37 species. Stonefly richness was highest in the upper river (21), with a total of 37 species, including *Pteronarcys*, *Pteronarcella*, *Arcynopteryx*, *Paraleuctra*, *Capnia*, and *Alloperla*. The number of stonefly species declined rapidly downstream, particularly in the transition zone between coldwater and warmwater communities (*Brachyptera*, *Acroneuria*). Caddisfly distribution was similar to that of stoneflies, with a steady decline in species richness with distance downstream. *Hydropsyche* and *Cheumatopsyche* were found at all stations and dominated the macroinvertebrate fauna in the lower 10 stations. Other caddisfly genera include *Glossosoma*, *Brachycentrus*, *Neotrichia*, *Oecetis*, and *Leptocella*. True flies, particularly chironomid midges, occurred throughout the river and were the most abundant and diverse of the remaining macroinvertebrate groups. Beetles were found in all samples, odonates and true bugs were found in the transition and coldwater zones, and lepidopterans were rare.

No comprehensive studies of other invertebrate groups have been made. Only two mussel species are known to occur in the Yellowstone River. One is the common fatmucket, and the other, a recent introduction, is the mapleleaf, native to the Midwestern United States. Based on size, this mussel was first established in the Tongue River and has recently spread downstream to the Yellowstone in the vicinity of the Tongue River confluence. Other recent invertebrate introductions are the New Zealand mudsnail and the rams-horn (native to the Snake River) (D. Gustafson, personal communication).

Vertebrates

The Yellowstone River supports a diverse fish community of 56 species representing 16 families; 20 species (36%) are nonnative. Except for a few sport fishes, little is known about the ecology or demographics of most species. Based on fish species distribution, the river can be divided into three zones: an upper coldwater zone extending 357km from the headwaters to the mouth of the Boulder River, followed by a transition zone (258 km) from there to the mouth of the Bighorn River (inhabited by both coldwater and warmwater species), and a lower warmwater zone (476 km) from there to the Yellowstone mouth. Although temperature records are incomplete, maximum summer water temperatures for the three zones were 23°C, 26.5°C, and 29°C, respectively, for the period of record. Longitudinal changes in the fish community appear to correlate with water temperature. The fish community between Upper

Falls and Yellowstone Lake (part of the coldwater zone) has only two native species, Yellowstone cutthroat trout and longnose dace, and two introduced species, redbreast shiner and longnose sucker. Of the 14 fish species known to occur in the coldwater zone, only 7 are abundant in a portion or all of this reach (Yellowstone cutthroat trout, rainbow trout, brown trout, mountain whitefish, longnose sucker, white sucker, and mottled sculpin) (White and Bramblett 1993). In the transition zone the abundance of warmwater species rapidly increases downstream, totaling 30 species representing 7 families. Salmonids all but disappear, whereas goldeye and burbot abundance increases. New species include sauger, walleye, five minnows, river carpsucker, and three catfishes. The largest change in the fish community occurs in the warmwater zone where 49 species representing 15 families occur. Two sturgeons, one esocid, seven minnows, two suckers, one catfish, one killifish, one smelt, six sunfishes, and one drum first occur here (see White and Bramblett 1993 for complete listing). The most ubiquitous species is white sucker, classed as abundant in all zones. Goldeye, common carp, longnose dace, shorthead redhorse, burbot, longnose sucker, mountain sucker, rainbow trout, and brown trout also occur in all river zones.

The fish assemblage includes 15 game species, of which 7 are nonnative (rainbow trout, brown trout, brook trout, northern pike, smallmouth bass, largemouth bass, and walleye). The four trout species and mountain whitefish are the only game fishes in the upper river. The stream reach from the boundary of Yellowstone National Park to the mouth of the Boulder River is the longest single reach (166 km) of blue-ribbon trout stream in Montana, making up 23% of the state's 727 km of blue-ribbon waters (White and Bramblett 1993). Yellowstone cutthroat is the only trout native to the drainage. Habitat degradation in tributary streams, introduction of nonnative salmonids, and human exploitation have led to the reduction in range and abundance of Yellowstone cutthroat trout and to its designation as a species of special concern by the Montana Natural Heritage Program and the Montana Department of Fish, Wildlife, and Parks (2004). In addition to the greatly reduced native range, many of the remaining populations have been genetically contaminated by hybridization with rainbow trout. The recent discovery of nonnative lake trout in Yellowstone Lake has raised additional concern and a large effort to control this population is underway. Of the 10 sport fishes in the lower Yellowstone, six provide substantial angling opportunity (sauger, walleye, shovelnose

sturgeon, paddlefish, channel catfish, and burbot). Steady declines in sauger populations resulted in its designation as a Montana species of special concern in 2001. Other state species of special concern that occur in the Yellowstone are blue sucker, paddlefish, pallid sturgeon, pearl dace, sicklefin chub, and sturgeon chub. Pallid sturgeon is also federally listed as endangered.

Riparian areas are vital habitats for many amphibians, reptiles, birds, and mammals, particularly in arid and semiarid environments. One amphibian species of concern, the northern leopard frog, is known to occur in riparian and wetland habitats in the watershed (Thompson 1982). Reptiles of concern include snapping turtle and spiny softshell turtle (both directly tied to the lower river), milk snake, and western hognose snake. A study on the lower Yellowstone showed that the riparian forest had the highest avian density and diversity of 10 habitat types evaluated (Silverman and Tomlinsen 1984). Of the 35 bird species of special concern in the watershed, 31% are associated with riparian or wetland habitat (Jean and Crispin 2001). Bald eagle and piping plover are federally listed as threatened and the interior least tern is listed as endangered. Other important birds include the great blue heron and common merganser. Most neotropical migrants rely on the riparian habitat within the watershed. Noted declines in several of these species have prompted concern for neotropical migrants as a group. Although no mammal species of special concern are dependent on the riverine habitat, many mammal species inhabit or frequent the riparian area, including river otter and beaver. Grizzly bear, a federally listed species, heavily utilize Yellowstone cutthroat trout during the spring spawning period.

Ecosystem Processes

Most ecosystem processes function today as they did historically. Fire and flooding continue to influence the landscape, providing habitats for the many species adapted to these disturbances (Jean and Crispin 2001). However, there is a general lack of information on ecosystem processes in the Yellowstone River system. Preliminary data from a U.S. Geological Survey evaluation of trophic conditions, using chemical (nutrient) and biological (algal biomass and productivity) variables, indicated oligomesotrophic conditions throughout its length (D. A. Peterson, personal communication). Nuisance algal conditions associated with eutrophy, however, have been documented in several sections of the river. Periphyton chlorophyll *a* and ash-free dry weight

concentrations were largest in the middle section of the river, where *Cladophora glomerata* abundance approached nuisance proportions. Rates of stream metabolism and respiration were also largest in the middle area of the river, and productivity was associated mostly with benthic algae. Production/respiration ratios indicated autotrophic conditions in the upper river and heterotrophic conditions in the lower river. Data on functional status of macroinvertebrate communities are not yet available.

Human Impacts and Special Features

The Yellowstone River is unique among western rivers in that it has no main-stem storage or hydroelectric dams. It is among the last remaining relatively unaltered large rivers in the conterminous United States. Its upper reaches, including the spectacular Grand Canyon of the Yellowstone, are protected within Yellowstone National Park. Also, a 33 km reach of Clarks Fork, a tributary arising in the Shoshone National Forest, is protected as a National Wild and Scenic River. Such free-flowing resources, important in their own right, will be key to understanding how large western rivers function, and subsequently to mitigation efforts in the Missouri River basin (White and Bramblett 1993).

Although relatively pristine compared to other large rivers in the coterminous United States, the Yellowstone is not without human impacts. Channel modification has been minimal but has accelerated in recent years, especially in the upper river. Bank armoring, closing side channels, and clearing riparian vegetation have affected channel characteristics locally. Downstream of the confluence of the Bighorn River the Yellowstone may be narrowing and deepening due to modification of sediment dynamics and flow pattern resulting from Yellowtail and Tongue river dams.

Large amounts of water are withdrawn from the river for irrigation. About 90% of all water use in the basin is for this purpose. Many tributary streams that are important as spawning habitat for migratory fish species are severely dewatered. In 1973 the Montana Water Use Act was passed, which allowed instream-flow advocates to compete with consumptive users for unreserved water. In 1978, 6.8 km³ of water at Sidney, Montana, was reserved for the Yellowstone. In addition, legislation to allow a pilot program of water leasing for instream use was passed in 1989. The first leases were on tributaries of the upper Yellowstone and the success of that program is being evaluated.

Although the Yellowstone has no dams on the main stem, there are three major cross-channel water-diversion structures in the lower river that are known to influence upstream movement of paddlefish, sturgeon, sauger, and walleye. Most other species would probably have difficulty passing upstream of these structures as well (White and Bramblett 1993). A fish passage structure was recently built at Huntley Diversion, and research on design criteria for passage of sturgeon around Intake Diversion is currently being conducted.

Nonnative species have contributed to the decline of some native fishes. Rainbow and brown trout have had a major impact on the abundance and distribution of native Yellowstone cutthroat trout in the river and its tributaries, and lake trout are thought to be having a negative impact in Yellowstone Lake. Other introduced species, such as walleye, may be influencing the abundance of native species like sauger, but little attention has been given to native–nonnative species interactions. *Myxobolus cerebralis* (a myxozoan parasite), the causative agent of whirling disease, was recently detected in the upper Yellowstone Basin. This organism is thought to be responsible for the large decline in nonnative rainbow trout populations in many Montana rivers, and native Yellowstone cutthroat trout are known to be susceptible to infection. Also, the recent discovery of the New Zealand mud snail is of considerable ecological concern.

Natural values that make the Yellowstone so attractive to humans are being affected by activities such as subdivisions on agricultural lands, overuse of water, and alteration of natural habitats by noxious weeds, nonnative species, and recreation. Considerable effort to reduce habitat loss and fragmentation is occurring in the form of land trusts dedicated to open space (Jean and Crispin 2001). In 1997, through executive order, the governor of Montana established a task force to develop a set of publicly supported river-corridor management recommendations that address potential adverse cumulative effects of channel modification, floodplain development, and natural events on the human community and riparian ecosystem. A number of research projects are currently ongoing (Governor's Upper Yellowstone River Task Force 2000).

WHITE RIVER

The 816km long White River (25,650 km²) originates in the pine ridge region (Sioux, Dawes,

Sheridan counties) of northwestern Nebraska and flows eastward through south-central South Dakota to its confluence with Lake Francis Case, a main-stem impoundment on the Missouri River (Fig. 10.19). The White River is a 6th order interjurisdictional river. It is an interstate river that also runs through the Pine Ridge and Rosebud Indian reservations, through national grasslands, forests, and wilderness areas (U.S. Forest Service), LaCreek National Wildlife Refuge (U.S. Fish and Wildlife Service) and Badlands National Park (National Park Service) (Fig. 10.5). The White River has been listed as one of 327 rivers in the United States that are critical for protecting freshwater biodiversity (Master et al. 1998).

One of the longest undammed rivers in the conterminous 48 states (Stanford and Ward 1979, Benke 1990), the White River is named for its white-gray color, derived from the heavy load of sands, clays, and volcanic ash in the middle and lower segments. Through geologic time, erosion in the White River basin has created a special landscape revealing rich fossil beds, sharp ridges and spires, and flat prairie grasslands through which winds a sinuous green riparian zone marking the course of the White River. The largest tributary, the Little White River (4100 km²) is also unique because its origin in Nebraska's sand hills causes more stable flows, higher gradient, and cooler water temperatures than in the main stem. The Little White River is so scenic as it passes through the LaCreek National Wildlife Refuge and Rosebud Sioux Reservation that it is included in canoeing guides.

The basin has supported humans for 12,000 years, beginning with ancient mammoth hunters who were followed much later by Paleo-Indian hunter-gatherers and then by the Arikara (or Ree) and Dakota peoples in the sixteenth century. Bands of the Teton tribe of the Dakota Sioux Nation dominated the basin for about 100 years before the arrival of fur trappers, soldiers, miners, cattlemen, and homesteaders in the 1800s. The attention of the United States was focused on Dakota Territory in the late 1800s when fully one-third of the U.S. Army was in combat with the Dakota Sioux Nation. The symbolic end of the war occurred in the White River basin in 1890 with the Indian massacre at Wounded Knee, after which the Dakota people were confined to reservations that make up a large part of the basin today. During the Dakota Land Boom (1878 to 1887), pioneer settlers called the area a "sea of grass" as they established ranches, which now average from 900 ha (lower basin) to 3600 ha (upper basin) each.

FIGURE 10.5 White River, Pennington County, South Dakota, near border of Pine Ridge Indian Reservation and Badlands National Park; white mineral deposits are visible on the banks (PHOTO BY C. BERRY).

Physiography, Climate, and Land Use

The White River basin is in the unglaciated Pierre Hills and Southern Plateau regions of the Missouri Plateau section of the Great Plains (GP) physiographic province (Hunt 1974, Hogan 1995). The basin lies primarily in the Northwestern Mixed Grasslands ecoregion, with a small portion of its headwaters within the Western Short Grasslands ecoregion. Chestnut soils and steppe vegetation (short to midgrasses such as buffalo, blue, and wheat grasses) develop on a landscape that drops in a series of steps and hills from the high-plains prairie in Nebraska (1485 m asl) to the confluence with the Missouri River (402 m asl).

The Dry Continental climate features hot summers and cold winters, with great daily temperature range (average monthly range 15°C). Mean annual temperature is 8.8°C, with mean monthly variation from -8°C in January to 24°C in July and August (Fig. 10.20). Mean January air temperatures ranged from -0.6°C to -13.9°C over a seven-year period when average river ice thickness ranged from 0.1 to 1.0 m (Ferrick et al. 1995). Precipitation is very

seasonal, with at least 5 cm/mo from April to August and only 1 to 2 cm/mo from November through February (see Fig. 10.20). Thunderstorms account for 85% of the precipitation.

There are no municipalities adjacent to the river and few in the basin. The largest towns are Chadron, Nebraska (about 6000), and Winner, South Dakota (about 3500). Population density varies from 0.3 to 3.0 people/km², depending on county. About 73% of the basin is in native grass or hay (e.g., alfalfa) and about 21% is in row crops, dominated by wheat with some sorghum, corn, oats, sunflowers, and soybeans. Land use in riparian zones at 11 reaches in South Dakota (Fryda 2001) was mostly pasture or prairie (66%), followed by 22% cropland and 10% wooded.

River Geomorphology, Hydrology, and Chemistry

The basin is divided into four eight-digit hydrologic units representing the upper, middle, and lower river main stem and the Little White River. The gradient

is about 170 cm/km in the upper unit, 60 cm/km in the middle unit, and 50 cm/km in the lower unit. Riverine habitat data are available only for the South Dakota main stem (Fryda 2001). The river at bank-full is about 7 m wide at the Nebraska–South Dakota border and about 120 m wide near the terminus, but widths downstream from the Little White River increase from about 50 m to 110 m. The dominant riverine macrohabitat is the run (80%), followed by riffle (19%) and pool (1%). Instream cover (e.g., woody debris, undercut banks, cobble substrate) is scarce except at certain reaches near the state border. Gravel-size substrates dominate (60%) upper-river reaches and decline to about 30% in the lower White, where fines (silt, sand, clay) become increasingly prevalent and the alluvium is 7.5 to 12.5 m deep over Pierre shale (Ferrick et al. 1995, Fryda 2001). The channel is highly mobile within the floodplain, and aerial photos of one reach showed four abandoned channel segments since 1986 (Fryda 2001). Sinuosity values range between 2.1 and 2.5. The main-stem channel at 11 reaches in South Dakota was classified as entrenched (Fryda 2001).

Most stream flow occurs in response to precipitation and snowmelt during spring and early summer, with peaks in both March and May–June (about 38 m³/s) and low flows (e.g., 2 m³/s) in January (see Fig. 10.20). Runoff averages only 0.17 cm/mo due to low precipitation and high evapotranspiration. Annual discharge was about 16 m³/s (range 4.3 to 49 m³/s) between 1928 and 1997, but water yield differs among subbasins because near-surface geology differs (Ellis et al. 1971). Tributaries are unreliable sources of water year-round, but flows are more stable in the upper main stem (Nebraska) and four creeks. The river is subject to periods of no flow in its middle segment, where it is perched (Ferrick et al. 1995); however it has been perennial since 1928 in the upper and lower basin except for five years. When river flow ceases, deep pools remain wet, reflecting the water-table level. Groundwater level is below the river surface during dry seasons and rises to river level during wet seasons (Ferrick et al. 1995). In the summer months of 1999–2000, velocity was 0.2 to 0.3 m/s at 0.3 to 1.2 m³/s discharge in the upper hydrologic unit and was 0.45 to 0.55 m/s at 3.6 to 11.1 m³/s in the lower unit (Fryda 2001).

The harsh physical conditions of the White River are largely responsible for its poor water quality. As a result, the basin fails to support designated beneficial uses (i.e., limited contact recreation, warmwater semipermanent fish-life propagation) and has been listed as an impaired water body, but it is excluded

from the Federal Total Maximum Daily Load program because the majority of its impairment is from natural sources (DENR 1998). The highly erosive soils in the badlands cause high suspended sediment levels and are the major source of poor water quality. Secchi depths of <5 cm are common. Upstream from the Badlands, suspended sediment concentrations average less than 250 mg/L, whereas downstream suspended sediment concentrations often exceed 5000 mg/L. Over 9.9 million metric tons of sediment is deposited annually into Lake Francis Case, where a substantial delta has formed. The delta partially blocks flow through the lake and has reduced reservoir capacity by about 10% since its creation in 1952. Elevated levels of total dissolved solids (270 to 540 mg/L), fecal coliforms, and pH (8.2 to 9.3) also contribute to nonsupport of designated uses and are highly influenced by runoff. During June, July, and August 1999–2000, dissolved oxygen ranged from 7 to 8 mg/L, morning water temperatures ranged from 18°C to 25°C, and afternoon temperatures ranged from 24°C to 34°C (Fryda 2001). Riparian shading in upstream reaches causes less diel variation in stream temperature than in downstream reaches, where summer temperatures varied about 10°C daily and reached 34°C, which is stressful to some fishes (Fryda 2001).

The Little White River is quite different than the main stem because it originates in sandhill terrain and drains mixed-grass prairie. Gradient ranges from 1.3 to 2.6 m/km, so the Little White meanders less (sinuosity 1.4 to 1.8) than the main stem. Hydrology is groundwater dominated, with high single-peak (March or April) spring flows. Average annual discharge is about 3.2 m³/s (Niehus 1999); winter discharges are about 2.6 m³/s, which accounts for most of the main-stem flow. Water quality is much better than in the main stem except in the lower Little White basin, where erosive badlands soils are intercepted and TSS concentrations become excessive (DENR 2000). Average water-quality values for selected characteristics at the Little White terminus are hardness 142 mg/L as CaCO₃, dissolved solids 282 mg/L, suspended sediment 1096 mg/L, NH₄-N 1.6 mg/L, and NO₃-N 1.8 mg/L (Niehus 1999).

River Biodiversity and Ecology

The White River is within the Upper Missouri freshwater ecoregion (Abell et al. 2000). As a river with harsh physical conditions in a rural environment, its biology and ecology are not well studied.

Plants

Submersed and emergent vegetation is rare in the White (Fryda 2001). Riparian vegetation includes grasses (41%), willows (36%), and other shrubs and trees (cottonwood, horsetail, green ash, wild grape, box elder, Russian olive, wild rose).

Invertebrates

Incidental observations of two mussel species (floater, fatmucket) in the upper basin were made during recent fisheries surveys, but no detailed invertebrate surveys have been done. However, a cursory survey of the adjacent river (Cheyenne) found representatives of four dipteran families (primarily chironomid midges and black flies), four families of mayflies (mostly Leptophlebiidae and Baetidae), many hydropsychid caddisflies, and a few elmids beetles and stoneflies (Hampton and Berry 1997).

Vertebrates

In spite of its harsh conditions, 41 native fish species are found in the White River, as are 8 non-natives (common carp, brown trout, rainbow trout, brook trout, black crappie, white crappie, largemouth bass, and bluegill), which are rarely found except for common carp (Fryda 2001). Ubiquitous species found in both states in the main river and in tributaries are channel catfish, green sunfish, long-nose dace, sand shiner, and white sucker. Relative composition of the species representing >1% of recent samples (Fryda 2001) from the South Dakota portion of the main river was flathead chub (44%), channel catfish (22%), plains minnow (13%), fathead minnow (6%), sturgeon chub (4%), common carp (3%), sand shiner (2%), Western silvery minnow (2%), and goldeye and stonecat (1% each). Sturgeon chub, flathead chub, and plains minnows have declined in other parts of the Missouri River basin. There are no federally listed species, but nine species are listed as state species of concern, mostly because of the number of glacial relicts and species on the edge of their range.

Certain fish assemblages have specific geographic associations within the basin. The spring-fed stable flows in the upper basin support introduced trout and mountain sucker, a relict species. The lower main stem is used by large Missouri River species (e.g., paddlefish, flathead catfish). The Little White River has glacial relict species and other natives that are adapted to clear headwater streams (e.g., pearl dace, finescale dace, blacknose dace, blacknose shiner, northern redbelly dace, central stoneroller). A

connection may have existed between the headwaters of the Little White River and the Niobrara River; hence the presence of the plains topminnow and bigmouth shiner (Mayden 1987).

Channel catfish make up 22% of the catch in hoop nets and seines (Fryda 2001). Ages ranged from 1 to 13 years, but 81% were less than 5 years old and 80% were <280 mm long. Relative weights (W_r) were 97, 79, and 85 for three length groups (<280, 281 to 410, 411 to 610 mm), which is a common pattern for regional populations (Doorenbos et al. 1999). However, growth was slow compared to other river populations in the region, especially for fish <4 years old. Channel catfish support a limited recreational fishery.

Two of South Dakota's seven turtle species (common snapping turtle, spiny softshell turtle) were collected in fish traps (Fryda 2001), and the Western painted turtle occurs in the basin. Five amphibians (e.g., northern leopard frog, bullfrog, Great Plains toad, chorus frog, Woodhouse's toad) and the tiger salamander occur in floodplain wetlands adjacent to the White River (Fischer et al. 1999).

Ecosystem Processes

Dominant factors controlling ecological processes and community structure in most of the main stem of the White River are a "harsh intermittent" or "intermittent runoff" discharge regime (Poff 1996) and unusually high turbidity. Exceptions are in the main-stem headwaters (Nebraska) and in the Little White River, where soils are less erosive and discharges more stable than in the main stem. Although no studies have been done on ecological processes, limited biological data conform to the hypothesis that abiotic controls dominate. For example, depauperate mussel fauna have been associated with high turbidity, suspended solids, and unstable substrates (Hoke 1983). The fish community, represented by channel catfish, cyprinids, and suckers, is typical of low-gradient, high-turbidity warmwater rivers (the type III river of Rabeni 1993). Species richness ($n = 49$) and fish feeding guilds (mostly insectivores and omnivores) are similar to communities in adjacent basins (Hampton and Berry 1997). Native fish species (e.g., sturgeon chub, flathead chub) with special adaptations to turbid conditions are present, and many fishes are classed as tolerant or moderately tolerant of environmental degradation (Barbour et al. 1999). More benign conditions in the headwaters and Little White River allow survival of coldwater species and glacial relicts.

Population data for channel catfish suggests poor habitat quality. The lack of pool habitat probably limits the density of large channel catfish, but the abundant run and riffle habitats are suitable for smaller fish and young year classes, which were more abundant than expected (Fryda 2001). The White River is probably a nursery area for channel catfish and other species (e.g., flathead catfish, paddlefish) from Lake Francis Case.

The slow growth rate of the channel catfish suggests that productivity may be limited. High turbidity, harsh flow, sand substrate, and lack of instream structure probably limit autotrophic productivity and macroinvertebrate community biomass, which makes up a large part of the diet of young channel catfish. Allochthonous inputs may also be limited. Although there is annual floodplain inundation, the frequency can be low and the duration short, depending on river segment (S. Sando, personal communication), and riparian zones and floodplains are dominated by grasses that yield small inputs of coarse organic matter and woody debris compared to forested areas. The relatively high water temperatures during summer equal or exceed the optimum for channel catfish growth (Fryda 2001).

Human Impacts and Special Features

The remote, sparsely populated White River basin is unique because of the natural beauty of hills, plateaus, tablelands and badlands topography (so named because of the lack of water and vegetation), the rugged landscape, and the hindrances to travel and agriculture. The unimpounded, free-flowing river is unique because the headwaters are relatively cool and clear compared to the warm, exceedingly turbid main stem, where harsh physical conditions challenge survival.

Human impacts have been negligible in the basin, except for poor range management in some areas. Watershed management is underway to reduce the amounts of suspended solids and fecal coliforms, especially in the middle and lower basin (DENR 2000). Livestock grazing impacts on riparian vegetation were judged low to moderate at 96% of transects measured by Fryda (2001). Trace metals were not found in sediments (Ruelle et al. 1993). Elevated levels of arsenic occur in groundwater wells in the Little White River basin but not in surface waters (USGS 1998). There are no main-stem dams or other impediments to fish migration. Stock dams (about 1120) and small reservoirs (about 20) have been constructed on tributaries, but about 6000 1st and 2nd

order streams remain unimpounded. A preliminary analysis of monthly flows before and after 1950 did not indicate that main-stem discharges had changed. However, 156 irrigation appropriations in Nebraska have decreased virgin (natural) flows entering South Dakota by about 11 million m³ (Sando 1991). Fish biomonitoring data indicate that all fish species found in historical studies (e.g., Bailey and Allum 1962) are still extant, although historical data are limited (Fryda 2001).

PLATTE RIVER

From its headwaters in the Southern Rocky Mountains and the Wyoming Basin, the Platte River sweeps easterly across the Great Plains as a river of sand festooned with interlacing ribbons of water to its confluence with the Missouri River (Fig. 10.21). For about half of its length the Platte is really two rivers: the North Platte, which primarily drains southeastern Wyoming, and the South Platte, which primarily drains north-central Colorado. Their confluence does not occur until these rivers have independently traversed their way halfway across the Great Plains to the city of North Platte, Nebraska. Within its total drainage of 230,362 km² the Platte River system traverses montane, foothills, and plains habitats before reaching the Missouri River just south of Omaha, Nebraska (Fig. 10.6).

Spaniards were apparently the first Europeans to see the Platte River. In 1720 an expedition under the direction of Villazur was massacred near the present site of Columbus, Nebraska. It is designated on early maps as either the Platte River or the Nebraska River, names derived from the 1739 French designation “La Riviere Plate” (Flat River), which corresponds in meaning to the Oto (*Ni brathka*), Omaha (*Ni bthaska ke*) and Pawnee (*Kits Katus*) Indian names for the stream, all of which mean “flat water” (Link 1933). Other names for the Platte include the Dakota name (*Pankeska wakpa*), which refers to its importance as a site for the trading for shells (Link 1933).

