Dedication

Edmund Lawrence Dubois: 1923–1985

Edmund Lawrence Dubois (pronounced “Doo-Boyz”) was born on June 28, 1923, to a middle-class Jewish family in Newark, New Jersey. He was the only child of a general surgeon, and his mother worked in his father's office. Ed, as he was known, graduated from high school in Newark in 1939. He then attended Johns Hopkins University, graduating with a bachelor's degree in 1943. While serving in the Army, he stayed in Baltimore to attend Johns Hopkins Medical School, where he also did his internship under A. McGehee Harvey, the legendary Chief of Service who was a lupus pioneer in his own right. Ed's tendency to know and train under the best and the brightest continued with a residency in medicine at the University of Utah under Max Wintrobe (author of the *Hematology* textbook) and at Parkland Hospital in Dallas under Tinsley Harrison (author of *Harrison's Medicine* textbook). He also completed an autopsy pathology fellowship at Los Angeles County General Hospital in 1948.

Ed decided to stay in Southern California and went into private practice at his father's office in July 1950. In 1951, he met—and, in 1952, married—Nancy Kully, the beautiful daughter of Barney Kully, a local ear, nose, and throat specialist. To keep professionally busy, he volunteered his time at the Los Angeles County General Hospital. The “General,” as it was known, was the largest hospital in the United States at the time, with over 3,000 beds. Dr. Paul Starr, then Chairman of the Department of Medicine, asked him to start a clinic consisting of eight patients who had a newly diagnosed disorder that was characterized by a positive result on a recently described laboratory test known as the “LE cell prep.” Within 10 years, Ed had the largest lupus practice in the world, caring for 500 patients at the General Tuesday morning Lupus Clinic and another 500 patients in his private practice.

By the mid-1980s, more than one half of the rheumatologists in Southern California could say that Ed Dubois had taught them nearly everything they knew about lupus. His first publications on lupus appeared in the *Journal of the American Medical Association* (four of them!) and the *American Journal of Medicine* (two papers) in 1951 and 1952. They described autoimmune hemolytic anemia as a manifestation of systemic lupus erythematosus (SLE), showed that steroids ameliorate the disease, and described the general clinical and laboratory features of patients who had positive LE cell preps.

As the General became more closely affiliated with the University of Southern California, university resources allowed the establishment of lupus research laboratories. Ed Dubois' keen clinical instincts and his demands for perfection among those who worked with him permitted him to publish seminal works that established him as the first, or among the first, to propose insights that we now take for granted. These include: use of nitrogen mustard for serious SLE (1954); use of Atabrine for cutaneous and mild systemic lupus (1954); high-dose steroid protocol for managing central nervous system disease (1956); analysis of why hydralazine induced LE cells (1957); the first description of avascular necrosis in lupus (1960); the first description of steroid-induced peptic ulcers (1960); the first description of gangrene from lupus vasculitis (1962); anticonvulsant drug-induced lupus (1963); establishment of one of the first NZB/NZW mouse research laboratories in the United States (1963), detailed analysis of an accrued, incredible series of 520 patients with lupus (1964); one of the first probes into familial SLE (1964); use of cyclophosphamide in SLE (1967); the first large series of procainamide-induced lupus (1968); absence of erosions in lupus synovitis (1970); phenothiazine-induced lupus (1972); the first report of lupus with myelofibrosis (1973); the first large analysis of causes of death, containing 212 patients (1974); HLA typing of patients with lupus (1974); ibuprofen for SLE (1975); and the incidence of septic arthritis in lupus (1975).

In 1966, Ed wrote the first edition of his monograph, *Lupus Erythematosus: A Review of the Current Status of Discoid and Systemic Lupus Erythematosus and Their Variants.* Dedicated “to the patients from whom we have learned,” this remarkable, largely single-authored textbook was enormously successful and now—with this volume—is in its seventh edition. More than any other publication, this book has shaped how rheumatologists approach and treat this disease. Although he authored 175 papers, abstracts, book chapters, and received numerous international honors while traveling, Ed was most proud of being the founding medical director of The American Lupus Society and President of the Southern California Rheumatism Society.

Ed Dubois was a tireless workaholic. He would rise at 5 am and write for an hour or two before going to work. A humanist of the first order, one half of his time was spent giving free medical care. Ed was known to be exacting and did not suffer fools easily. Although he seemed to be a man of few words, his gentle kind-heartedness was always evident. Ed's probing intellect was apparent within moments of meeting him, and he was always relaxed, modest, and approachable. Ed could be a wonderful teacher when confronted with a student physician who had an inquiring mind and a capacity to work hard. Although he had well-known Hollywood luminaries as private patients, he was never snobbish or conceited, and he felt much more at home seeing indigent patients at the General's lupus clinic.

More than anything else, Ed Dubois was a private man who was devoted to his family. He was happily married and had four children, all of whom now have successful careers. His first grandchild (of six) was born shortly before he died. He was an expert yachtsman who relaxed best on his boat. (When he was terminally ill, he bought a new boat that he named Dubious.) His other consuming passion was photography. Able to be privately tutored by the likes of Ansel Adams, his office was filled with creative and wonderful pictures showing his love of life.

While still a youthful 54 years of age in 1977, Ed complained of low back and knee pain, which turned out to be a compression fracture from multiple myeloma. He privately confided to me that excessive exposure to radiation during his training and in various research laboratories was responsible for this. A fighter to the end, Ed lived with myeloma for 8 years, which must be close to a record. He saw a full schedule of patients 2 weeks before he died, in February 1985, from pneumonia complicated by renal shut-down. I was fortunate to meet Ed Dubois as a medical student at the University of Southern California and as a resident at Cedars-Sinai Medical Center. Among the greatest honors in my life was when he asked me to help in his office part-time in 1977, while I was still a fellow in training, and to edit his book along with him in 1982. I will always value his friendship.

Daniel J. Wallace MD

Acknowledgment: I gratefully acknowledge the assistance of Mrs. Nancy (Edmund) Dubois in preparing this dedication.

The Genetics of Human Lupus

Preface

Forty years have elapsed since Ed Dubois wrote the first edition of his monograph in 1966. He wrote 80% of the text himself, using notecards and a typewriter between 5 and 6 a.m. over a 2-year period. Ed would indeed be proud to see the explosion of information that has transformed what at the time was the arcane discipline of lupology. The 7th edition of *Dubois' Lupus Erythematosus* reflects the changes and developments in the field over the last 5 years. Lupus experts are now working together to form consortiums and registries which allow for clinical trials to be performed rapidly and efficiently; provide banks of shared sera, cells, and genetic materials; and permit new clinical indices and ascertainment methodologies to be developed and tested more rigorously. In keeping with the improved quality of studies and in order to focus on more evidence-based findings, we no longer cite every paper published on the subject of lupus but emphasize trends, treatment consensuses and practical clinical information along with succinct summaries of basic science insights. Ironically, the last time a drug was approved for lupus was also in 1966. Almost 20 biologics are now in various stages of clinical development for SLE, and this has created a palpable sense of excitement.

Chapters on cytokines and interferons, pathogenesis of atherosclerosis, immune tolerance, clinical indices, mixed connective tissue disease, reproductive immunology issues, fibromyalgia, women's issues, and biomarkers are included for the first time. We welcome 20 new authors and co-authors and thank our senior experts who graciously agreed to pass the baton on to young, promising investigators.

Dr. Wallace wishes to thank his family, Jody Stanley, and Nancy Winter for their hard work and support. Dr. Hahn thanks her mentors who started her off in lupus studies, Lawrence E. Shulman, MD, PhD and the late Mary Betty Stevens, MD; she also thanks her husband, Theodore John Hahn, MD, who further inspires her, and her daughters, Alysanne Yvonne Hahn and April Diane Hahn Lange, who make it all worthwhile.

History and Definitions

Chapter 1

Historical Background of Discoid and Systemic Lupus Erythematosus

Thomas G. Benedek

The Prescientific Period

Lupus (wolf) was an ancient Roman family name, and there was a St. Lupus who lived in central France in about 600 A.D. (1). How the name of this large carnivore came to have a disease association is obscure. The earliest known medical use of “lupus” appeared in a 10th century biography of St. Martin, who had lived in 4th-century Gaul. The Bishop of Liege was healed at St. Martin's shrine in Tours:

> He was seriously afflicted and almost brought to the point of death by the disease called lupus. … The location of the disease … was not to be seen, nonetheless, a sort of thin red line remained as a mark of the scar (2).

Toward the end of the 12th century, Rogerius Frugardi, a Salernitan surgeon, introduced the term *noli me tangere* (touch me not) to designate a facial ulcer. He also stated, “Sometimes lupus arises in the thighs and the lower legs [and is] distinguished from cancer” (3). This distinction was clarified somewhat by his student, Roland of Parma: “In the early stages it [cancer] is called sclirosis [hardening] or negrosis [blackening]. After it begins to rot it is called cancrena [gangrene ?]; finally it is called carcinoma [cancer].” This progressive lesion also is named according to its location: on the face he used Roger's term, *noli me tangere*, on the trunk, *cingulum* [girdle]. “However, in the lower body, as in the feet, thighs and hips, it is called *lupula* [little she-wolf] and it is incurable … in this place” (4).

“Lupus” remained associated with ulcerated lesions of the legs until the 16th century, after which it was considered primarily a facial lesion. Most authors considered it to be a distinctive disease rather than a phase of an evolving ailment, but no one described lupus in sufficient detail for a modern diagnosis to be inferred. Various ailments likely bore the name. Paracelsus (1493–1541)

> The art of medicine resides in recognizing the site wherein lies the cure, such as cancer, lupus, gout, plague, fever, hydrops, polyuria, menses, worms, etc. (5).

Differentiation from Tuberculosis

Discussion of whether this skin disease is merely a manifestation of tuberculosis, which itself was just being defined, began early in the 19th century. According to the dermatologist Thomas Bateman (1778–1821), his mentor, Robert Willan (1757–1812) had defined lupus:

> … to comprise, together with the “noli me tangere” affecting the nose and lips, other slow tubercular affections, especially about the face, commonly ending in ragged ulcerations of the cheeks, forehead, eyelids, and lips, and sometimes occurring in other parts of the body, where they gradually destroy the skin and muscular parts to a considerable depth (6). In 1853 Sir James Paget (1814–1899), calling the lesion a “rodent ulcer,” identified *noli me tangere* as a neoplasm (7).

In 1845 Ferdinand von Hebra (1816–1880, Vienna) proposed a classification of skin diseases based on abnormalities of specific components of the skin. Under “hyperactivity of sebaceous glands” he described “seborrhea congestiva,” which a few years later was renamed *lupus erythemateux*. Here is his description:

> One sees at the beginning of this illness—mainly on the face, on the cheeks and the nose in a distribution not dissimilar to a butterfly—on an erythematous but not infiltrated base the sebum filled openings of the sebaceous glands as white flat dots (8).

Laurent T. Biett (1761–1840, Paris) may in 1833 have described the same disease as “erytheme centrifuge,” but this was first published in 1851 (Fig. 1-1) by his student, Pierre L. Cazenave (1795–1877, Paris):

> It is a very rare occurrence, and appears most frequently in young people, especially in females, whose health is otherwise excellent. It attacks the face chiefly. It generally appears in the form of round red patches, slightly elevated, and about the size of a 30 sous piece: these patches generally begin by a small red spot, slightly papular, which gradually increases in circumference, and sometimes spreads over the greater part of the face. The edges of the patches are prominent, and the centre, which retains its natural color, is depressed … (9)

At a meeting in 1851, Cazenave also described a case and after giving credit to Biett for having described a variety of

lupus as “erytheme centrifuge,” introduced the term *lupus erythemateaux* (10).

Figure 1-1. (See color plate.) Disseminated lupus erythematosus (LE) showing “livid red slightly raised lesions with flat, depressed, paler centers resembling scars; or covered by an adherent thin scale which feels greasy.” (From

Kaposi M. Neue Beiträge zur Kenntnis des Lupus erythematosus. *Arch Dermatol Syph* 1872;4:36–78.

)

In the 1856 edition of his textbook Cazenave wrote extensively about lupus erythematosus (LE). He mentions the potential occurrence of “fever and even pain,” but his presentation is entirely dermatologic. Cazenave herein is the first to note alopecia as a symptom. He does not mention the “butterfly rash,” but states that the eruption “is very common on the face and the nose.” He emphasizes that lesions heal with scarring, but do not ulcerate—an important distinction from lupus vulgaris (LV)—and states that these patients are not necessarily scrofulous (11) (Fig. 1-2).

The distinction from scrofulous (i.e., tuberculous) was important because lupus was considered a tuberculous disease, “tuberculous” having a different meaning in this prebacteriologic time. According to Erasmus Wilson (1809–1884; 1862, London):

> Destruction, then, we may take as the leading character of lupus. A further inquiry into the nature of lupus is served, however, to show that this destructive disease was preceded by a circumscribed thickening and prominence of the skin, commonly termed a tubercle, hence, lupus is considered as a tuberculous affection of the skin. … Now, the destructive action implied by the term lupus was, in the first instance, intended to be restricted to that form of tubercle which commonly issues in destructive ulceration, but as cutaneous diseases came to be more carefully observed, it was perceived that there existed a kind of tubercle which did not of a necessity ulcerate, which was chronic and lasting in its nature, and which … left behind it a deep pit or a strongly marked cicatrix. … This form of cutaneous disease … has been distinguished by Cazenave under the name of lupus erythematosus (12).

Figure 1-2. (See color plate.) The first modern illustration of cutaneous lupus, labeled “Lupus erythemateux,” in Cazenave (11) in 1856. (From Wallace DJ, Lyon I. Pierre Cazenave and the first detailed modern description of lupus erythematosus. *Semin Arthritis Rheum* 1999;28:305–313. Reproduced with permission.)

Unfortunately, Wilson then confuses this finding with a syphilitic lesion. However, the fact that the medieval description of “lupus” depended mainly on ulceration makes it likely that the nonulcerative lupus was first recognized in the 1830s.

Moriz (Kohn) Kaposi (1837–1902, Vienna) with his publications of 1869 (13) and especially 1872 called attention to LE. He confirmed Wilson's observation that LE occurs more frequently in women and considered that it also is more likely to be severe in them (14). Kaposi believed that tuberculosis and LE may occur in the same patient, but was convinced that LE is not a manifestation of tuberculosis. He became quite annoyed at the confusion:

> … the disease called lupus erythematosus does not have the least in common with lupus vulgaris, and it is not enough to criticise even leading surgeons for confusing these two entirely different processes that have not the least in common, and even less to justify many dermatologic specialists who assume transitional or mixed forms of lupus erythematosus and lupus vulgaris, as has occurred recently (15).

From 1866 to 1871, Kaposi made the diagnosis of LE in 22 patients, while he diagnosed LV (cutaneous tuberculosis) in 279. He introduced the term “discoid” for lesions that

expand from single foci and “discrete and aggregate” for lesions that enlarge by the merger of multiple pinhead size foci (14). Subsequently he altered the latter term to “disseminate and aggregate” (15). Confusion resulted from Kaposi's intention for “disseminate” to refer to cases where the lesions were not limited to the head, while it so happened that systemic symptoms (Fig. 1-3) were observed only in patients with disseminate skin lesions:

Figure 1-3. (See color plate.) Disseminated LE involving scalp, face, trunk, and extremities. (From Kaposi M. Neue Beiträge zur Kenntnis des Lupus erythematosus. *Arch Dermatol Syph* 1872;4:36–78.)

> Lupus erythematosus may occur and progress with manifestations of a disseminated or universal acute or subacute febrile eruption, and may then frequently involve the entire body with intense local and general symptoms, indeed to endanger and destroy life (14).

Table 1-1: Distinctive Features of Lupus Vulgaris and Lupus Erythematosus

Feature	Lupus Vulgaris	Lupus Erythematosus
“Apple jelly” growth	Characteristic	Little or none
Tendency to ulcerate	Yes	No
Symmetrical lesions	No	As a rule
Childhood occurrence	Yes	No
Sex ratio	Almost equal	Far commoner in women
Related to chilblains	No	Yes
Fatal	Very seldom	Sometimes

Of the 11 cases Kaposi described in 1872, four had pneumonia, three had arthralgias, and three had major adenopathy. Of the three who came to autopsy, two had pneumonia, one of whom also had amyloidosis, and one had tuberculosis. No renal disease was described. He was uncertain whether the relationship between the cutaneous and other findings was more than coincidental. The first American publication on LE, by W.H. Geddings in 1869, described the cutaneous findings of the first case in Kaposi's 1872 publication (16).

Many investigators recognized that the relative prevalence of LE and LV was influenced by socioeconomic factors, LV being particularly associated with poverty. Thus, Jonathan Hutchinson (1828–1913, London) cited Wilson as having seen an equal number of cases of these two diseases among 10,000 dermatologic patients from among the “wealthier classes,” and attributed this to referral bias (17). One decade later, H.R. Crocker (1845–1909), another English dermatologist, found (LV) to be twice as prevalent as LE among 10,000 dermatologic clinic cases (1.27% versus 0.63%), while the opposite was true among 5,000 private patients (0.98% versus 1.80%) (18).

Hutchinson in 1888 made the principal distinctions between the major members of the lupus family (Table 1-1). Hutchinson concluded, “The features which distinguish these two diseases … are useful rather for the purposes of clinical diagnosis and arrangement than as implying essential differences. … The two are closely allied and … are in a general way induced by a similar kind of causative influence. … In the lupus family vulgaris and erythematosus stand as brother and sister, having many essential resemblances and many marked but superficial differences.” In his descriptions of the symmetry of LE lesions he substituted “the bat's wing form” for Hebra's “butterfly.” Six years after the discovery of the tubercle bacillus, Hutchinson conceded that no one had detected them in cases of LE, “but this, no doubt is only a question of time” (17). Hutchinson was in a shrinking minority of advocates of a direct tuberculous etiology of LE. In view of the inability to recover tubercle bacilli from LE lesions, but with no persuasive alternative etiologic hypothesis, the most acceptable compromise was that LE “is a chronic inflammatory process produced by toxic substances of tuberculous origin” (19). Goeckerman (20) in 1921 analyzed Mayo Clinic

data and found tuberculosis equally prevalent among cases of discoid lupus erythematosus (DLE) and those with other dermatoses. In 1933, Harry Keil, a dermatologist in New York, in reviewing autopsy reports of cases of systemic LE, found that only 20% showed evidence of active or remote tuberculosis. He also concluded that the occurrence of the two diseases is coincidental and, in view of the prevalence of tuberculosis, not surprising (21).

Recognition of Systemic Lupus Erythematosus

Between 1872 and the first of William Osler's (1849–1919) three long articles describing a disease he initially called “erythema exudativum multiforme” (EEM), a few cases of LE were described in which some extracutaneous symptoms were present (22 ,23). In 1895, Osler described a disease:

> … of unknown etiology with polymorphic skin lesions—hyperaemia, oedema, and hemorrhage—arthritis occasionally, and a variable number of visceral manifestations, of which the most important are gastro-intestinal crises, endocarditis, pericarditis, acute nephritis, and hemorrhage from the mucous surfaces. Recurrence is a special feature of the disease, and attacks may come on month after month, or even throughout a long period of years. … The attacks may not be characterized by skin manifestations; the visceral symptoms alone may be present, and to the outward view the patient may have no indication whatever of erythema exudativum (24).

The relevance of Osler's contributions to the understanding of LE have been misinterpreted. In 1900, he acknowledged that the cases he was assembling were not uniform: “While I feel that in bringing together a somewhat motley series of cases I may only have contributed to make the ‘confusion worse confounded,’ on the other hand there is, I think, a positive advantage in recognizing the affinities and the strong points of similarity in affections usually grouped as separate diseases” (25). Therefore, he withdrew the term EEM in favor of the less specific “erythema group.” At no time did he use “LE.”

In the last paper (1904), Osler summarized his 29 cases, and they differ markedly in gender and age from typical LE: 18 were male and 12 were between the ages of 3 and 12; 19 had purpura and “colic.” All had some sort of cutaneous findings. The most frequent extracutaneous symptoms were arthralgia in 17 and “nephritis” in 14. None of the seven fatal cases came to autopsy. Osler made no etiologic hypotheses, but in regard to pathogenesis he stated: “The essential process is a vascular change with exudate, blood, serum, alone or combined” (26).

Osler's three articles drew praise for calling attention to the association of cutaneous and visceral symptoms (27 ,28). The modern diagnosis of most of these patients undoubtedly would be Schönlein-Henoch purpura, a possibility about which Osler equivocated (25). Keil, a dermatologist in New York, in 1937 became the first to point out that Osler's 29 cases included two descriptions of typical acute (systemic) LE (29 ,30).

Various modifications of “lupus erythematosus” came to be preferred over Osler's “erythema group.” In 1908, Kraus and Bohac (31) in Prague introduced “acute LE” to indicate the presence of both cutaneous and visceral symptoms. “Chronic LE” became a synonym for DLE. “Acute disseminated LE” was used for “cases which start acutely [i.e., with systemic symptoms], assume a disseminated [cutaneous] form and run acutely throughout” (32). That cutaneous lesions are not a prerequisite for a diagnosis of SLE was rediscovered in 1936 (33), and emphasized in 1942 (34). While various authors used cumbersome descriptive terms, “LE” never was discarded. Brunsting (35) in 1952 in Rochester, Minnesota, introduced “disseminated (systemic) LE,” and Harvey et al. (36) in 1954 in Baltimore finally popularized the contemporary “systemic lupus erythematosus” (SLE) (Table 1-2).

Once visceral symptoms began to be associated with cutaneous LE, the question of whether they are causally related had to be resolved. Consequently there is a gap between the first description of many findings and the recognition that they are a component of LE. Kaposi had mentioned the occurrence of fever and pneumonia in 1872, but Kraus and Bohac (31) concluded in 1908 and 1909 from their eight cases that pneumonia may be a component of LE and that fever is not necessarily a result of infection.

In 1911, Emanuel Libman (1872–1946, New York) hospitalized a 10-year-old girl who had been ill for 10 weeks with polyarthralgia, followed by precordial pain, dyspnea, and oliguria. “There was an erythematous eruption of butterfly pattern, which resembled acute lupus erythematosus disseminatus.” Blood cultures were sterile. Hematuria and a precordial rub developed during a febrile 8-week course. The autopsy revealed “endocarditis of a peculiar type, particularly because of the unusual manner of spread of the endocardial lesions along the posterior wall of the left ventricle,” and also glomerulonephritis. This case was first reported in 1924 as the fourth of four cases of nonbacterial valvular and mural endocarditis treated by Libman and autopsied by Benjamin Sacks (37). Cases 1 and 2 had already been reported in 1923 (38). Two of the four had the butterfly facial eruption and three had nephritis. Libman and Sacks pointed out “the similarity of certain of the symptoms to those observed in the erythema group of Osler,” but declined to make a definite diagnosis of SLE in any case.

Dermatologists, upon reviewing published cases in 1936, came to the confusing conclusion that the “Libman-Sacks syndrome is a subvariety of the Osler erythema group,” but probably not LE (39). An internist and a pathologist finally stated unequivocally in 1940 that this form of endocarditis is a manifestation of SLE, irrespective of the presence of characteristic skin lesions (40). Libman-Sacks endocarditis has become a less common pathologic finding since the introduction of corticosteroid therapy—59% of cases of SLE reported during 1924 to 1951 versus 36% of cases during 1953 to 1976 (41).

At least two of the patients in whom Osler found signs of nephritis did have LE (26 ,30). Sequeira and Balean (42) in

1902 in London found proteinuria in five of ten cases of disseminated (cutaneous) LE, of whom the one fatal case had a pathologic diagnosis of nephritis. Similar single cases were published in the next few years. Keith and Rowntree (43) in 1922 in Rochester, Minnesota, pointed out that nephritis is “a common complication of disseminated LE.” In a pathologic study of 23 cases of SLE, Baehr et al. (44) in 1935 in New York differentiated a type of nephritis in 13 (56%), which they considered to be peculiar to LE. “The commonest and most characteristic glomerular alteration was a peculiar hyaline thickening of the capillary walls. … The thickened wall appears rigid, as if made of heavy wire. We have, therefore, called it the ‘wire loop lesion.’ … It is quite different from the hyaline degeneration seen in glomeruli of arteriosclerotic kidneys or of chronic glomerulonephritis. It apparently represents a toxic degenerative process” (44). Nevertheless, renal failure was not considered a principal cause of death in LE, probably because early death usually resulted from infection. The importance of renal involvement was recognized by Harvey et al., who found that in two thirds of their autopsied cases “SLE alone was responsible for varying degrees of renal damage.” They pointed out “the inability to correlate the degree of renal involvement disclosed clinically and the extent of renal damage at postmortem examination” (36).

Table 1-2: First Descriptions as Components of Systemic Lupus Erythematosus

Component	Author, Year	Site	Reference
Clinical			
Butterfly rash	von Hebra, 1845	Vienna	8
Panniculitis	Kaposi, 1869	Vienna	13
Arthralgia	Kaposi, 1872		14
Adenopathy	Kaposi, 1872		14
Arthritis	Philippson, 1892	Hamburg	23
Nephritis	Osler, 1895	Baltimore	24
Purpura	Osler, 1895		24
Psychosis	Bowen, 1896	New York	48
Pneumonia	Kraus & Bohac, 1908	Prague	31
Raynaud's phenomenon	MacLeod, 1908	London	46
Photosensitivity	Pulay, 1921	Vienna	125
Endocarditis	Libman & Sacks, 1923	New York	38
Retinopathy	Pillat, 1935	Vienna	55
Peritonitis	Friedberg et al., 1936	New York	33
Encephalopathy	Daly, 1945	Minneapolis	49
Myelopathy	Piper, 1953	Madison, WI	52
Laboratory			
BFP reaction	Reinhart, 1909	Hamburg	72
Leukopenia	Goeckerman, 1923	Rochester, MN	60
Anemia	Keefer & Felty, 1924	Baltimore	59
Hematoxylin bodies	Gross, 1932	New York	124
Thrombocytopenia	Lyon, 1933	Philadelphia	62
“Wire loop” glomeruli	Baehr et al., 1935	New York	44
“Onion skin” splenic lesion	Kaiser, 1942	Baltimore	45
Hypergammaglobulinemia	Coburn & Moore, 1943	Baltimore	76
LE cell	Hargraves, 1948	Rochester, MN	79
Lupus anticoagulant	Conley & Hartman, 1952	Baltimore	158
Antinuclear antibody	Miescher & Fauconnet, 1954	Geneva, Switz.	90
“Lupoid” hepatitis	Mackay, 1956	Melbourne, Australia	68

BFP, biologically false positive; LE, lupus erythematosus.

Libman and Sacks (37), incidentally to their description of the cardiac lesion, also described a splenic abnormality: “The greater part of each malpighian body [lymph follicle] was occupied by a number of arterioles, each of which was surrounded by a broad zone of hyaline-like connective tissue. The arteriolar lumen in each instance was diminished in caliber.” Kaiser (45) in 1942 in Baltimore studied this “onion skin” periarterial splenic fibrosis in detail and found it in 83% of cases of SLE, but in only 3% of other diseases. “Its discovery post mortem should at least raise the suspicion of that diagnosis … [and] its coincidence with the other well recognized lesions of the connective tissue such as verrucous endocarditis and the ‘wire loop’ glomerular changes can serve to strengthen the post mortem diagnosis of disseminated lupus erythematosus” (45).

Abdominal symptoms were recognized as peritonitis, which tended to be associated with pleurisy, but there were no primarily gastrointestinal (GI) findings (33).

In regard to cerebral involvement, Osler considered as “peculiarly obscure” the delirium in one case (no. 1), and in case no. 15 recurrent episodes of hemiplegia and aphasia, which he speculated “were associated with changes in the brain of essentially the same nature which subsequently occurred … in the skin. They remind one somewhat of the attacks of recurrent aphasia with paralysis in cases of Raynaud's disease” (24). Whether these patients actually had SLE is equivocal, but this allegation has repeatedly been made. Peripheral Raynaud's phenomenon was associated with SLE by MacLeod (46) in 1908 in London. Until the 1940s abnormalities of cerebral function were generally attributed to fever or uremia. Even though seizures are the most frequent cerebral manifestation of SLE, this symptom was alluded to only incidentally before 1951, when it was also pointed out that seizures may precede diagnosable SLE for years (47). Harvey et al. (36) attributed seizures to SLE in 11% of their patients. According to Bowen (1896), “I have often met with cases of extreme melancholia in the subjects of this disease [LE] and in a number of instances the mind has become really affected” (48). Toxic delirium was described (49), but the range of psychotic manifestations that may occur was not comprehensively reviewed until 1960 (50). Cerebral vasculitis to which the various manifestations might be attributed was described by Jarcho (51) in 1936 in Baltimore and Daly (49) in 1945 in Minneapolis. Paraplegia because of spinal vasculitis was identified in 1953 (52).

Attention to ocular symptoms antedates modern descriptions of cerebral symptoms. Retinal vasculitis was demonstrated pathologically in the 1930s (53 ,54). The first more extensive investigation (1935, Vienna) concluded that the ophthalmoscopic findings of some cases of DLE and SLE are further evidence of a tuberculous disease (55). Maumenee (56) in 1940 in Baltimore introduced the term “cotton-wool spots” for the retinal lesions as a synonym for the older term “cytoid bodies.” However, they “should not be regarded as pathognomonic of acute lupus erythematosus.” More recent investigations have shown that cotton-wool spots are ischemic lesions in the retina, while cytoid bodies are microscopic neural lesions; they coexist, but are not identical (57). Prior to 1970 cotton-wool spots were described in about 10% of cases of SLE, but less frequently more recently (58).

The absence of anemia in early descriptions of SLE can be attributed to the rudimentary state of hematologic methods. However, it is surprising that “secondary anemia often with a normal leukocyte count” was not described until 1924 (59). A case with leukopenia was cited by Goeckerman (60) in 1923. However, Rose and Pillsbury (61) in 1939 in Philadelphia were the first to consider this “the principal feature of the blood picture.” Purpura had been described by Kaposi (14) and by Osler (24), but the thrombocytopenia with which it occurs was not recognized until the 1930s (62 ,63). Conversely, the infrequency of purpura among platelet deficient patients was pointed out in 1951 (64).

Lupoid Hepatitis

In the mid-1950s a syndrome was recognized manifested by progressive liver disease usually associated with arthralgia and/or fever and a markedly elevated serum γ-globulin concentration that occurred predominantly in young women. Bearn et al. (New York) among 26 cases of liver disease (23 female) had eight (mean age 17) who had both fever and arthritis, a mean serum globulin content of 7 gm% and hyperbilirubinemia. The possibility that these were instances of SLE was not entertained. (65) In 1955, Zimmerman et al. (Chicago) evaluated patients with SLE for evidence of liver disease. The serum globulin concentration exceeded 3 gm% in 22 of the 25 cases. The investigators concluded that the numerous abnormal hepatic function test results in most cases reflected globulin abnormalities related to SLE rather than liver disease. (66) Coincidentally physicians in Melbourne, Australia demonstrated the LE cell phenomenon in patients with chronic hepatitis that they presumed to be viral. (67) In 1956, Ian R. Mackay (Melbourne) introduced the term “lupoid hepatitis” for this association (68). Bartholomew et al. (Mayo Clinic) found the serum γ-globulin concentration in seven cases consistently greater than 3.1 gm% (69) In various early descriptions the histopathology of the liver ranged from minimal changes to postnecrotic cirrhosis. In 1956, the first instance of lupoid hepatitis in a case of possibly drug-related SLE was also reported; a sulphonamide was implicated. (70) Mackay et al. (1959) proposed that the etiology may be “mediated via abnormal immunological responsiveness with auto-destruction of host tissues.” (71)

Serologic Aspects

The Wassermann test for syphilis was devised in 1906 and rapidly gained wide use. It soon was discovered that some, mainly tropical, diseases frequently gave positive results in nonsyphilitic individuals. The first such cases of SLE were reported from Germany in 1909 and 1910 (72 ,73). The latter author suggested that this result is evidence that LE is not a manifestation of tuberculosis, since falsely positive reactions had not been reported in the latter disease. The incidence of biologic false-positive (BFP) reactions has ranged from less than 3% to 44% of cases of LE (74 ,75). The variation may in part be a result of insufficient distinction having been made between DLE and SLE, since BFP rarely occurs in the former. Coburn and Moore (76) in 1943 in New York demonstrated hypergammaglobulinemia in SLE and related the BFP reaction to this. With the discovery of the specific *Treponema pallidum* immobilization (TPI) test for syphilis in 1949, complement fixation tests of the Wassermann type gradually were abandoned (77). Haserick and Long (78) in 1952 found that BFP reactions may precede clinical signs of SLE by years. Testing for BFP reactors was abandoned within a few years after the discovery of the LE cell.

In 1943, Malcolm M. Hargraves, a hematologist at the Mayo Clinic, found “peculiar rather structureless globular

bodies taking purple stain" in the marrow aspirate of a child with an undiagnosed disease; 2 1/2 years later he made a similar observation. Symptoms in a third case with this finding, in 1946, suggested that this patient had SLE. Two important observations were made in addition to the association of this unusual cell with the diagnosis of SLE: (a) more of these cells were found when the specimen was not fixed immediately; and (b) two similar cells needed to be differentiated. These findings were first reported in January 1948 (79). The "tart cell" (named after a patient, not the pastry) is not disease specific. Its distinguishing feature "is that the secondary nucleus has retained definite chromatin structure."

The "LE cell" … is the end result … either of phagocytosis of free nuclear material … or an actual autolysis of one or more lobes of the nucleus. … The "LE" cell is practically always a mature neutrophilic polymorphonuclear leukocyte in contradistinction to the "tart" cell which is most often a histiocyte (80).

John R. Haserick at the Cleveland Clinic suggested already in 1948 that "the greatest value of the 'LE' cell lies in its possible presence in suspected cases of acute disseminated lupus erythematosus in which the classic dermatologic manifestations are lacking" (81). Hargraves (82) in 1949 demonstrated LE cells in the buffy coat of centrifuged specimens of peripheral blood of patients in whose marrow LE cells had been detected. Then Haserick did the converse, inducing LE cells by incubating non-LE marrow with serum from LE patients. Thus, LE cells are formed by a factor in the blood of LE patients (83). Then in 1950 he showed that this factor is a γ-globulin (84). In the same year Klemperer et al. in New York discovered "hematoxylin bodies" (85). These appeared to be identical with the phagocytosed substance within LE cells, in various tissues obtained at autopsy of cases of SLE. This strengthened the hypothesis that the LE cell reaction is related to the pathogenesis of the disease (85). LE cells also were demonstrated in vivo in the content of artificially raised blisters (86). Peripheral blood replaced bone marrow as the source of LE cells, and of several techniques the one described by Zimmer and Hargraves (87) in 1952 was generally adopted.

Reliance on the LE cell to diagnose SLE began to diminish after a few years. Kievits et al. (88) in 1956 demonstrated LE cells in 16% of cases of rheumatoid arthritis, increasing doubt about the specificity of the reaction, and Rothfield et al. (89) in 1961 showed that LE cells cannot be detected in about a quarter of cases of SLE, proving poor sensitivity. In 1954, investigators in Switzerland had found that isolated cell nuclei can absorb the serum factor that induces LE cell formation. They therefore postulated that the factor is an antibody against a component of the nucleus (90). In 1957, Friou et al. (91) at Yale devised a technique to demonstrate the antibody semiquantitatively by indirect immunofluorescence microscopy. The reactive substance was identified in 1959 as a DNA-histone nucleoprotein (92) and Beck (93) in 1961 in London showed that at least three fluorescent staining patterns could be distinguished. In the next decade, refined laboratory methods permitted the discovery of numerous antibodies, some of which could be correlated clinically with subsets of SLE and other diseases. The discovery of the LE cell had initiated the discipline of immunopathology.

In 1957, three laboratories almost simultaneously demonstrated a factor in the serum of some cases of SLE that reacts specifically with DNA (94 ,95). Tan et al. (96) in 1966 in New York detected anti-DNA antibodies in SLE sera. Koffler et al. (97) in 1969 in New York found that the detection of native (double-stranded) deoxyribonucleic acid (dsDNA) is more specific for SLE, but less sensitive than antibody to denatured (single-stranded) DNA. Schur et al. (98) in 1971, using more sensitive techniques, confirmed the specificity of the reaction with dsDNA, but obtained positive reactions in only one half of SLE sera. Tan and Kunkel (99) in 1966 in New York detected a cytoplasmic (RNP) antigen in SLE serum that they designated Sm. It was the first antibody to a nonhistone nuclear antigen and highly specific for SLE, although found in only one third of cases.

The next discoveries about the antibody systems related to SLE were gained from the development of techniques to extract uncomplexed histones from nuclei and recombining them with DNA, free of other components (100). Histones are small basic proteins associated with nucleic acids in cell nuclei. Some extracted recombined antigens, depending on the precise histone structure, can be used to detect antihistone antibodies. The important findings were that antihistone antibodies occur more frequently in drug-induced than in idiopathic SLE, and that lupus-inducing drugs vary in their ability to induce these antibodies, procaine amide doing so most consistently (101 ,102).

The role of antinuclear antibodies (ANAs) in SLE became uncertain when clinically typical cases in which ANAs could not be detected began to be described (103). These cases comprise fewer than 5% of cases of SLE, and most have antibody reactive against the cytoplasmic RNA antigen Ro (104).

The introduction in 1963 of a convenient pathologic technique complemented the ever-increasing number of serologic tests. The "lupus band test" determines by immunofluorescence microscopy of skin biopsies whether immunoglobulins are deposited at the dermo-epidermal junction (105). In DLE it is positive in lesional but not in uninvolved skin. It also is positive in the "normal" skin of at least half of cases of SLE (106). It has proven not to be a highly specific finding, since it occurs in about 15% of cases of rheumatoid arthritis (107) and in various bullous dermatoses (108).

Epidemiology

In contrast to DLE, until the 1950s SLE was considered a rare disease. At the Johns Hopkins Hospital as of 1936 five cases were found among 7,500 autopsies (50). Twelve cases were diagnosed at the University of Pennsylvania Hospital during 1932 to 1938 (61). The large referral clientele of the Mayo Clinic included 154 cases from 1918(?) through 1937 and 132 cases during 1938 to 1947 (75). At Columbia-Presbyterian Hospital in New York, 44 cases were recognized

during 1937 to 1952 (109). SLE was diagnosed in 11 cases at the Los Angeles County Hospital during 1946 to 1949, but in 44 cases during the next 2 years. Dubois (110) attributed the increase to use of the LE cell test and better diagnostic acumen. On the other hand, the incidence of hospitalization for SLE in a Swedish city remained about 1 per 100,000 in 1938 to 1939 and 1948 to 1949, but increased to 4.8 per 100,000 during 1954 to 1955. These authors considered this increase genuine, although unexplained (111). The first survey of a circumscribed population in which case findings included outpatient records was conducted in New York in 1951 to 1960. SLE was found to have a higher incidence in the African-American than the white population, and the prevalence showed a greater increase than the incidence (112).

Various factors influencing the prevalence and survivorship with SLE were discussed by Merrell and Shulman (113) in 1955 in Baltimore. They also introduced the calculation of survival probability by life table analysis. Of the cases Harvey et al. (36) diagnosed during 1949 to 1953, 52% survived for 4 years. The extent to which the subsequent prolongation of survival should be attributed to the introduction in 1950 (114) of corticosteroid therapy has remained unsettled (115). Certainly, earlier diagnosis and recognition of less severe cases has contributed factitiously to lengthening the mean life expectancy. Urman and Rothfield (116) found that in a series of SLE patients treated principally with corticosteroids during 1957 to 1967, 10-year survival was 63%, while in a similarly treated series during 1968 to 1975 it increased to 84%. Haserick (117) in 1953 recognized that nephropathy benefits less from corticosteroids than do other manifestations. The 10-year survival of the patient cohort begun by Dubois' group (118), which was treated during 1950 to 1971 with multiple agents, was 87%, but only 65% in those with renal involvement.

SLE and “Collagen Disease”

Development of the modern pathogenetic concept of SLE required the rejection of two principles: that of Giovanni B. Morgagni (1682–1771, Padua) who had concluded in 1761 that every disease resides primarily in a certain organ, and that of Paul Ehrlich (1854–1915, Frankfurt) in 1901, who concluded that an organism cannot react against any of its own constituents. The former was first contradicted by the German pathologist, Fritz Klinge (119) (1892–1974), who showed in 1928 to 1934 that the morbid process in rheumatic fever is not limited to the synovium and heart, but affects connective tissue diffusely, and that such a process is also present in rheumatoid arthritis. Klemperer et al. (120) in 1941 in New York, in their study of the pathology of SLE, reported the following:

> The apparent heterogeneous involvement of various organs in this disease had no logic until it became apparent that the widespread lesions were identical in that they were mere local expressions of a morbid process affecting the entire collagenous tissue system. The most prominent of these alterations is fibrinoid degeneration—a descriptive morphologic term [E. Neumann, 1880] (120) indicating certain well-defined optical and tinctorial alterations in the collagenous fibers and ground substance (83).

This is the origin in 1942 of the term collagen disease, which initially was limited to SLE and scleroderma (120).

Ehrlich's doctrine was first questioned by Wilhelm Gennerich (122), a German dermatologist, who in 1921 speculated about the etiology of SLE:

> Lymphocytic [leukocytic ?] ferments are liberated by the disintegration of lymph nodes. They act on the organism as denatured protein and in sufficient quantity cause anaphylaxis. Furthermore, the liberated ferments exert their biologic effect, which seemingly consists of sensitizing the vascular endothelium and destroying certain components of connective tissue cells, especially, predisposed components of the skin and eventually also of all parenchymatous organs, if an abundant accumulation (acute LE) of the ferments develops in the blood.

This hypothesis gained acceptance in the 1940s because of the research of Arnold Rich (1893–1968, Baltimore), who advocated that the primary lesions of SLE-affected endothelium and collagen occur by anaphylaxis (123). The initiator of such hypersensitivity, however, remained obscure. Gross (124) in 1932 in New York had described microscopic “granular hematoxylin-stained bodies” in the hearts of cases of Libman-Sacks endocarditis. In 1950, Klemperer et al. (85) detected these abnormalities “in 32 of 35 cases of this disease, often widely distributed throughout the body.” Whether they were (or contained) the pathogen could not be ascertained.

Photosensitivity

The main symptom that the popular press has associated with LE is aggravation of the disease by exposure to bright sunlight. This was first described by a Viennese dermatologist in 1921 in regard to a fair-complected woman on whom DLE developed following intensive sun exposure. After several months, when the lesions had diminished, she received one ultraviolet irradiation to the back. On the next day there was a marked proliferation of lesions in the irradiated area (125). Rasch (126) in 1926 in Copenhagen stated that he had seen many such cases since 1907, with the lesions typically limited to the uncovered skin. He concluded that LE (i.e., SLE) “is very decidedly aggravated by light, in fact caused by it.”

Rose and Pillsbury (62) in 1939 in Philadelphia take precedence in the description of exacerbations of SLE following exposure to sun or therapeutic ultraviolet light, and also photosensitivity long preceding the development of recognized symptoms of this disease. Reports of the prevalence of photosensitivity have varied considerably: e.g., 11% of 105 cases (36), 32.7% of 520 cases (127).

Drug-Induced and Aggravated Lupus Erythematosus

Sulfonamides (initially sulfanilamide) began to be used to treat DLE in 1938 (128) and a few years later also SLE, with some benefit being described. In 1945, florid SLE developed in a young soldier who was being treated with sulfadiazine for presumed pyelonephritis (129). Gold (130) in 1951 in London hypothesized that the aggravation of LE by sulfonamide treatment, as had recently been reported, is because of the sensitization of patients by prior exposure to these drugs.

Gold compounds also acquired a reputation for exacerbating preexisting SLE. Their use in treating DLE began and ended long before their use in rheumatoid arthritis, the initial rationale also having been the presumed tuberculous etiology of the disease (131). A review in 1927 concluded that “in the treatment of lupus erythematosus we possess a systemic remedy of real efficacy. When one considers how refractory and unresponsive to therapeutic endeavor lupus erythematosus has been, … the results now achieved are all the more gratifying” (132). As recently as 1956, a therapeutic comparison of gold sodium thiosulfate and chloroquine, the latter first advocated for DLE in 1954 (133), showed similar efficacy (134).

Despite the lack of any effective treatment for SLE, as of 1937: “The general opinion that this method of treatment [gold] is contraindicated for acute and subacute disseminated lupus erythematosus is well founded on sad experience. … The capillaries seem unduly sensitive not only to gold therapy but also to a wide variety of therapeutic agents. … This is understandable in the case of therapy with gold preparations, since it affects the structures (capillaries) attacked by lupus erythematosus itself” (135). It still was deemed necessary in 1949 to warn that “gold is especially dangerous in the acute phases and probably should never be used” (136). This danger never was well documented.

Chronologically, the first commonly used drugs that were implicated to possibly induce rather than aggravate SLE were hydralazine (1954) (137), hydantoins (1957) (138), and procainamide (1962) (139). In the case of hydralazine the development of symptoms clearly was related to the chronic use of large doses to control hypertension. The first reported manifestation was arthritis, and additional symptoms more definitely suggestive of SLE developed if hydralazine was not discontinued. Comens and Schroeder (140) in 1956 found that, although LE cells were not found consistently in patients whose symptoms suggested SLE, these cells could also be demonstrated in some asymptomatic patients who were taking hydralazine. A Mayo Clinic study (1965) compared 50 cases of “hydralazine syndrome” with 100 hypertensive patients who were receiving another therapy. The authors concluded from the prehydralazine histories that “antedating manifestations possibly suggesting lupus diathesis” were nearly six times as frequent in the hydralazine cases as in the controls. Hence, this drug probably uncovers an “underlying lupus diathesis” (141).

Diphenylhydantoin and mesantoin were the first, but not the only, anticonvulsants to be related to the induction of SLE (138 ,142). Since seizures may be an early manifestation of this disease, the possibility that certain drugs “uncover” SLE gained support from these observations.

By far the most unequivocal inducing agent has been the antiarrhythmic drug procainamide. Dubois (143) in 1969 compared 33 well-documented cases against his cohort of 520 cases of idiopathic SLE. This supported the impression that the drug-induced disease tends to exhibit fewer and milder symptoms, particularly lacking GI, renal, and neurologic involvement. In a prospective study, Blomgren et al. (144) in 1969 in Rochester, New York, showed that ANA developed within 6 months in one half of patients who were placed on procainamide, “making it unlikely that the drug simply unveils a latent predisposition to idiopathic lupus erythematosus.”

Diagnostic Criteria

Valid, agreed-upon diagnoses are essential for epidemiologic and therapeutic research. The method for developing disease specific diagnostic criteria was pioneered in 1944 on rheumatic fever (145). When the technique was applied to LE in 1971, the extraordinarily large number of 74 clinical and laboratory items were considered and refined into 14 diagnostic criteria, one of which was the presence of DLE (146). The revision of 1982 placed greater reliance on serologic findings and the number of criteria was reduced to 11. The presence of at least four criteria was required in both schemes. Using the revised set, false-negative diagnoses decreased without a change in the small percentage of false-positive diagnoses (147).

The Relationship of DLE to SLE

Agreement with Kaposi's belief that DLE and SLE are expressions of the same disease has waxed and waned. For example, MacLeod (148) in 1913 in London concluded: “Lupus erythematosus of the acute disseminated type has from time to time been found to occur in association with more or less general toxaemia. … The circumscribed cases have probably a different etiology from those of the acute disseminated type.” Reliance on skin lesions to diagnose SLE was abandoned reluctantly. According to a 1952 textbook, “Diagnosis may be impossible until the appearance of the characteristic rash” (149). Of the pre-1938 cases of SLE diagnosed at the Mayo Clinic, the onset was considered to be with DLE in 47%. This decreased to 17% of those seen in the next decade, perhaps because of greater experience (75). Keil (135) in 1937 pointed out the lack of correlation between the severity of cutaneous and internal manifestations, and considered it probable that the two are variants of the same disorder. However, Baehr et al. (150)

still held in 1951 that “disseminate lupus erythematosus bears no relationship whatever … to the benign indolent skin lesion known to dermatologists as discoid lupus.” Among Dubois' 520 cases of SLE (1950–1963), 10.8% initially had discoid lesions, thrice as many as had a “butterfly rash” (127). According to a more recent multicenter study, 13% of 353 cases of SLE “at some time during the course of their illness” manifested discoid lesions (151). Conversely, none of 120 cases of DLE developed systemic findings during a 5-year follow-up (152). The two opinions were moderated by Burch and Rowell (153) in 1968 in Leeds, England, who theorized that there is a different polygenic predisposition for the development of DLE and SLE: “When a genuine transition from DLE to SLE occurs, the affected patient is genetically predisposed to both diseases.” The question remains open.

Four Subsets of Lupus Erythematosus

Antiphospholipid Syndrome

In 1941 Pangborn (154) in Albany, New York, discovered that the substance in the beef heart extract that was used in the complement fixation test for syphilis was a phospholipid. Keil (155) had recently surmised that the “false positive” reactions in cases of SLE are not merely coincidental. However, evidence of a mechanism to explain “biologic false positive reactivity did not accrue until 1983, when a sensitive method to test for anti-cardiolipin [anti-phospholipid] antibodies was devised” (156).

In 1948, Conley et al. (157) in Baltimore demonstrated an endogenous circulating anticoagulant in nonhemophilic bleeding patients. Four years later two cases of SLE with hemorrhaging attributed to such an anticoagulant were briefly described (158). Lee and Sanders (159) in 1955 in New York found that this substance is not a rarity in SLE, but that it usually does not cause bleeding. This observation was followed in 1963 by the surprising discovery that the anticoagulant may be associated not only with bleeding, but also with thromboses (160). In 1975 spontaneous abortion during the course of SLE was first associated with the lupus anticoagulant (161), and this relationship was subsequently confirmed prospectively (162). In 1988 anticardiolipin antibodies associated with syphilis were differentiated from those related to SLE (163).

Lupus Erythematosus Profundus

“Lupus erythematosus profundus” was coined by Samuel Irgang (164) in 1940 in New York to differentiate from DLE cases with nodular lesions in the deeper portions of the skin, but little epidermal involvement. Such a case had been described by Kaposi (13) in 1869, and this manifestation has been called Kaposi-Irgang syndrome in the dermatologic literature (165). The first American report is attributed to Fordyce (166) in 1924 in New York. Before the 1940s this variant probably was usually misdiagnosed as sarcoid (167). Winkelmann (168) in 1970 suggested that “LE panniculitis” would be a more accurate term, thereby endorsing the pathologic interpretation of Fountain (169) in 1968 in London.

Subacute Cutaneous Lupus Erythematosus

“Subacute cutaneous LE,” described by Sontheimer et al. (170) in 1979 in Dallas, appears to be clinically intermediate between DLE and SLE. The lesions may be preceded by those of DLE and coincide with these at some time in about 20% of cases. They differ from discoid lesions in being annular or resembling psoriasis, lacking follicular plugging, and are less likely to heal with scarring. Patients are more frequently light sensitive than those with either DLE or SLE. About half fulfill the diagnostic criteria for SLE. Most cases are ANA-positive, but resemble “ANA-negative SLE” in being anti-Ro positive (170). Occurrence as a drug-induced phenomenon was first described in 1985, associated with hydrochlorothiazide (171).

Neonatal Lupus Erythematosus

The innocuous transplacental transfer of the LE factor (anti-DNA antibody) was demonstrated in 1954 (172). In the same year a case of transient DLE was described in an infant whose mother subsequently developed SLE (173). Since then, neonatal DLE has usually been found to resolve within the first year. In 1957 a woman with SLE delivered a boy who had complete heart block and died on the second day. His myocardium was found to contain hematoxylin bodies (174). By 1977, sufficient cases of neonatal complete heart block had been described that this became recognized as the most characteristic sign of neonatal LE, occurring in about half of these infants (175 ,176 ,177). Second most frequent are cutaneous lesions. SS-A (anti-Ro) antibody was pointed out in 1981 to be the most consistent serologic finding in both neonatal DLE and SLE (178 ,179).

How Did SLE Come to be Transferred from the Realm of Dermatology to Internal Medicine?

With few exceptions, such as the clinical observations of Osler and of Libman, the delineation and treatment of LE remained in the domain of dermatologists until the 1940s. There are two complementary explanations for this: (a) SLE was recognized by its cutaneous findings and thereby was linked, albeit equivocally, to DLE, a cutaneous disease. SLE was diagnosed much less frequently than DLE and its visceral manifestations were considered secondary to the cutaneous. The 1939 edition of Sutton and Sutton's

Diseases of the Skin contained 13 pages on DLE and SLE (180), while the 1944 edition of Comroe's *Arthritis and Allied Conditions* had three (181). It only became accepted in the 1940s that SLE may occur without skin lesions (35), one factor that moved the disease toward the internist. (b) A medical specialty, when it is circumscribed by more than the patient's age or gender, results from particular technical and/or therapeutic expertise. Although the beginnings of rheumatology may be placed in the late 1920s, its pioneers had neither technical nor therapeutic superiority over other internists. This changed abruptly with the almost simultaneous discovery of two diagnostic methods: the rheumatoid factor and the LE cell in 1948, and cortisone therapy in 1949, followed in 1950 by the establishment of the Institute of Arthritis and Metabolic Diseases in the National Institutes of Health. The LE cell test increased the diagnosis of SLE, and corticosteroids conveyed not only that these patients could be helped, but that the treatment required specialized knowledge, thereby enhancing the status of rheumatology (182).

Interest in LE has shifted from clinical description to immunologic research, with the still frustrated goal of elucidating the etiology, whether it be single or multiple. The continued intensification of scientific interest is reflected in the listing of articles in the *Index Medicus*. These have been increasing steadily, from eight columns in 1960 to 21 in 1982, 25 in 1987, 31 in 1992, and 47 in 1997 to thousands of references in 2006!

Chapter 2
The Definition and Classification of Systemic Lupus Erythematosus

Zuhre N. Tutuncu

Kenneth C. Kalunian

Definition of Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystem disease that is caused by antibody production and complement-fixing immune complex deposition that result in tissue damage. As potentially many different antibodies can be produced in SLE patients, the different organ-specific targets of these antibodies can cause a wide spectrum of clinical presentations, which are characterized by remissions and exacerbations. The pathogenic immune responses probably result from environmental triggers acting in the setting of certain susceptibility genes. Ultraviolet light and certain drugs are the only known environmental triggers identified to date.

SLE Classification Criteria

In 1971, the American Rheumatism Association (ARA) published preliminary criteria for the classification of SLE. These criteria were developed for clinical trials and population studies rather than for diagnostic purposes (1). The criteria were based on information from 52 rheumatologists in clinics and hospitals in the United States and Canada; each physician provided 74 items of information on five of their own patients in each of the following categories in which they had classified these patients using their own clinical judgment: unequivocal SLE, probable SLE, classic RA, and medical patients with nonrheumatic diseases. The committee examined the sensitivity and specificity of each item alone and of 140 selected combinations of two or more items. Only 57 of 74 items were included in the final analysis for there was scarcity of information in some of the requested items.

Based on computer analysis of the data, 57 items were reduced to 14 manifestations, which included 21 items. The ARA committee proposed that a person can be said to have SLE if any four or more of the following manifestations are present, either serially or simultaneously, during any period of observation:

- Facial erythema (i.e., butterfly rash): Diffuse erythema, flat or raised, over the malar eminence(s) and/or bridge of the nose; may be unilateral.
- Discoid lupus: Erythematous-raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions; may be present anywhere on the body.
- Raynaud's phenomenon: Requires a two-phase color reaction, by patient's history or physician's observation.
- Alopecia: Rapid loss of a large amount of scalp hair, by patient's history or physician's observation.
- Photosensitivity: Unusual skin reaction from exposure to sunlight, by patient's history or physician's observation.
- Oral or nasopharyngeal ulceration.
- Arthritis without deformity: One or more peripheral joints involved with any of the following in the absence of deformity: (a) pain on motion, (b) tenderness, (c) effusion or periarticular soft-tissue swelling. (Peripheral joints include feet, ankles, knees, hips, shoulders, elbows, wrists, metacarpophalangeal, proximal interphalangeal, and terminal interphalangeal and temporomandibular joints.)
- LE cells: Two or more classical LE cells seen on one or more occasions, or one cell seen on two or more occasions, using an accepted, published method.
- Chronic false-positive serologic test for syphilis (STS): Known to be present for at least 6 months and confirmed by *Treponema pallidum* immobilization (TPI) or Reiter's tests.
- Profuse proteinuria: Greater than 3.5 g/d.
- Urinary cellular casts: May be red cell, hemoglobin, granular, tubular, or mixed.
- One or both of the following: (a) pleuritis, good history of pleuritic pain; or rub heard by a physician; or radiographic evidence of both pleural thickening and fluid; and/or (b) pericarditis, documented by electrocardiogram (ECG) or rub.
- One or both of the following: (a) psychosis, and/or (b) convulsions, by patient's history or physician's observation in the absence of uremia and offending drugs.
- One or more of the following: (a) hemolytic anemia; (b) leukopenia, white blood cell count of less than 4000/mL on two or more occasions; and/or (c) thrombocytopenia, platelet count less than 100,000/mL.

These criteria were chosen because of their high sensitivity and specificity compared to the gold standard, physicians' clinical judgment of the diagnosis; the committee noted 90% sensitivity and 99% specificity against rheumatoid arthritis and 98% specificity against a miscellany of nonrheumatic diseases (1). In a retrospective pilot study of 500 male veterans with scleroderma, only 10 patients satisfied the SLE criteria at the time of diagnosis (1).

These criteria were subsequently tested in other centers; in these various studies, sensitivities varied between 57.2% to 98.0% (2 ,3 ,4 ,5 ,6). The studies with the lowest sensitivities involved patients who were seen either initially or at only one particular point in time (4 ,7); these investigators noted that a higher proportion of their patients eventually demonstrated four or more criteria over time. Lom-Orta et al. (8) studied 31 patients who were thought to have SLE but who did not fulfill the ARA criteria; 21 of them fulfilled the criteria within a few years.

Numerous suggestions were made for improvement of the classification criteria, including the inclusion of antinuclear antibody (ANA) and other autoantibodies (9 ,10 ,11) and the use of a weighted scoring system in which certain criteria are given more weight than others based on clinical importance (12). An ARA subcommittee was created to evaluate these considerations; their study led to the publication of revised criteria in 1982 (13). Thirty potential criteria were studied, including numerous serologic tests and histologic descriptions of skin and kidney, as well as each of the original 1971 criteria. These variables were compared in SLE patients and matched controls. Eighteen investigators representing major clinics contributed patient report forms; these forms indicated the presence or absence of each variable at the time of examination or at any time in the past. Abnormalities that could be attributed to comorbid conditions or concurrent medications were not reported (14). Each investigator was instructed to report prospective data on 10 consecutive patients and the next age-, race-, and sex-matched patient with a nontraumatic, nondegenerative, connective tissue disease seen at that clinic. This generated data from 177 patients with SLE and 162 control patients from 18 institutions. Cluster and other multivariate analysis techniques were used in studying the variables; numerous potential criteria sets were analyzed.