Physiography, Climate, and Land Use

The Platte basin begins in the Southern Rocky Mountains (SR) and Wyoming Basin (WB) physiographic provinces in the west, spans the entire width of the Great Plains (GP), and includes a small portion of the Central Lowland (CL) province in the east (see Fig. 10.21). The North Platte and South Platte rivers and their tributaries are the modern remnants of drainage

FIGURE 10.6 Platte River near North Bend, Nebraska (PHOTO BY E. PETERS).

systems that transported vast quantities of alluvial materials from the Rocky Mountains, uplifted approximately 60 million years ago, to the plains of what is now Nebraska during the early Cenozoic era. During the Pleistocene, wind-deposited and -rearranged sediments ranging from sand in the west to loess in the east covered much of the Platte River basin across the Great Plains (Swinehart and Diffendal 1989). For most of the past 5 million years regional uplift has resulted in channel degradation and provided abundant sediments for the Platte. Soils in the drainage are generally mollisols, with entisols appearing in areas of most recent sand deposition. In the headwaters, alfisols (boralfs) have developed in steeply sloping forested regions.

The Platte basin includes parts of five terrestrial ecoregions. The headwaters of both the North Platte and South Platte rise in the Colorado Rockies Forests ecoregion, vegetated by conifers such as Douglas fir and ponderosa pine, as well as stands of aspen and mountain meadows and foothill grasslands (Ricketts et al. 1999). The North Platte then flows through the arid Wyoming Basin Shrub Steppe ecore-

gion, where sagebrush, wheatgrasses, or fescue are common. Both the North and South Platte flow eastward across the Western Short Grasslands ecoregion, with its grama and buffalo grass. As it continues eastward the Platte crosses the Nebraska Sand Hills Mixed Grasslands ecoregion and the Central and Southern Mixed Grasslands ecoregion and terminates at the Missouri River in the Central Tall Grasslands ecoregion. There is a transition of dominant grasses capable of surviving low precipitation (sand bluestem, little bluestem, western wheatgrass) to those that require greater precipitation (big bluestem, switchgrass, and Indian grass).

The climate of the Platte River basin is generally continental, with wide variations in temperature and precipitation. Precipitation ranges from an average of about 76 cm/yr near the mouth of the Platte, to 50 cm/yr at North Platte, Nebraska, to approximately 25 cm/yr in central Wyoming, to over 100 cm/yr in mountain areas of central Colorado. However, high-intensity rainfall events and droughts produce wide annual variations around these means. At North Platte, Nebraska, average monthly rainfall totals are

greatest during May, June, and July, when they average approximately 8 cm/mo, and least during December and January, when they average barely 1 cm/mo (Fig. 10.22). Average annual temperatures range from about 11°C in the eastern portion of the drainage to 9.1°C at North Platte and 3°C in the western headwater portion of the drainage. At North Platte, mean monthly air temperature is highest in July at 23.3°C and lowest in January at -5.2°C (see Fig. 10.22). The frost-free growing season ranges from less than 120 days in the west to over 160 days in the eastern portion of the basin. Another major climatic factor in the Platte River basin is the wind, which contributes to high evapotranspiration rates.

Land use in the basin is dominated by agriculture (>90%), with concentrated areas of urbanization along the river and the Front Range in Colorado. East of 100°W longitude (near North Platte, Nebraska) dry-land row crops of corn and soybeans dominate, whereas to the west wheat and livestock grazing are more important. Irrigation technologies have fostered expanded corn production to the west and increased yields throughout the basin. Forestry land use is mostly confined to montane coniferous forests of Colorado and Wyoming, but timber harvest utilizing riparian cottonwood forests along the river occurs in Nebraska.

River Geomorphology, Hydrology, and Chemistry

Both the North Platte and South Platte rivers begin in the Rocky Mountains in Colorado as incised high-gradient mountain streams. However, after they emerge from the mountains, and for their entire length across the Great Plains, they typically exhibit wide shallow braided channels with shifting sand and gravel substrates. Eastern tributaries that drain sandy and loess soils contribute finer textured materials to the Platte. Therefore, there is a general decrease in substrate particle size from west to east.

The North Platte River originates from snowmelt in northern Colorado at an elevation of approximately 3353 m asl. It flows northward into Wyoming, joins with the Sweetwater River in the Wyoming Basin province, and curves southeastward toward the panhandle of Nebraska, joining the South Platte at an elevation of 841 m asl. It traverses 1070 km, with an average slope of 2.35 m/km, and drains approximately 90,352 km². The South Platte River originates in central Colorado at an elevation of approximately 3810 m asl and after leaving the mountains flows

generally northeast to its confluence with the North Platte. Its average slope is 4.10 m/km over its 724 km length, and it drains approximately 62,888 km².

The Platte River proper begins at the confluence of the North Platte River and the South Platte River on the Great Plains near the city of North Platte, Nebraska. It flows generally eastward in a S-shaped course for 503 km, with an average slope of 1.11 m/km, until it reaches the Missouri River at an elevation of 286 m asl. The Platte and its tributaries in this 503 km reach drain an additional 77,122 km². Most of this area is in the Loup River, Elkhorn River, and Salt Creek drainages, which join the Platte in the lower 170 km of its length.

In pre-European settlement times, Platte River flow patterns were dominated by snowmelt in the Rockies, which produced high discharge in late spring and early summer, followed by low flows in late summer and early fall. This pattern was probably punctuated, as it is today, by spikes of flooding caused by localized heavy rain events. During times of drought, flows in the Platte River may have reduced it to a trickle or isolated pools upstream from the mouth of the Loup River (Zorich and Associates 1988), but downstream consistent flows from the groundwater-fed Loup and Elkhorn rivers likely kept the Platte flowing.

Average annual discharge near the mouth (Louisville, Nebraska) from 1953 to 2004 was 202.7 m³/s, but diversions, dams, transbasin diversions, power developments, and groundwater withdrawals influence these flows. Mean monthly discharge from 1953 to 2000 ranged from 119.4 m³/s (runoff 0.17 cm/mo) in August to 325.6 m³/s (runoff 0.46 cm/mo) in March and June (see Fig. 10.22). The March high flow corresponds to snowmelt in the Great Plains, whereas June high flow results from a combination of Rocky Mountain snowmelt and runoff from rain within the basin. The low coincides with heavy irrigation demands during August.

It is difficult to find preirrigation flow data for the Platte, but flows in the North Platte River near North Platte, Nebraska, from 1896 to 1942 averaged 74.1 m³/s and since 1943 averaged 21.9 m³/s. The closing and filling of Lake McConaughy occurred upstream of North Platte in 1943, but after the construction of four other North Platte River dams in Wyoming. South Platte flows have been augmented since before 1900 by transmountain diversions from the Colorado River drainage, which average approximately 3.7×10^8 m³/yr, making it difficult to interpret the hydrograph. A significant portion of the base flow of the Platte River comes from the

groundwater-fed Loup and Elkhorn rivers, which exhibit some of the most stable flows of any rivers in the world (Bentall 1989).

Over most of its length the Platte River is generally a warm, turbid, slightly alkaline river. Temperatures range up to 36°C, suspended solids concentrations range up to 11,600 mg/L, and specific conductance readings of 3450 $\mu\text{S}/\text{cm}$ have been recorded. Yu (1996) found that from 1987 to 1993, temperature and conductivity tended to be lower during years of higher discharge, whereas suspended solids concentrations tended to be higher. Median pH is 8.1, but pH values range from 6.0 to 9.0. Total alkalinity averages 153.5 mg/L as CaCO_3 . Annual median $\text{NO}_3\text{-N}$ concentrations range from 0.68 to 1.4 mg/L (Frenzel et al. 1998) and total $\text{PO}_4\text{-P}$ concentrations average 0.73 mg/L.

River Biodiversity and Ecology

The Platte River basin lies within the Middle Missouri freshwater ecoregion. Changes in slope, substrate, temperature, and riparian vegetation from its headwaters to its mouth have considerable influence on the biodiversity and ecology of individual Platte River segments. The coarse substrate, steep slope, and conifer-dominated headwater reaches contrast with the fine shifting substrates, shallow slopes, and deciduous forest riparian vegetation in the lower basin.

Algae

Dominant algal genera in the Platte River include *Cyclotella* and *Fragilaria* (Bacillariophyta), *Scenedesmus* and *Dictyosphaerium* (Chlorophyta), and *Oscillatoria*, *Anabaena*, and *Agmenellum* (Cyanophyta).

Plants

Aquatic macrophytes are not a common feature of the Platte River, but backwater areas support stands of cattail, waterweed, and pondweed. Riparian plant species vary from east to west, but cottonwood, willows, and box elder are common along most of the Platte. The extent and density of woody riparian cover along the Platte prior to European settlement is a matter of contention among ecologists and habitat managers.

Invertebrates

Aquatic invertebrates of the Platte River in Nebraska include 18 species of unionid mollusks (Hoke 1995) and 63 taxa of insects (McBride 1995).

Common insects include mayflies (*Caenis*, *Tricorythodes*, and *Heptagenia*), stoneflies (*Isoperla*), odonates (*Argia* and *Gomphus*), true bugs (Corixidae and Gerriidae), beetles (Elmidae and Dytiscidae), caddisflies (*Hydropsyche* and *Cheumatopsyche*), and chironomid midges (*Dicrotendipes*, *Cladotanytarsus*, and *Rheotanytarsus*). Most are classified in the collector-gatherer or collector-filterer functional feeding groups and occupy shoreline habitats rather than shifting sand bar habitats. Analysis of macroinvertebrate densities in the Platte River downstream from the mouth of the Loup (Peters et al. 1989) found that rock substrates supported the highest numbers of individuals per unit area (65,245/m²), with most being chironomids and caddisflies. Invertebrate densities on sand, gravel, silt, and wood substrates were 8218/m², 7576/m², 6610/m², and 6572/m², respectively.

Comparisons of the current invertebrate community structure in the Platte River to the community prior to European settlement are problematic. Today, woody debris is an important substrate for aquatic invertebrates, but debate continues on whether woody plants composed a significant portion of historical Platte River vegetation. However, rock substrate in the lower Platte was virtually absent and this is apparently important to the fauna today.

Vertebrates

The fish fauna of the Platte River includes 100 species comprising 20 families, of which 76 are native to at least a portion of the basin (Peters and Schainost 2005). Flood flows with high turbidity followed by low flows with high water temperatures impose special restrictions on the biota of the Platte River. Many native main-stream species in the Platte, including red shiner, sand shiner, river shiner, bigmouth shiner, western silvery minnow, plains minnow, speckled chub, flathead chub, river carp-sucker, quillback, and channel catfish, are adapted to these conditions. Pre-1900 records also indicate that several species, such as shovelnose sturgeon, sturgeon chub, and sauger, were found in the Platte River drainage as far west as Wyoming (Baxter and Stone 1995) but have been extirpated from the North Platte basin. Headwater, tributary, and spring-fed side channel reaches support species that require clear and/or coolwater conditions. Some, such as lake chub, have been extirpated from the basin, but others, such as northern redbelly dace, finescale dace, hornyhead chub, plains topminnow, and Topeka shiner, are found in isolated populations in the drainage. In general, the number of native species declines in the

western portion of the basin, where 30 native species have been recorded in the North Platte basin in Wyoming and 26 species have been recorded in the South Platte in Colorado. In addition, the proportion of nonnative species increases to almost 50% in the North Platte in Wyoming and 41% in the South Platte basin in Colorado (Peters and Schainost in press). By contrast, the South Platte River tributaries are the only localities for the endangered greenback cutthroat trout, the only salmonid native to the basin (Behnke 1992). Species characteristic of the main-stem Missouri River, such as paddlefish, lake sturgeon, pallid sturgeon, shovelnose sturgeon, longnose gar, shortnose gar, and goldeye occur in the lower 100 km of the Platte River, along with big-river suckers (bigmouth buffalo, smallmouth buffalo, and blue sucker) and turbid river chubs (flathead chub, sicklefin chub, sturgeon chub, and speckled chub) (Peters and Schainost in press). Today, channel catfish are probably the most sought after sport fish of the Platte River drainage, whereas shallow-water minnows, including red shiner, sand shiner, river shiner, western silvery minnow, and plains minnow, compose the numerically most abundant species (Peters et al. 1989, Yu 1996). Side-channel and backwater habitats include both plains killifish and plains topminnow, the latter being nearly endemic to the Platte drainage (Lynch 1988).

The 24 nonnative fish species introduced to the Platte drainage include the common carp and widely stocked game fish species like walleye, largemouth bass, and bluegill. Brook trout, brown trout, and rainbow trout populations are either maintained by regular stocking or are self-sustaining in headwater tributaries, cool spring-fed reaches, and deep reservoirs. These species may compete with the native greenback cutthroat trout in Colorado. Other species, such as the western mosquitofish (Lynch 1988) and Asiatic carps, are threatening native species through competition for food resources and predation on larvae and fry.

Herpetofauna of the Platte drainage includes salamanders (2 species), frogs and toads (11), turtles (8), lizards (11), and snakes (29). The most common representatives of these groups along the Platte River are the tiger salamander, Woodhouse's toad, chorus frog, painted turtle, and spiny softshell turtle.

Records for 409 species of birds have been confirmed from the Platte River drainage, and of these at least 208 species have been confirmed nesting in the area. This list includes wood warblers (41 species), shorebirds (40), waterfowl (35), and emberizid finches (32). Probably the most spectacular avian

display along the Platte is the nearly 500,000 sandhill cranes that stage in their northward migration in the 200 km downstream from North Platte, Nebraska, each spring. Added to this are concentrations of snow geese, other waterfowl, and shorebirds that use the wet meadow complexes associated with the Platte River. In addition, beaver, muskrat, and river otter are found along the river.

Ecosystem Processes

We are aware of no studies of ecosystem processes for the Platte River, but the relative abundance of collector-filterer and collector-gatherer functional feeding groups among the invertebrates point to a mix of allochthonous and autochthonous organic inputs for the food chains (McBride 1995). The numerically most abundant fishes include plains minnow and western silvery minnow, which are primarily herbivorous, and red shiner, river shiner, and sand shiners, which are primarily insectivorous. In addition, larger fishes represented by the omnivorous carpsuckers, insectivorous shovelnose sturgeon, and piscivorous gars and large catfish are important links in the Platte's food web. The broad expanses of sandbars and shallow water in the Platte also provide energy resources critical to migratory species of waterfowl and shorebirds.

Human Impacts and Special Features

Prior to European settlement the Platte River conducted the meltwater-rich flows from the Rocky Mountains onto the drier Great Plains in a seasonal pulse that fostered a rich diversity and abundance of animal and plant life. The drainage was populated by farming cultures (Pawnee and Otoe) in the east and nomadic bison-hunting cultures (Arapaho, Cheyenne, and Dakota) in the west. The river also provided additional resources from fishes, migratory waterfowl, and freshwater clams, all of which have been found in middens along the Platte.

Initial European settlements along the Platte began by the 1850s and the first irrigation canal in Nebraska was dug in 1863. Irrigation development along the North Platte River installed diversions that totaled over 56.6 m³/s by 1890 (Kepfield 1994). The push for more irrigation along the North Platte led to the construction of Pathfinder Dam upstream of Casper, Wyoming, in 1909. This was the first of five North Platte main-stem dams that concluded with the construction of Lake McConaughy in 1943. These reservoirs, diversions, canals, and off-channel impoundments that store water for irrigation and

power generation have altered the flow regime of the North Platte River. In addition, tailrace areas below reservoirs have been changed from warmwater or coolwater to coldwater habitats that support introduced salmonids.

Extensive water diversions for mining, agricultural, and municipal uses occurred by 1858 with the discovery of gold in the South Platte basin, which apparently supported the only native trout population (greenback cutthroat). However, flows in the South Platte and several major tributaries, including the Cache la Poudre River, have been augmented by diversions from the Colorado River drainage; much of this is stored in a series of off-channel reservoirs to be used for municipal systems in Colorado. Virtually all of the flow of the South Platte River is diverted for use by the Denver metropolitan area and virtually all of the downstream flow resumes from sewage treatment facilities.

Flow is controlled and depleted by diversions downstream from the confluence of the North Platte and South Platte rivers into a series of irrigation and power generation canals that parallel the Platte. Flows from the Loup and Elkhorn basins into the lower Platte are also diminished by diversions and groundwater withdrawals in the alluvial aquifer. Instream flow water rights have been granted in the Platte River in Nebraska to protect habitat for endangered whooping crane and for fish populations, including the endangered pallid sturgeon, in downstream reaches. These flows are also important to the water supplies for the cities of Lincoln and Omaha, Nebraska.

Channelization is an important disturbance on tributaries, but bank stabilization is probably a more important perturbation on the main channels of the Platte because revetments and wing dikes also act to restrict the channel. Channels have been narrowed from 40% to 60% of their historical widths and banks that were formerly covered with mostly herbaceous vegetation are now covered with trees like eastern cottonwood, green ash, and eastern red cedar (Rothenberger 1987).

Point sources of water pollution are generally associated with municipalities; however, large cattle facilities and some industrial operations are also important. Most pollutants tend to be nitrogen compounds and oxygen-demanding wastes. Drainage from abandoned mines in headwater areas of the South Platte can raise metal concentrations to toxic levels, but they are generally present as chronic stressors to the system. Nonpoint sources of nutrients and pesticides in the lower Platte basin, especially

atrazine, alachlor, and cyanazine, contribute background levels that often spike during runoff events in the spring planting season. Negative relationships between fish species tolerance and proportion of stream basin that is cropland have been shown (Frenzel et al. 1998).

Management of the Platte River ecosystem is a complex balance among competing interests for a limited and overappropriated water supply. Expansion of urban centers from the Front Range in Colorado, along the North Platte in Wyoming, and downstream to the mouth of the Platte in eastern Nebraska has exacerbated the competition for water among agricultural and environmental interests within the basin. The importance of the Platte River to migratory birds of the Central Flyway, including the endangered whooping crane and other rare and endangered species, expands concern about management of this resource to the continental and international scales.

GASCONADE RIVER

The Gasconade is a 6th order river whose 9258 km² basin is in the rolling uplands of south-central Missouri. It meanders northeast 436 km to join the Missouri River at Rkm 168 (Fig. 10.23). Major tributaries from south to north and their approximate proportion of the total basin are Osage Fork (14%), Roubidoux River (8%), Big Piney River (16%), and Little Piney River (8%). The basin lies about 161 km southwest of St. Louis and is roughly triangular, 80 km at its widest point and 209 km in length. It is divided into two USGS eight-digit hydrological units. Few towns are located along the river and there are no major urban centers in the basin. Large segments of the Gasconade and its tributaries are relatively undeveloped, unpolluted, and free flowing. Portions of the basin contain some of the most rugged topography and scenic areas in the region (Fig. 10.7).

Late Woodland peoples (400 to 900 AD) living in semipermanent villages were the principal prehistoric Native Americans within the basin, although the area was also under the influence of the Mississippian Mound Builder metropolis at Cahokia–St. Louis to the northeast (900 to 1200). From about 1675 until the United States gained control of “Louisiana” in 1804, the region was dominated by the powerful Osage hegemony. French trappers plied the lower reaches of the Gasconade by the 1740s. Early American settlers immigrated to the upper basin as

FIGURE 10.7 Gasconade River, Missouri (PHOTO BY J. RATHERT, MISSOURI DEPARTMENT OF CONSERVATION).

early as 1826, attracted by abundant game. Immigration increased in the 1840s, when public lands were opened for sale and further expanded with rail service in 1870. Early land-use practices of forest clearing, uncontrolled burning and livestock grazing, poor farming, and unregulated gravel mining adversely affected basin streams. Burning and grazing resulted in topsoil removal, exposing the cherty, gravelly subsoils, which eventually accumulated in streams.

Physiography, Climate, and Land Use

The Gasconade River basin lies wholly within the Springfield–Salem plateaus section of the Ozark Plateaus (OZ) physiographic province, a part of the Interior Highlands physiographic division. Its watershed is unglaciated and hillslope soils are thin and thoroughly leached. Surface geological formations are composed of Ordovician dolomites and sandstones. The main stem and tributaries cut through Gunter sandstone and Gasconade dolomite, the latter

having many springs that contribute to the river's base flow. The Gasconade formation is replaced upland from the floodplain by the Roubidoux formation, which contains sandstone and cherty dolomite. Further upland in the headwaters is a composite of well-weathered dolomite formations with numerous cracks, joints, and solution openings. The basin is characterized by a large subterranean drainage, creating numerous caves and springs.

The Gasconade basin traverses three land resource areas: Deep Loess Hills, Ozarks, and Ozark Border. The thickest soil deposits of the Deep Loess Hills are found along river bluffs, with other deposits on ridgetops and broad uplands. Most soil formations of the Ozarks and Ozark Border were formed under forest vegetation, with occasional glades. Slopes within the Ozarks contain cherty alluvium soils, whereas within the Ozark Border they contain more gravelly alluvium soils. Both areas have fragipans that can restrict plant growth. Estimated soil loss is $1.0 \text{ metric tons ha}^{-1} \text{ yr}^{-1}$, and the amount reaching streams is low, about $0.29 \text{ metric tons ha}^{-1} \text{ yr}^{-1}$.

Most of the Gasconade basin lies within the Central U.S. Mixed Hardwood Forests terrestrial ecoregion (Ricketts et al. 1999). Upland forests contain distinctive tree associations related to geology, soil type, temperature, and precipitation. Forests are mainly post and blackjack oak to the north, with white and black oak forest, white oak and shagbark hickory forest, and an increase in shortleaf pine and oak forest to the south.

Climate of the basin is continental, with frequent daily and seasonal changes in weather. Mean annual air temperature in the basin is 13.3°C and ranges from a mean low of -0.1°C in January to a mean high of 25.7°C in July (Fig. 10.24). Precipitation averages 107 cm/yr and monthly averages range from a low of 5.3 cm in January to a high of 12.9 cm in May (see Fig. 10.24). Snowfall is limited and seldom accumulates. The rainy season is April through June (32% of annual total) and heavy rains can cause flooding.

Logging began in the mid 1800s, and the river served to float logs to yards and railroad ties to railroad crossings. Most of the uplands of old-growth oak-hickory and short-leaved pine were harvested by 1900, particularly in the headwaters. Regeneration has been slow due to the region's steep topography and poor soils. Farming in the late 1800s included wheat and corn, and the region led the nation in apple production in the 1890s. Grain and fruit production has largely been replaced by cattle grazing and hay production. Cattle populations and grazing density have shown a general increase from the 1920s to the 1990s, averaging about 0.3/ha in 1995. Overgrazing occurs and streams and rivers in the basin are commonly used for cattle watering. Confined dairy (~2200 animal units), hog (~19,000 units), and poultry (~840,000 units) operations are also present in the basin and can be significant sources of organic pollutants. Present land use is primarily forest (55%) and grassland/pasture (35%). About 10% of the basin is in public ownership, with major portions in the Mark Twain National Forest and Ft. Leonard Wood U.S. Army Military Reservation.

Zinc, lead, and iron surface mining were important in the upper basin in the late 1800s, but little mining occurs today. Clay and limestone were also quarried, and limestone quarrying is ongoing. Ozark streams have been an important source of sand and gravel since the early 1900s. Gravel mining has been regulated since the 1990s and should be confined to gravel bars and damage to stream banks and vegetation restricted.

River Geomorphology, Hydrology, and Chemistry

Portions of the Gasconade channel meander through wooded banks or towering bluffs featuring caves and springs. Gravel bars, quiet pools, and turbulent chutes are numerous. The region's karst topography causes portions of the Gasconade and several of its tributaries to lose flow into an aquifer (i.e., segments are losing streams). About 53 km in the central portion of the main stem is the longest losing segment in the basin. The Gasconade basin is one of the most cavernous regions in the United States, with 131 named caves and 76 reported springs.

There are 9682 linear kilometers of stream (loops, braids, and disconnects excluded) within the Gasconade drainage. The main channel is highly sinuous and often entrenched in exposed limestone and dolomite formations. The most meandering section is above the confluence of the Big Piney River (see Fig. 10.23), where bluffs are 60 to 90 m tall and channel sinuosity is >30. Water depths vary from 0.3 m in the upper river to 9.1 m near the mouth, and average high-bank channel width ranges from 12.2 m to 94 m. Average gradient is 1.95 m/km for the upper Gasconade and 1.10 m/km in the lower river. Stream bottoms consist of bedrock, boulders, rubble, and gravel, with little or no sand or mud except in backwaters. Major riverine habitat groups (percentage area) for the upper Gasconade basin include pool-riffle complex (29.1%), temporary-semipermanent pool (12.7%), and gravel bar (8.3%). For the lower Gasconade basin these are gravel bar (6.6%) and temporary-semipermanent pool (4.4%) (Blanc 2001). The high percentage of gravel bars in the main-stem Gasconade and other Ozark rivers has been associated more with unstable channel conditions in headwater tributaries due to poor land-use practices than conditions within the local riparian corridor (Jacobson and Pugh 1997).

April through May is the period of highest discharge for the Gasconade River, with maximum discharge usually in April (132.5 m³/s) (see Fig. 10.24). Lowest flows occur in late summer and early fall. Most floods occur from February through June but can occur at any time of year. Runoff is rapid due to the steep valley slopes and stage increases of 1.5 to 2.4 m/d occur. Percentage of time flow exceeded a given discharge over the 75 years from 1923 to 1998 at the Jerome gage was 253 m³/s (5%), 36.1 m³/s (50%), and 12.7 m³/s (95%) (Blanc 2001). Springs make important contributions to the Gasconade River's base flow, particularly in the middle basin.

Major springs and their discharge include Bartlett Mill (1.92 m³/s), Boiling (1.84 m³/s), Roubidoux (1.65 m³/s), and Piney (1.4 m³/s). Differences in precipitation versus runoff (see Fig. 10.24) are due to three factors: (1) evapotranspiration, (2) springs contributing to river discharge somewhat independent of local precipitation, and (3) sections of the river losing discharge to the aquifer. Water temperature of Ozark springs is fairly constant at 13°C to 15°C and their discharge locally moderates temperatures of receiving streams. No dams occur on the main-stem Gasconade, whereas two 3 m high rock dams occur on its largest tributary, the Big Piney River.