The resulting 1982 revised criteria are a simplified and updated version of the 1971 preliminary criteria that incorporated newer immunologic criteria and aggregates of some organ system manifestations into single criteria. It consists of 11 items, compared with 14 in the initial criteria. As with the initial criteria, patients must fulfill four or more criteria; no single criterion is absolutely essential. ANA, anti-DNA, and anti-Sm antibodies were included in the revised 1982 set; ANA was felt to be the most important addition to the criteria set, because this serologic marker was present at some point during the course of disease in 176 of the 177 patients. Despite the nonspecificity (the marker was present in 51% of the controls studied), the subcommittee felt its almost universal positivity made it a necessary criterion. Because of the scarcity of skin and kidney biopsies, they were excluded from the final revised criteria set. Raynaud's phenomenon and alopecia were also eliminated as a result of low combined sensitivity/specificity scores. Renal criteria were consolidated. In the preliminary criteria set, cellular casts and proteinuria were separate criteria; in the revised set, there is only a single renal criterion, which is satisfied if a patient has cellular casts and/or proteinuria. In addition, the revised criteria reduced the amount of proteinuria that is needed for fulfillment, from greater than 3.5 g/d in the preliminary set to more than 0.5 g/d (or >3 + if quantitation is not performed) in the revised set.

Using the patient database on which they were based, the revised criteria were 96% sensitive and specific, compared with 78% and 87%, respectively, for the 1971 criteria (13). The subcommittee further tested the revised criteria against an ARA database of 590 patients with SLE, scleroderma, or dermatomyositis/polymyositis. Using the revised criteria against this database population, sensitivity in SLE patients was 83%, and specificity against the combined scleroderma and dermatomyositis/polymyositis patients was 89%. Using the preliminary criteria, sensitivity for SLE was only 78% and specificity only 87% (14).

In a subsequent comparison of the relative sensitivities of the 1971 and 1982 criteria, Levin et al. (15) studied 156 SLE patients at the University of Connecticut. Eighty-eight percent met the preliminary criteria, whereas 83% met the revised criteria when arthritis was strictly defined (i.e., nonerosive arthritis). Ninety-one percent met the revised criteria when arthritis was more liberally defined (i.e., nondeforming arthritis). These differences were not statistically significant. Their analysis also noted that of the three serologic tests added in the revised criteria (i.e., ANA, anti-Sm, and anti-DNA antibodies), ANA accounted for the increased sensitivity of the revised criteria. Levin et al. noted that both the preliminary and the revised criteria were inappropriate for diagnostic purposes, in that over 50% of their patients fulfilled neither set of criteria when tested at the time of diagnosis. These patients subsequently fulfilled both sets of criteria at the same rate (77.5% fulfilled preliminary criteria and 78.5% revised criteria 5 years after diagnosis, and 84.5% and 83.0% for preliminary and revised criteria, respectively, at 7 years).

Passas et al. (16) compared specificity of the preliminary and revised criteria in 207 University of Connecticut patients with non-SLE rheumatic diseases that are important in the differential diagnosis of SLE. The specificity was 98% for the preliminary criteria and 99% for the revised criteria. The preliminary and revised criteria also were tested on 285 Japanese SLE patients and 272 control patients with non-SLE connective tissue diseases (17). The preliminary criteria had a sensitivity of 78% and a specificity of 98%, compared with a sensitivity of 89% and specificity of 96% for the revised criteria. Davis and Stein (18) applied the preliminary and revised criteria to 18 Zimbabwean patients with SLE reported up to 1989; they noted a sensitivity of

83% for the preliminary and 94% for the revised criteria. When serologic criteria were excluded, the sensitivity of the revised criteria was only 78%. They concluded that in many areas of Zimbabwe, where serologic tests are not readily available, the preliminary criteria may be more valuable than the revised criteria in the classification of patients with SLE, because the preliminary criteria rely more on clinical rather than serologic variables.

Table 2-1: The 1997 Revised Criteria for the Classification of Systemic Lupus Erythematosus (SLE)

Criterion	Definition
1. Malar rash	Fixed malar erythema, flat or raised
2. Discoid rash	Erythematous-raised patches with keratic scaling and follicular plugging; atrophic scarring may occur in older
3. Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulcers, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion) OR b. Pericarditis (documented by ECG, rub, or evidence of pericardial effusion)
7. Renal disorder	a. Persistent proteinuria (>0.5 g/d or >3+) OR b. Cellular casts of any type
8. Neurologic disorder	a. Seizures (in the absence of other causes) OR b. Psychosis (in the absence of other causes)
9. Hematologic disorder	a. Hemolytic anemia OR b. Leukopenia (<4,000/mL on two or more occasions) OR c. Lymphopenia (<1,500/mL on two or more occasions) OR d. Thrombocytopenia (<100,000/mL in the absence of offending drugs)
10. Immunologic disorder	a. Anti-double-stranded DNA OR b. Anti-Sm OR c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody (ANA) by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with “drug-induced lupus syndrome”

For identifying patients in clinical studies, a person shall be said to have SLE if any four or more of the 11 criteria are present, either serially or simultaneously, during any interval of observation.
Ig, immunoglobulin.
From Hochberg MG. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus (letter). *Arthritis Rheum* 1997;40:1725.

Because the presence of antiphospholipid antibodies and the antiphospholipid syndrome (APS) was increasingly recognized in SLE patients, the Diagnostic and Therapeutic Criteria Committee of the ACR updated the 1982 revised criteria for

SLE in 1997 (Table 2-1) (19). Immunologic criteria were modified by removing the LE cell preparation and the item “false-positive test for syphilis” was expanded to “positive finding of IgG or IgM anticardiolipin antibodies or a lupus anticoagulant.” No formal validation studies of these modifications have been performed.

The 1997 revised criteria have not been free from criticism. Classification of neurological and psychiatric manifestations of SLE were expanded to include 19 different syndromes in 1999 (20), whereas all versions of classification criteria for SLE have included only psychosis and seizures. Although the current classification criteria include the presence of certain isotypes of anticardiolipin antibodies and the lupus anticoagulant, it does not include IgA anticardiolipin antibodies, other assessments of antiphospholipid antibodies or any of the clinical features of APS as outlined in the preliminary classification criteria for definite APS, which were published in 1999 (21) including small-vessel thrombosis and prematurity as a result of severe preeclampsia, severe placental insufficiency, venous and arterial thrombosis, recurrent miscarriage, and fetal death.

The heterogeneity of SLE extends to the type of clinical manifestations at disease onset and to the time it may take for these manifestations to evolve and make the diagnosis of SLE possible. As the understanding of the pathogenesis of SLE is improving and more advanced tests are available, it is more evident that there is a growing need for a more organized and more easily translatable classification. Current ACR classification for SLE has allowed the universality of SLE clinical research and has also served as a guide in clinical practice, but the performance of ACR classification needs to be improved for it has inherent limitations, including bias toward more severe disease and longer duration of disease, equal weighing of features that vary in clinical significance, lacking accurate definitions for certain conditions, and not including important and serious forms of lupus that may occur in patients who do not meet the full criteria.

The Systemic Lupus International Collaborating Clinics (SLICC) has proposed to revise the current SLE criteria in order to develop a relatively simple classification system that captures the key considerations used in determining clinical diagnoses of SLE, cutaneous lupus, and APS. Thirty-two international centers are included in the SLICC registry to collect clinical and laboratory data in 600 patients with SLE, APS, and cutaneous lupus cases and disease controls. The study will include data sets of only those cases and controls for which there is agreement on the diagnosis by a “consensus panel” of rheumatologists, dermatologists, and nephrologists. A wide array of multiple variables will be evaluated to individually estimate the sensitivity and specificity of each criterion. Preliminary data from the initial 70 patients recruited for the SLICC database have been evaluated (22); they were categorized based on the diagnosis given to them at the enrollment site: 56 SLE, two undifferentiated connective tissue disease (UCTD), five rheumatoid arthritis, one primary APS, three secondary APS, four vasculitis, and two dermatomyosites. Thirteen SLICC members were asked to enter their diagnosis without regard to the number of ACR criteria for each case. The agreement in diagnosing SLE among members was fair. Perfect consensus was reached for only 33 (47%) patients: 24 SLE and nine non-SLE patients. The difference between consensus rates among SLE patients with three or four ACR criteria did not reach a significant level and there was a large overlap between SLE and UCTD diagnosis. These results suggest that ACR criteria for SLE do not closely reflect clinical diagnoses as assigned by lupus experts. This ongoing cooperative effort will hopefully result in redefining the confusing criteria and validation of new classification criteria.

Chapter 3
Environmental Aspects of Lupus

Frederick W. Miller

Glinda S. Cooper

The relative rarity, heterogeneity, and multifactorial etiologies of autoimmune diseases have limited our understanding of their pathogeneses. Although mechanisms for the development of autoimmune diseases have not been fully elucidated, evidence from a number of lines of investigation suggests that these increasingly recognized disorders result from environmental exposures in genetically susceptible individuals (1 ,2 ,3 ,4 ,5). Despite the significant progress that has been made in understanding a number of genetic risk factors for lupus and other autoimmune diseases (see Chapter 6), relatively little information is now available regarding the role of specific environmental agents in the development of these disorders. Nonetheless, there has been a substantial increase in research pertaining to environmental influences on lupus over the past decade.

Environmental risk factors may be considered to be all those susceptibility factors that are not inherited. Exposures that have been suspected of being involved in the pathogenesis of autoimmunity may be divided into two general categories: noninfectious and infectious agents. Here, we focus on the evidence for the role of selected noninfectious and infectious environmental agents in the pathogenesis of systemic lupus erythematosus (SLE) as classified by the American College of Rheumatology (6) as well as lupus-like disorders that do not meet current SLE classification criteria (together referred to as “lupus” in this chapter). Drug associated lupus will not be discussed here as it is covered in Chapter 44 .

Difficulties in the Assessment of Environmental Risk Factors

There are many reasons why so little information is available about the environmental risk factors for lupus and other autoimmune diseases (Table 3-1). First, SLE, like most other autoimmune conditions, is a relatively rare condition and heterogeneous in its phenotypes, genotypes, and likely pathogeneses. Therefore, only a subset of any population of lupus patients is likely to share common gene-environment interactions that would lead to the syndrome under study. Thus, low effect sizes, which often result in odds ratios less than 2.0 for many exposure risks, dictate the need for studying relatively large populations to have adequate statistical power to identify environmental risk factors.

The relative lack of validated exposure biomarkers that allow for confirmation of a given exposure, and can pinpoint exposure to a specific time period, is another difficulty. This is a critical deficiency given the potential long latency (time from agent exposure to disease onset) of some causal factors and the increasing problems of recall bias the longer the period from exposure. The fact that there are few practical clinical assessment tools that have been validated for the identification and quantitation of exposures is another deficiency in the field.

As is the case for some cancers (7), there may be certain exposures that initiate autoimmunity (inducers) and quite different ones that promote (promoters) and sustain (sustainers) the pathologic states we recognize as autoimmune diseases. This possibility is suggested by investigations showing that autoantibodies precede the development of clinical disease by months to years (8 ,9 ,10). Therefore, in some cases, a change induced by one exposure may be necessary before a subsequent exposure can have its effect. This may result in variable latencies for certain causal factors depending on the prevalence of the required secondary exposure and dependent host factors. Alternatively, mixtures of exposures, including possible combinations of infectious and noninfectious agents, perhaps occurring during critical periods when persons may be more susceptible to them (i.e., in utero, in childhood, during puberty, pregnancy, lactation or other stressful conditions) may be necessary in order to overcome tolerance. It is also possible that certain environmental exposures, as is the case for certain genes (see Chapter 6), may be protective for the development of a disease.

In certain circumstances it can be relatively clear when a given exposure is inducing an illness in an individual patient. The definition of an environmental disease in selected persons can be accomplished by identifying a new clinical disorder that develops soon after a novel exposure, resolves when the exposure is removed (dechallenge) and then recurs after reintroduction of the same exposure (rechallenge) (11). This approach is most easily applied in the case of exposures to defined chemical entities that undergo rapid metabolism and elimination such as many drugs, foods, and topical or inhaled toxicants. Unfortunately, a number of xenobiotics (compounds not naturally found in the body) cannot easily be removed from an organism after exposure, and therefore, for these agents this approach is not usually helpful. Exposures in this latter category include inhaled silica, vaccines, fat-soluble oils, and collagen or silicone implants. It is also likely that certain causative agents

induce a positive reinforcement cycle in the pathogenesis of autoimmune disease, so that removing them after some critical point is reached may not result in disease improvement.

Table 3-1: Difficulties in Assessing the Role of the Environment in the Pathogenesis of Lupus

Relatively rare syndromes
Heterogeneity of disease phenotypes, genotypes, and likely pathogeneses
Possible requirement for gene-environment or environment-environment interactions
Lack of validated biomarkers for many exposures
Few practical clinical assessment tools to accurately identify and quantitate exposures
Possibly different agents are needed to initiate autoimmunity (inducers) and promote (promoters) and sustain (sustainers) autoimmune disease
Variability in latencies (time from exposure to disease onset) for different causal factors
Difficult to “remove” many environmental exposures so that a “challenge-dechallenge” study is not feasible
Little formal training in environmental medicine
Lack of comprehensive national registries, databases, and specimen repositories
Little information on the long-term human effects of tens of thousands of xenobiotics registered for commercial use

Other difficulties are that there is little formal training in environmental medicine and there are few resources generally dedicated to this area. Finally, the lack of comprehensive national registries, databases, and specimen repositories means that almost every environmental study in the United States needs to be initiated anew and cannot build on prior efforts in the field.

More than 80,000 chemicals are registered for use in commerce in the United States, and an estimated 2,000 new ones are introduced annually to be included in our foods, personal care products, drugs, household cleaners, and a host of industrial processes (http://www.ntp-server.niehs.nih.gov/). This does not include the many poorly documented xenobiotics present in imported products that are increasing yearly as a result of our ever more global economy. Although relatively few of these are thought to result in significant adverse effects on human health, the long-term impacts of most of these compounds are unknown. It will be increasingly necessary to be able to determine the effect of complex environmental exposures on the development and course of autoimmune diseases.

Evidence Supporting Environmental Aspects of Lupus

Despite the many difficulties listed above that confront investigators, evidence for the role of environmental agents in the pathogenesis of lupus has been accumulating from a variety of approaches for nearly half a century (Table 3-2). Although some of these methods are indirect or may be applicable only to single patients, taken together these complementary findings from many different investigations strongly support the contention that lupus, like most autoimmune diseases, does have an important environmental component (2).

Table 3-2: Lines of Evidence Supporting the Role of the Environment in the Pathogenesis of Lupus

Less than 50% disease concordance in monozygotic twins
Dechallenge (disease resolution or improvement after removal of the suspect agent)
Rechallenge (disease recurrence or worsening after re-exposure to the suspect agent)
Changes in the incidence or prevalence of lupus over time
Different incidence or prevalence rates in the same ethnic group in different locations
Strong biologic plausibility from laboratory studies and animal models
Epidemiologic associations with particular exposures

One line of evidence for the role of the environment in lupus and other autoimmune illnesses is that there is generally less than 50% disease concordance in monozygotic twins who have an identical genetic makeup (2 ,12). Disease concordance for lupus in a series of 45 monozygotic twin pairs was only 24% (13). While this low level of concordance has been suggested to be the result of stochastic or other events, the consistently low disease concordance in genetically identical persons among all the autoimmune disorders studied, and the other lines of evidence suggesting the role of environmental factors, argue against this. These findings also hint that even if all the genetic risk factors for a given autoimmune disease could be fully identified, this would not allow for prediction of disease with any greater accuracy than the flip of a coin, without the incorporation of environmental or other etiologic factors.

As mentioned above, in certain individuals environmental agents may be directly associated with a lupus syndrome by the development of disease in an appropriate time frame after exposure to the suspect agent (challenge), resolution, or dramatic improvement of the condition after removal of the agent (dechallenge) and then redevelopment of the disorder upon re-exposure to the agent (rechallenge).

Significant increases or decreases in the incidence or prevalence of disease over time imply a nongenetic etiology given the relatively slow rate of genetic change in a population. Although data are limited in this area—and studies are possibly confounded as a result of improvements in the ability to diagnose some conditions over time—it appears that lupus, as is the case for some other autoimmune illnesses, may be increasingly prevalent (14 ,15 ,16 ,17), while rheumatoid arthritis may be decreasing in frequency in some populations (15).

Studies of genetically similar populations living under different conditions or in different geographic locations may also be illuminating in understanding possible environmental

or lifestyle effects on autoimmunity. In this regard, the incidence of lupus appears to differ in persons of African or Chinese ancestry in different locales (18 ,19). These differences may be the result of referral, ascertainment, or other biases, however, and more study in this area is needed to understand the true reasons for such differences. Strong biologic plausibility from laboratory studies and animal models (see Chapter 18) is another line of evidence supporting the role of noninfectious and infectious agents in the pathogenesis of lupus.

Finally, epidemiologic associations between particular exposures and lupus, despite their high costs and limitations, are perhaps the most important investigations that have recently widened our perspectives on the role of environmental agents in the development of lupus. Epidemiologic studies linking specific exposures are limited and too often consist of relatively small, underpowered investigations resulting in low effect sizes and wide confidence limits. Yet much of the data presented below have come from such studies, which, when replicated by different study designs in various populations, provide greater confidence in the findings. Larger, well-designed, multicentered, and sometimes international studies, using appropriate controls and collecting adequate information to minimize confounding, are needed in the future to more fully define the specific environmental risk factors for the lupus syndromes and their component phenotypes.

Noninfectious Agents Associated with Lupus

Exposures to a wide variety of compounds with different structures, chemical properties, metabolic pathways, and modes of action have been reported to be associated with lupus. The evidence supporting these proposed associations range from case reports to epidemiologic and laboratory studies, and most of the proposed associations are speculative at this time. We will focus on describing those agents for which more information is available and the strength of the association seems strongest. Table 3-3 lists epidemiologic studies for these agents.

Silica

Crystalline silica or quartz is a very abundant material in sand, rock, and soil. Occupational exposure to respirable silica dust (particles <5 μm) has been associated with the chronic inflammatory and fibrotic lung disease called silicosis (20) as well as a number of autoimmune disorders (21 ,22 ,23). It is possible that the development of silicosis is further modulated by immunogenetic risk factors (24 ,25). The dusty trades, including pottery and china manufacturing, quarry work, masonry, and mining are the traditional occupations that involve significant respiratory silica exposure, although others, including scouring powder manufacturers, some dental workers, and professional housecleaners, can also come into extensive contact with silica dust during their jobs.

Initial case reports and series dating back to the early 20th century focused on the role of silica in rheumatoid arthritis and scleroderma. These early studies encouraged case series and later epidemiologic investigations of the role of silica in SLE (22). Evidence for the association of occupational silica with lupus comes from case series (26 ,27 ,28), animal investigations (29 ,30) and epidemiologic studies (31 ,32 ,33). After therapeutic drugs (see Chapter 44), silica is one of the best-studied environmental agents associated with lupus, and has perhaps the greatest scientific support as an environmental risk factor.

Three epidemiologic investigations have demonstrated significant risks for the development of lupus after occupational silica exposure (31 ,32 ,33). These studies—which utilized different designs and were conducted in different countries and populations—have revealed consistent associations across gender, racial, and educational subgroups, and have shown evidence of a dose-response effect (Table 3-3). These findings increase confidence that potential confounders associated with each approach have been overcome and the association of occupational silica exposure with lupus is real. The limited data, however, do not allow for a comprehensive and precise comparison of clinical features among subjects who have developed lupus after silica exposure to those who have developed lupus without significant silica exposure. Nonetheless, Conrad et al. (34) have described an increase in the prevalence of the 16/6 idiotype, which is a major cross-reactive idiotype of anti-DNA autoantibodies that have been reported in SLE and patients treated with procainamide (35), among uranium miners exposed to quartz dust who developed lupus. All the miners with the 16/6 idiotype had antibodies to double-stranded deoxyribonucleic acid (dsDNA). Furthermore, two of the minors who were 16/6 positive had progression of their disease compared to none who were 16/6 idiotype negative, suggesting this may be a risk factor for progression to SLE. It is also possible that the autoantibody distributions differ in those who develop lupus after significant silica exposure compared to those without such exposure (36).

In addition to the human studies above, a number of laboratory investigations have been undertaken in vitro and in vivo in an attempt to understand pathogenetic mechanisms for the role of silica in inducing autoimmune disease. Silica has been shown to have an adjuvant effect in a variety of animal models and disease states. Respirable silica particles are phagocytized by alveolar macrophages, leading to cellular activation and the release of soluble mediators such as chemokines, proinflammatory cytokines, including tumor necrosis factor-α and interleukin-1-β, transforming growth factor-β, lysosomal enzymes, and reactive oxygen species (20). These soluble mediators act to recruit and activate additional inflammatory cells that may lead to increased antigen processing and accelerated antibody production. Other processes include activation of cell signaling pathways, including the mitogen-activating protein kinase (MAPK) pathways, and phosphorylation and activation of specific transcription factors (e.g., NF-κB). Furthermore, these effects

are not limited to the lung. Migration of silica-containing macrophages to the lymph nodes and increased systemic immunoglobulin production have also been shown to occur (37 ,38).

Table 3-3: Epidemiologic Studies of Noninfectious Agents and Risk of Lupus

Exposure	Setting, Design; (N)*	Association**	Reference
Silica	Sweden, registry linkage silicosis patients, discharge diagnoses; (1052)	RR 23.8 (10.3–47.0)	(31)

In murine models, silica has been shown to increase the levels of antigen-specific antibodies in the lung following intranasal or intratracheal instillation (39) and in the blood following intravenous administration (40). In the New Zealand mixed lupus mouse strain, silica exposure accelerated disease expression in that it increased autoantibody production, immune complex deposition, proteinuria, and glomerulonephritis (29). This series of studies provide potential mechanisms through which silica exposure may affect the development of autoantibodies and autoimmune disease. autoantibodies from the exposed mice recognized specific epitopes on apoptotic macrophages and changes in CD4 T cell counts and other T cell populations were also seen (30 ,41).

In vitro studies also provide evidence that silica's properties as an adjuvant may be relevant in inducing autoimmunity. Incubation of silica and silicate with isolated human T cells cause polyclonal lymphocyte activation—which in vivo could lead to a breakdown of tolerance via nonspecific stimulation of autoreactive T cell clones (42) and might also lead to apoptosis (43)—which could result in human cells releasing, concentrating, and altering autoantigens and thereby focusing an autoimmune attack (44). Silica is also present in particulates in air pollution. Studies of particulate air pollutants indicate that silica particles stimulate a Th1 type response, with increased production of interferon-γ and increased levels of antigen-specific IgG, although the effects may vary depending on the particle type and mouse strain (45 ,46). This skewing toward a Th1 response and release of reactive oxygen species promotes the continued secretion of pro-inflammatory cytokines resulting in chronic macrophage activation. Indeed, one

hallmark of silica-induced lung injury is its self-perpetuating nature. In alveolar macrophages, the intracellular release of proteolytic enzymes in response to phagocytosis of silica particles leads to cell death. Silica is released from the dying cells, and is re-ingested by other macrophages, creating a cyclical process of inflammation and necrotic cell death.

Hair Dyes

Since the first epidemiologic study suggesting a strong association of permanent hair dyes and related hair products with SLE (47), an additional five studies have assessed this issue (Table 3-3). The interest in these exposures is based in part on similarities of some of the constituents of these products (arylamines) to medications associated with drug-induced lupus (such as hydralazine and procainamide). None of the subsequent studies, however, many of which were larger than the initial report, have shown the same strong association—four have been negative and only one has found a weak association. Of interest, a significant threefold risk was seen among hair dye users who had the *N*-acetyl transferase (NAT) allele*10 and the NAT2 slow acetylation genotype (48), suggesting a possible gene-environment interaction for this exposure. In summary, it appears that there is not a strong association between hair dye use and the development of lupus, although there may be a weak association and it may be that certain individuals with slow acetylation genotypes may be at increased risk. Additional study is needed in larger cohorts to definitively answer this question.

Pesticides

Pesticides are a varied group of agents that may be classified based on function (herbicides, insecticides, fungicides, fumigants, etc.) or by chemical composition (triazenes, organophosphates, organochlorines, etc.). The pesticides most commonly used in the United States are herbicides (atrazine, glyphosate, acetochlor, and 2,4-D) fumigants (metam sodium and methylbromide) and the insecticide malathion (49). Interest in the possible role of pesticides in the development of autoimmunity has come from animal studies suggesting their role in immunosuppression and hypersensitivity (50) and their capacity to act as endocrine disrupters (51).

Few studies have evaluated pesticides as risk factors for the development of SLE. There were no significant differences in blood levels of DDE (dichlorodiphenyldichloroethylene, the persistent metabolite of DDT, dichlorodiphenyltrichloroethane) and several organophosphate pesticide metabolites in a small case-control study in Nogales, Texas (52). However, in a larger case-control study of self-reported pesticide use in the Carolinas, there was a strong but imprecise association with mixing pesticides, but not applying them (23) (Table 3-3). A community based study in Saskatchewan demonstrated an association of low titer antinuclear autoantibodies (≥1:40) with farming tasks, including the use of pesticides, and a twofold increase in those with a history of exposure to insecticides and herbicides, but not fungicides or algicides (53). Additional study is needed in larger cohorts, utilizing bioassays when possible, to address further this question.

Sobel et al. studied three estrogen-disrupting organochlorine pesticides (o,p'-dichlorodiphenyltrichloroethane (o,p'-DDT), methoxychlor, and chlordecone) in ovariectomized female (NZB × NZM)F1 mice (54). Disease expression (time to renal damage) and anti-dsDNA autoantibody production was accelerated, particularly with chlordecone exposure. These effects were not related to the estrogenic effect of the pesticides as measured by uterine weight, suggesting that pesticides may influence autoimmune disease through mechanisms that are not related to estrogen or endocrine disruption.

Tobacco Use

In addition to several types of cancer and cardiovascular disease, cigarette smoking has been associated with the development of rheumatoid arthritis and other autoimmune diseases (55). Given that smoking is a common habit worldwide and a potentially modifiable risk factor, it is an important exposure to define as a possible risk factor for SLE. The mechanisms by which tobacco smoke may alter the immune system remain unclear. Smoking is anti-inflammatory in some respects, resulting in impaired secretion of pro-inflammatory cytokines and decreased activity of natural killer cells, but other immunomodulating effects may also occur—including rebound sympathetic bias and associated Th2 inflammation—since the effects of smoking differ considerably among the different autoimmune diseases (56). Of possible relevance is that cigarette smoke from certain sources can contain high levels of cadmium and other toxins, likely derived from pesticide applications and local soil conditions (57). An interesting issue with respect to tobacco use is the potential interaction between smoking and other exposures. For example, in a population-based case-control study of silica exposure and SLE, the effects of silica were significantly higher among smokers than among nonsmokers (58). A similar interaction between silica and smoking was seen in a recent case-control study of rheumatoid arthritis (59). It is also possible that the complex mix of chemicals in tobacco smoke may have different effects in different genetic backgrounds, given the interaction of smoking with the human leukocyte antigen (HLA) DRB1 shared epitope in increasing risk for seropositive rheumatoid arthritis (60).

In the meta-analysis recently reported by Costenbader et al., a weak association between current smoking and the development of SLE was found (61). This meta-analysis reviewed nine studies (seven case-control and two cohort studies) published between 1990 and 2003. Six of the nine investigations did not show a significant association between smoking and SLE, and among the three studies showing a significant association, one is an outlier with a much higher odds ratio, which accounts for much of the

association seen in the meta-analysis. In summary, whether cigarette smoking is a risk factor for SLE is controversial and further studies should address this issue, yet, for a variety of reasons, all persons should be encouraged to avoid smoking and second-hand smoke.

Solvents

Solvents are a heterogeneous group of liquid compounds used as degreasers and cleansers in many industries, especially in metal cleaning and dry-cleaning. They include chemicals such as alcohols, glycols, aromatic hydrocarbons (benzene, toluene, xylene), and chlorinated products (carbon tetrachloride and trichloroethylene). Exposure assessment is difficult because of the rapid metabolism of most solvents and the wide variety of solvents used even the same occupations in the same industry. Interest in solvents as a risk factor for lupus comes from data in systemic sclerosis and mixed connective tissue disease consistently showing a moderate (OR 1.5–3.0) association with solvents (22), and recent studies in medical research laboratory (MRL) +/+ mice demonstrating an increase in antinuclear autoantibodies and immunoglobulins, via $CD4^+$ T cell stimulation, by adding trichloroethylene or its metabolites to drinking water (62 ,63). Effects were also seen with specific metabolites of trichloroethylene, but this was blocked when the cytochrome P450 CYP2E1 pathway through which trichloroethylene is metabolized was blocked by the addition of diallyl sulfide (64).

Several studies have evaluated areas contaminated by solvents for a possible association with lupus. Kilburn and Warshaw (65) assessed 362 subjects exposed to trichloroethylene, trichloroethane, inorganic chromium, and other chemicals in water obtained from wells in an industrially contaminated aquifer in Tucson, Arizona for SLE criteria, and compared them to an Arizona control group, to published series, and to laboratory controls. The number of subjects with SLE symptoms was 2.3 times higher in the study group compared to referent women and men, and anti-nuclear autoantibody titers greater than 1:80 were approximately 2.3 times higher in women but equally frequent in men as in laboratory controls. Their conclusions have been challenged (65a) Wallace DJ, Quisinorio FPJr, *The elusive search for geographic clusters of systemic lupus erythematosus,* Arthrites rheum 1995,38: 11564–1567. Another study reported a higher prevalence of SLE compared to published series in a small African-American community in Georgia that experienced long-standing exposures to industrial emissions (66). The only case-control study of solvents in SLE did not find a significant association (23), however, implying that additional focused study is needed in this area to define the association more fully.

Sex Hormones

The predominance of lupus in females, the frequent increase in disease activity with pregnancy, decreased activity in postmenopausal women and the many known immunomodulatory effects of sex hormones in humans and animals are the basis for the interest in the role of sex hormones in the development of the disease (67 ,68 ,69). Some studies have reported an increased risk of SLE among women using hormone replacement therapy (70), but this finding has not been confirmed by other studies (71). If greater estrogen exposure is related to lupus, then one might predict that those with an earlier menarche would be at increased risk for disease. Surprisingly, this has not been the case in the several studies evaluating this issue (Table 3-3). In fact the opposite was found in one study in which a later age of menarche was a risk factor (72). In other studies, no significant associations were seen or a later age at menarche was associated with lupus (71 ,73). Of note, menstrual irregularities were a risk factor in one study (73). Many unanswered questions remain in this area and the issue of possible endocrine dysfunction prior to clinical presentation is one of the many unresolved issues that would benefit from directed investigation.

Infectious Agents

Based upon animal models and more limited human data, infectious agents appear to be able to induce autoimmune disease in some cases and, paradoxically, protect from autoimmune disease in other circumstances (74). The protective aspect has given rise to the "hygiene hypothesis," which is the theory that improved standards of hygiene in the industrialized world have resulted in decreased childhood infections and may account for the noted increases in the incidence of allergies and autoimmunity over recent decades (75 ,76). Based upon case reports, animal models and other studies, a variety of viruses, bacteria, and other infectious agents have been proposed to be associated with SLE (77). Fewer studies, however, have assessed this possibility using more rigorous epidemiologic approaches and we will focus our review on those investigations (Table 3-4).

Epstein-Barr Virus

Investigations showing elevations in titers of anti-Epstein-Barr virus (EBV) antibodies in SLE patients compared to controls (78 ,79), case reports of temporal association of disease onset with EBV infection (80 ,81), animal models in which lupus can be induced by EBV antigens (82) and possible molecular mimicry between Sm B/B' autoantigen and Epstein Barr nuclear antigen (EBNA) 1 (83) resulted in a number of studies to evaluate the possible association of EBV with lupus. Recent case-control investigations in children and adults have suggested an increased proportion of anti-EBV seroconverters and those with EBV DNA in SLE (82 ,84 ,85). This association was not seen in other autoimmune diseases or with related viruses. A different case-control study discovered increased EBV-IgA seroprevalence associated with SLE, and that race, gender and the CTLA-4 genotype influences immune responsiveness to EBV (86).

Table 3-4: Epidemiologic Studies of Infectious Agents and Risk of Lupus*

Exposure	Setting, Design; (N)*	Association**	Reference
Epstein-Barr virus	United States children, EBV antibodies or DNA, cohort-control; (117,153)	Serology OR 50 (9.3–1025) DNA OR >10 (2.5-infinity)	(82)

*For case control studies, N, (number of cases, number of controls)
**OR, odds ratio and (95% confidence interval when available)

In another study, 50% of the patients with SLE and 100% of the patients in the acute phase of infectious mononucleosis, but none of the EBV-seropositive normal individuals, produced IgG antibodies to an EBNA-2-derived synthetic peptide that cross reacts with SmD1 (87). This suggests that EBV may establish a persistent infection in some SLE patients and elicit antibodies to the viral antigen EBNA-2, which may cross-react with SmD1 and result in these autoantibodies in SLE patients. Of interest, a recent investigation has also suggested that the frequencies of EBV-infected cells are higher in patients with SLE, as is EBV gene expression in these cells, compared to healthy individuals and patients with other autoimmune diseases (88).

Taken together, these and other data are suggestive of higher rates of EBV infection and persistent or altered expression of that infection in lupus. Yet, as is the case for all studies of infectious agents in SLE to date, it remains unclear if there is a causal relationship or whether there may simply be a predisposing immunosuppression in lupus patients to allow for these infections to occur more frequently after the initiation of the disease process. Nonetheless, a recent study has suggested the possibility that early immune responses to the 60 KD Ro antigen, prior to the development of clinical lupus, cross react with EBV nuclear antigen 1 epitopes, and animals immunized with either of these antigens later develop clinical signs of lupus (89). Thus, these findings, if confirmed, may be an example of molecular mimicry in which early responses to EBV antigens lead to antibodies that are cross-reactive with lupus autoantigens and to later clinical disease.

Cytomegalovirus

Cytomegalovirus (CMV) has been of interest as a possible pathogenetic factor in SLE. A group in the United Kingdom demonstrated a significantly higher prevalence of anti-CMV antibody by enzyme immunoassay in SLE compared to controls but not compared to RA patients (Table 3-4) (90). Interestingly, herpes simplex virus-1 (HSV-1) seropositivity was not different among these same groups suggesting a specific association between infection with CMV and SLE. CMV infection has also been suggested to be a factor in the increase of disease activity in several patients with SLE (91).

Herpes Zoster (Varicella-Zoster Virus)

Herpes zoster (shingles) before the clinical diagnosis and therapy was associated with risk of lupus in three case-control studies, with odds ratios between 2.5 and 6.4 (92 ,93 ,94). It is of note that the viruses that have been associated with lupus in epidemiologic studies (EBV, CMV, and Varicella-zoster virus) are all herpetoviruses, which can persist in a latent state for years before reactivation and the development of clinical disease. Factors affecting the re-activation of the infection (e.g., stressor immunosuppression) may also affect the risk of lupus.

Other Agents Suggested as Possible Risk Factors for SLE

A variety of additional noninfectious and infectious agents have been proposed to be possible risk factors for SLE, although the data supporting these assertions has not been as well studied or reproduced as the other examples given in this chapter. These agents include allergens, selected foods, metals, stressful life events, vaccines, ultraviolet radiation, certain bacteria, retroviruses, and parvovirus B19 (Table 3-5). While part of the limitation in understanding the role of some of these agents relates to the lack of adequate study, in other cases, extensive basic and clinical investigations have been undertaken with contradictory findings in subsequent studies.

Table 3-5: Other Exposures Proposed as Possible Risk Factors for Lupus

Exposure	Evidence	Comments (references)
Noninfectious Agents		
Allergens	Case reports, epidemiologic studies	Hives and medication allergies were both found to be significant risk factors in a case-control study (92); asthma also a risk factor (72)
Foods	Case reports, animal models, epidemiologic studies	Monkeys develop lupus-like illness after alfalfa sprouts or L-canavanine seeds with dechallenge and rechallenge in some animals; case reports of lupus after alfalfa and some dietary supplements (18;107); frequent meat intake a risk factor (73); alcohol consumption may be protective (108)
Heavy metals	Multiple lupus-like syndromes described in case reports and animal models	“Pink disease” (acrodynia), elevated autoantibodies and glomerulopathy in humans from mercury toxicity; related syndromes with elements of autoimmunity from cadmium and gold salt toxicity; granulomatous pneumonitis from beryllium exposure; strong support for glomerulopathy, multiple autoantibodies and genetic risk factors in mercury treated animal models (109,110,111)
Stress	Case reports and series	Case series suggest emotional stress or stressful life events were precipitating events prior to diagnosis and disease flares; biologic plausibility (112,113,114,115)
Ultraviolet B radiation	Case reports, case control study, animal models	A type I/II sun-reactive skin type was a risk factor for developing lupus (108)); UV up-regulates interferon inducible products in cutaneous lesions (116); decreased minimal erythemal dose in lupus (117); increased UV is associated with disease activity (118) and mortality (119)
Vaccines	Case reports and a case-control study for SLE; epidemiologic data for other syndromes	Case reports of SLE after multiple vaccines; increased vaccines in SLE vs. controls (OR 2.2); arthritis after rubella virus vaccines; thrombocytopenia after measles vaccines; Guillain-Barré syndrome after swine flu vaccine and tetanus, but controversy remains over others (93,120,121)
Infectious Agents		
Bacteria	Animal models	Bacterial DNA serves as an adjuvant in mouse models and can induce specific reactivities (122)
Endogenous and exogenous retroviruses	Case reports and series, animal and lab studies	Unconfirmed increased antibodies to retroviral transcripts and proteins in humans and animal models (reviewed in (123))
Parvovirus B19	Case reports and case-control study	Case reports described similarities between infection and lupus (124) but a case-control serology study did not find an association (125)

Identifying and Defining Environmentally Associated Lupus

Many of the exposures described in this chapter are common and the research pertaining to their role in lupus has been conducted primarily within the population of SLE patients as defined by current classification criteria. It is likely, however, that a number of cases of lupus developing as a result of environmental exposures do not meet these criteria. Drug associated lupus-like disorders are examples in which most cases in fact will not fulfill SLE criteria (95 ,96). Additionally, there are circumstances in which a novel "lupus-like" or related disease is seen, and a relevant question is whether specific environmental triggers may be associated with such atypical or new syndromes. Examples of this phenomenon include the epidemics of the toxic oil syndrome (97) and eosinophilia myalgia syndrome following L-tryptophan exposure (98). Members of the American College of Rheumatology Environmentally Associated Rheumatic Disorders Study Group have developed consensus on a general approach to the identification of such environmentally associated disorders (11). In this scheme, the overall process, from the identification of the first possible patient who developed a disease after an exposure, to the refinement of classification criteria for the disease, is divided into four stages (Table 3-6).

The first stage of this process is the identification and reporting of a case, or a series of cases, with a condition or syndrome that is suspected of resulting from a given exposure. The consensus proposal is that such cases that may have resulted from an environmental agent should meet certain criteria to assure that certain attribution elements are present (11). At least four of eight possible attribution elements should be present, including at least three of five primary or critical elements. These five primary attribution elements are temporal plausibility (after considering the pharmacokinetics/pharmacodynamics of the suspect agent, the minimum possible induction time and the maximum possible latency, if known); exclusion of other likely causes for the syndrome; dechallenge (if possible); rechallenge (if appropriate), and evidence for biologic plausibility. An additional three secondary elements are previous reports of cases that are similar in many respects (analogy); prior publication of essentially identical cases (specificity); and some evidence for a dose-response effect. In addition to meeting these criteria, however, demographic information, the medical history, laboratory testing, family history, prior infections or other immune-altering exposures, prior diagnoses and support for them, and the type/route/dose/duration of the suspect exposure should all be detailed in the report.

Table 3-6: Proposed Stages for Identifying and Defining Environmentally Associated Autoimmune Disorders*

Stage	Description	Nomenclature (Example)
Stage 1—Proposing the association	Case reports, defined by certain ascertainment criteria, propose the possible association of a specific clinical syndrome with a given exposure	Syndrome following exposure (Lupus following hepatitis B vaccination)
Stage 2—Testing the association	After a number of such cases are reported, surveillance criteria are proposed and epidemiologic and laboratory studies test that hypothesis	Cardinal signs, symptoms, and laboratory findings but without the putative exposure (Eosinophilia Myalgia syndrome)
Stage 3—Defining criteria for the condition	If studies above are positive, then specific preliminary classification and other criteria are defined for that specific environmental disease	Exposure associated disorder (L-tryptophan-associated Eosinophilia Myalgia syndrome)
Stage 4—Refining criteria for the condition	Criteria are reassessed and refined as additional data are obtained about the disease	Exposure induced disorder (Hydralazine-induced lupus-like disorder)

*Modified from Miller FW, Hess EV, Clauw DJ, et al. Approaches for identifying and defining environmentally associated rheumatic disorders. *Arthritis Rheum* 2000;43:243–49.

After a sufficient number of cases are reported in the first stage, the next step is to formally test the possible association of the suspect environmental exposure with the syndrome. This could include epidemiologic studies, using validated criteria or consensus surveillance criteria, if necessary, to assess the strength of the relationship between a given exposure and a given syndrome. The biologic effects of the agent, via in vitro, in vivo, and animal studies should also be determined to gauge the plausibility of, and assess possible modulators of, the development of the syndrome. Other approaches, such

as clinical, laboratory or genetic risk factor studies, could determine in case-control settings if individuals with a given phenotypic syndrome developing after a suspect environmental agent differ from those with similar diseases but without the exposure or differ from subjects similarly exposed who do not develop disease.

The third stage would be developing preliminary criteria for that specific environmentally associated syndrome or disease. This would be undertaken only if several lines of evidence from the second stage support a strong association between the exposure and the syndrome. Classification criteria would be developed to segregate, with reasonable sensitivity and specificity, groups of patients with this environmentally associated disorder from closely related diseases. Such criteria could be developed by expert committee consensus, using Delphi or nominal group techniques (99), mathematical algorithms, or other approaches. Symptom, sign, and laboratory criteria should be expressed in clinically sensible and practical formats with precise definitions of all constituent elements. If adequate data are available, diagnostic, prognostic, and outcome criteria, and disease activity and damage indexes should be considered. The fourth stage repeats the same processes used in the third stage if sufficient new information is collected to warrant a redefinition of the disease or the redefinition of diagnostic, prognostic, or outcome criteria.

This proposed staging approach clearly has limitations, in that the decisions as to when to progress from one stage to the next remain poorly defined and would be dependent on the number of cases reported, the resources available and the wider public health or medical-legal implications of the syndrome. Nevertheless, this approach does provide a practical framework to organize studies and it allows the classification of current environmental agents into groups with different levels of evidence for their association with specific syndromes. In this regard, nearly all environmental agents suspected of being associated with lupus and other autoimmune diseases today remain in stages 1 or 2 using this scheme.

Summary and Future Directions

The multifactorial nature of autoimmune diseases, as well as their rarity and heterogeneity, has inhibited understanding of the mechanisms that initiate, promote, and sustain them. Nonetheless, the information presented in this chapter, taken together with other findings, suggests that autoimmune syndromes arise from a complex and poorly understood interplay of predisposing, as well as possibly protective, genetic, and environmental risk factors. While some progress is being made in defining genetic risk and protective factors, we are in our infancy in the identification of the environmental risk and protective factors for SLE and other autoimmune illnesses because of the many difficulties in the field mentioned above. Although selected environmental agents can clearly be associated with the development of lupus in certain individuals, based on dechallenge and rechallenge methods, support for the role of the environment in most cases is often circumstantial and relies on imperfect clinical, epidemiologic, and laboratory studies. As a result, we usually cannot answer the question so often posed by patients: “Doctor, do you think my exposure to “X” before coming down with lupus had anything to do with the onset of this disease, and if so, should I or my family continue to be exposed?” Many patients are also convinced that they know the environmental trigger that caused their disease. However, because most of us in the industrialized world live in an increasingly complex sea of infectious and noninfectious agents, over which we have little control, none of us really knows the full range of environmental agents we are exposed to on a daily basis.

Beyond the need to identify additional risk factors, there is also a need to understand the mechanisms by which the few documented risk factors for the development of lupus induce their effects. The lack of common structures, shared metabolic pathways, or biochemical actions of suspect environmental agents suggests that mechanisms will vary from exposure to exposure and that the a priori prediction of future risk factors based on their characteristics alone will be difficult. Certainly, there is no lack of hypotheses for how agents may induce lupus. Current conjectures range from the alteration of target tissue autoantigen structure (with supporting data for bystander drugs and heavy metals), to upregulation or altered locations of normally sequestered autoantigens (as occurs with UV radiation), to cytotoxic, inhibitory, or stimulatory effects on components of the immune system (from therapeutic cytokines for example), to molecular mimicry (where antigenic structures are shared between infectious agents and self), and finally to other effects and combinations of the above (100).

Understanding the interactions of those elements that are necessary for disease development offers the promise of preventing or treating autoimmune diseases in novel ways. But before these approaches can be considered, important questions need to be answered. Which specific combinations of genetic and environment risk factors lead to which specific clinical syndromes? After such gene-environment interactions occur, which processes or mechanisms then lead to the observed pathology? Is lupus, as currently understood, actually composed of many subsets or elemental disorders, each of which may be defined by a unique pathogenesis resulting from interactions of the necessary and sufficient risk factors? Can lupus or other autoimmune diseases be better treated, cured, or even prevented through answers to some of the above questions?

Many difficulties have prevented a complete understanding of the environmental risk factors that might trigger lupus and other autoimmune diseases in genetically susceptible individuals. A number of coordinated initiatives may be useful in overcoming these obstacles and making more progress in the future (Table 3-7). Fundamental to all these efforts though are greater attention to and funding for understanding the necessary and sufficient environmental

exposures that initiate, promote, sustain, or even possibly prevent autoimmune disorders. Although such studies are time-consuming and expensive, they should be excellent investments, which will likely be very cost effective, in eventually minimizing new cases of lupus and ultimately improving the public health.

Table 3-7: Possible Approaches to Enhance Identification of Environmental Risk Factors for Lupus and Other Autoimmune Diseases*

Foster national and international collaborations and coordination to integrate existing and developing clinical databases, registries, specimen repositories and other resources
Develop and validate clinically useful standardized environmental exposure assessment tools
Develop and validate standardized biomarkers for environmental exposures
Increase support for well-designed, population-based, and case-control hypothesis-testing studies for suspected environmental agents
Increase support for hypothesis-generating studies to identify new agents and syndromes
Collect systematic descriptive epidemiologic data for autoimmune diseases as a baseline for future comparisons
Increase use of information technology and other novel approaches to enhance communications, coordinate efforts, and facilitate clinical studies
Improve coordination between animal model and epidemiologic studies
Develop novel mathematic, statistical and bio-informatic approaches to enhance epidemiology studies
Define gene-gene, gene-environment, and environment-environment interactions
Elucidate mechanisms by which risk factors result in lupus
Establish an international coordinating committee to oversee and facilitate the above, encourage multidisciplinary research, and prepare for and respond to new epidemics of environmentally induced immune-mediated diseases

Chapter 4
The Epidemiology of Systemic Lupus Erythematosus

Violeta Rus

Erinn E. Maury

Marc C. Hochberg

Epidemiology can be defined as the study of the frequency and distribution of disease and the determinants (i.e., factors) associated with disease occurrence and outcome in populations. Epidemiologists design and conduct four major types of studies to evaluate chronic disease: (1) descriptive studies to estimate the incidence and prevalence of and the mortality from disease in relation to characteristics of person, place, and time; (2) observational studies, either retrospective or prospective in design, to derive inferences about etiologic factors associated with the occurrence of disease; (3) observational cohort studies to determine the course and prognosis of patients with a disease; and (4) experimental studies to evaluate preventive or therapeutic measures.

Epidemiologic studies of systemic lupus erythematosus (SLE) have focused on: (1) development and validation of criteria for disease classification; (2) estimation of morbidity and mortality rates in different populations at different times; (3) determination of etiologic factors, both host and environmental; (4) estimation of prognosis and survival of patients; and (5) evaluation of treatments in randomized controlled trials. This chapter reviews major findings in the epidemiology of SLE in the first two areas: disease classification and morbidity and mortality rates. The reader is referred to chapters 3 , 6 , and 69 for discussion of association of genetic and environmental etiologic factors with SLE and estimation of prognosis and survival.

Classification Criteria

In 1971, the American Rheumatism Association published preliminary criteria for the classification of SLE (1). Currently, the American College of Rheumatology (ACR) 1982 revised criteria for the classification of SLE (2), as modified in 1997 (3) are used for case definition (Table 4-1). The original 1982 data set was reanalyzed by Edworthy et al. using recursive partitioning to generate two classification trees in an attempt to identify simpler and more explicit rules to classify patients with SLE (4). The resulting simple classification tree requires knowledge of only two variables: immunologic disorder and malar rash. A more complex tree requires knowledge of six variables, including serum complement levels, which are not included within the 1982 revised criteria. The sensitivity, specificity, and accuracy were 96% for the 1982 revised criteria and 92% for the simple classification tree (Table 4-1). Perez-Gutthann et al. (5) compared the sensitivity of the 1982 revised criteria in the traditional format and both classification trees in 198 patients from the Johns Hopkins Lupus Cohort. The revised criteria were significantly more sensitive than the simple classification tree, correctly identifying 184 (93%) compared with 168 (85%) cases, respectively (p = 0.016); the full classification tree correctly identified 186 cases (94%). Thus, these data support the use of the 1982 revised criteria in the traditional format to classify patients with SLE.

Other groups have examined the relative value of individual criterion in selected patient populations using receiver operating characteristic curves (6) and Bayesian theory (7 ,8 ,9). Although weighted criteria have a higher sensitivity compared to the ACR criteria and allow the identification of a larger number of lupus patients (9 ,10), their specificity is lower and their use might result in inclusion in clinical trials of patients that do not have SLE according to experienced rheumatologists (10).

There has been little cross-cultural or ethnic validation of the 1982 ACR criteria. A validation study performed in Japan in 1985 demonstrated a sensitivity of 92% and a specificity of 89% (11). Individual criterion items were detected with different frequencies in the Japanese compared to U.S. SLE patients, demonstrating the need for generalizable, internationally valid criteria.

In 1997, the Diagnostic and Therapeutic Criteria Committee of ACR updated the 1982 criteria (3). Within criterion 10, item (a) the positive LE cell test was deleted and item (d) was changed to positive test for antiphospholipid antibodies including (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization (TPI) or fluorescent treponemal antibody adsorption (FTA) test. The updated version was more sensitive (78% vs. 72%), but slightly less specific (88% vs. 91%) than the 1982 criteria in a cohort of 346 patients with connective tissue disease (12).

As patients with primary antiphospholipid syndrome (APS), as defined by the Sapporo criteria can present three or more of the current SLE criteria, confusion between SLE and primary APS can occur in borderline cases.

Table 4-1: 1982 Revised Criteria for SLE

	Sensitivity	Specificity	Accuracy*
1. Malar rash	57	96	76
2. Discoid rash	18	99	57
3. Photosensitivity	43	96	68
4. Oral ulcers	27	96	60
5. Nonerosive arthritis	86	37	63
6. Pleuritis or pericarditis	56	86	70
7. Renal disorder	51	94	71
8. Seizures or psychosis	20	98	57
9. Hematologic disorder	59	89	73
10. Immunologic disorder	85	93	88
11. Positive antinuclear antibody	99	49	77
>4 criteria	96	96	96
Simple classification tree	92	92	92
Full classification tree	97	95	96

*Accuracy is defined as the average of sensitivity and specificity. For definitions of individual criterion items, see Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1271–1277.
Data from Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982; 25:1271–1277 and Edworthy SM, Zatarain E, McShane DJ, et al. Analysis of the 1982 ARA lupus criteria data set by recursive partitioning methodology: new insights into the relative merit of individual criteria [see comments]. *J Rheumatol* 1988;15:1493–1498.

None of the methods for classifying patients with SLE was designed for diagnostic purposes. These criteria should be used mainly for the purpose of classifying patients in clinical, epidemiologic, and pathogenetic studies of SLE. Assuring homogeneity of the case population is ideal for epidemiologic studies that address etiology or risk factors. However, classification criteria lack sensitivity for recognizing milder cases of SLE, which becomes a limitation for descriptive studies of morbidity and observational studies of prognosis, because subjects with a multisystem disease that is consistent with SLE will not be included if they fail to fulfill the criteria. Data from the Rochester study suggest that the prevalence of suspected SLE is comparable to that of definite SLE: 64 versus 54 per 100,000 in white females and 33 versus 40 per 100,000 overall, respectively (13). For understanding the social burden of the disease and guiding health care and research policy, all patients should be included.

Criteria for classifying the subsets of neuropsychiatric (NP) syndrome of SLE were developed by an Ad Hoc Neuropsychiatric Workshop Group in 1990 (14). The ad hoc multidisciplinary committee developed standard nomenclature as well as detailed diagnostic and exclusion criteria for 19 NP syndromes in 1997 (Table 4-2). Chapter 37 includes a detailed discussion of these criteria.

The ACR nomenclature and case definitions for neuropsychiatric syndrome of SLE (NP-SLE) have been validated in a cross-sectional, population based study by Ainiala et al (15). The overall prevalence of NP-SLE in four different SLE cohorts varied between 37% to 95% (16 ,17 ,18 ,19). However, attribution of NP events to SLE is a challenge, with as much as 41% of all NP events in SLE patients being attributable to factors other than lupus (17).

Despite the fact that the revised ACR criteria have performed well, certain deficiencies have been recognized (20): (1) emphasis on skin involvement with the inclusion of four criterion items for mucocutaneous features but only one item for many of the other organ systems involved (21); (2) the omission of hypocomplementemia, which is one of the laboratory features characteristic of SLE (4); (3) lack of coverage of the entire spectrum of organ involvement (especially for renal and neurologic criteria); (4) lack of validation of the criterion for antiphospholipid antibodies and the potential confusion between SLE and primary APS; and (5) the criteria are not generalizable to multiple ethnic groups and need international validation. The Systemic Lupus International Collaborating Clinics (SLICC) have suggested that the above limitations justify an attempt to identify new classification criteria for SLE. Among proposed revisions, the SLICC group discussed the inclusion of abdominal serositis to the current serositis criterion, inclusion of additional NP manifestations such as mood disorder, cerebrovascular disease, neuropathy, mononeuritis multiplex, acute confusional state, and myelopathy and the introduction of a clinical APS criteria

(22 ,23 ,24). Nonetheless, the current ACR criteria perform well for their original stated purpose (2 ,3).

Table 4-2: Neuropsychiatric Syndromes in SLE as Defined by the ACR Research Committee

Central	Peripheral
Aseptic meningitis	Guillain-Barré syndrome
Cerebrovascular disease*	Autonomic neuropathy
Demyelinating syndrome	Mononeuropathy*
Headache	Myasthenia gravis
Movement disorder	Cranial neuropathy*
Myelopathy*	Plexopathy
Seizure disorders*	Polyneuropathy
Acute confusional state*	
Anxiety disorder	
Cognitive dysfunction	
Mood disorder*	
Psychosis*	

*Under consideration by SLICC for inclusion in potential revision of ACR classification criteria for SLE.

Morbidity Data

Prevalence

The overall prevalence of SLE in the continental United States and Hawaii has been reported to range between 14.6 and 122 cases per 100,000 persons (Table 4-3). Studies have varied over time and place and used different methods of case ascertainment (13 ,25 ,26 ,27 ,28 ,29 ,30). The studies conducted in San Francisco, California, and Rochester, Minnesota, used both inpatient and outpatient records for case identification and published criteria for case validation; the major differences were the sampling frame (members of Kaiser Foundation Health Plan and residents of Olmsted County, respectively) and racial composition of the populations (81% and 99% white, respectively). The sex- and race-specific prevalence estimates for white males and females, however, are comparable, because the 95% confidence intervals for these ratios overlap. Estimates of the overall prevalence in whites were 44 and 40 per 100,000, respectively (Table 4-3). The most current estimate in blacks is that from the San Francisco study, but it is based on only 19 patients, 16 of whom were women. Thus, the confidence intervals are wide, limiting the reliability of this estimate. There is no recent study that has estimated the prevalence of SLE in African-Americans.

Applying the rates obtained from the San Francisco study to the 1990 U.S. population, the National Arthritis Data Workgroup estimated that 239,000 cases of suspected or definite SLE were present in the United States: 4000 white males, 31,000 black males, 163,000 black females, and 41,000 white females (31). Because of limited data on other racial and ethnic groups no estimates for Hispanics and Asians were attempted. Both of these groups have a higher reported prevalence of SLE than whites (*vide infra*). In a recent meta-analysis based on 16 population-based prevalence studies from Europe and North America, Jacobson et al. estimated the weighted mean prevalence rate of SLE at 23.8 per 100,000. By applying these rates to the 1996 U.S. census data the authors estimated that a total of 63,052 persons are afflicted with the disease (32). Most recently the National Arthritis Data Workgroup revised the previous estimates (R. Lawrence, personal communication, September 27, 2005). Applying prevalence rates to 2002 U.S. Census data, we estimate that at least 153,000 persons in the United States between the ages of 15 and 64 years have definite SLE: 11,000 white men, 78,000 white women, 7,000 African American men, 51,000 African American women, 1,000 men of other race, and 5,000 women of other race. Using a prevalence of 80 to 160 per 100,000 persons, the number of cases of suspected and definite SLE ranges between 153,000 and 306,000 cases.

Three studies based on self-reported, physician-diagnosed SLE in the United States using data from telephone screening (25 ,30 ,33) suggest that the prevalence of SLE might be much higher. In one study, the prevalence of SLE by unsubstantiated claim was 1 in 177 (30). The prevalence reported by Hochberg et al. after validating the diagnosis of SLE by medical record review was 124 per 100,000 (25). This higher prevalence was confirmed in the study from Rochester, Minnesota, that reported age- and sex-adjusted prevalence rates of 1.22 in 1000 (29) and by the most recent study of Ward MM (33) who found a prevalence of treated SLE in adult women of 100 per 100,000.

International studies to estimate the prevalence of SLE have been conducted in Sweden (34 ,35 ,36), Finland (37), Iceland (38 ,39), the Arctic region of Norway (40) New Zealand (41 ,42), Malaysia (43), England and Wales (44 ,45 ,46 ,47), China (48 ,49), Japan (50 ,51), the Caribbean island of Curacao (52), Northern Ireland (53), Saudi Arabia (54), Greece (55), and Italy (56) (Table 4-4). Of the studies conducted in countries with predominantly white populations, prevalence estimates varied from a low of 12.5 per 100,000 females in England (47) to a high of 39 per 100,000 of both sexes combined in Sweden (35). This variability may result from differences in methodology of case ascertainment, including use of general practice diagnostic registries (47), hospital discharge records (37 ,42 ,50), outpatient clinic records, surveys of physicians, or combinations thereof (35 ,39 ,44 ,45 ,46) as well as from differences in host and environmental factors among different populations. In comparing studies using similar methodologies for case identification and validation, the prevalence of SLE

is almost identical. Studies from the United States and Sweden that used hospital records for case identification, reported similar prevalence rates of about 40 per 100,000 (13 ,35) while studies from the United Kingdom using multiple case-finding methods found consistently lower prevalence rates of about 25 per 100,000 (44 ,45 ,46). The lowest rate at 12 per 100,000 was determined through use of general practice diagnostic registries (47). True geographic differences in the prevalence of SLE among whites cannot however be excluded and may result from differences in genetic and other host or environmental factors (57).

Incidence

The average annual incidence of SLE in the continental United States has been estimated in several studies; incidence rates vary from 1.8 to 7.6 cases per 100,000 persons per year (13 ,26 ,27 ,28 ,29 ,58 ,59) (Table 4-5). International studies from Iceland (39), Sweden (34 ,46 ,60), the United Kingdom (45 ,46), Japan (51), and the Caribbean island of Curacao (52) reported incidence rates for SLE of similar magnitude. A recent study from Brazil reported a higher overall incidence of 8.7 in the tropical region of Natal (61) while a study from northwest Greece reported a lower annual incidence rate of 1.9 (55) (Table 4-6).

Table 4-5: Incidence of SLE by Sex/Race Group in the United States*

Study	Location	Date	WM	WF	BM	BF	Overall
Siegel and Lee (28)	New York	1956–1965	0.3	2.5	1.1	8.1	2.0
Fessel (26)	San Francisco	1965–1973	ND	ND	ND	ND	7.6

		1980–1992	ND	ND	ND	ND	5.56

*Incidence rates per 100,000 persons per year.
BF, Black females; BM, black males; ND, no data; WF, white females; WM, white males.

Despite using different methods for case ascertainment, average annual incidence rates of SLE from 1985 to 1990 in Allegheny County, Pennsylvania (59), are quite similar to those reported in Baltimore during an earlier period (58). Of particular interest are the differences in incidence reported by Kurland et al. (27), Michet et al. (13) and Uramoto et al. (29) for the same population using or identical medical record retrieval system. Michet et al. attributed these differences to changes in diagnostic classification.

Nonetheless, a temporal trend in incidence among whites can be inferred from the Rochester data. Rates nearly tripled from 1.5 in the 1950 to 1979 cohort to 5.56 per 100,000 in the 1980 to 1992 cohort (29). Possible explanations for the increase in incidence is improved recognition of mild disease, increased exposure to hormones such as oral contraceptives and estrogen replacement therapy and greater exposure to ultraviolet light because of depletion in the ozone layer because of global warming. In contrast, in a recent study in Sweden the incidence of SLE over a period of 11 years (1981 to 1991) has been constant (36).

Table 4-6: Incidence of SLE: Selected International Studies

Effects of Age and Sex on Morbidity Rates

The variability in prevalence and incidence rates in different published studies may be explained in part by the effect of age, gender, and race. Overall, prevalence and incidence rates are higher in females compared to males, and higher in African Americans, Afro-Caribbeans, and Asians than in Caucasian populations.

Among white females, age-specific incidence rates have varied among studies and peak incidence rates per 100,000 per year occurred in the 15- to 44-year age group (28), the 20- to 39-year age group (59), the 25- to 44-year age group (13), the 35- to 54-year age group (58), the 45- to 64-year age group (35), the 50- to 74-year age group (39), the 50- to 59-year age group (45), and among those aged 18 and 19 years (46). Median age at diagnosis for white females in these studies ranged from 37 to 50 years, emphasizing that SLE is not necessarily a disease of young women.

Age-specific incidence rates in white males are difficult to interpret because of the small numbers of cases. In those studies with adequate data, peak rates occurred in the 50- to 59-year age group (45) and in those aged 65 and older (13 ,28). The later onset of SLE in white males compared with white females was also noted in the Baltimore study (58) and the Leicester, United Kingdom study (44).

Age-specific incidence rates in black females were greatest in the 15- to 44-year age group in New York City (28), the 20- to 39-year age group in Pittsburgh (59), and the 25- to 34-year age group in Baltimore (58) and Birmingham, United Kingdom (46), exceeding 20 per 100,000 per year. Age-specific rates in black males can be reliably estimated only from the Baltimore study and reached a peak in the 45- to 64-year age group of 5 per 100,000 per year (58). Among Afro-Caribbeans on the island of Curacao, peak age-specific incidence rates occurred in the 45- to 64-year age group in women and among those aged 65 and older in men (52).

Age-specific prevalence rates for females in the United States are best estimated by the data of Fessel: approximately 1 and 4 per 1000 for white and black women aged 15 to 64 years, respectively (26). The prevalence of SLE among white women in southern Sweden, 99 per 100,000, is similar to that among white women in the United States (34). Age-standardized prevalence among white women in Iceland was slightly lower, at 62 per 100,000 (39), while that among white women in the United Kingdom was markedly less, at 32 per 100,000 (44) and 36 per 100,000 (46).

Clinical studies have consistently demonstrated a female predominance approaching 90% of SLE cases. This excess is especially noteworthy during the 15- to 64-year age group, wherein ratios of age- and sex-specific incidence rates show a six- to tenfold female excess in whites and blacks (Table 4-7). No such excess was noted in the 14 and younger or the 65 and older age groups in New York City (28), Rochester, Minnesota (13), Sweden (34), or Nottingham, UK (45). A fourfold greater incidence rate in females age 65 and older than in males was found among whites but not blacks in Baltimore (58). These age-related differences in the ratio of sex-specific incidence rates have been thought to relate to hormonal changes that occur during puberty and the childbearing years.

Table 4-7: Female-to-Male Sex Ratio at Age of Onset or Diagnosis in SLE

Age of Onset (*y*)	Female (*n*)	Male (*n*)	F:M Ratio
0–9	39	19	2.0
10–19	220	39	5.6
20–29	369	49	7.5
30–39	298	37	8.0
40–49	183	35	5.2
50–59	98	25	3.9
60+	58	25	2.3
TOTAL	1265	229	5.5

Adapted from Masi and Kaslow (80)

Effect of Race on Morbidity Rates

The relative increased frequency of SLE in people of African origin was examined by Symmons et al. (62) and more recently by Bae et al. (63). A greater incidence and prevalence of SLE has consistently been found in blacks than in U.S. whites (26 ,28 ,58 ,59). Studies in both New York City (28) and San Francisco (26) found three- to fourfold greater prevalence in black females aged 15 to 64 than in white females (Table 4-3) and studies in Baltimore and Pittsburgh found a threefold greater age-adjusted average annual incidence rate in black females compared with white females (58 ,59) (Table 4-5). A study in Birmingham, England, found higher age-adjusted incidence and prevalence rates in Afro-Caribbeans than in whites (46). Age-adjusted incidence rates were 25.8 and 4.3 per 100,000 for Afro-Caribbeans and whites, respectively, and age-adjusted prevalence rates were 112 and 21 per 100,000 for Afro-Caribbeans and whites, respectively. Despite the apparent predilection for women of African origin in Northern Europe, North America and the Caribbean, the frequency of SLE in West African countries where most of their ancestors originated, as estimated from case reports and small series is low (63). This “prevalence gradient” may be related to genetic and environmental factors as well as gene-environment interactions (63 ,64).

In a number of studies, the age distribution of incident cases differed significantly, with a younger median age and earlier peak incidence rates in women of African origin. Mean age in Afro-Caribbean females was of 34.5 years, compared with 41 years in white females, and, the peak incidence rate was in the 30- to 39-year age group compared with the 40- to 49-year age group, respectively (46). These results are almost identical to those from a study in Baltimore, wherein the mean age of black females with SLE was 35.5 years, compared with 41.7 years for white females (58), those from a study in Pittsburgh, wherein the mean age of black females was 35.2 years, compared with 39.8 years for white females (59) and those from another population-based study performed in North Carolina where mean age at diagnosis was 6 years younger among African-American compared to white patients (65). The mean age at diagnosis was 31 years, with a peak age at diagnosis in the 21- to 30-year age group, in 93 Afro-Caribbean patients from Jamaica; no comparison with white patients was available (66). On the island of Curacao, the mean age at diagnosis was 34 years, with a peak age at diagnosis in the 45- to 64-year age group, in 94 Afro-Caribbean patients; again, no comparison with whites was available (52).

Conflicting data exist regarding excess prevalence of SLE among Asians compared with whites (41 ,44 ,45 ,46 ,48 ,49 ,50 ,67 ,68 ,69). In Hawaii, compared to Caucasians, the prevalence odds ratio was 1.3 for Japanese, 1.5 for Filipinos, 2.4 for Chinese, and 0.8 in Hawaiians (70). An earlier study performed by Serdula and Rhoads (67) from 1970 through 1975 reports an estimated age-adjusted prevalence of 5.8 per 100,000 in whites, compared with 17.0 per 100,000 among Asians (Chinese, Filipino, and Japanese). Age-adjusted prevalence rates of SLE in Auckland, New Zealand were 14.6 and 50.6 per 100,000 in whites and Polynesians, respectively (41). Three studies from the United Kingdom (44 ,45 ,46), found higher age-adjusted incidence and prevalence rates of SLE in Asians (Indian, Pakistani, Bangladeshi) than in whites. In Leicester, England, the age-adjusted prevalence of SLE was 64.0 per 100,000 in Asians, compared with 26.1 per 100,000 in whites (44). In Birmingham, England, the age-adjusted incidence and prevalence rates of SLE in Asians were 20.7 and 46.7 per 100,000 compared with 4.3 and 20.7 per 100,000 in whites, respectively (46). Of interest, neither incidence nor prevalence rates differed by country of birth among Asians in this study.

Casting doubt on real differences between Asians, specifically Chinese, and whites are the findings of Fessel (26) and Nai-Zheng (48 ,49). In the San Francisco study, the prevalence of SLE was not increased among Chinese compared with whites (26). Data from China based on population surveys suggest a prevalence of SLE between 40 to 70 per 100,000 (49). Finally, a survey in Taiwan identified only one case of SLE among 1836 residents and no cases among 2000 female students (68). Thus, population-based data in three countries fail to support an excess prevalence of SLE among Chinese compared with Caucasians. Prevalence data from Japan also fail to support the observations in Hawaii of an excess prevalence in Japanese compared with whites (50).

No published data exist about incidence rates in Hispanic Americans, but the LUpus in MInority populations: NAture vs. nurture (LUMINA) study has compared genetic, clinical, and outcome features in Hispanics, African Americans and Caucasians (71 ,72 ,73) demonstrating significant ethnic disparities between these groups with respect to time to accrual of ACR criteria, time to initial damage accrual, and disease severity with African Americans and Hispanics from Texas having more severe disease than Caucasians and Hispanics from Puerto Rico.

The incidence and prevalence of SLE estimated in an Australian Aboriginal population in the Top End Northern

Territory (74) were 11 per 100,000 per year and 52 per 100,000, respectively. The authors suggested these rates were higher than those for Australian whites; however, estimates for the European population in Australia are not available.

An excess incidence and prevalence of SLE among Native American Indians compared with whites was suggested by three studies (75 ,76 ,77). This excess was isolated to only 3 of 75 American Indian tribes (75); a single Pacific Northwest Indian population, the Nootka (76); and three different Indian groups, the Tlingit, Haida, and Tsimshian, living in coastal southeast Alaska (77). Of interest, the prevalence of SLE among Alaskan Inuits is not increased over what would be expected (78 ,79). These isolated observations could represent chance findings; on the other hand, inbreeding and/or environmental factors may explain this clustering. Further studies of American Indian populations could identify additional clusters with excess morbidity from SLE in an effort to test hypotheses regarding risk factors.

Mortality Data

Mortality attributed to SLE in the continental United States has been estimated from community-based (28) as well as national data (80 ,81 ,82 ,83 ,84 ,85) (Table 4-8). These data need to be interpreted with caution as SLE was recorded as an immediate, underlying, or contributory cause of death in only 60 percent of known deaths of patients enrolled in the LUpus in MInority populations: NAture vs. nurture (LUMINA) and Carolina Lupus Study cohorts (86).

Lopez-Acuna et al. (82) identified all deaths attributed to both discoid and systemic lupus erythematosus from National Center for Health Statistics (NCHS) data tapes for the period 1968 to 1978. A total of 11,156 deaths were identified, 2568 (23.0%) of which were attributed to discoid lupus and 8588 (77.0%) to SLE. There were no differences in the distribution of deaths from discoid lupus and SLE by sex/race, region, or year; therefore, the authors combined results for their analysis. There were a total of 6452 deaths in white females, 2573 in black females, 1760 in white males, and 371 in black males, with average age-adjusted mortality rates of 6.0, 17.6, 1.8, and 3.0 per 1 million persons per year, respectively (Table 4-8). Age-specific average annual mortality rates showed a unimodal distribution for all sex/race groups, with maximum rates occurring in the 45- to 54-year age group for blacks and the 65- to 74-year age group for whites (Fig. 4-1).

Table 4-8: Cause-Specific Mortality from SLE by Sex/Race Group in the United States*

Study	Years	WM	WF	BM	BF
Cobb (92)	1959–1961	1.1	4.0	1.8	10.6
Siegel and Lee (28)	1956–1965	1.6	6.6	4.4	20.0
Kaslow and Masi (82)	1972–1976	1.5	5.2	2.2	14.8
Gordon, et al. (81)	1972–1976	1.2	4.5	1.9	13.1

BF, Black females; BM, black males; WF, white females; WM, white males.

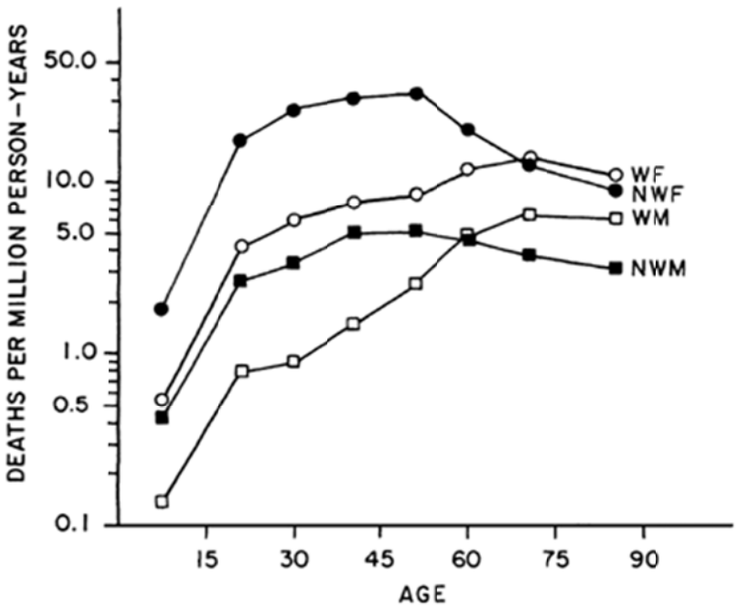

Figure 4-1. Average annual age-specific mortality rates attributed to lupus erythematosus by sex/race group in the United States, 1968 to 1978. (White males □, white females ○, black males ▪ black females •).

Kaslow (83) analyzed a subset of these mortality records and examined deaths attributed to SLE alone from 1968 through 1976 in 12 states with 88% of U.S. residents of Asian descent. Mortality rates were threefold greater among blacks and twofold greater among Asians compared with whites: 8.4, 6.8, and 2.8 per 1 million person-years, respectively. Age- and sex-adjusted mortality rates for

Chinese, Japanese, and Filipinos were 7.5, 6.8, and 5.1 per 1 million persons-years, respectively. Age- and sex-adjusted race-specific mortality rates in Hawaii were greatest among Filipinos and higher in the combined Asian group than for the U.S. mainland population, confirming previous observations (67). A study from Hawaii reported that mortality rates were three times higher in non-Caucasian than Caucasians in 1985 to 1989 (70). It is unclear whether the differences in mortality rates between Asians and whites mirror true differences in incidence rates as seen with blacks (*vide supra*).

Siegel and Lee (28) noted greater mortality and morbidity from SLE among Puerto Ricans compared with whites in New York City. Lopez-Acuna et al. (87) analyzed mortality from SLE in Puerto Rico from 1970 through 1977 as well as a subset of the NCHS data set for five southwestern states with the highest proportion of Hispanics: Arizona, California, Colorado, New Mexico, and Texas. A total of 92 deaths from SLE occurred in Puerto Rico; the average age-adjusted mortality rates of 7.5 and 2.0 deaths per 1 million person-years in females and males, respectively, were not significantly different from those noted among U.S. whites over this period. A correlation between the proportion of Spanish-heritage population and county-specific mortality rates from SLE was noted for females but not males in these five states; the implications of this finding may reflect both ethnic/racial and socioeconomic factors. Indeed in a recent study, Ward demonstrated that socioeconomic status, as measured by education level is associated with mortality due to SLE in whites (84). Relative odds of mortality due to SLE were almost double in white women and white men with <8 years of education compared to those with >16 years of education. In contrast to the findings in whites, and in contrast to many prior studies, higher education levels were not associated with lower mortality due to SLE in African-Americans or Asian/Pacific Islander women most likely as a result of underdiagnosis of SLE in minorities with low education levels. Cause-specific mortality data from Latin American countries have not been reported.

Data on nationwide mortality from SLE have been reported from Finland (37), Iceland (39), England and Wales (88), and the island of Curacao (52). Average mortality rates were 4.7, 2.5, and 17.0 per 1 million person-years in Finland, England and Wales, and Curacao, respectively. Patterns of age-specific mortality rates in Finland as well as England and Wales were similar to those in U.S. whites. The fourfold greater age-adjusted mortality among English females compared with males is similar to that seen in the United States as well. Patterns of age-specific mortality rates in Curacao were similar to those in blacks, with a peak mortality rate in the 45- to 64-year age group and a fourfold greater mortality in women than in men (52).

Temporal trends in mortality rates have been examined in the United States (81 ,82 ,85) and in England and Wales (88). In the United States, there was a significant decline in age-adjusted annual mortality rates between 1968 and 1978 for all sex/race groups (82) (Fig. 4-2). More recently, the Center for Disease Control and Prevention (CDC) reviewed SLE deaths during 1979 to 1998 and reported an overall increase in the annual number of deaths from 879 in 1979 to 1,406 in 1998 (Table 4-9) (85). The crude death rate increased from 3.9 to 5.2 per 1 million population. Of all SLE deaths, 36.4% occurred among persons aged 15 to 44. For each year, crude death rates increased with age, were >5 times higher in women than men, and were >3 times higher among blacks than whites. Among black women, death rates were highest and increased most (69.7%) among those aged 45 to 64 (Fig. 4-3). Of all death from arthritis, SLE accounts for 44% of deaths among persons aged <45 years (85). This report indicates marked age, sex, and race-specific disparities that exist in SLE death rates. Differential ascertainment and reporting of SLE death by race is possible but probably does not account for the magnitude of observed differences. A higher incidence of SLE among black women along with later diagnosis, problems in access to care and less effective and poorer adherence with treatment might account for the racial differences in death rates. Rates for racial/ethnic populations other than white or black were not calculated because numbers were too small for meaningful analysis. A large population-based registry of SLE will be developed by CDC to examine the causes of these marked disparities and the temporal changes in death rates.

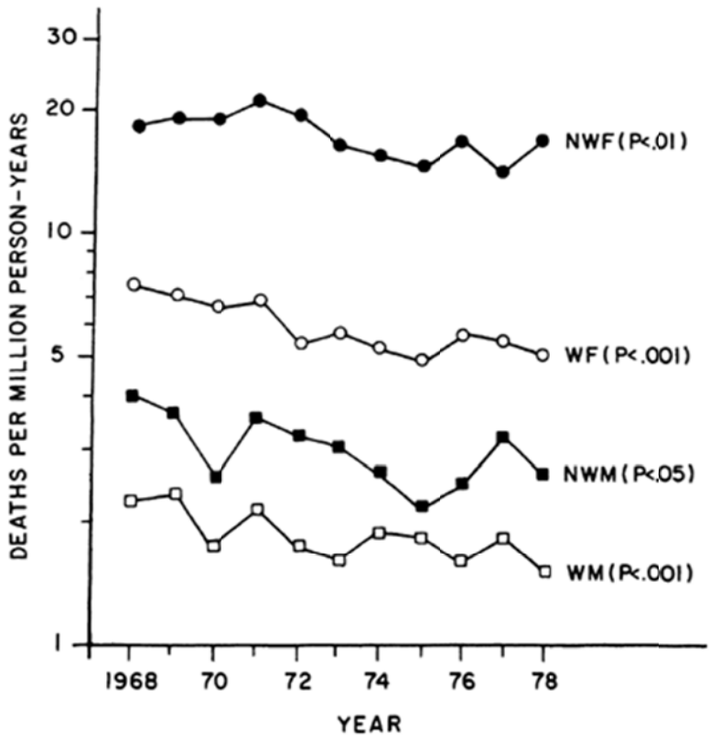

Figure 4-2. Trends in age-adjusted annual mortality rates from lupus erythematosus by sex/race group in the United States, 1968 to 1978. (White males □, white females ○, black males ▪, black females •).

A significant temporal decline in age-adjusted annual mortality rates from SLE also was observed among females in England and Wales from 1974 to 1983 but not among males, probably because of the small numbers of deaths

from SLE among males (88). A similar decline in mortality was observed in the Toronto Cohort, where estimated risk for death was compared for patients entered in the cohort between 1970 to 1977, 1978 to 1986, and 1987 to 1994 (89). The standardized mortality ratios declined from 10.1 in the first group to 3.3 in the last group. The same decline was observed for the first two groups followed over the next time period. The decline in mortality rates observed in these developed countries is probably a result of improved survival in patients with SLE, as reflected by improving 10-year cumulative survival rates approaching or exceeding 90% in some studies (90 ,91) (see Chapter 69).

Table 4-9: Numbers of Deaths from SLE by Age Group, Sex, and Race in the United States, 1979-1998

Summary

Descriptive epidemiologic studies of SLE have been conducted worldwide; the most extensive data are available for the United Kingdom, Scandinavia (especially Sweden), and the United States. In the United States, blacks have a threefold higher incidence and prevalence of SLE, as well as cause-specific mortality rates, compared with whites, whereas in England, Asian Indians and Afro-Caribbeans have higher incidence and prevalence rates than whites. The reasons for this excess, however, remain unknown. Finally, observational epidemiologic studies have demonstrated an increasingly favorable prognosis for patients with SLE, allowing the identification of potentially preventable causes of death and a better understanding of long-term morbidity and impact on overall health status.

Section II

Pathogenesis of Lupus

Chapter 5

Overview of Pathogenesis of Systemic Lupus Erythematosus

Bevra Hannahs Hahn

The purpose of this brief chapter is to review how systemic lupus erythematosus (SLE) evolves and is sustained. Ideas reflect the author's opinions, which are based largely on the information provided throughout this book. References are not extensive because each topic is addressed in detail in other chapters.

The Phases of SLE: Evolution of Disease in Susceptible Persons

As shown in Fig. 5-1 , individuals who ultimately develop SLE do so in a series of steps. There is a long period of predisposition to autoimmunity, then (in a small proportion of those predisposed) development of autoantibodies, which usually precede clinical symptoms by months to years (1). A proportion of individuals with autoantibodies develop a clinical prodrome with nonspecific symptoms that do not meet criteria for classification as SLE, and then among those a proportion develop full-blown SLE with various symptoms, autoantibodies, and laboratory abnormalities that make the diagnosis clear. Finally, individuals with clinical SLE usually experience over a period of many years intermittent disease flares and improvements (usually not complete remission), and compile organ damage and comorbidities related to chronic inflammation, to therapies, and to aging.

Genetic Predisposition

Genetic predisposition is probably the single most important factor in phase 1 (2 ,3). The risk for SLE is increased approximately 10-20-fold in monozygotic compared to dizygotic twins, and in siblings of patients with SLE compared to the healthy population. However, concordance for SLE in monozygotic twins is considerably less than 100%, suggesting that nongenetic factors play a major role in disease susceptibility. With the possible exception of the very rare homozygous deficiency of C1q (>90% of those individuals develop SLE) (4), there is no single gene polymorphism or abnormality that accounts for SLE in all affected individuals in one family, or in the various populations that develop the disease. Approximately 75% of SLE patients in all ethnic groups have at least one human leukocyte antibody (HLA) gene that increases risk (subsets of DR2, DR3, DR4, or DR8, particularly in Caucasians). However, each of these alleles increases risk a relatively small amount (1.7-fold to 2.5-fold), indicating that multiple susceptibility genes, and/or other factors such as environment are required for disease development. At the time of this writing (June 2006), genome scan studies of different populations from several laboratories have identified at least eight chromosomal regions that contain susceptibility genes; the regions are not the same in all racial/ethnic populations. In addition, individual genes have been associated with or linked to risk for SLE in more than one cohort (but not all) including the Fcγ receptors IIA, IIIA, and RIIB, which in some groups (especially African Americans) predispose more to lupus nephritis than to SLE itself. Other predisposing genes identified by at least two groups include alleles of interleukin 10 (IL-10), monocyte chemotactic protein-1 (MCP-1), mannose binding ligand (MBL), protein tyrosine phosphatase non-receptor type 22 (PTPN22) and interferon-response-factor-5 (IRF5). Finally, some genes are associated with high risk for damage, such as end stage renal disease (FcRIIIA). One gene region (16q12) is linked to several different autoimmune diseases, including SLE. Thus, it is possible that some individuals are predisposed genetically to autoimmunity, and other genes determine whether the disease that develops will be SLE, type 1 diabetes mellitus, Crohn's disease, and so on. There is one report of a gene that confers protection from SLE (5)—a polymorphism for the Toll-like receptor (TLR)5 that reduces the levels of pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), interleukin-1-beta (IL-1β), and IL-6 released from cells stimulated by bacterial flagellin. One can speculate that 1. HLA-DR genes predispose to autoimmunity because they determine what peptides can be presented to T lymphocytes to activate help for autoantibody production and T-mediated immune responses. 2. FcγR genes predispose because those that increase risk for SLE bind the Ig in immune complexes and antibodies less well than the other alleles (probably impairing clearance). 3. Deficiency of C1q or predisposing alleles of MBL predispose by impairing clearance of apoptotic

bodies (which bind C1q) that contain self-antigens recognized by individuals with SLE. 4. Alleles of IL-10 that increase B cell maturation predispose by increasing autoantibody production. 5. Alleles of PTPN22 predispose if their product has less negative regulation of T cell function than do other alleles. However, these ideas have not been proven. In addition to identification of genes and gene regions that increase susceptibility to SLE, genes and/or regions have been identified that predispose to certain phenotypes of disease, such as nephritis, vasculitis, arthritis and hemolytic anemia. In addition, genes have been identified that increase the risk for end stage renal disease in people with lupus nephritis. Now that single nucleotide polymorphisms (SNPs) identifying the entire human genome are available (the haplotype map-HapMap- project), we can expect more precise analysis of small chromosomal DNA regions containing suspect genes. For example, a major experiment is in progress in which deoxyribonucleic acid (DNA) from multiple cohorts with large numbers of SLE patients is being analyzed for genomic content using 500,000 single nucleotide polymorphisms (SNPs), which promises to identify more genes that influence disease susceptibility, phenotype and outcome. Hopefully this work will also result in better understanding of the mechanisms of disease. For now, it is safe to say that almost all patients have inherited multiple susceptibility genes, that each gene has a relatively small impact on immune or inflammatory response, and that the sum of these many small differences results in autoimmunity with characteristics of SLE.

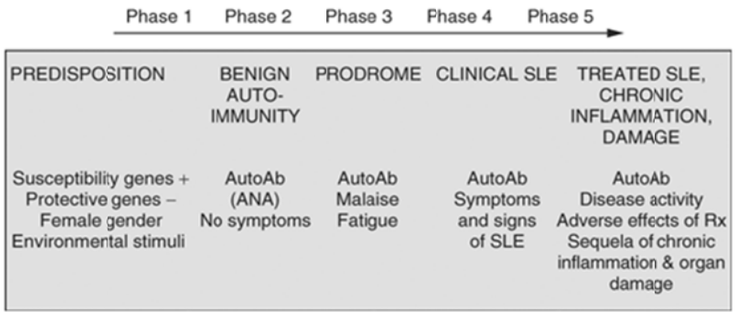

Figure 5-1. The five phases of SLE. Time is shown from left to right. Many individuals inherit susceptibility genes increasing risk for SLE. The progression from health to benign autoimmunity characterized by autoantibodies with no symptoms, to disease and to chronic damage is shown. See discussion in text. AutoAb, autoantibodies, Rx, treatment.

The Influence of Gender

Gender influences on disease susceptibility must be of major importance, since there are nine females for every male with SLE. The most important impact may be hormonal, since sex differences in susceptibility are largest during reproductive years. Estradiol probably prolongs the life of autoreactive B and T lymphocytes (6). Women exposed to oral contraceptives, or to hormone replacement therapy regimens containing estrogenic compounds, have a small but statistically significant increased risk for SLE. Prospective, randomized, blinded, controlled trials showed that administration of one hormone replacement therapy containing conjugated estrogens and a progesterone significantly increased the risk of mild/moderate disease flare in women with established SLE (in contrast, one oral contraceptive tested did not) (7 ,8). There are many experiments in murine SLE showing that alteration of sex hormones that increase estrogen or progesterone-like effects worsen disease. However, other features of femaleness may also be important in predisposing to SLE. For example, most women after pregnancy have circulating stem cells from their fetuses (microchimerism), which might set up a graft-versus-host type immune reaction (9). Women may be predisposed to SLE because their inactive X chromosome is enriched in hypomethylated regions. The CpG in these regions can be bound by TLR9 receptors thus activating innate immune responses and increasing risk for autoimmunity (10 ,11).

The Influence of Environment

Environmental factors that predispose to SLE are undoubtedly important, although many are unknown at this time. Ultraviolet light clearly exacerbates disease in a majority of people with SLE, and in some the clinical onset of disease is preceded by unusually large exposure. Mechanisms might include alteration of the structure of DNA in the dermis to render it more immunogenic, and induction of apoptosis in keratinocytes and other dermal cells, presenting self antigens to the immune system via apoptotic bodies. Infections have long been suspect as inducers and enhancers of SLE. Recent work from several laboratories has linked infection with Ebstein Barr virus (EBV) to SLE (12 ,13 ,14). EBV infection activates B lymphocytes, which might cause a genetically predisposed person to make large quantities of autoantibodies, overwhelming regulatory mechanisms. The Epstein-Barr (virus) nuclear antigen (EBNA) 1 molecule of EBV has molecular mimicry with a sequence in the Ro particle; immunization with the sequence can induce multiple autoantibodies and lupus-like disease in animals (14). Of course, there are many potential toxins in the environment that may initiate and influence immune and inflammatory responses.

Autoantibodies as Disease Effectors

Autoantibodies are the main effectors of disease in SLE. In humans, they are probably necessary for disease, but not sufficient. That is, their deposition must be followed by activation of complement and/or other mediators of inflammation, and a series of events that include chemotaxis for lymphocytes and phagocytic cells, and release of cytokines, chemokines, and proteolytic enzymes, as well as oxidative

damage, must occur for organ inflammation and damage to be severe. There are several experiments in mice showing that autoantibodies and/or immune complexes can deposit in glomeruli without inducing significant renal damage, if the processes listed above do not occur (15 ,16). Recent data (1) suggest that in nearly 85% of SLE patients, autoantibodies precede the first symptom of disease by an average of 2 to 3 years—sometimes as long as 9 years. The autoantibodies appear in a temporal hierarchy, with antinuclear antibody (ANA) first, then anti-DNA and antiphospholipid, and finally anti-Sm and anti-RNP. These observations imply that immunoregulation of potentially pathogenic autoantibodies can occur for a sustained period of time, and only in individuals whose regulation becomes “exhausted” does disease appear (17). Among autoantibodies, some are clearly pathogenic, such as certain subsets of anti-DNA that cause nephritis upon transfer to healthy animals, antibodies to neurons that cause neuronal death, antibodies to Ro which cause damage to the fetal heart conduction system (proven in mice), antibodies to phospholipid that cause fetal loss (proven in mice), and antibodies to platelets and erythrocytes that cause the cells to be phagocytized and destroyed. Additionally, antibodies to DNA/nucleosomes contain amino acid sequences that are T cell determinants (18); these peptides activate helper T cells to further expand autoantibody production. Mechanisms of pathogenicity are discussed in detail in other chapters, and for many autoantibodies are not entirely known.

Development of Clinical Disease

The “later” phases of SLE include the prodrome of fatigue and malaise that many patients describe, which may last months prior to development of classical SLE. That prodrome may resolve, or may evolve into recognizable disease that fits criteria for classification as SLE. At this point, treatment designed to suppress SLE is introduced. Most patients improve and reach a point where they endure mildly active disease in the setting of tolerable side effects of treatments. As relatively low levels of chronic inflammation and oxidative damage continue in tissues, patients age, and adverse effects of treatment accumulate, damage accrues. For example, clinically important atherosclerosis, including myocardial infarcts and strokes, become increasingly common in SLE patients after the first decade of disease. Risk for atherosclerotic disease is five- to 10-fold increased in SLE patients compared to age-matched non-SLE populations. Renal failure, hypertension, obesity, and reduced physical activity combine to add to the morbidity and mortality of the disease.

The Immune Abnormalities of SLE

Two major immune networks contribute to generation of autoreactive T cells and autoantibodies in individuals with SLE—the innate immune network, and the adaptive immune network.

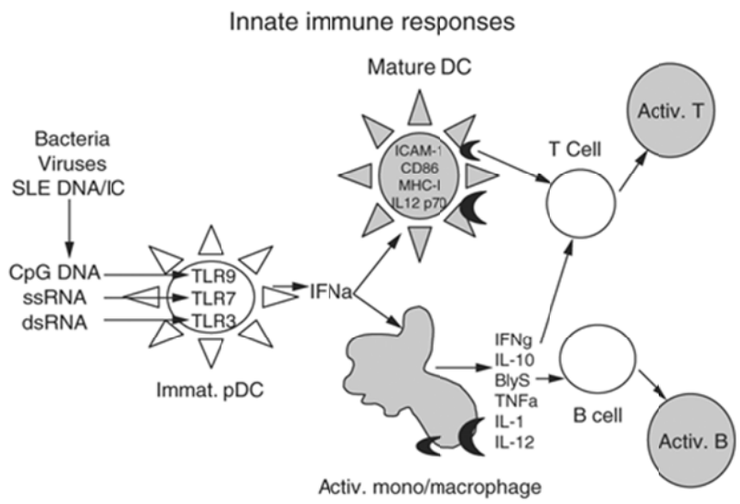

Figure 5-2. The role of innate immunity in promoting development and continued activity of SLE. Danger provided by bacterial, viruses, and some self antigens are recognized primarily by the plasmacytoid dendritic cells (pDC) deposited in tissues as a first defense. Immature, inactive cells are shown as white throughout this figure. Cytosine/guanosine nucleotides in DNA, (characteristic of bacterial DNA but also found in mammalian DNA, enriched in SLE patients), and DNA in immune complexes bind TLR9 in pDC; dsRNA from viruses binds TLR7 and 8; single-stranded RNA from viruses binds TLR3. Each of these bindings can trigger release of IFNα from the pDC, which then acts on monocytes/macrophages and DC to promote expression of the molecules indicated, as well as increases in MHC I and II expression on cell surfaces with conversion to potent antigen-presenting cells. MHC/peptide complexes are shown as crescent-shaped black-filled surface structures. These APC provide first activating signals to T cells. Second signals are provided by CD86 on activated macrophages and DC. Some cytokines released by the monocytes (IL-10, BLyS) promote maturation of B cells and Ig secretion; others promote maturation/activation of T cells (IFN-γ). Thus, in response to environmental dangers and some self molecules (cytosine/guanosine nucleotides in DNA), DC, monocytes/macrophages, T cells and B cells become mature and activated (depicted in light gray). This sets the stage for production of autoreactive T cells and pathogenic autoantibodies that cause and perpetuate SLE. IC, immune complexes, TLR, Toll-like receptor, Immat, immature, pDC, plasmacytoid dendritic cell, IFN, interferon.

Figure 5-2 shows generation of T and B cell activation via innate immunity. External and internal danger signals, including infections and self antigens, activate innate immunity primarily via dendritic cells (DC) located in tissues that sample the environment (lungs, intestines, skin, peripheral lymphoid tissues). Pathogen-associated molecular patterns (PAMPs) shared by many bacteria and viruses are recognized by Toll-like receptors in DC. Quite important to SLE is the fact that TLR9 in DC and B lymphocytes can bind CpG DNA sequences (11 ,19 ,20). Such sequences are fairly common in bacterial DNA, are uncommon in mammalian DNA, but are increased in patients with SLE. Therefore, lupus DC can be activated by CpG nucleotides in tissue or circulation. Furthermore, DNA in DNA/anti-DNA immune complexes binds TLR9, and the anti-DNA binds FcRγRIIA receptors on

DC, thus further activating innate immunity. Other TLR (TLR 3,7,8) recognize viral single-stranded DNA (ssRNA) or double-stranded (dsRNA); RNA/protein complexes characteristic of SLE can also bind TLR7 (21). Binding of any of these TLR, particularly in plasmacytoid DC (pDC), results in release of IFNα and other cytokines from the immature pDC; interferon-α (IFN-α) promotes maturation of DC and of monocytes/macrophages. Both cell types then express peptides in their major histocompatibility complex (MHC) surface molecules, becoming potent antigen-presenting cells (APCs) for activation of T lymphocytes. Additionally, the activated macrophages release multiple cytokines that promote maturation and activation of T lymphocytes (particularly toward the Th1 phenotype) and of B cells, with increase in immunoglobulin production and in switching to pathogenic IgG subclasses. Thus, the stage is set with activated T and B cells (some of which are autoreactive) ready to participate in adaptive immune responses. All of these processes occur in healthy individuals. What is probably different about persons with SLE compared to healthy people is that they have greater quantities of hypomethylated DNA with CpG sequences (22), circulating DNA/anti-DNA complexes, and possibly recent or reactivated infection with EBV (12 ,13 ,14). Additionally, certain polymorphisms in various TLR and in FcγR may predispose these individuals to abnormal innate responses. Thus, it is likely that innate immune responses are upregulated in patients with SLE, promoting antigen processing/presentation and the activated state of T and B lymphocytes participating in and driving adaptive immunity against self.

Figure 5-3 illustrates generation of activated, autoreactive T and B cells by adaptive immunity in SLE. Antigens, both external (foreign) and internal (auto), encounter activated APCs, which internalize them and process them into peptides, subsequently presenting the peptides in surface MHC molecules. B lymphocytes and monocyte/macrophages are the main APC in adaptive immunity, whereas DC are prominent APC in innate immunity. Some non-immune cells, when activated, such as mesangial cells, also express MHC class II on their surfaces and serve as APC for local T cell activation. T lymphocytes with antigen-specific TCR receive first activating signals from MHC/peptide complexes, and then second signals from molecules such as CD86, which are also expressed on activated APC. In the case of helper T cells (mostly $CD4^+$, can include $CD8^+$ in people with SLE), cells are activated to secrete cytokines (IFN-γ, IL-6, IL-10), that help B lymphocytes produce autoantibodies. Some antibodies fix directly to target organs, such as platelet surface molecules or α-actinin in glomeruli (23). Other autoantibodies form pathogenic immune complexes of correct size, charge, conformation, and antigen-reactivity to bind to tissue (platelets, glomeruli, skin, blood vessels are frequent targets). Antibody-dependent cell cytotoxicity, or complement activation with subsequent inflammation can result, leading to clinical disease and to tissue damage. While this process of autoantibody production is quite active in SLE patients, many of the regulatory networks designed to shut off antibody production are defective. This includes decreased phagocytosis of apoptotic cells, and of immune complexes (24). Additionally, generation of regulatory $CD4^+CD25^+$ T cells and suppressive $CD8^+$ T cells is probably defective (17). Defects in function of these cells have been well documented in several models of murine lupus; evidence that they occur in human disease is accumulating. For example, patients with SLE compared to normals produce abnormally small quantities of transforming growth factor beta (TGF-ß) from peripheral blood cells (25). TGF-ß, along with IL-2 (production of which is also reduced in T cells of many SLE patients), is required for generation of $CD4^+CD25^+$ Treg, and some $CD8^+$ inhibitory cells in humans. With regard to $CD8^+$ T cells, one group has shown that such cells from SLE patients cannot suppress proliferation of $CD4^+$ T cells and autoantibody production in the normal manner, particularly when disease is clinically active (26).

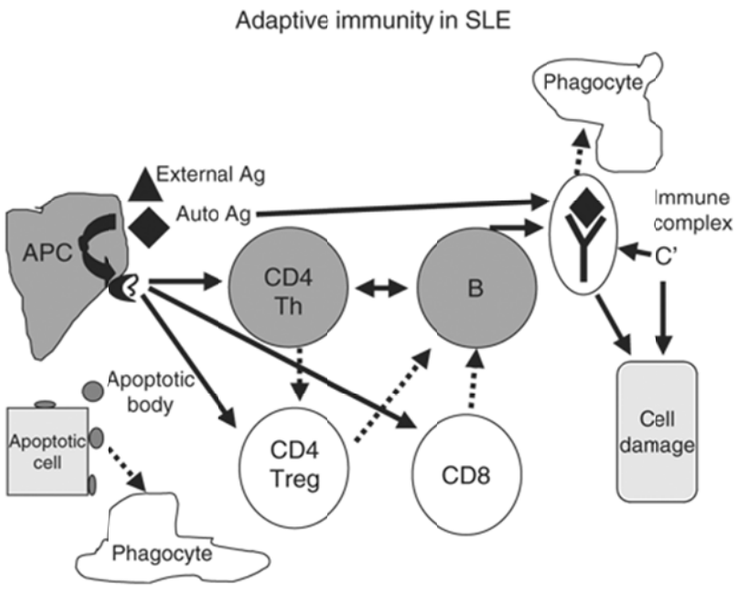

Figure 5-3. Adaptive immunity in SLE. Activated hyperfunctioning cells are filled with gray; underfunctioning cells are filled with white. Solid arrows indicate active, ongoing processes that result in production of autoantibodies and immune complexes. Dashed arrows indicate hypofunctioning processes that contribute to failed regulation of autoantibody/immune complex production. External and autoantigens are taken up by APC and processed into peptides that are presented in MHC molecules on the surface of the APC. These Ag are present in the environment; many self Ag are exposed to the immune system in apoptotic cells and bodies, which are not disposed of by phagocytes in the normal fashion. T cells receive first activating signals from the MHC/peptide complexes; helper type T cells receive second signals from activated APC and are activated to drive B cell production of autoantibodies (circled in bold oval). In contrast, regulatory $CD4^+$ and $CD8^+$ T cells after receiving first signals are either anergic or are driven to apoptosis rather than to activation. Therefore, autoantibody and immune complex production are favored. Regulatory networks, including phagocytosis of the complexes, are impaired so that autoantibody/immune complex formation continues to occur until quantities and properties reach levels that can fix to target cells and activate complement to cause cell damage and clinical disease. APC, antigen-presenting cell, Ag, antigen, MHC, major histocompatibility complex, C', complement, Th, helper T cells, usually $CD4^+$; Treg, regulatory T cell, usually $CD4^+$.

In summary, the immune abnormalities characteristic of SLE include 1. brisk production of autoantibodies and immune complexes that contain pathogenic subsets, 2. enhanced upregulating mechanisms, and 3. defective downregulating mechanisms.

Why Do Some Persons with Autoantibodies Develop SLE While Others Do Not?

If we assume that anyone with sustained autoantibodies has at least a few susceptibility genes predisposing to SLE, we must still address the reasons that SLE develops in only some. Why do some people progress from phase 2 to phases 3 through 5? It is well known that in normal individuals autoreactive T and B lymphocytes are detectable in lymphoid tissues, as well as in circulating peripheral blood cells. Thus, it is not unusual to detect autoantibodies (especially rheumatoid factor and ANA) transiently during infections, or even sustained for long periods of time, sometimes associated with aging. Table 5-1 , lists some ideas about what might distinguish a person destined to develop SLE from a person who" tolerates" autoantibodies and never develops clinical disease.

With regard to genetic predisposition, it seems likely that some individuals develop clinical SLE because they have a "critical mass" of susceptibility genes. Each gene contributes an abnormality that permits enhanced autoreactivity, or impaired immune regulation, or both. After repeated stimulation of immune responses by the usual external stimuli, such as infections, SLE develops. Although no single environmental stimulus has been identified as sufficient and necessary for triggering clinical SLE, several are known to participate (EBV infection, ultraviolet light). An antibody to pneumococcal polysaccharide can become an antibody to DNA after a single mutation (27); it is likely that this process can occur in many antibodies to infectious agents. Furthermore, toxins released by infectious agents (e.g., lipopolysaccharide) can disrupt the blood-brain barrier and allow access of antibodies that react with central nervous system (CNS) antigens, such as glutamate receptors on neurons (27 ,28). Thus, a previously healthy person with this autoantibody develops CNS lupus. Stress, caused by infections or injury, may also contribute to going from healthy but predisposed to full clinical SLE. Proteins released from cells during stress, including many heat shock proteins, can induce autoantibody responses and can activate T cells (29). People who develop SLE may be exposed by predisposition or environmental stressor to higher quantities of autoantigens or to altered forms that are more antigenic. When cells of the lymphoid system undergo apoptosis or necrosis, enzymes are activated that alter composition of some intracellular antigens to more immunogenic forms (30). Apoptotic blebs on cells contain many of the self antigens recognized in SLE—nucleosomes (DNA/histone), Ro, La, Sm (RNA/protein), and phospholipids. Individuals with increased numbers of apoptotic cells, or who cannot clear those cells properly by the usual phagocytic mechanism, might develop SLE (4 ,24). In a person genetically programmed to "hyperrespond" to antigenic stimuli, the development of autoantibody with one specificity may induce reactivity to others—a phenomenon known as "antigen spreading." As immune responses to one antigen mature, the expanding T and B cells develop cross-reactivity or even new reactivity to other autoantigens. The data showing addition of different autoantibodies over time following appearance of ANA in people who later develop SLE supports this idea (1), and immunization of animals with an autoantigen such as Ro or the SmD1 peptide can induce ANA and other autoantibodies over time (14 ,27 ,31).

Intrinsic abnormalities of cells of the immune system contribute to development of SLE. These abnormalities are likely to be genetic in origin, although only a few have been identified. For example, some SLE patients have a mutation in an RI α a gene that results in deficient functions of protein kinase (PKA)-I and PKA-II enzymes important in transmitting intracellular signaling after TCR stimulation: the end result is increased calcium signaling and probably hyperactive T cell responses (32). Several additional abnormalities in responses to TCR-signaling characterize SLE T cells and result in abnormal cell function, including underproduction of IL-2 (33). IL-2 is required to generate regulatory and cytotoxic T cells that dampen autoimmunity. People with SLE are more likely than healthy people to have circulating T cells that recognize self antigens (18), and smaller quantities of antigen are required to trigger T- and B cells activation (34). Higher proportions of B and T cells from SLE patients compared to normals are activated, with expression of surface molecules induced by activation, such as Fas, CD86, CD40L, and ICAM (35 ,36). Such cells are resistant to deletion and anergy (33 ,37)—mechanisms of tolerance that prevent T or B cells from going to full activation after first signals are delivered. These combined abnormalities in T and B lymphocytes could account for a predisposed person developing full-blown SLE.

Although we know many of the characteristics that contribute to an autoantibody being pathogenic—the antigens it binds, its ability to activate complement, its charge, its idiotypes, its contents of T cell determinants, etc., we do not know whether the important differences between inducing disease or not are primarily quantitative, or depend on these qualitative differences, or both. We also do not know whether the qualitative characteristics of pathogenic autoantibodies are shaped primarily by genetics or by the environment in which the B cell produces the autoantibodies. For example, can the quantities of IFN-γ or IL-10 or BLyS in the immediate environment of B and T cells influence mutations in the variable region of the Ig molecule that introduce amino acids (e.g., arginine) that increase binding of the molecule to DNA? If so, does the release of the influential molecule depend on the genetics of the individual, or is it a normal response to a particular stimulus?

Table 5-1: Possible Explanations for Development of SLE in Genetically Predisposed Individuals with Autoantibodies

1. Genes: Critical “dose” of susceptibility genes causing enough immune response abnormalities to permit sustained production of pathogenic autoantibodies and immune complexes, once that response has begun.
2. Environment:
a. An infection that increases autoantibody/immune complex production and/or impairs downregulatory mechanisms (EBV, pneumococcus, etc). Such an infection might also disrupt the blood-brain barrier and permit access of antibodies that cross-react with central nervous system antigens.
b. Increased exposure to ultraviolet light or other environmental toxins
c. Exposure to a drug or biologic that tilts the immune response to autoimmunity (interferons, TNFα inhibitor isoniazid, some anti-hypertensives, etc.)
d. Exposure to increased estrogen/progesterone/prolactin sex hormones
e. Severe stress
3. Antigens:
a. Alteration to more immunogenic forms during cell activation, apoptosis, or necrosis than in normal circumstances
b. Antigens find their way to normal “protected” environments such as the brain.
c. High quantities of apoptotic cells are present and/or the presence of apoptotic bodies/cells is sustained longer than normal. This would allow presentation of nucleosome, Ro, La, phospholipids, and other autoantigens to the immune system.
d. An infection, bacterial or viral, provides foreign antigens that mimic self, and induce autoreactive T and B cells (molecular mimicry)
e. One autoantigen present in high quantities, or in an immunogenic form, triggers antigenic “spreading” within the immune system, so that T and B responses are educated to recognize additional self antigens.
4. Intrinsic abnormalities of cells of the immune system (B and T lymphocytes):
a. Cells are activated by lower concentrations of antigen than normal
b. Cells are more easily activated by normal stimuli than in healthy individuals. They have sustained surface expression of activation markers some of which provide second signals. This may relate to mutations or abnormal functions of receptors and kinases involved in signaling that occurs after T cell antigen receptor (TCR) or B cell antigen receptor (BCR) engagement (first signals), including generation of certain cyclooxygenase-2 (COX-2) molecules.
c. Cells that are activated are relatively resistant to apoptosis and anergy: they persist too long, escaping regulation.
d. Activation of cells in a person with SLE, compared to normals, results in increased numbers of activated cells, as well as increased quantities or qualities of the cytokines and chemokines released (for example, the typical signature of IFN type 1-related gene increase in peripheral blood cells of patients with SLE).
5. Differences in the characteristics of autoantibodies made by someone with SLE compared to someone without:
a. More autoantibody subsets are pathogenic in SLE than in healthy individuals. For example, more autoAb with cationic charge, ability to bind with high avidity to self antigens in tissues—such as α-actinin or laminin in glomeruli or glutamate receptors on neurons in the brain.
b. Idiotypes within the antibodies identify them as pathogenic or activate idiotype/anti-idiotype networks that promote more autoantibody production. For example, IdGN2 is present in glomeruli of patients with proliferative, but not membranous, forms of lupus glomerulonephritis.
c. Autoantibodies in SLE patients are enriched in T cell determinants that activate help for more autoantibody production.
d. Characteristics of immune complexes favor tissue capture rather than elimination.
6. Differences in the composition of target tissue in SLE permit the tissue to become a target of antibodies, which are usually benign.
a. In rats, the structure of myosin in the heart determines whether autoantibodies and autoreactive T cells can induce myocarditis.
b. In people, tissue responses to injury differ in terms of susceptibility to damage. For example, African Americans with any type of glomerular disease are more likely than Caucasians to develop end stage renal disease. This may be because of differences in enzymes (ACE for example), chemokines, cytokines, growth factors released upon initial injury, or to differences in tissue structure.
7. Responses to therapy: There is evidence for some immunosuppressive drugs that persons with certain genetic polymorphisms that influence metabolism of or effects of the drugs respond differently. Similar information should be discovered for most of the medications/biologics used in SLE over the next few years.
a. Azathioprine
b. Cyclophosphamide

It is also possible that the nature of the response of activated immune cells is at least as important in determining disease as the antigens that stimulate the response, and the antibodies that result. What is the importance of the recent observations that peripheral blood cells of SLE patients are enriched in upregulated genes induced by interferons (probably more specifically by type 1 than type 2 IFN)? It seems unlikely that this response merely reflects activation of cells in a person with ongoing inflammation, since individuals with other inflammatory diseases, just as juvenile arthritis, do not show this gene “signature” in their cells (38). There is substantial evidence that in some individuals increased cell and/or serum and/or urine levels of certain cytokines, chemokines, products of activated complement and soluble receptors such as IFN-α, IFN-γ, TNF-α, IL-6, IL-2R, IL-6R, IL-10, intracellular adhesion molecule (ICAM), C4d, and monocyte chemoattractant protein-1 (MCP-1) are associated with active disease or predisposition to SLE (33 ,39). The specificity of these changes for SLE and their utility as biomarkers of disease activity are under intense study. Again, we do not know if these “abnormalities” are controlled genetically or are products of the particular response initiated by disease triggers, or both.

We should also consider the possibility that difference in composition of tissue targeted by autoantibodies play a role in why some persons develop SLE while others do not. There is an example in two mouse strains—one resistant and one susceptible—of differences in two amino acid residues in the α heavy chain of cardiac myosin that influence susceptibility to autoimmune carditis (40). In another example, one strain of mice developed sclerosing glomerular disease after deposition of autoantibody, whereas another strain did not (16). This might relate to different abilities to secrete cytokines that promote scarring, such as TGFß, rather than to differences in composition of glomerular antigens. To date, it is not possible to corroborate the data in human SLE as to whether sequence or other structural differences in tissue target molecules determine susceptibility to disease, but it is likely that differences in the individual's response to autoantibody/immune complex deposition are critical in whether or not tissue injury occurs.

Finally, as there are more patients with SLE surviving to enter phase 5—chronic disease with periods of flare and improvement—the characteristics of each patient in terms of response to therapies will have to be dealt with, both the probability of clinical response and of adverse effects. It is customary to think of patients who are “resistant” to therapy as having particularly severe disease, but it may be that in some differences are not in disease but in genetically determined responses to treatments. For example, cyclophosphamide is metabolized via cytochrome P450 (CYP) enzymes. A recent study (41) suggests homozygosity for certain polymorphisms of CYP enzymes strongly influence both ovarian toxicity and clinical responses of patients with lupus nephritis treated with cyclophosphamide. Azathioprine is metabolized in part by thiopurine methyltransferase (TPMT), which influences tissue and blood concentration of the active thioguanine metabolite. Homozygous deficiency of the enzyme is highly correlated with bone marrow suppression. Some experts have suggested that testing for the presence of TPMT, and for polymorphisms in both coding and promoter regions of its genes, should be used to determine dosing. In some series (42), this approach has prevented toxicities; in others (43), it has not been effective, probably because there is not a clear correlation between the multiple polymorphisms and drug levels, with the exception of homozygous deficiency. Clinical experience tells us that some patients are good responders to azathioprine or to cyclophosphamide or to mycophenolate; others are not. Some patients respond well to only one of these agents; others respond to several. The same is likely to be true of the interventions coming into clinical trials; antibodies to CD20, CTLA4Ig, Edratide, and so on. It will be a great advance in management of SLE when patients can be screened for drug response and risk for adverse effects before exposing them to these potentially toxic agents. In the same regard, it will be a great advance to learn more about preventing the comorbid conditions that result from chronic inflammation and treatment toxicities, such as atherosclerosis, osteoporosis, and infections. Although there are effective preventive strategies for some of these problems, there is much room for improvement.

When there is a more complete understanding of the pathogenesis of SLE, preventive strategies in order to keep individuals “locked” in phase 2, never progressing to clinical disease, can be developed. This is the most exciting aspect of the future with regard to this disease.

Chapter 6
The Genetics of Human Lupus

Betty P Tsao

Hui Wu

Cumulative genetic epidemiology studies have clearly demonstrated the importance of genetic influences on systemic lupus erythematosus (SLE). Early studies have focused on genes located within the major histocompatibility complex (MHC). Subsequently, both MHC genes and non-MHC genes are shown to participate in the pathogenesis of SLE. Using a candidate gene approach, many immunologically relevant genes, including certain MHC loci, deficiencies of complement components, Fcγ receptors, and cytokines, have been associated with SLE using the case-control, population-based studies. Complementary to association studies of candidate genes, linkage analysis is another tool that tests whether a particular chromosomal region is likely to harbor a disease susceptibility gene by testing whether genetic markers and a disease phenotype show correlated transmission within pedigrees. Eleven whole-genome scans have been performed using family collections containing multiple members affected with SLE, resulting in at least eight susceptibility loci (1q23, 1q31, 1q41–42, 2q37, 4p16, 6p21, 12q24, and 16q12–13) reaching the threshold for significant linkage and confirmation in independent cohorts. Within the linked intervals, fine mapping experiments (6p21 and 16q12) and positional candidate gene studies (1q23, 1q41–42, and 2q37) have further supported the presence of lupus susceptibility gene(s). These linkage results have shown that (1) no single locus is shared in all collections of SLE-multicase families, and (2) susceptibility genes contributing to the development of SLE may vary depending on ethnic and genetic heterogeneity. Recently, candidate genes encoding immunoregulatory molecules have been implicated in susceptibility to SLE including programmed cell death 1 (PDCD-1) and protein tyrosine phosphatase (PTPN22). These gene variants have also been associated with multiple autoimmune diseases, which may help to explain the observed familial clustering of multiple autoimmune diseases. Increased levels of interferon (IFN)-inducible gene expression has been consistently found in peripheral blood cells of many SLE patients. In addition, a few gene variants encoding proteins participating in the type 1 IFN pathway have been associated with SLE, suggesting the important role of type I IFN-inducible genes and pathway in the pathogenesis of SLE. The identification of susceptibility genes and the delineation of genetic mechanisms mediating the disease pathogenesis should provide new targets for more focused therapy in the near future. All these studies will be reviewed in this chapter, with an emphasis on the more recent publications since the last edition.