Water quality of the Gasconade River is generally good, with a few problem areas. The upper Gasconade River is identified as a Category I watershed and the lower basin as Category II. Its chemistry is basic (pH 8.0), alkaline (151 mg/L as CaCO₃), and relatively hard (total hardness 130 to 200 mg/L as CaCO₃) with moderate conductivity (240 to 360 µS/cm). Turbidity is generally very low (<10 NTU) except during high water. Chemistry is fairly uniform along the river and mean ranges of annual concentrations of major dissolved inorganic constituents are calcium (24 to 39 mg/L), magnesium (14 to 25 mg/L), iron (3 to 32 mg/L), and sulfate (3.9 to 11 mg/L as SO₄). Nutrient concentrations are generally low except in reaches below municipal effluent discharge or where livestock have access to the river. Dissolved NO₂-N + NO₃-N near Jerome averages 0.37 mg/L and ranges from <0.05 to 1.20 mg/L. Dissolved PO₄-P averages 0.015 mg/L and ranges from <0.010 to 0.070 mg/L. Dissolved silica concentrations are high, ranging from 8.7 to 9.7 mg/L as SiO₂. Total phosphorus and total suspended solids concentrations are lower in Ozark streams (including the Gasconade) than in Ozark Border and Glaciated Plains streams in Missouri, whereas total nitrogen concentrations are similar. Fecal coliforms are generally below the state limit of 200 colonies/100 mL.

One of the largest oil pipeline spills in the nation occurred in December 1988, releasing >3266 m³ of crude oil into a tributary of the Gasconade River. Approximately 105 km of the lower Gasconade River were affected and only 50% of the oil from the spill was recovered.

River Biodiversity and Ecology

The Gasconade River is part of the Central Prairie freshwater ecoregion (Abell et al. 2000) and is characterized by a rich and diverse flora and fauna. Significant features within the river corridor include

mesic deciduous bottomland forests, limestone and dolomite cliffs, and influent and effluent caves.

Algae

Although no studies of algae have been done in the Gasconade, periphyton from nearby Northern Ozark rivers are volumetrically dominated by Bacillariophyta (*Cocconeis*, *Cymbella*, and *Surirella*), Chlorophyta (*Cladophora*, *Cosmarium*, and *Oedogonium*), and Chrysophyta (*Bumellaria*).

Plants

Aquatic macrophytes within the channel are confined to backwater areas and include pondweeds, naiads, arrowheads, and yellow pondlily. Coldwater springs have a distinctive macrophyte community; whitewater crowfoot, watercress, water speedwell, and *Fontinalis* mosses are common taxa. Water willow is the dominant vascular plant at the water's edge on gravel bars. Black and sandbar willows invade gravel bars along the lower river where soil is mixed with gravel. At higher elevation, more stable bars support river birch, buttonbush, sycamore, silver maple, and green ash. Trees on floodplain alluvium include Shumard's oak, bur oak, and box elder, and in seldom-flooded locations, sugar maple, black walnut, and bitternut hickory. Flowering dogwood, redbud, and sassafras are common understory trees.

Invertebrates

Mussels, crayfishes, and insects compose the rich aquatic invertebrate fauna of the Gasconade River. Forty-two mussel species, composing 27 genera, have been collected. Dominant genera of mussels are *Lampsilis* (6 species), *Quadrula* (3 species), and *Fusconaia* (2 species). Asiatic clams have been introduced into the main-stem Gasconade. The plain pocketbook mussel is widely distributed. Seven mussels of state conservation concern (S1) reside in the upper basin: scale shell (also G2), elephantear, spectaclecase, elktoe, black sand shell, bullhead (also G3), and Ouachita kidneyshell. The federally endangered pink mucket is present in the main-stem Gasconade.

Five species of crayfishes are in the basin, but >99% of crayfish composition is within the genus *Orconectes*. In decreasing order of abundance the crayfishes are spothanded crayfish, golden crayfish, digger crayfish, devil crayfish, and the Salem cave crayfish. The Salem cave crayfish is listed by NatureServe (2002) as globally imperiled (G2), and another troglobite present in the Gasconade basin, the central Missouri cave amphipod, is listed as globally criti-

cally imperiled (G1). *Hyalella azteca* is a more abundant amphipod in the river.

Sampling from various locations in the basin has yielded 52 families of aquatic insects. *Acentrella*, *Baetis*, *Ephemerella*, *Stenonema*, *Tricorythodes*, and *Caenis* are major mayfly genera. Abundant odonates include *Argia*, *Erpetogomphus*, and *Gomphus*. *Chimarra*, *Cheumatopsyche*, *Hydropsyche*, *Psychomyia*, and *Helicopsyche* dominate the caddisflies. *Taeniopteryx*, *Strophopteryx*, and *Neoperla* are abundant stoneflies. Beetles include *Dubiraphia*, *Psephenus*, and *Stenelmis*. *Simulium*, *Polypedilum*, *Dicrotendipes*, and *Paratanytarsus* are important Diptera. A globally imperiled (G2) stonefly, *Acroneuria ozarkensis*, is recorded only in the Gasconade River basin and a few other streams in the United States. Scrapers and collectors are the most abundant functional feeding groups.

Vertebrates

Five families dominate the rich fish fauna (105 species) of the Gasconade River. Most species occur in the Cyprinidae (29), Catostomidae and Percidae (14), Centrarchidae (12), and Ictaluridae (8). The most widely distributed cyprinids are bleeding shiner, hornyhead chub, largescale stoneroller, and central stoneroller. Longear sunfish, rock bass, bluegill, smallmouth bass, largemouth bass, and spotted bass are widely distributed centrarchids. Spotted bass are a recent addition to the Gasconade basin due to range expansion. Ten Gasconade basin fishes are of conservation concern in Missouri (S1–S3), including the southern cavefish. The anadromous Alabama shad is a candidate for federal listing, and the Gasconade is one of the few Mississippi basin rivers where it still spawns. The bluespotted darter is endemic to the Gasconade and nearby Osage River basins and is globally listed as imperiled (G2). In addition, the crystal darter is identified as globally vulnerable to extinction (G3) (<http://www.natureserve.org/explorer/servlet/NatureServe?init=Species> 2002).

Rock bass, smallmouth bass, largemouth bass, walleye, and channel catfish are the most sought after sport fishes. Night gigging for suckers and redhorse is also popular. Size and harvest of rock bass and smallmouth bass are controlled in several special management areas to provide a high-quality angling experience. Coldwater sections of several tributaries below springs are designated as Wild Trout Management Areas. Protection and management of self-sustaining populations of introduced rainbow trout occur here.

All major groups of amphibians and reptiles are well represented in the basin: frogs and toads (13 species), salamanders (11), turtles (12), lizards (6), and snakes (29). Stream-dwelling salamanders include the state-imperiled Ozark hellbender (S1), mudpuppy, and western lesser siren. Northern water snakes are abundant, and map turtle, red-eared slider, and western painted turtle are often seen basking on logs. Both smooth and spiny softshell turtles are observed in the Gasconade's clear waters.

Bird life along the river is outstanding, with about 290 species recorded. Wood ducks, belted kingfishers, green herons, and great blue herons are common along the river, and ospreys and bald eagles are occasionally observed during migration. Common aquatic mammals along the river corridor include river otter, beaver, mink, and muskrat.

Ecosystem Processes

There are no studies of ecosystem processes for the Gasconade River, although evidence on periphyton biomass and nutrient limitation exists from nearby rivers. Concentrations of benthic chlorophyll *a* from Northern Ozark streams (upper Moreau and Maries rivers) with similar low nitrogen and phosphorous concentrations as the Gasconade ranged from 33 to 59 mg/m² (Lohman et al. 1991). Northern Ozark streams appear to be primarily nitrogen limited based on nutrient enrichment studies conducted during low flow periods (Lohman et al. 1991). Low NO₃-N and molar TN/TP ratios (<20 to 1) support these results.

Fish growth in the Gasconade River is generally higher than average for Missouri streams (Funk 1975). Growth rates equaled or exceeded the statewide average for 9 of the 14 species examined, illustrating the river's high fish production. Growth rates of the river's two most popular sport fishes, rock bass and smallmouth bass, were excellent: 149% and 127%, respectively, of the statewide average.

Human Impacts and Special Features

The Gasconade River is one of the few free-flowing rivers in the conterminous United States (Benke 1990) and the only free-flowing major tributary to the Missouri from the Ozark Highlands. It is in a largely rural, well-forested karst basin harboring numerous coldwater springs and caves and their characteristic flora and fauna. Approximately 357 km of the Gasconade and Big Piney rivers were recommended for designation as "scenic" or "recre-

ational” under the National Wild and Scenic Rivers Act due to their outstanding natural resource and aesthetic values; however, such designation never occurred. The river is popular for shoreline and float angling, sightseeing and nature study, boating, camping, and swimming. Days fished per total watershed area ranged from 0.038 to 0.063 between 1983 and 1991 (Blanc 2001).

Primary future threats to the high quality of this Ozark river include further expansion of cattle grazing and concentrated animal feedlots, stream bank erosion, poor gravel mining practices, expanding urban and suburban populations, and increased recreational use. Improved land-use practices, particularly excluding cattle and off-road vehicles from streams and leaving riparian buffers when logging, will help address major causes of bank erosion and nonpoint organic pollution. Agency incentives are in place to assist repair of stream bank damage, including corridor reforestation, stream bank revegetation, cedar tree revetments, and willow staking. There has been encouraging movement toward minimizing gravel mining impacts through mandated best management practices (BMPs) for commercial operations and voluntary BMPs for noncommercial uses. Enforcing existing water-quality regulations will help reduce violations and citizen activism through the Missouri Stream Team and similar programs will promote public awareness of the river’s ecological values.

ADDITIONAL RIVERS

The Madison River is a coldwater system located in the Northern Rocky Mountains of Wyoming and Montana and is one of three rivers that merge to form the Missouri River (Fig. 10.25). About one-fourth of its drainage is in Yellowstone National Park, where geothermal inputs result in naturally high concentrations of arsenic. The river is relatively low gradient throughout much of its length and meanders through a broad floodplain, dominated in Montana by cattle ranches (Fig. 10.8). Human population density is low, with no major urban development, and water quality is good. Much of the river corridor in Montana is being subdivided into ranchettes. Three main-stem dams fragment the river and influence flow and water temperature. The river is very productive and internationally known for its high-quality trout fishery, dominated by nonnative rainbow trout and brown trout. Infestation of whirling disease caused major declines in the rainbow

trout population during the past decade and the recent discovery of the New Zealand mud snail is of ecological concern.

The Milk River originates in Glacier National Park, Montana, flows into Canada, and then back into Montana (Fig. 10.27). Over much of its length the meandering channel is highly braided, with unstable sand substratum (Fig. 10.9). Land use is principally range and agriculture and population density is low, with no major urban development. The river is fragmented by one major dam (Fresno), one municipal water weir, and four irrigation diversion dams, none with fish passage structures. The river above Fresno Dam is one of the few remnant, relatively intact Great Plains river ecosystems. Overall species diversity is low and nonnative fishes dominate the assemblages below Fresno Dam.

The Cheyenne River begins as two separate rivers: a north fork (Belle Fourche River), and a south fork (Little Cheyenne River) (Fig. 10.10, Fig. 10.29). With their ephemeral headwaters in the Wyoming prairie (40% of basin), both forks collect the cold water of Black Hills streams (18% of the basin) and then join to flow across a prairie landscape to Lake Oahe. The Belle Fourche captured the headwaters of the Little Missouri River and its upper Missouri River basin fishes (e.g., mountain sucker, longnose sucker). Three Bureau of Reclamation irrigation projects dominate the valley of the Belle Fourche and Little Cheyenne rivers. Contaminants from gold mining (e.g., mercury, mine tailings) have been the major pollution issue. Black Hills streams are clear and cold with stable flows, whereas the main-stem Cheyenne is a turbid, warmwater river with high spring and low winter flows. Trout in the Hills arm and walleye in the Cheyenne arm of Lake Oahe provide important sport fisheries. The main stem is used for canoeing, fishing for channel catfish, and camping on the numerous sandbars and gravel bars.

The Big Sioux River courses north to south along the borders of South Dakota, Minnesota, and Iowa (Fig. 10.11, Fig. 10.31). Much of the watershed is a fertile, rocky coteau (hill) of glacial origin that features numerous lakes and thousands of small pothole wetlands. Exposed Sioux quartzite forms the Sioux Falls (30 m drop over 0.8 km), dells, palisades and other rocky outcroppings that are unique to the region. The upper river flows over gravel and sand substrates through pastures and woodlots, whereas the lower river is sluggish and meanders through a wooded corridor. Agriculture dominates the landscape, but human density is relatively high. The river was once one of the most polluted rivers in the

FIGURE 10.8 Madison River near West Yellowstone, Wyoming (PHOTO BY C. E. CUSHING).

country, but water quality has improved since the 1960s. Nutrients, fecal coliforms, and suspended solids are still problems. Only 3% of the stream length has been altered and only 30% of the wetlands drained. Consequently, the river is relatively natural, has healthy fish populations, and supports river-oriented recreation and municipal parks.

The Niobrara River is a swift-flowing prairie river that intersects the boundaries of northern, eastern, and western forest flora. It flows in an easterly direction along most of the length of northern Nebraska before emptying into the Missouri River upstream of Lewis and Clark Lake (Fig. 10.33). It has been less

affected by major habitat alterations than other eastward-flowing plains tributaries to the Missouri. A large volume of groundwater supports a consistent high-quality base flow. Ranching, supported by native grassland forage, and low human population density have resulted in good water quality. Low fragmentation by dams makes this one of the least impacted rivers in the Great Plains (Fig. 10.12).

The Kansas or Kaw River and its tributaries flow eastward, draining all of northern Kansas and southern Nebraska before joining the Missouri River at Kansas City (Fig. 10.13, Fig. 10.35). Its major tributaries, the Republican, Solomon, and Smoky Hill

FIGURE 10.9 Milk River east of Havre, Montana (PHOTO BY TIM PALMER).

rivers, arise in the high plains of eastern Colorado and southern Nebraska. The Kansas was historically a turbid, warmwater, prairie river with unstable sand substrates that was subsequently altered by water diversions, damming, and dredging. Much of the basin is in agriculture, with row crops dominating bottomlands. Pollution from pesticides, agricultural fertilizers, and municipal sewage systems has impaired water quality. Impoundments have altered habitat conditions so that mainly introduced sight-feeding fishes dominate the fauna.

The Grand River, the largest prairie river in Missouri largely unaffected by impoundments and channelization, lies within the Central Lowland glaciated

prairies of northwest Missouri and southwest Iowa (Fig. 10.37). Its basin is largely rural cropland, with a declining population and no major urban areas. Although it has always been a turbid river, poor land-use practices and tributary channelization has resulted in steep eroding stream banks (Fig. 10.14). Filling of the channel with sand and silt has reduced pool habitat and coarse substrate and limits invertebrates and fishes. Sixty-one species of fishes are present, and most are habitat generalists, tolerant of turbidity. Angling for catfishes is a popular pastime. Water-quality standards for iron, magnesium, and fecal coliform bacteria are frequently exceeded. Most water-quality problems are associated with

nonpoint-source pollutants such as soil erosion and manure runoff.

ACKNOWLEDGMENTS

We thank the following persons for information on topics included in this chapter: Sue Bruenderman (mussels), Michael Chapman (Missouri River engineering structures), David Fryda (White River), Barry Poulton and Linden Trail (insects), Matt Winston and Robert Bramblett (fishes), Julie Fleming (nonfish vertebrates), Timothy Smith (vegetation), Raymond Wood (Native Americans), Gust Annis, David Greenlee, John LaRandeau, and Scott Sowa (geography). Sandy Clark, Chad Kopplin, and Jeff Shearer helped gather and summarize data. Charles Rabeni, Nick Bezzerides, and Sandy Clark edited and reviewed portions of the chapter. The University of Nebraska, Agricultural Research Division through the School of Natural Resource Sciences provided support to E. Peters during the completion of this chapter.

This chapter is a contribution from the Missouri, Montana, and South Dakota Cooperative Fish and Wildlife Research Units (U.S. Geological Survey; Missouri Department of Conservation; Montana Department of Fish, Wildlife, and Parks; South Dakota Department of Game, Fish, and Parks; University of Missouri; Montana State

University; South Dakota State University; and Wildlife Management Institute cooperating).

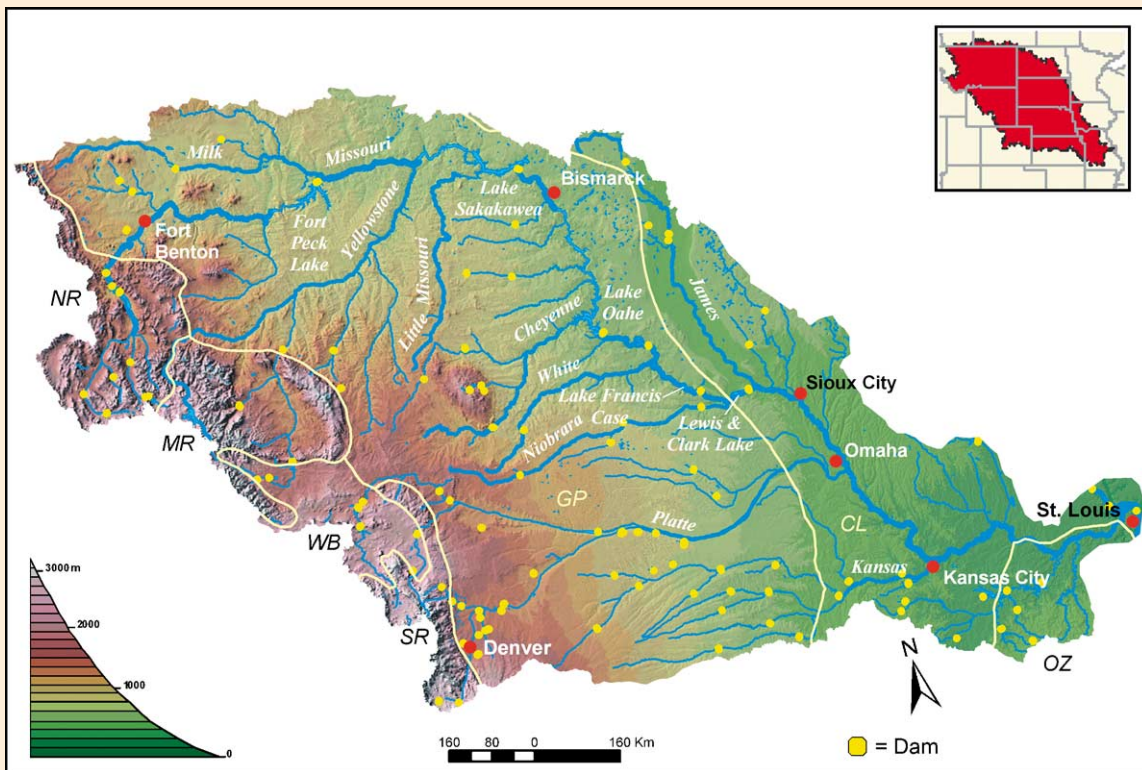

FIGURE 10.15 Map of the Missouri River basin. Physiographic provinces are separated by yellow lines.

MISSOURI RIVER

Relief: 4277 m

Basin area: 1,371,017 km²

Mean discharge: 1956 m³/s

River order: 9

Mean annual precipitation: 50.1 cm

Mean air temperature: 7.4°C

Mean water temperature: 9.3°C (Bismarck, North Dakota) 13.4°C (Boonville, Missouri)

Physiographic provinces: 7 provinces (see text); most in Rocky Mountains (NR, MR, SR), Great Plains (GP), Central Lowland (CL)

Biomes: Temperate Mountain Forest, Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregions: Upper Missouri, Middle Missouri, Central Prairie

Terrestrial ecoregions: 13 ecoregions (see text)

Number of fish species: main stem ~136 (108 native), basin ~183 (138 native)

Number of endangered species: 1 insect, 1 fish, 3 birds, 2 mammals

Major fishes: shovelnose sturgeon, goldeye, gizzard shad, emerald shiner, red shiner, river shiner, flathead chub, sturgeon chub, *Hybognathus* minnows, common carp, spotfin shiner, river carpsucker, shorthead redhorse, white sucker, channel catfish, flathead catfish, white crappie, freshwater drum

Major other aquatic vertebrates: false map turtle, softshell turtles, great blue heron, wood duck, beaver

Major benthic vertebrates: mayflies (*Baetis*, *Heptagenia*, *Ephemerella*, *Tricorythodes*, *Isonychia*, *Hexagenia*, *Caenis*, *Stenonema*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Neureclipsis*, *Oecetis*), beetles (*Heterlimnius*, *Optioservus*), odonates (*Gomphus*), crustaceans (*Isopoda*)

Nonnative species: Russian olive, reed canary grass, Johnson grass, *Daphnia lumholtzi*, Asiatic clam, 28 fishes (rainbow trout, brown trout, cisco, common carp, goldfish, bighead carp, grass carp, rainbow smelt, white perch, striped bass), salmonid whirling disease parasite

Major riparian plants: cottonwoods, willows, American elm, green ash, box elder, red mulberry, Virginia creeper, prairie cordgrass, Canada wild rye, switchgrasses, giant ragweed, smartweeds

Special features: longest named river in North America (3768 km); primary water route for settlement of western United States

Fragmentation: 6 major main-stem dams; 581 total large dams

Water quality: pH = 8.0 to 8.3, alkalinity = 145 to 162 mg/L as CaCO₃, NO₃-N = 0.08 to 1.24 mg/L, PO₄-P = 0.007 to 0.09 mg/L

Land use: (within 5 km of river) 33% cropland, 26% grassland, 10% shrub, 6% forest, 17% developed

Population density: 8 people/km²

Major information sources: Galat and Frazier 1996, Hesse et al. 1989, Patrick 1998, Revenga et al. 1998

FIGURE 10.16 Mean monthly air temperature, precipitation, and runoff for the Missouri River basin.

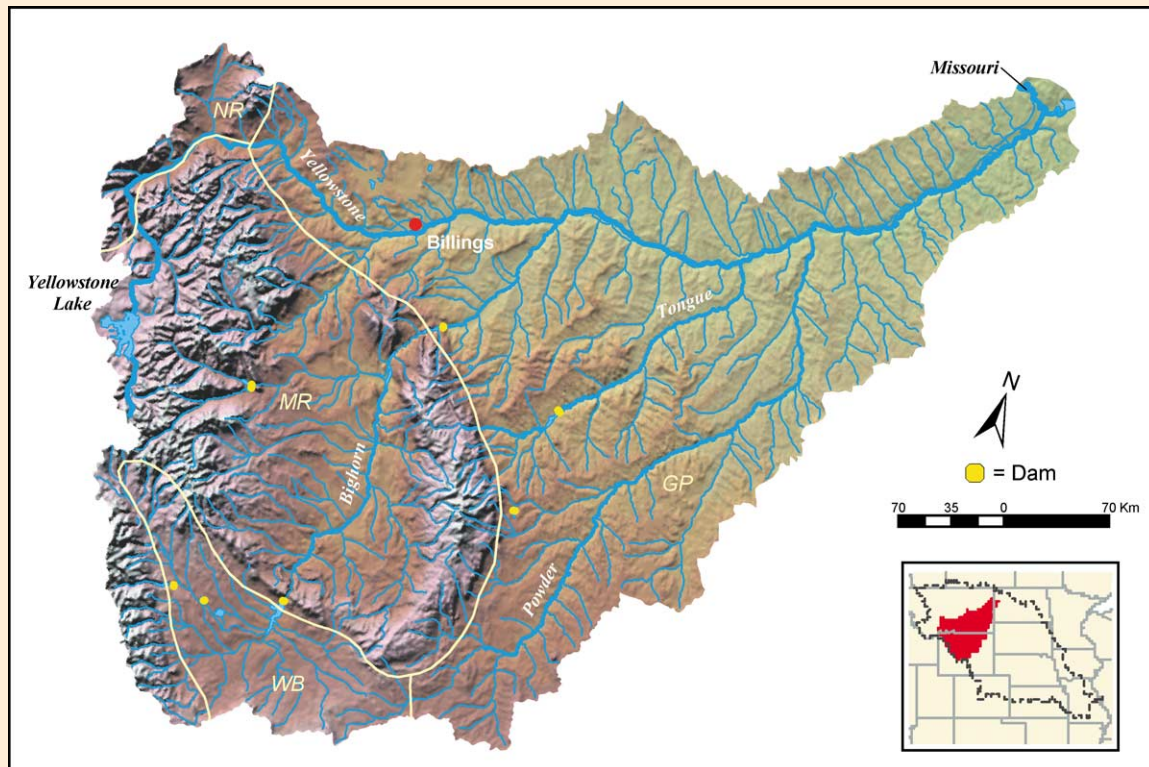

FIGURE 10.17 Map of the Yellowstone River basin. Physiographic provinces are separated by yellow lines.

YELLOWSTONE RIVER

Relief: 3050 m

Basin area: 182,336 km²

Mean discharge: 362 m³/s

River order: 8

Mean annual precipitation: 29.5 cm

Mean air temperature: 7.8°C

Mean water temperature: NA

Physiographic provinces: Northern Rocky Mountains (NR), Middle Rocky Mountains (MR), Wyoming Basin (WB), Great Plains (GP)

Biomes: Temperate Mountain Forest, Temperate Grasslands

Freshwater ecoregion: Upper Missouri

Terrestrial ecoregions: South Central Rockies Forests, Montana Valley and Foothills Grasslands, Northwestern Mixed Grasslands, Wyoming Basin Shrub Steppe

Number of fish species: 56 (36 native)

Number of endangered species: 1 fish

Major fishes: Yellowstone cutthroat trout, rainbow trout, brown trout, mountain whitefish, white sucker, longnose dace, mottled sculpin, shovelnose sturgeon, paddlefish, freshwater drum, channel catfish, sauger, goldeye, river carpsucker, shorthead redhorse, chubs, shiners

Major other aquatic vertebrates: river otter, beaver, bald eagle, osprey, great blue heron, common merganser, spiny softshell turtle, snapping turtle, painted turtle

Major benthic invertebrates: mayflies (*Baetis*, *Ephemerella*, *Epeorus*, *Ephemera*, *Ametropus*, *Lachlania*, *Ephoron*, *Caenis*, *Centropilum*, *Isonychia*), stoneflies (*Acroneuria*, *Pteronarcys*, *Pteronarcella*, *Arcynopteryx*, *Paraleuctra*, *Capnia*, *Alloperla*), caddisflies (*Rhyacophila*, *Amiocentrus*, *Glossosoma*, *Brachycentrus*, *Lepidostoma*, *Neotrichia*, *Oecetis*, *Leptocella*)

Nonnative species: black bullhead, black crappie, white crappie, brook trout, brown trout, rainbow trout, common carp, green sunfish, largemouth bass, northern pike, rainbow smelt, walleye, salmonid whirling disease parasite

Major riparian plants: black cottonwood, narrowleaf cottonwood, plains cottonwood, Geyer willow, wolf willow

Special features: longest free-flowing river in the conterminous United States (1091 km)

Fragmentation: no major dams

Water quality: pH = 7.5, alkalinity = 45 mg/L as CaCO₃, NO₃-N = 0.08 mg/L, PO₄-P = 0.3 mg/L

Land use: 47% range, 28% forest, 20% agriculture, 5% National Park, 1% urban

Population density: 10 people/km²

Major information sources: White and Bramblett 1993, Newell 1977, Varley and Schullery 1983, Silverman and Tomlinsen 1984

FIGURE 10.18 Mean monthly air temperature, precipitation, and runoff for the Yellowstone River basin.