Genetic Epidemiology Studies

Familial Aggregation of SLE and Other Autoimmune Diseases

The prevalence of SLE in the U.S. population is 15 to 122 cases per 100,000 persons reported among studies varying over time, place, and methods of case identification (1). This variation may be partially attributed to ethnic diversity that the disease is more prevalent in Hispanics and African-Americans. A recent survey of 20,050 adult Americans yields an estimate of 241 self-reported, physician-diagnosed SLE cases per 100,000 persons, projecting 108,300 adult women afflicted with SLE (2). Compared to the population prevalence of SLE, the disease is much more prevalent among family members of SLE patients. A familial prevalence of 10% to 12% has been documented using surveys of several hundreds of SLE patients who reported having at least one first-degree relative with the disease (3 ,4). Using a case-control design of 77 SLE patients and 77 controls (matched for age, gender, and race), Hochberg also reported significant familial aggregation of SLE that 10% of the SLE probands have at least one first-degree relatives affected with disease compared to only 1% in the controls (5). The prevalence of SLE in female first-degree relatives was estimated to be 2.64 per 100 SLE patients and 0.4 per 100 normal controls. A study examining 1,177 Latin American patients affected with SLE has reported familial aggregation of SLE in 9.9% of relatives of the SLE probands (6% first-degree relatives, 2.6% second-degree relatives, and 1.3% third-degree relatives), as well as familial aggregation of rheumatoid arthritis (6.7% of the relatives) and other autoimmune diseases (2.0%) (6). Comparing risk for SLE between relatives of various degrees, their data support a polygenic additive model rather than multiplicative model for SLE inheritance. Familial clustering of autoimmune diseases may be explained by a common set of susceptibility genes shared among in family members controlling clinically distinct autoimmune diseases (7). Examples of a single susceptibility gene shared in more than one autoimmune diseases include cytotoxic T lymphocyte antigen-4 (CTLA-4) gene in both type 1 diabetes and Graves disease (8), NOD2/CARD15 in Crohn

disease, psoriatic arthritis, and Blau syndrome (9 ,10 ,11), PDCD1 in SLE, type 1 diabetes, and rheumatoid arthritis (12 ,13 ,14), and PTPN22 in type 1 diabetes, rheumatoid arthritis, SLE, and/or autoimmune thyroid disease (15).

Twin Studies

Twin studies can offer clues to distinguish between genetic and environmental influences in the pathogenesis of a disease. Because twins usually share the same environment, concordance of disease in monozygotic twins and discordance in dizygotic twins imply genetic contribution to disease susceptibility. The concordance rate in monozygotic twins (24% to 58%) is approximately ten times the rate in dizygotic twins or in siblings (2% to 5%) (16 ,17). The deviation from 100% concordance in monozygotic twins indicates nongermline factors also are required for the development of disease, which may include environmental triggers, the diverse repertoire of immunoglobulin genes and T cell receptor genes, the inactivation of X chromosome, or genetic imprinting (18). In the largest twin study in SLE thus far, the 24% concordance rate in 45 monozygotic versus 2% in 62 dizygotic twins (17), is similar to those found in type 1 diabetes, multiple sclerosis, and rheumatoid arthritis (18 ,19).

Sibling Recurrence Risk

The risk for siblings of SLE patients to develop disease (λs, sibling recurrence risk (20)) has been estimated to be as high as 29 times than that of the general population (6). The value of λs has been used to assess evidence for sibling familial clustering of a disease. The λs of 29 in SLE is in the range of that observed in other autoimmune diseases, for example, 8 in rheumatoid arthritis, 15 in type 1 diabetes, 20 in multiple sclerosis, and 54 in ankylosing spondilitis (19). Comparing risk for SLE between relatives of various degrees, their data support a polygenic additive model rather than multiplicative model for SLE inheritance.

In summary, the importance of genetic influences on SLE has been consistently supported by studies of populations, twin concordance rates, and aggregation of disease in families. In addition, the existence of multiple inbred strains of mice that spontaneously develop lupus-like disease further lends support for a genetic basis for SLE (reviewed in Chapter 7). What were these genes that increase risk for SLE? Many investigators have addressed this question. These studies are reviewed below.

Genetic Studies in SLE

Genetic Terms and Methods for Genetic Studies

The term “complex trait” refers to the lack of direct correlation between a phenotype and a genotype (21). For example, SLE is a complex trait that does not exhibit classic Mendelian recessive or dominant inheritance attributable to a single gene locus. The complexity can arise either because the same genotype can result in different phenotypes (modified by effects of environment, stochastic events, or interactions with other genes) or different genotypes can result in the same phenotype. Since the disease definition is dependent upon fulfillment of 4 of the 11 ACR criteria (22 ,23), SLE represents an array of heterogeneous phenotypes and thus further increases its complexity.

Genetic dissection of complex traits has been approached by two main methods: association and linkage (21). Historically, association studies that use the case-control design have been commonly used to compare unrelated affected and unaffected individuals from a given population. An allele A of a candidate gene is associated with the disease of interest if it is present at a significantly higher frequency in affected patients than unaffected controls. This method is suitable to detect genes with small effect because it is relatively easier to recruit large numbers of unrelated subjects than families with particular family structures. This study design needs to carefully match the subjects and the controls with respect to the age, gender, genetic background, and environmental exposure to avoid false-positive assertions caused by unanticipated differences between the two groups.

The availability of large numbers of mapped DNA markers throughout the whole genome has facilitated linkage analysis. Linkage analysis use families with multiple affected members to assess cosegregation of the test maker allele with a phenotype of interest. A model can be proposed to explain the inheritance pattern of phenotypes and genotypes observed in pedigrees (21). Alternatively, in the absence of a known mode of inheritance of the trait, an allele-sharing method can be used because affected relatives should show excess allele sharing of the test marker if it is near the gene conferring the phenotype. The commonly used markers include microsatellites (di-, tri-, or tetranucleotide repeats varying greatly among individuals in size) and single nucleotide polymorphisms (SNPs). Traditionally, the application of genome-wide scans using approximately 400 microsatellites in complex diseases have led to the identification of many large linked genomic intervals of 20 to 30 cM (1cM is about 1 million base pairs of DNA) that are likely to contain disease susceptibility genes. In the past decade, dramatic advances in high-throughput technology and bio-informatics have led to the determination of the complete human genome as well as the chromosomal location of almost all human genes (24 ,25). The most common DNA variations in the human genome are SNPs, occurring on average once every 200 base pairs. Although biallelic SNPs are not as polymorphic as individual microsatellite, the abundance of SNPs in the human genome makes them well suited to generate high-resolution genetic maps. Recently, whole genome scans using >10,000 SNPs have dramatically decreased the intermarker spacing, improved the information content, and vastly narrowed the linked intervals in comparison to traditional microsatellite based scans (26 ,27).

Once an approximate estimate of the linked interval has been s identified, one can make use of linkage disequilibrium for a more accurate location. Linkage disequilibrium occurs when certain alleles of two physically closely located genes (or DNA markers) appear to be jointly transmitted more frequently than expected from their respective frequency. As the result of linkage disequilibrium, a particular combination of alleles at a set of closely linked loci, termed a haplotype, tends to be transmitted as a block from generation to generation. Thus, marker loci near a susceptibility gene are often observed to be in linkage disequilibrium with the disease, resulting in significant differences in the relative frequencies of marker alleles among affected individuals from those in the general population. Although population-based association studies are powerful, the family-based association design, for example, the transmission disequilibrium test (TDT), has the advantage of avoiding population stratification that may cause spurious associations (21). The TDT method on families uses the preferential transmission of the test allele(s) from heterozygous parents to affected children as evidence for association between the test allele and the disease (28). Currently, a large international consortium, the HapMap Project, is working to identify a large portion of SNPs in different human populations, haplotype blocks derived from these SNPs, and tagSNPs that depict a particular haplotype structure by eliminating redundant SNPs in strong linkage disequilibrium (29). Common SNPs (a minor allele frequency >10%) are of interest because of the common disease/common variant hypothesis (CDCV)(30). Because association analysis is expected to be more powerful for the detection of common disease alleles that confer modest disease risks (31), mapping complex disease loci using whole genome association studies has been gaining popularity (32). This promising approach has been supported by the recent success in the identification of a major gene variant, the Tyr402His of the complement factor H, that accounts for 20% to 50% of the overall risk in developing age-related macular degeneration (33 ,34). The international consortium for SLE genetic study has begun a whole-genome association study using 500,000 SNPs. In the coming years, we anticipate many SLE susceptibility genes will be identified.

Genetic Linkage of Genomic Loci to Human SLE

Linkage analysis studies families containing multiple relatives affected with the same disease. The rationale is that DNA markers located near a susceptibility gene will be transmitted together with the disease gene in affected members of each family because they are likely to share the same susceptibility gene allele at a particular disease locus (21). The identified murine lupus susceptibility loci (the overlapping Sle1/Nba-2/Lbw-7 loci mapped to the distal end of mouse chromosome 1, reviewed in (35)) provided a guide to explore the syntenic human chromosomal region, which led to the initial identification of linkage to human SLE of the chromosome 1q41-q42 region (36). Subsequently, 11 genome-wide scans (37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46) and 8 fine mapping linkage analyses in various cohorts (47 ,48 ,49 ,50 ,51 ,52 ,53 ,54) have shown many genomic locations that may harbor SLE susceptibility genes (Table 6-1). Despite tremendous variations in their ethnic compositions, sample sizes, family structures (affected sibpairs containing nuclear families and pedigrees containing multiple generations), and geographic locations (Table 6-1), eight loci (1q23, 1q31, 1q41–42, 2q37, 4p16–15.2, 6p21–11, 12q24, and 16q12–13) have reached the threshold for significant linkage to SLE (38 ,39 ,40 ,43 ,45 ,46 ,47 ,51) (Table 6-2), and all eight have been confirmed in at least one independent cohort for linkage to SLE (37 ,39 ,40 ,44 ,45 ,46 ,48) (Table 6-2) using Lander and Kruglyak's criteria for interpretation of linkage statistics (55). Of interest, not a single, common locus was identified in all these scans, and the MHC containing region (6p21) is not the strongest locus detected in these scans. Replication of significant linkage of a locus provides the best evidence for the presence of putative susceptibility gene(s), which warrants further fine mapping studies to localize the disease predisposing gene(s).

Four recent genome scans for lupus susceptibility genes have been reported since the last edition, and their major findings include (1) 12q24 is a newly established and confirmed locus that is mainly observed in Hispanic and European American families (46); (2) a nationwide study in Finland (a geographically isolated population) including 35 multiplex SLE families (containing 73 patients and 96 healthy relatives) has provided support for linkage at 14q21–23, the HLA region, 5p13, and 6q25–27 (42); (3) a genome scan of 62 multiplex SLE families (containing 88 affected and 456 total sibling pairs) has provided evidence for linkage to four previously reported (1q23, 2q33, 16q12, and 17q21–23) and four novel (3p24, 10q23–24, 13q32, and 18q23) genomic intervals (37); (4) evidence for linkage of 17p12-q11 to SLE has been reported using 20 Argentine SLE multiplex families (41). A meta-analysis of 9 individual genome scans containing 605 families with 1,355 SLE patients has identified two loci, 6p22.3–6p21.1 and 16p12.3–16q12.2, reaching genome-wide significance (56), which further confirms chromosomes 6 and 16 harboring lupus susceptibility genes.

The extensive heterogeneity of clinical and laboratory manifestations among SLE patients has prompted various approaches to reduce disease heterogeneity, and presumably genetic heterogeneity. One methodology adopted by Dr. Harley and his colleagues, stratifying linkage analysis on a subset of pedigrees in which one SLE patient has a particular clinical manifestation, has yielded more than 10 publications reporting strong evidence for linkage (57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67) (Table 6-3). Because many parallel studies have been conducted, SLE patients who exhibit multiple manifestations used in pedigree stratifications. Stratification on a disease subset can result in a reduction in sample size, which makes the result more vulnerable to random fluctuations, thus highlights the importance of independent confirmation of the findings. Furthermore, may skew linkage

results by being overrepresented in many parallel studies. To this end, linkage at 5p13 (SLER1) to SLE stratifying on families containing one member affected with SLE and self-reported RA has been confirmed (65) (Table 6-3). Similarly, the SLEV1 (17p13), SLEN1 (10q22.3), and SLEN2 (2q34–35) have also been verified (Table 6-3). Alternatively, a principal component approach has used seven major SLE-related phenotypes plus age at SLE onset and race to conduct multivariate analysis of the genome scan data, which identifying suggestive linkage of several SLE-related traits, however the clinical implication of this method seem less clear (68). Since the same (or enlarged) genome scan data
from the OMRF SLE multiplex pedigrees have been used to conduct one principal component analysis (68), 4 affected relative pair linkage analyses (40 ,45 ,46 ,69), and 11 linkage analyses on selected pedigrees in which one affected member exhibiting a specific disease feature (46 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,66 ,67), the possibility of false discoveries as the result of multiple testing needs to be considered. Familiality of thrombocytopenia, discoid rash, neurologic disorder (defined as seizure or psychosis), hemolytic anemia, co-occurring neurologic disorder plus hemolytic anemia, and age at SLE diagnosis has been observed in 159 sibpairs affected with SLE (70). Linkage to familial component phenotypes of SLE may reduce the disease heterogeneity facilitating to the localization of susceptibility genes for a particular clinical manifestation. The identification of many chromosomal regions linked to SLE has paved the way to fine map the genomic intervals of interest for the identification of putative SLE susceptibility genes.

Table 6-1: Comparisons of 11 Whole Genome Scans in Human SLE

Compared to other autoimmune diseases such as type 1 diabetes mellitus and multiple sclerosis, currently available results from independent linkage analyses in human SLE have been remarkably consistent. Of interest, 1q23–42 is syntenic to the identified susceptibility loci on murine chromosome 1 (71). Several putative murine susceptibility genes located in the distal end of the mouse chromosome 1 have been identified including Ifi202 (an interferon [IFN]-inducing gene for the Nba2 locus derived from the NZB strain), Cr2 (complement receptor 2 gene for the Sle1c locus), and the Slam/Cd2 gene cluster (for the Sle1b locus derived from NZW strain) (72 ,73 ,74). Although none of these murine candidate susceptibility genes have been reported to be associated with human SLE, their gene products may participate in molecular pathways common in the pathogenesis of both murine and human SLE.

Within the 8 genomic segments (1q23, 1q31, 1q41–42, 2q35–37, 4p16–15.2, 6p21–11, 12q24, and 16q12–13) that strongly linked to human SLE, 10 positional candidate susceptibility genes have also been associated with human SLE (Table 6-4). Because evidence implicating these genes in susceptibility to SLE includes both linkage and association that are two independent and complementary approaches, these genes (or gene complexes) (MHC haplotypes, CRP, FCGR2A, FCGR3A, FCGR2B, PARP, TLR5, PDCD1) will be reviewed as followed.

Genes within SLE Significantly Linked Regions (Table 6-4)

(1) SLE-Associated Genes at 6q21

The General Review of the MHC Region

The MHC (also referred as HLA) region contains more than 200 identified loci within about 4 × 106 base pairs (75). It is the most gene-dense region of the human genome that has been completely sequenced thus far (76). Historically, the MHC region is known to specify histocompatibility genes and can be subdivided into class II (centromeric), class III, and class I (telomeric) regions. The class I and class II molecules are the most polymorphic human proteins known to date. Since these molecules shape the immune repertoire of an individual, the extreme polymorphism is thought to evolve in response to infectious pathogens. Perhaps it is the reason why the MHC is associated with more diseases than any other region of the human genome, and is linked to most, if not all, autoimmune disorders (76 ,77).

Table 6-4: Genomic Segments That Have Reached the Threshold for Significant Linkage to SLE and Have Been Confirmed in an Independent Cohort

Cytogenetic Location	Locus Name	Candidate Genes
1q23		CRP, FCGR2A, FCGR3A, FCGR2B
1q31		
1q41–42	SLEB1	PARP, TLR5
2q35–37	SLEB2	PDCD1
4p16–15.2	SLEB3	
6p21–11		MHC haplotype
12q24	SLEB4	
16q12–13		NOD2/CARD15, OAZ

The MHC class I region contains the HLA-A, B, C, E, F, G, H, J, and X loci (75 ,76 ,78). Each individual expresses at least three different class I proteins encoded by HLA-A, B, and C in combination with a nonpolymorphic protein—ß2 microglobulin. The gene for ß2 microglobulin, despite it encodes a part of the MHC class I molecule, is located on chromosome 15. The MHC-class I A, B, and C molecules are extremely polymorphic, expressed on all nucleated cells, and most highly in hematopoietic cells. The additional genes in the class I region, E, F, G, H, J, and X loci, are class I-like genes encoding class IB molecules, which are important in innate immunity such as mediating recognition by natural killer (NK) cells.

The MHC class II region includes the genes for the α and ß chains of the antigen-presenting class II MHC-molecules HLA-DR, DP, and DQ, the genes encoding the DMα and DMß chains, and the genes encoding the α and ß chains of the DO molecule (encoded by DNα and DOß) (75 ,76 ,79). Additionally, the LMP 2 and 7 genes encoding proteosome subunits (necessary for generating peptide fragments form endogenous proteins to bind class I molecules), and the TAP-1 and 2 genes (jointly encoding a TAP heterodimer to transport peptide from the cytosol to the endoplasmic reticulum) are also in the class II region. The DM molecules act as a chaperone and catalyze peptide binding to class II- DR, DP, and DQ molecules, while DO molecules serve as a negative regulator of DM. The class II molecules are highly polymorphic, there are 239 DRß alleles, 20 DQα, 35 DQß, 12 DPα, and 80 DPß alleles found mainly in

Caucasian populations with the exception of a single DRα allele. The true polymorphic nature of these molecules awaits detailed studies worldwide. An individual can use DR, DP, or DQ molecules to present peptide antigens to T cells that are recognized by T cell receptors initiating immune responses. These MHC class II molecules are glycosylated heterodimer membrane proteins normally expressed in a subset of hematopietic cells and thymic stromal cells. Upon exposure to inflammatory cytokine interferon-γ, other cell types can be induced to express class II molecules.

It is worth noting that there is no wild type for class I and II molecules. Particular alleles of these antigen-presenting molecules that have been associated with autoimmune diseases are also commonly found in a normal, unaffected population (76). The presence of multiple class I and II loci allows a broad spectrum of peptides that can be presented to T cells of an individual. Allelic variation of these molecules appears to be restricted to the amino-terminal domains (α1 and α2 domains of class I molecules and ß1 domain of class II molecules) at positions that line the peptide-binding cleft or at exposed surfaces of the outer domain of the molecule. Additionally, most individuals are heterozygotes expressing different alleles inherited from both parents at class I and II loci. The large number of different alleles of these antigen- presenting molecules also allows a diverse immune response to a pathogen in any population. The distribution of allelic frequency of class I and II molecules varies among ethnic groups, and may show regional differences as well. This frequency variation and linkage disequilibrium of the MHC region give rise to various extended haplotypes frequently observed among separate populations.

The MHC class III region contain genes encoding the complement component C4 (C4A and C4B genes), C2 and Factor B (Bf gene), cytokine tumor necrosis factor alpha (TNF-α) (TNFA gene) and lymphotoxins (LTA and LTB genes), and heat-shock protein HSP 70. Physically near the two C4 genes is the gene encoding 21-hydoxylase, an enzyme involved in steroid synthesis. Within the class III region C4A and C4B are the most polymorphic genes including at least 14 C4A and 17 C4B alleles (80 ,81). Frequent deletions and gene duplication events of the C4 genes further contribute to their genetic polymorphism (82 ,83 ,84).

Genetic Association of MHC Alleles with SLE

MHC Class II Molecules and SLE

Approximately 30 years ago, positive association between HLA-B8 and SLE was reported (85 ,86 ,87). Later studies showed weak or no association between SLE and class I molecules, but very consistent association with HLA-DR2 and DR3 in many populations (88 ,89 ,90). The more recent DNA typing has subdivided the previous DR2 and DR3 specificity into continuously increasing numbers of DRB1 alleles. Case-control studies have demonstrated the association between SLE and HLA-DR3 (or HLA-DRB1*0301; one of the allele from the previous DR3 specificity) in many Caucasian populations including American Caucasians, Australians, British Caucasians, Spaniards, Italians, Germans, Greeks, Scandinavians and Koreans (91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113). The association of SLE susceptibility and DR2 (or HLA-DRB1*1501; one of the allele from the previous DR2 specificity) has also been shown in studies of Caucasians from the United States, Australia, United Kingdom, Germany, Dutch, as well as Asians from Japan, China, Korea, and Singapore (94 ,96 ,103 ,106 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123). There are reports showing no association between SLE susceptibility and DR3 and/or DR2, which include studies of Bulgarians, Greeks, Indians, and Chinese in Taiwan (124 ,125 ,126 ,127 ,128 ,129). Taken into account of the heterogeneous manifestations of SLE including various autoantibodies, the confirmed association of DR2 and DR3 with SLE is an important and remarkable finding. The estimated relative risk of either DR2 or DR3 for the development of SLE is approximately two- to threefold in Caucasians. A recent multicenter study of 534 SLE patients and 958 controls from seven European countries has shown association of DRB1*03, DRB1*15, and DRB1*16 with SLE with odds ratio of 2.2 (95% confidence interval [CI] 1.8 to 2.9), 1.6 (1.2 to 2), and 1.4 (1.1 to 2), respectively (130).

In Mexican Americans (who have ancestry of Mexicans, European Caucasians, and Native Americans), HLA-DRB1*0301(DR3) (131 ,132) and DRB1*08 (DR8) (100 ,132) have been associated with SLE. This result was not confirmed in a study of Mexican Mestizo population (133). African Americans are known to have varying degrees of African, European Caucasian, and Native American ancestry. Several studies of African Americans yielded weak and varying associations of DR alleles (none, DR2, DR3, or DR7) with SLE (100 ,105 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141). In genetic studies of Mexican Americans and African Americans, it is especially challenging to match ethnic ancestry of the cases and controls.

The lack of consistency of the observed association might be derived from the unmatched SLE cases and normal controls (21). The family-based association test, such as the TDT that uses intrafamily controls (28), can avoid this problem in assessing the association between MHC class II alleles and SLE susceptibility. Association between the DRB1*1501(DR2) and SLE has been observed in our 91 Caucasian families using the TDT (142).

MHC Class II Alleles and Autoantibodies

MHC class II alleles may be more strongly associated with autoantibody subsets than with the disease status of SLE because of their pivotal role in T cell dependent antibody responses. A few examples of genetic association between class II alleles and specific autoantibodies are described below.

Anti-Ro (SSA) and anti-La (SSB): These antibodies are frequently present in patients affected with either SLE or Sjogren syndrome. These antibodies were initially associated with HLA-DR3 (114 ,143 ,144 ,145) or DR2 in Caucasians. Hochberg et al. showed that the presence of both anti-Ro and anti-La together with DR3 occurred

frequently in SLE patients with older age of disease onset, while anti-Ro in the absence of anti-La and DR2 were present in patients with younger age of disease onset (136). Subsequently, antibodies to Ro and La seem to be most significantly associated with the HLA-DQ alleles in linkage disequilibrium with DR2, DR3, and other MHC haplotypes (146 ,147 ,148). The strong association between anti-La and DR3 (OR = 71) and DQB1*0301 (OR = 35) was recently observed in a UK case-control study (112). Molecularly, they are commonly the HLA-DQA alleles with glutamine at position 34 and DQB alleles with leucine at position 26 (149 ,150). The anti-Ro response has been resolved into antibodies to 52kD and 60kD Ro/SSA molecules. The response to the 52kD Ro protein has been associated with HLA-DR3 and DRB1*0301, DQA1*0501, and DQB1*0201 (151 ,152). The presence of anti-Ro/SSA alone is mainly associated with DR2, and DQw1 (153), while the presence of both anti-Ro/SSA and anti-La/SSB is associated with HLA- B8, DR3, DRw52, and DQw2 (153).

Antiphospholipid antibodies: These antibodies (anticardiolipin [aCL] antibodies and lupus anticoagulant [LAC]) are frequently found in patients affected with primary antiphospholipid syndrome (APS) and a subset of SLE patients. Clinically, they are associated with both venous and arterial thrombosis, and recurrent fetal loss. An increased frequency of class II alleles HLA-DR7, DR4, and DRw53 (DRB4*0101) were reported in studies of primary APS (154 ,155 ,156) and supported by studies of patients affected with SLE or with secondary APS (157 ,158 ,159 ,160 ,161). The DRB1*0402 allele (one of the alleles of DR4 specificity) was highly represented in both aCL and anti-ß2 glycoprotein I positive patients from a large cohort of European SLE patients (161). A sharing of HLA-DR4 haplotype in affected members was noted in two families multiplex for SLE and manifestations of APS (162 ,163). However, a study of seven families in which 30 of the 101 family members met criteria for APS failed to show linkage of HLA with APS (164). Segregation studies of these families suggested an autosomal dominant (or codominant) inheritance of the disease. Debastiani et al. (165) concluded that the genetic predisposition to APS is partially resulted from HLA alleles including DR4, DR7, and DRw53. DR4 and DR7 are independently associated with aCL while the association of DRw53 may be linked with either DR4 or DR7. A subset of aCLs bind to ß2 glycoprotein I (ß2GPI), a phospholipid-binding plasma protein. In a combined cohort of patients with primary APS, SLE, or another connective tissue disease, anti-ß2GPI autoantibodies were found to be associated with HLA-DQB1*0302 carried on DR4 haplotypes and DRB4*0101 in Mexican Americans, with HLA-DR6 (DR13) haplotype DRB1*1302-DQB1*0604/5 in blacks, but not with HLA-DR7 in any of the studied Caucasians, Mexican-Americans, and African Americans (166). When analyzed as a combined multiethnic cohort, HLA-DQB1*0302, and the combined DQB1*0301, *0302, and *0303 alleles showed the most powerful association with anti- ß2GPI (166). ß2GPI is a member of the complement control protein (CCP) superfamily. Genetic variations of the 5th CCP domain of ß2GPI (at amino acid positions 247, 306, and 316) that may affect its binding to phospholipids have been suggested to influence the generation of anti-ß2GPI antibodies in APS patients (166 ,167 ,168 ,169 ,170). A correlation between the valine/leucine polymorphism at position 247 and the production of anti-ß2GPI in primary APS patients was observed in British Caucasians (168), and was subsequently supported by studies of Asian patients with APS (especially as a major risk factor in those V/V homozygotes) but not of American Caucasians and African Americans (169). Kamboh et al. reported that polymorphisms at codons 306 and 316 had a gene-dosage effect on plasma concentrations of ß2GPI, and the Trp to Ser at codon 316 protected against the production of anti-ß2GPI in American Caucasian SLE patients (171). The protective association of this polymorphism was not supported by studies of SLE and APS patients from the Netherlands (172) and the United States (170). Instead, Gushiken et al. suggested that Ser316 polymorphism may be an independent risk factor for thrombosis in patients with SLE (170).

Anti-Sm and RNP antibodies: Anti-Sm antibodies are highly specific for SLE including the binding specificity to U1, U2, U4, U5, and U6 small nuclear ribonuclearproteins (snRNPs). These autoantibodies are present frequently in African-American SLE patients (173). Anti-RNPs often occur with anti-Sm in SLE patients, or in the absence of anti-Sm in patients with mixed connective-tissue diseases (MCTD). Many class II alleles have been implicated in association with anti-Sm or anti-RNP including HLA-DR4 in Caucasians (144 ,174) and Asians (175) and DR2 in Caucasians (174) and blacks (176), as well as HLA-DQB1*0302 in Caucasians (175) or in Mexican Americans (131).

Anti-dsDNA antibodies: These antibodies may contribute to the development of glomerulonephritis. This antibody response has been associated with HLA-DR3 (177), DR2 (114 ,178), and DR7 (179). Their respective linked HLA-DQ alleles may also responsible for the observed associations.

In summary, the MHC associations with many autoantibodies including anti-dsDNA, antiphospholipid, anti-RNP, and Sm are very complex and inconclusive at present. Other MHC class II genes including DP, DM, Tap1, and Tap2 alleles have either no or weak and inconsistent associations with SLE.

SLE-Associated Genes within MHC III Region

Complement Component C2 and C4

The complement component genes within the class III region include C2, C4A, C4B, and factor B. They are closely linked and usually inherited as a single group termed a

complotype. Hereditary C2 deficiency in Caucasians is located on an HLA-A25, B18, DR2 (DRB1*1501), DQB1*0602 haplotype (180 ,181). This deficiency is the result of a 28-bp deletion leading to a splicing defect of the C2 transcript (182). Heterozygous deficiency is common in Caucasian populations (approximately 1% to 2%), and is increased among SLE patients in several studies (181 ,183 ,184), but not in another report (185). Homozygous C2 deficiency is present in approximately 1 in 10,000 Caucasians, and about 30% of them develop SLE or lupus-like disease (186 ,187). These patients frequently have anti-Ro (but not anti-La) autoantibodies (188) (189). In summary, C2 deficiency may represent an infrequent risk factor for SLE in Caucasian patients (181), but not in Asians (124) or African Americans (184).

Plasma C4 is the protein product of two C4A genes and two C4B genes. Although double homozygous deficiency of C4 (producing no C4) is rare, approximately 70% of these individuals develop SLE or lupus-like disease (190 ,191 ,192 ,193 ,194 ,195 ,196 ,197). More commonly, individuals have homozygous null alleles at either C4A or C4B locus, often with reduced levels of serum C4. Functional differences between C4A and C4B have been demonstrated. Many Caucasian populations studied revealed an association of C4A deficiency with SLE in which C4A*QO (the null allele of C4) allele frequencies are 0.25 to 0.41 in patients versus 0.10 to 0.23 in controls (96 ,198 ,199 ,200 ,201 ,202 ,203). The C4A*QO is most often caused by the deletion of the C4A and 21-OHA genes on the HLA-B8, Cw7, DR3, C4A*QO, C4B1 haplotype, a common MHC haplotype in Caucasians (202 ,204 ,205 ,206). Because the frequency of DR3 is also increased in patients, and because the C4A null allele is not increased in DR3-negative patients (96 ,207), it is difficult to determine the relative contribution of separate loci within the extended MHC haplotype. Studies of Asians in whom C4A null alleles are within other MHC haplotypes have supported that the lack of C4A protein may predispose to SLE. A recent review of more than 35 publications has concluded that 40% to 60% of SLE patients from multiple ethnic/race groups (including northern and central Europeans, Anglo-Saxons, U.S. Caucasians, African Americans, Asian Chinese, Koreans, and Japanese) have heterozygous or homozygous deficiencies of C4A genes (208). Among different ethnic groups, various molecular mechanisms result in C4AQ0 (the null allele of C4) with the estimated relative risk in the range of 2.3 to 5.3 for SLE (208). The significant association between C4AQ0 and SLE in the context of multiple MHC haplotypes, ethnic/racial groups, and molecular mechanisms strongly support the notion that no or low expression level of C4A protein predisposes to SLE susceptibility. C4B deficiencies have been associated with SLE in Spanish, Mexican, and Australian Aborigine populations (208). Taken together, both C4A and C4B proteins are important regulators of autoimmunity, which is supported by the observation that C4 deficient mice spontaneously develop autoantibodies to dsDNA and have glomerular depositions of immune complexes (209).

Tumor Necrosis Factor

In addition to complement components C2 and C4 loci, within the MHC class III region the loci for TNF encoding TNF-α, TNF-ß, and lymphotoxin-ß have also been implicated in SLE susceptibility. Polymorphisms of the TNF-α gene, which is located within the MHC class III region, have been associated with SLE. Reduced levels of TNF-α production associated with genetic polymorphisms at or near the TNF-α, gene were observed in one lupus-prone mouse model and in DR2 positive SLE patients (210 ,211 ,212). Compared to the DR3 positive SLE patients, DR2 positive patients were also associated with increased incidence of lupus nephritis (210). In mice, recombinant TNF-α replacement could delay in the development of lupus nephritis (211 ,212). In humans, treatment with a monoclonal antibody to TNF-α (Remicade, Centocor, Malvern, PA) in rheumatoid arthritis patients occasionally induced anti-dsDNA antibody and a self-limiting clinical lupus syndrome (213). These findings suggest that (1) reduced levels of TNF-α may predispose to SLE, and (2) polymorphisms of TNF-α gene may influence its level of production.

In recent years, polymorphisms in the promoter region of the human TNF-α gene have been studied extensively in association with many autoimmune diseases (reviewed in (214)). Among them, -308A TNF-α has been a major focus of these studies for its association with SLE either independently or as a part of an extended MHC haplotype HLA-A1-B8-DRB1*0301-DQ2 (215) in Caucasians (109 ,216 ,217 ,218), Asians (124), African Americans (219) and Mexican Mestizos (133). The -308A TNF-α allele has been shown to confer higher transcriptional activity than the –308G TNF-α allele (220). However, neither the disease association nor the enhanced activity has been consistently demonstrated in other similar studies (214 ,220). Therefore, additional studies are needed to help clarify the role of genetic polymorphisms of the TNF-α in susceptibility to SLE.

MHC Haplotypes and SLE

The early finding of the association of B8 with SLE is likely attributable to B8-DR3 (DRB*0301 according to the new nomenclature) extended haplotype that contains a complement C4A null allele (C4A*QO), DQA*0501, and DQB1*0201. This haplotype is fairly common in Caucasian populations at a frequency of approximately 25%, and is associated with multiple autoimmune disorders. The other DR3 containing extended haplotype—HLA-B18-C4B*QO-DRB1*0301-DQA1*0501-DQB1*0201 frequently found in Spain and Mexico has also been associated with SLE. Null alleles of C4 (especially C4A*QO) have been implicated in the pathogenesis of SLE, while the rare deficiency of all four C4 genes clearly confers increased risk for lupus-like symptoms. The DR2-containing SLE-associated haplotype (HLA-B7-DRB1*1501-DQA1*0102-DQB1*0602) frequently found in Western Europeans and Asians is not linked to a C4 null allele. Various studies have used different ethnic populations to investigate the role of C4A null in SLE. Because of the

tight linkage disequilibrium of the MHC region, it has been difficult to determine whether a single locus or multiple independent loci mediate the observed association of extended haplotypes. In summary, the MHC region is likely to contain multiple genes influencing susceptibility to lupus via separate pathways. The impact of these genes appears to be quite variable among the studied groups using the current approaches. It is generally agreed that determination of relative contribution of each implicated locus within the MHC is a very difficult but important task for the next decade.

Finemapping of HLA Region

The genomic segment harboring the HLA is one of the eight major SLE susceptibility loci that have reached the threshold for significant linkage and have been confirmed in at least one independent cohort using guidelines proposed by Lander and Kruglyak (55). Fine mapping of the linked region have narrowed the search to a chromosomal segment containing the HLA class II gene of three risk haplotypes: DRB1*1501 (DR2)/DQB1*0602, DRB1*0301 (DR3)/DQB1*0201, and DRB1*0801 (DR8)/DQB1*0402 (221). This study used approximately 100 microsatellite markers and a collection of >300 families (mainly Caucasians) to narrow the SLE-associated haplotype blocks to approximately 500 kb except the DRB1*0301 containing block which is approximately 1 Mb because of the extremely strong linkage disequilibrium. Nearly two thirds of Caucasian SLE patients harbor at least one of the three risk haplotypes, in which the DRB1*0801 containing haplotype is relatively rare. The estimated haplotype relative risk is in the range of 1.5 to 2.3 for harboring one copy and 1.7 to 5.2 for any two copies of risk haplotypes. Of interest, both the class I and III regions, containing the genes encoding TNF-α, and complement components C2 and C4, have been excluded in the DRB1*1501 containing risk haplotype (221).

(2) SLE-Associated Genes at 1q23

CRP (1q23)

The genes for acute phase reactants CRP and serum amyloid P component (SAP) are positional candidates for a murine lupus susceptibility locus (222). Both of these proteins bind to major autoantigens in SLE such as membrane components and nuclear materials released during cell death and/or exposed on the cell surface during apoptosis (223). Abnormally low CRP levels in SLE was attributed to reduced synthesis (224). Low basal levels of serum CRP were associated with inheritance of minor alleles at two SNPs of the CRP gene (rs1800947 located within codon 188 and rs1205 in the 3′ UTR), and the minor allele of the latter SNP was also associated with SLE in 586 UK simplex families (225). Another study showed two CRP promoter SNP haplotypes (rs3093062 located at –409 and rs391244 at –390), which could influence binding affinity to transcription factors and the promoter activity, were associated with basal levels of serum CRP in 267 healthy controls independent of age, gender, or race (226). Of interest, CRP may prevent inflammation and tissue damage as shown that a single dose of CRP can reverse lupus nephritis and nephrotoxic nephritis in a murine model (227).

FCGR2A, FCGR3A, and FCGR2B (1q23–24)

The Fcγ receptors expressed on the cell membrane of different leukocytes are a family of molecules that bind to the Fc portion of IgG molecules that each recognizes one or a few closely related IgG isotypes (75 ,228). The low affinity FcγRII and FcγRIII bind to polymeric IgG present in immune complexes, which mediate internalization of immune complexes, antibody-mediated cytotoxicity, and the release of cytokines (229). These receptors have cytoplasmic tails containing either the immunoreceptor tyrosine-based activation motif (ITAM) or the immunoreceptor tyrosine-based inhibition motif (ITIM). Co-aggregation of ITAM-containing FcγR molecules triggered by binding to immune complexes results in cell activation, phagocytosis, and the release of proinflammatory cytokines. In contrast, co-aggregation of ITAM and ITIM-bearing FcγR molecules causes abrogation of Ca2+ influx, inhibition of phagocytosis, and release of pro-inflammatory cytokines. The important role of impaired clearance and tissue deposition of immune complexes in the pathogenesis of SLE has led to the identification of functional polymorphisms of FcγRII and FcγRIII genes and their association with SLE as described below.

FcγRIIa (CD32) molecules, expressed on cell membranes of monocytes, macrophages, neutrophils, and platelets, is an ITAM-containing stimulatory receptor (230). FcγRIIa is the major receptor for the IgG2 subclass, but it is capable of binding to all IgG isotypes (230 ,231). A functional SNP that results in either the histidine [H] or the arginine [R] residue at codon 131 are two codominantly expressed alleles in multiple studied ethnic groups, in which the R131 binds less efficiently to IgG2 resulting in delayed clearance of immune complexes (229). In lupus nephritis patients of Dutch Caucasians, the R131 allele and R131 homozygotes were significantly overrepresented (231). Simialrly, African-American lupus nephritis patients had significant under-representation of FcγRIIa-H131 homozygosity (232). This skewed distribution of FcγRIIa alleles was further confirmed in Korean lupus nephritis patients and SLE patients as a whole (233), supporting the conclusion that the FCγRIIa-R131 allele increases the risk for lupus nephritis. However, this notion was not supported in many similar studies including American, British, Italian, Dutch, or German Caucasians, Afro-Caribbeans, Chinese, or Koreans. Despite the lack of association in German Caucasians, SLE patients homozygous for the FcγRIIa-R131 allele had higher frequencies of proteinuria, hemolytic anemia, hypocomplementemia, and an earlier age of onset of SLE. There was a strong trend toward skewing of FcγRIIa in Dutch SLE patients, and in a subset of 13 SLE patients, homozygous R/R patients showed significantly slower clearance of in vivo clearance of IgG-coated erythrocytes than

H/R and H/H patients (238)). These data are consistent with the interpretation that either the FcγRIIa-R131 allele can be a weak risk factor or a disease modifier for certain clinical manifestations. FcγRIIa-R131 may not be a genetic risk for the development of SLE, but may be a risk factor for lupus nephritis, especially in SLE patients positive for IgG2 antibodies to C1q. The investigators postulated that IgG2 autoantibodies to C1q might be particularly nephritogenic in lupus patients with R131/R131 genotypes because of poor efficiency in clearing IgG2 containing immune complexes. A meta-analysis of 17 studies concluded that the low-binding R131 allele confers a 1.3-fold risk for developing SLE, but not for lupus nephritis (234). The modest relative risk for SLE (and no significant risk for lupus nephritis) might be an underestimate influenced by genetic heterogeneity, genotyping errors, and/or low-penetrance of genotypic effects. Genotyping errors are a serious concern because extensive sequence homology among FcγR genes makes it difficult to achieve highly specific PCR-based genotyping assays, especially in earlier studies when the human genome sequence database was not available.

FcγRIIIa (CD16) expressed on cell surfaces of NK cells, monocytes, and macrophages binds to both IgG1 and IgG3 subclasses (228 ,230). A common polymorphism of T to G substitution at position 559 results in an amino acid substitution from phenylalanine (F) to valine (V) (at amino acid 176 counting from the leader sequence or at amino acid 158 of the mature sequence) (235). Individuals homozygous for F/F bind IgG1- and IgG3-containing ICs less efficiently than those with V/V genotypes (reviewed in (229)). Wu et al. (1997) showed a strong association between the low affinity allele and SLE in an ethnically diverse population, and especially an under-representation of homozygous V/V in lupus nephritis patients (235). This skewed allele distribution of FcγRIIIa-158V/F in SLE patients was further supported by studies of Caucasians (236)and Koreans (237), but not by similar studies of Dutch Caucasian (238) and African Americans (239). Seligman et al. have recently demonstrated an association between the low affinity FcγRIIIa-158F allele and risk of lupus nephritis among Caucasians but not among non-Caucasians (240). In contrast, the low affinity FcγRIIa-131R allele was not associated with lupus nephritis in the examined Caucasians, Hispanics, African Americans, and Asian/Pacific Islanders (240). Taken together, association between the FcγRIIIa-V/F158 polymorphism and susceptibility to SLE and/or to lupus nephritis has been reported in some but not in other similar studies. A meta-analysis of more than one thousand subjects in each of the three categories (lupus nephritis, SLE without renal involvement, and non-SLE controls) has concluded that the F158 allele confers a 1.2-fold risk for developing lupus nephritis in patients of European, African, and Asian descent, but not for SLE susceptibility per se in the absence of nephritis (241).

FcγRIIa and FcγRIIIa are transmembrane proteins. In contrast, FcγRIIIb is attached to cell membrane by a phosphatidylinositol anchor. FcγRIIIa and FcγRIIIb both bind to IgG1 and IgG3 but are expressed in different cell types; the former mainly in NK cells and macrophages and the latter in neutrophils. Earlier reports of a few SLE patients with rare alleles deficient in surface expression of FcγRIIIb suggested its possible involvement in the development of SLE (242 ,243). Additionally, two common variants of FcγRIIIb gene, NA1 and NA2 alleles, were identified with differences in four amino acids (244). Functionally, individuals homozygous for NA2 have lower capacity to mediate phagocytosis than NA1 homozygotes. Hatta et al. have reported that individuals with FcγRIIIB-NA2/NA2 are at risk for lupus nephritis in a Japanese population (245). Of interest, in this study genetic association between alleles of FcγRIIa, FcγRIIIa, or FcγRIIIb and SLE were simultaneously compared. Only the FcγRIIIB-NA2 but not the FcγRIIA-R131or FcγRIIIA-158F was a risk factor for SLE. However, a similar study of Dutch Caucasians found NA1 allele was at a significantly higher frequency among lupus nephritis patients than non-nephritis patients (238). Another study conducted in a combined American and Dutch Caucasian cohort, however, found significant association of the FcγRIIIA-158F allele with SLE, but not the FcγRIIA-R131 or FcγRIIIB-NA2 allele (236).

Since IgG2 and IgG3 are major subclasses of ICs deposited in renal biopsies of lupus nephritis patients (246), the relative importance of FcγRIIa-H/R131 and FcγRIIIa-V/F158 polymorphisms might depend on the IgG subclass of pathogenic autoantibodies in each patient. FcγRIIa-R131 and FcγRIIIa-F158 may not be independent risk alleles, they often are inherited together on the same chromosome as a single risk haplotype for SLE (247), and the presence of multiple at-risk alleles of genes affecting immune complex clearance may interact to enhance risk for SLE (248). Haplotype studies suggest LD between FcγRIIa-H/R131 and FcγRIIIa-V/F158 in some but not in other studied populations (discussed in (241)). Although both of these gene variants have shown evidence for linkage to SLE (45 ,249), they may not be sufficient to account for the observed linkage at 1q23 to SLE, suggesting the possibility of additional SLE susceptibility genes in their flanking regions. Other neighboring genes have also been associated with SLE including Fc_RIIb and CRP.

FcγRIIb, expressed on B cells, monocytes/macrophages, dendritic cells, and mast cells, contains an immunoreceptor tyrosine-based inhibitory motif in its cytoplasmic tail to negatively regulate cell activation. The FcγRIIb-I/T 232 polymorphism that may alter the inhibitory function (250) has been associated with SLE susceptibility in Japanese (251), but not in African American, U.S. Caucasian, and Swedish populations (247 ,250). Recently, the association of FcγRIIb-T232 allele and SLE has been confirmed in Thais and Chinese (252 ,253), suggesting it may be a common susceptibility gene in Asian populations. Recently, 10 SNPs of the human FcγRIIb have been shown to define two haplotypes, in which the less frequent promoter haplotype exhibits increased expression of the reporter gene in both B cells and myeloid cell lines and has been associated with SLE in US Caucasians (OR = 1.65; p = 0.0054) (254 ,255). The FcγRIIb haplotype is not in linkage disequilibrium with the previously identified FcγRIIa and FcγRIIIa polymorphisms; hence the

association of the high-expression haplotype with SLE demonstrates a role for FcγRIIb in SLE susceptibility independent of the stimulatory FcγRIIa and FcγRIIIa.

Fc receptor-like genes (FCRLs, also known as FCRHs) clustered at 1q21–22, encode a set of proteins with high structural homology with classical FcγRs. Recently, a functional SNP (-169 C->T) in the promoter region of FCRL3 was associated with multiple autoimmune diseases including SLE in a Japanese case-control study (256). Whether this finding has implications in other ethnic groups awaits further studies.

TCRZ (1q23)

Decreased expression of TCR ζ chain in studies of the TCR/CD3-mediated signaling was observed in the majority of SLE patients, and this defect is independent of disease activity, medication, or clinical manifestations (257). Each of the TCR ζ chain or the CD3-γ, -δ, -ε chain contains one or more ITAM. They associate non-covalently with the antigen-binding TCR α/ß (or γ/δ) chains to mediate signal transduction in T lymphocytes. A critical early event in the signal transduction pathway of TCR activation is phosphorylation of ITAM and its subsequent dephosphorylation. Given the known T cell defects in SLE patients and the pivotal role of ζ chain in T cell activation, several studies focused on this gene as a candidate susceptibility gene for SLE. The absence of exon 7 (encoding the GTP/GDP binding site proximal to the third ITAM) of TCR ζ mRNA was observed in two Japanese SLE patients (258). Subsequently, frequent mutations in the cloned PCR products of TCR ζ mRNA were demonstrated in 6/8 Japanese SLE patients, but not in two systemic sclerosis patients and two normal controls (79). However, no unique mutations in TCR ζ mRNA were found in a study using direct sequencing of PCR products derived from Caucasian, African American, Hispanic, Chinese, or Japanese SLE patients living in North America (259). Instead, novel single-nucleotide polymorphisms of the ζ chain gene were shared similarly among normal and SLE patients (259). These investigators suggest that polymorphisms of TCR ζ chain gene are unlikely to play an important role in genetic susceptibility to SLE. It appears that the discrepancy in mutations of TCR ζ mRNA of the reported SLE patients may be attributed to how mutations are detected. Mutations in the cloned PCR products but not in PCR products from the total amplified ζ mRNA suggest that these mutations are present somatically in a small proportion of mRNA without corresponding alterations in genomic DNA. This interpretation is consistent with recent findings that peripheral B and T cells derived from SLE patients contain abnormal mRNA transcripts (260 ,261).

(3) SLE-Associated Genes at 1q41–42

PARP (1q41-42)

Poly (ADP-ribose) polymerase (PARP) is a zinc-finger DNA-binding protein that is involved in DNA repair and apoptosis (262). The potential involvement of PARP in SLE was previously suggested by its subnormal levels of activity and of mRNA in SLE patients, and by its intermediate levels in unaffected relatives of SLE patients (263 ,264 ,265). Autoantibodies that bind to the two zinc-finger motifs of PARP are frequently found in patients with autoimmune rheumatic and bowel diseases (266). These autoantibodies do not significantly affect PARP enzyme activity, but efficiently prevent caspase-3-mediated PARP cleavage during apoptosis and prolong cell survival, which can cause failure to eliminate autoimmune cells and sustain autoimmune stimulation (267). Recently, genetic polymorphisms of the PARP gene were tested for association with SLE because the gene is located within the genomic interval linked to human SLE in several independent studies (38 ,39 ,45 ,47 ,48).

Tsao et al. originally linked a 15-cM region on chromosome 1q41-q42 with susceptibility to SLE, and subsequently narrowed this region approximately 5-cM (47). Three positional candidate genes within the narrowed region were tested for an association with SLE using the transmission-disequilibrium test (TDT) (28). The TDT tests whether alleles of the test candidate gene are preferentially transmitted from heterozygous parents to the oldest affected offspring in each nuclear family, thus can avoid the potential spurious association caused by the population admixture in the case-control study. Of the three tested candidate genes, only PARP alleles showed an overall skewed transmission of to affected offspring using a multiethnic cohort containing124 families (47). A particular PARP allele (85 bp allele) appeared to be preferentially transmitted to affected offspring but not to unaffected offspring. Tsao et al. concluded that PARP might be the susceptibility gene within the chromosome 1q41-q42 region, or might be close to it (47).

Subsequently, case-control studies in French and German Caucasians found no significant association of the 85 bp PARP allele with SLE (268 ,269). Additionally, no association of the 85 bp PARP allele with SLE susceptibility was observed using the TDT analysis of three multi-ethnic cohorts comprised of 187 sibpair families, 126 multiplex families, and 119 simplex families (270). A case-control study of PARP alleles in African Americans found a significant difference between the PARP allele frequencies in SLE patients and controls, and a significant deviation from Hardy-Weinberg equilibrium (HWE) in SLE genotypes, but not in controls (271). Departure from HWE at a marker locus can provide evidence for linkage disequilibrium between the marker and susceptibility locus, and for heterogeneity of disease susceptibility (272 ,273). Considering this growing body of studies, it appears that the studied PARP polymorphism is not a risk factor for SLE (274), but may be in linkage disequilibrium with the SLE susceptibility locus within the 1q41-q42 region (271). An additional positional candidate gene, HRES-1, has been recently suggested (275). HRES-1 is an endogenous retrovirus related to human T lymphotropic virus. Many SLE patients have autoantibodies to the HRES-1 encoded nuclear protein (276). Further studies will help identify the gene variant that increases risk for SLE within the 1q41-q42 region linked to lupus susceptibility.

TLR5 (1q41–42)

The critical role of toll-like receptors (TLRs) in activating innate and adaptive immune response by differentially recognizing microbial or nonmicrobial components raises the possibility of their potential role in the development of autoimmune disease (277 ,278). One member of TLRs, TLR5, maps to chromosome 1q41, a chromosomal region linked to SLE susceptibility (36 ,45 ,49) and syntenic to murine lupus susceptibility region Sle1d (71), encodes a protein acts as an innate immune receptor for bacterial flagellin (279). A C to T alteration of the C1174T SNP changes the encoded position 392 amino acid from arginine to a stop codon (R392X), which results in truncating the extracellular domain and eliminating the transmembrane domain and cytoplasmic tail (280). The ligand-binding domain of TLR5 bearing the minor T allele of this SNP (which encodes the stop codon) is unable to mediate flagellin signalling (280). Using the family-based transmission disequilibrium test, the allele 1174C (but not the stop codon encoding 1174T allele and the other 3 TLR5 SNP alleles) was preferentially transmitted to 199 Caucasian SLE patients from their 326 parents (281). In contrast, the allele 1174C was not preferentially transmitted to their 75 unaffected siblings. The decreased frequency of the stop codon allele in SLE patients (3%) in comparison to unaffected individuals (6%) is consistent with a protective association. Subjects with the stop codon produced less pro-inflammatory cytokines (IL-6, TNF-α and IL-1β) compared to those with the wild-type genotype, suggesting the stop codon SNP allele may contribute to protection from the development of SLE (281). These observations support a novel role for flagellated bacteria and the innate immune response in the pathogenesis of SLE.

(4) SLE-Associated Genes at 2q37

PDCD1

PDCD1 has recently been associated with SLE (14). PDCD1 is a member of the CD28/CTLA4/ICOS costimulatory receptor family, which delivers inhibitory signals that have profound effects on T- and B cell immunity (reviewed in (282)). Mice deficient in PDCD1 develop glomerulonephritis and arthritis in the C57BL/6 background (283), and autoimmune dilated cardiomyopathy in the BALB/c background (284). A large study of approximately 2,500 individuals has shown association between an intronic SNP (PD1.3A; i.e., the minor A allele of 7146 G/A) in PDCD1 and SLE susceptibility in Europeans and Mexicans (14). This association between the PD-1.3A allele with susceptibility to SLE has been confirmed in another study comparing European controls to 224 SLE patients recruited in California of European American descent (285), but not in many subsequent case-control, population-based studies of Northern Sweden (286), Denmark (287), Spain (288), Eastern United States (289), and China (12). The observed contradictive results may be attributed to, at least in part, variations of the allele frequency and the haplotype structure of PDCD1 among populations. This SLE-associated SNP affects a binding site of a transcription factor RUNX1 in an intronic enhancer, suggesting a potential functional mechanism predisposing to SLE (14). Considering currently available data, the minor A allele of 7146 G/A of PDCD1 may contribute to susceptibility to SLE and/or lupus nephritis in a few specific populations, but appears not to be a strong predisposing polymorphism for SLE (and/or lupus nephritis) in most studied populations.

(5) SLE-Associated Genes at 16q12

The 16q12 region is linked to SLE, but also to other autoimmune diseases (290 ,291 ,292 ,293), suggesting the possibility of a shared susceptibility gene interacting with other susceptibility loci to manifest multiple autoimmune disorders. In SLE, evidence for genetic interaction of the 16q12 locus and other susceptibility loci has been reported by two groups (52 ,294). The identification of three SNPs of NOD2/CARD15 as independent risk factor for Crohn disease has made this gene an excellent positional candidate gene for SLE. However, case-control studies in Spanish and Chinese populations have shown no association between NOD2/CARD15 and SLE (295 ,296). Fine mapping of 16q12 has supported the presence of SLE susceptibility gene(s) within this genomic interval (54), and led to the identification of a novel gene OAZ (OLF1/EBF-associated zinc finger protein) associated with SLE and/or lupus nephritis in Chinese (297 ,298). Whether OAZ plays a role in other ethnic groups is not known at present. Further studies are in progress to identify the causal gene variants and to delineate their roles in developing SLE.

(6) Other Linked Regions

These regions include 1q31, 4p16, and 12q24, and the genomic intervals identified by disease stratification listed. Thus far, no candidate susceptibility genes within these genomic intervals have been associated with SLE.

(7) Other Candidate Susceptibility Genes Associated with SLE (Table 6-5)

These genes may not be located within genomic segments exhibiting strong linkage to SLE, but their gene polymorphisms have been associated with SLE in multiple cohorts.

C1q (Mapped at 1p36)

Three genes (a, b, and c genes) encode the first component of the complement system. Homozygous deficiency in any of the three C1q genes is almost invariably associated with SLE (Morgan & Walport, 1991). This is a powerful disease susceptibility gene since >90% identified individuals with this deficiency developed SLE. However, homologous C1q deficiency is extremely rare in the population (approximately 40 cases in the world reported thus far). Despite various ethnic

and genetic backgrounds, these patients develop disease at a young age without a female predominance. They share a nearly invariant feature of severe photosensitive skin rash, often with high-titers of anti-Ro autoantibodies (188).

Table 6-5: Genes within the Associated with SLE

Names	Gene Symbols	Chromosomal Locations	Locus Name
Genes within SLE linked regions			
C-reactive protein	CRP	1q23	
IgG Fc receptor IIa (CD32)	FCGR2A	1q23	
IgG Fc receptor IIb	FCGR2B	1q23	
IgG Fc receptor IIIa	FCGR3A	1q23	
Fc receptor-like 3	FCRL3	1q21.2–22	
Poly(ADP-ribose) polymerase	PARP	1q42	SLEB1
Toll-like receptor 5	TLR5	1q41–42	SLEB1
Program cell death 1	PDCD1	2q37	SLEB2
MHC class II genes	DRB1	6p21	
MHC class III genes	C2, C4, TNF	6p21	
Caspase recruitment domain-containing protein 15	NOD2/CARD15	16q12	
OLF1/EBF-associated zinc finger protein	OAZ	16q12	
Genes not within SLE linked regions			
Complement component C1q	C1q	1p36	
Tumor necrosis receptor 2	TNFR2	1p36	
Interleukin –10	IL10	1q32	
Complement receptor 1	CR1	1q32	
Interleukin –6	IL6	7p21-p15	
Mannose binding lectin	MBL	10q11	
Monocyte chemoattractant protein 1	MCP1	17q11.2–12	
Interleukin-4 receptor	IL4R	16p11–12	
The MHC class II transactivator	MHCIITA	16p13	
Interferon α receptor 1	IFNAR1	21q22.11	
Interferon α receptor 2	IFNAR2	21q22.11	
T cell receptor γ locus	TCRG	7p15–14	
T cell receptor ß locus	TCRB	7q35	
T cell receptor α locus	TCRA	14q11.2	
T cell receptor δ locus	TCRD	14q11.2	
Ig heavy chain locus	IGH	14q32–33	
Autoimmunity genes			
Protein tyrosine phosphatase 22	PTPN22	1p13	
Program cell death 1	PDCD1	2q37	
Cytotoxic T lymphocyte antigen 4	CTLA4	2q33	
Type 1 IFN pathway genes			
Tyrosine kinase 2	TYK2	19p13.2	
IFN regulatory factor 5	IRF5	7q32	

To understand how the absence of C1q can predispose to SLE, C1q-deficient mice were established. A significant portion developed glomerulonephritis with immune deposits in certain genetic backgrounds but not in others. These data are consistent with genetic interactions, suggesting that either a single susceptibility gene (C1q) is necessary but not sufficient for expression of murine SLE, or genetic modifiers are present in resistant strains to suppress phenotypes mediated by C1q. Interestingly, significantly higher numbers of glomerular apoptotic bodies were observed in C1q deficient mice independent of their disease status, but not in wild type mice. These in vivo findings are consistent with the previous in vitro data showing direct binding of C1q to apoptotic blebs on UV-irradiated keratinocytes in the absence of antibody. The investigators postulate that C1q plays a role in the maintenance of immunological tolerance by clearing apoptotic cells, thus preventing the autoimmune response to autoantigen–containing apoptotic blebs.

TNFR2 (1p36)

The p75 tumor necrosis factor receptor (TNFR2), the larger of the two membrane receptors that bind to either TNF-α or TNF-ß, mediates effector functions in different cell types. TNFR2 may be particularly important in T cells for being the major TNF receptor on circulating T cells and the

major known mediator for autoregulatory apoptosis of CD8+ T cells (299). Since TNF-α is a strong candidate gene for SLE susceptibility, molecules participating in the TNF-mediated pathway are also likely to influence the pathogenesis of SLE.

TNFR2 has been considered as a candidate gene within the murine susceptibility loci (the NZB-derived Nba-1, Imh-1, and Mott-1 loci) for SLE (300 ,301 ,302). The autoimmune phenotypes linked to these loci include fatal glomerulonephrits, IgM hypergammaglobulinemia, and formation of aberrant plasma cells (Mott cells). TNFR2 is located on the distal end of mouse chromosome 4, a region homologous to the short arm of human chromosome 1 (1p36) where tentative linkage to human SLE has been reported in two independent genome scans (38 ,44). A SNP of TNFR2 results in arginine instead of methionine at position 196 of exon 6, which was associated with SLE in Japanese (303) but not in a Spanish or UK population (304). Whether this amino acid difference has functional significance is yet to be determined. No association between SLE and a TNFR2 intronic microsatellite was found in a recent Italian case-control study (305). Thus, current evidence for association between SLE and polymorphisms of TNFR2 is weak and inconsistent. Further studies will help clarify whether genetic variants of TNFR2 are risk factor for lupus.

Interleukin-10 (1q32)

IL-10 is an excellent candidate gene for SLE susceptibility because (1) increased IL-10 production promotes B cell hyperactivity and autoantibody production (306), (2) the frequency of IL-10 secreting cells is elevated in peripheral blood samples of sporadic cases of SLE (307), and (3) studies of SLE patients and their relatives suggest genetic influences on IL-10 production (308 ,309). Llorente et al. showed that both SLE patients and their relatives from 13 Mexican extended pedigrees had higher levels of spontaneous release of IL-10 and mRNA than normal controls (308). Grondal et al. subsequently confirmed this finding in Caucasians; both SLE patients and their relatives from an extended Icelandic pedigree had higher numbers of IL-10 secreting cells than healthy controls (309). The increased production of IL-10 in SLE patients appears to be constitutive and not affected by disease activity or treatment. Additionally, environmental factors may impact on IL-10 production; spouses of SLE patients had significantly higher number of IL-10 producing cells compared to controls.

The molecular mechanisms that cause increased IL-10 production among SLE patients have been actively explored. Levels of IL-10 secretion have been correlated with specific haplotypes containing either two microsatellite markers or three single nucleotide polymorphisms within the IL-10 promoter (310 ,311 ,312). Association between these IL10 promoter polymorphisms and SLE has been reported in case-control studies of two Caucasian (305 ,310) and one Mexican-American (313) but not in similar studies of another Caucasian (314) or one Asian (315) population(s). Association between these IL10 promoter polymorphisms and SLE has been reported in case-control studies of Caucasians (310 ,316 ,317 ,318), Mexican-American (313) and Asians (319 ,320). However, this association was not observed in other groups (314 ,315 ,321 ,322 ,323 ,324). Mehrian et al. also reported synergistic effect between IL-10 and bcl-2 genotypes in susceptibility to SLE (313). To our knowledge, this finding has not been replicated in another cohort. In the two negative association studies with SLE, there was significant association with renal disease in lupus patients (314 ,315). Subsequent identification of new SNPs and SNP haplotypes within the IL10 promoter region have led to their correlation with a high or low IL-10 production (305 ,325), in which the high IL-10 haplotypes is associated with SLE in African Americans. Recently, a meta-analysis combining 15 relevant IL-10 studies showed a significant association between the G11 allele (23 CA repeat at –1.1 kb) and SLE (OR = 1.28, 95% CI = 1.03–1.59, p = 0.028), but no association of any of the IL-10 promoter SNPs (326). However, when stratified by ethnicity, IL-10 promoter –1082 G allele was associated with SLE in Asians (OR = 1.358, 95% CI = 1.015–1.816, p = 0.039). Taken together, IL-10 polymorphisms confer modest risk for the development of SLE in multiple ethnic groups.

CR1 (1q32)

Complement receptor 1 (CR1) is the binding receptor for complement component C3b and C4b expressed on the cell membrane of erythrocytes, granulocytes, all B and some T lymphocytes, monocytes, glomerular podocytes, and follicular dendritic cells (327). Functionally, it is important in effective removal of circulating immune complexes that have fixed complements. Excessive amounts of immune complexes in SLE may be caused by dysregulated overproduction of autoantibodies or impaired clearance of immune complexes. Wilson et al. (328) quantified the C3b receptors on erythrocytes from 38 SLE patients, 14 of their spouses, and 47 relatives, as well as from 113 normal subjects and concluded that the decreased number of C3b receptors frequently observed in lupus patients was inherited in an autosomal codominant manner. Subsequently, a HindIII restriction enzyme RFLP (7.4 or 6.9 kb fragment) that correlated with the number of CR1 on erythrocytes further supported the genetic basis of decreased CR1 receptors observed in SLE patients (329) (330 ,331). However, the correlation between HindIII RFLP and SLE susceptibility was not found in 9 SLE multicase Mexican families (332) or in Indian case-control study (333). Kumar et al. observed while the numbers of CR1 remained stable in consecutive patients among controls, they varied significantly in lupus patients correlating with serum levels of C3d and circulating immune complexes, and the severity of the disease (333). Thus, low levels of CR1 expression in erythrocytes among lupus patients may be an acquired defect.

CR1 exhibits allelic size variants that has different numbers of C3b-binding sites (327 ,330 ,334 ,335 ,336). Because this

molecular weight polymorphism may affect clearance of immune complexes, several studies investigated whether the smallest allele (the CR1-C allele with the lowest C3b binding site) was associated with SLE susceptibility. An association between SLE and the C allele was suggested in one large SLE multiplex pedigree (334), but not in case-control studies of a French (337), Hispanic, African-American, or American Caucasian populations (100 ,338). Recently, a meta-analysis, combined with 13 studies, showed no significant association of CR1 functional polymorphisms (329), which determine the quantitative expression of CR1 on erythrocytes with SLE (326). In contrast, the S structural variant, which is characterized by an additional C3b binding site on a fifth long homologous repeats of CR1 (335), was associated with SLE (OR = 1.54, 95% CI = 1.22–1.96, $p < 0.001$) (326).

IL-6 (7p21-p15)

Interleukin-6 is an important B cell growth and differentiation factor. Polymorphisms of the 3′ flanking region of the IL6 have been shown to be associated with SLE in Caucasians and African-Americans, which may enhance the stability of IL-6 mRNA thus contributing to elevated levels of IL-6 in SLE patients (339 ,340 ,341). However, this polymorphism appears only weakly associated with disease, as it was only present in the minority patients (342). Another SLE-associated polymorphisms are short AT-rich minisatellite alleles that were found exclusively in SLE patients (13% among the studied Caucasian and 9% among African Americans). To our knowledge, this finding has not been replicated in independent studies.

Mannose-Binding Lectin (10q11)

Mannose-binding lectin (MBL) binds mannose on surfaces of bacteria or viruses, initiates a pathway for opsonization of pathogens, and activates complement components by MBL-associated proteases. MBL deficiency results in low levels of circulating MBL, impaired opsonization of microorganisms, and frequent infections, which occurs in 5% to 10% of the general population (343). MBL is very similar to C1q in three-dimensional structure. The well-known association of complement deficiencies and SLE has prompted genetic studies of MBL in SLE patients. Case-control studies in Caucasians, African Americans, and Southern Chinese have found polymorphisms in the promoter region and exon 1, which correlate with lower levels of MBL, are significantly more frequent in SLE patients than in controls (344 ,345 ,346). Subsequently, Garred et al. (347) reported that homozygosity of MBL variant alleles could explain the increased risk for infections in a small subset of Danish SLE patients, in addition, it could represent a minor risk factor for developing SLE. Cardiovascular disease is an important complication in SLE patients. Homozygosity for MBL exon 1 variants has been associated with an increased risk (relative risk of 5.8 to 7.0 without and with correction for other known risk factors) of arterial thrombosis, but not of venous thrombosis in 91 Danish SLE patients (348).

Monocyte Chemoattractant Protein 1 (17q11.2–12)

Monocyte chemoattractant protein-1 (MCP1), a ß-chemokine, plays role in monocyte and lymphocytes recruitment and is considered as a main chemokine responsible for initiating the glomerulonephritis in animal models (349 ,350). The functional SNP (–2518G/A) was first reported o affect the expression level of MCP-1 in response to IL-1ß stimulation in vitro (351). Subsequent studies found the G allele of this SNP was related to the higher MCP-1 protein level in PBMC from SLE patients and associated with SLE and lupus nephritis in a case-control study (352). The association of –2518G was also observed for the development of cutaneous vasculitis, but not SLE or lupus nephritis in a Spanish population (353).

MHCIITA (16p13)

The MHC class II transactivator (CIITA) plays a pivotal role in the regulation of MHCII gene expression. An absence of CIITA was associated with severe immunodeficiency resulted from the defect production of MHC class II molecules (75). The transcription of human CIITA gene is controlled by four alternative promoters, which exhibits cell-type specific activity. The promoter I (pI) and pIII are responsible for the CIITA expression in dendritic cells and B cells respectively, while pIV mediates the interferon γ induced CIITA expression (354). The analysis of four promoters showed no sequence difference between rheumatoid arthritis, type I diabetes, and normal controls (355), but the sample size of this study is rather small. Subsequently, one Caucasian (356) and one Japanese study (357) revealed only pIII of four promoters is polymorphic. The pIII SNP and four exonic SNPs were not associated with SLE in the latter Japanese cohort (357). In contrast, an intronic SNP (485 A->A/G), not in LD with previous 5 SNPs (r2 = 0.0074–0.071), was associated with SLE in this group (357). Further studies are needed to test the CIITA polymorphisms in multi-ethnic groups with larger sample size for evidence of association with SLE.

Interleukin-4 Receptor (IL4R, 16p11–12) and Interferon-α Receptors (IFNAR, 21q22)

Cytokine profiles of SLE patients have been a subject of great interest. Because IL-4 and IL-4 receptor (IL-4R)-mediated signaling pathway is important for the commitment of the Th2 phenotype, functional polymorphisms of these two genes may predispose susceptibility to autoimmune diseases. A recent study of 50 Japanese SLE patients and 100 Japanese controls showed significant association of SLE with the IL-4R α chain gene polymorphisms (codons 50 and 551) but not with the IL-4 gene promoter polymorphism (358). One of an important cytokine that Th1 cell type

produces is IFN-α. Genetic association between SLE susceptibility and variants of IFN-α receptor 1 and 2 genes were recently reported in Japanese population (359 ,360). These findings await confirmation in other populations.

T Cell Receptor Genes

The most common T cell receptor (TCR) is the αß TCR present on the majority of T cells. Other T cells bear the γδ TCRs. The TCR α and δ chain genes reside on human chromosome 14, while the TCR ß and γ chain genes map to human chromosome 7. Within a TCR gene locus, the DNA rearrangement process brings together one variable gene segment, (one diversity gene segment), one joining gene segment, and one constant gene segment to encode gene products. A diverse TCR repertoire can present various processed peptides to MHC class I/II molecules to mount immune responses. A number of studies examining TCR RFLP in SLE patients have yielded weak and inconsistent results. Tebib et al. reported an association between the constant region of the TCR α chain and SLE in American Caucasians but not in Mexicans (361). Huang et al. did not support this observation in a study of North American Caucasians (14 SLE multiplex families as well as 41 cases and 88 controls) (362). Dunckley et al. found no association between TCR (α,ß, and γ) RFLP and SLE or MHC class II molecules (363). Frank et al. reported an association of TCR ß RFLP with anti-Ro(SSA) antibodies but not with SLE (364). No linkage of TCR α, ß, and γ chain genes to SLE was observed in 5 multiplex Caucasian families (365). The family studies had fairly small sample sizes and might lack power to detect linkage. Data available thus far fail to support the contribution of TCR gene variants to risk for SLE.

Immunoglobulin Heavy and Light Chain Genes

Earlier association studies of the immunoglobulin heavy chain locus (map to chromosome 14) and gene products (Gm allotypes) as well as the κ light chain gene (chromosome 2) and gene products (Km allotypes) yielded conflicting results. An association of Gm phenotype to SLE was observed in American and Australian Caucasians (366 ,367), Japanese (368), African Americans (369), but not in Hungarians or central Europeans (370 ,371). An association between Km phenotype and SLE was reported in North American Caucasians (372) but not in central Europeans (371). Kumar et al. found a significant association of a Ig heavy chain constant region polymorphism with SLE in unrelated Mexicans and Mexican SLE multiplex families but not in SLE patients from the United States (373). No association between the λ light chain polymorphism and SLE was observed by Blasini et al. (374). Since the Gm/Km allotypes or Ig RFLP can only detect limited polymorphism present within the vast variation of immunoglobulin gene loci, these studies do not rule out the possibility that immunoglobulin gene variants can confer genetic risk for SLE.

The expression of a particular V gene and receptor editing may regulate the production of autoantibodies (375). Olee et al. reported the deletion of the Humhv3005 gene (likely to encode heavy chains of rheumatoid factors) in 25% of the studied rheumatoid arthritis and SLE patients and 2% of the normal controls (376). A subsequent study from the same group concluded the deletion of this V gene contributed weak genetic risk for SLE (362).

Autoimmunity Genes (Table 6-5)

PDCD1: The minor allele of the intronic 7146G/A SNP of the PDCD1 gene has recently been associated with type 1 diabetes (13). Other SNPs and or SNP haplotypes of the PDCD1 gene have been implicated in nephropathy among SLE patients (287) and in susceptibility to rheumatoid arthritis (12 ,377). It appears that PDCD-1 polymorphisms may be a shared genetic factor for multiple autoimmune diseases in humans, similarly to observations in knockout mice. However, the specific disease-associated genetic polymorphism, and the resulting functional consequences leading to the occurrence of the disease have not been well characterized as yet. Of interest, two recent publications describe that individual SNPs affecting a transcription factor binding site (RUNX1) are associated with RA (378) and psoriasis (379), highlighting the potential importance of polymorphisms involved in regulation of gene expression in susceptibility to autoimmune diseases (380). These novel findings await validation by independent confirmation and further functional studies.

CTLA-4 (mapped at 2q33): The cytotoxic T lymphocyte antigen 4 gene (CTLA4), which encodes a vital negative regulatory molecule of the immune system, is a logical candidate gene for multiple autoimmune disorders. A systematic survey of 109 polymorphisms of a 2q33 interval containing the T-lymphocyte regulatory genes CD28, CTLA4, and inducible costimulator (ICOS) revealed polymorphisms within a noncoding 6.1kb 3′ region of CTLA4, which correlated with lower messenger RNA levels of the soluble alternative spliced CTLA4. These polymorphisms are associated with Graves disease, autoimmune hypothyroidism and type 1 diabetes (8). Genetic studies investigating polymorphisms within the CTLA4 promoter (-1722T/C, -1661A/G, -319C/T) and exon1 (+49G/A) in Korean, Spanish, European American, and African-American population studies yielded negative or inconsistent evidence for association with SLE (381 ,382 ,383 ,384). A SNP (CT60A/G) within the 3′UTR of CTLA4, one of the polymorphisms within the 6.1 kb interval associated with multiple autoimmune diseases (8), has recently been associated with SLE in a study of 396 Spanish SLE patients and 293 controls (384).

PTPN22 (1p13): Protein tyrosine phosphatases (PTPs) have been recognized as negative regulators for stimulatory signaling pathways, which are critical in maintaining homeostasis of cellular immunity. The PTPN22 gene is expressed primarily in cells of hematopoietic lineage. The minor T allele of the C1858T polymorphism, which

causes the R620W amino acid substitution and disrupts an important motif of PTPN22 for interaction with a negative regulatory kinase Csk (385), has recently been associated with multiple autoimmune diseases in Caucasians (15), including type 1 diabetes (T1D) (385 ,386 ,387 ,388), autoimmune thyroid disease (388 ,389), rheumatoid arthritis (RA) (390 ,391), and SLE (391 ,392), but not with multiple sclerosis (MS) (393). Supporting these findings, the PTPN22 missense SNP has been associated with four autoimmune diseases (T1D, autoimmune thyroid disease, RA, and SLE) in 746 affected individuals from a collection of 265 Caucasian families multiplex for at least 2 of the 9 autoimmune diseases (T1D, RA, SLE, MS, autoimmune thyroid disease, juvenile RA, inflammatory bowel disease, psoriasis, and primary Sjögren syndrome) (394). In this study, the absence of any evidence for association of this SNP with MS is strong, but the other four autoimmune diseases have very small sample sizes to draw definitive conclusions (394). Taken together, these recent findings support the hypothesis that genes shared in non-MHC regions contributes to multiple autoimmune diseases despite their diverse, and unrelated phenotypes (7). A note of caution is that all these studies use the population-based case-control design in which several studies have used the same control samples. A family-based TDT design containing >600 Caucasian trios failed to confirm the association between the PTPN22 missense SNP and SLE, and the 1858T allele frequency in cases from these trios was not different from the reported allele frequency of controls, but was increased in SLE patients with autoimmune thyroid disease (395). Most recently, a RA study (396) has reported other PTPN22 SNPs, independent of C1858T, may contribute to the development of RA. Considering current available data, genetic polymorphisms within the PTPN22 gene clearly confer risks for several autoimmune diseases, and the genetic contribution is more evident in individuals with multiple autoimmune diseases.

Type 1 IFN pathway genes associated with SLE (Table 6-5): Several groups have independently shown IFN-inducible gene expression patterns using peripheral blood samples from SLE patients (397 ,398 ,399). The type I IFN system has been proposed as having a pivotal role in the development and maintenance of SLE clinical symptoms (400). A recent study has shown the polymorphisms in the genes participating in type 1 IFN pathway (tyrosine kinase 2 and interferon regulatory factor 5 genes) are associated with SLE (401). Further studies are needed to clarify the importance of type 1 IFN in SLE.

Summary

There has been tremendous progress in genetic studies of SLE in recent years. Hundreds of families containing multiple members affected with SLE have participated in genetic studies. Linkage analyses of these families have suggested several chromosomal regions that are likely to contain SLE susceptibility genes. Within the linked regions, promising candidate genes have also been associated with SLE. The continued advances in the identification of haplotype-tagged SNPs and block boundaries through out the human genome and the high throughput SNP genotyping platform will greatly facilitate the identification of disease-associated polymorphisms. We anticipate that the identification of specific SLE susceptibility genes will further our understanding of the pathogenesis of this disease, and will facilitate the development of more targeted therapies in the near future.

Chapter 7

The Genetics of Murine Systemic Lupus Erythematosus

Dwight H. Kono

Argyrios N. Theofilopoulos

Although the etiology of systemic lupus erythematosus (SLE) is multifactorial, genetic susceptibility appears to be an important and possibly essential component. Elucidation of the processes leading to disease induction and maintenance will likely require knowledge of the key genetic alterations and their contributions. Deciphering the genetics of lupus, however, has proven to be formidable, largely because of the size of the human genome and the complexity of polygenic inheritance in heterogeneous human populations. Studies of inbred strains of mice that, spontaneously or by induction, develop SLE-like systemic autoimmunity have provided an excellent opportunity to examine genetic susceptibility and genes vital to the development of lupus in well-defined model systems. Mouse models are particularly useful in dissecting polygenic traits because of homogeneous genetic backgrounds, standardized environmental conditions, and the ability to obtain sufficient numbers for genetic mapping and for accurate phenotype determination. Furthermore, the mouse genome is well characterized and its gene composition is sufficiently similar to the human genome to allow comparative analysis. Mice are also the premier mammalian species for genetic manipulation and, importantly, their immune system is nearly identical to humans, making it possible to study in considerable detail the immunologic alterations associated with different genetic backgrounds. This chapter will cover the mouse lupus susceptibility loci, the candidate and known susceptibility genes for spontaneous or induced models of SLE, and other potential lupus-predisposing genes identified by genetic manipulation.

Spontaneous and Induced Mouse Models of SLE

Mouse models of systemic autoimmunity used in genetic studies include monogenic, polygenic, spontaneous, and induced diseases (Table 7-1). Descriptions of the major strains can be found in Chapter 18 . Most genetic studies have focused on the spontaneous models, particularly the NZB, NZW, MRL-*Fas*^{lpr}, and BXSB strains. autoimmunity in these mice is polygenically inherited, although both the MRL-*Fas*^{lpr} and BXSB strains have single genetic alterations (*Fas*^{lpr} and *Yaa*, respectively) that exhibit Mendelian transmission of lupus traits. A number of recombinant inbred lines, derived from crosses of lupus-prone and nonautoimmune strains (RI lines in Table 7-1), have also been generated. These lines develop a spectrum of phenotypes indicating polygenic inheritance of traits, however, the relatively small number of substrains have precluded more detailed analysis. RI lines, derived from the NZB and NZW strains (NZM/Aeg2410 and NZM/Aeg2328), have been useful for studying recessive susceptibility genes (see below). Two long-lived (-*II*) sublines derived from the BXSB and MRL-*Fas*^{lpr} strains have also been described (1 ,2). Both have less severe disease than the original parental strain from which they spontaneously arose, and may be caused by single mutations. Studies of the MRL-*Fas*^{lpr}-*II* mice revealed decreased interferon-γ (IFN-γ), as well as IgG2a and IgG3 subclasses, suggesting that a reduction in pathogenic Th1-type responses may play a role in disease resistance (3). Recently, the BXD2 RI line derived from the B6 and DBA/2 strains was discovered to develop lupus-like manifestations as well as erosive inflammatory arthritis (4). This suggests that significant autoimmune predisposing alleles are present in the two parental nonautoimmune strains, and perhaps other nonautoimmune strains as well, that can predispose to autoimmunity when the optimal combinations occur, although spontaneous mutation(s) cannot be excluded.

Genetic predisposition is also important for the induced mouse models, particularly mercury-induced autoimmunity (HgIA). Exposure of susceptible strains to mercury results in a constellation of immunopathologic manifestations including lymphoproliferation, hypergammaglobulinemia, autoantibodies, and immune complexes (5 ,6). Although most strains develop lymphoid hyperplasia and elevated immunoglobulin G (IgG) levels, autoantibody and immune complex deposits are dependent on H-2 haplotype and other background genes (7 ,8). Notably, the antinucleolar antibody response, which is mainly directed against fibrillarin (9) (a specificity also observed in scleroderma (10)), requires the I-A^{s} haplotype (8). Among the various backgrounds examined, the DBA/2 strain is the most resistant (7), and strains susceptible to

spontaneous lupus appear to be more sensitive to mercury exposure (11).

Table 7-1: Spontaneous and Induced Mouse Models of Lupus

- Spontaneous disease models
  - NZ and related strains
    - NZB
    - NZW
    - (NZB × NZW)F1

- Induced disease models
  - Heavy metal–Induced autoimmunity (5)
  - Drug-induced lupus (411)
  - Pristane-Induced (412)
  - Anti-idiotypic (413)
- Graft-versus-host disease
- BCG-injected NOD (13,14)
  - 1–3-galactose-deficient mice (12)

Two induced models of lupus-like disease have been added since the previous edition (Table 7-1). Nonautoimmune prone galactose-α1–3-galactose-deficient mice exposed topically to commercial bovine thrombin preparations commonly used in human surgical procedures developed antibodies to the xenogeneic galactose-α1–3-galactose and, in a few cases, autoantibodies to clotting factors. Unexpectedly, they also produced anti-double-stranded DNA (dsDNA) and anticardiolipin autoantibodies, and developed immune complex-mediated GN with a higher frequency of disease in females (12). The other model, type I diabetes mellitus-susceptible NOD mice, were given intravenous *Mycobacterium bovis* (bacillus Calmette-Guérin), which prevented diabetes but, surprisingly, induced systemic autoimmunity manifested by accelerated hemolytic anemia, antinuclear antibodies, exacerbation of sialadenitis, and immune complex-mediated glomerulonephritis (GN) (13). Although it was initially hypothesized that susceptibility to two different types of autoimmune diseases might be because of common autoimmune–predisposing genes, later mapping studies revealed no colocalization of loci predisposing to lupus or diabetes other than the MHC region (14). These models provide striking examples of the complex interactions between genetic susceptibility and environmental factors that influence predisposition to SLE and other autoimmune diseases, and demonstrate the utility of mouse models to help address this issue.

In addition to the above models, gene knockout/knockin, transgenic, or mutagenic manipulation of non-autoimmune background strains has generated novel autoimmune mouse models with manifestations similar to spontaneous SLE. Finally, interval-specific congenic strains with introgressed genomic regions encompassing susceptibility loci have also provided another important resource for genetic studies.

Lupus Susceptibility Loci and Genes

The forward genetics approach to identify genes predisposing to quantitative traits generally entails four main steps. First, mapping of traits is performed by genome-wide scans using evenly distributed markers spanning the chromosomes. Next, interval-specific congenic strains, each containing an introgressed genomic fragment encompassing a specific locus, are generated to confirm the mapping studies and more clearly define the effects of individual loci on normal immune responses and autoimmunity. Third, more precise mapping is performed by generating and screening panels of congenics with crossovers or smaller intervals, which may be accomplished in one or two stages, i.e., localization first to approximately 5 cM sized fragments and then to <1 cM sized fragments (15). The final step entails screening candidate genes within the narrowed intervals (typically 0.5 to 1.0 cM). Selection of candidates is based on function, expression profile, or other characteristics suggested by the phenotype of the interval congenics. The recently assembled annotated mouse genome sequence has greatly facilitated this process.

Genome-wide scans involving a variety of crosses have revealed multiple quantitative and binary trait loci. At least 75 named loci, distributed over all 19 autosomal chromosomes and linked to one or more lupus traits, have been reported and are listed by chromosome and chromosomal location (distance in cM and Mb from the centromere) in Table 7-2 . Lupus susceptibility loci were not only identified in lupus-prone strains, but in many nonautoimmune backgrounds as well, including the 129, B6, BALB/c, C57L, DBA/2, NOD, and SWR strains. The large number of loci may be somewhat overestimated since suggestive linkages are included and since some loci, identified by different groups, overlap and may be identical. Conversely, several loci (*Sle1*, *Nba2*, *Sle2*), upon more precise mapping with subinterval congenic lines, were found to be composed of multiple subloci (16 ,17 ,18), suggesting underestimation of the number of loci. Based on the mapping studies, there is considerable

genetic heterogeneity even among inbred strains with susceptibility to spontaneous lupus not because of a few common predisposing loci, but rather to a large pool of loci, with individual strains containing different sets of common and unique predisposing variants.

Table 7-2: Loci Predisposing to Lupus-Related Traits in Spontaneous Disease Models

Name	Chr	cM/Mb	Marker	Cross	Major Associations	Parental Allele	Ref.

Table includes only named loci with linkages p <0.01 or *lod*>1.9. Loci are listed by their approximate chromosomal locations based on the marker with the highest association. Chr, chromosome. cM distances are from the Mouse Genome Informatics (http://www.informatics.jax.org/) and Mb distances from the Ensembl Mouse Genome Database (http://www.ensembl.org/Mus_musculus). NM, not mapped to mouse genome. Abbreviations for mouse strains (Cross column): B, NZB, B6, C57BL/6, B10, C57BL/10, Ba, Balb/c, *CAST, CAST/Ei, Ipr, Fas*^{lpr}, NZM, NZM/Aeg2410, W, NZW, (MRL-*lprx*C3H-*lpr*)BC & F2, both MRL-*lprx*(MRL-*lprx*c3h-*lpr*)F1 & (MRL-*lprx*C3H-*lpr*)F2 crosses. Original phenotypes that mapped to loci are shown: chr, antichromatin autoantibody, CL, anticardiolipin autoantibody, dsDNA, anti-dsDNA autoantibody, GN, glomerulonephritis, gp70, gp70 immune complexes, histone, antihistone autoantibody, LN, lymphadenopathy, Lprn, lymphoproliferation, MI, myocardial infarct, platelet, antiplatelet autoAb and thrombocytopenia, RBC, antiRBC autoAb, spleen, splenomegaly. Autoantibodies are IgG unless otherwise specified.

Loci Identified in Crosses of NZB and NZW Mice

The NZB and NZW strains are the most extensively studied of the lupus-prone mice. Genome-wide scans of intercrosses, backcrosses, and crosses to normal background strains resulted in the identification of 13 named NZB and 20 named NZW loci, covering 7 and 10 autosomal chromosomes, respectively, that contribute to one or more lupus-related traits (Table 7.2). Four NZW chromosomal regions associated with suppression of lupus (designated *Sles1–4*) were also identified (19). Loci were also mapped in these crosses to chromosomes from several nonautoimmune strains, including B6, BALB/c, C57L, and SWR.

Several loci, in addition to the MHC region, appear be confirmed in more than one cross. These include *Sle1/Cgnz1/Agnz1* (NZW-derived) and the overlapping *Lbw7/Nba2* (NZB) on chromosome 1, *Lbw2/Sle2/nba1/Imh1/Mott/Spm1* (NZB) on chromosome 4, *Sle3/Sle5/Lbw5* (NZW) and *Nba5/Aem2* (NZB) on chromosome 7, *Lbw8* (NZB) on proximal chromosome 8, *Sgp3* (NZB and NZW) on chromosome 13, and *nwa1* (NZW) on chromosome 16 (Table 7.2). Many of these loci have also been verified by interval congenic lines. In addition to identification of individual loci, mapping studies indicate that inheritance of lupus traits is multiplicative, dependent on the number and specific combination of susceptibility loci (epistasis) and that different sets of loci contribute to different traits, i.e., lymphoid hyperplasia, autoantibody production, GN, and mortality (19 ,20 ,21 ,22).

The NZW *Sle 1* locus on chromosome 1 is the best characterized. This interval overlaps with a region on human chromosome 1 linked to SLE (23 ,24 ,25) and therefore, may have relevance to human disease. *Sle1* congenic mice (B6.NZM*c1*) develop elevated IgG antinuclear antibodies (particularly targeting H2A/H2B/DNA subnucleosomes), but no GN (26). Bi- or tri-congenics of *Sle1* with *Sle2* (chromosome 4) and/or *Sle3/Sle5* (chromosome 7) intervals, however, result in GN and early mortality with severity dependent on the specific combination of loci (26 ,27). Bone marrow transfer studies have shown that the *Sle1* interval is functionally expressed in both B cells and T cells (28). More recently, others have generated interval-specific NZM2328 congenic mice (NZMC57L*c1*) in which the susceptible NZW *Cgnz1* interval on chromosome 1 (essentially *Sle1*) has been replaced with the nonautoimmune *Cgnz1* interval from C57L. Such congenics have significant reductions in anti-dsDNA and GN (29) and clearly demonstrate the significance of this single interval in disease susceptibility.

The *Sle1* locus has subsequently been shown using subinterval congenic mice to consist of a cluster of at least three loci (*Sle1a-c*), of which *Sle1b* appears to be the most potent (16 ,30). *Sle1a-c*, however, do not induce severe GN when combined individually with other SLE loci, indicating the importance of the entire interval. Physical mapping and cloning of the 900kb genomic segment of *Sle1b* identified 24 expressed genes and 2 pseudogenes (31). Of significant interest was the fact that this interval contained the SLAM/CD2 family genes, which encode surface molecules on hematopoietic lineage cells that mediate stimulatory or inhibitory signals. Furthermore, extensive polymorphism was discovered between the B6.*Sle1b* (*Sle1b* haplotype) and B6 genomes involving 10 genes, *Usp23, Nit1, Refbp2, Cd229, Cs1, CD48, CD84, Ncstn, Copa*, and *Pxf*. These differences included the expansion of *Cd224* in B6 mice to a 4-locus cluster, from which transcripts from 3 of the genes could be detected. Among the SLAM/CD2 family genes, however, the most likely lupus-promoting candidates appear to be CD48, CD150, CD84, and Ly108, although the entire haplotype may play a role. The NZW *Sle1b* haplotype is present in most inbred strains, including 129/SvJ, A/J, AKR/J, BALB/cJ, C3H/HeJ, CBA/J, CE/J, DBA/2J, DDY, Jc1, LP/J, MRL/MpJ, NOD/Lt, NZB/B1WJ, P/J, PL/J, SB/Le, SEA/GnJ, SJL/J, SM/J, WB/Re, PERA/EiJ, PERA/RkJ, PERC/EiJ, SK/CamEiJ, and SF/CamEiJ. Contrastingly, the B6 haplotype is limited to B6, C57BR/cdJ, C57L/M, RF/J, MOLF/EiJ and MOLE/EiJ. Thus, the *Sle1b* and B6 haplotypes are almost certainly of ancestral origin. Interestingly, a 129 locus on chromosome 1 that overlaps with *Sle1b* was shown to promote lupus when backcrossed onto the B6 background (32). It is possible that this might be due to the *Sle1b* haplotype, which suggests that chromosome 1 intervals from most inbred strains would have a similar effect.

The complement receptor 2 (*Cr2*) gene has been identified as a candidate gene for *Sle1c* (33). Comparison of the *Cr2* alleles of NZM2410/NZW and B6 strains revealed considerable polymorphism, with differences in 16 nucleotide residues (11 resulting in amino acid changes) and a 3 nucleotide insertion/deletion (33). Most significant, was a C→A (His→Asn) mutation at residue 1342 located in either the external domain short consensus repeat 7 (SCR7) of CR1 or the SCR1 of CR2, which introduced a new N-linked glycosylation site within the ligand-binding domain. This mutation reduced C3dg binding, CR1/CR2-mediated signaling, and IgG response to T-dependent antigens. Based on the known structure of CR1/CR2, glycosylation of the Asn residue apparently altered the function of CR2 by inhibiting its dimerization (33). The *Cr2* gene in mice encodes by alternative splicing both CR1 and CR2 glycoproteins (34 ,35). CR1/CR2 is expressed primarily on the surfaces of mature B cells and follicular dendritic cells, and binds C3 and C4 split products on antigens or immune complexes. CR2 reduces the B cell activation threshold and plays a role in both B cell apoptosis and antigen processing/presentation, particularly within the germinal center. Mice lacking *Cr2* have reduced T-dependent responses, generation of memory B cells, and germinal center formation. CR2 appears to help establish tolerance by enhancing the presentation of self-antigens, as suggested by the accelerated disease

observed in *Fas*^{lpr} mice when combined with *Cr2*-deficiency (36 ,37). However, to what extent transfer of the *Sle1b* SLAM/CD2 haplotype (present in the 129 genome where the knockout of *Cr2* was generated) contributes to lupus-like disease in *Cr2*-deficient mice remains to be determined.

B6 congenic mice containing the NZB chromosome 1 interval (B6.*Nba2*) have also been generated and characterized (38). These mice, similar to the *Sle1* congenics, spontaneously produce IgG anti-DNA and antichromatin autoantibodies, but do not develop GN. Furthermore, combining this interval with the *Yaa* also leads to higher levels of autoantibodies, including those to DNA, chromatin and gp70, as well as the development of severe lethal GN. At least part of this effect must be because of the *Sle1b* SLAM/CD2 haplotype present in NZB mice. In this regard, other studies attempting to more precisely map alterations in B cell activation induced by the NZB chromosome 1 interval, suggest that the *Nba2* interval is also composed of more than one susceptibility gene (17).

Analysis of microarray expression profiles of spleen cells from B6 and B6.Nba2 congenic identified *Ifi202* as a potential candidate gene for the *Nba2* (38). In mice containing the NZB *Nba2* interval, there was more than 10-fold increase in *Ifi202* and decrease in *Ifi203* (both within the *Ifi200* cluster), and impressively, of 11,000 genes these were the only differences detected. The specific polymorphism responsible for the increased expression is not known although several differences identified in the promoter region of the *Ifi202* gene are suspected. *Ifi202* is an interferon-inducible family of two genes (*Ifi202a* and *Ifi202b*) that has been suggested to play a role in cell survival, proliferation, and differentiation (39). *Ifi202* is also upregulated by IL-6 through STAT3 activation (40).

Another candidate for *Nba2* is the inhibitory Fc receptor, Fcγ RIIb, which on B cells inhibits B cell antigen receptor signaling following the engagment of immune complexes and colocalization of Fcγ RIIb and the antigen receptor (41). Inhibition is mediated by dephosphorylation of the antigen receptor by SHIP and possibly to a lesser extent SHP-1, which are bound to the immunoreceptor tyrosine-based inhibition motif on Fcγ RIIb (42 ,43). In NZB mice, there are two deletions in the promoter region associated with lower expression of Fcγ RIIb in germinal centers and with hypergammaglobulinemia (44). A more recent study, however, found that lower levels of Fcγ RIIb on germinal center B cells in NZB mice was a result of impaired upregulation, and that similar reduced levels were also present in several other lupus-prone strains indicating a lack of correlation with genetic background (45).

Congenic mice for the chromosome 4 loci have also been studied. B6.NZM*c4* congenic mice, which contain the *Sle2* locus (a mixture of NZW genome on the acromeric portion and NZB genome on the telomeric part of the interval), were found to develop generalized B cell hyperactivity, expansion of B1 cells and increased polyclonal IgM levels, but no increase in IgG antinuclear antibodies or GN (46). It was suggested that the expanded B1 cell population, which expresses higher levels of costimulatory molecules such as B7, might promote autoimmunity by enhancing self-antigen presentation T cells (47). More recently, BWF1 congenics that contain one or no copies of the NZW chromosome 4 interval (*Lbw2*) showed reduced B cell activation to LPS, decreased IgM levels and autoantibodies, less glomerular immune complex deposits and GN, and reduced mortality, but unexpectedly no difference in levels of IgG autoantibodies (48). Nevertheless, spontaneous IgG autoantibody–secreting cells were significantly reduced and the number of these cells correlated with amount of kidney deposits, but not serum levels.

Furthermore, kidney eluates did not demonstrate significant difference in the autoantibody repertoire in deposits from BWF1 mice with one or no copy of the NZB *Lbw2* locus. Thus, it was concluded that serum levels of IgG autoantibodies did not reflect the actual differences in production of autoantibodies and that the primary defect of *Lbw2* is B cell hyperactivity. Interestingly, congenic NZM2328 mice with replacement of the *Adnz1* chromosome 4 interval that overlaps *Sle2* and *Lbw2* (NZM.C57L*c4*) developed severe GN similar to wild-type NZM2328, but had markedly reduced to normal levels of anti-dsDNA antibodies (29). This model is particularly interesting since elucidation of the responsible genetic alteration should yield significant insights about the etiopathogenesis of antinuclear antibodies. Overall, findings in these various interval congenic mice suggest the presence of multiple subloci within the NZ chromosome 4 interval and/or considerable influence of background genes.

A NZB C1q polymorphism located within the *Nba1/Lbw2/Imh1/Mott* interval on chromosome 4 that down-regulates C1q levels is an attractive candidate since deficiencies of the early complement components (C1q-s, C2, or C4) predispose to SLE in humans (49). Moreover, homozygous C1q knockout mice develop a strain background-dependent loss of tolerance to nuclear antigens and abnormal accumulation of apoptotic bodies in the kidney glomeruli, suggesting that C1q may prevent systemic autoimmunity by playing a nonredundant role in the clearance of apoptosis byproducts (50 ,51). More recent fine mapping, however, has indicated that C1q is not within the *Lbw2* interval (48).

The chromosome 7 interval is similar to chromosome 1 in that both NZW and NZB loci have been mapped to this region. In terms of the NZW locus, the B6 congenic for *Sle3/Sle5* (B6.NZM*c7*) was found to develop elevated, but low, levels of antinuclear antibodies and a low incidence of GN, but when combined with other SLE loci promoted more severe lupus manifestations depending on the combinations (27 ,52). *Sle3* was initially thought to promote generalized T cell activation because of a marked increase in activated T cells, elevated CD4:CD8 ratios and resistance to activation-induced cell death in congenic mice (52). More recently, however, using bone marrow chimera experiments with allotype labeled B and T cells from B6 and B6.*Sle*3/5 mice, it was shown that the susceptibility genes was expressed in a nonlymphocyte bone marrow-derived population that affected T cell selection, survival, or both (53).

B6.*Yaa* mice congenic for the NZB chromosome 7 locus (B6.*Nba5*) have also been generated and characterized (54). Compared with B6.*Yaa* mice, congenics develop increased gp70 immune complexes and more severe GN, although the incidence was low and onset delayed compared with B6.*Yaa* congenic for the *Nba2* (NZB chromosome 1) locus. Remarkably, *Nba5* had no effect on either anti-DNA or antichromatin IgG autoantibodies. Thus, *Nba5* represents another locus that affects autoantibody specificity.

A CD22a variant in NZW and NZB mice located within the *Sle5* and *Lbw5* intervals on chromosome 7 has been suggested as a possible candidate (55). CD22a has a 794 base pair insertion within the second intron of a cluster of short interspersed nucleotide elements, which leads to aberrant alternative splicing. This is associated with reduced LPS-stimulated expression of CD22 in B cells to about half the level observed with the CD22b (B6 mice) allele. The CD22 is a candidate gene for *Sle5*, but it is not a candidate for *Lbw5*, since congenic NZB mice containing the NZW *Lbw5* interval have enhanced disease (unpublished observations).

The *Sgp3* locus on chromosome 13 has also been confirmed in B6 mice containing either the relevant NZW or NZB intervals (54 ,56). *Sgp3* was primarily associated with increased production of gp70, however, in autoimmune–prone *Yaa* mice *Sgp3* also enhanced GN and in some cases autoantibodies to DNA and chromatin.

Loci Identified in MRL-Fas^{lpr} Crosses

Although the *Fas^{lpr}* mutation promotes loss of tolerance and autoimmunity, the type of manifestations and severity of lupus-like disease are highly dependent on background susceptibility genes. This has led several groups to define lupus-related QTL in crosses of MRL-*Fas^{lpr}* mice, a strain that develops particularly severe spontaneous accelerated systemic autoimmunity (Table 7.2). Fifteen named QTL for one or more lupus traits have been identified on 8 of the 19 autosomal chromosomes. Many of the loci are linked to the different traits, such as sialadenitis, GN and vasculitis, which are likely caused by overlapping, but distinct, sets of susceptibility genes. Several loci on chromosomes 5 (*Lmb2, Lprm4*), 7 (*Lmb3, Ldrm1*), and 10 (*Lmb4, Asm1*) have overlapping intervals and may be identical (57 ,58 ,59 ,60). Interestingly, the Lmb1 locus (chromosome 4), which mapped to the nonautoimmune B6 background, had an additive effect on lymphoproliferation equal to the other *Lmb* QTL (57). This further demonstrates that so-called nonautoimmune mice can harbor bonafide susceptibility genes, but apparently the number and combination of such genes are insufficient for disease induction. Such genes undoubtedly account for the background effects observed when using different strain combinations to map QTLs.

The CD72c variant in MRL mice, which originated from the LG/J strain, has 13 amino acid substitutions compared with the CD72b allele (C3H strain), including acidic, basic, and neutral changes, and is a candidate for the *Arvm1* locus on chromosome 4 (61). CD72 is a member of the C-type lectin superfamily expressed on the surface of B cells (62). It is a negative regulator of B cell activation and also plays a role in B cell development.

Loci Identified in BXSB Crosses

The *Yaa* gene is the major predisposing gene in BXSB males, however, susceptibility is also highly dependent on other BXSB genes (63 ,64 ,65). Genome-wide searches to define those genes have identified 12 named BXSB-derived loci encompasssing 8 chromosomes in backcrosses of BXSB to C57BL/10 (B10) or to NZW strains (Table 7.2). In reciprocal male BXSB × B10 backcrosses, five QTL were found to be linked to one or more traits, including antinuclear antibodies, lymphoproliferation, and GN (66 ,67). Four were located in different regions on chromosome 1 and one was mapped to chromosome 3. Other loci with suggestive linkages were also identified on chromosomes 4, 10, and 13. Contrastingly, in a male BXSB × NZW backcross study, a completely different set of BXSB loci for other traits that included anticardioliolipin antibodies, antiplatelet antibodies, thrombocytopenia, and myocardial infarction, were found to map to chromosomes 4, 7, 8, 14, and 17 (68). Finally, in another study of female (BXSB × NZW)F2 mice, two BXSB loci were identified, one on chromosome 1 to splenomegaly and the other on chromosome 4 (*Lxw1*) to antichromatin autoantibodies (69). Interestingly, although female (BXSB × NZW)F1 and female (NZB × NZW)F1 mice both develop accelerated disease compared with parental strains, the genetic contributions of BXSB and NZB loci to this additive effect were completely different. This suggests that at least some of the susceptibility gene variants in these strains may not be derived from the common ancestral Asian and European mouse strains.

BXSB loci (*Bxs1–4*) on chromosome 1 have also been largely confirmed with 4 congenic B10.*Yaa* mice containing sizeable and overlapping chromosome 1 fragments of the BXSB genome (70). Three of these intervals, however, contain more than one *Bxs* locus, and therefore more precise mapping using congenic mice with smaller introgressed chromosomal regions will be required to verify the presence of these loci and to delineate their individual characteristics.

Loci in Other Spontaneous Lupus Crosses

A recent study documented significant lupus-like disease with immune complex GN in (129xB6) hybrids and identified loci on chromosomes 1 (129-derived), 3 (B6-derived), and 4 (B6-derived) that promote autoantibodies to nuclear antigens, including DNA and chromatin (32). Furthermore, B6 congenic mice containing a 129 chromosome 1 interval was sufficient to cause loss of tolerance to nuclear antigens and the production of autoantibodies. The 129 chromosome 1 region overlaps with *Sle1b* and the findings may be related to the previously described polymorphisms of the SLAM/CD2

locus (31). Since 129 × B6 mixed backgrounds are often used to define characteristics of mice with gene knockouts, these results suggest caution in ascribing lupus manifestations solely to the deficient gene, particularly if the gene is located on chromosome 1 (71).

Another recently identified model of lupus and rheumatoid arthritis is the BXD2 recombinant inbred strain (4). This line is one of approximately 80 B6xDBA/2 recombinant inbred strains originally developed at the Jackson Laboratory (72). BXD2 mice spontaneously develop a systemic autoimmune disease, characterized by anti-DNA autoantibodies, rheumatoid factor (RF), immune complex GN, severe erosive arthritis, and a reduced lifespan of 14 months (4). Mapping susceptibility loci using 20 recombinant BXD strains identified two loci, a DBA/2 locus on chromosome 2 that was linked to anti-DNA autoantibodies and a B6 locus on chromosome 4 linked to RF levels.

Loci Identified in Induced or Mutant Models of Lupus

Loci contributing to systemic autoimmunity have also been identified in several induced or mutant models of SLE. In mercury-induce autoimmunity, most strains are susceptible with the notable exception of the DBA/2. Mapping of F2 crosses between the DBA/2 and susceptible SJL or NZB, identified a single DBA/2 locus on chromosome 1 (*Hmr1*) that was linked to reduced glomerular immune complex deposition (73). Interestingly, antibodies to nucleoli, a characteristic specificity observed in this disease, was only affected by the H-2^s haplotype and no other background genes.

Intravenous *M. bovis* (bacillus Calmette-Guérin) given to type I diabetes mellitus-susceptible NOD mice prevents diabetes but, remarkably, induces systemic autoimmunity manifested by hemolytic anemia, antinuclear antibodies, immune complex-mediated GN, and exacerbation of sialadenitis (13). When backcrosses to BALB/c mice were analyzed for prediposing loci, hemolytic anemia mapped to two loci on chromosomes 17 (*Bah1*) and 16 (*Bah2*) and antinuclear antibody (ANA) to 17 (*Bana1*) 10 (*Bana2*), and 1 (*Bana3*). No locus was identified for GN. Interestingly, two of the four regions (*Bana3, Bah1/Bana1*) overlap with previously identified lupus-predisposing loci. Another interesting observation is that, other than the MHC region, none of the lupus-predisposing loci colocalized with diabetes loci. Thus, there is no evidence for common autoimmune–predisposing genes in NOD mice, although lupus- and diabetes-susceptibility genes shared by both NOD and BALB/c mice have not been ruled out (14).

Deficiency of Fcγ RIIb has been shown to enhance autoimmunity in several different disease models, including spontaneous lupus (74). Other complementation studies documented that the Fcγ RIIb knockout synergizes with the *Yaa* gene and, to a lesser extent, with the *Sle1* locus, but surprisingly not with the *Fas^{lpr}* defect (75). In terms of lupus, background genes are also critically important as evidenced by the fact that lack of Fcγ RIIb in B6, but not BALB/c, mice results in systemic autoimmunity. Genome-wide analysis to define the genetic basis for this difference in susceptibility revealed three regions, designated *sbb1–3* on chromosomes 9, 12, and 17, that were linked to ANA, spleen weight, and/or proteinuria (75) (Table 7.2). One of these loci, *sbb1*, was derived from the nonsusceptible BALB/c genome. Notably, none of the B6 loci identified in the (129xB6) cross (chromosomes 3 and 4) were found in this study, suggesting suggesting that the 129 gene segment may not contribute to lupus development in the Fcγ RIIb knockouts or may reflect differences in the BALB/c and 129 genomes (different sets of susceptibility genes that overlap with B6).

Specific “Lupus” Predisposing Genes

Spontaneous variants or mutations that predispose to autoantibody production or other lupus-like manifestations in mice have been documented for the major histocompatibility complex (MHC) class II genes, Fas, Fas ligand (*Fasl*), and hemopoietic cell phosphatase (*Hcph* or SHP-1) (Table 7-3). The Y accelerator of autoimmunity and lymphoproliferation (*Yaa*) “gene”, which is responsible for the male predisposition to lupus in BXSB mice, has recently been shown to be an expansion of the pseudoautosomal region of the Y-chromosome with duplication of several X-chromosome genes. Defects or polymorphisms in other immune-related genes have been postulated to predispose to lupus, but their roles have not been firmly established. These genes include the T cell receptor (TCR) (76 ,77 ,78 ,79 ,80 ,81), immunoglobulin (Ig) (82 ,83 ,84) and TNF-α (Tnf) (85 ,86 ,87 ,88), Fcγ RIIb (44), and CD22 (55). *Cr2* (33), C1q (49), SLAM family genes (31), and P2X7 receptor (89).

MHC Class II Genes

Predisposition to systemic autoimmunity is strongly linked to specific MHC (H-2 in mice) haplotypes in certain lupus backgrounds, particularly the BXSB (90) and BWF1 mice (91 ,92). For the BXSB strain, H-2^b is the lupus-predisposing haplotype (90 ,93), whereas the heterozygous H-$2^{d/z}$ is associated with the greatest susceptibility in BWF1 hybrids (reviewed in (63)). Although certain MHC haplotypes can promote susceptibility, additional predisposing genes are required for the development of SLE, since autoimmunity does not develop when the predisposing MHC haplotypes are on normal backgrounds or crosses (63 ,94). For example, (NZBxNZW)F1 mice (H-$2^{d/z}$) are highly susceptible to lupus, whereas F1 hybrids between NZB and PL/J or B10.PL (H-2^u, identical to H-2^z in the antigen-binding domains), or BALB/c mice congenic for H-2^z, are not susceptible (95 ,96 ,97). Other examples are the BXSB.*1l* and MRL-*Fas^{lpr}.1l* (*1l* for long-lived) substrains that have identical H-2 haplotypes, but are much less susceptible to disease because of possible single mutations in non-MHC genes (1 ,2 ,3).

The actual gene (or genes) within the MHC complex that promotes lupus susceptibility remains to be determined.

Polymorphic class II genes are strong candidates based on findings in H-2 congenic mice and their central roles in both repertoire shaping and antigen recognition (90 ,98 ,99). NZB mice congenic for H-2^{bm12}, but not the closely related H-2^{b}, develop accelerated disease despite the fact that these haplotypes are apparently similar except for the I-A molecule. This seems to implicate three amino acids in the I-A ß-chain at positions 67, 70, and 71, since the H-2^{bm12} and H-2^{b} sequences differ by these residues in the MHC peptide-binding groove. Strong linkage with lupus disease in NZ background mice is conferred the hemizygous H-2^{z} haplotype in combination with either the d, b, or v haplotypes (91 ,92 ,100 ,101 ,102). It has been proposed that in this instance, autoimmune-promoting MHC class II specificites are created by transcomplementation of the different α- and ß-chains with formation of novel hybrid molecules (103 ,104). The finding that other heterozygous H-2^{z} haplotypes, including H-$2^{v/z}$ (102) and H-$2^{b/z}$ (100 ,101), also increases susceptibility makes it less likely that novel class II hybrid molecules are responsible. Another possibility is that the two different H-2 haplotypes regulate the production of different sets of nephritogenic autoantibodies (105). In this case, heterozygous H-$2^{d/z}$ haplotype mice would produce both sets of pathogenic antibodies resulting in greater susceptibility to nephritis. Studies attempting to directly implicate class II molecules by expressing I-A^{z} or I-E^{z} transgenes in the NZB × C57BL/6 background, however, found no increased susceptibility with either transgene (106 ,107). Although the inference is that the class II molecules are not responsible, it is also possible that the transgene did not adequately recapitulate the expression patterns required to promote autoimmunity, since it is known that slight changes in class II expression result in substantial effects on disease susceptibility, e.g., homozygous versus heterozygous expression (108) or the presence or absence of I-E (109). In this regard, transgenic mice would not have the same levels of class II molecules as wild-type mice since they would have normal levels of class II in addition to the transgene.

Table 7-3: Spontaneous Mutations Associated with Lupus-Like Manifestations

Name	Gene	Chr*	Mb	Susceptible Allele	Alteration	Major Autoimmune Manifestations
Fas ligand	*Fasl*	1	85.0	*gld*(generalized lymphoproliferative disease)	T→C, 847 nt. (Phe→ Leu)	lymphoproliferation, DN T cells, autoAbs, GN
SHP-1, PTP-1C, hemopoietic cell phosphatase (protein tyrosine phosphatase, nonreceptor type 6)	*Ptpn6*	6	60.2	*me*(motheaten) me^{v}(viable motheaten)	C deletion, 228 nt. aberrant RNA splicing T→A 1076 nt. disrupts splice donor site	autoAbs (both me and mev mutations)
MHC complex	*H2*	17	32.0	depends on background strain	H-$2^{d/z}$(BWF1) H-2^{b}(BXSB) H-2^{bm12}(NZB) others.	enhanced autoimmunity, including autoAb, GN, lymphoproliferation (depending on MHC and background)
Fas, APO-1, CD95	*Fas*	19	33.6	*lpr* (lymphoproliferation)	ETn insertion with aberrant RNA splicing	lymphoproliferation, expansion of DN T cell subset, autoAbs, GN, arthritis depending on background (both *lpr* and lpr^{cg} mutations)
				lpr^{cg} (lymphoproliferation complementing *gld*)	T → A, 786 nt. (Ile → Asn) disrupts binding of Fas to Fasl	
Y accelerated autoimmunity and lymphoproliferation		Y		*Yaa*	4 Mb expansion due to duplication of X-chromosome pseudo autosomal region; includes TLR7 gene	accelerated autoimmunity, enhanced Ab responses to foreign and self-antigens

*Chr, chromosome; chromosomal locations are based on the Mouse Genome Informatics (http://www.informatics.jax.org/). See text for references.

Other studies have sought to explain why H-2^d (I-E^+) congenic BXSB mice (normally H-2^b (I-E^-)) do not develop lupus (99 ,109 ,110). Lack of susceptibility was not from I-E-dependent, endogenous superantigen-induced modifications of the TCR BV repertoire imposed by H-2d, because H-$2^{b/d}$ haplotype mice are susceptible to disease despite similar deletion of the appropriate BV bearing T cells (90). Interestingly, BXSB mice expressing a high copy number (~50) of an I-Eα^d transgene with approximately 20-fold higher Eα^d mRNA levels than H-$2^{b/d}$ mice were found resistant to the development of autoimmunity, similar to H-2^d BXSB mice (109). Protection by the I-Eα transgene has also been reported for I-E^+ haplotype lupus backgrounds (111 ,112). It is postulated that this resistance is a result of competitive inhibition of autoantigenic peptide binding to I-A^b by a large excess of transgenic I-Eα peptide. This, however, does not fully explain the lack of susceptibility of H-2^d BXSB mice that have normal copy number of I-Eα^d. Nonetheless, these findings suggest a novel mechanism wherein excess production of MHC-binding peptide from I-Eα or perhaps other proteins alters antigen presentation and, possibly, disease susceptibility. Whether the mechanism is due to inhibition of autoantigen presentation or repertoire shaping during central thymic selection or in the peripheral immune system is not known.

Other potential lupus-predisposing genes within the H-2 complex include a polymorphic NZW TNF-α gene that appears to promote lupus in BWF1 hybrids independently of the H-2 (85 ,86), complement components C2 and C4 (35), IEX-1 (113) and a recessive NZW locus (*Sles1*) that appears to suppress autoimmunity in NZW mice (19). The *Sles1* locus has been mapped to 956 kb, but still includes the H-2 complex (114).

Fas and Fas Ligand

Fas (APO-1 or CD95) is a 306-amino acid, 45 kDa, cell surface membrane protein related to the TNF receptor superfamily of type I membrane glycoproteins. Fas is expressed on actively proliferating cells in the thymus, liver, ovary hear, skin, and gut epithelium with particularly high levels on $CD4^+CD8^+$ thymocytes, activated T and B cells, and some neoplastic cells (115 ,116). Following binding to its ligand, Fas transduces signals leading primarily to apoptotic cell death (117 ,118). The ligand for Fas, FasL, is a 40 kDa type II transmembrane glycoprotein belonging to the TNF ligand family of proteins. It is expressed almost exclusively on T cell lineages, primarily upon activation (119), and in certain immunologically sequestered sites such as the testis, eye and placenta (119 ,120 ,121 ,122). In these areas, FasL may contribute to maintenance of immune privilege by inducing Fas-mediated apoptosis in invading inflammatory cells, reducing inflammatory responses (123) and, in the case of the retina, may also control the growth of new vision-damaging subretinal blood vessels (124). Further details on Fas/FasL-induced apoptosis can be found in Chapter 8 .

Two spontaneous loss-of-function mutations in Fas (*Fas^{lpr}* and *Fas^{lpr-cg}*) and one in FasL (*$Fasl^{gld}$*) result in similar autoimmune manifestations (Table 7.3). The *Fas^{lpr}* (lymphoproliferative) defect is caused by an early retroviral transposon (ETn) insertion within the second intron between exons 2 and 3, which causes aberrant RNA splicing, a frame shift, and premature termination of the mRNA at the long terminal repeat region of the ETn (125 ,126 ,127 ,128 ,129). Low levels (~10%) of wild-type Fas mRNA and surface protein, however, are detectable (127 ,128 ,129 ,130 ,131), and recombinant Fas knockout mice, but not *lpr* mice, develop liver hyperplasia in addition to lymphoproliferation (132). The *Fas^{lpr-cg}* mutation is caused by a single point mutation (T → A at nucleotide 786; isoleucine→asparagine; this residue is valine in humans) within the intracytoplasmic domain of Fas that modifies an amino acid in the so called “death domain” essential for signal transduction (126 ,133). Finally, the *$Fasl^{gld}$* allele is a point mutation in

the carboxy-terminal extracellular domain (T→C at nucleotide 847, phenylalanine→leucine) of FasL on chromosome 1, which abolishes the binding of Fas to the FasL (134 ,135 ,136 ,137).