FIGURE 10.19 Map of the White River basin.

WHITE RIVER

Relief: 1112 m
Basin area: 26,418 km²
Mean discharge: 16 m³/s
River order: 6
Mean annual precipitation: 44.2 cm
Mean air temperature: 9.3°C
Mean water temperature: 12.7°C
Physiographic province: Great Plains (GP)
Biome: Temperate Grasslands
Freshwater ecoregion: Upper Missouri
Terrestrial ecoregions: Northwestern Mixed Grasslands, Western Short Grasslands
Number of fish species: 49 (41 native)
Number of endangered species: 1 mammal
Major fishes: flathead chub, plains minnow, fathead minnow, sturgeon chub, common carp, sand shiner, western silvery minnow, channel catfish
Major other aquatic vertebrates: northern leopard frog, bullfrog, Great Plains toad, Woodhouse's toad, chorus frog, tiger salamander, common snapping turtle
Major benthic invertebrates: NA
Nonnative species: Canada thistle, saltcedar, Russian olive, smooth brome, leafy spurge, brown trout, rainbow trout, brook trout, common carp, black crappie, white crappie, largemouth bass, bluegill
Major riparian plants: plains cottonwood, green ash, sandbar willow, buffalo grass
Special features: harsh aquatic conditions; badlands and xeric landscape; Little White River (major tributary) has more benign conditions
Fragmentation: no main-stem dams
Water quality: pH = 8.2, alkalinity = 408 mg/L as CaCO₃, NO₃-N = 1.6 mg/L, PO₄-P = 1.9 mg/L, total suspended solids = 4171 mg/L, fecal coliforms may exceed state standards (2000 colonies/100 mL); high suspended sediments from natural sources
Land use: 21% agriculture, 73% grassland/pasture, 2% forest/shrub, 4% sparse vegetation/badlands
Population density: 1.3 people/km²
Major information sources: Ferrick et al. 1995, Niehus 1999, Fryda 2001

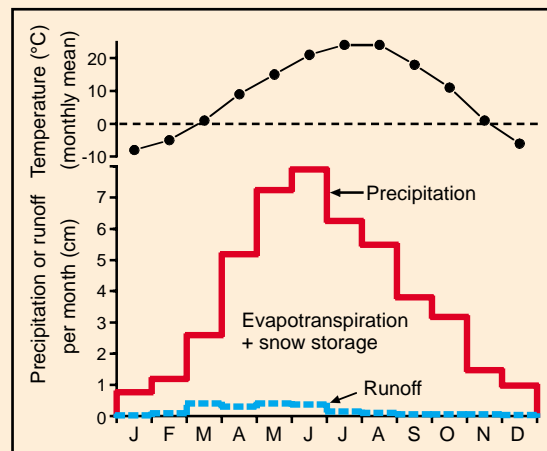

FIGURE 10.20 Mean monthly air temperature, precipitation, and runoff for the White River basin.

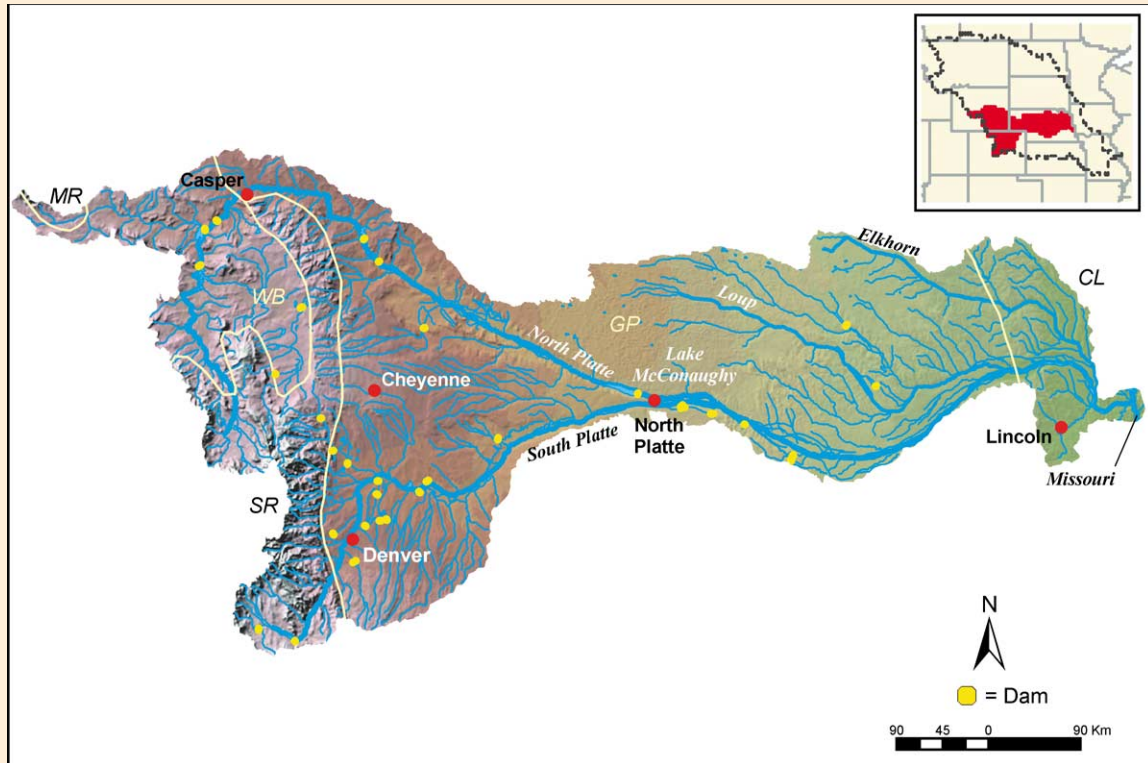

FIGURE 10.21 Map of the Platte River basin. Physiographic provinces are separated by yellow lines.

PLATTE RIVER

Relief: 3524 m

Basin area: 230,362 km²

Mean discharge: 203 m³/s

River order: 5

Mean annual precipitation: 50.2 cm

Mean air temperature: 9.1°C

Mean water temperature: 11.8°C

Physiographic provinces: Southern Rocky Mountains (SR), Wyoming Basin (WB), Great Plains (GP), Central Lowland (CL)

Biomes: Temperate Mountain Forest, Temperate Grasslands

Freshwater ecoregion: Middle Missouri

Terrestrial ecoregions: Colorado Rockies Forests, Wyoming Basin Shrub Steppe, Western Short Grasslands, Nebraska Sand Hills Mixed Grasslands, Central and Southern Mixed Grasslands, Central Tall Grasslands

Number of fish species: 100 (76 native)

Number of endangered species: 4 plants, 3 insects, 2 fishes, 1 amphibian, 6 birds, 1 mammal

Major fishes: shovelnose sturgeon, longnose gar, flathead chub, speckled chub, sand shiner, red shiner, river shiner, western silvery minnow, plains minnow, river carpsucker, quillback, plains killifish, channel catfish, freshwater drum

Major other aquatic vertebrates: snapping turtle, spiny softshell turtle, painted turtle, migratory waterfowl, beaver, muskrat

Major benthic invertebrates: snails (*Physa*), crustaceans (*Hyallela azteca*, *Orconectes*), mayflies (*Heptagenia*, *Hexagenia*, *Caenis*, *Baetis*, *Isonychia*), odonates (*Gomphus*, *Progomphus*), stoneflies (*Acronuria*, *Isoperla*, *Pteronarcys*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), true flies (*Chaoborus*, *Simulium*, *Chernovskia*, *Chironomus*, *Robackia*, *Saetheria*)

Nonnative species: 24 fishes (brown trout, rainbow trout, common carp, grass carp, bighead carp, western mosquitofish, striped bass, yellow perch, walleye)

Major riparian plants: eastern cottonwood, eastern red cedar, rough leaf dogwood, silver maple, green ash, sandbar willow

Special features: a wide, shallow braided river with shifting sandbars

Fragmentation: 7 main-stem dams, 20 diversions

Water quality: pH = 8.0, alkalinity = 153.5 mg/L as CaCO₃, NO₃-N = 1.35 mg/L, PO₄-P = 0.73 mg/L

Land use: >90% agriculture, 2% forest, 3% urban

Population density: 9.1 people/km²

Major information sources: National Research Council 2004, Peters and Schainost in press

FIGURE 10.22 Mean monthly air temperature, precipitation, and runoff for the Platte River basin.

FIGURE 10.24 Mean monthly air temperature, precipitation, and runoff for the Gasconade River basin.

GASCONADE RIVER

Relief: 380 m

Basin area: 9258 km²

Mean discharge: 87 m³/s

River order: 6

Mean annual precipitation: 108 cm

Mean air temperature: 13.4°C

Mean water temperature: 15.2°C

Physiographic province: Ozark Plateaus (OZ)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Central Prairie

Terrestrial ecoregions: Central Forest/Grassland

Transition Zone, Central U.S. Hardwood Forests

Number of fish species: 105 (98 native)

Number of endangered species: 1 mussel, 1 bird, 2 mammals

Major fishes: bleeding shiner, Ozark minnow, largescale stoneroller, wedgespot shiner, striped shiner, bigeye shiner, southern redbelly dace, longear sunfish, smallmouth bass, rock bass, northern orangethroat

Major other aquatic vertebrates: bullfrog, green frog, common map turtle, red-eared slider, midland smooth softshell turtle, common snapping turtle, western painted turtle, northern water snake, wood duck, belted kingfisher, beaver, mink, muskrat, river otter

Major benthic invertebrates: mussels (mucket, spectaclecase, purple wartback, Wabash pigtoe, plain pocketbook), crustaceans (spothanded crayfish, golden crayfish), mayflies (*Acentrella*, *Baetis*, *Isonychia*, *Stenonema*), odonates (*Argia*, *Erpetogomphus*, *Gomphus*), caddisflies (*Chimarra*, *Cheumatopsyche*, *Hydropsyche*), stoneflies (*Taeniopteryx*, *Strophopteryx*, *Neoperla*), beetles (*Psephenus*, *Ectopria*)

Nonnative species: Asiatic clam, rainbow trout, common carp, goldfish

Major riparian plants: silver maple, American sycamore, green ash, river birch, Ward's willow, swamp dogwood, buttonbush, water willow

Special features: located in karst topography, sections lose flow to groundwater, 76 springs; largest undammed tributary to Missouri River draining Ozark Plateau; bluestripe and Missouri saddled darters endemic to Gasconade and adjacent drainages in Missouri

Fragmentation: no main-stem dams

Water quality: pH = 8.0, alkalinity = 151 mg/L as CaCO₃, NO₃-N = 0.365 mg/L, PO₄-P = 0.015 mg/L; 3266 m³ oil spill in December 1988

Land use: 55% forest, 35% grassland/pasture, 6% cropland, 4% urban

Population density: 13.5 people/km²

Major information source: Blanc 2001

FIGURE 10.26 Mean monthly air temperature, precipitation, and runoff for the Madison River basin.

MADISON RIVER

Relief: 1959 m

Basin area: 6537 km²

Mean discharge: 50.7 m³/s

River order: 6

Mean annual precipitation: 33.7 cm

Mean air temperature: 6.4°C

Mean water temperature: NA

Physiographic province: Northern Rocky Mountains (NR), Middle Rocky Mountains (MR)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Upper Missouri

Terrestrial ecoregions: South Central Rockies Forests, Montana Valley and Foothills Grasslands

Number of fish species: 17 (10 native)

Number of endangered species: 0

Major fishes: westslope cutthroat trout, rainbow trout, brown trout, mountain whitefish, mountain sucker, longnose sucker, white sucker, longnose dace, mottled sculpin

Major other aquatic vertebrates: northern leopard frog, spotted frog, osprey, bald eagle, American dipper, great blue heron, common merganser, river otter, beaver, water shrew

Major benthic invertebrates: mayflies (*Baetis*, *Epeorus*, *Tricorythodes*, *Rhithrogena*, *Paraleptophlebia*, *Ephemera*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Brachycentrus*, *Micrasema*, *Glossosoma*), stoneflies (*Pteronarcys*, *Acroneuria*, *Claassenia*, *Isoperla*)

Nonnative species: rainbow trout, brown trout, brook trout, Utah chub, New Zealand mud snail, salmonid whirling disease parasite

Major riparian plants: black cottonwood, narrowleaf cottonwood, Geyer willow, wolf willow, sandbar willow

Special features: geothermal inputs, notably near headwaters in geyser basins of Yellowstone National Park

Fragmentation: Madison (Ennis), Hegben, and Quake Lake dams on main stem

Water quality: relatively free of major pollutants, naturally high concentrations of arsenic from geothermal water; pH = 8.5, alkalinity = 89 mg/L as CaCO₃, NO₃-N = 0.100 mg/L, PO₄-P = 0.01 mg/L

Land use: 26% forestry, 41% agriculture, 2% urban, 8% wilderness area, 23% National Park

Population density: 1.2 people/km²

Major information sources: Brooks 1979, Varley and Schullery 1983, Holton 1990

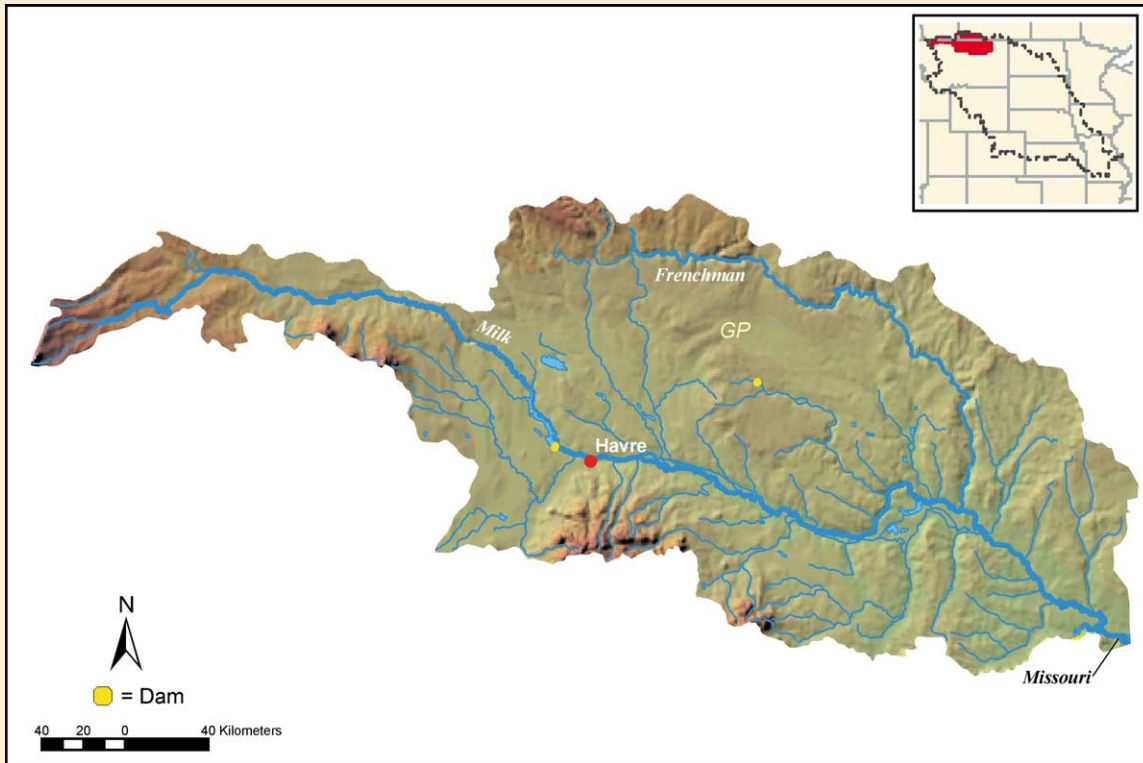

FIGURE 10.27 Map of the Milk River basin.

MILK RIVER

Relief: 1930 m

Basin area: 57,839 km²

Mean discharge: 18.9 m³/s

River order: 7

Mean annual precipitation: 28.8 cm

Mean air temperature: 6.1°C

Mean water temperature: NA

Physiographic province: Great Plains (GP)

Biomes: Temperate Mountain Forest, Temperate Grasslands

Freshwater ecoregion: Upper Missouri

Terrestrial ecoregions: Northern Mixed Grasslands, Montana Valley and Foothills Grasslands, Northwestern Mixed Grasslands

Number of fish species: 45 (30 native)

Number of endangered species: 0

Major fishes: shovelnose sturgeon, paddlefish, freshwater drum, channel catfish, sauger, Iowa darter, river carpsucker, blue sucker, bigmouth buffalo, smallmouth buffalo, shorthead redhorse, brook stickleback, chubs, shiners

Major other aquatic vertebrates: osprey, common merganser, snapping turtle, spiny softshell turtle, painted turtle, muskrat

Major benthic invertebrates: mayflies (*Anaetris*, *Camelobaetidius*, *Ametropus*, *Lachlania*, *Raptoheptagenia*, *Macdunnoa*, *Cercobrachys*, *Hexagenia*), odonates (*Gomphus*, *Ophiogomphus*), stoneflies (*Oemopteryx*, *Acroneuria*)

Nonnative species: common carp, spottail shiner, bluegill, smallmouth bass, white crappie, black crappie, yellow perch, walleye, black bullhead, rainbow trout, brown trout, lake whitefish, northern pike, virile crayfish

Major riparian plants: plains cottonwood, red-osier dogwood, peach-leaved willow, Rocky Mountain juniper, box elder

Special features: meandering, highly braided channel with very unstable sand bottom in upper reaches; reach above Fresno Dam one of few remnant Great Plains river ecosystems

Fragmentation: Fresno dam on main stem; one municipal water weir; four diversion dams

Water quality: pH = 7.6, alkalinity = 150 mg/L as CaCO₃, NO₃-N = 0.19 mg/L, PO₄-P = 0.02 mg/L

Land use: 55% range, 43% agriculture, 2% forestry, 1% urban

Population density: 0.8 people/km²

Major information sources: Stash 2001, Needham and Gilge 1987, D. Guftason, personal communication

FIGURE 10.28 Mean monthly air temperature, precipitation, and runoff for the Milk River basin.

FIGURE 10.29 Map of the Cheyenne River basin.

CHEYENNE RIVER

Relief: 1410 m
 Basin area: 63,455 km²
 Mean discharge: 2.5 m³/s
 River order: 4
 Mean annual precipitation: 51.3 cm
 Mean air temperature: 7.6°C
 Mean water temperature: 12.7°C
 Physiographic province: Great Plains (GP)
 Biomes: Temperate Mountain Forest, Temperate Grasslands
 Freshwater ecoregion: Upper Missouri
 Terrestrial ecoregions: South Central Rockies Forests, Northwestern Mixed Grasslands

Number of fish species: 56 (37 native)
 Number of endangered species: 2 birds

Major fishes: brook trout, brown trout, rainbow trout, longnose dace, white sucker, green sunfish, sand shiner, fathead minnow, common carp, flathead chub, channel catfish, plains minnow, shorthead redhorse, red shiner

Major other aquatic vertebrates: northern leopard frog, Great Plains toad, Woodhouse's toad, chorus frog, plains spadefoot toad, tiger salamander, common snapping turtle, spiny softshell turtle

Major benthic invertebrates: caddisflies (*Glossosoma*, *Hydropsyche*, *Hesperophylax*), mayflies (*Baetis*), stoneflies (*Acroneuria*, *Isoperla*), odonates (*Ophiogomphus*, *Argia*), beetles (*Naropus*), true flies (*Tipula*, *Atherix*), crustaceans (*Gammarus*, *Hyallorella*), bivalves (fingernail clams, white heelsplitter)

Nonnative species: tamarisk, Russian olive, Canada thistle, leafy spurge, smooth brome, common carp, brown trout, rainbow trout, brook trout, cutthroat trout, largemouth bass, bluegill, pumpkinseed, smallmouth bass, rock bass, golden shiner

Major riparian plants: white spruce, aspen, Bebb willow, plains cottonwood, green ash, salt grass, buffalo grass, sandbar willow
 Special features: Black Hills coldwater streams and hot springs; harsh conditions; section proposed for National Wild and Scenic River

Fragmentation: three major dams on main stem; Lake Oahe isolates Cheyenne from other Missouri River tributaries

Water quality: pH = 8.2, alkalinity = 236 mg/L as CaCO₃, NO₃-N = 2.0 mg/L, PO₄-P = 0.05 mg/L, conductivity = 2145 μS/cm, dissolved solids = 1636 mg/L, fecal coliform = 266 col/100 mL

Land use: 8% agriculture, 69% grassland/pasture, 18% forest/shrub, 5% sparse vegetation/badlands, 1% urban

Population density: 3.3 people/km²

Major information sources: Hampton and Berry 1997, Doorenbos 1998, Newman et al. 1999

BIG SIOUX RIVER

Relief: 305 m

Basin area: 23,325 km²

Mean discharge: 35.4 m³/s

River order: 5

Mean annual precipitation: 62 cm

Mean air temperature: 7.8°C

Mean water temperature: 12.0°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Grasslands

Freshwater ecoregion: Middle Missouri

Terrestrial ecoregion: Central Tall Grasslands

Number of fish species: 70 (66 native)

Number of endangered species: 1 fish, 1 bird

Major fishes: northern pike, common carp, common shiner, fathead minnow, red shiner, sand shiner, river carpsucker, shorthead redhorse, white sucker, black bullhead, channel catfish, tadpole madtom, brook stickleback, green sunfish, walleye, Johnny darter, freshwater drum

Major other aquatic vertebrates: American toad,

Canadian toad, chorus frog, Great Plains toad, northern leopard frog, tiger salamander, spiny softshell turtle, common snapping turtle, western painted turtle, beaver, mink

Major benthic invertebrates: caddisflies (*Cheumatopsyche*, *Hydroptila*), odonates (*Calopteryx*, *Lestes*, *Libellula*), mayflies (*Baetis intercalaris*, *Hexagenia*, *Caenis*, *Stenacron*), beetles (*Coptotomus*, *Laccophilus*, *Hydrobius*), chironomid midges (*Chironomus*), crustaceans (*Hyalella azteca*), bivalves (*Sphaerium*, *Pisidium*, *Anodonta grandis*)

Nonnative species: bighead carp, common carp, grass carp, smallmouth bass, smooth brome grass, reed canary grass, Russian olive, buckthorn, Canada thistle, bindweed

Major riparian plants: green ash, American elm, eastern cottonwood, sandbar willow, smooth brome grass, reed canary grass

Special features: relatively intact floodplain wetlands and river channel; geological features related to quartzite formations; recreational use for hunting and fishing

Fragmentation: Sioux Falls is natural barrier to fish movement; three low-head (2 to 5 m high) dams impede fish movements

Water quality: pH = 8.1, alkalinity = 260 mg/L as CaCO₃, NO₃-N = 4.5 mg/L, PO₄-P = 0.4 mg/L, conductivity = 975 μS/cm, turbidity = 54 NTU, fecal coliforms may be >2000 colonies/100 mL

Land use: 62% agriculture, 27% grassland/pasture, 3% forest shrub, 7% wetlands/river, 1% urban

Population density: 17.4 people/km²

Major information sources: Diertman and Berry 1998, Doorenbos et al. 1996, Milewski et al. 2001

NIOBRARA RIVER

Relief: 1182 m

Basin area: 32,600 km²

Mean discharge: 49 m³/s

River order: 4

Mean annual precipitation: 47 cm

Mean air temperature: 8.3°C

Mean water temperature: 12.3°C

Physiographic province: Great Plains (GP)

Biome: Temperate Grasslands

Freshwater ecoregion: Middle Missouri

Terrestrial ecoregions: Western Short Grasslands, Nebraska Sand Hills
Grasslands, Northwestern Mixed Grasslands

Number of fish species: 67 (43 native)

Number of endangered species: 1 plant, 1 insect, 1 fish, 2 birds,
1 mammal

Major fishes: sand shiner, red shiner, river shiner, emerald shiner,
bigmouth shiner, flathead chub, river carpsucker, channel catfish

Major other aquatic vertebrates: spiny softshell turtle, painted turtle, beaver, muskrat, river otter

Major benthic invertebrates: snails (*Physa*), crustaceans (*Hyalella azteca*), mayflies (*Isonychia*, *Caenis*, *Baetis*, *Pseudocleon*,
Callibaetis), caddisflies (*Hydropsyche*, *Brachycentrus*), true bugs (*Belostoma*), chironomid midges (*Rheocricotopus*)

Nonnative species: 24 fishes (brown trout, rainbow trout, brook trout, alewife, common carp)

Major riparian plants: eastern red cedar, ponderosa pine, eastern cottonwood, box elder, paper birch, American elm

Special features: swift-flowing Great Plains prairie river with eastern, western, and northern forest species in riparian zone;
groundwater a major source of discharge

Fragmentation: three main-stem dams

Water quality: good water quality, but high fecal coliforms; pH = 7.0, alkalinity = 23 mg/L as CaCO₃, NO₃-N = 0.40 mg/L,
PO₄-P = 0.162 mg/L

Land use: >95% agriculture, 2% forest

Population density: 1.1 people/km²

Major information source: Kuzelka et al. 1993

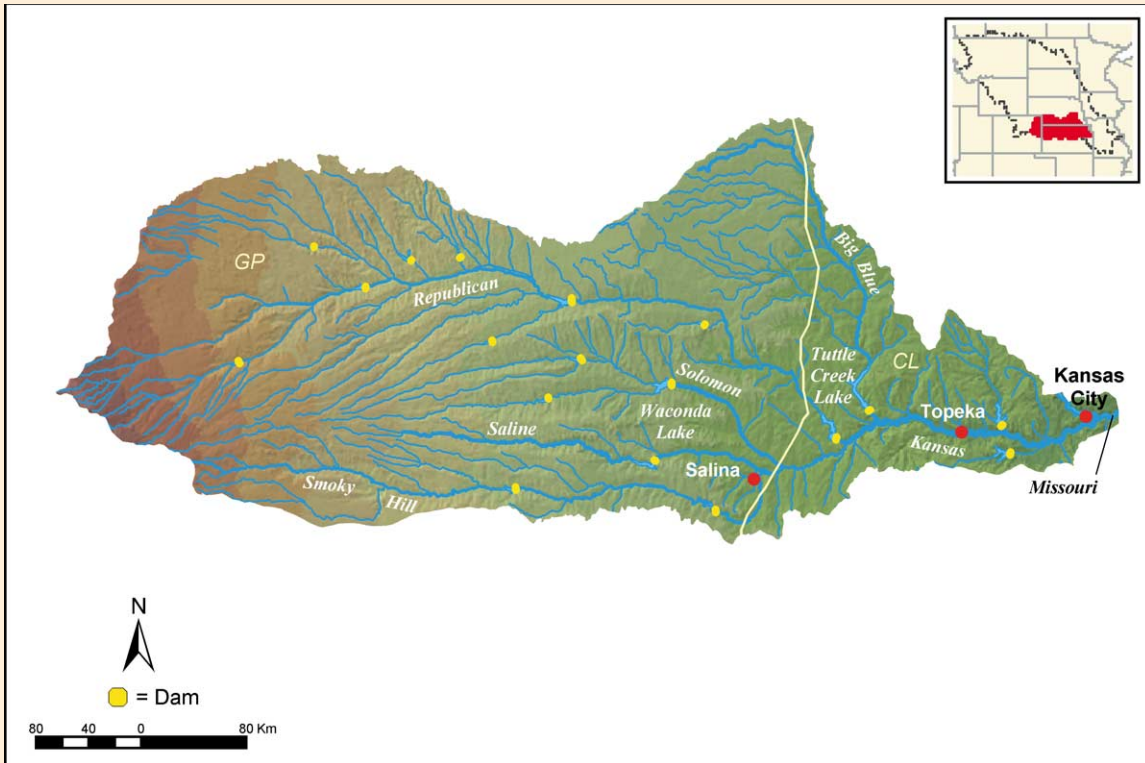

FIGURE 10.35 Map of the Kansas River basin. Physiographic provinces are separated by a yellow line.