Mice homozygous for these mutations have accumulation of CD4-CD8- (double negative, DN), $B220^+$, TCRab^+ T cells and the induction or acceleration of systemic autoimmunity (63 ,138). Both severity of the autoimmune disease and degree of lymphoproliferation, however, depend on other background genes (63). *Fas*^{lpr} does not complement *Fasl*^{gld}, whereas the *Fas*$^{lpr\text{-}cg}$ allele, as suggested by its name, can complement both the *Fas*^{lpr} allele and to a slightly lesser degree, the *Fasl*^{gld} allele. Furthermore, in contrast to the recessive *Fas*^{lpr} mutation, autoimmunity and lymphoproliferation is observed in heterozygous MRL-*Fas*$^{lpr\text{-}cg/+}$ mice, although less severe and without the characteristic expansion of DN T cells (139). In humans, defects in *Fas* have been identified as a cause of the rare autoimmune lymphoproliferative syndrome (ALPS or Canale-Smith syndrome) (140 ,141 ,142). This syndrome has also been described with loss-of-function mutations in caspase 10, a cysteine protease involved in the downstream apoptosis-promoting pathway of Fas (143). The majority of SLE patients, however, do not appear to have deficiencies or mutations in *Fas* or *FasL* (144 ,145 ,146 ,147).

As a result of the important role that Fas/FasL plays in apoptosis, defects in clonal deletion of T and B cells have been sought to explain the *lpr* phenotype. Clearly a T cell defect is evident by the accumulation of DN *lpr* cells. Most studies, however, have found no defects in central thymic deletion in Fas-deficient mice to exogenous and endogenous superantigens (148 ,149 ,150 ,151) and conventional class I and II presented antigens (152 ,153 ,154). In contrast, abnormalities in the receptor-mediated apoptosis of mature T cells (151 ,152 ,155 ,156) along with the early expansion of a distinct BV8.3/BD1.1/BJ1.1 T cell receptor in $CD4^+$ cells from MRL-*Fas*^{lpr}, but not *MRL*-$^{+/+}$ (157 ,158), have implicated defective peripheral T cell deletion as a possible mechanism contributing to autoimmunity. Thus, Fas/FasL interactions are important for activation-induced cell death (AICD) (159 ,160). AICD is initiated by antigen receptor engagement, which upregulates Fas and induces FasL in T cells, primarily in $CD8^+$ cells and the Th0 and Th1 $CD4^+$ subsets. Subsequent binding of Fas and FasL leads to RNA-dependent apoptosis (159 ,161 ,162 ,163). Fas-mediated killing is essential for $CD4^+$ Th1 T cell-mediated cytotoxicity and is one of at least two cytotoxic T lymphocyte (CTL) pathways for $CD8^+$ T cells (164 ,165 ,166 ,167 ,168). The Fas-dependent CTL pathway, however, in contrast to the perforin-dependent CTL pathway, cannot kill pathogen-infected targets (169), suggesting that Fas/FasL functions primarily in maintaining cell homeostasis, i.e., killing expanded clones that have outlived their immunologic function.

Evidence from the TCR BV repertoire of DN $B220^+$ T cells (150 ,158), DN cell cytolytic activity and positive perforin expression (170), anti-CD8 treatment and targeted gene knockouts of MHC class I (ß2-microglobulin) (171 ,172 ,173 ,174), CD8 (175), or CD4 (175) indicate that the majority of DN cells are derived from $CD8^+$ T cells. DN *lpr* cells are likely activated peripheral T cells that fail to undergo AICD, a finding consistent with their activated phenotype, which includes $CD44^{hi}$, expression and phosphorylation of $p57^{fyn}$, constitutive tyrosine phosphorylation of Vav and high expression of FasL in both *gld* and *lpr* mice (176 ,177). The elevated constitutive expression of FasL has been postulated to cause the unidirectional *lpr*-associated wasting syndrome (i.e., graft-versus-host disease-like abnormality) observed when *lpr* bone marrow is adoptively transferred to wild-type recipients (176 ,178 ,179 ,180).

An important role for T cells in *lpr* disease was suggested by reversal of both lymphoaccumulation and autoimmunity in MRL-*Fas*^{lpr} mice expressing a wild-type Fas transgene under the control of the CD2 promoter (181). However, the significance of this became less certain when subsequent studies of non-autoimmune mice expressing the same CD2-*Fas* transgene revealed a lack of thymic atrophy and other T cell characteristics normally associated with aging (182), thereby indicating alteration of normal T cell development. Subsequently, more specific transgenic expression of Fas in T cells, but not B cells (lck promoter), was found to block lymphoproliferation, but not autoimmunity (183), whereas expression in both B and T cell (lck distal promoter) reduced both lymphoproliferation and autoimmunity (184). This suggests that Fas expression in B cells may be a critical factor, as supported by other studies that clearly implicate B cells in the development of *lpr*-mediated autoimmunity.

Mixed bone marrow chimera studies have demonstrated that autoantibodies are produced from Fas-defective, but not wild-type, donor B cells (185). B cells from *lpr* and *gld* mice exhibit resistance to spontaneous apoptosis in vitro (186). Double-transgenic mice expressing the antibody to hen egg-white lysozyme (HEL) and either membrane-bound or soluble HEL were used to study the fate of autoreactive B cells in Fas-deficient *lpr* mice (187). Elimination of self-reactive *lpr* B cells recognizing membrane-bound HEL and functional inactivation of B cells to soluble HEL appeared to occur normally; however, an age-related breakdown of tolerance to soluble HEL was observed, suggesting a defect in the censoring of autoreactive B cells. Further studies indicated that anergic B cells normally are eliminated by $CD4^+$ T cells through the Fas/FasL pathway but, without Fas killing, B cells are triggered to proliferate (188 ,189). Consistent with this are findings that anti-dsDNA B cells in Fas-deficient mice are not developmentally arrested and excluded from splenic follicles as in nonautoimmune mice, but migrate into the follicles (190), and abnormal increases in IgG2a- and RF-secreting B cells in the T-rich zones of the PALS (191) Fas/FasL-mediated apoptosis also may further contribute to B cell homeostasis by eliminating bystander B cells that are activated by CD40L alone (192). More recent studies, however, using selective ablation of Fas in T cells, B cells, T and B cells, or all cells found that full development of lymphoproliferative disease required deletion of Fas in both lymphoid and nonlymphoid tissues (193).

Protein Tyrosine Phosphatase and Motheaten Mice

SHP-1 is a protein tyrosine phosphatase (PTP) ubiquitously expressed in hemopoietic lineage cells. Two recessive spontaneous mutations, motheaten (*me*) and motheaten viable (me^v), result in similar severe developmental and functional abnormalities of multiple hematopoietic cells lineages, leading to mortality of *me* and me^v mice around 3 and 9 weeks of age, respectively (194). Motheaten mice are immunodeficient, but paradoxically develop features of systemic autoimmunity such as hypergammaglobulinemia, antinuclear antibodies and immune complex deposits in multiple tissues (195). The hypergammaglobulinemia is produced by an expanded population of atypical plasmacytoid cells and a reduced B cell population composed primarily of $CD5^+$ B1 cells. The T cell compartment is normal at birth, but by 4 weeks of age there is involution, absent lymphoid follicles, impaired CTLs, and reduced responses to both mitogens and allo-antigens. Other hematopoietic alterations include defective natural killer (NK) cell differentiation and function, increased erythroid precursors, and enormous expansions of monocytes/macrophages and neutrophil populations. The term motheaten refers to a characteristic skin pattern of patchy inflammation and alopecia caused by large subcutaneous and dermal acccumulations of neutrophils that rupture and scar.

SHP-1 consists of an N-terminal catalytic domain and two in tandem SH2 (src homology 2) domains that are important for its function. The me mutation is a single cytidine residue deletion at position 228 within the N-terminal SH2 domain that converts the normal sequence to a donor splice-site consensus sequence. This results in aberrant splicing and deletion of the 101-bp portion of exon downstream from the newly created splice site. The me^v mutation disrupts a normal GT 5′ splice donor site (GT→GA, residue 1076), which also leads to aberrant splicing, this time within the SHP-1 catalytic domain, 15-bp upstream of the normal splice site (196 ,197). SHP-1 activity in the me mutant is absent, whereas a profound reduction is found in the me^v mutant (198); findings consistent with the greater severity of disease in me mice.

SHP-1 is recruited by negative regulatory molecules that contain immunoreceptor tyrosine-based inhibitory motifs (ITIM) (199), such as CD22, Fcγ RIIb, and CD72, to specific sites where it then inhibits molecular complexes that require tyrosine phosphorylation for activation, such as the BCR and TCR. Loss of this essential inhibitory function in me mice appears responsible for the exuberant activation and expansion of hematopoietic cell populations and the resulting disease manifestations. Although me mice have increased immunoglobulin levels and autoantibodies, the major clinical sequelae that lead to early mortality in these mice are not observed in spontaneous SLE, and the disease is not mediated by autoantibodies or T and B lymphocytes (196 ,197 ,200 ,201 ,202). Autoantibody production may be caused by the inability of CD22 and possibly Fcγ RIIb to negatively regulate the B cell antigen receptor when SHP-1 is absent (203). Nevertheless, heterozygous deficiency of SHP-1 can synergize with partial deficiencies of CD22 and lyn to promote loss of B cell tolerance (204).

Yaa Gene

BXSB mice have a marked male predilection to systemic autoimmunity, in contrast to the female predominance in humans and other susceptible mouse strains. This striking sexual dichotomy is not because of hormonal factors, but to a Y-chromosome alteration, designated *Yaa* (205,206,207a) that was recently identified as an approximately 4 Mb expansion containing at least 13 known and 4 unknown X-chromosome-specific genes (207b). Among the genes in this duplicated interval, TLR7, which is activated by single-strand RNA, appears to be a strong candidate. In support of this, Yaa^+ B cells have enhanced response to TLR7 (imiquimod), but not TLR9 (CpG) ligands. Other genes within the *Yaa* fragment, however, have not been excluded.

Transfer of the *Yaa* gene (Y-chromosome) to nonautoimmune and autoimmune mice has demonstrated that it contributes additively to lupus, but is dependent on other background genes. Nonautoimmune strains such as CBA/J or C57BL/6 are largely unaffected, whereas all lupus-susceptible strains examined, including BXSB, NZB, NZW, and MRL-Fas^{lpr}, show accelerated disease that generally maintains the clinical characteristics of the background strain (63 ,64 ,65 ,208). Mice with mild lupus appear affected more by the *Yaa* duplication than strains with already accelerated disease (90). This selective augmentation by *Yaa* contrasts with the induction of generalized autoimmunity by the *lpr* and *gld* mutations (208) and suggests different mechanisms, as further supported by the findings that *lpr* and *Yaa* congenic mice with identical backgrounds have different phenotypes (63), and that the *lpr* and *Yaa* are additive (209). Interestingly, DBA/1.*Yaa* (consomic for the BXSB Y-chromosome) were less susceptible to collagen-induced arthritis (CIA) than wild-type DBA/1 mice, suggesting that *Yaa* plays different roles in CIA and lupus (210).

Regarding the mechanisms responsible for the *Yaa* phenotype, double bone-marrow chimera experiments using a mixture of Yaa^+ and Yaa^- cells of different IgH allotypes revealed selective production of anti-DNA antibody and hypergammaglobulinemia by Yaa^+ B cells (211). The antibody-promoting effect of *Yaa* is applicable not only to self-antigens, but to foreign-antigens as well (212) and, analogous to the effects in lupus mice, enhancement was observed mainly for antigens eliciting low, T cell–dependent antibody responses and not for those eliciting high antibody responses (212). Accordingly, *Yaa* was postulated to increase the expression of an “intercellular adhesion molecule” on B cells, which promotes low-avidity, T-helper–B cell interactions (207a). Thus, nontolerant T-helper cells that are normally quiescent in Yaa^- animals because of insufficient antigen presentation become activated in Yaa^+ animals. Other mechanisms that increase antigen presentation, intracellular signaling, and coreceptor molecule expression are also possible. Interestingly, Yaa^+ mice of lupus

and nonautoimmune backgrounds have reduced numbers of marginal zone B cells, consistent with the notion that their B cells are more hyperreactive, and which argues against a major pathogenic role for MZ B cells in this model (213 ,214).

Similar mixed bone marrow chimera experiments, but with *Yaa*$^{+}$ and *Yaa*$^{-}$ T cells of different Thy-1 allotypes, revealed similar disease severity regardless of whether *Yaa*$^{+}$ cells were present or eliminated by anti-Thy-1 antibodies (112). Consistent with this, T cells from *Yaa*$^{+}$ mice do not have enhanced proliferative responses compared with T cells from *Yaa*$^{-}$ mice (214). Finally, no difference in disease severity was found when T cell-deficient (TCR α-chain knockout) BXSB male mice were reconstituted with either *Yaa*$^{+}$ or *Yaa*$^{-}$ T cells (215). Overall, these findings clearly indicate that expression of the *Yaa* defect in T cell is not required for autoimmunity.

Genetically Manipulated Genes That Promote SLE-Like Disease

Genetic manipulation of specific genes for other reasons in nonautoimmune strains has sometimes serendipitously yielded novel and informative models of SLE. Thus far, at least 50 different genes have been identified by this approach, although in some cases autoimmunity may be due to the use of the mixed (B6x129) background. Nevertheless, several common mechanistic pathways have been identified, including enhanced activation of B and T cells, defective apoptosis, defective clearance of self-antigens, enhanced antigen presentation, and cytokine-mediated activation (Tables 7-4 and 7-5).

Genes Related to B Cell Activation

The fate of B cells following antigen receptor (BCR) engagement is a complex process that involves direct or indirect interaction of the BCR with numerous molecules that can promote or inhibit cell activation. Among these are several tyrosine kinases (lyn, fyn, Btk, Blk, Syk), phosphatases (CD45, SHP-1, SHP-2, and SHIP) and accessory molecules (CD19, CD22, FcRγIIb, CD72). Genetic manipulation of many of these B cell regulatory molecules have resulted in mice with features similar to lupus.

Lyn is a nonreceptor Src-related tyrosine kinase involved in negative regulation of BCR signaling (216 ,217). Although lyn also plays a role in positive signaling, this function appears largely redundant since deficiency of lyn leads to hypersensitivity to BCR-mediated triggering. Mice with homozygous deletions of lyn have increased activation and higher turnover rates of B cells, splenomegaly, elevated IgM levels, autoantibodies, and GN. Homozygous deficiency of CD22, a B cell-specific cell surface sialoadhesin that specifically binds to asialoglycoproteins, results in a similar picture with hyperresponsiveness to BCR signaling, expansion of the peritoneal B1 cell population, and autoantibodies (218 ,219 ,220). Similarities between the lyn and CD22 knockouts stem from the fact that the inhibitory action of CD22 requires the recruitment and phosphorylation of lyn, which, in turn, recruits SHP-1, bringing it in proximity to the BCR where it can dephosphorylate the BCR and downregulate the response. Heterozygous deletions of CD22, lyn and SHP-1 were shown to have additive effects on B cell abnormalities consistent with the notion that they are limiting elements to a common pathway (204).

CD19, along with CD21 and Tapa-1 (CD81) on B cells, form the functional cell surface receptor complex for C3 fragments, which enhances BCR signal transduction and is crucial for B cell development and tolerance. Mice overexpressing a CD19 transgene develop hyperresponsive B cells to BCR cross-linking, marked expansion of the B1 cell population, hypergammaglobulinemia, and autoantibodies (221). Furthermore, expression of the CD19 transgene in anti-hen egg lysozyme Ig (HEL-Ig)/soluble HEL double-transgenic mice led to the appearance of anti-HEL antibodies, suggesting that a defect in anergy to certain soluble antigens might be the underlying mechanism (222).

As discussed previously, the Fcγ RIIb on B cells is an important inhibitor of B cell antigen receptor signaling. Gene knockout of FcγRII amplifies humoral and anaphylactic responses (223), and leads to the development of lupus-like disease (74) as well as increased severity of type II collagen-induced arthritis (224) and type IV collagen-induced Goodpasture syndrome (225). The lupus-like disease, however, only occurs in B6, but not BALB/c, mice indicating a significant role for background susceptibility or resistance (74). To what extent this is a result of the *Sle1b* SLAM/CD2 haplotype or to 129 background genes will need to be determined particularly since Fcγ RIIb is located on chromosome 1. In this regard, a more recent study found that autologous bone marrow reconstitution of Fcγ RIIb$^{-/-}$ mice with Fcγ RIIb-expressing retrovirus-transduced cells, not only increased expression of Fcγ RIIb on B cells, but also markedly reduced anti-dsDNA antibodies and GN (226). Although this supports the association of lupus with Fcγ RIIb deficiency, the same disease ameliorating outcomes were also observed in similarly-treated NZM2410 and BXSB mice indicating that increased Fcγ RIIb expression had more global effects on autoimmunity. Interestingly, increased expression of Fcγ RIIb by 40% in 40% of B cells was sufficient to inhibit autoimmune disease.

Aiolos is a zinc finger DNA-binding protein that shares a common GGGA core sequence binding motif with the closely homologous nuclear factor Ikaros (227). It is highly expressed in mature B cells and, to a lesser extent, in developing bone marrow B cells and thymocytes. In the nucleus, Aiolos is mainly localized to the 2 MD chromatin remodeling complex that also contains Ikaros, the Mi-2 ATPase, histone deacetylases and other components of the NURD (nucleosome remodeling histone deacetylase complex (227 ,228 ,229 ,230). NURD complexes have been suggested as participants in transcriptional repression by promoting DNA methylation and allow repressors to gain access to chromatin

(228 ,229 ,230). Ikaros was also found to interact with the mSin3 family of corepressors (231). These findings suggest that Ikaros family members regulate gene expression during lymphocyte development by recruiting certain histone deacetylase complexes to specific promoters (231). Mice with homozygous deletions of the Aiolos gene develop defects primarily in the B cell compartment, with hyperresponsiveness to BCR and CD40 stimulation, increased number of conventional B cells but a marked reduction in B1 cells, increased proportion of B cells with activated phenotype, hypergammaglobulinemia (particularly of IgE and IgG1), a three-fold reduction in IgM and positive ANAs in about half of animals by 16 weeks of age (232). Detected T cell abnormalities were limited to a slight increase in proliferative capacity of thymocytes and mature T cells. Thus, deficiency of Aiolos appears to facilitate B cell entry into cell cycle, maturation to germinal center lymphocytes, and a breakdown of B cell tolerance.

Table 7-4: Genetically-Manipulated Single Gene Alterations That Promote Lupus-Like Manifestations

Name	Gene	Chr*	Mb	Major Autoimmune Manifestations	Ref.
Knockouts/Mutations					
CTLA-4	*Cd152*	1	61.2	multiorgan lymphoproliferative dis., myocarditis, pancreatitis	(265,266,267)
PD-1 (programmed cell death 1)	*pdcd1*	1	93.7	prolif. arthritis, GN, glomerular IgG3 deposits.	(276)
mannoside acetyl glucosaminyltransferase 5	*Mgat5*	1	127.0	proliferative GN, enhanced EAE	(314)
CD45 (protein tyrosine phosphatase, receptor type C	*Ptprc*	1	137.9	lymphoproliferation, anti-dsDNA, splenomegaly, GN	(251)
Ro, SS-A (TROVE domain family, member 2)	*Trove2*	1	143.6	antiribosome and antichromatin autoAb, GN	(371)
roquin (RING CCCH (C3H) domains 1)	*Rc3h1*	1	160.8	autoAbs, lupus-like disease, incr. follicular T helper cells and GCs. M199R mutation.	(323)
FcgR2 (Fc receptor, IgG, low affinity IIb) serum amyloid P component	*Fcgr2b*	1	170.9	exacerbation of lupus-like disease in B6-Faslpr mice	(430)
	Apcs	1	172.8	anti-chromatin Ab, GN, female predom.	(357)
IL-2Rα	*Il2ra*	2	11.6	lymphoproliferation, hyperIgG, autoAb, anti-RBC Ab	(340)
Ras GRP1 (RAS guanyl releasing protein 1)	*Rasgrp1*	2	116.8	spont. recessive mutation prevents translation of Ras GRP1 protein, $CD4^+$ T cells resistant to AICD, lymphoprolif., autoAb	(353)
Nrf2 (nuclear, factor, erythroid derived 2, like 2	*Nfe2l2*	2	75.4	hyperIgG, anti-dsDNA Ab, GN, splenomegaly	(403)
TYRO3 protein tyrosine kinase 3 (Tyro 3 family)	*Tyro3*	2	119.3	triple knockout (Tyro3, Axl, Mer): lymphoproliferation, increased activated T and B cells, autoAb, GN	(364)
Bim (Bcl2 interacting mediator of cell death, Bcl2-like 11)	*Bcl2l11*	2	127.6	lymphoid/myeloid cell accumulation, autoAb, GN, vasculitis	(328)
c-mer proto-oncogene tyrosine kinase (Tyro 3 family)	*Mertk*	2	128.2	autoAb (Mertk knockout alone), (also see TYRO3 above)	(368)
IL-2	*Il2*	3	36.6	lymphoproliferation, hyperIgG, autoAb, anti-RBC Ab	(339)
GADD45 (growth arrest and DNA-damage-inducible 45 alpha)	*Gadd45a*	3	67.3	autoAb, GN, mortality, defective T cell death	(307)
TSAd (SH2 domain protein 2A)	*Sh2d2a*	3	87.6	hyperIgG, autoAbs, GN	(431)
lyn (Yamaguchi sarcoma viral (v-yes-1) oncogene homolog	*Lyn*	4	3.6	enhanced B cell activation, splenomegaly, hyperIgM, autoAb, GN	(216, 217)
E2F2 (E2F transcription factor 2)	*E2f2*	4	135.1	late onset autoimmunity with widespread inflammatory infiltrates, GN, ANA, enhanced T cell activation with accumulation autoreactive memory/effector T cells.	(322)
C1q, α, ß, γ polypeptides (different genes)	*C1q a,b,c*	4	135.8	autoAb, GN	(50, 432)

Tgfß1	*Tgfb1*	7	20.9	multiorgan lymphocytic and monocytic infiltrates	(288)
Zfp-36 (tristetraprolin)	*Zfp36*	7	23.8	complex systemic disease: cachexia, dermatitis, arthritis	(388, 390, 433)
CD22	*Cd22*	7	26.3	enhanced B cell activation, autoAb	(218, 434)
MFG-E8 (milk fat globule-EGF factor 8)	*Mfge8*	7	72.9	splenomegaly, incr. GCs, autoAbs, GN. reduced engulfment of apoptotic cells.	(378)
LAT (linker for activation of T cells)	*Lat*	7	120.4	mutation inhibits T cell development, but induces lymphoproliferation	(310)
PCMT (protein-L-isoaspartate (D-aspartate) *O*-methyltransferase 1	*Pcmt1*	10	7.5	wild-type mice reconstituted with PCMT(-/-) BM develop high titer anti-DNA Ab and GN	(325)
fyn (+lyn)	*Fyn*	10	39.4	synergizes with the Lyn ko to accelerate disease; in MRL-Fas*lpr* mice suppresses autoimmune dis., but exacerbates lymphoprolif.	(435, 436)
Gadd45ß	*Gadd45b*	10	81.1	splenomegaly, glomerular immune complexes, no autoAbs; synergizes with Gadd45 $ß^{-/-}$ to produce marked splenomegaly, dsDNA/histone Abs, immune complex GN.	(308)
TACI (tumor necrosis factor receptor superfamily, member 13b)	*Tnfrsf13b*	11	60.9	fatal lymphoprolif., autoAb, GN	(244)
Aiolos (zinc finger protein, subfamily 1A, 3)	*Znfn1a3*	11	98.3	activated B cells, increased IgG, autoAb	(232)
PECAM-1, CD31 (platelet/endothelial cell adhesion molecule 1)	*pecam1*	11	106.5	ANA, immune complex GN with age	(259)
Stra13 (stimulated by retinoic acid 13)	*Stra13*	11	120.5	lymphoid organ hyperplasia, autoAb, IC GN	(354)
G2A (G protein-coupled receptor 132)	*Gpr132*	12	108.3	lymphoid hyperplasia, hyperIgG, autoAb, GN	(312)
Gadd45 γ	*Gadd45g*	13	50.4	synergizes with Gadd45 ß knockout (chr 10).	(308)
Protein kinase C δ	*Prkcd*	14	28.7	splenomegaly, lymphadenopathy, hyperIgM/IgG1/IgG2a, dsDNA, GN	(253)
IL-2Rß	*Il2rb*	15	78.5	lymphoproliferation, hyperIgG, autoAb, anti-RBC Ab	(341)
DNase1	*Dnase1*	16	3.7	ANA, immune complex GN	(359)
Cbl-b (Casitas B-lineage lymphoma b)	*Cblb*	16	50.9	multiorgan lymphoid infiltrates, anti-dsDNA Ab	(298)
p21 (cyclin-dependent kinase inhibitor 1A)	*Cdkn1a*	17	26.9	antichromatin Ab, GN, female predominance	(300)
Complement component 4	*C4*	17	32.4	impaired immune complex clearance, ANA, GN, female predom.	(356)
Emk (ELKL motif kinase, Par-1, MAP/microtubule affinity-regulating kinase)	*Mark2*	19	7.0	growth retardation, hypofertility, splenomegaly, lymphoid infiltrates, immune complex GN	(399)
Pten	*Pten*	19	32.1	lymphadenopathy, autoAb, GN, decr. survival, female predom. (+/- knockout mice)	(349)
Transgenics					
FLIP (retrovirus-mediated expression)	*Cflar*	1	59.0	hyperIgG, autoAbs, GN	(346)
Bcl-2 (B cell promoter)	*Bcl2*	1	106.5	lymphoid hyperplasia, hyperIgG, autoAb, GN	(329)
CD19	*Cd19*	7	120.4	increased B cell activation, B1 cell population, IgG, autoAb	(221)

BAFF (α1antitrypsin or β-actin-promoter)	*Tnfsf13b*	8	9.4	autoAb (RF, CIC, dsDNA Ab), GN	((242, 243))
Fli-1 (class I promoter)	*Fli1*	9	32.3	lymphoid hyperplasia, autoAb, GN	(256)
IFN-γ (keratin promoter)	*Ifng*	10	118.0	autoAb, GN, female predom.	(380)
IL-4 (class I promoter)	*Il4*	11	53.4	hyperIgG1/E, autoAb, GN	(381)
IEX-1 (Ig μ enhancer)	*Ier3*	17	33.5	lymphoproliferation, autoAb, GN, skin lesions, arthritis	(113)
LIGHT (lck promoter)	*Tnfsf14*	17	54.9	enlarged hyperactive periph. T cell compartment, lymphoid hyperplasia, autoAb, GN, lymphocytic infiltrates of tissues	(318)
CD154, CD40L (B cell- or epidermis-specific promoter)	*Cd40lg*	X	52.0	B cell promoter: late onset autoAb, GN epidermis promoter: dermatitis, lymphadenopathy, hyperIgG, dsDNA, GN)	(260) (379)

Genes are listed by chromosomal locations. Gene names and chromosomal locations are from the Mouse Genome Informatics (http://www.informatics.jax.org/) and Ensembl Mouse Genome Database (http://www.ensembl.org/Mus_musculus).
*ND, not determined.

Table 7-5: Mechanisms for Induction of Systemic Autoimmunity Defined by Single-Gene Alterations

Enhanced B Cell Activation*
Lyn knockoutCD22 knockout
SHP-1 loss-of-function mutations
Fcγ RII knockout
Aiolos knockout
CD19 transgenic
Tnfsf13b (BAFF, BlyS, TALL-1, or THANK) transgenic
TACI knockout
CD45 E613R knockin mutation
PKCδ knockout (tolerance pathway)
Fli-1 transgenic
PECAM-1 knockout
CD40L transgenic (B cell–specific expression)
Enchanced T Cell Activation
CTLA-4 knockout
PD-1 knockout (probably B cells as well)
TGF-ß deficiency (knockout/dominant negative)
Cbl-b knockout (possibly B cells as well)
$p21^{cip1/waf1}$ knockout (pancyclin kinase inhibitor, primarily T cells)
Gadd45α knockout
Gadd45ß knockout (with and without Gadd45γ knockout)
LAT Y136F knockin mutation
G Protein-Coupled Receptor G2A knockout
Mgat5 knockout (enhanced T cell activation)
LIGHT transgenic (with proximal Lck, but not CD2 promoter)
E2F2 knockout
Roquin M199R mutation
PCMT knockout
Defective Apoptosis
Fas or FasL mutations (*lpr* and *gld* mice, ALPS in humans)
Bim knockout
Bcl-2 transgenic
TSAd knockout (primarily T cells)
IL-2 or IL-2R knockout (primarily T cells)
Flip transgenic
Pten+/- knockout
IEX-1 transgenic
RasGRP1 mutation (loss-of-function RNA splicing defect)
Stra13 knockout
Defective Clearance of Proinflammatory/Immunostimulatory Apoptotic Material
C1q knockout
C4 knockout
DNase I knockout
Tyro3 family (Tyro3, Axl, Mer) triple-gene knockout
Ro (Trove2) knockout
MFG-E8 knockout
Enhanced Antigen Presentation
CD40L transgenic (keratin-14 promoter)
Cytokine-Mediated Activation
IL-4 transgenic
IFN-γ; transgenic
TTP (Zfp-36) deficiency (excessive TNFα)
TNFα transgenic
Other Mechanisms
α-mannosidase II knockout
Emk knockout
Nrf2 knockout (anti-oxidant)

*Genes are tentatively categorized by the most likely mechanism.

BLyS (BAFF, Tnfsf13b) is a member of the TNF ligand superfamily expressed primarily on cells of myeloid origin, such as monocytes and dendritic cells (233 ,234 ,235 ,236). Both the transmembrane protein and a secreted homotrimeric form, released by cleavage at a furin canonical motif in the stalk region, are active in the costimulation of B cells, the main cell type known to express its receptor. Three TNF family members, BR3, TACI, and BCMA, are the receptors for BLyS, of which TACI and BCMA are also receptors for APRIL (237 ,238 ,239). BLyS promotes peripheral B cell survival, particularly the transitional type 2 B cells; a subset of splenic immature B cells that are considered targets for negative selection (240 ,241). Overexpression of BLyS in the liver (α_1-antitrypsin promoter with the APO E enhancer) (242) or in multiple tissues (ß-actin promoter) (243) resulted in a similar picture, consisting of elevated numbers of B cells and, to a lesser extent, T cells, as well as increases in activated Bcl-2-expressing mature B cells, memory/effector phenotype T cells and syndecan-1-positive plasma cells. B cells from transgenic mice survived longer in culture than those from wild-type controls. Furthermore, transgenic mice developed a lupus-like disease characterized by elevated levels of all immunoglobulin subclasses, rheumatoid factor, anti-DNA antibodies, circulating immune complexes, and kidney immunoglobulin deposits with proteinuria and elevated blood urea nitrogen. Importantly, elevations in BLyS was also shown in both BWF1 and MRL-*Fas*^{lpr} mice, and treatment of BWF1 mice with a soluble TACI-Ig fusion protein, which blocks BLyS function, inhibited proteinuria and prolonged survival (237).

Deficiency of the BLyS and APRIL receptor, TACI (*Tnfrsf13b*) also leads to the development of anti-DNA autoantibodies, immune complex-mediated GN and early mortality (40% mortality at 18 months) (244). TACI$^{-/-}$ mice exhibit marked B cell hyperplasia along with enhanced antigen-specific antibody production, and in vitro activation of the TACI intracellular domain could inhibit B cell activation and, in the A20 B cell line, induce apoptosis (244 ,245 ,246). These studies suggest that TACI plays a significant negative regulatory role in B cells. Interestingly, loss of function mutations of TACI in humans is primarily associated with common variable immunodeficiency and IgA deficiency, and not systemic autoimmunity (247 ,248). The reason for this difference remains to be determined, but might be a result of species-specific differences or possibly background gene effects.

CD45 is a receptor protein tyrosine phosphatase expressed on all nucleated hematopoietic lineages, where it is required for antigen receptor signal transduction and functions to promote cell activation. Homodimerization of CD45 inhibits phosphatase activity by symmetrical interactions, wherein the catalytic site of one molecule is blocked by a structural wedge from the other (249 ,250). Replacement of the glutamine at residue 613 by an arginine (E613R) destroys the inhibitory capacity of the wedge, and knockin mice with this mutation were generated to examine the significance of dimerization (251). Although mice appeared normal at 4 weeks, they subsequently developed progressive lymphadenopathy and splenomegaly, increased number of activated T and B cells, anti-dsDNA autoantibodies, immune-complex GN and early mortality. Autoimmunity was dominantly transmitted. Expression of the E613R mutation in B cells, but not T cells, is critical for the development of autoimmunity and leads to B cell hyperresponsiveness (252).

Protein kinase Cδ (PKC-δ) is highly expressed in developing pro- and pre-B cells, and is involved in B cell receptor (BCR) signaling. Mice homozygous for the null mutation in the PKC-δ gene developed splenomegaly, lymphadenopathy, increased numbers of B2 cells, germinal center formation and IL-6 production, mild increases of IgM, IgG1, and Ig2a, antinuclear and IgG1 anti-DNA autoantibodies, as well as GN (253 ,254). Further studies in PKC-δ-deleted mice transgenic for the HEL Ig receptor exposed to soluble HEL (as artificial autoantigen) indicated that absence of PKC-δ prevented B cell tolerance, and allowed maturation and terminal differentiation of self-reactive B cells (253). Since deficiency of PKC-δ did not affect BCR-mediated B cell activation in vitro and in vivo, it was concluded that PKC-δ plays a selective and essential role in tolerogenic, but not immunogenic, B cell responses.

Fli-1 is s member of the Ets family of transcription factors that bind to DNA sequences containing the consensus GGA(A/T) core motif and regulate gene expression (255). Overexpression of a Fli-1 transgene, under the control of the MHC class I promoter, was found to result in lymphoid hyperplasia, hypergammaglobulinemia, elevated antinuclear antibodies, and severe immune complex GN (256). Fli-1 transgenic B cells were hyperresponsive to a variety of stimuli, showed resistance to AICD and had prolonged survival compared to nontransgenic B cells. Although Fli-1 expression is increased in murine SLE (257), the significance of this finding is difficult to assess because of nonphysiologic expression of Fli-1. Additional studies in heterozygous Fli-1$^{+/-}$ MRL-*Fas*^{lpr} showing reduced serum

IgG, autoantibodies, and GN as well as improved survival (257), however, suggests that Fli-1 plays an important role in lupus pathogenesis. Homozygous Fli-1-deficiency is lethal in utero and therefore Fli-1$^{+/-}$ mice, which are viable and express half the level of Fli-1 protein, were studied.

Platelet endothelial cell adhesion molecule-1 (PECAM-1/CD31), a member of the immunoglobulin superfamily expressed on endothelial and hematopoietic cells, has two cytoplasmic ITIM domains suggesting a role in regulating cell activation. Nevertheless, initial studies of PECAM-1 knockout mice were focused on the role of PECAM-1 on adhesion, however, it was not found to play an essential role in either vascular development or leukocyte migration (258). On further examination, PECAM-1-deficient mice were found to develop antinuclear autoantibodies by 9 months of age and significant immune complex GN by 17 months (259). Several B cell alterations, including increased response to BCR engagement, LPS, and DNP-Ficoll, reduced B2, but increased B1a cells, and an apparent block in the transition of immature to mature B cells in the bone marrow were observed. These findings suggest that PECAM-1 may play a significant role in the regulation of B cells and autoimmunity.

Ectopic expression of a transgenic CD40L on B cells (VH promoter, IgH intron enhancer, and Ig 3′ enhancer) was shown to result in enhanced polyclonal IgG, anti-dsDNA and, in about half of the mice, the development of immune complex GN (260). CD40L is a member of the TNF ligand family, expressed mainly on activated T cells (261). It interacts with CD40 on B cells, and plays a pivotal role in promoting B cell proliferation and survival. Of interest, previous studied have reported ectopic expression of CD40L in patients with SLE (262 ,263) and in BXSB mice (264).

Genes Related to T Cell Activation

Systemic autoimmunity also develops after knockout deletion of certain genes that primarily alter T cell function. CTLA-4, a surface glycoprotein expressed exclusively on T cells, acts as an inhibitor of the CD28-B7.1/B7.2 costimulatory pathway in part by binding with higher affinity to B7.1 and B7.2. Consequently, mice with homozygous deletion of CTLA-4 develop a multi-organ lymphoproliferative disease associated with increased frequency of activated B and T cells, hypergammaglobulinemia and early mortality at 3 to 4 weeks of age with severe myocarditis and pancreatitis (265 ,266 ,267). The abnormal T cell expansion and disease manifestations are not a result of alteration in thymocyte development (268), but to a failure to maintain homeostasis of activated peripheral T cells, primarily the CD4+ subset (269 ,270). The precise mechanism through which this occurs has yet to be determined (271).

PD-1 is a 55 kDa ITIM-containing transmembrane cell surface glycoprotein expressed on activated T and B lymphocytes and monocytic cells that appears to play an important nonredundant role in maintaining the homeostasis of lymphocytes and myeloid cells following their activation (272 ,273). Engagement of PD-1 by its ligands, PD-L1 and PD-L2, has been shown to inhibit TCR-mediated lymphocyte proliferation and cytokine secretion (274). Mice deficient for PD-1 develop moderate hyperplasia of lymphoid and myeloid cells, increases in several Ig isotypes (particularly IgG3), enhanced responses to IgM cross-linking, and alterations in peritoneal B1 cells (275). Older (14-month-old) C57BL/6-PD-1$^{-/-}$ mice spontaneously develop GN and proliferative arthritis, but not elevated anti-dsDNA antibodies or rheumatoid factor (276). Further acceleration of GN and arthritis occurs when the PD-1 deletion is combined with the *Fas^{lpr}* mutation. Interestingly, manifestations appear highly dependent on background genes. For example, in contrast to the findings in the C57BL/6 strain, BALB/c mice-PD-1$^{-/-}$ mice develop a dilated cardiomyopathy as a result of anticardiac troponin I antibodies (277). Thus, PD-1 deficiency may accelerate background predisposition to autoimmunity, similar to the *Fas^{lpr}* and *Yaa* mutations. Lack of PD-1 also enhances EAE (278) and diabetes in NOD mice (279 ,280). While the mechanistic details not yet fully elucidated, it is evident that PD-1 plays an important nonredundant role in maintaining lymphocyte and myeloid cell homeostasis following their activation (273). Interestingly, human SLE has been linked in one population group to a regulatory polymorphism in the PD-1 gene (PDCD1) (281) and in other studies to other autoimmune diseases (282 ,283 ,284 ,285).

TGF-ß1 gene knockout mice rapidly develop massive necrotizing lymphocytic and monocytic infiltrates in multiple organs soon after birth, and succumb by around 3 weeks of age (286 ,287). Serum IgG autoantibodies to nuclear antigens as well as Ig glomerular deposits are detected, but appear to play a minor role in overall disease severity (288). Although deficiencies of either class II or class I (ß2m) molecules combined with TGF-ß1$^{-/-}$ reduced both tissue inflammation and autoimmunity, implicating both CD4^{+} and CD8^{+} T cells in these processes, in both instances there was only partial improvement in survival because of the remaining lethal myeloproliferative abnormalities (289 ,290). Direct inhibition of TGF-ß1 in T cells by a dominant negative TGFß receptor type II transgene under the control of a modified CD4 promoter specific for CD4^{+} and CD8^{+} T cells resulted in sickness, wasting, and diarrhea around 3 to 4 months of age, monocytic infiltrates in multiple tissues, enlarged peripheral lymphoid organs, increased percentage of memory/effector phenotype T cells, hypergammaglobulinemia, autoantibodies and glomerular immune complex deposits (291). Thus, TGF-ß is crucial for maintenance of T cell homeostasis and suppression of autoimmunity.

Cbl-b is member of the cbl family of adaptor proteins that predominantly function to inhibit receptor and nonreceptor tyrosine kinases (292 ,293). Two members, cbl-b and cbl, share a complex structure consisting of an amino-terminal phosphotyrosine-binding domain (PTB), a C3HC4 RING finger, a proline-rich region capable of binding proteins with SH3 domains, several phosphotyrosine residues for binding SH2 domains, a ubiquitin recognition

sequence and, at the carboxy-terminal, a putative leucine zipper. A smaller third member (cbl-c or cbl-3) was identified that contains the PTB, RING finger and a truncated proline-rich region, but is missing the rest of the carboxy portion (294 ,295). Cbl-b proteins appear to function as a negative regulator by inhibition of receptor clustering and raft aggregation in cell membranes (296). Cbl-b is expressed in normal and malignant mammary epithelial cells, a variety of normal tissues, and in hematopoietic tissues and cell lines. In accordance with their negative regulatory role, T cells from mice homozygous for the cbl-b gene knockout exhibit enhanced proliferation to antigen receptor signaling and do not require CD28 costimulation for IL-2 production or generation of T-dependent antibodies (297 ,298). Significantly, enhanced basal and activated levels of Vav, a guanine exchange factor for Rac-1/Rho/CDC42, was the only alteration in TCR signaling identified in these knockout mice. This was consistent with the previous findings that cbl-b binds to Vav and, when overexpressed, inhibits Vav stimulation of the c-Jun terminal kinase (299). Cbl-$b^{-/-}$ mice exhibit increased susceptibility to autoimmunity, both to experimental autoimmune encephalomyelitis (297) and to a spontaneous generalized autoimmune disease (298). The latter consisted of multiorgan lymphoaccumulation of polyclonal activated B and T cells with parenchymal damage, increased plasma cells, and antibodies to dsDNA by 6 months of age. Curiously, spontaneous autoimmunity occurred in only one (298) of the two Cbl-b knockout studies, suggesting that background strain, environment, or other factors are important.

Gene knockout of the cyclin inhibitor $p21^{cip1/waf1}$ in mixed background (C57BL/6 and × 129/Sv) also resulted in the development of systemic autoimmunity characterized by lymphoid hyperplasia, elevated IgG1, IgG antinuclear antibodies, GN, and early mortality (300). In vitro T cell proliferation was enhanced in these mice and there was an accumulation of effector/memory phenotype ($CD44^{high}$) $CD4^+$ T cells, although levels of other activation/effector/memory cell markers, such CD25, CD62L, CD69, and CD45RB, were similar to wild-type mice. An increased proportion of splenic B cells also expressed an activated (HSA^{low}, IgG^{low}) phenotype. Interestingly, females had more severe disease than males, similar to human SLE. Based on these findings, it was suggested that p21 negatively regulates T cell proliferation following long-term stimulation, as is presumably the situation for autoantigen-reactive $CD4^+$ T cells. In sharp contrast, other studies of mixed B6/129 or BXSB female p21-deficient mice were not able to confirm the development of lupus suggesting that background effects may have been responsible for the intial findings (301 ,302). Moreover, studies of lupus-prone male BXSB mice found an increase in p21 and other cyclin inhibitors in the expanded memory/effector $CD4^+$ T cells that are predominantly arrested in G1 (303) and, in fact, BXSB-$p21^{-/-}$ males had significantly reduced disease (304). This led to the opposite hypothesis, that the accumulating $CD4^+$ T cells, following successive rounds of division, become unable to enter into cell cycle and are resistant to apoptosis because of the build-up of cyclin inhibitors, a state similar to replicative senescence. Although no longer cycling, such cells may nonetheless secrete cytokines and activate B cells. Further studies will be needed to determine the precise role of p21 in spontaneous SLE.

The Gadd45 (growth arrest and DNA damage-inducible gene) family is composed of three members, α, ß, and γ, that play pivotal roles in replication, growth arrest, and apoptosis (305 ,306). Of these, Gadd45α is the only member regulated by p53, and is an important molecule in several processes, including maintenance of genomic stability, cell growth control, nucleotide excision repair, chromatic accessibility, and apoptosis. Several of these effects may be mediated by interactions of the Gadd45α with Cdc2, PCNA, and the MEKK4/MTK1 kinases (307). Studies in Gadd45α-deficient mice have shown that this molecule is a negative regulator of T cell proliferation induced by antigen receptor-mediated activation, and that deletion of the Gadd45α gene leads to the development of a lupus-like syndrome, particularly when coupled with deletion of the p21 cyclin-kinase inhibitor (307). While disease in Gadd45α-deficient mice was more severe in females than males, equal severity was seen when mice were deficient for both Gadd45α and p21. More recently, it was found that Gadd45ß deficiency is associated with enhanced T cell proliferation and resistance to AICD, splenomegay, and mild immune complex glomerular deposits (308). Gadd45$ß^{-/-}$ mice are also more susceptible to EAE. The related Gadd45γ also regulates proliferation and death of $CD4^+$ T cells, however, Gadd45γ-deficiency is not associated with significant autoimmunity (308). Nevertheless, the addition of the Gadd45γ knockout mutation to Gadd45$ß^{-/-}$ mice results in significant worsening of all lupus-like disease parameters suggests that Gadd45γ deficiency may be able to promote autoimmunity in certain susceptible backgrounds.

LAT (linker for activation of T cells) is a transmembrane scaffolding protein that, after TCR engagement, becomes tyrosine-phosphorylated and recruits multiple signaling molecules important for T cell activation (309). The distal four tyrosine residues of LAT (Y132, Y171, Y191, and Y226) are required for its activity. “Knock-in” mutation of LAT in mice in which the Tyr136 position was mutated to phenylalanine showed severe, but incomplete, block in T cell development associated with marked reduction in immature $CD4^+8^+$ and mature $CD4^+$ and $CD8^+$ thymocytes and splenocytes (310). However, by 4 weeks of age, homozygous mutant mice exhibited lymphadenopathy and splenomegaly with elevated markers of activated polyclonal $CD4^+$ T cells, B cells, macrophages and eosinophils, lymphocytic infiltrates in various organs, high production of IL-4, hypergammaglobulinemia (especially IgE and IgG1), and autoantibodies to nuclear antigens (310 ,311). These phenomena were attributed to defective PLCγ 1-calcium signaling pathway in early T cell development, leading to

inefficient negative selection of self-reactive T cells and their exportation to the periphery wherein activation of these cells may not depend on LAT or PLC-γ 1 (310).

G2A is an orphan G protein-coupled receptor (GPCR) expressed in various tissues, including lymphoid tissues (312). A variety of studies have suggested that G2A is a negative regulator of proliferation and integration of extracellular signals with cytoskeletal reorganization. Mice with targeted disruption of the gene encoding G2A showed a normal pattern of T and B lineage differentiation. As they aged, however, they developed secondary lymphoid organ enlargement, expansion of T and B cells, enhanced T cell proliferation responses and, when over 1 year of age, a progressive wasting syndrome, lymphocytic infiltration into various tissues, hypergammaglobulinemia, immune complex GN, and antinuclear autoantibodies (312). Although the molecular basis underlying the hyperresponsiveness of $G2A^{-/-}$ lymphocytes to TCR stimulation is presently unknown, the results reinforce the concept that lower thresholds for TCR activation can lead to overt autoimmune disease. Such a lower threshold for activation coupled with defective Fas-mediated apoptosis has also been considered to be a major contributor to the MRL-*lpr* lymphadenopathy and spontaneous lupus-like disease (313).

Mice deficient of the of the β1,6 N-acetylglucosaminyltransferase V (Mgat5), an enzyme in the N-glycosylation pathway develop late onset proliferative GN suggestive of an autoimmune–mediated pathogenesis, however, autoantibodies were not examined (314). Absence of this enzyme led to lowering of the T cell activation threshold by enhancing TCR clustering. Thus, T cells from deficient mice showed increased recruitment of TCRs to anti-CD3η antibody-coated polystyrene beads and required lower concentration of anti-CD3 plus anti-CD28 for efficient proliferation compared to control cells. Additional experiments showed that Mgat5 initiates GlcNAc β1,6 branching on N-glycans, thereby increasing N-acetylactosamine, the ligand for galectins, which are proteins known to modulate T cell proliferation and apoptosis (314 ,315 ,316). The findings indicate that a galectin-glycoprotein lattice strengthened by Mgat5-modified glycans restricts TCR recruitment to the site of antigen presentation, and therefore, dysregulation of Mgat5 increases T cell activation and susceptibility to autoimmunity.

LIGHT (*Tnfsf14*), a TNF superfamily member expressed transiently on activated T cells and on immature dendritic cells, binds to both the LTα1β2 heterotrimeric and HVEM (herpesvirus entry mediator) receptors and the DcR3 decoy receptor (317). LIGHT has been proposed to act as a costimulatory molecule for T cell activation (318). Transgenic expression of LIGHT on T cells by the proximal Lck promoter resulted in peripheral lymphoid organ hyperplasia, activation, and expansion of mature T cells, and increased T cell cytokine production, including IFN-γ and IL-4 (318). Transgenic mice also developed manifestations of lupus, including anti-DNA antibodies, RF, and immune complex GN, and also inflammation of the intestines and skin. In contrast, another LIGHT transgenic driven by the CD2 promoter had many of the same manifestations, but differed by the expansion of B cells in the lamina propria, the destruction of reproductive organs by bone marrow-derived cells, no increase in peripheral organ T cells, and, importantly, no lupus-like manifestations (319). These disparities have been ascribed to differences in the tissue-specific expression of the promoters (320).

E2F2 is a member of the E2F family of DNA binding heterodimers that are sequestered by Rb and released after Rb phosphorylation by activated cyclin/CDK kinases (321). Mice lacking E2F2 developed late-onset autoimmune features characterized by perivascular inflammatory infiltrates of multiple organs, splenomegaly, skin lesions, anti-dsDNA autoantibodies, and immune complex GN (322). Similar to spontaneous lupus, there were increased numbers of autoreactive effector/memory T cells with age. The most likely mechanism appeared to be lowering of the TCR activation threshold and more rapid entry of activated T cells into S phase in E2F2 deficiency. No defects in Fas- or dexamethasone-mediated apoptosis were detected. Further studies suggested that E2F2 might function as a transcription repressor of genes required for normal S phase entry, particularly E2F1 (322).

Roquin (*Rc3h1*) is a 1130 residue ubiquitously expressed member of the E3 ubiquitin ligase family based on the presence of a highly conserved amino terminal RING-1 zinc finger domain (323). Recently, a loss-of-function M199R mutation within the highly conserved ROQ domain of Roquin was generated by ENU mutagenesis (sanroque mouse strain) that resulted in the development of ANA, anti-dsDNA autoantibody, GN, necrotizing hepatitis, anemia, and immune thrombocytopenia (323). Lymphoid organ hyperplasia, polyclonal hypergammaglobulinemia, increased germinal centers, and expansion of memory/effector $CD4^{+}$ T cells, particularly follicular helper T cells, were evident, along with overexpression of the ICOS costimulatory receptor and IL-21. The presence of a CCCH zinc finger common to several RNA-binding proteins and localization of Roquin to cytosolic RNA granules suggested that Roquin regulates mRNA translation and stability, and likely acts as a repressor of ICOS.

Protein carboxyl methyltransferase (PCMT) is a highly conserved enzyme that repairs isomerized and racemized derivatives of L-asparaginyl and L-aspartyl residues produced in cells by spontaneous degradation (324). The critical importance of this function has been clearly demonstrated by $PCMT^{-/-}$ mice, which accumulate significant amounts of the aspartyl derivatives in brain, heart, liver, and RBCs, have growth retardation, and develop fatal seizures around 42 days of age (324). T cells from PCMT knockout mice are hyperresponsive to mitogen and antigen-receptor-mediated stimulation, while B cell responses are similar to wild-type animals (325). Despite the T cell defect, no significant alterations in T cell number or proportions of CD4, CD8, or effector/memory phenotypes,

were observed in young PCMT$^{-/-}$ mice. Mice reconstituted with PCMT-deficient bone marrow, however, developed positive ANA and dsDNA autoantibodies 7 to 9 months after transfer. At this time, kidney sections showed perivascular infiltrates, focal areas of necrosis and vasculitis, but no apparent immune complex GN. Overall, the effects of PCMT deficiency on bone marrow-derived cells is less severe than in other tissues, such as the brain, and appears limited to significant enhancement of T cell activation in vitro, and mild lupus-like disease in bone marrow chimeras.

Defective Apoptosis

Bim is a proapoptotic ligand of the Bcl-2 family that shares homology with other members in only the short (nine amino acid) BH3 motif (326). Through this domain, Bim binds to anti-apoptotic Bcl-2 molecules and blocks their function. Bim is largely bound to the cytoplasmic dynein light chain LC8 that is normally sequestered in the microtubule-associated dynein motor complex (327). Certain apoptotic signals release LC8, allowing LC8, together with Bim, to translocate to Bcl-2 and inhibit its function. Homozygous knockout of Bim resulted in an incompletely penetrant embryonic lethal phenotype apparently for nonimmunologic reasons. In the surviving offspring, however, alterations in the homeostasis of multiple hematopoietic cell lineages developed (328). As anticipated, Bim-deficient B and T lymphocytes were resistant to certain apoptosis-promoting signals, but not to FasL. The knockout mice were found to have lymphoid hyperplasia with increases in naive T and B cells, altered thymocyte subset composition, and increases in granulocytes and monocytes in the peripheral blood. With age, these mice developed systemic autoimmunity manifested by progressive lymphadenopathy and splenomegaly, dramatic expansion of plasma cells, hyper IgM, IgG, and IgA, antinuclear antibodies, immune complex GN, and vasculitis with a 55% survival at 1 year.

Similarly, transgenic expression of the Bcl-2 gene in B cells under the immunoglobulin enhancer resulted in lymphoid hyperplasia, hypergammaglobulinemia, high titers of antinuclear antibodies, and immune complex GN (329). Studies thus far have suggested that the constitutive Bcl-2 expression may promote autoimmunity by blocking apoptosis of autoantibody–producing B cells that normally arise spontaneously in germinal centers during the primary response to foreign antigens (330 ,331 ,332).

The T cell–specific adaptor protein (TSAd), encoded by the *Sh2d2a* gene and expressed in thymocytes and activated T cells, is an intracellular adaptor molecule whose specific role in T cell signaling transduction is not yet known (333 ,334). Nevertheless, TSAd-deficient mice develop elevated levels of IgG and IgM, autoantibodies to dsDNA, cardiolipin, and IgG (RF), immune complex GN, and lymphocytic infiltrates, particularly in the lung (318). TSAd$^{-/-}$ mice also exhibited greater susceptibility to pristane-induced autoimmunity. The development of autoimmunity may be related to the finding that TSAd-deficient T cells were more resistant to superantigen-induced cell death in vivo (similar to Bim knockout mice). In the case of TSAd, the impaired death response may be caused by reduced IL-2 synthesis (335). Although no studies have been reported for SLE, a GA repeat polymorphism within the SH2D2A promoter region associated with lower levels of TSAd has been linked to multiple sclerosis (336).

Gene knockouts of IL-2 (337 ,338 ,339) or either of its high (IL-2Rα) (340) or low (IL-2Rß) (341) affinity receptors result in a similar syndrome consisting of late immunosuppression with defective antibody and CTL responses, but also lymphoproliferation, expansion of memory/effector phenotype T cells, polyclonal hypergammaglobulinemia, autoantibodies, and immune-mediated hemolytic anemia. Inflammatory bowel disease similar to human ulcerative colitis occurs in mice lacking IL-2 (342) or IL-2Rα (340), but not IL-2ß (341). Autoantibody production depends on the expanded CD4^{+} T cells (341) and CD40/CD40L interaction (337). The accumulation of T lymphocytes appears to be a result of resistance of IL-2-deficient T cells to AICD, at least partly from decreased Fas-mediated apoptosis (343).

FLIP (gene name *Cflar*, for Caspase 8 and FADD-like apoptosis regulator) is a death-effector domain-containing protein similar in structure to the apoptosis-promoting CASP8 (FLICE), but devoid of a caspase domain. In contrast to FLICE, FLIP inhibits death receptor-induced apoptosis by blocking the recruitment and activation of CASP8 (344 ,345). Transplantation of bone marrow cells retrovirally transfected with FLIP resulted in the resistance of B and T cells to AICD, expansion of these cell populations and, in 4- to 6-month-old animals, the development of hypergammaglobulinemia, anti-dsDNA autoantibodies, and glomerular immunoglobulin deposits with histologic evidence of GN characterized by glomerular sclerosis and thickening of mesangium and basement membranes (346). Despite the fact that FLIP blocks Fas signaling of AICD, there were no accumulations of B220^{+} or CD4^{-}CD8^{-} DN T cells, or activated T cells. This suggests that Fas and/or FLIP may affect nonoverlapping pathways.

PTEN is a protein/lipid phosphatase initially identified as a tumor suppressor gene on chromosome 10q23, which is associated with a wide range of human malignancies (347 ,348). Germline mutations of PTEN also cause three autosomal dominant disorders: Cowden disease, Lhermitte-Duclos syndrome, and Bannayan-Zonana syndrome. Homozygous knockouts of PTEN are embryonic lethal, but heterozygous mice develop an autoimmune disorder characterized by severe polyclonal lymphadenopathy, diffuse inflammatory cell infiltrates of most organs, hypergammaglobulinemia, anti-DNA antibodies, immune complex GN, and decreased survival (349). Females were more severely affected, with survivals younger than 12 months of age compared with males older than 15 months. Defective Fas-mediated AICD of T and B lymphocytes was observed in PTEN-deficient mice as a result of impaired Fas signaling associated with increases in the survival factor, Akt. It was, therefore,

postulated that uninhibited increases in phosphatidylinositol (3 ,4 ,5)-triphosphate (PIP-3), the major substrate for PTEN (350), leads to the recruitment and activation of Akt and possibly other factors, which then inhibit Fas-mediated killing (349). PTEN-deficient mice, however, in contrast to *Fas^{lpr}* mice, did not have increases in either B220^{+} or CD4^{-}CD8^{-} DN T cell populations, and furthermore, PTEN heterozygous knockouts had more severe disease than nonautoimmune background Fas-deficient mice.

IEX-1 (Immediate Early response gene X-1, also named IER3, p22/PRG1, Dif-2, or mouse homology gly96) is a regulator of cell growth and apoptosis. Expression of this molecule is regulated by a variety of factors, including x-irradiation, ultraviolet radiation, steroids, growth factors, inflammatory stimuli, and various activators of the NF-κB/rel transcription factors (351). Mice transgenic for IEX-1 (under an H-2k^{b} promoter at the 5′ end and an Ig heavy chain (**(mu)**) enhancer at the 3′ end for specific expression in lymphocytes) exhibited decreased apoptosis of activated T cells, increased duration of an immune response effector phase, splenomegaly, lymphadenopathy, accumulation of activated T cells, increased polyclonal IgG2a and anti-dsDNA autoantibodies, alopecia of the skin, arthritis, and immune complex GN (113). These findings are particularly intriguing considering that the IEX-1 gene maps within the MHC locus of humans and mice.

RasGRP1 is a Ras guanine nucleotide exchange factor critical for the Ras-dependent maturation of thymocytes transitioning from the double-positive (CD4^{+}8^{+}) to single-positive (CD4^{+}CD8^{-}, CD4^{-}CD8^{+}) stages (352). Despite this, mice with a spontaneous RasGRP1 mutation (designated *lag* for lymphoproliferation-autoimmunity-glomerulonephritis), which blocked normal joining of exon 3 to exon 4 resulting in undetectable RasGRP1 protein levels, developed severe systemic autoimmunity by 5 to 8 months of age (353). Major manifestaions included enlarged spleens and LNs, hyperplastic germinal centers, hypergammaglobulinemia, ANAs, anti-dsDNA autoantibodies, diffuse proliferative GN with IgG and C3 deposits, and early mortality. In young *lag* mice, the number of peripheral T cells were reduced presumably from the block in thymocyte development. In contrast, older *lag* mice exhibited marked increases in CD4^{+} T cells that were predominantly of the memory/effector phenotype, consistent with a significant peripheral expansion of these cells. *Lag* CD4^{+} T cells had reduced responses to antigen and mitogens, but secreted significant amounts of IL-4 after activation. Importantly, CD4^{+} T cell from *lag* mice were resistant to AICD, which likely contributed to the lymphoproliferation and autoimmunity. B cells were also expanded and activated in lag mice, but, in contrast to T cells, they exhibited normal proliferation and apoptosis, suggesting that the B cell alterations were secondary to the T cell defects.

Stra13, a member of the basic helix-loop-helix family of transcriptional repressors, is expressed in lymphoid cells and activated CD4^{+} T cells (354 ,355). Although Stra13-deficient CD4^{+} T cells had reduced proliferation, as a result in part of impaired IL-2 secretion, Stra13 knockout mice developed manifestations of systemic autoimmunity by 4 to 5 months with lymphoid organ hyperplasia, increased number and activation of T and B cells, germinal center expansion, antinuclear antibodies, and immune complex GN (354). Activated CD4^{+} T cells in older knockout mice were polarized to the TH2 phenotype. The gradual accumulation of T and B cells appeared because of greater resistance of these cells to AICD from impaired differentiation of CD4^{+} T cells into effector cells and reduced expression of FasL following T cell activation. These studies indicate that Stra13 is a key regulator of T cell homeostasis and self-tolerance.

Defective Clearance of Proinflammatory/Immunostimulatory Self-Antigens

Deficiencies of early complement components (C1q-s, C2, or C4) have long been known to predispose to SLE, indicating an important regulatory role for the complement pathway in suppressing autoimmunity. Although inadequate clearance of immune complexes was postulated to be the most likely mechanism, this did not fully explain the loss of tolerance to nuclear antigens. Gene knockout mice for C1q and C4 were therefore generated to address this issue. Homozygous C1q-deficient mice recapitulated the human disorder with the development of typical, but mild, features of lupus, including autoantibodies and a 25% incidence of immune complex GN (50). A large number of apoptotic bodies were discovered in the glomeruli of these mice, suggesting that C1q plays an essential role in the clearance of apoptotic bodies.

In the case of C4 deficiency, accelerated lupus-like disease has been reported in both *Fas^{lpr}* (36) and normal background mice (356). Using a HEL Ig transgenic model, B cells from C4-deficient mice were shown to have a tolerance defect to soluble HEL (36). Thus, it was hypothesized that early complement components may be vital for maintaining self-tolerance by virtue of their role in presenting tolerizing antigens to B cells. Clearance of immune complexes is also impaired in C4 knockout mice by a mechanism independent of CR1/CR2 complement receptors (356).

A similar mechanism was also proposed to explain the unexpected development of lupus-like autoimmunity in mice with homozygous deficiency of serum amyloid P component (SAP), a highly conserved plasma protein named for its presence in amyloid deposits (357 ,358). Manifestations included female predominance, autoantibodies to chromatin and its components, but not to other nuclear, tissue, or organ antigens, immune complex GN, and low incidence of mortality. In contrast to C1q deficiency, no accumulation of apoptotic bodies was detected in glomeruli. SAP binds to DNA and chromatin, and can displace H1-histones, thereby increasing solubility and reducing the rate of degradation and clearance of chromatin (357). It was hypothesized that SAP promotes self-tolerance to chromatin and its subunits

by preventing immunogenic antigen-processing and/or by tolerizing chromatin-reactive lymphocytes. Subsequent studies, however, have strongly suggested that the association of SAP deficiency with lupus-like disease may have been entirely a result of the mixed 129xB6 background used in the initial study. SAP-deficient pure 129/Sv mice did not develop autoimmunity or produce significant autoantibodies following immunization with chromatin or apoptotic bodies, further backcrossing of the SAP knockout mutation to the B6 background resulted in reduced autoimmunity, and transgenic expression of human SAP in B6 SAP knockout mice did not correct the autoimmune phenotype (71). Moreover, comparison of (129xB6)F2 mice with and without the SAP knockout mutation, and comparison of the B6 SAP knockout with congenic B6 mice containing an introgressed chromsome 1 fragment that included the SAP *Apcs* (SAP) gene, indicated that essentially all of the traits previously ascribed to SAP deficiency could be accounted for by the 129 interval alone (32).

Dnase1, a 32–38 kDa protein, is the major nuclease present in the blood, urine, and secretions. Interestingly, knockout of the Dnase1 gene in nonautoimmune background mice was reported to increase the incidence of SLE manifestations, including positive ANA, anti-DNA antibodies, and immune complex GN (359). This finding is supported by recent observations that mammalian DNA in apoptotic material can stimulate B cells and dendritic cells via their TLR9 receptor (360 ,361 ,362). Interestingly, a loss-of-function mutation of DNASE1 has been associated with SLE in two patients (363).

Mutant triple knockout mice lacking a group of closely-related receptor tyrosine kinases, Tyro3, Axl and Mer (the Tyro3 family, TAM) have recently been reported to develop severe systemic autoimmunity characterized by splenomegaly, lymphadenopathy, increases in activated T and B cells, autoantibodies to phospholipids associated with thromboses and hemorrhage, autoantibodies to collagen and dsDNA, and deposition of immune complexes in tissues (364). The Tyro3 family of proteins are not expressed by quiescent lymphocytes, but are expressed by many other cell types, including APCs (macrophages, dendritic cells). Macrophages freshly isolated from TAM-deficient mice have increased expression of MHC class II molecules and produce elevated amounts of IL-2 and IFN-γ, suggesting their activation in vivo. Expression of these molecules and of CD86 (B7.2) was increased by these cells as well as by $CD11c^+$ cells subsequent to in vitro incubation with LPS. Moreover, CFSE-labeled B and T cells transferred to TAM-deficient mice hyperproliferated compared to cells transferred in the wild-type controls. Although Tyro-3 receptors are known to convey growth-promoting and prosurvival signals to cells (365), the findings with the mutant mice suggest that these receptors are also able to activate negative feedback loops that attenuate the positive signaling pathways that they have activated, and that the loss of negative signals from these receptors has more profound effects than the loss of the positive growth-promoting signals. Another means by which absence of these receptors may promote autoimmunity is by ineffective removal of apoptotic cells, which are increased in TAM-deficient mice (366). This latter possibility has been supported by the finding that mice with a cytoplasmic truncation of mer have macrophages deficient in the clearance of apoptotic thymocytes and develop a mild form of lupus-like disease with antibodies to chromatin (367 ,368).

Ro, a conserved RNA-binding protein encoded by the Trove2 gene, is a common target for autoantibodies in SLE, Sjogren syndrome, subacute cutaneous LE, neonatal lupus, and primary biliary cirrhosis (369). Ro binds to Y RNAs as well as other small cellular RNAs, such as 5S rRNA, and is thought to play a role in the stabilization and quality control of certain types of RNA (370). Interestingly, mice deficient in Ro were found to develop antinuclear autoantibodies and immune complex GN, and it was hypothesized that Ro may prevent autoantibody formation by sequestering defective and potentially autogenic ribonucleoproteins (371). Unsequestered RNA might also promote autoimmunity by activating B cells and dendritic cells through engagement of TLR7 (and also TLR8 in humans) or through TLR-independent pathways (360 ,372 ,373 ,374 ,375). However, other than slightly increased levels of IgG, IgM, and IgG2a, no other immunological alterations were observed. Furthermore, disease severity lessened as the knockout mutation was backcrossed to the B6 background, suggesting that 129xB6 background effects might account for some or all of the autoimmunity observed.

Milk fat globule EGF factor 8 (MFG-E8) protein, expressed in mammary glands, brain, spleen, and LN, functions as a bridging protein between phosphatidylserine on apoptotic cells to αvβ3 or αvβ5 integrins on phagocytic cells, thereby promoting the engulfment of apoptotic cells (376 ,377). In the spleen and LN, MFG-E8 is primarily expressed on tingible body macrophages ($CD68^+$) within germinal centers (378). Mice deficient for MFG-E8 developed splenomegaly with numerous germinal centers and increased numbers of B and T cells. Tingible macrophages in knockout animals were associated with increased numbers of unengulfed apoptotic cells. By 40 weeks, $MFG\text{-}E8^{-/-}$ mice had increased ANA and anti-dsDNA antibodies, as well as large glomerular deposits of IgG and hypercellular glomeruli. These findings suggest that inefficient phagocytosis of apoptotic B cells within germinal centers can lead to autoimmunity and is consistent with recent studies demonstrating that DNA and RNA in apoptotic material can activate B cells and dendritic cells through TLR9, TLR7, and TLR8 (360 ,361 ,362 ,372 ,373 ,374).

Enhanced Antigen Presentation

Targeted expression of CD40L to the basal keratinocytes of the epidermis of mice using the keratin-14 promoter was reported to lead to activation of resident tissue APCs (Langerhans cells) associated with dermatitis, lymphadenopathy, hypergammaglobulinemia,

anti-dsDNA autoantibodies, and immune complex GN (379). These findings are reminiscent of observations in mice transgenic for IFN-γ under the involurin promoter (380). Overall, they indicate that in situ activation of APCs in the skin can lead not only to local, but also systemic, autoimmune, and inflammatory responses, presumably a result of the migration of activated APC to the secondary lymphoid organs, and the management of pre-existing, previously quiescent, nontolerant self-reactive T cells.

Cytokine-Mediated Activation

Under certain circumstances, systemic autoimmunity also develops in mice transgenic for the major Th1 and Th2 cytokines, IFN-γ and IL-4, respectively. Expression of INF-γ in the suprabasal layer of the epidermis under the control of the involucrin promoter resulted in not only a severe inflammatory skin disorder, but also generation of autoantibodies to dsDNA and histone, and immune complex proliferative GN, particularly in females (380). This suggests that presentation of nuclear antigen by skin Langerhans cells and perhaps keratinocytes may be sufficient for the production of antinuclear autoantibodies, and provides a possible explanation for the UV sensitivity of SLE patients. Similarly, C3H mice transgenic for the IL-4 gene under the control of the MHC class I promoter also developed systemic autoimmunity characterized by elevated MHC class II molecules and CD23, enhanced responses to polyclonal stimuli in vitro, increased levels of IgG1 and IgE, anemia, antinuclear antibodies, and immune complex GN (381). These manifestations were likely a result of direct IL-4-induced polyclonal activation of B cells, since $CD4^+$ T cells were not required and there was no evidence for inefficient negative selection of B cells. The role of IL-4 in promoting lupus, however, is more complicated since autoimmunity was not observed in other transgenics expressing IL-4 on B cells or T cells (382 ,383 ,384 ,385), and expression of an IL-4 transgene in a spontaneous model of lupus did not exacerbate disease, but was protective (386). This would imply that a number of factors, such as the level and site of IL-4 production, and background genetic susceptibility, can modify the effects of IL-4 on systemic autoimmunity.

Tristetraprolin (*Zfp-36*) is a widely expressed zinc-binding protein initially thought to function as a transcription factor, particularly in lymphoid tissues, where high levels are found (387). Mice with homozygous knockout of tristetraprolin develop a complex syndrome consisting of cachexia, patchy alopecia, dermatitis, conjunctivitis, erosive arthritis, myeloid hyperplasia, glomerular mesangial thickening, and antinuclear antibodies (388). These manifestations are mainly caused by excessive TNF-α production by macrophages and are reversed almost entirely by treatment with anti-TNF-α antibody (388 ,389). Thus, tristetraprolin must function as a nonredundant negative regulator of TNF-α. The mechanism was later discovered to be due to the binding of tristetraprolin to an AU-rich element contained in the TNF-α mRNA, which destabilizes the mRNA (390). In contrast to the autoimmune–promoting effects of elevated levels of TNF-α, physiologic amounts may, under certain circumstances, play a role in suppressing systemic autoimmunity. In studies of *TNFR1* (p55) knockout mice, nonautoimmune mice did not develop defects in apoptosis or autoimmunity (391 ,392), yet the same knockout in lupus-prone C57BL/6-Fas^{lpr} mice resulted in accelerated lymphoproliferation and autoimmune disease (393). Since TNF can induce death of activated peripheral T cells (154), these findings might be attributable to TNF compensating for the lack of Fas in Fas^{lpr} mice.

Other Mechanisms

The α-mannosidase II enzyme is encoded by a single gene in mammals and resides in the Golgi apparatus, where it trims two mannose residues from hybrid N-linked oligosaccharides. This trimming of the mannose residues allows the subsequent addition of multiple glycan branches by glycosyltransferases required for generation of complex N-glycans found on mammalian cell surfaces (394 ,395). Mice rendered deficient in α-mannosidase II were reported to develop a lupus-like syndrome characterized by various autoantibodies, including anti-dsDNA, anti-Sm and antihistone, as well as hypergammaglobulinemia and immune complex GN (396). Nevertheless, lymphoid cell development, composition, and responses were normal. No clear explanation for appearance of systemic autoimmunity was evident, but alterations in N-glycan branching among some glycoproteins and tissues may lead to the formation of neoepitopes for which tolerance has not been established.

Emk (ELKL motif kinase) is a serine/threonine kinase with a conserved region of about 100 amino acids that terminates with the sequence glutamate-leucine-lysine/asparagine-leucine (a region referred to as the ELKL domain) (397). Emk has also been called MARK2, (microtubule affinity-regulating kinase 2), and mPar-1 based on homology with the Par-1 protein kinase of Caenorhabditis elegans (398). Evidence suggests Emk regulates cell polarity, cell cycle progression, and microtubule dynamics. It is expressed in several tissues, including the thymus and mature T and B cells (399). $Emk^{-/-}$ mice showed growth retardation and hypofertility (399 ,400). Additionally, as the deficient mice aged, they showed splenomegaly, lymphadenopathy, increased activated phenotype T cells ($CD44^{hi}CD62^{low}$, but no increases in IL-2R or CD69), increased responses to thymus-dependent antigens, lymphoid infiltrates in lungs, salivary glands and kidneys, and membranoproliferative GN with immune deposits and proteinuria (399).

The basic leucine zipper transcription factor Nrf2 (NF-E2-related factor 2) regulates an anti-oxidant response element (ARE) or EpRE (electrophile response element), whose consensus sequence is found in the 5′ regulatory region of a number of genes encoding detoxifying and anti-oxidant enzymes (401 ,402). Nrf-2-deficient female mice

over 5 mo of age reportedly developed severe GN with immune complex deposits together with higher serum IgG, anti-dsDNA antibody, and slight splenomegaly (403). In this regard, it is of interest that reactive oxygen species have been considered to be potential participants in the pathogenesis of lupus nephritis (404). Moreover, homozygosity for glutathione-S-transferase GSTM1 null alleles correlated with autoantibodies and lupus predisposition in humans (404) and mice deficient in heme-oxygenase-1 (a gene containing ARE) were noted to develop GN resembling that of the Nrf-2-deficient mice (405). In contrast, Nrf2 deficiency in MRL-*Fas*^{lpr} mice results in increased sensitivity to TNF-mediated apoptosis and disease suppression (406). Thus, the role of Nrf2 in lupus appears highly dependent on the underlying disease pathogenesis.

Conclusion

Considerable strides in defining the genetics of lupus have been made using spontaneous, induced, and genetically-manipulated mouse models. A clearer definition of the genetic landscape of lupus-predisposing loci/genes among lupus-predisposed and nonautoimmune strains has emerged, and progress in identifying susceptibility genes has advanced to cloning of candidates within finely mapped intervals. Studies of specific single-gene alterations that predispose to autoimmunity have suggested common mechanisms and identified unexpected pathways. Although complex, elucidation of the genetics of lupus should ultimately have a profound effect on our understanding of disease pathogenesis and therapy.

Chapter 8

Apoptosis

David A. Martin

Keith B. Elkon

Apoptosis, Necrosis, and Autophagy

- *Apoptosis*: The modern understanding of apoptosis began with the electron microscopic descriptions of morphologic changes characterized by shrinkage of hepatocytes (i.e., shrinkage necrosis) after ischemic or toxic injury to the liver. The name *apoptosis* was coined by Kerr, Wyllie, and Currie in 1972 to describe the form of death that was "consistent with an active, inherently controlled phenomenon" characterized by cell shrinkage, nuclear condensation, and cell blebbing (Fig. 8.1) (1). This term also conveyed the concept of cell death that was similar to leaves falling from a tree (*apo* means "from" and *ptosis* "a fall" in Greek), implying a regulated "mechanism of cell deletion, which is complementary to mitosis" (1).

  Further developments in our understanding of apoptosis paralleled advances in molecular biology, genetics, and biochemistry. The detection of a nucleosomal ladder (2) was of considerable importance, because it defined a biochemical event (i.e., nucleosomal cleavage) and provided a simple electrophoretic test for detection of apoptotic cell death that remains a standard in the field. Studies in the 1980s demonstrated that the death of cells during nematode development was under strict genetic control. Remarkably, the death of these cells could be perturbed by mutation of a small number of genes called ced (for cell death abnormal) genes (3). Horvitz and colleagues determined that two ced genes, ced3 and ced4, encoded death effectors, whereas ced9 was an anti-apoptotic gene. Most of the remaining ced genes were responsible for engulfment and removal of the "corpses." This simple model in which CED-3 is the main death protease that is activated by CED-4 and inhibited by CED-9 has served as a paradigm for defining apoptotic pathways in mammalian cells. In 2002, Robert Horwitz was awarded the Nobel Prize for "discoveries concerning the genetic regulation of … programmed cell death" (http://www.nobel.se/medicine/laureates/2002/index.html).

  Mammalian cells are more complex and, as will be discussed in detail, have multiple defined pathways that follow the basic *Caenorhabditis elegans* model. The molecules within these pathways, the downstream effectors of apoptosis, the caspases (cysteine aspartate proteases), and the proteins implicated in the clearance of apoptotic cells are discussed in detail below. The control of cell death is of seminal importance in a number of diseases, including cancers, autoimmune diseases, and degenerative disorders (4 ,5). Regulation of apoptosis and handling of dying cells is especially relevant to SLE as discussed below.

- *Necrosis*: Necrosis has traditionally been viewed as a passive form of cell death resulting from toxic or physical insults leading to adenosine triphosphate (ATP) depletion. Morphologically, necrosis is notable for plasma cell membrane disruption leading to cellular swelling and cytoplasmic vacuolation (Fig. 8-1). In contradistinction to the genetically controlled program of apoptosis, necrotic death induces inflammation around the dying cell due to the release of various intracellular components (Fig. 8-1) (6). Although chromatin degradation is evident in necrotic cells, the condensation and organized DNA fragmentation seen in apoptotic cells is usually absent. Notably, the same inducers (e.g., ischemia, hydrogen peroxide) may produce apoptosis or necrosis, depending on the severity of the injury and the rapidity of cell death (7). The cell's fate is determined in part by cellular energy reserves such as ATP (8). Some inducers may initially cause apoptosis followed by necrosis (postapoptotic necrosis). This will be evident when removal of the apoptotic cells is delayed. The transition from apoptotic to necrotic cells is likely to be important in the context of autoimmunity (see below).
- *Autophagy*: Autophagy is an alternative, nonapoptotic form of programmed cell death that has gained much attention over the past several years. Autophagy means literally, to eat oneself, and in this process cells switch to a catabolic program in which cellular constituents are degraded for energy production as a survival mechanism during periods of nutrient stress. In cells undergoing autophagy a double membrane vesicle forms, and encapsulates whole organelles leading to degradation following fusion with lysosomes (Fig. 8-1). The ATG gene family, including ATG7 and beclin1, that is highly conserved from yeast through humans, is involved in autophagic cell death (9). Interestingly beclin1 is monoallelically deleted in a variety of human cancers, and may function in cell-growth control and tumor suppression (10). Autophagy shares a number of morphologic features with necrotic cell death and may also be seen in neuronal cell death associated with polyglutamine repeats. It has also been observed that autophagy may play a role in the survival of lymphocytes following growth factor withdrawal (11). The reader is directed to reviews of autophagy for more details of this process (12 ,13).

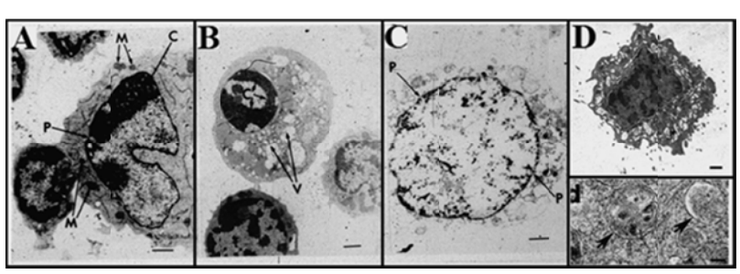

Figure 8-1. Electron microscopic morphology of cell death. A, A cytotoxic T cell (lower left) conjugated to its target, P815, a murine mast cell before the initiation of cell death. *B,* Induction of apoptotic changes in P815. Note the reduction in target cell size, nuclear condensation, and vacuoles with the relative preservation of organelles. *C,* Osmotic lysis and necrosis in P815 induced by antibody and complement. Note the increased size of the nucleus and apparently random fragmentation of the chromatin. Organelles are severely disrupted. *D,* Autophagic cell death of L929 cells treated 12h with caspase inhibitor (zVAD). Arrows show membrane-bound vacuoles characteristic of autophagosomes. Biochemistry of Apoptosis

Figures 8-2 and 8-3 show schematic overviews of the cell death program. A brief outline of each major functional component within the program, from the signals for death to removal of the apoptotic cells, is discussed here, but space limitations preclude a detailed analysis of the layers of regulation at each step of the pathway. For a more comprehensive discussion of the biochemical pathways controlling apoptosis the reader is referred to recent excellent reviews (5 ,14).

Numerous proteins involved in apoptosis, including receptors, adaptors, effectors, and inhibitors, contain modules/domains that are structurally similar and evolutionarily conserved. Interestingly these motifs are predominantly involved in promoting homotypic protein-protein interactions (Fig. 8-3). Furthermore, as will be discussed below, these domains occur in proteins involved in apoptosis as well as inflammation. It has been suggested that death domain (DD), death effector domain (DED), caspase recruitment domain (CARD), and Pyrin domains all evolved from the prototypic DD–fold corresponding to an antiparallel six helix bundle (15). Because of the central role for caspases, DNases and the bcl-2 family of proteins, we will briefly describe each in greater detail below prior to discussing how these families of proteins interact.

The cell death process can be divided into a number of stages: inductive stimulus, signal transduction, activation of caspases, activation of nuclease(s) with nuclear condensation, redistribution of the cellular contents into apoptotic bodies, and removal of the dying cells (see Figs. 8-2 and 8-3). Since the nature of the inductive stimulus dictates the initial biochemical pathways engaged, we will separately discuss extrinsic (“death receptor”) and intrinsic (“stress-induced”) pathways.

Caspases

The cysteine protease family of caspases plays a central role in apoptosis and the orthologs in *C. elegans* and Drosophila demonstrate evolutionary conservation. Caspases are produced as catalytically inactive zymogens and function as homodimers, with each monomer comprised of a large and small subunit. Caspases can be divided into two categories reflecting both structural and functional differences; “initiator” and “effector” caspases (Table 8-1) (for a comprehensive review see (16 ,17)).

The “initiator” caspases, which, in mammals, include caspase-2, -8, -9, and -10, have extended N-terminal prodomains that allow for clustering and autoactivation of the zymogens. The clustering of the initiator caspases depends on adaptor proteins that utilize homophilic interactions between conserved nonenzymatic domains present on both the adaptor and the caspase. These adaptors include Fas-associating protein with death domain (FADD), which recruits caspase-8 via a homophilic interactions between death effector domains in both proteins (DED, see below and Figs. 8-2 and 8-3), and Apaf-1 that recruits caspase-9 through a homophilic interaction through the aptly named CARD. Although the recruitment and activation of various initiator caspases occurs in response to unique sets of stimuli and in separate cellular compartments (see below), the structural basis of the homotypic recruitment has a remarkable degree of similarity between different interactive motifs (death domains, DEDs, CARD) (18). Autoactivation of initiator caspases likely occurs through oligomerization (17 ,19 ,20), ultimately leading to the activation of downstream effector caspases (caspases 3, 6, and 7). As discussed below, caspase-8, considered a pro-apoptotic protease, functions both in Fas-induced apoptosis (21) as well as lymphocyte activation and protective immunity (22 ,23).

The effector caspases are necessary for the execution of apoptosis. They cleave specific substrates such as the structural proteins fodrin, gelsolin, and lamins, key intracellular enzymes involved in DNA repair (e.g., poly (ADP)ribose polymerase, DNA-PK). These changes facilitate inactivation of synthetic functions of the cell, dissolution of the nuclear membrane, and packaging of cellular proteins into apoptotic blebs on the cell surface. Caspases also cleave regulatory proteins such as Bcl family members and the inhibitor of caspase-activated DNase (ICAD). Cleavage of ICAD leads to the release of active CAD, which enters the nucleus and cleaves nucleosomes at the linker region, yielding the characteristic “DNA ladder”(24 ,25).

Not all caspases are involved in the execution of apoptosis. Human caspases 1, 4, 5, and mouse caspase 11 and 12 are most likely involved in inflammation. Caspase 1, was originally defined as the enzyme that cleaves IL-1

(interleukin-1-converting enzyme (ICE)) into its active form. It has been shown that caspase 1 and caspase 5 interact and form a multiprotein complex that has been called the inflammasome (analogous to the apoptosome) (26). Caspase 1 and 5 bind to the adaptor proteins, ASC (PYCARD) and NALP1 (DECAP), respectively by their CARD domains. The protein, pyrin, that is in mutated in familial mediterranean fever (FMF), binds to ASC. Mutation of pyrin therefore most likely leads to inflammation through uncontrolled activation of caspase 1 and IL-1 and IL-18 (27 ,28). Furthermore, mutations in NALP3, a homologue of NALP1, are responsible for three genetic autoinflammatory syndromes (Muckle-Wells syndrome, familial cold autoinflammatory syndrome (FCIS), and chronic infantile neurological cutaneous and articular syndrome (CINCA). Macrophages from Muckle-Wells patients spontaneously secrete active IL-1ß as a result of increased activity of the inflammasome (29).

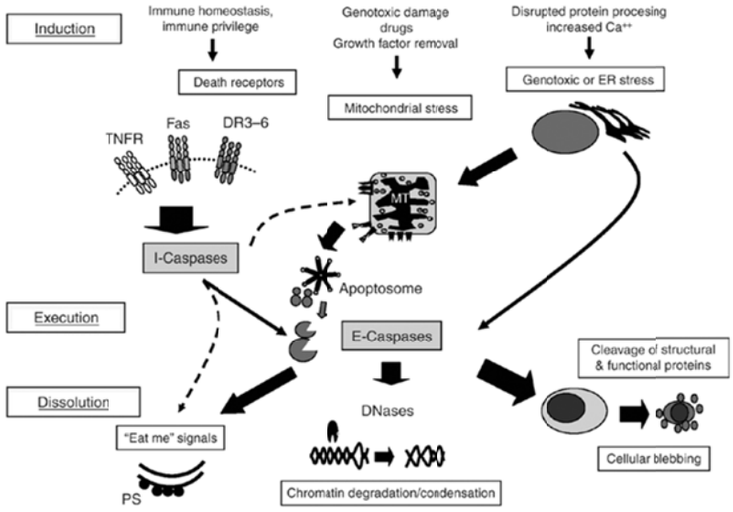

Figure 8-2. Mammalian apoptotic pathways. Cell death can be initiated by multiple pathways, including an extrinsic (left panel) and intrinsic pathways (middle and right panel). Apoptosis occurs in discrete stages, with induction stimuli leading to further execution and dissolution steps. Examples of stimuli that can induce each of these pathways are shown and discussed in further detail in the text. These various death pathways differ in the upstream initiator caspases (I-Caspases) activated but converge to cleave the effector caspases (E-Caspases) such as caspase 3 during execution of apoptosis. Central to the apoptotic program is the formation of the “apoptosome” which functions to amplify the death signal and leads to activation of the effector caspases 3, 5, and 7. The alterations that occur during dissolution of the cell are too numerous to mention but a few are highlighted in view of their potential relevance to autoimmunity (see text). Exposure of phosphatidylserine (PS) on the cell surface (left lower) may be relevant to the generation of antiphospholipid autoantibodies and coagulation disorders in vivo. Cleavage products of chromatin by various DNases (lower middle) as well as proteins, such as lamins and DNA-PK may be antigenic.

Inhibition of Caspases—Intracellular Inhibitors of Apoptosis (IAPs)

IAPs are a family of anti-apoptotic proteins that are highly conserved through evolution. The neuronal apoptosis inhibitory protein (NAIP) was discovered through the association of NAIP mutations in patients with the severe form of spinal muscular atrophy. Four additional members of the family (i.e., c-IAP-1, -2, X-IAP, and survivin) that share a baculovirus IAP repeat domain have subsequently been identified. The main function of IAPs appears to be inhibition of caspase 3 and 9 (30). IAPs block apoptosis induced by a variety of stimuli, including

Fas, tumor necrosis factor-α (TNF-α), ultraviolet irradiation, and serum withdrawal, and survivin is overexpressed in certain cancers and in the rheumatoid arthritis synovium (31).

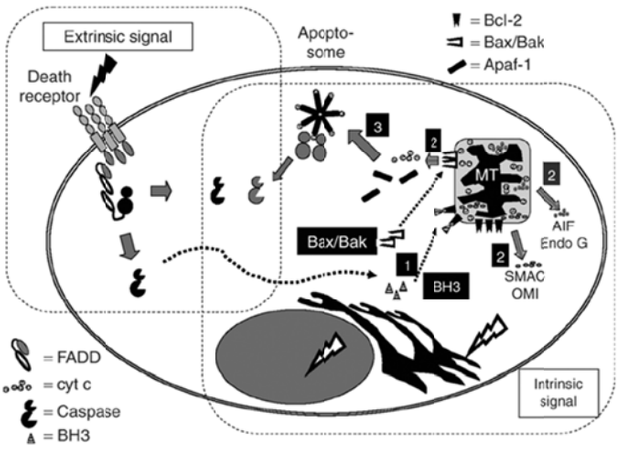

Figure 8-3. Overview of extrinsic and intrinsic apoptotic pathway. Death receptor extrinsic signaling is shown on the left as modeled by Fas-induced apoptosis. Fas aggregation leads to formation of the "death inducing signaling complex" (DISC), which contains the bifunctional adaptor FADD and the initiator caspase 8. High local caspase concentrations lead to the dimerization, activation and subsequent release of caspase 8 from the cell membrane. The intrinsic apoptotic signaling pathway is schematized on the right (see text for specifics of various pro- and anti-apoptotic proteins). Signals from cellular stress lead to the translocation of the pro-apoptotic Bax/Bak and BH3-only proteins to the mitochondria (shown as 1). BH3-only proteins antagonize the protective effects of Bcl-2 on cellular viability. Bax/Bak in turn aggregate and form large oligomers in the mitochondrial membrane leading to the release of cytochrome c into the cytosol (shown as 2). Apaf-1 forms a large scaffold for caspase activation known as the apoptosome in the presence of cytochrome C (shown as 3). Both pathways lead to the activation of effector caspases and subsequent cleavage of a multiplicity of cellular substrates.

IAPs themselves are inhibited by two mitochondrial proteins named Smac/Diablo and HtrA2/Omi, which are released into the cytosol during the intrinsic and some extrinsic apoptotic programs (Fig. 8-3). Mutations in the IAP inhibitor, HtrA2/Omi, have been implicated in a lethal neuromuscular disorder in mice, ostensibly due to increased sensitivity of embryonic fibroblasts to apoptosis (32).

In addition to the IAPs, various viral proteins inhibit caspases, which probably function to enhance viral fitness. The baculoviral protein p35 is a pan-caspase inhibitor that functions through the covalent linkage of the viral protein to an active site catalytic residue. The poxvirus apoptosis inhibitory protein, CrmA, likely functions similarly to p35. To date, no mammalian orthologues of p35 or CrmA have been identified. As discussed below, both an endogenous cellular protein (cFLIP) as well as a virus encoded protein, (vFLIP), inhibit Caspase 8 signal activation from the Fas/CD95 death receptor (21).

DNases and Degradation of Apoptotic DNA

One of the hallmarks of programmed cell death is nuclear condensation and subsequent DNA fragmentation. Numerous mammalian DNases have been implicated in the degradation of DNA, but the precise role of each DNase has not been completely elucidated. DNases in mammalian cells that are clearly implicated during apoptosis include the caspase activated DNase (CAD/DFF40), and the caspase independent DNAses including DNase II (located in lysosomes) and apoptosis-inducing factor (AIF)/endonuclease G (located in mitochondria) (Table 8-1).

Initially, degradation of chromatin into large DNA fragments to produce large (50–200kb) fragments occurs through co-operative interaction between Endonuclease G and AIF. Subsequently CAD/DFF40 cleaves DNA into internucleosomal units producing a characteristic 180 bp ladder. Mice deficient in CAD/DFF40 or ICAD (required for functional CAD) have defects in thymocyte DNA degradation, confirming an absolute requirement for CAD/DFF40 in cell-autonomous DNA fragmentation (24).

Table 8-1: Families of Intracellular Proteins Involved in Apoptosis

Caspases	Pro-domain	Function
Initiator		
Caspase 8, 10	long, with DED	Extrinsic (death receptor)
Caspase 9	long, with CARD	Intrinsic pathway
Caspase 2	long, with CARD	Both Extrinsic (death receptor) and Intrinsic (chemotherapy) pathways
Executioner		
Caspase 3/6/7	short	Cleavage of apoptotic substrates
Caspase inhibitors		
IAPs	—	Active-site blockage of caspases
p35, CrmA	—	Pan-caspase inhibitors
cFLIP	DED	Cell inhibitor of DISC formation
Bcl-2 members		
	Prototype	**Others**
Anti-apoptosis		
Bcl-2 sub-family	Bcl-2	Bcl-xL, Bcl-w, Mcl-1
Pro-apoptosis		
Bax sub-family	Bax	Bak, Bok
BH3-only sub-family	Bid	Bim, Bad, Puma, Noxa, Bik
DNases		
	Activation	**DNA degradation**
CAD	Caspase	Cell autonomous, generates nucleosomes
AIF + Endo G	Mitochondrial	Cell autonomous, cleaves chromatin
DNase II	Low pH	Ingested DNA in phagocytes
DNase I	?	Extracellular DNA

DED, death effector domain; CARD, caspase recruitment domain; IAP, inhibitor of apoptosis; cFLIP, cellular FLICE-inhibitory protein; DISC, death-inducing signaling complex; CAD, caspase-activated DNase; AIF, apoptosis-inducing factor, EndoG, endonuclease G.

The discovery that CAD/DFF40-null mice have terminal transferase-mediated dUTP-biotin nick-end labeling (TUNEL)-positive cells engulfed by macrophages led to a search for a cooperative DNase. The function of the lysosomal DNase, DNase II, was established by gene targeting as mice lacking DNase II accumulate undigested DNA-containing bodies in phagocytes (33 ,34). These findings emphasize the importance of non-cell autonomous DNA degradation that occurs following phagocytic ingestion of apoptotic cells. Intriguingly, mice deficient in both CAD/DFF40 and DNase II have additional defects in thymic development associated with inflammatory cytokines, including type I IFNs (35), further supporting a model in which DNA degradation during apoptosis is a sequential process that requires initiation in a cell autonomous way and is then fully executed by the phagocyte.

DNase I, the predominant serum DNase, is crucial for the degradation of DNA released from dead and dying cells into the bloodstream. Mice deficient in DNase I, at least on some strain backgrounds, develop a lupus-like phenotype including glomerulonephritis and antinuclear antibodies (ANA), ostensibly a result of the elevated levels of undigested DNA (36). It is unclear precisely how endogenous DNA becomes immunogenic under these circumstances.

The Bcl-2 Family: Central Regulators of Apoptosis

Bcl-2, the first protein described in this family, was originally discovered in the context of promoting B cell lymphomas through an ability to block apoptosis (37 ,38). There are at least 20 known Bcl-2 family members in mammals that have diverse cellular localization and function, and are broadly divided into three interacting groups (Table 8-1 and reviewed in (39)).

All Bcl-2 family members possess one or more BH (Bcl-2 Homology) domains, which allow for interaction with a variety of pro- or anti-apoptotic proteins. Multidomain prosurvival members Bcl-2, and closely related Bcl-xl, Mcl-1, and A1, can protect cells from a wide range of potentially death-inducing stimuli, including irradiation (UV and gamma), growth factor withdrawal, and chemotherapy. The pro-apoptotic multidomain group that includes Bax, Bak, and Bok likely functions by altering the permeability or conductance of mitochondrial and other membranes resulting in the release of additional pro-apoptotic mediators (see below). Finally, the “BH3-only” group of pro-apoptotic proteins contains at least eight members and functions primarily by

antagonizing the protective effects of the Bcl-2 family. Some BH3-only proteins may sensitize cells for apoptosis while others likely function more directly in activating apoptosis (5). The BH3-only members act as sentinels in various organelles, integrating proximal death or survival signals, and ultimately facilitating Bax/Bak induced apoptosis. A possible mechanism is to compete with Bax and Bak for binding to anti-apoptotic Bcl-2 members thereby releasing Bax and Bak to permeabilize organelle membranes (40).

The cellular localization of the Bcl-2 family members is diverse and likely reflects the complexity of networks that sense cellular damage and govern life or death. The anti-apoptotic Bcl-2 sub-family is associated with membranes, including the cytoplasmic face of the mitochondrial membrane. While Bcl-2 itself inserts into membranes in healthy cells, other related proteins must undergo allosteric changes prior to membrane association, allowing for the unique response to cytotoxic stressors. Similarly, the pro-apoptotic Bax family has both cytosolic (e.g., Bax) and membrane associated (e.g., Bak) members in healthy cells that translocate to the outer mitochondrial membrane after appropriate stimuli. The BH3-only family adds to the complexity of apoptosis regulation as individual members are expressed in a cell-type specific manner, and may allow for the response to organelle specific signals (see below). Constitutively expressed BH3-only members remain latent until released by a variety of stimuli. Examples include Bad (sequestered to 14-3-3 scaffold proteins) and Bid (undergoes cleavage). Finally, some BH3-only members are transcriptionally regulated so that certain forms of apoptosis resulting from cellular stress increase the expression of pro-apoptotic proteins (40).

Abnormalities in the Expression of Bcl-2 Family Members Cause Lupus-Like Autoimmunity in Mice

Mice that overexpress the anti-apoptotic protein, Bcl-2, or are deficient in the pro-apoptotic protein, Bim, develop a lupus-like disease on certain strain backgrounds (41 ,42). Bcl-2 is not a critical player in positive or negative thymic selection but may promote autoimmunity by enhancing cell survival in peripheral lymphocytes. In contrast, loss of Bim does impact thymic selection as evidenced in a Bim-deficient T cell receptor transgenic model where T cells targeted against the male antigen, HY, have impaired deletion of autoreactive $CD4^+8^+$ thymocytes in male mice (43). Bim may also regulate B cell survival.

Table 8-2: Death Receptor Family Members

Receptor	Ligand	Main Functions
Fas/CD95	FasL	Activation induced cell death, T-cell proliferation
TNF-R1	TNF	Immune activation and cell survival, apoptosis
TNF-R2	TNF	Immune activation and cell survival
DR3	TL1a (TWEAK)	T-cell costimulation
DcR3*	TL1a, FasL	Suppress T-cell responses
TRAIL-R1	TRAIL	For all TRAIL family, cell death of certain transformed cells and in some cells activation of NF-κB
TRAIL-R2	TRAIL	
TRAIL-R3*	TRAIL	
TRAIL-R4*	TRAIL	
OPG	TRAIL, RANKL	
DR6	unknown	Suppress T- and B-cell responses

*decoy receptors

Initiation and Pathways of Apoptosis

Extrinsic Signaling through Death Receptors

Our understanding of the molecular basis for apoptosis has been guided by the dissection of the signal transduction pathways downstream of Fas and TNF. The “death receptor” family consists of six members all of which contain an eighty amino acid cytoplasmic tail known is the “death domain” and which is required for apoptosis (Table 8-2 , Fig. 8-4). In addition to receptors for signaling apoptosis, there are a number of “decoy receptors” (DcRs) that also bind the same ligands of the TNF superfamily. These receptors either lack functional intracellular death domains (e.g., DcR3) or exist as soluble receptors (e.g., OPG) and are therefore unable to transmit an intracellular signal. By sequestration of death ligands, decoy receptors may prevent signal transduction from death receptors.

Fas/CD95 is a member of the TNFR-superfamily and plays a central role in T cell homeostasis (44). Restimulation of activated human T cells through the TCR results in Fas translocation into lipid raft microdomains and renders the cells sensitive to apoptosis by uncrosslinked FasL, most likely due to increased proximity and pre-association of receptor subunits (45) (Fig. 8-4). The localization of Fas to lipid rafts is likely cell-type specific as murine thymocytes have constitutive localization of Fas to lipid rafts.

Upon binding by Fas ligand, Fas further oligomerizes, and a number of apoptosis-related proteins are recruited via homotypic interactions and collectively form the death-inducing

signaling complex (DISC). Fas itself binds to the adaptor protein FADD via death-domain interactions, and FADD binds to caspase 8 through DEDs (Fig. 8-4). The recruitment and activation of caspase 8 requires “induced proximity” (20 ,46), and likely proceeds through dimerization of monomeric zymogens. Signaling through other death receptors, including TNF, DR3, and others, depends on the FADD as well as other adapter-induced recruitment of caspases. Activation of initiator caspases by death receptors leads to initiation of the “effector” caspase cascade as described in greater detail below (*intrinsic death pathways*).

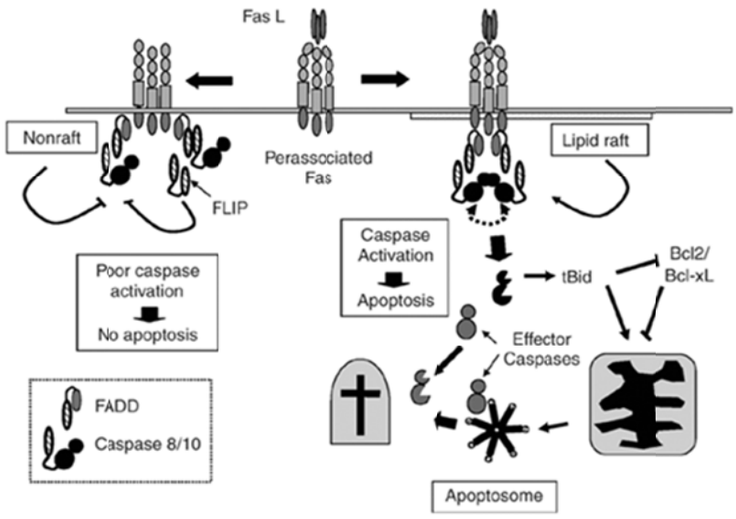

Figure 8-4. Death Receptor Signaling through Fas. Fas recruits the death-domain containing adaptor FADD and caspase-8 following engagement by FasL. In order to efficiently signal for apoptosis, Fas needs to translocate into lipid rafts which allows for caspase-8 autoactivation. Caspase-8 also cleaves tBid which functions to inhibit Bcl-2/Bcl-xl and promote the formation of the “apoptosome” consisting of Cytochrome C and Apaf-1 as described in the text.

Although the six DD-containing receptors initiate cell death in certain contexts, all may signal cell survival/proliferation in different cell types and/or in different contexts. The ability to signal an opposite cell fate, seems to depend on the recruitment of proteins such as the tumor necrosis factor receptor-associated factors (TRAFs) that activate nuclear-factor-kappa ß (NF-κB), thereby promoting cell survival (see below). The increasingly complex roles of “death” receptors and caspase 8 are illustrated by impaired T cell activation coupled with lymphocyte accumulation in patients with caspase 8 deficiency (22). Caspase 8 can also mediate NF-κB signaling in response to signals in response to antigen-, Fc-, or Toll-like receptor 4 in lymphocytes and natural killer (NK) cells (23).

TNF receptor 1 (TNFR 1) can trigger cellular activation via NF-κB or apoptosis via activation of apical caspases. Under most conditions TNFR1 signaling results in NF-κB activation, however when protein synthesis is blocked or NF-κB is specifically inhibited cell death can be triggered. In vivo, when NF-κB activation is blocked, endogenous TNF signaling through TNFR1 can lead to embryonic lethality because of massive liver cell death during development (48).

Similar to Fas, TNFR1 signals through FADD and caspase 8, and this signaling depends on the adaptor molecule TRADD, which has a region homologous to the FADD death domain. TNFR1 signaling involves assembly of two molecularly and spatially distinct signaling complexes that sequentially activate NF-κB and caspases (45 ,49). Early after TNF binding, RIP1, TRADD, TRAF2, and cIAP1 are recruited to TNFR1 to form complex I, leading to NF-κB translocation, which protects cells from apoptosis (50 ,51). At later time points, RIP1, TRADD, and TRAF2 dissociate from TNFR1 and recruit FADD and caspase-8 to form complex II. In the absence of NF-κB activity from complex I, complex II can initiate caspase-8 activation and cell death (49).

Regulation of Death Receptors

In most resting cell types that express Fas on their cell surface, the receptor does not appear to signal apoptosis and in lymphocytes may actually promote proliferation (52). Resistance to death is explained both by low levels of expression of the receptor, by physical separation of Fas from lipid rafts (45), and by active inhibition by a protein

called FLIP. FLIP resembles the structure of FADD, binds to Fas and prevents the adaptor protein, FADD, from initiating apoptosis. When lymphocytes become activated, FLIP is usually degraded allowing Fas signal transduction to occur unimpeded (Fig. 8-4) (21). FLIP can affect sensitivity to both Fas and TNFR signaling by competing with caspase 8 for FADD. Although numerous studies suggest that FLIP is a negative apoptotic regulator, the exact role of FLIP in Fas signaling is controversial, explained in part by the existence of different isoforms (21). The first FLIP described was from Herpesvirus (53) and likely contributes to viral persistence by activation of NF-κB pathways leading to both protection from cell death as well as growth and proliferation (54).

Function in Immune Regulation

Although the role of Fas and FasL interactions in the thymus remains controversial (55), this pathway is involved in the maintenance of immune privilege in the eye and the testis, in the pathogenesis of graft-versus-host disease, and in immune evasion by tumors (56). The major physiologic function of Fas and FasL in the immune system is the preservation of peripheral tolerance. This is achieved by the phenomenon of activation-induced cell death (AICD) whereby CD8 T cells, Th1 CD4 T cells, and possibly NK cells induce apoptosis of activated T cells, B cells, and macrophages. The deletion of activated immune cells removes the source of proinflammatory molecules, prevents the continued presentation of self peptides by primed (high levels of costimulatory molecules) antigen-presenting cells and eliminates B cells that have mutated to self-specificity in the germinal centers (57). Neutrophil homeostasis is also maintained by the Fas/FasL system. The Foxo3a forkhead transcription factor maintains neutrophil viability during inflammation by suppressing FasL, and blockade of Fas-FasL rendered Foxo3a$^{-/-}$ mice susceptible to two models of neutrophilic inflammation (immune complex-mediated arthritis and thioglycollate-induced peritonitis) (58).

It should be noted that, whereas TRAIL signals apoptosis through DR4 and DR5 predominantly in tumor cells, TRAIL may play a role in negative selection of thymocytes (59). Similarly, DR3 (the receptor for TWEAK) has also been implicated in negative selection (60). Finally, DR6, plays a role in immunologic homeostasis as evidenced by enhanced T- and B cell proliferation in DR6 deficient mice (61).

Deficiencies in Death Receptor Signalling Lead to Systemic Autoimmunity

Death receptors have been clearly implicated in both murine and human autoimmune diseases (62). The first clue that regulation of apoptosis was relevant to autoimmunity came with the identification of mutations in Fas and Fas ligand in the lpr and gld mouse models of lupus (reviewed in (56)). Since that time numerous spontaneous and induced genetic alterations that effect apoptosis have been shown to predispose to systemic autoimmunity (63). The autoimmune lymphoproliferative syndrome (ALPS) is an extremely rare disease usually detected during childhood (64 ,65 ,66). ALPS patients present clinically with a nonmalignant accumulation of lymphocytes in lymphoid organs, hypergammaglobulinemia, cytopenias, autoantibodies, and occasionally, glomerulonephritis or arthritis. The diagnosis of ALPS requires the aforesaid clinical features coupled with resistance of lymphocytes towards FasL-mediated apoptosis/AICD (67) and increased numbers of CD4-CD8- circulating T cells. The vast majority of patients have mutations in Fas, FasL or caspase 10. Either environmental and/or other genetic modifiers are necessary for disease onset, as not all humans and mice (lpr) with Fas mutations develop disease.

Mutations in the p55/TNFR1/CD120a receptor in humans results in a periodic autoinflammatory syndrome called tumor necrosis factor receptor-associated periodic syndrome (TRAPS). Mutations predominantly occur in the first two CRD of the receptor, which may in some cases result in reduced shedding of the extracellular domain of the receptor and reduced neutralization of circulating TNF-α (27).

Intrinsic Death Pathways from Cellular Stress

Cells depend on a variety of signals for active maintenance of survival including those relating to overall nutritional and bioenergetic status. Loss of signals from neighboring cells (68) or withdrawal of growth factors or cytokines results in initiation of a cell death program. Damage or stress to intracellular organelles may be induced from outside or within the cell, and these pathways depend on the dynamic interplay of Bcl-2 family of proteins and other regulators (14).

The Mitochondria as an Integrator of Cell Metabolism and Apoptosis

Mitochondria are cytoplasmic organelles that contain their own 16-kb genome encased by inner and outer membranes with a number of proteins, including cytochrome-c, situated between these membranes. Mitochondria help to maintain redox potential and are the energy powerhouse of the cell through the generation of ATP by oxidative phosphorylation. The discovery that many bcl-2 family members constitutively or inducibly localize to the mitochondrion, illuminated a central role for this organelle in orchestrating apoptosis.

The mitochondria contains numerous proteins that are crucial to the apoptotic machinery. Cytochrome c, an indispensable cofactor with Apaf-1 in the activation of caspase-9, is found only in the inner mitochondrial membrane. Additionally, the inner mitochondrial membrane contains inhibitors of anti-apoptotic proteins, Smac/Diablo and HtrA2/Omi, as well as inactive endonucleases (Endo G, AIF), which become active following release from the mitochondria (Fig. 8-3). The pro-apoptotic BAX and BAK proteins are essential for mitochondrial permeabilization, and mice doubly deficient in both BAX and BAK are resistant to multiple forms of apoptosis (69).

These proteins undergo changes allowing oligomerization and permeabilization of the mitochondrial outer membrane. This permeabilization in turn promotes release of pro-apoptotic proteins and formation of a complex including Apaf-1, cytochrome-c (Apaf-2) and caspase 9 (Apaf-3). This multiprotein complex, aptly termed the “apoptosome” (70), amplifies the death signal and leads to activation of the effector caspase-3, 5 and 7 (Figs. 8-3 and 8-4). The mechanism whereby BAX/BAK promotes release of these proteins is controversial, and may involve the formation of pores (71) or by alteration of intrinsic mitochondrial proteins triggering permeability transition. Once the mitochondrial membrane has been disrupted, multiple pro-apoptotic molecules are released, including cytochrome c, the IAP inhibitors Smac/Diablo and HtrA2/Omi as well as the proteins involved in chromatin degradation (Endo G, AIF).

Metabolic Stress

Withdrawal of either growth factors or nutritional sources leads to metabolic changes including lower oxygen consumption and a reduction in both ATP levels and protein production. In many cell types, these conditions lead to a form of apoptosis that can be blocked by overexpression of either Bcl-2 or Bcl-xL (14). A link between proteins involved in sensing bioenergetic status of a cell with those that control apoptosis has been identified. The pro-apoptotic BH3-only protein, BAD, forms part of a multiprotein complex that includes glucokinase and that regulates glucose-driven mitochondrial respiration (72). In response to withdrawal of survival factors, BAD is phosphorylated and orchestrates cell death. BAD additionally serves to help regulate blood glucose levels, and mice deficient in BAD have defective glucokinase activity that manifests as diabetes.

Another example connecting the apoptotic machinery with mitochondrial function is the interaction between a mitochondrial voltage-dependent anion channel (VDAC) and Bcl-2 family members (73). The Akt kinase, which promotes cell growth and inhibits apoptosis, also facilitates localization of hexokinase to the mitochondrial membrane (74). Hexokinase in turn, associates with VDAC and prevent Bax toxicity (75). Interestingly, Akt requires glucose to regulate hexokinase (and hence to protect against apoptosis), demonstrating a connection between the protein machinery regulating energy stores and the promotion of survival with the interface at the mitochondrial membrane.

Genotoxic Stress

Mutations occur frequently in mammalian DNA and are usually promptly repaired. However, if repair fails or DNA is severely damaged by radiation or drugs, the transcription factor, p53, is upregulated and phosphorylated by DNA damage sensors such as ATM. Activated p53 induces a cell cycle arrest through induction of the cyclin-dependent kinase inhibitor, p21. If the DNA damage is repaired, cell cycle arrest is abrogated, whereas if the injury cannot be repaired, the cell undergoes apoptosis. The critical importance of p53 as a tumor suppressor is illustrated by the high frequency of p53 mutations in cancers (76). p53 induces apoptosis, in part, by transcription of death effectors such as Bax that cause mitochondrial stress as well as two BH3-only bcl-2 family members Puma and Noxa (77).

Additional proteins, including both p53 and histone H1.2 may have a direct role in apoptosis following DNA damage. Following translocation to the mitochondria (78), p53 can directly activate the pro-apoptotic protein, Bax, to permeabilize mitochondria and engage the apoptotic program (79). p53 also functions in the release of Histone H1.2 from the nucleus into the cytoplasm (80). Once released into the cytoplasm, H1.2 can induce cytochrome c release from mitochondria in a Bak-dependent manner. These examples illustrate how apoptotic signals that originate in the nucleus are transmitted to the mitochondria.

Endoplasmic Reticulum Stress

The endoplasmic reticulum (ER) is now recognized as an important organelle that regulates the intrinsic apoptotic pathway. The ER is the major intracellular store of calcium, and in addition, functions to ensure proper protein folding. Disruptions in protein folding can lead to the “unfolded protein response” (UPR) and trigger cell death (81). One ER-stress response in mice has been shown to depend upon caspase 12 (82). Both Huntington disease and Alzheimer disease have been implicated in ER stress-induced apoptosis due to misfolded or mutant proteins. The signal for apoptosis due to ER stress may depend on calcium release, although the mechanism remains uncertain. The calcium binding protein Annexin V has been shown to be required for ER stress induced apoptosis (83).

Bcl-2 and Bax/Bak also function in ER stress-induced apoptosis in opposing ways. Bcl-2 blocks transmission of a stress signal from the ER to the mitochondria (84). Mice doubly deficient in Bax and Bak have markedly reduced ER calcium concentrations and defects in ER stress-induced apoptosis that could be corrected with overexpression of calcium pumps [sarcoplasmic/endoplasmic reticulum calcium ATPases (SERCA)] (85). These studies highlight the role of calcium dynamics in apoptosis and the functional interaction between the ER and mitochondria.

Removal of Apoptotic Cells

Receptors and Ligands

Within the immune system alone, more than 10^{12} apoptotic cells are removed from the body each day. These apoptotic cells are generated in vast numbers in the central lymphoid organs such as the thymus and bone marrow by out of frame rearrangements of antigen receptors, negative selection, or simple “neglect.” A significant load of apoptotic cells is produced in the peripheral immune system because of the relatively short life span of lymphocytes and myeloid cells and secondary selection of high-affinity B cells in germinal centers.

The specialized sites of selection (e.g., thymus, bone marrow, lymphoid follicles) have remarkably efficient phagocytes that rapidly remove the dying cells.

An early event in apoptosis is the appearance of phosphatidylserine (PS) on the cell surface membrane (Fig. 8-5). This membrane asymmetry (PS is usually located on the inner surface of the membrane) is caused by the reduced function of a translocase and possibly by activation of a lipid scramblase (86). PS is an important ligand for phagocytosis of apoptotic cells (87) Similarly, sugars such as N-acetyl-glucosamine and N-acetyl-galactosamine may be selectively exposed on the apoptotic membrane, triggering their recognition by phagocytes (88).

Despite the detection of only limited chemical alterations on the apoptotic cell membrane, blockade of a large and diverse number of receptors on phagocytes can impair the uptake of apoptotic cells (reviewed in (89)) (Fig. 8-5). This diversity may in part be explained by the different cells, activation states, and conditions used for phagocytic assays, but it undoubtedly also reflects the overlapping and partially redundant function of each individual receptor. All of the receptors identified have other functions, perhaps reflecting an evolution from receptors designed to remove apoptotic cells during development to pattern recognition receptors useful for host defense (90). Many of the receptors are integrins comprising the vitronectin receptor, $\alpha_v\beta_3$, $\alpha_v\beta^5$, complement receptors 3 (CD11b/CD18) and 4 (CD11c/CD18), and class A and B scavenger receptors. Nonintegrin receptors include the ATP-binding cassette transporter (ABC1) and CD14 and CD91.

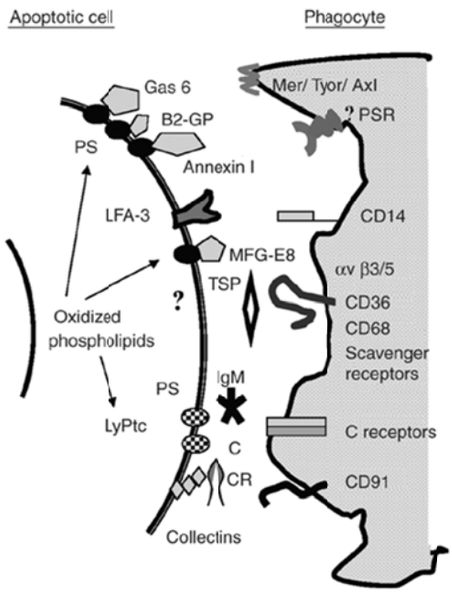

Figure 8-5. Receptors and ligands implicated in recognition or phagocytosis of apoptotic cells. A number of different “eat me” signals (ligands) are expressed on apoptotic, but not live, cells. In fact, live cells may express repulsive signals, such as CD47, that prevents them from being engulfed. The multiplicity of signals reflect different contexts and kinetics and the fact that certain ligands promote (‘tethering’) and others engulfment (‘tickling’) (135). Note that many ligands are actually serum proteins that coat exposed cell surface molecules and serve as opsonins for phagocytosis. It remains to be determined whether a unique phosphatidylserine receptor exists or whether PS is coated by protein opsonins. PS, phosphatidylserine; TSP, Thrombospondin; LyPtC, lysophosphatidylcholine; C, complement; CR, calreticulin.