KANSAS RIVER

Relief: 975 m

Basin area: 159,171 km²

Mean discharge: 214 m³/s

River order: 7

Mean annual precipitation: 61 cm

Mean air temperature: 12.2°C

Mean water temperature: 11.6°C

Physiographic provinces: Great Plains (GP), Central Lowland (CL)

Biome: Temperate Grasslands

Freshwater ecoregion: Middle Missouri

Terrestrial ecoregions: Western Short Grasslands, Southern Mixed Grasslands, Central Tall Grasslands

Number of fish species: 99 (75 native)

Number of endangered species: 1 fish

Major fishes: shovelnose sturgeon, longnose gar, gizzard shad, creek chub, suckermouth minnow, plains minnow, sand shiner, red shiner, river carpsucker, shorthead redhorse, blue sucker, white sucker, flathead catfish, channel catfish, largemouth bass, sauger, freshwater drum

Major other aquatic vertebrates: smooth softshell turtle, migratory waterfowl, beaver, muskrat

Major benthic invertebrates: mollusks (*Potamilus ohioensis*, *Lampsilis siliquoidea*), mayflies (*Isonychia*, *Heptagenia*, *Tricorythodes*), stoneflies (*Neoperla*, *Isoperla*), odonates (*Gomphus*, *Argia*), caddisflies (*Hydropsyche*, *Cheumatopsyche*)

Nonnative species: 24 fishes (common carp, grass carp, bighead carp, western mosquitofish, striped bass, yellow perch, walleye)

Major riparian plants: eastern red cedar, eastern cottonwood, box elder, American elm, sycamore, silver maple, willows

Special features: a large river that starts in the Great Plains and ends in the Central Lowland

Fragmentation: 18 large reservoirs, >13,000 small impoundments, dewatering by irrigation withdrawals

Water quality: reduction of turbidity from damming; pH = 8.4, alkalinity = 190 mg/L as CaCO₃, NO₃-N = 0.60 mg/L, PO₄-P = 0.16 mg/L

Land use: >90% agriculture, 2% forest, 3% urban

Population density: 12.7 people/km²

Major information sources: Cross 1967, Sanders et al. 1993, Patrick 1998

GRAND RIVER

Relief: 238 m

Basin area: 20,390 km²

Mean discharge: 117 m³/s

River order: 7

Mean annual precipitation: 92 cm

Mean air temperature: 11.8°C

Mean water temperature: 13.0°C

Physiographic province: Central Lowland (CL)

Biomes: Temperate Grasslands, Temperate Deciduous Forest

Freshwater ecoregions: Middle Missouri, Central Prairie

Terrestrial ecoregion: Central Forest/Grassland Transition Zone

Number of fish species: 61 (55 native)

Number of endangered species: 2 fishes, 1 mammal

Major fishes: shortnose gar, bigmouth shiner, red shiner, creek chub, sand shiner, central stoneroller, fathead minnow, bluntnose minnow, common carp, river carpsucker, channel catfish, flathead catfish, bluegill, green sunfish, Johnny darter

Major other aquatic vertebrates: bullfrog, green frog, false map turtle, red-eared slider, smooth softshell turtle, common snapping turtle, western painted turtle, northern water snake, wood duck, belted kingfisher, beaver, mink, muskrat, river otter

Major benthic invertebrates: mayflies (*Baetis*, *Isonychia*, *Stenonema*, *Caenis*), stoneflies (*Neoperla*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Potamyia*), beetles (*Stenelmis*), true flies (*Hemerodromia*), mollusks (fragile papershell, pink papershell, giant floater, yellow sandshell), crustaceans (northern crayfish, papershell crayfish)

Nonnative species: common carp, goldfish, bighead carp, grass carp, rainbow smelt, white perch, striped bass, Asiatic clam, Johnson grass

Major riparian plants: cottonwood, silver maple, green ash, American sycamore, hackberry, aromatic sumac, gray dogwood, giant ragweed, stinging nettle, poison ivy, grapes

Special features: preglacial channel of ancestral Missouri River; largest prairie river in Missouri relatively unaffected by dams or channelization (mouth to Rkm 56)

Fragmentation: no main-stem dams; ~30 impoundments >20 ha on tributaries

Water quality: pH = 7.8, alkalinity = 152 mg/L as CaCO₃, NO₃-N = 0.74 mg/L, PO₄-P = 0.04 mg/L; standards for Fe, Mg, and fecal coliforms frequently exceeded

Land use: 57% cropland, 32% grassland/pasture, 5% forest, 6% other

Population density: 6.3 people/km²

COLORADO RIVER BASIN

INTRODUCTION

The Colorado River Basin lies within the Intermontane Plateaus of the American Southwest. The basin encompasses a large geographic area from 42°N to 32°N latitude ranging from the high mountains of the Rockies in Wyoming and Colorado to the Colorado River delta in Mexico (Fig. 11.2). The Colorado basin drains seven states, or nearly 8% of the United States, including parts of Colorado, Wyoming, Utah, New Mexico, Nevada, and California, and 95% of Arizona's land mass. The entire basin encompasses some 642,000 km², with the Upper Basin draining about 45% of the total area (Pope et al. 1998). The majority (75%) of the river's flow is supplied by mountain headwater streams, but most of the catchment lies in a semiarid desert. Therefore, the annual unit area discharge (29,800 m³/km²) or runoff (2.98 cm/yr) makes the Colorado basin one of the driest in the world (Stanford and Ward 1986). In spite of this water scarcity, there are heavy demands from urbanization, agriculture, and hydropower. Nearly 64% of the runoff is used for irrigation and another 32% is lost by evaporation from reservoirs (Dynesius and Nilsson 1994).

The drainage basin has been divided into upper and lower basins at the confluence of the Paria River, near Lees Ferry, Arizona (36°52'N latitude), in order to administer the allocation of Colorado River water among the western states and Mexico. Much of the Colorado that runs through the upper basin was once called the Grand River. In 1921, President Warren Harding approved the name change to the Colorado River for the entire river corridor.

A series of creeks and rivers and numerous arroyos drain the region, with water mostly flowing in a northwesterly or south-southwesterly direction. The major rivers originate in the Wind River Range of the Wyoming Rockies, the Colorado Rockies, and the Mexican Highlands of west-central New Mexico and east-central Arizona. Over 80% of the entire basin includes semiarid shrub lands and desert scrub and two major North American deserts (Sonoran and Mojave), each with sparse vegetation (Brown 1994). Consequently, rivers in the lower basin generally carry limited upland terrestrial carbon but large loads of suspended sediments, especially after storm events.

Twenty-two major rivers converge with the Colorado after it begins its descent from Rocky Mountain National Park and winds through the

FIGURE 11.2 Rivers of the Colorado River basin covered in this chapter.

plateaus of Colorado, Utah, and Arizona, onto the deserts of southwestern Arizona, and finally into the Gulf of California, where inflows from the Río Hardy and Río Sonoita in Mexico complete the drainage. As the Colorado flows into drier and lower latitudes, significant discharges from tributaries may only occur after major summer storms. These storms play a major role in the community structure and ecological processes of these desert streams (Fisher and Grimm 1988). We will discuss the Colorado River main stem and four important tributaries: the Green, Yampa, Little Colorado, and Gila rivers. Summary paragraphs and one-page summaries are also provided for seven additional tributaries in the drainage: the Gunnison, San Juan, Virgin, Bill Williams, Verde, Black, and Salt rivers.

Physiography and Climate

Rivers in the upper basin (Upper Colorado, Green, Yampa, Gunnison, and San Juan) flow through four physiographic provinces (Middle Rocky Mountains [MR], Wyoming Basin [WB], Southern Rocky Mountains [SR], Colorado Plateaus [CO]) and four sections within these provinces (Uinta Basin, High Plateaus of Utah, Canyon Lands, and Navajo; Hunt 1974). Rivers in the lower basin (Lower Colorado, Little Colorado, Virgin, Black, Bill Williams, Verde, Salt, and Gila) pass through two provinces (Colorado Plateaus and Basin and Range [BR]) that include six sections (Mexican Highlands, Datil, High Plateaus of Utah, Navajo, Grand Canyon, and Sonoran Desert). The northernmost section of the Baja California (BC)

province includes the mouth of the Colorado River (Hunt 1974).

The geology of the basin is varied, but much of it consists of uplifted, highly erodible sedimentary deposits through which rivers have carved the spectacular canyons characteristic of the region. The headwaters of the basin generally lie in crystalline, granite bedrock, whereas the larger rivers flow through expansive and highly weathered sedimentary deposits.

Soils are generally shallow and derived from shale or sandstone. These soils are relatively poor in organic matter due to low vegetative production but contain large quantities of soluble minerals. Following evaporation or the consumptive use of water by plants, these minerals accumulate on or near the surface. Invasion of nonnative plants and increased irrigation have augmented the surface deposition of these salts, which are delivered to the main channels via overland flow by numerous arroyos during storm events (Ghassemi et al. 1995).

The Intermountain Plateaus receive little precipitation compared to the uplifted mountain ranges on either side. Annual air temperatures range from sub-freezing to 38°C in the upper basin and from 15°C to >45°C in the lower basin. Annual precipitation is ≤26 cm/yr in the valleys of the upper basin and from 25 to <5 cm/yr in the lower basin. In higher elevations of the upper basin an average of 2 m of snow accumulates during winter and spring, providing a surge in meltwater in late spring for much of the river system. Convective storms carry moisture from the Gulf of Mexico and the Gulf of California and cyclonic storms originating over the Pacific Ocean cause short-term storm events during the summer in the lower basin.

Basin Landscape and Land Use

The Colorado River basin encompasses a variety of landscapes, from subalpine in the Rockies to deserts in southwestern Arizona and Mexico, which are divided into nine terrestrial ecoregions (Ricketts et al. 1999). The terrestrial ecoregions in the highest elevations (>3000 m asl) include Colorado Rockies Forests, South Central Rockies Forests, Wasatch and Uinta Montane Forests, and Arizona Mountain Forests. These are primarily coniferous forests with Douglas fir, subalpine fir, and Engelmann spruce interspersed with ponderosa pine in the lower mountainous areas. The shrublands, located at intermediate elevations (1500 to 3000 m asl), include the open and arid Wyoming Basin Shrub Steppe, with sage-

brush, wheatgrass, and fescue, and the Colorado Plateau Shrublands, with sagebrush, mountain mahogany, pinyon pine, and several junipers as the dominant vegetation. The Colorado Plateau Shrublands is the largest (326,390 km²) terrestrial ecoregion in the river basin, with approximately 90% of the ecoregion drained by the Colorado River and its tributaries (Ricketts et al. 1999). The lower elevations (>1500 m asl) of the Colorado River Basin include the Mohave, Sonoran, and Chihuahuan Desert ecoregions. The vegetation in the Mohave includes all-scale, brittlebush, creosote bush, desert holly, white burrobush, numerous species of cacti, and the endemic Joshua tree, whereas the Sonoran Desert contains creosote, white bursage, palo verde, ironwood, and an assortment of tall cacti, including the giant saguaro. The Chihuahuan is characterized by shrubs such as creosote, tarbush, mesquite, and acacia.

The riparian communities at higher elevations (>2000 m asl) in both the upper and lower basins consist of alder, dogwood, birch, elderberry, Rocky Mountain maple, and several willows. At elevations between 1800 and 2000 m asl cottonwoods and willows dominate, along with nonnative salt-cedar in many locations. In lower latitudes, Arizona sycamore and Arizona walnut can be common. As elevation decreases the width of the riparian band shrinks to only a few meters with decreasing precipitation (Brown 1994).

Common desert riparian plants include acacia, black greasewood, cat-claw, mesquite, saltbush, and seep willow. Cattails, sedges, and common reed occur in some of the backwater marshes of the lower Colorado River. These narrow bands of vegetation provide critical organic matter to desert streams otherwise surrounded by a depauperate terrestrial flora.

Several nonnative species, including salt-cedar and camelthorn, are rapidly invading the riparian communities. Salt-cedar was imported into California by farmers to control erosion, but quickly invaded the lower Gila River basin. Today salt-cedar is found all the way into the headwaters of the Gila River and is slowly moving up the entire Colorado River drainage as far as the Green River, especially in disturbed areas or flow-regulated reaches. There is concern that this nonnative plant may not perform the same ecological functions in desert stream communities as native riparian plants (Pomeroy et al. 2000).

The archaeology of the upper basin shows evidence of widespread human culture dating back 11,000 years (Smith 1974). About two millennia ago

the agrarian Anasazi culture arose in the southern part of the basin; numerous cliff dwellings, including Mesa Verde National Monument in southwestern Colorado, remain as testaments to their presence. Around 800 AD the Fremont culture arose throughout most of Utah and western Colorado, but they were supplanted from the north and west by the Utes, who ultimately spread to occupy most of the upper basin province by the time of European arrival. Eventually, seven loose confederations formed in the Ute Nation. These often coincided with major river drainages. For example, the Weeminuche occupied the San Juan River valley, the Tabeguache lived in valleys along the Gunnison River, the Yampa band inhabited the Yampa River valley, and the Uintah Utes occupied the Uintah basin (Jefferson et al. 1972). The Spanish made first contact with the Utes in the 1630s.

The great influx of English-speaking settlers into the upper basin began in 1847, when the Mormons migrated to the Salt Lake valley, and about the same time the gold rush began in Colorado. Most new inhabitants settled outside the upper basin drainage divide, to the west in Salt Lake valley and to the east along the Colorado Front Range near Denver. But these human population centers quickly began exerting an influence on the rivers of the upper basin through agriculture and ranching. For example, the headwaters of the upper Colorado River have been diverted to the Missouri River drainage since 1890 via the Grand Ditch through Rocky Mountain National Park (Wohl 2001).

In the upper basin states (Wyoming, Colorado, Utah, and New Mexico), 90% of the water used is spread on land irrigated for crops, leaving 10% for urban and other uses. Of the 1.6 million acres irrigated, feed for livestock is raised on 88% of the irrigated land. The largest urban center in the drainage is Grand Junction, Colorado (population ~42,000). About 100 years ago fire spread across this region, resulting in major vegetation changes that included declines in grassy vegetation and increases in woody plants, a trend that continues today.

The lower basin states (Arizona, California, and Nevada) also have a long history of agricultural occupation. The Mogollon culture first developed an agricultural civilization in the upper Gila River region in western New Mexico as early as 2200 years ago (McNamee 1998). Evidence of their culture remains at the Gila Cliff Dwellings National Monument in New Mexico and the Casa Malpais and Raven ruins near Springerville, Arizona. Other Native American cultures later developed on the Gila River near the

present site of Coolidge Dam and at the confluence of the Colorado rivers. Many of these cultures were presumably absorbed into the Hohokam culture that occupied the central region of the Gila River. These Native Americans also used the Gila and lower Colorado rivers to fish for Gila trout and the large and once abundant Colorado pikeminnow. Spanish explorers ventured into the American Southwest from Mexico in the late 1600s, where they encountered a harsh environment and a network of canals that had previously irrigated prehistoric crops along the middle Gila River (Fradkin 1981).

In the late 1800s, Mormon settlers moved into the Little Colorado River basin in eastern and central Arizona and developed extensive sheep and cattle ranches as well as crop farms where wheat, oats, and barley were grown. These regions remain active ranching communities today. Also, the San Pedro and Santa Cruz rivers, both intermittent north-flowing tributaries to the Gila River, provided southern corridors for early Europeans to explore the American Southwest and beyond (Fradkin 1981).

The arid landscape in the lower basin shows evidence of heavy use from agriculture, ranching, and mining over the last century, with dense urbanized areas in metropolitan Las Vegas, Phoenix, and Tucson. Even metropolitan areas outside the Colorado River basin, such as Denver and Los Angeles, exert an influence on the basin via transbasin diversions for municipal and agricultural water use. Heavy demands on a restricted water supply to satisfy expanding agriculture and mining needs and the rapid expansion of dense urban communities over the last century have resulted in reduced water flows, deterioration of water quality, reduced groundwater levels, and ground subsidence, especially in the Tucson area, where large quantities of groundwater are pumped for human use. Heavy grazing in certain regions has enhanced soil erosion, caused the invasion of nonnative plants, and destroyed riparian communities. Over 85% of the native riparian communities in the lower basin have been modified or lost and <2% remain natural (Brown 1994). Mine wastes are of concern along sections of the Gila River in the lower basin, and storage reservoirs and irrigation have greatly increased secondary salinization. In the lower basin, 85% of water goes to agricultural purposes, with a significant percentage going to grow feed for livestock. Of the 99 million acres in the lower basin, 82 million acres are rangeland or pasture, whereas only 500,000 acres are classified as urban.

The Rivers

The principal tributaries along the Colorado main stem in order of their occurrence include the Gunnison, Green/Yampa, and San Juan river systems in the upper basin and the Little Colorado, Virgin, Bill Williams, and Black/Salt/Verde/Gila river system in the lower basin (Fig. 11.2). Combined, the four tributaries in the upper basin deliver over 11 billion m³ of water to the main stem annually, of which over 50% is delivered during May and June from snowmelt. In contrast, the main tributaries in the lower basin deliver <0.5 billion m³ annually, most of which comes from the Little Colorado and Virgin rivers, often during summer monsoonal storms.

The Colorado River basin contains three freshwater ecoregions according to the classification of Abell et al. (2000). In all ecoregions, river headwaters are clear and have steep gradients and stony substrates. However, once these rivers descend onto the plateaus they become highly depositional, with a substratum of fine sediments and a high degree of embeddedness. Woody debris dams are rare in the turbid, desert rivers.

The Colorado ecoregion of southwestern Wyoming, western Colorado, eastern Utah, and northern Arizona contains several major rivers: the upper Colorado, Green, Yampa, Gunnison, San Juan, Bill Williams, and Little Colorado (Fig. 11.2). These rivers originate in the Rocky Mountains in Wyoming and Colorado and in the White Mountains in east-central Arizona. The Vegas-Virgin ecoregion of southwestern Utah and northwestern Arizona is represented by the Virgin River, which originates at the edge of the Markagunt Plateau in southwestern Utah. The Gila ecoregion of west-central New Mexico and east-central Arizona contains the Gila River and associated drainages, including the Black, Verde, and Salt rivers. The Gila River proper has headwaters in the Gila National Forest, New Mexico (Fig. 11.2). All of these rivers have similar headwater and downstream conditions as outlined for the aforementioned rivers.

The rivers in the three freshwater ecoregions of the Colorado Complex have a relatively high degree of biological distinctiveness in that all are considered continentally outstanding (Abell et al. 2000). The Colorado is the 16th largest (507,245 km²) freshwater ecoregion in North America and has the richest native fauna of the three ecoregions, with its 29 fishes, 26 herpetofauna, and 3 mussels. The Vegas-Virgin (34,565 km²) is the 5th smallest in North America and has a native fauna of 11 fishes, 8 herpetofauna, and 1 mussel, whereas the Gila

(159,875 km²) has a native fauna of 19 fishes, 27 herpetofauna, and 1 mussel (Abell et al. 2000).

The American Southwest has some of the highest rates of fish endemism on the continent. For example, in the Colorado River basin, 35% of all native genera and 64% of the species are endemic (Carlson and Muth 1989). Over 85% of the fish fauna in Arizona are threatened and all three ecoregions have a conservation status of either critical or endangered with a high likelihood of future threats (Abell et al. 2000). All of the endemic fish species in the Colorado and Vegas-Virgin ecoregions are considered imperiled and over 40% are imperiled in the Gila ecoregion. All three ecoregions have high vulnerability to the deterioration of water quality, with urban development, nonpoint-source pollution, groundwater pumping, mining, diversions for agriculture and ranching, and fragmentation by dams the major threats. Recently Minckley et al. (2003) proposed an extensive conservation plan for native fishes of the lower basin.

The Colorado River drainage is one of the most regulated rivers in the world, with over 40 large flow-regulation structures and countless diversions along its river corridors (Dynesius and Nilsson 1994). The large metropolitan areas of Phoenix and Tucson started to expand in the early 1900s, as did Las Vegas in the mid-1900s. With the continued growth in the American Southwest, settlers began to divert Colorado waters into the deserts, eventually leading to the construction of major dams, including Theodore Roosevelt on the Salt River in 1911, Coolidge on the Gila in 1930, and Hoover and Glen Canyon on the Colorado in 1935 and 1963, respectively. Major dams were also built in the upper basin for storage and hydropower. These include Flaming Gorge on the Green River in 1962, Navajo on the San Juan in 1963, and Blue Mesa on the Gunnison River in 1963, all of which greatly altered the hydrology, ecology, and water quality of the Colorado River (Marzolf 1991, Blinn et al. 1998, Vinson 2001). These alterations, in addition to the introduction of nonnative species, have directly contributed to the endangered or threatened status of 24 native fish species; 4 are now extinct (Minckley 1991, Minckley and Deacon 1991, Starnes 1995).

The Colorado River is managed and operated under compacts and regulatory guidelines collectively known as the "Law of the River," which apportions and regulates the management and use of the Colorado among the seven basin states and Mexico (Gleick et al. 2002). The cornerstone for the Law of the River was the Colorado River Compact of 1922, at which time President Herbert Hoover suggested

the Colorado River basin be divided into an upper and lower half, each having the right to develop and use river water. Since that time there have been at least 10 additional amendments released on the management and allocation of water from the river. The Mexican Water Treaty was signed in 1944. These interstate and international issues will only escalate as water continues to become a diminishing resource in the southwestern United States. The recent applications to double the number of coal-burning power facilities within the lower basin will further impact groundwater levels and water quality. Currently, the lower basin has four such plants in operation. Future threats to water quality in the upper basin include agriculture and the possible mining of the extensive and highly saline oil shale deposits in western Colorado.

COLORADO RIVER MAIN STEM

The Colorado River originates in alpine meadows on the western slopes of the Continental Divide in Rocky Mountain National Park, Colorado, at an elevation of ~3105 m asl (Stanford and Ward 1986). The Colorado is the largest waterway in the American Southwest and has the seventh-largest drainage area and the seventh-longest river corridor in North America. The river meanders in a southwesterly direction between 105°W, 40°N and 114°W, 31°N for over 2300 km through the Great Basin and Sonoran deserts, and portions of five states (Figs. 11.2 and 11.13). On its course it winds through broad aggraded valleys and bedrock uplifts and passes through Arches and Canyonlands National Parks in Utah and Grand Canyon National Park in Arizona, and then delineates the borders of California and Arizona as it flows southward. Ultimately, what remains of its highly altered flows reach its oceanic outlet, the Gulf of California, approximately 50 km into Mexico. Nearly three-fourths of the basin lies on federal lands.

As described earlier in more detail, an ancient agricultural culture may have occupied parts of the lower basin as early as 2200 years ago (McNamee 1998), with occupation of the upper basin dating back to 11,000 years ago (Smith 1974). Native American cultures later developed on the Gila River near Coolidge Dam and at its confluence with the Colorado River. Spanish explorers ventured into the American Southwest in the late 1600s, where they found evidence of prehistoric agriculture along the middle Gila River (Fradkin 1981). Mormon settlers

migrated into the upper basin in the mid 1800s, with similar settlements along the Little Colorado River in eastern and central Arizona in the late 1800s.

Physiography, Climate, and Land Use

The Colorado River flows out of the Middle Rocky Mountains (MR), Southern Rocky Mountains (SR), and Wyoming Basin (WB) physiographic provinces, through the Colorado Plateau (CO) province for over 1500 km, into the Basin and Range (BR) province, and ultimately into the Baja California (BC) province (see Fig. 11.13) (Hunt 1974). This area corresponds to the Colorado Rockies Forests, Colorado Plateau Shrublands, Mohave Desert, and Sonoran Desert terrestrial ecoregions (Ricketts et al. 1999).

The Colorado River flows through at least seven Merriam Life-zones (Brown 1994). The river starts in the Colorado Rockies, which contain alpine fir, Douglas fir, and Engelmann spruce. The Colorado meanders through Montane Conifer Forests of ponderosa pine onto the Great Basin Conifer Woodland of pinyon-junipers; the Great Basin Grasslands, with wheatgrasses and fescues; the Desertscrub Zone of sagebrush, shadscale, and winterfat; the Mohave Desert, with all-scale, brittlebush, creosote bush, Joshua trees, white burrobush, and assorted cacti; and finally through the Sonoran Desert (<500 m asl) of creosote bush, giant saguaro, white bursage, and assorted cacti (Brown 1994, Ricketts et al. 1999).

Most of the water is delivered as snow in the upper basin, whereas summer monsoons deliver much of the precipitation in the lower basin. The lower Colorado meanders through the most arid portions of the Sonoran Desert, with summer air temperatures >45°C. Precipitation is >100 cm/yr in the headwaters of the Colorado, <15 cm/yr at the start of the lower basin (952 m asl), and about 1.5 cm/yr near the mouth of the river (Brown 1994). In the upper basin, mean monthly highs and lows in air temperature are 25.3°C and -3.6°C, respectively, compared to 33.4°C and 8.9°C for the lower basin (Fig. 11.14). Annual mean precipitation for the combined upper and lower basins averages about 16.4 cm.

The landscape through the river basin is largely influenced by agriculture, ranching, and, to a lesser degree, mining. Dense urban areas are generally lacking along the main stem except for the metropolitan area of Las Vegas, which is rapidly approaching a million residents. Other population centers along the Colorado include Grand Junction, Colorado, and Page and Lake Havasu City, Arizona, all with

populations of less than 50,000 people. Even though large metropolitan areas such as Denver are outside the Colorado basin, the Colorado–Big Thompson Project in the upper basin diverts a substantial volume of water (over 370 million m³/yr) in the Colorado River headwaters to Denver and other cities in the Mississippi River drainage. Similarly, cities such as Los Angeles and Phoenix receive large quantities of river water in underground and open aqueducts from below Lake Havasu as a result of the Colorado River Compact in 1944. Water from diversions along the Colorado River irrigates over 750,000 ha of landscape and serves over 30 million people (Gleick et al. 2002). Although the basin itself has only

about 7 people/km², each drop of water in the Colorado is estimated to be used an average of 17 times.

River Geomorphology, Hydrology, and Chemistry

The Colorado River is divided into upper (Wyoming, Colorado, New Mexico, and Utah) and lower basins (Arizona, Nevada, and California) at the confluence of the Paria River near Lees Ferry, Arizona (Fig. 11.3). By the time it reaches the lower basin the river has dropped over 1750 m. The average river gradient is about 2.2 m/km in the upper basin, 0.7 m/km in the

FIGURE 11.3 Colorado River near Lees Ferry, Arizona (PHOTO BY E. BENENATI).

lower basin, and 1.8 m/km for the entire river corridor.

During its course the river flows through deep canyons comprised largely of interbedded sandstone, siltstone, and shale. The basin contains igneous and metamorphic rock types in the upper watersheds and sedimentary formations, rich in sodium chloride (halite) and calcium sulfate (gypsum) deposited in ancient marine and brackish water environments, on the plateaus (Patrick 2000). In sections of the upper basin, the river has carved deep, narrow canyons in the highly erodible sedimentary deposits at a rate of approximately 17 m/1000 yr (Stanford and Ward 1986). On the plateaus a ribbon of water winds through a wide alluvial floodplain. Through Grand Canyon, the Colorado cuts over 1100 m deep through several distinct geological strata ranging in age from 180 million (Jurassic) to nearly 2 billion years (Precambrian). The river drops over 570 m through the canyon, where whitewater rafters encounter over 75 major rapids. Much of the lower basin is ≤ 750 m asl and the rivers typically have low gradients, wide floodplains, elevated solutes, seasonally heavy silt loads, embedded substrates, and regulated flows.

Based on morphometric criteria, the Colorado River may be considered a 6th order stream by the time it reaches the lower basin and continues as such until it empties into the Gulf of California. Others consider the Colorado to be a 4th or 5th order stream at the head of the lower basin (Shannon, Blinn, McKinney et al. 2001). This disparity suggests that traditional classification schemes for rivers should be used with caution, especially in arid biomes. The greatest difficulty in using ordering schemes lies in properly characterizing the first several orders in the upper watersheds and ephemeral drainages (W. Osterkamp, personal communication).

Discharge in the upper basin of the Colorado River is seasonably variable (<30 to >2000 m³/s), with an annual mean stream flow of 74 m³/s at Grand Junction, Colorado, and ~ 210 m³/s near Cisco, Utah (USGS 2004a <http://water.usgs.gov/public/nasqan>). The annual virgin discharge for the Colorado River is 550 m³/s (Dynesius and Nilsson 1994). In 1905, floodwaters from the Colorado flowed into the Salton basin in southern California to form the Salton Sea.

Glen Canyon Dam (GCD) has regulated flows below Lake Powell since 1963. This 216 m high structure currently inundates over 160 km of riverine habitat through the spectacular Glen Canyon National Recreational Area. Before closure of GCD,

annual discharge through the Grand Canyon from melting mountain snowpacks ranged from ~ 85 m³/s during late summer, fall, and winter to ~ 2300 m³/s during late spring and early summer, with a flood maximum of 8500 m³/s recorded on July 7, 1884 (Pope et al. 1998). Historic shoreline deposits suggest a flood larger than 14,160 m³/s within the last 1600 years. The range of annual stage for the Colorado River in the Grand Canyon prior to GCD was an impressive 6.4 m, but after closure this was reduced to 4.1 m (Stanford and Ward 1991). Today the average depth of the river through the Grand Canyon is about 9 m, with a maximum depth of nearly 40 m near Phantom Ranch. After the closure of GCD, flows have a peak discharge of 566 m³/s and a minimum of 141 m³/s, with daily fluctuations of 170 to 226 m³/s (Shannon et al. 1996). During the spring of 1996 a controlled flood of 1275 m³/s for 4 days was conducted below GCD to determine its effect on the geomorphic and ecological resources of the Colorado through the Grand Canyon (Webb et al. 1999).

Major spring-fed tributaries in the Grand Canyon (Vasey's Paradise, Nankoweap, Bright Angel, Tapeats, Havasu, and Spring Canyon) contribute <98 million m³/yr to the Colorado, with base discharges <2 m³/s (Pope et al. 1998). The Little Colorado River is the primary tributary in the canyon, with an average annual discharge of about 8 m³/s. Short-duration flood flows (up to 700 m³/s) provide most of the annual runoff from the Little Colorado.

Discharges diminish throughout the Lower Colorado River basin due to municipal and agricultural diversions and evaporation from reservoirs. Today, the annual mean streamflow is <100 m³/s through much of the Lower Basin (USGS 2004a <http://water.usgs.gov/public/nasqan>). Prior to the construction of Hoover Dam (Lake Mead) in 1935 the river supplied the Colorado Delta in Mexico with 6 to 18 billion m³ of water annually, compared to today's <0.7 billion m³ (Rodriguez et al. 2001). Even though discharges from the upper basin are seasonably variable, the numerous diversions and reservoirs greatly dampen the seasonal patterns in annual runoff in the lower basin. Presently, runoff below Hoover Dam ranges from only 0.20 to 0.28 m/mo, with an annual runoff of only 2.8 m (see Fig. 11.14).

Large amounts of sediment delivered from the semiarid regions of the Colorado Plateau in southern Utah, southwestern Colorado, northwestern New Mexico, and northern Arizona are transported by the Colorado. The arid plateau represents 37% of the total drainage area, but it delivers only 15% of the total runoff and over 80% of the sediment load

(Andrews 1991). Suspended sediment loads are <5 mg/L in the headwaters of the upper Colorado River but increase to >600 mg/L by the time the river reaches the Colorado–Utah border. Prior to the closure of GCD the river transported nearly 86 million tons of sediment through the Grand Canyon each year and the Paria and Little Colorado rivers supplied only 10% of that sediment load. Today the Paria and Little Colorado rivers supply most of the sediment to the regulated canyon river (3.0 and 9.3 million tons, respectively), with the greatest deliveries from July through September, when waters rapidly turn to a thick, reddish-brown color below these two tributaries (Andrews 1991). In addition, over 65 dry washes and creeks periodically deliver sediment to the canyon river at lesser loads. Debris flows inside canyons also transport sediment to the Colorado in Grand Canyon. Presently, the desert reservoirs in the lower basin are rapidly collecting these sediments as depositional deltas in their upstream bays. In addition, the river below GCD is accumulating sediment in pools above rapids and along shoreline eddies below rapids because delivery from the Paria and Little Colorado rivers exceeds the current sediment transport capacity of the highly regulated Colorado. Highest suspended sediment concentrations (>5000 mg/L) occur during the summer, when intense local storms produce flash floods in the numerous ephemeral drainages.

There are 40 large flow-regulation structures along the Colorado, including five complete main-stem dams (Davis, Parker, Imperial, Laguna, and Morelos) across the river and two partial rock and earthen dams (Palo Verde and Headgate Rock) used for control and diversion below Hoover Dam. The 654 km corridor between Flaming Gorge Dam and the lower portions of the Green and Colorado rivers through Canyonlands National Park represents the longest unregulated portion of the Colorado River system and may approach the closest natural riverine conditions along the Colorado prior to excessive regulation (Haden et al. 2003).

The combined storage capacity for all reservoirs on the Colorado River is 17 billion m³, equal to approximately four times the total average annual flow in the Colorado River (Andrews 1991). Most of the reservoirs on the Colorado River were completed by 1963, including the four largest main-stem reservoirs (Powell, Mead, Mojave, Havasu; see Fig. 11.13). These storage basins are used for flood control, hydropower, municipal water supplies, irrigation of crops, and recreation (Andrews 1991). The high evaporation rates on these desert reservoirs have

increased salinities and adversely affected irrigated agriculture in the lower basin. Furthermore, dams below the impoundments have modified the timing and amplitude of discharge as well as water quality and water temperature throughout the basin (e.g., Rader and Ward 1988, Marzolf 1991, Blinn et al. 1998, Vinson 2001).

Dams create highly altered temperature patterns in desert streams. Air temperatures exceed 40°C in the summer in the semiarid region of Grand Canyon National Park and are below freezing in the winter, yet annual water temperatures below GCD range from 9°C to 14°C due to hypolimnial releases. Summer water temperatures approached 30°C through the Grand Canyon prior to the dam (Stanford and Ward 1986). Recently there has been discussion on increasing water temperatures below GCD by releasing water from different reservoir depths. Regulated water temperatures are 13°C to 14°C below Hoover Dam and 13°C to 26°C below Parker Dam (Lake Havasu).

Water quality changes dramatically along the 2300 km river corridor of the Colorado, especially specific conductance, in part due to high evaporation rates on desert reservoirs, where average annual air temperatures exceed 24°C in the lower basin. Conductance in the upper watershed of the Rocky Mountains is <100 µS/cm (TDS 80 mg/L). By the time the river reaches the Colorado–Utah border, conductance is an order of magnitude higher, and it is over 3000 µS/cm (TDS 1200 mg/L) at the international boundary between the United States and Mexico. Alkalinity ranges from <50 mg/L as CaCO₃ in the headwaters to >175 mg/L at the mouth, and pH ranges from 7.7 to 8.6 throughout the upper and lower basins. Water temperatures range from near 0°C to 15°C in the headwaters to 30°C in the lower basin, and dissolved oxygen generally exceeds 8 mg/L throughout the river corridor. The headwaters are CaCO₃ dominated; however, waters at the Colorado–Utah border and throughout much of the remainder of the river corridor are dominated by CaSO₄ due to increases in gypsum in bedrock formations. Dissolved silica concentrations average about 10.4 mg/L throughout the river corridor. Average concentrations of PO₄-P and NO₃-N are 0.002 mg/L and 0.2 mg/L in the upper basin and 0.01 mg/L and 0.3 mg/L in the lower basin, respectively (Tadayon et al. 2001).

River Biodiversity and Ecology

The main channel of the Colorado River lies within the Colorado freshwater ecoregion, although two of

its tributaries (Vegas-Virgin and Gila) are sufficiently distinct to merit their own ecoregion designation (Abell et al. 2000).

Algae and Cyanobacteria

Heavy loads of sediment carried by spring floods greatly reduce the diversity and densities of algae in the river through the upper basin, with attached diatoms and filamentous green algae (*Cladophora*, *Microspora*, *Stigeoclonium*) and cyanobacteria (*Anabaena*, *Oscillatoria*, *Phormidium*) common taxa (e.g., Rader and Ward 1988). Planktonic forms are rare. Few studies were conducted on the algal flora prior to the closure of GCD (Blinn and Cole 1991). Today, attached diatoms, filamentous green algae, and cyanobacteria make up nearly 90% of the algal community in the Grand Canyon, with *Achnanthisium*, *Cladophora*, *Cymbella*, *Cocconeis*, *Diatoma*, *Fragilaria*, *Gomphonema*, *Nitzschia*, *Oscillatoria*, *Phormidium*, *Rhoicosphenia*, *Tolypothrix*, *Ulothrix*, and assorted zygnemataleans the most widespread genera in the regulated river (Czarnecki et al. 1976, Czarnecki and Blinn 1978). Many of the algal species in the Colorado in the Grand Canyon are cold-adapted forms due to the altered thermal regimes below GCD. Numerous isolated “hanging garden” springs along the canyon walls support a rich algal flora. Also, filamentous cyanobacteria interweave their mucilaginous trichomes through fine channel sediments to form extensive surface mats, called “elephant skin,” in the lower reaches through Grand Canyon.

Plants

Mosses largely occupy the higher-gradient headwaters, whereas submerged macrophytes are generally found in the lower-gradient downstream reaches. As suspended sediment loads increase, aquatic macrophytes are replaced by filamentous green algae, especially *Cladophora* and zygnemataleans, and eventually by cyanobacteria. Extensive stands of an asexual horsetail population (*Equisetum ferrissi*) provide habitat for invertebrates and fishes along the shorelines of the Colorado through Grand Canyon. Also, large monospecific stands of common watermilfoil, Eurasian watermilfoil, and sago pondweed occur in the slow-moving waters of lower Colorado River. A nonnative water fern has invaded the lower Colorado River over the last several years and has spread rapidly along the Colorado River below Blythe, California, forming thick floating mats in slow-moving backwaters (C. O. Minckley, personal communication).

The riparian vegetation in the subalpine forest (>2100m asl) includes Englemann spruce and willows, and winter deciduous shrubs such as gooseberry, raspberry, and red elderberry. In the Montane Forests (1700 to 2100m asl), Arizona alder, Arizona sycamore, gamble oak, and narrowleaf cottonwood are common riparian constituents. Lowered streamflow has reduced the number of mixed broadleaf species to scattered individual trees, opening the canopy and reducing its desirability for wildlife. The scrubland riparian community includes catclaw, common reed, desert-broom, and mesquite. The riparian communities along the lower Colorado include common reed, Fremont cottonwood, Goodding's willow, and/or velvet mesquite. However, the continued clearing along the lower Colorado has led to invasions by salt-cedar that have moved high into the upper drainage. Bulrushes, cattails, and common reeds border the many marshes along the lower Colorado that provide important wintering grounds and nesting sites for avifauna.

Invertebrates

The aquatic insect assemblages in the headwaters of the Colorado are quite diverse. Ward and Kondratieff (1992) reported 63 stoneflies, 57 caddisflies, and 48 mayflies in the upper reaches of the Colorado drainage. These insect categories along with true flies and beetles contribute over 97% of the total invertebrates in the headwaters. Insect diversity is greatly reduced by the time the silt-laden Colorado reaches the Colorado Plateau and even more reduced in the lower basin. Ward et al. (1986) reported the mayflies *Traverella albertana* and *Heptagenia* spp. and only a few caddisflies and stoneflies in the upper Colorado Plateau.

More recently, Haden et al. (2003) reported a more diverse fauna of 28 insect taxa approximately 20 to 110km above Lake Powell in Canyonlands National Park, Utah. The dominant taxa included mayflies (*Baetis*, *Ephoron*, *Heptagenia*, *Paracloeodes*, *Traverella*), caddisflies (*Ceratopsyche*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Smicridea*), a hellgrammite (*Corydalus*), a damselfly (*Argia*), beetles (*Neelmis*, *Microcylloepus*), and high densities of chironomid midges and black flies.

Few studies on invertebrates were conducted on the Colorado River prior to the closure of GCD (Blinn and Cole 1991). Trophic groups such as collectors and shredders are now absent in the Colorado throughout the Grand Canyon due to the extensive river alteration (Stevens, Shannon, and Blinn 1997). Filtering and piercing caddisflies (*Ceratopsyche*

oslari, *Chimarra*, *Hydroptila arctica*), and three species of *Ochrotrichia* (*O. dactylophora*, *O. logana*, *O. stylata*) and dipterans, namely chironomid midges and black flies (*Simulium chromatinum*), are the primary aquatic insects in the main-stem Colorado through Grand Canyon National Park. Adjoining tributaries have a number of aquatic insect species more typical of ephemeral desert streams (Oberlin et al. 1999). Chironomid species richness increases from 11 taxa in the clear tailwaters below GCD to 24 in the highly turbid downstream waters of the Colorado through the Grand Canyon (Stevens et al. 1998). Oligochaete worms (*Limnodrilus hoffmeisteri* and *Pristina* spp.), the nonnative amphipod *Gammarus lacustris*, and numerous snail species, including a recent invasion of the New Zealand mudsnail, make up the remainder of the invertebrate fauna throughout the Grand Canyon (Spamer and Bogan 1993, Stevens, Shannon, and Blinn 1997). Oligochaetes and chironomids are the dominant benthic organisms in the lower basin. The Asiatic clam became established in the 1940s and the common American prawn, red swamp crayfish, gammarid amphipods, and snails have been introduced as fish food in various sections of the lower Colorado River (Stanford and Ward 1986). The nonnative virile crayfish occurs above Lake Powell reservoir.

Vertebrates

Historically, the Colorado River drainage had 49 native freshwater fish species, represented by seven families, plus two marine species (machete and striped mullet; Starnes 1995). Of the indigenous fish species that remain, 42 are considered endemic to the system and 40 of these are considered endangered and/or threatened. Four species (Pahrnagat spinedace, Las Vegas dace, Monkey Springs chub, and the Monkey Springs pupfish) are extinct (Minckley and Deacon 1991, Starnes 1995, Minckley et al. 2002). The already extinct Monkey Springs pupfish (from museum specimens) and the headwater chub have recently been described in the lower basin (Minckley and DeMarais 2000, Minckley et al. 2002). Others suggest that only 36 or as few as 29 native fish species formerly lived in the Colorado River basin (Carlson and Muth 1989, Abell et al. 2000).

The lower basin has the greatest diversity of native fish species (35), whereas the upper basin is less diverse, with 14 indigenous species (Carlson and Muth 1989, Starnes 1995, Minckley 1991). Most of the native species are extant in the upper Colorado, but many species are rapidly declining (e.g., razor-

back suckers and bonytail chubs). Approximately 500 razorback chubs occur in the upper basin and about 4000 wild adults remain in Lake Mojave in the lower basin, where there has been no reproductive success since closure of the dam. Historically, bonytail chubs were probably one of the most abundant fishes in the Colorado River basin, but they now only occur in a few locations in Cataract Canyon and the Green River in the upper basin and in Lake Mojave in the lower basin. They have been called functionally extinct by Carlson and Muth (1989). The Colorado pikeminnow, a large (1.5 m in length and over 20 kg in weight) predatory and highly migratory fish with a life span of >40 years, was last reported in the lower basin in 1975 (Minckley 1991). Pikeminnows are relatively abundant in the upper basin, but their distribution is restricted by dams and diversions.

The humpback chub, which lives up to 35 years and was once abundant in the upper and lower basins, occurs in the Grand Canyon river corridor, especially near the confluence of the Little Colorado River and from the Paria River to Rkm 420 on the main stem (Douglas and Marsh 1996, Gorman and Stone 1999). Estimates suggest that <1500 adults remain in the canyon corridor. There are also reproducing populations of humpback chub in Black Rocks and Westwater canyons in the Colorado River, Gray and Desolation canyons in the Green River, and Yampa Canyon in the Yampa River in the upper basin. The roundtail, humpback, and bonytail chubs, Colorado pikeminnow, and razorback suckers all evolved in the large, turbulent, sediment-laden rivers of the Colorado River basin and have adapted features such as large body size, highly streamlined bodies, large predorsal humps or keels, thin caudal peduncles, tiny or absent scales, thick and leathery skins, and slow growth (Minckley 1991).

At least 72 nonnative fishes have been successfully introduced in the Colorado River system over the years (Starnes 1995). Many of these introductions, including channel and flathead catfish and red shiner, have been linked to the decline and/or displacement of native species. Reservoirs (Lake Powell and Lake Mead) contain large populations of introduced species, including black crappie, common carp, largemouth bass, and striped bass. Many of these nonnative fishes are known predators on larval and juvenile native fishes (Minckley 1991). Introductions of salmonids to establish trophy fisheries in the clear, cold tailwaters below dams have also impacted the native fish communities. Presently over 85% of the fish species through Grand Canyon National Park are

nonnatives (Minckley 1991). Populations of small fish species such as the desert pupfish and the Quito-baquito pupfish occur in disjunct populations near the Salton Sea, California, on Organ Pipe National Monument, Arizona, and in hypersaline pools in the Colorado River delta. Dewatering and predation pressures from nonnative tropical fishes such as Mexican mollies and sailfin have created these disjunct populations.

Beaver occur along various reaches of the river corridor where their preferred tree species (cottonwoods and willows) occur, especially in the upper sections of the Colorado in the Grand Canyon. Recently, there have been discussions on the reintroduction of river otter into Grand Canyon National Park to help control nonnative fish species. The last sighting of a river otter in the canyon was at the mouth of Bright Angel Creek in 1958. Muskrats are common along the lower Colorado. The nonnative bullfrog is also found throughout the river corridor and the Great Basin spadefoot toad occurs along the Colorado River within the Grand Canyon.

Ecosystem Processes

Much of the work on ecosystem processes in the Colorado River has been conducted in the river corridor through Grand Canyon National Park due to concerns over the listing of several endangered fishes and the reduced transport of sediment through the canyon. The construction of GCD greatly reduced the transport of allochthonous organic matter, increased armored substrata and water clarity, dampened flood discharges, and produced an unnaturally cold tailwater environment. As a result of these alterations, the filamentous green alga *Cladophora glomerata* and especially the associated diatom epiphytes became important components in the tailwater food web (Angradi 1994, Shannon et al. 1994, Shannon, Blinn, Haden et al. 2001, Blinn et al. 1998). Although *C. glomerata* does not directly provide food to tailwater communities except as detritus, it does serve important roles as a substratum for epiphytic diatoms and refugia for invertebrates and juvenile fishes.

Upland and riparian vegetation, rather than autochthonous algal carbon, were the most available food resources throughout the Grand Canyon river corridor during the experimental "control flood" conducted in March 1996, thus providing some indication of natural processes (Shannon, Blinn, McKinney et al. 2001). More recent studies with stable isotopes revealed a food web that varied spatially downstream, where aquatic communities were continually adjusting between the effects of upstream

impoundment and landscape/tributary influence (Shannon, Blinn, Haden et al. 2001).

Several investigators have examined the effects of river regulation on algal communities below Glen and Boulder dams. For example, studies have tested the role of daily fluctuations in discharge below dams on benthic communities (Angradi and Kubly 1993, Blinn et al. 1995, Peterson 1986). Others have examined the interactions of regulated flows and tributary sediment on algal community structure (Shaver et al. 1997) and the role of inflow patterns on reservoir chemistry and discharge regimes on benthic algal communities (Benenati et al. 2000).

In situ studies have shown that over 50% of the *C. glomerata* mass is lost from established algal communities along fluctuating shorelines below GCD after several weeks of repeated atmospheric exposure and resubmergence (Angradi and Kubly 1993, Blinn et al. 1995). Dislodged floating tufts of *C. glomerata* and associated invertebrates make up a large part of the downstream drift (Shannon et al. 1996, McKinney et al. 1999) and provide substantial sources of autochthonous carbon for the river food web. Regulated discharges also influenced the structure of algal communities along the river corridor (Hardwick et al. 1992). Rader and Ward (1988) reported the absence of heptageniid mayflies, reductions in stoneflies and caddisflies, and an increase in chironomids in the Colorado River below Lake Granby Reservoir in the upper basin.

The cold (11°C to 14°C) hypolimnetic releases from GCD have allowed a number of Nearctic invertebrate species to invade the river corridor through Grand Canyon National Park, many of which are dipterans (Stevens et al. 1998). In addition, the controlled flood during the spring of 1996 and recent low flows during the summer of 2000, designed to increase water temperatures for native fish spawning, are coincident with dramatic increases in the nonnative snails *Fossaria parva* and *F. obrussa* and the New Zealand mudsnail. Finally, processing times for leaf material in the river have been slowed due to the perennial cold water and the low number of leaf-shredding invertebrates (Pomeroy et al. 2000). Over 50% of the leaf mass of the native willow remained after being submerged for 142 days in the cool waters (10°C to 12°C) below GCD. Schade and Fisher (1997) reported similar losses in leaf mass for willow in <30 days in a warm, nonregulated desert stream in Arizona without leaf-shredding invertebrates.

Altered conditions below GCD not only affect structure of biotic communities, but they affect function as well. In a series of in situ experiments Shaver

et al. (1997) reported nearly 12 times more energy as invertebrate mass in a clear reach (<0.005 g/L suspended sediments) below GCD (Rkm 0) than in a turbid reach below the Paria River (Rkm 5), with 300 times the elevated suspended sediment loads, probably due to elevated autochthonous production. Indeed, gross primary production estimates in the same clear-water and turbid reaches were over sixfold higher than the downstream reach, and annual secondary production estimates for the amphipod *G. lacustris* were fourfold higher.

Haden et al. (1999) reported that floating driftwood provided a suitable alternative habitat to submerged substrata for aquatic insects in the turbid Colorado River with high suspended sediment loads and channel embeddedness. Hyporheic communities at the confluences of major tributaries with the Colorado River through the Grand Canyon are poorly represented, which is likely due to the high degree of embeddedness associated with reduced main-stem sediment transport capacity (J. A. Stanford, personal communication).

The heavy stream regulation throughout the Colorado River has modified community structure in a way that reduces the food supply available to fishes all the way to the Gulf of California in Mexico. Since the completion of Hoover Dam in 1935, the Colorado River delta has experienced a near cessation in freshwater flows, which historically helped mix estuarine waters nearly 60 km into the Gulf (Carbajal et al. 1997, Gleick et al. 2002). Much of the water released into Mexico is used for agriculture and only a few canal systems are concrete lined. Therefore, much of the water is lost through seepage through old river delta sediments that are very porous.

The large reductions in freshwater flows into the Gulf have now increased salinity to >40‰ and dramatically changed the mixing patterns in the estuary. The greatly reduced or complete lack of freshwater flows into the Gulf has also caused concentrations of selenium in water, sediment, and fish tissue to increase (Gleick et al. 2002). These changes in freshwater influx and water quality have caused declines in the once common bivalve mollusk *Mulinia coloradoensis* (Rodriguez et al. 2001), the Gulf of California harbor porpoise, the Totoaba fish (Cisneros-Mata et al. 1995), the vaquita, and the overall shrimp industry (Gleick et al. 2002).

Human Impacts and Special Features

The Colorado River is the largest desert river in North America, with enormous canyons, spectacular

desert scenery, and many endangered endemic fishes. The 360 km river corridor through Grand Canyon National Park traverses one of the most spectacular canyonlands in the world and was formerly home to some of the oldest Native American cultures in North America. Some of the exposed rock formations in the inner gorge of the canyon are nearly 2 billion years old.

The Colorado River is one of the most physically developed and controlled rivers in North America, even though it passes through some of the most arid and remote regions in North America. The high demands for water throughout the semiarid and arid regions of the Colorado River basin have created heated debates over water allotments between states and at international boundaries. Major John Wesley Powell first recognized the potential for these conflicts in his historic descent of the uncharted Colorado River in 1869.

Historically, the Colorado River drained to the Sea of Cortez (Gulf of California), forming a large estuarine delta at the mouth of the river in Mexico. Today, with the construction of numerous diversions and reservoirs, the channel is nearly dry by the time it reaches the Gulf. Floodplains were developed for agriculture and/or channelized and controlled by bank stabilization or levees. Backwater and marsh habitats are gone except for a few that are maintained by human efforts.

The disappearance of native fishes in the lower basin was primarily caused by loss and/or dramatic change in habitat following river regulation and the introduction and spread of nonnative, predaceous fishes. As a result, the rate at which native fishes are jeopardized has dramatically increased, especially in the lower basin (Minckley and Deacon 1991). Although the number of native species has declined, the total number of fish species has increased two- to threefold due to successful introductions of nonnative species.

The modified conditions below Glen Canyon Dam have resulted in increased winter and breeding waterbird populations in certain reaches of the Colorado River in the Grand Canyon (Stevens, Buck et al. 1997). Also, native species within the regulated river corridor through the Grand Canyon are now relying on nonnative species as food resources. For example, great blue heron populations have increased at Lees Ferry due to the high numbers of nonnative trout, and farther downstream, native insectivorous birds are utilizing more Nearctic species of adult aquatic dipterans (J. Shannon, personal communication). Resource managers will con-

tinue to face these and new dynamic issues in the highly altered artificial Colorado River.

Recently, three states and various stakeholders and water and power agencies in the lower basin formed a regional partnership to develop a multi-species conservation program after the Fish and Wildlife Service's designation for critical habitat for the four endangered large river fishes in the basin. The Lower Colorado River Multi-Species Conservation Program is designed to protect sensitive, threatened, and endangered species of fishes, wildlife, and their habitats.

The placement of GCD above the gateway to Grand Canyon National Park has recently caused some to advocate the decommissioning of the dam with the hope of restoring a more natural hydrologic and thermal environment in the canyon that would favor native species and historical ecological processes. Arguments against the removal of GCD include the logistical difficulties and downstream ramifications in removing a large concrete structure, and recreational boating and fishing on Lake Powell and river rafting through Grand Canyon, which are important economic factors in the region.

GREEN RIVER

The Green River originates in the Wind River Range of Wyoming at an elevation of ~4100 m asl in alpine and spruce–fir zones. As it flows southward it drains portions of Utah and Colorado and winds to the east as it encircles the eastern edge of the Uinta Mountains and ultimately joins the upper Colorado River in Canyonlands National Park at an elevation of 1200 m asl (Fig. 11.15). It is a dramatic, high desert river, as documented by John Wesley Powell on his famous descent of the Grand Canyon, which began on the Green River in Wyoming. The Green River has a drainage area of 116,200 km², and as the largest tributary of the Colorado River it contributes nearly half of the total annual flow to the Colorado. Flaming Gorge Dam was built in 1962 and it regulates 35% of the Green River drainage. Several important tributaries feed into the Green below the dam: the Yampa and White rivers draining northwestern Colorado and the Duchesne, Price, and San Rafael rivers draining eastern Utah. All these tributaries contribute water and sediment along the main course of the river. Today more than 20 dams modify the Green River and its tributaries, but a single dam

on the main stem (Flaming Gorge) in northeastern Utah has had the greatest influence on the contemporary ecology of the river.

The prehistory in the Green River basin is highlighted by the origins of the Fremont culture in Utah and western Colorado around 1200 years ago. They were supplanted from the north and west by the Utes, who eventually came to dominate the region. The Uintah Utes occupied the Uintah basin at the time of European contact. By the time of extensive western settlement in the 1850s, Shoshone had also moved into some Green River valleys. Settlement of the region occurred mostly in the 1800s, and although sparse, many travelers passed through the Green River basin. This region was a major thoroughfare, serving as part of the Mormon Trail, the Oregon Trail, and a major route to the California gold rush.

Physiography, Climate, and Land Use

The Green River basin lies in the Middle Rocky Mountain (MR), Wyoming Basin (WB), Colorado Plateaus (CO), and Southern Rocky Mountains (SR) physiographic provinces (see Fig. 11.15) and includes the South Central Rockies Forests, Wyoming Basin Shrub Steppe, Wasatch and Uinta Montane Forests, and Colorado Plateau Shrublands terrestrial ecoregions (Ricketts et al. 1999).

Although the mountainous headwaters drain alpine and spruce–fir zones, dryland vegetation dominates most of the basin, including big sage, black greasewood, pinyon pine, western red cedar, and several grasses, including Indian rice grass, needle-and-thread grass, and the invasive cheat grass.

Precipitation in the mountainous headwaters of the Green River can exceed 100 cm/yr, and most of this moisture accumulates as snow in winter (Fig. 11.16). The lower elevation portions of the basin are semiarid and generally receive less than 25 cm/yr precipitation. Peak precipitation occurs in April and May (~4 cm/mo), and maximum temperatures occur in July (~20°C), whereas minimum temperatures occur in January (~-7°C; see Fig. 11.16). Climate along the Green River is characterized by cold winters and hot, dry summers. Near Vernal, Utah, average January highs are -7°C and July highs are 32°C.

The two largest urban centers in the drainage are Rock Springs, Wyoming (population ~19,000), and Vernal, Utah (~8000). Land use in the basin is largely agricultural (80%), with about 15% forests and 5%

urban. Of the water extracted in the basin, about 90% is used for irrigated crops, with 80% of the total going for feed for livestock. About 100 years ago fires across this region caused declines in grassy vegetation and increases in woody plants, a trend that continues today. The entire basin has <0.5 people/km².

River Geomorphology, Hydrology, and Chemistry

The Green River flows through rugged terrain. There are a number of mountain streams in the basin that drop quickly in elevation as high-gradient, coarse-bedded streams and merge into larger tributaries that

flow at a low to moderate gradient and eventually join the main-stem Green River. Over its 1230 km course the Green River's average gradient is 2.4 m/km. Based on morphometric criteria, the Green is a 5th order stream.

The Green River below Flaming Gorge Dam can be divided into three main reaches (Muth et al. 2000). Reach 1 is the 104 km long segment that is completely regulated above the Yampa River confluence (see Fig. 11.15). This reach is straight to meandering, with a gradient of about 2.7 m/km. It is characterized by steep-walled canyon topography, with the exception of Browns Park, a 51 km long alluvial segment (Fig. 11.4). Above Browns Park the

FIGURE 11.4 Green River in Browns Park National Wildlife Refuge, northeastern Utah (PHOTO BY D. M. MERRITT).

riverbed is heavily armored by coarse sediment and the channel width ranges from 70 to 150m and the depth from 1 to 10m (Vinson 2001). As the river flows through the park, the channel widens to >200m and becomes more shallow (0.5 to 2m), and bank erosion restores finer sediment to the bed. The 158 km long Reach 2 occurs between the confluences with the Yampa and White rivers. It is largely a meandering reach, with a milder gradient of 0.85 m/km and a more natural flow and sediment regime than Reach 1 due to the contributions from the unregulated Yampa River. Major canyons in this reach include Whirlpool Canyon and Split Mountain Canyon, and flat, meandering segments include Island Park, Rainbow Park, and the broad valley of the Unita Basin. The range of bed materials spans cobbles to sand, and vegetated and unvegetated islands are common. Reach 3 is a 394 km segment below the White River to the confluence with the Colorado River. Given the more natural sediment regime, this reach has numerous low-elevation floodplains in flat segments (the Uinta Basin and most of the last 200 km of the reach). It also has the mildest gradient of 0.58 m/km. Major canyon segments include Gray, Desolation, Labyrinth, and Stillwater canyons, where gradients approach 0.1 m/km.

The mean annual discharge for the Green River is 172 m³/s, most of which is provided by snowmelt. Therefore, natural flow is very high in late spring and early summer and diminishes rapidly in midsummer (see Fig. 11.16). Although late summer and autumn flows can increase following rain events, natural flow in late summer, autumn, and winter months is generally low.

The main-stem segment of the Green River above the junction with the Yampa River provides 37% of the total natural annual flow volume in the Green River basin. The Yampa River is the largest tributary of the Green, providing another 36% of the total annual basin yield. Other tributaries include the White River in Colorado (12%) and three Utah rivers, the Duchesne (9%), Price (2%), and San Rafael (2%).

The main stem has been greatly modified by the construction and operation of Flaming Gorge Dam in northeastern Utah, approximately 655 km above the Green River's confluence with the Colorado River. This 149 m tall dam began operation in 1962 and currently inundates about 146 km of formerly riverine habitat. It is capable of storing twice the annual inflow of the Green River (Muth et al. 2000). Most of the modifications have occurred approxi-

mately 100 km below the dam and above the Green River's confluence with the Yampa River. The dam operates to capture and store peak flows, and base flows are elevated as stored water is released. Although the annual average flow of ~60 m³/s has not changed since dam construction, the magnitude and timing of seasonal high and low flows have been greatly altered by the dam (Merritt and Cooper 2000). Since dam closure maximum daily discharges have declined from more than 300 m³/s to less than 140 m³/s, whereas minimum flows increased from less than 10 m³/s to more than 20 m³/s. However, current proposals for recovering endangered native fishes in the Green River call for restoration of higher peak flows. A smaller dam, Fontanelle, was constructed upstream of Flaming Gorge in 1964, but its influence on the main-stem river is relatively small compared to the larger downstream structure, the operation of which is central to the contemporary ecology of the main-stem Green River.

The Green River basin is largely sedimentary, and as such it yields a naturally high sediment load, most of which is contributed by the lower-elevation portions of the basin. For example, the annual suspended sediment discharge of the Green River basin (prior to regulation by large dams) was almost 25,350,000 metric tons (Iorns et al. 1965). About 13% of this total load originated in the Green River basin above the Yampa River, ~6% from the Yampa River basin, ~26% from the Green River basin between the Yampa and White rivers, and ~54% from the basin downstream of the White River. Flaming Gorge Dam captures suspended sediment in the Green River, and Andrews (1986) estimated that mean annual sediment discharge was reduced by about 50% for up to hundreds of kilometers downstream of the dam. This alteration in sediment transport has resulted in distinctive changes in channel processes far downstream from the reservoir. These include a narrowing of the channel and decreased sediment deposition on point bars (Andrews 1986).

The resulting channel incision, combined with the loss of overbanking peak flows due to reservoir operations, has contributed to an effective isolation of historic floodplains along the lower Green River. This has strongly diminished the recruitment success of native cottonwoods, which require saturated, fine-textured soils away from the active channel to establish, survive, and eventually reproduce (Cooper et al. 1999, Merritt and Cooper 2000).

Water quality in the Green River is greatly affected by regulation. Prior to construction of the Flaming Gorge Dam, the Green River was free

flowing and turbid, with natural seasonal dynamics. For example, water temperatures varied from freezing to near freezing in winter to above 20°C in summer (Vanicek et al. 1970). Data collected by the U.S. Geological Survey (USGS 2004b <http://water.usgs.gov/ut/nwis/qwdata>) from 1990 to 1999 just below Flaming Gorge Dam shows that water temperature now ranges from 2°C to 4°C from January through March and up to 12°C to 14°C in July and August. Oxygen concentration typically exceeds 8 mg/L year-round, but occasionally drops below 7 mg/L in summer and often exceeds 11 mg/L in winter and spring. Specific conductance typically ranges from 500 to 800 µS/cm throughout the year. The pH is typically between 8.0 and 8.5 year-round. Further downstream, within 200 km of the confluence with the Colorado River, water quality is much more reflective of a large, desert river, although some residual effects of regulation by Flaming Gorge occur. Water temperature ranges from 2°C in midwinter to up to 24.5°C in late July or early August. Oxygen concentration typically drops below 7 mg/L in summer and exceeds 11 mg/L in winter. Specific conductance typically ranges from 350 to 400 µS/cm in May and June to >900 µS/cm in fall and winter. The pH is consistently between 8.0 and 8.5 year-round and alkalinity is about 165 mg/L as CaCO₃ (Haden et al. 2003).

River Biodiversity and Ecology

The main channel of the Green River represents the northernmost tributary within the Colorado River freshwater ecoregion (Abell et al. 2000). Biological information for the Green is sufficient to provide excellent insight into how alteration in flow, temperature, and sediment regimes by a large main-stem dam interact to influence benthic species and communities (Vinson 2001). Such documentation is relevant to assess the preimpoundment fauna for many other regulated rivers in the Colorado River basin.

Algae and Cyanobacteria

A biotic survey was conducted in the lower Green River in Dinosaur National Monument around the confluence with the Yampa River in the summer of 1962, just one month before the closure of Flaming Gorge Dam (Woodbury 1963). Attached filaments of *Cladophora*, *Stigeoclonium*, and *Vaucheria*, as well as filamentous cyanobacteria (*Anabaena*, *Nodularia*, *Oscillatoria*), were common taxa in the turbid, unregulated desert river.

Plants

The riparian vegetation along the Green River before regulation was adapted to periodic flooding associated with the snowmelt hydrograph. Annuals and scour-tolerant perennials grew along the banks, and floodplains were occupied by box elder, coyote willow, and Fremont cottonwood, among others (Holmgren 1962). Above Flaming Gorge Reservoir, spring flows are adequate to maintain some natural recruitment of these riparian plants.

The severe modification of the natural flow regime below Flaming Gorge Dam has greatly altered the riparian communities along the Green River. Conditions are no longer favorable for cottonwood recruitment, and invasive salt-cedar has become widely established along the Green; this species may even contribute to channel narrowing (Allred and Schmidt 1999). Merritt and Cooper (2000) did an extensive vegetation survey at Browns Park (1636 m asl), an unconfined reach of the Green River ~70 km downstream from Flaming Gorge Dam and above the confluence with the free-flowing Yampa River (see Fig. 11.4). On stabilized in-channel islands, wetland plants such as common three square, coyote willow, and jointed rush occur. On rarely flooded surfaces the nonnative salt-cedar dominates, often in dense stands where only shade-tolerant species such as whitetop and Wood's rose can survive in the understory. Fremont cottonwood now occurs at low densities, and the understory is dominated by native desert shrubs, such as big sage, black greasewood, and Douglas rabbitbrush, and grasses and herbs, such as alkali sacaton and salt grass, as well as an assortment of introduced species, such as beggar's tick, cheat grass, Russian thistle, and summer cypress.

Invertebrates

The macroinvertebrate fauna of the lower Green River before construction of Flaming Gorge was dominated by a diverse assemblage of warmwater species, many of which no longer occur (Woodbury 1963, Holden and Crist 1981). The extent of the change in invertebrate species has been documented by Vinson (2001), who used more than 50 years of invertebrate data to document long-term changes about 20 km below the dam. The predam fauna consisted of 27 species in 15 mayfly genera (*Ametropus*, *Brachycercus*, *Caenis*, *Callibaetis*, *Camelobaetidius*, *Choroterpes*, *Ephemera*, *Ephoron*, *Isonychia*, *Lachlania*, *Leptophlebia*, *Pentagenia*, *Pseudiron*, *Siphonurus*, *Traverella*), 5 stonefly genera (*Alloperla*, *Claassenia*, *Isogenoides*, *Isoperla*, *Perlesta*), and

3 caddisfly genera (*Leptocerus*, *Nectopsyche*, unidentified phryganeid). The only common insect taxa following dam closure were *Baetis tricaudatus*, Chironomidae, and Simuliidae. New insect taxa found below the dam have coldwater affinities and include the mayfly *Paraleptophlebia*; the stoneflies *Arcynopteryx*, *Hesperoperla pacifica*, *Taenionema*, *Zapada*; and the caddisflies *Hesperophylax*, *Hydroptila*, *Leucotrichia*, *Oecetis*, *Psychoglypha*, and *Rhyacophila*.

In 1978, operations at Flaming Gorge were modified to increase water temperatures (by releasing water from different reservoir depths) for the rainbow trout fishery, and a dramatic shift from insects to crustaceans, particularly *Hyaella azteca*, occurred. This was facilitated by flow stabilization that allowed the proliferation of macrophytes, a good amphipod habitat. Interestingly, only a few kilometers further downstream the amphipods were replaced by insects, namely *Baetis tricaudatus*. Here, a large intermittent tributary adds warmer water and fine sediment during occasional floods to reduce growths of macrophytes and filamentous algae that favor crustaceans.

A few collections have occurred further downstream in the Green River main stem. For example, Wolz and Shiozawa (1995) characterized the invertebrate fauna of soft sediments from June to August in Ouray National Wildlife Refuge, about 350 km downstream from Flaming Gorge Dam and above the confluence with the White River. The dominant taxa in all sampled habitats (main river channel, ephemeral side channels, river backwaters, and seasonal wetlands) were 6 to 15 genera of chironomid midges, Ceratopogonidae, nematodes, and oligochaetes. Additional insects encountered in the main channel included mayflies (*Baetis*, *Tricorythodes*), a stonefly (*Isoperla*), a dragonfly (Gomphidae), and true flies (Simuliidae). In the more standing water habitats, additional insects included mayflies (*Baetis*, *Caenis*, *Callibaetis*), a damselfly (*Ischnura*), true flies (Empididae, Simuliidae), and beetles (Hydrophilidae).

Another 300 km downstream in Canyonlands National Park, Haden et al. (2003) reported a more diverse assemblage of invertebrates, which may suggest a partial recovery from the altered conditions below Flaming Gorge Dam. These included 29 species in nine mayfly taxa (*Acentrella*, *Baetis*, *Camelobaetidius*, *Ephoron*, *Heptagenia*, *Lachlania*, *Rhithrogena*, *Traverella*, *Tricorythodes*), seven stonefly genera (*Acroneturia*, *Doroneuria*, *Frissonla*, *Iso-genoides*, *Isoperla*, *Oemopteryx*, *Taenionema*), seven

caddisfly genera (*Brachycentrus*, *Ceratopsyche*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Nectopsyche*, *Smicridea*), four odonate genera (*Argia*, *Erpetogomphus*, *Ophiogomphus*, *Stylurus*), the hellgrammite *Corydalus*, the beetle *Microcylloepus*, and high densities of chironomid midges and black flies. Nearly 80% of these taxa were found on floating driftwood and only 40% on cobbles (Haden et al. 1999). The signal crayfish occurs in reaches of the Green River that run through Wyoming and the virile crayfish occurs in downstream reaches in Utah (M. Vinson, personal communication).

Vertebrates

Fishes indigenous to the Green River are represented by four families, which include five cyprinid minnows (Colorado pikeminnow, humpback chub, bonytail chub, roundtail chub, speckled dace), four catostomid suckers (razorback sucker, flannelmouth sucker, bluehead sucker, mountain sucker), two salmonids (cutthroat trout, mountain whitefish), and one cottid (mottled sculpin) (Muth et al. 2000).

Several big-river fishes (bonytail chub, Colorado pikeminnow, humpback chub, razorback sucker) used to reproduce in the 100 km above the Yampa confluence, but since the closure of Flaming Gorge Dam, with its year-round release of cold water, this activity has stopped (Vanicek et al. 1970, Holden and Stalnaker 1975). This long reach is now primarily a fishery for native Colorado River cutthroat trout (which were historically uncommon in this part of the river) and nonnative trout. The river downstream of the dam does support native fishes, but they now compete with many introduced fishes.

A total of 25 nonnative fish species in nine families have been reported from reaches of the mainstem Green River between Flaming Gorge and the Colorado River confluence and from lower portions of tributaries. Of the coolwater or warmwater nonnative fishes, channel catfish, common carp, fathead minnow, sand shiner, and rainbow trout are most common.

These nonnative fishes have been implicated as contributing to reductions in the distribution and abundance of native fishes as a result of competition and predation (Carlson and Muth 1989). Behnke and Benson (1983) attributed the dominance of nonnative fishes to dramatic changes in flow regimes, water quality, and habitat characteristics. They observed that water development has converted a turbulent, highly variable river system into a relatively stable system, with flow and temperature pat-

terns that allowed for the proliferation of nonnative fish species.

Beaver occur along various reaches of the Green River, where their preferred tree species (alders, cottonwoods, and willows) occur, as do dwarf shrews, muskrat, and river otters. Boreal western toads (Northern Rocky Mountain population) and northern leopard frogs also occur along selected reaches of the Green.

Ecosystem Processes

The presence of Flaming Gorge Dam has promoted dramatic changes in flow, sediment, and temperature regimes over most of the entire 655 km course of the Green River before its confluence with the Colorado River. These physicochemical alterations have fundamentally modified habitat availability and dynamics and organism bioenergetics, resulting in significant modifications of energy flow, food web structure, and species composition for aquatic and riparian communities. These modifications are particularly dramatic in the 100 km reach between Flaming Gorge and the Green River's confluence with the Yampa River (Muth et al. 2000).

Sediment capture by Flaming Gorge Reservoir, combined with the loss of peak flows, has resulted in channel degradation, elimination of lateral channel migration, and loss of overbank flooding along alluvial reaches below the dam, such as in Brown's Park. Consequently, invasive nonnative species (salt-cedar) now dominate these reaches due to the failure of recruitment by flood-dependent native cottonwoods (Merritt and Cooper 2000). Channel fossilization and degradation also have simplified aquatic habitat and reduced backwater habitat for fishes and invertebrates. In addition, cold temperatures have created conditions that prevent native fishes from reproducing and a shift in higher trophic levels to salmonids (a pattern seen in other regulated segments of the Colorado River). Substantially colder water temperatures, combined with flow stabilization, have also promoted large changes in the aquatic food web. Extensive macrophyte beds and filamentous green algae now flourish along some reaches of the regulated Green River, providing ideal habitat for previously rare crustaceans that now exclude aquatic insects (Vinson 2001). With tributary inputs of sediment and warmer water downstream, the Green River recovers some of its natural character as a large, turbid, high desert river driven by allochthonous energy sources and with extensive river-floodplain interactions in alluvial reaches (Wolz and

Shiozawa 1995, Muth et al. 2000, Haden et al. 2003).

Human Impacts and Special Features

The Green River above its confluence with the Colorado River and below its confluence with the unregulated Yampa River represents the longest stretch of relatively free-flowing desert river in the Colorado River basin. Many of the 26 major reservoirs (Muth et al. 2000) in the basin are in headwater reaches of the Green's tributaries. Some of these reservoirs support transbasin diversions, such as on the Duchense and Strawberry rivers in Utah. The Flaming Gorge Dam on the main stem is by far the largest dam, with a storage capacity of >4600 million m³. The Green River currently supports two of the remaining six populations of humpback chub, the largest populations of Colorado pikeminnow, and the largest riverine population of razorback suckers (Muth et al. 2000). These species are endangered due to both river regulation and the proliferation of introduced, nonnative fish species that compete or feed upon the natives. Given the status of these native fishes, intense restoration efforts have occurred in the Green River, primarily via the operation of temperature and water releases from Flaming Gorge Dam. Starting in 1978, the dam was retrofitted with a multilevel outlet to improve downstream water temperatures, primarily to improve the nonnative rainbow trout fishery. In 1985, an interim flow agreement was established to change reservoir releases to protect endangered fish nursery habitats in the Green River downstream of the Yampa River. In 1992 the U.S. Fish and Wildlife Service issued a biological opinion concluding that a more natural hydrograph below Flaming Gorge was needed to avoid likely jeopardy of the continued existence of these rare and endangered fish species. Several years of study ensued and in 2000 a final report was issued with recommendations to the Bureau of Reclamation for managing the flow and temperature regimes below Flaming Gorge Dam for the recovery of these species (Muth et al. 2000). Chief among these recommendations is moderating flow fluctuations due to hydropower generation and largely restoring the magnitude and timing of peak and low flows. The magnitude of the annual peak flow is recommended to vary depending on annual runoff into the reservoir from snowmelt. The timing of peak releases from Flaming Gorge is recommended to coincide with peak and immediate postpeak spring flows in the Yampa River to create maximum floodplain inundation and backwater

duration downstream of the confluence of these two rivers in the lower Green River. Base flows are recommended to be low and stable from August through February, with daily changes in discharge caused by hydropower operations not to exceed 3% (or a stage difference of 0.1 m) below the Yampa River confluence. Finally, release of warmer water from Flaming Gorge Dam was recommended so that native warmwater fishes would have more thermally suitable habitat.

This proposed alteration of operations at Flaming Gorge Dam is deemed critical to the continued persistence of endangered fishes in the Green River. However, it is important to note that success is largely dependent on the maintenance of the unregulated Yampa River, which not only provides critical habitat for Green River populations, but also greatly normalizes the hydrologic and thermal characteristics after 100 km of severe regulation.

YAMPA RIVER

The Yampa River is the largest tributary to the Colorado River in the upper basin that remains largely unregulated (Fig. 11.17). It originates as small mountain streams in the alpine and spruce–fir zones (~3800 m asl) in the Park Range and White River Plateau of northwestern Colorado. Its largest tributary, the Little Snake River, originates in the mountains of southern Wyoming and contributes 28% of the total drainage basin of about 24,595 km² (Tyus and Karp 1989). From its source, the Yampa flows westward for about 320 km before finding its confluence with the Green River at an elevation of 1524 m asl (Fig. 11.5).

The headwater tributaries of the Yampa River coalesce as they flow off the western slope of the Rocky Mountains. At Steamboat Springs (2060 m asl) the river has reached about 20% of its ultimate

FIGURE 11.5 Yampa River, Colorado (PHOTO BY D. J. COOPER).

size with only an 8% contributing watershed. It turns westward and begins its meandering path across the high desert toward Craig and beyond through low-gradient agricultural valleys surrounded by sagebrush highlands. It passes through the canyons of Juniper Mountain and Cross Mountain and picks up its main tributary, the Little Snake River, before entering Dinosaur National Monument and the Yampa Canyon, where it flows through dramatic and steep terrain, eventually finding its confluence with the Green River at Echo Park in extreme north-western Colorado.

The prehistory of the Yampa River basin is not well described, but it shares affinities with the Green River basin. The Fremont culture extended into this region around 1200 years ago but was eventually supplanted from the north and west by the Utes. The Yampa band occupied the Yampa River valley until the time of European displacement.

Physiography, Climate, and Land Use

The Yampa River basin lies within the Southern Rocky Mountains (SR), Wyoming Basin (WB), and Middle Rocky Mountains (MR) physiographic provinces and drains primarily in a west-southwest direction from its headwaters to its confluence with the Green River (see Fig. 11.17). The basin includes the Colorado Rockies Forests, Wyoming Basin Shrub Steppe, and the Colorado Plateau Shrublands terrestrial ecoregions (Ricketts et al. 1999). The upper tree-line-krummholz consists of bristlecone pine that is replaced by ponderosa pine and extensive aspen stands in the lower mountainous regions. The region also contains mountain meadows, foothill grasslands, and riparian woodlands. Sagebrush and various wheat and fescue grasses make up the vegetation in the sagebrush-steppe region, with pinyon pine and several junipers and a sparse understory of grama grass and sagebrush and alderleaf cercocarpus (mountain mahogany).

Climate in the Yampa Valley is characterized by long, cold winters and mild summers. Average highs along the Yampa River in December and January are as low as -8°C , and temperatures as low as -52°C have been recorded near Craig. Summers are mild, with average July highs of 29°C , although subfreezing temperatures can occur at night in the summer months. Mean monthly temperature ranges from highs in July ($\sim 19^{\circ}\text{C}$) to lows in January ($\sim -9^{\circ}\text{C}$; Fig. 11.18). Annual mean precipitation for the drainage basin is $\sim 43\text{ cm/yr}$, with over 60 cm/yr falling in the upper elevations and less than 40 cm/yr

falling in the lower elevations. Precipitation falls in the basin rather uniformly throughout the year, with much of the precipitation falling and accumulating as snow from the fall through early spring (see Fig. 11.18).

The predominant form of land use in the Yampa basin is ranching and grazing, especially along the relatively verdant floodplains. Overall, about 65% of the basin is in agriculture, with most irrigation withdrawals from the river going to support irrigated hay pastures. About 30% of the basin is forested and less than 5% is urbanized, with Craig (8700) and Steamboat Springs (6500) the largest population centers in the basin. The entire basin has $<0.5\text{ people/km}^2$.

River Geomorphology, Hydrology, and Chemistry

The Yampa drainage can be divided into three zones. The first consists of montane headwater streams characterized by cold water, steep gradients, and coarse substrata. The middle section, seasonally cold due to snowmelt runoff but warm in late summer and early fall, flows across a high plain with fine substrates and a channel width at base flow of $<20\text{ m}$. The lower section of the Yampa is a primarily warmwater canyon river, with high-gradient reaches of rocky runs and rapids interspersed with low-gradient reaches in incised bedrock meanders. Based on morphometric information the Yampa River is considered a 4th order stream. Over its entire length, the Yampa averages a gradient of $>7\text{ m/km}$. Most of this is achieved before the river reaches Steamboat Springs, after which the river descends at about 2 m/km on average, with the greatest drop occurring in the Yampa Canyon prior to the confluence with the Green River in Echo Park. In the headwaters, substrates are coarse and fine in the downstream direction, especially in the middle section of the river, where silted substrates are common. Coarser gravel and cobble characterize the Yampa Canyon.

Given its snowmelt origins and relatively high elevation, the Yampa River is perennial over its entire length. It has a typical snowmelt hydrology, characterized by low fall and winter flows and a predictable late spring pulse driven by snowmelt (see Fig. 11.18; Poff 1996). Thus, the difference between precipitation and runoff throughout the year is due to a combination of evapotranspiration and snow storage. The average annual discharge of the Yampa at its confluence with the Green is about $61\text{ m}^3/\text{s}$. Flow begins to rise in the Yampa River in late March due to spring runoff and can remain high through June.

The mean flow during spring runoff in the Yampa River is about 153 m³/s (Tyus and Karp 1989). During the spring runoff periods river levels may undergo large fluctuations due to rapid warming that causes flash floods. Following spring runoff, flows of the Yampa River decline toward a monthly base flow of about 14 m³/s for August through March (Tyus and Karp 1989). Late summer or fall peak flows caused by monsoonal air flow are rare in the Yampa River due to its northerly location and orographic isolation from sources of tropical moisture.

Water quality in the Yampa River is generally good. Data collected by the U.S. Geological Survey below Craig, Colorado, from 1990 to 1999 (USGS 2004b <http://water.usgs.gov/co/nwis/qwdata>) show that water temperature ranges from 0°C in mid-winter to up to 24°C in late July or early August. Dissolved oxygen generally exceeds 9 mg/L. Specific conductance ranges from <100 to >700 µS/cm and is generally highest in late winter and early spring. The pH ranges from about 7.5 to 9.0 and alkalinity is about 85 mg/L as CaCO₃. At this site the river ranges in size from <20 m width at low flow in late summer and fall to up to 85 m during high flow.

River Biodiversity and Ecology

The Yampa River basin, like the Green River basin, lies within the northernmost portion of the Colorado freshwater ecoregion (Abell et al. 2000). As the largest free-flowing tributary of this ecoregion, the distribution of its biota is relatively well studied along its length.

Algae and Cyanobacteria

A biotic survey was conducted in the lower Yampa River in Dinosaur National Monument around the confluence of the Green River in the summer of 1962 (Woodbury 1963). Attached filaments of *Cladophora*, *Stigeoclonium*, and *Vaucheria*, as well as filamentous cyanobacteria (*Anabaena*, *Nodularia*, *Oscillatoria*), were the common taxa in the river.

Plants

Because the Yampa River is unregulated, it retains a dynamic channel morphology that serves to maintain dynamic variation in environmental conditions for a wide variety of riparian plant species. The steep environmental gradients in soil moisture characteristic of the Yampa River floodplains maintain diverse plant communities and a largely native vegetation. Merritt and Cooper (2000) did an extensive survey

at Deerlodge Park (1697 m asl), a wide alluvial valley immediately below the confluence with the Little Snake River, where the river migrates naturally across an unconfined valley. They found a vegetation continuum along an elevational (and fluvial disturbance) gradient from the active channel to the high floodplain. Plants on active point bars include mostly annual species such as cocklebur, cudweed, mudwort, and smartweed, as well as short-lived perennials such as foxtail barley. Intermediate-elevation floodplain stands are dominated by Fremont cottonwood saplings and several species of perennial grasses and herbs, including foxtail barley, horseweed, sage, and slender wheatgrass. The highest-elevation stands have a cottonwood overstory, with an understory consisting mostly of native grasses, such as Canada bluegrass, Kentucky bluegrass, needle-and-thread grass, slender wheatgrass, and western wheatgrass.

Invertebrates

The aquatic invertebrate species and communities in the Yampa River change dramatically along the course of the river. Ames (1977) conducted a longitudinal study of the aquatic insects in riffles of the Yampa, documenting assemblages at six sites along a 177 km reach (305 m elevation drop) from the cool, high-gradient headwaters with coarse substrates to the warm, turbid waters just above the confluence with the Little Snake River. At the most upstream site, communities were composed of mayflies (45%), caddisflies (22%), beetles (13%), stoneflies (12%), and true flies (5%). Mayflies and caddisflies did not change appreciably in percentage composition downstream; however, stoneflies declined (to 4% at the last site), as did beetles (2%). True flies increased to become the second most represented group (25% at last site). Overall, a total of ten mayflies, eight stoneflies, eight caddisflies, four beetles, four true flies, and one aquatic moth taxa were collected.

The upstream site was characterized by cool-water mayflies (*Paraleptophlebia*, *Rhithrogena*), stoneflies (*Alloperla*, *Pteronarcella*, *Pteronarcys*), caddisflies (*Lepidostoma*), beetles (*Optioservus*), and true flies (*Atherix*, *Hexatoma*, black flies). The most downstream sites were characterized by mayflies with silty and/or warmwater habitats (*Choroterpes*, *Ephoron*, *Traverella*, *Tricorythodes*), stoneflies (*Capnia*), caddisflies (*Helicopsyche*, *Oecetis*, *Protoptila*), beetles (*Microcylloepsis*), true flies (chironomid midges), and aquatic moths (*Cataclysta*). Some taxa were widely distributed across the range of conditions represented, including certain mayflies

(*Baetis*, *Ephemerella*), stoneflies, and caddisflies (*Cheumatopsyche*, *Hydropsyche*). The virile crayfish occurs in certain reaches of the Yampa.

Vertebrates

The Yampa River is one of the most important rivers in the upper Colorado River basin in terms of conservation potential for native big-river fishes. In contrast to other major tributaries in the upper Colorado River basin, the Yampa River supports all its native fish fauna (including some self-sustaining populations of rare species), and because of its largely unregulated flow regime contains high-quality fish habitat. It also contributes to the maintenance and availability of useable rare fish habitat in the heavily regulated Green River below its confluence with that river because it helps normalize the Green River's flow, sediment, and thermal regimes. The distribution and abundance of fishes indigenous to the Yampa River have been studied since the early 1900s (Ellis 1914). The 12 fish species indigenous to the Yampa River are represented by four families, which include five cyprinids (Colorado pikeminnow, humpback chub, bonytail chub, roundtail chub, speckled dace), four catostomids (razorback sucker, flannelmouth sucker, bluehead sucker, mountain sucker), two salmonids (Colorado River cutthroat trout, mountain whitefish), and one cottid (mottled sculpin) (Tyus et al. 1982, Behnke and Benson 1983, Tyus and Karp 1989).

All mainstream fishes persist today despite the introduction of at least 18 nonnative fishes (Tyus et al. 1982), including channel catfish, common carp, green sunfish, northern pike, and red shiner. Colorado River cutthroat trout persist in high-elevation streams above barriers that restrict invasion by introduced salmonids, such as brook trout. Indeed, the largest population of Colorado River cutthroat trout occurs in the headwaters of the North Fork of the Little Snake River on U.S. Forest Service lands in Wyoming.

The lower Yampa is particularly important for spawning and nursery habitat for rare and endangered native cyprinids and catostomids. For example, the Colorado pikeminnow and razorback sucker depend on habitats in the Yampa River (and lower Green River) to meet certain life-history requirements. The Colorado pikeminnow now occurs only in the upper Colorado basin, and the Yampa Canyon provides important spawning habitat. Some adults make annual round-trip migrations 950 km up the river to spawn here and in the nearby White River, another tributary of the Green (Irving and Modde

2000). Colorado pikeminnow migrate in response to rising waters associated with spring runoff, and they spawn after waters decline and water temperatures exceed 16°C. Eggs hatch quickly and larvae are swept downstream, where they rear in warm, backwater habitats (created by high flows) in the Green River (Muth et al. 2000).

The self-sustaining population of humpback chub in the Yampa River represents one of the few remaining extant populations of this species in the whole Colorado River basin (Muth et al. 2000). A population of up to 600 individuals has been estimated for the Yampa Canyon (compared to 500 in Cataract Canyon on the upper Colorado and 1500 for Desolation and Gray canyons on the Green; Muth et al. 2000). The species occupies a specialized niche in canyons and is a warmwater fish requiring growth temperatures in the range of 16°C to 22°C (Muth et al. 2000). The humpback chub uses shoreline eddy and run habitat in the Yampa Canyon (Rkm 19 to Rkm 64). There is some speculation that the relatively unaltered riverine conditions of the Yampa has prevented hybridization between closely related *Gila* species (humpback and bonytail), because in the regulated Green River morphologically "intermediate" forms of humpback chub are seen (Tyus and Karp 1989).

Beaver occur along selected reaches of the Yampa River where their preferred tree species (alder, cottonwoods, willows) occur, as do river otters. The boreal western toad, Great Basin spadefoot toad (Southern Rocky Mountain population), and wood frog also occur along selected reaches.

Ecosystem Processes

The largely unregulated nature of Yampa's flow regime makes this river an important reference for understanding natural biophysical processes for snowmelt-driven rivers in the upper Colorado basin (e.g., Green, White, Gunnison, upper Colorado rivers). The natural geomorphic processes operating in the Yampa promote dynamic channel migration and associated habitat diversity critical to sustaining native riparian forests and large-river fishes that continue to flourish in the lower Yampa. Further, the unaltered thermal regime provides suitable temperature conditions for native aquatic fauna.

For example, the Yampa provides important spawning habitat for the Colorado pikeminnow. Adults residing year-round in the Yampa (as far upstream as Craig) and adults from the downstream Green River migrate to spawning habitat in the Yampa Canyon. Migrations are in response to high

spring flows, and fish predictably lay eggs on the descending limb of the spring hydrograph in newly scoured and silt-free bed sediments. Emerging larvae drift downstream to nursery areas, backwaters in alluvial reaches created by the high flows. Many of these nursery areas are in the Green River and have been created by the high spring flows contributed to the Green by the Yampa.

The natural flow regime on the Yampa also maintains a self-sustaining, natural riparian community. Merritt and Cooper's (2000) study showed that the vegetation community on higher floodplain surfaces in the Yampa is quite different than that in the nearby regulated Green River. The natural dynamic of channel migration during floods serves to maintain a much more diverse riparian community, including robust, multiaged stands of native cottonwoods where invasive species such as salt-cedar fail to dominate. Richter and Richter (2000) modeled the flow conditions needed to maintain cottonwood forests along the Yampa and determined the duration of flooding at or above 209 m³/s (125% of bankfull discharge) to be important in driving the lateral channel migration that initiates ecological succession in the Yampa's riparian forest. These high flows may also help reduce the grazer-induced mortality of small cottonwood seedlings from mammals such as voles (Anderson and Cooper 2000).

Human Impacts and Special Features

The lack of dams on the Yampa River make it unique as the largest free-flowing tributary in the arid intermontane plateau of the upper Colorado basin. The relatively unmodified flow, sediment, and thermal regimes of the Yampa are recognized as critical to its natural functioning and to the restoration of big-river fishes on a regional scale. Indeed, because the Yampa helps normalize the heavily regulated Green River, recommendations for managing the flows below Flaming Gorge Dam on the Green River explicitly incorporate the natural flow regime of the Yampa (Muth et al. 2000). The Yampa retains its natural seasonal flow variability because there are only three small headwater dams within its basin and only about 10% of its annual flow is diverted for municipal or agricultural use. There is some concern that the late-summer low flows are being adversely affected by diversion for irrigation of hay meadows in the Yampa valley. The Yampa River has enjoyed special status in Colorado due to its relatively unaltered condition and critical role in sustaining federally endangered fish species. However, water

demands on the western slope are growing, and in 2000 the Colorado state legislature relaxed the protected status of the Yampa, possibly opening the door to more water development in the basin.

LITTLE COLORADO RIVER

The Little Colorado River (LCR) originates in the White Mountains on Mt. Baldy in eastern Arizona in the spruce–fir zone at an elevation of ~3400 m asl (Fig. 11.19). The LCR flows mostly in a northwesterly direction through an arid region for about 550 river km and drains a basin of 69,000 km². Four headwater streams (West, East, and South forks and Hall Creek) converge to form the LCR near Greer, Arizona. After leaving Greer, the LCR flows through grasslands for about 150 km and continues through desert scrub for another 400 km. The surface flow of the LCR disappears into the consolidated materials of the Moenkopi sandstone below Winslow, Arizona, and reemerges in the lower 21 km, where a series of permanent springs in the Redwall and Muav Limestone discharge water. The river starts its descent through the Little Colorado River Gorge near Cameron, Arizona (Rkm 480), near the Painted Desert and finally joins the Colorado River at an elevation of 823 m asl. Over 85% of the river meanders through the Desert Grassland and Great Basin Desert Scrub (Fig. 11.6). Relatively little alpine and forest habitat occur in the basin.

Early occupants of the region were the Mogollon (MUGGY-own), mountain and desert dwellers whose homeland stretched from the Little Colorado River to Chihuahua, Mexico, and from the Pecos River in New Mexico west to the Verde River in Arizona. These early dwellers, along with the Anasazi, Sinagua, and Hohokam Indians, lived off the land as early as 2200 years ago until about 1450, as evidenced by the Casa Malpais and Raven site ruins in the Springerville/Eagar area. Spanish explorers crossed the river in the late sixteenth century and commented on the groves of cottonwoods and willows along the LCR (Colton 1937). The first permanent settlers were Mormon families from Utah in the early 1870s, who utilized LCR water for ranching.

Controversy still exists regarding the perennial nature of the middle reaches of the LCR prior to early Anglo colonization in the 1880s. Some claim the middle reaches were perennial; however, C. Hart Merriam reported the LCR was an ephemeral stream in its middle reaches during his ecological

FIGURE 11.6 Little Colorado River near Holbrook, Arizona (PHOTO BY D. BLINN).

survey of the region in 1889 (L. E. Stevens, personal communication).

Physiography, Climate, and Land Use

The Little Colorado River basin lies almost entirely in the Colorado Plateau (CO) physiographic province (see Fig. 11.19). The basin includes the Arizona Mountains Forests and the Colorado Plateau Shrublands terrestrial ecoregions (Ricketts et al. 1999). The LCR drains a number of life zones, from alpine and spruce–fir and pine forests in the White Mountains and San Francisco Peaks, through expansive pinyon juniper zones at intermediate elevations, to grasslands and desert scrub, and finally the edge of the Mohave Desert near the confluence with the Colorado River. Grazing has increased the invasion by junipers onto the grasslands, especially on rocky thin-soil habitats. Much of the desert scrub is dominated by nonpalatable perennial shrubs, including sagebrush and saltbush, and to a lesser degree by blackbrush, black greasewood, rabbitbrush, and winterfat (Brown 1994).

Mean air temperature throughout the LCR basin is 13.5°C; 8°C in the upper basin and 15°C throughout most of the lower 450 km. Mean monthly temperatures are as high as 27°C in July and fall to 5°C in December (Fig. 11.20). Extreme summer air temperatures may reach >38°C in the lower LCR. Winter extremes for the upper and lower portions of the LCR are ~–15°C and –10°C, respectively. Precipitation in the basin varies greatly with season and elevation. Winter precipitation is generally in the form of snow. Summer precipitation results from convective storms carrying moisture from the Gulf of Mexico or Gulf of California or large-scale cyclonic storms originating over the Pacific Ocean. Average precipitation in the headwaters of the LCR is over 65 cm/yr, with highs of 12 and 11 cm in July and August, respectively, during the summer monsoons (Brown 1994). Total rainfall in the remaining watershed is considerably lower, ranging from nearly 25 to 15 cm/yr, again with highs in July and August (see Fig. 11.20). Evapotranspiration rates range from 76 cm/yr in the mountains to well over 150 cm/yr in the lowest deserts.

Since the arrival of early Spanish explorers ranching has modified the LCR basin and aquatic communities along much of the river corridor, especially around Springerville/Eagar and St. Johns. Today, over 80% of the basin is federally managed (four National Forests, six National Parks and Monuments, six American Indian reservations or allotments), with <20% privately owned, and <1% agriculture and/or industry (L. E. Stevens, personal communication). Some grazing occurs on the reservations and National Forests and over 500 mines occur within the basin. Dense urban areas are generally lacking in the basin, with the small community of Greer (<1000 people) in the headwaters and Springerville/Eagar, St. Johns, Holbrook, and Winslow, each with less than 10,000 people, distributed along the river on the semiarid plateaus (see Fig. 11.19). Flagstaff, with about 53,000 people, is located on the western edge of the basin. The entire drainage basin has ~1.5 people/km².

River Geomorphology, Hydrology, and Chemistry

Presently, perennial flows occur only in about the upper 125 km of the LCR and in the lower 21 km before it joins the Colorado River. Snowmelt and storm events regulate the intermittent flows between the upper and lower sections of the river. The river goes underground and resurfaces at several points along the corridor, resulting in isolated sections of permanent pools and slowly flowing water. Also, Lyman Reservoir and several irrigation diversions in and around Springerville/Eagar regulate downstream flows. A dam was constructed below Zion Reservoir in 1905, but it was breached in 2000. Now water flows more freely during floods in the channel below. The LCR basin contains approximately 37,000 km of stream channel, of which only 2.5% are perennial (L. E. Stevens, personal communication).

The average gradient along the entire LCR corridor is ~4.9 m/km. A cascading falls (43 m drop), active only during spring snowmelt, is located at Grand Falls, 377 km downstream from the headwaters. This falls prevents upstream migration of fishes from the Colorado main stem, but upstream fishes may be transported to the lower reaches during heavy floods. The LCR is considered a 4th order stream when it joins the Colorado River.

The main stem in the headwaters consists of riffle/runs, with coarse materials and pools with fine sediments. The remainder of the river channel is

composed primarily of fine sediments. The upper headwaters have <5% of their hard surfaces embedded by sediments compared to over 25% throughout the remainder of the river. Channel width during base flow ranges from 0.5 to 5 m in the headwaters, whereas in the central part of the basin, a floodplain up to 0.5 km wide is bisected by an intermittent, narrow ribbon of water (see Fig. 11.6). Little woody debris accumulates in the active channel due to the limited amount of woody vegetation throughout the catchment and the sporadic floods that clear and strand debris high on the floodplains.

Mean runoff for the LCR basin is <0.03 cm/mo, largely due to the high annual mean evapotranspiration and low precipitation (see Fig. 11.20). Peak runoff occurs during March and April from snowmelt. Mean discharge ranges from <0.1 to 0.8 m³/s in the headwaters, but is more variable (“flashy”) throughout the remainder of the river corridor. In the early 1900s, annual mean stream flow near St. Johns, Arizona, was about 2 m³/s but has been reduced to <0.5 m³/s over the past half century (Pope et al. 1998). Mean discharge for the lower river is approximately 6.5 m³/s, but this has little meaning for a system that ranges from no flow along much of its length to large flash floods. For example, a gage at Cameron, Arizona, recorded a maximum discharge of 3400 m³/s in September 1923. Flash discharges (>250 m³/s) from storm events have occurred at a frequency of one every four years over the past seventy years. These flash discharges result from the sparse vegetation in the arid catchment and the high density of arroyos that deliver water to the LCR during intense monsoonal storms. During brief periods of flash floods, suspended sediment loads can exceed 100 g/L.

Three north-flowing subbasins (Silver, Chevelon, Clear creeks), all with annual mean discharges of <2.5 m³/s, produce much of the streamflow in the middle region of the LCR. In addition, there are approximately 30 major intermittent washes along the LCR corridor that receive water from their own multidrainage networks. These intermittent drainages deliver discharges of up to 100 m³/s into the lower 362 km of the LCR from July through September following storm events. After flash floods, water flows in the main channel for several weeks and eventually loses its ribbon of connectivity and forms standing pools. Water in the pools reaches specific conductance values >4000 μS/cm, but <1000 μS/cm during periods of flow. The headwaters have low solutes (<40 μS/cm) and are relatively clear (suspended sediments <5 mg/L).

The headwaters are dominated by CaCO_3 ; however, as solutes concentrate downstream, water becomes strongly dominated by NaCl . Alkalinity averages $<50 \text{ mg/L}$ as CaCO_3 in the headwaters and $>165 \text{ mg/L}$ in the river corridor below. Water temperatures range from near 0°C in the winter to 18°C in the summer in the headwaters and $\sim 3^\circ\text{C}$ in the winter to $>26^\circ\text{C}$ in the summer throughout the remainder of the river corridor. Nutrient concentrations vary along the river corridor depending on the intensity of agricultural use.

Blue Springs is the largest of the springs in the lower 21 km reach, supplying approximately 56% of the $6.3 \text{ m}^3/\text{s}$ base flow. Discharges from Blue Springs have high specific conductance ($>4500 \mu\text{S}/\text{cm}$) and alkalinity ($>400 \text{ mg/L}$ as CaCO_3), high concentrations of dissolved CO_2 ($>300 \text{ mg/L}$), and a pH of 8 (Robinson et al. 1996). As CO_2 degasses with exposure to the atmosphere and aggressive photosynthesis, carbonate precipitates to form travertine dikes that are important geomorphic fish barriers. The rate of carbonate precipitation has been estimated to be about $1 \times 10^{-5} \text{ moles L}^{-1} \text{ s}^{-1}$. The high mineral content of the water gives the lower LCR its characteristic light blue-green color during base flow. However, the traditional aqua-blue color can be quickly replaced with a chocolate brown from flash floods as far away as St. Johns some 500 river km upstream.

River Biodiversity and Ecology

The Little Colorado River lies in the east-central part of the Colorado River freshwater ecoregion, one of the driest portions of the ecoregion (Abell et al. 2000). Although there have been a few studies in the upper tributaries and lower reaches of the LCR, studies in the intermittent main stem are largely lacking. Ecologically important riparian habitats are found in the headwater reaches and along the perennial flows below Blue Springs to the confluence with the Colorado River.

Algae and Cyanobacteria

The canopied riparian reaches of the headwaters of the LCR are dominated by epilithic diatoms, with *Eunotia*, *Frustulia*, *Gomphonema*, *Meridion*, *Nedium*, *Pinnularia*, and *Staurosira* the dominant taxa. Diatom assemblages in the lower river corridor include more salt-tolerant taxa, such as *Campylodiscus*, *Mastogloia*, *Navicula*, *Nitzschia*, *Rhopalodia*, and *Surirella* that occupy the fine sediments. The cyanophyte *Nostoc* and the aquatic buttercup are also common in headwater reaches.

Plants

The riparian vegetation in the headwaters includes Douglas fir, Engelmann spruce, subalpine fir, thin-leaf alder, and willows, with understory shrubs of blueberry, elderberry, and hawthorn. Disturbed north-facing sites consist of lodgepole pine and/or quaking aspen. The riparian community along the remainder of the river corridor is either open or invaded by salt-cedar and desert grasses, although native willows still flourish along many of the more perennial reaches. In the open, high meadows of the headwaters and in selected lowland areas where the water table is relatively high, broadleaf cattails, common reed, and sedges border the river channel. Aquatic macrophytes are typically absent in the lower, more turbid, and intermittent reaches of the LCR.

Invertebrates

Summer macroinvertebrate assemblages in the cool headwaters near Greer are diverse, with relatively high densities. Mean densities for macroinvertebrates are $>700 \text{ animals/m}^2$ in the headwaters, reduced to one-half that number $\sim 50 \text{ km}$ downstream and $<150 \text{ animals/m}^2$ 250 km downstream in the highly turbid waters. Macroinvertebrate diversity also decreases quickly downstream from the headwaters. For example, the headwaters have over 25 species of caddisflies, with the dominant taxa including *Anabolia bimaculata*, *Atopsyche sperryi*, *Brachycentrus americanus*, *B. occidentalis*, *Glossosoma ventrale*, *Gumaga*, *Helicopsyche borealis*, *Hesperophylax occidentalis*, *Hydropsyche* spp., *Lepidostoma unicolor*, *Limnephilus sperryi*, *Oecetis disjuncta*, *Oligophlebodes minutus*, *Polycentropus arizonensis*, and *Rhyacophila* (D. W. Blinn and D. E. Ruiters, unpublished data). In contrast, only three caddisfly species (*Cheumatopsyche enonis*, *Hydropsyche* sp., and *Limnephilus lithus*) have been reported 50 km downstream and a few microcaddisflies reported from the intermittent and highly turbid sections of the river corridor. Coolwater stoneflies (*Claassenia sabulosa*, *Suwallia pallidula*, *Sweltsa coloradoensis*) and mayflies (*Baetis*, *Cinygmula*, *Drunella grandis*, and *Epeorus*) are common in the headwaters. Stoneflies have not been reported 50 km downstream and headwater mayflies are replaced by *Baetis*, *Choroterpes*, *Leucrocuta*, and *Tricorythodes* and not reported in the intermittent section of the river corridor. The macroinvertebrate assemblages in the intermittent and highly turbid reaches are composed primarily of chironomids and oligochaetes.

Although the reach below Blue Springs is perennial and frequently clear, total annual macroinvertebrate biomass is low ($<0.2\text{g/m}^2$) due to high carbonate deposition (Oberlin et al. 1999). With the exception of the Paria River, the LCR has the fewest species and lowest invertebrate biomass of any major tributary in Grand Canyon National Park. The lower reach has primarily one mayfly (*Baetis*), several caddisflies (*Hydropsyche* and microcaddisflies), an hemipteran (*Rhagovelia*), and several chironomid species (Oberlin et al. 1999).

The nonnative virile crayfish is common in the LCR between Greer and Springerville and has greatly restructured the invertebrate and plant communities, as well as fish communities, in the river. White (1995) conducted a series of in situ experiments in a headwater tributary of the LCR and found that crayfish preyed heavily on eggs of the native Little Colorado spinedace. A few specimens of the Asiatic clam have been reported in the LCR below Springerville, and there are records of the native California floater in the headwaters.