In some cases, phagocytosis of apoptotic cells requires serum factors such as thrombospondin to bridge the $\alpha_v\beta_3$ and CD36 receptors (91) as well as serum complement (92) that is amplified on apoptotic cell membranes by natural IgM antibodies (93), mannose binding protein and acute phase proteins such as C-reactive protein (CRP). Other proteins such as MFG-E8, Gas6, β2-microglobulin, Annexin I (bind to PS or oxidized PS) or calreticulin (binds to collectins), have been implicated in promoting the phagocytosis of apoptotic cells in certain contexts (Fig. 8-5) Finally, engagement of the closely related Tyro 3 family receptor tyrosine kinases, MER, TYRO, and Axl by their ligands such as Gas6, protein S appear to be required to prevent production of IL-12 or TNF-α from macrophages that have ingested apoptotic cells (94).

Function in Immune Regulation

Apoptotic cell death is an integral part of development as well as normal tissue homeostasis so it is necessary that the immune consequence of removal of these cells is absence of inflammation. Removal may occur through professional (macrophages and dendritic cells) or nonprofessional (epithelial cell, fibroblasts) cells. Macrophages are the most abundant professional phagocyte and both in vitro and in vivo studies support the concept that when macrophages engulf apoptotic cells, activation is suppressed by the release of multiple inhibitory cytokines including IL-10 and TGF-β, (95 ,96). Although dendritic cells (DC) are less abundant, they are much more potent than macrophages at T cell activation and appear to be pivotal to the maintenance of T cell tolerance via the presentation of self-antigen derived from apoptotic cells in the absence of costimulation (“steady state” condition) (97). Apoptotic cells suppress DC activation of T cells, in part, through suppression of IL-12 (98), which is caused by activation of a transcriptional repressor, GC binding protein (GC-BP) (99). The interaction of apoptotic cells with phagocytes therefore appears to be necessary for tolerance to self.

In contrast, DCs exposed to necrotic or tumor cells undergo maturation and activate both CD4 and CD8 T cells (100). Necrotic cells release pro-inflammatory constituents including heat shock proteins (HSPs), HMGB-1, and possibly nucleoproteins themselves (6 ,101). Maturation of DCs has clearly emerged as a critical switch to stimulate effector T cell development and administration of DCs loaded with apoptotic cells can accelerate lupus in NZB/W F1 mice (102) and mature DCs can induce autoantibodies to nucleoproteins in normal mice (103).

Defective Clearance of Apoptotic Cells Predispose to Lupus-Like Disease in Mice

Deficiencies of a number of proteins implicated in the removal of apoptotic cells have been reported to cause lupus-like diseases in mice. These include deficiencies of receptors such as mer as well as serum opsonins such as natural IgM antibodies, C1q, SAP, and MFG-E8 (reviewed in (104)). The mechanisms involved differ; mer deficiency results in APC receiving a pro- rather than anti-inflammatory signal upon ingestion of apoptotic cells. Defective clearance of apoptotic cells in mice deficient (knockout) in sIgM, C1q, SAP, and MFG-E8 may predispose to lupus through slow clearance of apoptotic cells (105 ,106) leading to postapoptotic necrosis and/or through lack of engagement with specific inhibitory receptors on the phagocyte. Interestingly, the sites at which defective apoptosis manifests differs—in C1q deficient mice apoptotic cells accumulate in the kidney whereas in MFG-E8 knockout mice—apoptotic cells accumulate in germinal centers.

Apoptosis Abnormalities in Human SLE

A large number of abnormalities in the apoptotic process or handling of apoptotic cells has been reported in SLE patients. A brief outline of the observations and possible mechanisms are discussed (see Fig. 8-6).

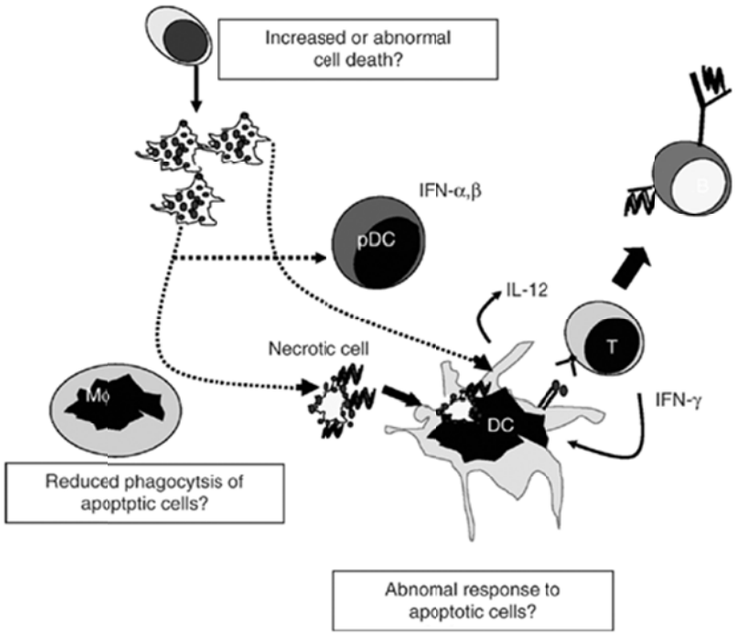

Figure 8-6. Role of apoptotic cells in the generation of autoantibodies to self antigen in SLE. Autoantibodies to cellular antigens in SLE may be generated by abnormalities in one or more of the pathways shown. See text for details.

Is the Process of Cell Death Normal in SLE?

As discussed above, although mutations in Fas and Fas ligand predispose to the ALPS syndrome in children, Fas/FasL mutations are exceptionally rare in SLE. However, the generation of autoimmunity to blood cells in ALPS as well as positive ANA in patients with caspase 10 mutations, indicate that the extrinsic pathway remains informative with regard to understanding loss of tolerance to cellular antigens.

Lymphopenia is a prominent feature in SLE and indicates that either cell death is excessive or that lymphocyte homeostasis is abnormal. An increase in apoptosis of SLE peripheral blood mononuclear cells has been observed in vitro (107 ,108). This may result from the increased number of activated lymphocytes in SLE or be an effect of elevated cytokines such as IL-10 (109) or IFN-α (see below). Although alterations in FasL or Bcl-2 have been reported, there is currently no compelling evidence for an intrinsic defect in apoptosis regulators in SLE.

Why the immune system targets a select subset of self antigens in each disease has never been satisfactorily explained. Of interest, it was observed that during apoptosis autoantigens, including those normally found in the nucleus, cluster and concentrate in surfaces blebs (110). As noted above, apoptosis leads to the controlled activation of multiple intracellular nucleases and proteases which, in turn, leads to the cleavage of a numerous cellular molecules; one consequence of this autodigestion is the generation of

“neoepitopes” (111). Some of these antigens undergo modification, including cleavage, phosphorylation and oxidation. However, it is expected that under normal conditions, these “neoepitopes” are also generated in the thymus and bone marrow leading to tolerance. On the other hand, inflammatory changes in the peripheral immune system that might occur secondary to UV light, oxidation, or cleavage by granzyme B delivered by cytotoxic T cells may qualitatively alter self antigens released by dying cells to stimulate immune responses. Good examples of alerted self in apoptosis are the lipid antigens, PS, and lysophosphatidyl choline (LPC), both of which may become oxidized and are recognized by certain anticardiolipin or natural anti-LPC antibodies (112 ,113 ,114).

Additional evidence implicating the products of dying cells in the immunization of SLE patients includes the strong focus of the autoimmune response on nucleosomes. Nucleosomes are detected in the circulation of SLE patients with active disease (115). Autoantibodies to nucleosomes precede those to DNA and histones, (116 ,117) and nucleosomes are more strongly antigenic for T cells and B cells than DNA or histones alone (118). Nucleosomes, but not isolated DNA or histones, deposit in the glomeruli, suggesting that it is the in situ fixation of nucleosomes, rather than DNA/anti-DNA immune complexes, that causes lupus nephritis (119 ,120).

Is the Response to Dying Cells Abnormal?

Type I interferons (IFNs) have emerged as critical cytokines in SLE (121 ,122). Studies of both SLE patients and lupus-prone mice suggest that activation of type I IFNs likely plays an important role in disease pathogenesis. It has long been known that serum levels of IFN-α are elevated in many SLE patients, and gene expression profiling revealed that patients demonstrate upregulation of IFN-responsive genes in their peripheral blood mononuclear cells (PBMC) (122 ,123). Of note, Ronnblom et al. reported that IgG antinucleic acid autoantibodies in combination with apoptotic cells stimulate a strong IFN response by SLE PBMC (124). A possible mechanism for IFN production under these circumstances has been identified. Mammalian DNA, similar to exogenous (e.g., bacterial or viral DNA), can act as an adjuvant when ingested by B cells or DCs in the form of immune complexes (125 ,126 ,127). DNA-stimulated pro-inflammatory signaling in these systems utilized a combination of an innate signaling receptor (TLR9 for DNA) with a second receptor (BCR or Fc-receptors) that facilitated uptake of the immune complexes. Together, these results strongly implicate endogenous DNA or nucleoproteins from dead or dying cells as immunostimulants for B cells and dendritic cells. While these very important experiments support a role whereby IFN production can by amplified by circulating immune complexes to perpetuate disease, the stimulus driving the original loss of tolerance remains unclear (Fig. 8-6).

Do SLE Patients Have Reduced Clearance of Apoptotic Cells?

Like several spontaneous lupus strains of mice, lupus patients are reported to have reduced clearance of apoptotic cells (128), although there are additional interpretations of these results (92). Inherited C1q deficiency in humans is sufficient to cause lupus in >90% of individuals in whom this mutation has been observed, and inherited C2 or C4 deficiency also predispose to SLE in 10% and 75% of patients respectively (reviewed in (129)). These observations suggest that deficiencies of the classical complement components offer a clue of fundamental importance in the pathogenesis of SLE. Although other interpretations are possible, both in vitro and in vivo experiments strongly support the idea that the early complement components are required for the clearance of apoptotic cells (92 ,130).

Another relevant serum abnormality observed in SLE is low serum levels of CRP that is associated with a polymorphism in the CRP promoter (131). Since CRP is potent scavenger of intact apoptotic cells (132) as well as snRNP and chromatin (133), reduced levels of CRP are likely to impair efficient removal of apoptotic cells and their debris.

Conclusions

Our understanding of the apoptotic program has grown exponentially over the past decade. Numerous human diseases have been directly linked to genetic defects in the apoptotic pathways, including cancer, neurodegenerative disorders and autoimmune diseases. Caspases initiate and amplify a variety of death signals allowing for selective and ordered cellular demolition. The fine balance between pro- and anti-apoptotic Bcl-2 family members regulate the cell fate in response to many (but not all) stress or signaling pathways. Recent discoveries highlight the complex integration of signals from various organelles that determine cell fate, and the multiple functions of central players in the apoptotic process. It is likely that the knowledge obtained in a relatively short space of time will translate into better diagnostics and therapies to enhance or retard cell death or to facilitate the removal of cell debris in the appropriate clinical circumstances.

Acknowledgments

The authors appreciate the helpful comments from Dr. Richard Siegel, and Drs. Li Yu, Eric Baehrecke, and Mike Lenardo for the use of published electron micrographs.

Chapter 9

The Interaction of T Cells with Cells of the Innate Immune System and B Cells in the Pathogenesis of SLE

David A. Horwitz

J. Dixon Gray

Systemic lupus erythematosus (SLE) is a systemic disease that is characterized by generalized autoimmunity. Unlike organ-specific autoimmune diseases such as insulin-dependent diabetes mellitus or myasthenia gravis, SLE is characterized by autoantibodies against nuclear, cytoplasmic, or cell surface molecules that transcend organ-specific boundaries. It is the inflammatory responses triggered by local formation and/or deposition of antigen antibody immune complexes that are responsible for the clinical manifestations of vasculitis and multi-organ system disease.

SLE is a T Cell-Dependent Disease

The production of pathogenic autoantibodies in SLE is T cell–dependent (1 ,2 ,3 ,4 ,5 ,6). In murine models of SLE, depletion of $CD4^+$ T cells blocks disease onset (7), and athymic mice do not develop SLE (8 ,9). In humans, the effects of human immunodeficiency virus (HIV) infection on $CD4^+$ lymphocytes may ameliorate SLE activity and spur remission (10).

Although numerous abnormalities of T cell function have been described in this autoimmune disease, investigators have failed to find a common abnormality expressed by all patients. There is no evidence that autoantigen–specific T cells in SLE patients reflect a defect in the generation of the T cell repertoire. Instead, the T cell response to self antigens reflects a breakdown of tolerance to these structures.

It is now appreciated that T cell recognition of foreign and self-antigens is similar and self-reactivity to histocompatibility molecules is not only physiologic, but is indispensable to the generation of normal immune responses. Moreover, since a T cell receptor can recognize multiple peptide antigens, one might ask how a limited number of highly cross-reactive T cells can respond to the large number of foreign peptides and yet remain tolerant, or nonresponsive to self peptides? In fact, thymic deletion of T cells that are capable of reacting against certain self-peptides is incomplete and autoreactive T cells capable of initiating SLE exist in healthy individuals (11) and have the potential to cause lupus (12). Immunoregulatory mechanisms normally render these cells nonresponsive or tolerant to self peptides. In SLE, however, various intrinsic and acquired cell T cell defects that will be summarized result in a breakdown of tolerance and development of disease. This is because B cells with the potential to make antinuclear autoantibodies also are not deleted during ontogeny (13). Once T cells capable of providing help for these B cells are activated, a circuit is initiated that ultimately results in the production of pathogenic IgG-DNA and other autoantibodies (14 ,15 ,16). Moreover, ineffective attempts by the immune system to downregulate the ongoing autoimmunity may lead to further T cell abnormalities that perpetuate the disease.

In this chapter we will consider the general properties of T cells, their functional development, and how they are regulated. Since it has become apparent that cells of the innate immune system greatly affect T cell functional properties, this topic will also be discussed. A link between the innate and adaptive immune systems has been established in the development of SLE. This link explains the appearance of autoantibodies reactive with nucleic acid-protein particles (17).

General Properties of T Cells

T cells are thymus-derived lymphocytes that develop effector or regulatory functions depending upon how they are stimulated by antigen and professional antigen-presenting cells (APCs) called dendritic cells (DC). Unlike B cells, T cells are unable to bind antigen directly; rather, they recognize antigen complexed to major histocompatibility complex (MHC) molecules. $CD4^+$ T cells recognize peptides complexed to MHC class II (HLA-DR, -DP, -DQ) $CD4^+$ typically recognize microbial peptides after phagocytosis and processing by DC, $CD8^+$ cells recognize peptides complexed to MHC class I (HLA-A, -B, -C). These cells generally recognize peptide fragments of newly synthesized intracellular proteins, and therefore can eliminate viral infected cells. The T cell antigen receptor (TCR) expressed on the surface consists of a two-chain, heterodimer that is noncovalently complexed to the signal-transducing CD3 structure. Most T cells display antigen receptors (TCRs), which are αß chain heterodimers.

They are positively selected by self histocompatibility antigens in the thymus and following release, they recirculate continuously between blood and peripheral lymph nodes. Although most $CD4^+$ cells have helper functions and $CD8^+$ cells become killer cells (18), each can develop the opposite function in SLE (Table 9-1).

T cells are called naive or virgin when they leave the thymus. Because naive $CD4^+$ cells lack receptors for adhesion molecules that are expressed by memory or previously stimulated cells, they require antigen presentation by mature DC under optimal conditions for activation. Once they acquire characteristic adhesion receptors, they can be restimulated under much less stringent conditions (19 ,20 ,21 ,22). Such $CD4^+$ cells respond well to soluble antigens and support B cell differentiation. Corresponding memory $CD8^+$ cells, which are the precursors of antigen-specific killer cells, also are generated (23 ,24). In humans, naive and memory T cells can be identified by reciprocal expression of CD45 isoforms on their cell surfaces (CD45 is a membrane tyrosine phosphatase that has a vital role in signal transduction). Naive T cells display the high-molecular-weight CD45RA isoform, and memory T cells express the low-molecular-weight CD45RO isoform (19 ,20 ,21 ,22).

The distinction between naive and memory T cells is especially important in the development of autoimmunity, because potentially harmful autoreactive T cells are in the immature, naive state. Because of clonal anergy or T cell suppression, these cells will be maintained in the resting state. Once tolerance is broken, however, and these autoreactive T lymphocytes become memory cells, autoimmunity is easily sustained.

Table 9-1: Human T and Natural Killer (NK) Cell Populations

Population	TCR Structure	Comment
$CD4^+$	αß chains	Recognize peptide antigens complexed to self MHC class II structures (HLA-DR, -DP, -DQ)
$CD8^+$	αß chains	Recognize peptide antigens complexed to self MHC class I structures (HLA-A, -B, -C). Generally develop cytotoxic activity, but a subset of CD28-cells can develop cytokine-dependent suppressive activity in mice.
$CD4^+$ $CD25^+$	αß chains	Heterogeneous populations of natural, thymus-derived cells and peripheral $CD4^+$ cells that have been induced by IL-2 and TGF-ß to become suppressor cells. Express the transcription factor FoxP3 Control the proliferation, migration and effector functions of other T cells. Prevent autoimmunity
γδ $CD3^+$ $CD4^-$ $CD8^-$	Restricted expression of γδ chains	Minor population in blood, abundant in intestine; directly recognize phosphorylated and stress-induced proteins; important immunoregulatory functions
NKT, express CD3 and NK markers (CD56); generally $CD4^-$, $CD8^-$	Restricted expression of αß chains	Minor population in blood, but present in skin and mucosal tissues such as intestine, liver, lungs; recognize CD1, glycolipid antigens
Natural killer (NK) $CD56^+$, $CD16^+$, $CD11b^+$ $CD3^-$, $CD4^-$, $CD8^{+/-}$	Germline	Found in blood, spleen, and mucosal tissues including female reproductive organs; rare in peripheral lymph nodes; generally produce IFN-γ, but can produce other immunoregulatory cytokines such as TGF-ß

HLA, human leukocyte antigen; IFN, interferon; MHC, major histocompatibility complex; TCR, T-cell receptor; TGF, transforming growth factor.

T cells can be divided into T effector cells and regulatory cells that control the activation and functional properties of effector cells. T effector cells proliferate in response to antigen stimulation, produce cytokines and become helper cells for antibody production or killer cells. Regulatory cells generally do not proliferate in response to antigen and block other T cells from becoming activated or block their effector functions. Effector T cells can be divided into T helper 1 (Th1) or T helper 2 (TH2) cells depending upon the cytokines they produce. Th1 cells produce IL-2 and IFN-γ, cytokines that favor eliminating microbial invaders, and Th2 cells produce IL-4 and IL-13 that are associated with allergy and helminthic infections. Regulatory cells control the activity of both Th1 and Th2 cells.

Regulatory T Cells

Regulatory or suppressor T cells are heterogenous populations that consist of subsets of $CD4^+$, $CD8^+$ and NKT cells (see below). They can originate in the thymus or develop from T cells in the periphery.
While previously interest was focused on $CD8^+$ suppressor cells, in recent years $CD4^+$ cells that constitutively express CD25, the α chain of IL-2 receptor, have received considerable attention.

$CD4^+CD25^+$ cells can be divided into a natural subset that develops in the thymus (25 ,26 ,27), and a peripheral subset that develops from $CD4^+CD25^-$ cells in the periphery (28 ,29). Both natural and peripheral $CD4^+CD25^+$ cells express the forkhead family transcription factor, FoxP3 that controls their development (30). In the periphery IL-2 and TGF-ß induce $CD4^+CD25^-$ cells to express CD25 and become suppressor cells (29 ,31 ,32). Natural $CD4^+CD25^+$ cells have a TGF-ß independent origin. The mechanism of action of both of these subsets is contact-dependent and probably depends upon TGF-ß (33). The principal function of natural $CD4^+CD25^+$ cells regulatory cells is to prevent organ-specific autoimmune diseases such as gastritis, thyroiditis, or sialadenitis (25 ,26). In mice, separation of regulatory T cells from effector cells leads to organ-specific autoimmune diseases. Thus, so called “ignorant” self-reactive T cells that are not eliminated by the thymus cause disease because they are held in check by regulatory T cells.

Natural $CD4^+CD25^+$ cells probably have limited effects in SLE. Depletion of these cells in lupus-prone mice does enhance the onset of autoimmunity, but does not alter the course of the disease (34). Although regulatory T cell function appears to be intact in young lupus prone mice, they become deficient following the onset of disease. This is probably because production of IL-2 and TGF-ß, the two principal cytokines required for the generation of peripheral $CD4^+CD25^+$ regulatory cells (35) is decreased in SLE (36 ,37 ,38).

IL-2 and TGF-ß also induce $CD8^+$ cells to develop potent suppressive activity that have a cytokine-dependent mechanism of action (39 ,40). In addition, tolerogenic peptides can also induce $CD8^+$ suppressor cells that express FoxP3 and have a TGF-ß dependent origin and mechanism of action (41 ,42). The adoptive transfer of $CD8^+$ suppressor cells in lupus-prone (NZB × NZW)F1 mice can markedly prolong their survival (43). $CD8^+$ suppressor cells could either complement the effects of $CD4^+CD25^+$ suppressor cells, or enhance their development. TGF-ß induces $CD8^+$ cells to develop suppressive activity within 2 days (39). The TGF-ß produced by these cells could then induce $CD4^+$ cells to become $CD4^+CD25^+$ cells. A combination of $CD4^+$ and $CD8^+$ regulatory T cells generated with IL-2 and TGF-ß have long term protective effects in animal models in vivo (see below). $CD4^+CD25^+$ regulatory T cells can induce other $CD4^+$ cells to develop suppressive activity by a phenomenon called infectious tolerance (31 ,44).

Table 9-2: Effects of Triggering Toll-Like Receptors on Immune Cells

Cells	TLR	Ligand	Effects
Myeloid dendritic cells	TLR3, TLR8	viral nucleic acid acids	Induce IFN-alpha and IL-12
	TLR4	Bacterial lps	Induce IL-6 that confers resistance to Tregs
Plasmacytoid dendritic cells	TLR9	Bacterial DNA (CpG)	Increased maturation and antigen-presenting properties
B cells	TLR 9	CpG	Enhancement of antigen-presenting properties and expansion.
CD4+CD25+ regulatory T cells	TLR2	Bacterial Lipoprotein	Expands regulatory cells
	TLR-4	Bacterial lps	Enhances survival and proliferation
	TLR5	Flagellin	Enhances suppressive activity

lps, lipopolysaccaride

$CD4^+$ cells repeatedly exposed to IL-10 or immature antigen-presenting cells can become IL-10 producing regulatory cells called Tr1 cells (45). Although IL-10 production is elevated in SLE, Tr1 cells have not been described in this disease. Regulatory cells can be generated in vivo indirectly by the administration of certain combinations of immunosuppressive drugs (46 ,47), by blocking costimulatory CD40/CD40L interactions (48), or with anti-CD3 monoclonal antibodies administered in vivo (49).

Dendritic Cells

Cells of the innate immune system have pattern-recognition receptors on their cell surface that enable them to recognize microbial invaders. Before the evolution of T cells and adaptive immunity, infectious agents were eliminated by phagocytic cells and natural killer (NK) cells. The phagocytic cells have evolved into specialized antigen-presenting cells for T cells that are called dendritic cells. Like their primitive precursors, they bear Toll-like receptors (TLRs), capable of binding microbial products. These cells also express receptors for the Fc portion of IgG and complement receptors capable of clearing immune complexes. A subfamily of TLR consisting of TLR3, TLR7, TLR8, and TLR9 specifically bind nucleic acid motifs expressed by various infectious agents (50). Unlike Fc and complement receptors, these TLRs are not expressed on the cell membrane. Triggering of TLRs greatly affect the functional properties peripheral T cell develop (Table 9-2).

Antigen-presenting DC can be divided into two principal subsets, those derived from myeloid and those from lymphoid precursors. Their principal difference is the TLRs they express. Myeloid DC migrate to the skin and other peripheral

tissues. Once they phagocytose and process antigens, they migrate to lymphoid organs where they mature and trigger an immune response. Human myeloid DC characteristically express TLR3 and TLR8. Plasmacytoid or pDC that are derived from lymphoid precursors characteristically express TLR7, and TLR9 that binds bacterial DNA (51). Importantly, the triggering of TLR induces the cells to produce large amounts of type 1 interferons, cytokines now believed to be important in the pathogenesis of SLE (52 ,53).

DC in peripheral tissues and lymphoid organs are mostly immature and lack the co-stimulatory molecules to induce T cells to become effector cells. Therefore, presentation of self-peptides to potentially dangerous autoreactive T cells by immature DC renders them nonresponsive or tolerant to these antigens. However, once viruses or other infectious agents trigger TLRs on these DC, they mature and become capable of activating autoreactive T cells. These cells now express costimulatory molecules such as CD40, B7.1 (CD80), and B7.2 (CD86) that can induce T cell activation. They also produce cytokines such as IL-12 and type 1 interferons that promote T helper cell 1 (Th1) differentiation. Fortunately, self-reactive T cells that had been rendered tolerant generally cannot respond to mature dendritic cells that express these costimulatory molecules. Moreover, certain mature DC can also induce T cells to become regulatory cells (54). Thus, it is an oversimplification to consider immature DC as inducers of tolerance and mature DC inducers of effector cells.

It has been reported that $CD4^+CD25^+$ regulatory T cells express TLR-4, -5, -7, and -8 and that exposure of these cells to the TLR-4 ligand lipopolysaccharide (LPS) induces upregulation of several activation markers and enhances their survival/proliferation (55). On the other hand, LPS triggering of TLR-4 on DC induces them to produce IL-6, a cytokine that increases the resistance of T cells to the suppressive effects of $CD4^+CD25^+$ cells (56).

Some interactions with TLR can induce immunosuppression instead of activation and some organisms are able to promote their survival by ligating these TLR. An example of this is the response of DC exposed to *Candida albicans*. Ligation of TLR2 by this organism results in increased production of IL-10. Mice deficient in TLR2 exhibit decreased IL-10 production and, interestingly, a decrease in T regulatory cells (57). A similar link between TRL2 ligation and IL-10 production with associated T regulatory activity was found upon stimulation with schistosomal lysophosphatidylserine (58).

NK Cells

Natural killer (NK) cells were named for their ability to lyse particular tumor target cells in the absence of any obvious activating stimulus (59 ,60 ,61) and can also kill certain cells that are infected by intracellular organisms (62). NK recognize classical class I HLA molecules by killer cell inhibitory receptors (KIRs) and bind the nonclassical class I molecule, HLA-E to a heterodimer receptor formed by the association of CD94 with various members of the NKG2 proteins (63). The monoclonal antibodies to CD11b, CD16, and CD56 react predominantly with NK cells (64 ,65 ,66 ,67). Both CD11b and CD56 identify virtually identical lymphocyte populations (68). All NK cells express CD11b, but those that express CD56hi produce cytokines rather than kill by contact (51). An important feature that distinguishes NK cells from T and B cells is their ability to respond directly to IL-2 and IFN-γ (69 ,70). Resting T and B cells generally require a first signal through their antigen receptors to respond to these cytokines.

NK cells can spontaneously lyse certain tumor target cells and can kill IgG coated cells by a mechanism called antibody-dependent cellular cytotoxicity (ADCC). In addition to their cytotoxic properties, NK cells can enhance or suppress antibody production (71 ,72 ,73). IL-2 activated NK cells express CD40 ligand (74) and can induce resting B cells to become antibody-producing cells (75). Depending upon the subset and the way they are stimulated, NK cells can produce IFN-γ, TNF-αγ, IL-10, or TGF-ß (75). When NK cells are added to $CD4^+$ cells and B cells they enhance antibody production. However, when $CD8^+$ cells are also present, IgG production is markedly inhibited. The interaction of activated NK cells and $CD8^+$ cells results in NK release of active TGF-ß and this cytokine induces $CD8^+$ T cells to suppress antibody production (39). NK cells can constitutively produce active TGF-ß and are the principal immediate lymphocyte source of this cytokine (75). NK cells produce large amounts of IFN-γ that is induced by viral induce triggering of TLR2, 3, and 4 (76). NK cells can synergize with or eliminate DC depending upon their numbers and the way they were stimulated (51).

NKT Cells

NKT cells may be considered an intermediate between the innate and adaptive immune system. They may be derived from the thymus or the liver from a common precursor of T and NK cells (77 ,78). They express markers common to both of these lymphocyte populations. Two thirds of them express TCRs that are comprised of α and ß chains and one third express γ and δ chains. Unlike conventional cells that respond to peptide antigens, NKT cells respond to glycolipid antigens such as CD1. Also unlike conventional T cells that require two signals for activation, NKT cells require only a single signal (79). While rare in peripheral lymphoid tissue, these cells are present in mucosal tissues and have cytotoxic or immunoregulatory effects (79 ,80). Activated NKT cells in the lupus prone NZB/W mice produce IFN-γ that accelerates the progression of the disease (81).

Interplay Between T Cells and Cells of the Innate Immune System

There is constant cross-talk between DC, NK cells, NKT cells, and T cells that determines whether a given immune response can ultimately trigger an inflammatory response, or will suppress inflammation. Infectious agents activate DC through TLRs that induce NK cells to produce IFN-γ

and TNF-α. These cytokines enhance DC maturation, which, in turn, promotes the T cell–dependent B cell responses of the adaptive immune system (51).

On the other hand, DC, NK cells, NKT cells, and T cells all have the capacity to inhibit immune reactivity. These cells can produce TGF-ß, and if the response to antigen favors TGF-ß production, the paracrine effects of this cytokine can induce T cells and other cells to also produce TGF-ß (82). Moreover, TGF-ß inhibits NK and T cells from producing IFN-ß (83). The result will normally be the generation of T suppressor cells instead of T helper cells.

Development of Immunity, Autoimmunity, or Tolerance

The outcome of T cell response to antigen is multifactorial and includes the strength of the peptide/MHC complex binding to the T cell receptor, costimulation by antigen-presenting cells, and the cytokine environment. As a result, the T cell can become a Th1 or Th2 effector cell, a regulatory cell, or nonresponsive (Fig. 9-1). Strong persistent stimulation results in T helper cell differentiation whereas weak or brief T cell stimulation results in nonresponsiveness or tolerance. As stated above, the triggering of dendritic cell TLRs induces them to become mature antigen-presenting cells that favor T effector cell development. By contrast, antigen-presentation by immature cells favor anergy. The cytokines produced by DC also influence the T cell response. For example, the IL-10 and TGF-ß produced by DC of the mucosal immune system favor regulatory T cell development (84).

As an immune response proceeds and availability of antigen becomes exhausted, certain cell surface molecules expressed by activated T cells now induce “activation-induced apoptosis,” and most of the expanded T cell populations are eliminated. Late in an immune response production of IL-10 and TGF-ß increases and these cytokines induce regulatory T cells that also contribute to the termination of the immune response.

The presence of aggressive, self-reactive T cells in a lymphoid microenvironment where a strong immune response is progressing has the potential to trigger an autoimmune disease. Here mature antigen-presenting cells could break down self-antigens to cryptic peptides that are recognized by pathogenic T cells that have escaped thymic deletion. Other T cells could recognize foreign antigen determinants that cross-react with self (molecular mimicry). Generally, however, pathogenic T cells are inhibited by regulatory T cells that block their activation, their migration to inflammatory sites, or their functional activity. Even if these auto-aggressive T cells became activated, these cells should undergo activation-induced apoptosis like most T cells. Thus, persistent antigen-stimulation, a failure of activation-induced apoptosis, or defective T regulatory cell function can each favor naive disease-causing T cells to proliferate and convert them to pathogenic memory cells that could cause lupus.

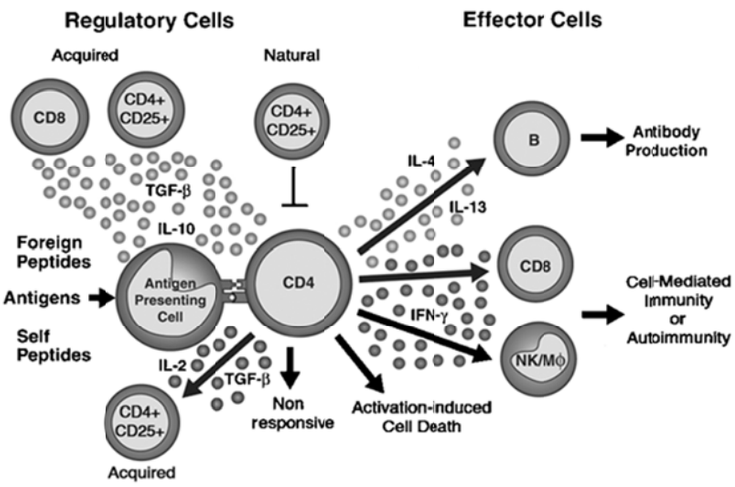

Figure 9-1. Development of immunity, autoimmunity, or tolerance. T cells respond to antigen by either becoming activated or anergic (nonresponsive). Immature antigen-presenting (dendritic cells) lack costimulatory molecules and induce anergy. Infectious agents trigger Toll-like receptors (TLRs) expressed by immature dendritic cells (not shown) and drive then maturity. These antigen-presenting cells activate T cells to provide help for antibody production or to induce cell-mediated immunity. An immune response is terminated as the availability of antigen decreases and most of the T cells are eliminated by activation-induced apoptosis. T-cell activation is also controlled by CD4+ and CD8+ regulatory T cells that maintain tolerance to self antigens. These cells occur naturally, or can be induced by IL-2 and TGF-ß. Thus, antigen-activated T cells can be induced to become either helper or suppressor cells depending upon how they are stimulated and the cytokine microenvironment.

In SLE the products of apoptotic cells trigger TLR expressed by dendritic cells and B cells and enhance their ability to process and present nuclear autoantigens to self-reactive T cells. These activated cells expand because of a lack of T-cell regulation and because they are resistant to activation-induced apoptosis. Thus, tolerance to nuclear autoantigens is broken and autoimmunity is initiated.

The Properties of T Cells and NK Cells in Sle

Percentage and Absolute Numbers of T Cell Subsets

Decreased numbers of T, B, and NK cells is a common manifestation of active SLE (85 ,86 ,87 ,88 ,89 ,90 ,91). Most patients with active SLE have total lymphocyte counts of less than 1000 cells/mm^3. Because of the relative decrease of lymphocytes in SLE in comparison to monocytes, the percentage of $CD3^+$ T cells often is decreased in mononuclear cell preparations. The apparent percentage of T cells may be further decreased by the contamination of immature granulocytes that copurify with mononuclear cells in patients with active disease.

Within the context of T cell lymphopenia, certain T cell subsets may be affected more than others in SLE. Early reports indicated a relative decrease in $CD8^+$ cells in SLE (92 ,93). One group indicated that patients with sicca syndrome, central nervous system (CNS) disease, lung disease, and muscle disease exhibit increased CD4-to-CD8 ratios (94). Other studies

have indicated that the relative percentage of $CD8^+$ cells is either normal or increased, and that $CD4^+$ cells often are decreased in active SLE (95 ,96). In such cases, the decrease in $CD4^+$ cells results in an abnormally low CD4-to-CD8 ratio, a finding that frequently is observed in patients with severe lupus nephritis (94 ,97). Corticosteroid therapy preferentially decreases $CD4^+$ cells and thus decreases the CD4-to-CD8 ratio (95). Decreased $CD4^+$ cells correlate with antilymphocyte antibodies (ALAs) that are specifically reactive against this T cell subset (98 ,99), and a strong relationship exists between high titers of ALAs, lymphopenia, and disease activity (85 ,98 ,100). Within the $CD4^+$ and $CD8^+$ T cell subsets, $CD28^+$ cells are decreased in SLE (101 ,102).

In addition to alterations in the number or percentage of $CD4^+$ cells, Stohl and coworkers reported an association between SLE and expression of a genetically determined variant of the $CD4^+$ molecule in Jamaican black individuals (103 ,104). Whether expression of this variant CD4 molecule truly predisposes certain individuals to develop SLE or simply acts as a marker for some other SLE-predisposing factor remains unknown at present.

NK Cells

Both the percentage and the absolute numbers of NK cells generally are decreased in patients with active SLE. The percentages of $CD16^+$ cells are decreased (105 ,106 ,107 ,108), and the percentages of CD3-$CD11b^+$ and $CD16/CD56^+$ lymphocytes also are decreased (91 ,107). In patients with inactive SLE, values for NK cells usually are normal. In comparison to normal donors, patients with SLE have decreased NK cytotoxic activity; the decrease tends to be more pronounced in more active patients (109 ,110 ,111 ,112 ,113 ,114). Decreased NK activity may be explained by decreased percentages of NK cells. However, since the numbers of lymphocytes binding NK-sensitive targets are comparable between normal donors and patients with SLE (111), it is more likely that NK cells in patients with active SLE have an impaired capacity to lyse target cells. A detailed analysis using purified NK cells is supportive of a defective NK lytic activity in a significant percentage of SLE patients. In fact there was significant inverse correlation between NK activity and global SLE disease activity score (115). Antibody-dependent cellular cytotoxicity mediated by CD16 is also decreased in SLE (115 ,116 ,117 ,118).

The mechanism(s) responsible for decreased cytotoxic activity of NK cells in SLE are not well understood. Serum factors such as immune complexes or ALAs could possibly account for this defect, at least in part. Serum from lupus patients can contain high levels of both immune complexes and ALAs. Immune complexes have been shown to suppress or decrease NK cytotoxic activity (110 ,114 ,119). Several groups have reported that incubation with serum from patients with SLE followed by treatment with complement greatly decreased NK cytotoxic activity (109 ,113 ,114). The inability of serum alone to decrease NK activity suggests that immune complexes, by themselves, were not sufficient. Whether certain ALAs are specific for NK cells is unknown. One study demonstrated that serum from patients with SLE plus complement did kill a substantial number of NK cells (113). In this study, preincubation of the serum with T lymphocytes removed the cytotoxic activity, suggesting that the antibodies were not NK cell specific. However, another study described the presence of autoantibodies that were specific for CD16 (120). There are ALAs in SLE that react with a variety of cell surface structures, some of which may have the potential to react with NK cells specifically or to prevent mediation of full functional activity. A study comparing NK activity of patients with that of relatives found a moderate reduction in activity of relatives (115).

As stated above, the combination of NK cells and $CD8^+$ cells suppresses T cell–dependent antibody production in healthy individuals (39 ,40). In SLE, however, the effect is the opposite. NK cells and $CD8^+$ cells added separately together enhance IgG production (121). This is probably because of defective production of TGF-ß by NK cells in SLE (36).

The significance of the NK cells' role in the suppression of antibody production has been demonstrated in several murine models of SLE. With certain strain combinations, the injection of parental spleen cells into F1 hybrid mice can result in the development of a lupus-like disease with autoantibody production. An inverse correlation was found between the levels of anti-dsDNA antibody and both the number and function of NK cells (122). The significance of this observation was shown by the reduction of autoimmunity through procedures that elevate NK activity and the exacerbation of symptoms by depleting the animals of NK cells. Similarly, it has been reported that development of autoimmunity in C56BL/6 lpr mice correlated with the disappearance of NK cells (123). In a more recent study of C57BL/6 lpr mice, the onset of autoimmunity correlated with the disappearance of a distinct population of cells that expressed the phenotype of NK cells but that also expressed TCRs (124). Taken together, these studies suggest that NK cells have an important role in the regulation of antibody production in vivo.

NKT Cells and CD4-CD8- (Double Negative) γδ Cells

In addition to almost all $CD4^+$ and $CD8^+$ T cells, which are restricted to protein MHC class I and II molecules (see above), a small percentage of T cells recognize glycolipid determinants such as CD1. These cells express the NK cell marker NKR-P1 and are called NKT cells. Most but not all of these cells lack CD4 and CD8 and had been called double negative cells. Increased percentages of DN T cells have been reported in SLE. Moreover, cloning these cells revealed that some αß and γδ cells could provide help for autoantibody production (3 ,19). These observations have been confirmed and extended. Three groups reported an increase in the DN subset in Caucasian or Japanese populations (125 ,126) although another could not find a significant

increase in Chinese patients with SLE. One group reported an increase in the γδ subset (127).

$CD3^+$ CD4 CD8 double negative cells that predominantly express αß TCR chains have been cloned and, like NKT cells, these T cells are restricted by CD1d (126). The DN T cells were stimulated by CD1c on human B cells and could provide help for IgG production. While in healthy subjects, they produced only IFN-γ; in SLE they produced both IFN-γ and IL-4. Interestingly, in active SLE, they produced high levels of IFN-γ. Another group reported that DN T cells in SLE produced IL-4.

Besides helper activity, certain subsets of DN or NKT cells possess potent suppressive effects. A small subset that bears an invariant Vα24JαQ TCR is one example. These T cells are decreased in the affected sibling of identical twins discordant for autoimmune diabetes and marked changes in gene expression have been reported in T cell clones from these twin pairs (128). There is one report of decreased Vα24JαQ positive T cells in a Japanese SLE population (129). Decreased percentages of the NKT γδ subset also been reported with an inverse correlation with disease activity (130). γδ T cells have been proposed to have an important role in mediating self tolerance. Thus, although NK T cells are present in only small numbers, different subsets may have important opposite effects in the pathogenesis of SLE.

Naive and Memory T Lymphocyte Subsets

$CD4^+$ T cells with the naive phenotype (i.e., $CD45RA^+$) were reported to be decreased in SLE (131 ,132 ,133). Because serum from patients with SLE contains autoantibodies against CD45RA, it was suggested that this subset was deleted (134 ,135). However, decreased $CD45RA^+$ cells and a proportionate increase $CD45R0^+$ cells could reflect T cell activation in vivo with the expected increase in the activated state.

T Cell and Antigen-Presenting Cell Function in SLE

In the early 1970s, workers from several laboratories reported that patients with active SLE responded poorly to intradermal injected skin test antigens (136 ,137 ,138 ,139). Thus, SLE was not a disease of immunologic overreactivity, but an imbalance between the cellular and humoral arms of the immune system. Many defects of T cell function were described in parallel with evidence of B cell hyperactivity. Table 9-3 presents a partial summary of T cell functional defects. The significance of these T cell defects was difficult to understand because B cells generally need T cell help to become antibody-producing cells. Moreover, other workers reported evidence of T cell hyperactivity in SLE.

It is now possible to reconcile apparently conflicting reports of both T cell hyperactivity and hypoactivity in SLE. In both human lupus and mouse models of lupus there is evidence of spontaneous and persistent T cell activation. Studies of lupus prone mice have revealed inherited intrinsic defects in the T cells of these animals that result in T cell hyperactivity and increased resistance to cell death. These self-reactive T cells of these mice have a lower threshold of activation to autoantigens, and following their response to these antigens, their survival is increased (140). It is also known that activated T cells are hyporesponsive to further antigen stimulation. Thus, chronic, persistent, T cell activation could explain, at least in part, T cell hypoactivity in SLE documented in in vitro studies.

Table 9-3: T Lymphocyte Functional Activities in Vitro

Function	Activity
Proliferation	
Mitogenic lectins	Decreased or normal
Anti-CD3	Decreased or normal*
Anti-CD2	Decreased
Soluble antigens	Decreased
Allogeneic mixed lymphocyte reaction	Decreased
Autologous mixed lymphocyte reaction	Markedly decreased
Response to IL-2	Decreased or normal
Helper cell activity	
Nonspecific	Decreased or normal
Antigen specific	Decreased
Suppressor cell activity	
ConA induced	Decreased or normal
Antigen specific	Decreased
Spontaneous inhibitors of IL-2 production	Increased
Cytotoxic cell activity	
In response to allogeneic or xenogeneic antigens	Decreased
In response to hapten-modified antigens	Increased
In response to anti-CD3	Decreased
In response to IL-2	Decreased

*When isolated T cells are used instead of peripheral blood mononuclear cells (PBMCs), the response to anti-CD3 is normal or increased.
ConA, concanavalin A; IL-2, interleukin-2.

Increased Spontaneous T Cell Activation In Vivo

Blood lymphocytes isolated from patients with active SLE exhibit numerous signs of activation in vivo (Table 9-4). Increased numbers of circulating T cells from these patients proliferate spontaneously (141) and express cyclin, a marker associated with proliferation (142). Increased numbers of T cells have undergone somatic mutation (143 ,144), or are undergoing apoptosis (145 ,146 ,147 ,148). There is increased T cell expression of MHC class II molecules (149 ,150 ,151), protein tyrosine kinase activity and c-rel [nuclear factor (NF)-κB] mRNA (152 ,153), release of soluble IL-2 receptors (154 ,155 ,156 ,157 ,158), TNF

receptors (159 ,160 ,161 ,162 ,163), and CD40 ligand (164) into the serum is also increased (152). A study of recent thymic emigrants into the peripheral T cell pool has also suggests increased T cell proliferation in SLE (165). Moreover, blood lymphocytes of patients with active SLE express IL-2mRNA, a finding that reflects persistent antigen stimulation (166). Finally, in mouse models of lupus there is polyclonal $CD4^+$ T cell activation (167 ,168).

Table 9-4: Evidence of In Vivo T-Cell Activation in Subjects with Active SLE

Increased numbers of spontaneously proliferating T cells
Increased frequency of circulating T cells bearing somatic mutations
Increased cell surface expression in unstimulated T cells of MHC class II (HLA-DR, -DP) structures, Fas, Fas ligand, CTLA-4, and a modest increase in interleukin-2 receptors
Increased serum levels of soluble interleukin-2 receptors, tumor necrosis factor-α receptors (p55 and p75), soluble Fas, and soluble CD40L
Increased levels of mRNA transcripts for interleukin-2 and c-rel (NF-kappa B) in unstimulated T cells
Increased protein tyrosine kinase activity
High levels of circulating early apoptotic blood mononuclear cells

CTLA, cytotoxic T-lymphocyte associated; HLA, human leukocyte antigen; MHC, major histocompatibility complex; mRNA, messenger RNA; NF, nuclear factor.

T Cell Hypoactivity In Vitro

In contrast to studies of freshly prepared T cells from patients with SLE, the proliferative response of these cells to mitogenic lectins (i.e., phytohemagglitinin [PHA], concanavalin A [Con A] and pokeweed mitogen [PWM] and soluble antigens) is decreased in SLE (139 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179), with an occasional exception (180). T cell responsiveness to both allogeneic and autologous lymphocytes was decreased in SLE (181 ,182 ,183 ,184 ,185 ,186). The principal reason for these findings is defective co-stimulation by accessory cells, or humoral inhibitory factors (see below).

Pairs of receptor/coreceptor pairs on T cells and accessory cells that are crucial to T cell costimulation include CD2/CD58 (LFA-3), CD11a (LFA-1)/CD54 (ICAM-1), CD40/CD40L, and CD28 or CD152 (CTLA-4)/CD80 (B7–1) or CD86 (B7–2). Blockade with specific mAb or soluble fusion proteins of the receptor/coreceptor interactions can inhibit T cell proliferation, T cell–dependent B cell differentiation, and/or induction of T cell cytolytic activity (187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195). Expression of CD80 and CD86 following activation is decreased in SLE (196 ,197). The inhibitory CTLA-4 receptor is normally expressed on SLE T cells, but one study suggested that its inhibitory effect is decreased in this disease (198). This could be a result of decreased expression of CD80.

While accessory cell–dependent, CD3/TCR-mediated proliferation in unfractionated PBMC cultures was often abnormally low in SLE (172 ,174 ,178), the response of purified T cells in SLE was normal-to-enhanced (199 ,200 ,201). This is because immobilized anti-CD3 antibodies that bind the CD3/TCR do not require a second costimulatory signal to induce proliferation. The proliferative response to anti-CD2 also was depressed because of multiple defects (102 ,202). As was the case for anti-CD3, an accessory cell defect explained this result in the majority of patients, because the defect disappeared following depletion of these cells. Most important, the addition of anti-CD28 also reversed the defect (102). Others have found that the costimulatory effect of anti-CD28 markedly enhanced the capacity of patients with active SLE lymphocytes to produce IL-2. (101) A defective proliferative response to anti-CD2 in SLE may be important because signaling through this pathway selectively triggers a TGF-ß-dependent suppressor-cell pathway (40).

Costimulatory Markers Associated with T Cell Hyperactivity

Increased expression of CD11a and CD54 in SLE (203 ,204 ,205) has been associated with development of autoreactivity (203). Other T cell surface antigens that are upregulated during the course of an immune response that play vital roles in T cell helper function and T cell cytolytic function respectively are CD154 (CD40 ligand) and CD95L CD178 (Fas ligand) by interacting with CD40 on the surface of B cells, can deliver a differentiation signal as well as either rescuing B cells from or priming B cells for apoptosis (206 ,207 ,208 ,209 ,210 ,211 ,212). CD154 is transiently expressed by $CD4^+$ T cells soon after activation and is quickly downregulated, especially in the presence of B cells (213 ,214). This tight regulation of CD40 ligand expression presumably protects the host against induction of indiscriminate polyclonal B cell differentiation by activated T helper cells. CD154 is, in fact, hyperexpressed by both $CD4^+$ and $CD8^+$ T cells in SLE (215 ,216 ,217), and biologically active circulating soluble CD154 is increased in SLE (218).

T Cell Cytolytic Activity in SLE

The ability of $CD8^+$ cells to develop cytolytic activity in SLE is also decreased. Abnormalities in T cell–dependent or T cell–mediated cytolytic activity include impaired generation of cytotoxic T cells against allogeneic or xenogeneic targets (219 ,220), and impaired anti-CD3-driven cytolytic activity (201 ,221). In contrast to these reports, others have reported that $CD4^+$ cells in SLE kill autologous monocytes (222). Another group reported $CD8^+$ cells from patients with disease flares express higher levels of perforin- and/or granzyme B. In this study lupus serum promoted the development of DC. These dendritic cells in turn, enabled $CD8^+$ cells to become cytolytic cells that generated high amounts of soluble nucleosomes and autoantigen fragments (223).

The defect in cytolytic activities of $CD8^+$ cells may not be a result of an intrinsic abnormality, but because of inadequate costimulatory effects of accessory, non-T cells. Although the cytotoxic effects of SLE T cells was markedly reduced in cultures containing blood mononuclear cells, when purified T cells were assessed, the responses of SLE $CD8^+$ cells were only modestly and insignificantly less than $CD8^+$ cells from normal controls (224). Moreover, twin studies revealed that substitution of “healthy” non-T cells for SLE non-T cells in four of the nine monozygotic pairs appreciably enhanced cytolytic responses, and substitution of SLE non-T cells for “healthy” non-T cells in five of the seven twin-pairs tested appreciably diminished cytolytic responses (224 ,225).

T cell defects may explain the abnormally high levels of Epstein-Barr virus (EBV) loads in patients with SLE. EBV viral loads were inversely correlated with the frequency of EBV-specific $CD69^+$ $CD4^+$ T cells producing IFN-γ, and were positively correlated with the frequencies of $CD69^+$ $CD8^+$ T cells producing IFN-γ, and with EBV-specific, HLA-A2 tetramer-positive $CD8^+$ T cells (226).

Regulatory T Cell Activity

It is now evident that antibody production is principally controlled by regulatory/suppressor T cells. In the past, numerous investigators reported that $CD8^+$ cells had impaired suppressive activity in SLE (227 ,228 ,229 ,230 ,231 ,232 ,233 ,234 ,235 ,236 ,237 ,238 ,239 ,240). This function was generally measured by the ability of $CD8^+$ T cells to inhibit the proliferation of other T cells to mitogen. In SLE, one group analyzed DNA-induced antibody synthesis in a pair of identical twins who were discordant for SLE; only B cells from the SLE cotwin could produce anti-DNA antibodies. Addition of the SLE cotwin's T cells to her own B cells promoted anti-DNA antibody production induced by calf thymus DNA. On the other hand, T cells from the unaffected cotwin did not promote anti-DNA antibody synthesis unless $CD8^+$ cells were depleted. This finding suggested that the healthy cotwin had anti-DNA specific T helper cells, but that they were kept nonfunctional by $CD8^+$ suppressor cells (15). More recent studies support impaired functional activity of SLE $CD8^+$ cells (241).

There is considerable evidence that regulatory $CD4^+$ $CD25^+$ cells prevent the activation of autoreactive T cells (242). Both natural and $CD4^+CD25^+$ induced from $CD4^+CD25^-$ cells in the periphery with IL-2 and TGF-β express FoxP3 (see above), and each may participate in controlling autoimmunity in SLE. The principal effects of natural $CD4^+CD25^+$ cells, however, are to prevent organ-specific autoimmune disease (25 ,26). Natural $CD4^+CD25^+$ cells that lack the capacity to produce TGF-β or IL-10 are present in mice with genetic deletions of TGF-β1 and CTLA-4: these mice die from overwhelming autoimmunity within several weeks after birth (243 ,244). Thus it is likely that TGF-β and the peripheral Tregs they induce have a central role in the prevention of SLE.

A combination of $CD4^+$ and $CD8^+$ regulatory T cells generated ex vivo with IL-2 and TGF-β have long term effects in vivo in mice. They can prevent a lupus like syndrome and a single injection will double the survival of animals with established disease (245). These long-lasting effects could be because of the ability of $CD4^+CD25^+$ cells to educate other $CD4^+$ cells to develop suppressive activity (31 ,44). Immunogenic peptides that accelerate the development of lupus in mice have protective effects instead if injected intravenously. Instead of inducing self-reactive $CD4^+$ cells to become aggressive, tolerogenic approaches induce $CD4^+$ and $CD8^+$ regulatory T cells. One group has demonstrated that lupus prone mice tolerized by very low doses of a pathogenic lupus peptide injected intravenously developed $CD4^+CD25^+$and $CD8^+$ suppressor cells that produced and required TGF-β for its mechanism of action (42). Another group found that tolerization with another immunogenic peptide resulted in the appearance of $CD4^+CD25^+$ suppressor cells with a TGF-β–dependent mechanism of action (41). This group reported that $CD8^+$ suppressor cells only developed following immunization of mice resistant to the development of lupus (246). Recently, this group has observed that the transfer of TGF-β producing $CD8^+$ Tregs to lupus-prone mice could markedly increase survival (247). The antigen specificities of these tolerogenic peptides will be described below.

Another group prevented lupus in mice with intranasal injections of a histone peptide. In these mice the numbers of $CD4^+CD25^+$ T cells were normal until just before they developed lupus and were markedly decreased thereafter (248). Other workers have documented $CD4^+$ TR-1 like cells following high doses of a peptide derived from the Sm protein (249).

It has been reported that the T cells from lupus-prone mice are resistant to the suppressive effects of $CD4^+CD25^+$ cells (250). In humans there is only limited information about $CD4^+CD25^+$ regulatory T cells in lupus. Unlike mice, only the brightly staining $CD25^+$ cells have the phenotype and properties of natural $CD4^+$ regulatory cells. Two groups have reported decreased numbers of these cells in SLE (251 ,252).

The Effect of Serum Factors on T Cell Function

Factors extrinsic to the cells such as autoantibodies or nonantibody serum components can inhibit the T cell proliferative response. SLE sera inhibit lymphocyte proliferation in response to mitogenic lectins (253 ,254 ,255), soluble antigens (98), and allogeneic (256 ,257 ,258) as well as autologous MHC antigens (176 ,259 ,260 ,261). These sera also block the generation of cytotoxic T cells (220) and interfere with antigen presentation by macrophages (262). Much of this inhibitory capacity can be ascribed to IgM and IgG antibodies, which react with various lymphocyte cell surface molecules. SLE ALAs react with activated lymphocytes more strongly than resting lymphocytes (98 ,263 ,264). IgG ALAs inhibit suppressor cell generation and activity (228 ,265 ,266). Additionally, IgG ALAs inhibit mitogen- and

mixed lymphocyte reaction (MLR)-induced proliferation (228 ,253 ,254 ,256 ,257 ,260 ,264) and preferentially inhibit the T cell response to soluble antigens (98).

Autoantibodies against the CD3/TCR have been identified in SLE. One group reported autoantibodies directed against “public” idiotopes present in the first complementarity determining region (CDR1) and the third framework (FR3) of the Vbeta gene products. They suggested that these autoantibodies are generated in response to overproduction of autodestructive T cells bearing particular Vbeta gene products and function to modulate (downregulate) the expression of these T cells (267). Consistent with this suggestion, another group has recently reported anti-TCR/CD3 antibodies in SLE that can account for decreased IL-2 production in SLE (268).

Although initially reported only to react with T suppressor cells (228 ,265 ,266), ALAs react with both $CD4^+$ and $CD8^+$ cells (269 ,270) and may react preferentially with $CD4^+$ cells (135 ,271 ,272). Such autoantibodies may result in altered CD4/CD8 ratios, leading to altered immune function. Additionally, IgM autoantibodies that are reactive with the membrane tyrosine phosphatase CD45 molecule have been described in SLE (135 ,272). These antibodies preferentially react with the high molecular weight CD45RA isoform that is expressed on naive T cells (19). Such autoantibodies may interfere with T cell signal transduction. Autoantibodies against the MHC class I associated ß2-microglobulin (273) and MHC class II molecules (260) also have been described. Such autoantibodies could inhibit T cell function by blocking cell-to-cell interactions.

In addition to ALAs, which were described in the 1980s, it was reported more recently that hyperactive B cells secrete TGF-ß complexed to IgG, and these complexes inhibit macrophage and neutrophil function (274 ,275). Increased levels of IgG-TGF-ß complexes have been found in lupus sera (275) and can explain, at least in part, some of the inhibitory effects of lupus sera on T cell function.

Altered Cytokine Homeostasis

Although patients with active SLE have increased numbers of circulating IL-2 producing T cells, the production of this cytokine and many others is decreased in response to antigen or mitogen stimulation (37 ,38). Lymphocyte production of both latent and active TGF-ß is decreased in SLE (36). The defect in total TGF-ß production was related to disease activity (276). Defective production of IL-2 and TGF-ß in SLE may be important in the pathogenesis of this disease. These two cytokines are required for peripheral $CD4^+$ cells and $CD8^+$ cells to become suppressor cells (28 ,29 ,35 ,39) SLE is characterized by B cell hyperactivity and autoantibody production. Patients with SLE have increased numbers of circulating B cells that secrete IgG and autoantibodies. A brief exposure of blood mononuclear cells from these patients to IL-2 and TGF-ß markedly decreased spontaneous IgG and antinuclear autobody production (277). It is likely that these cytokines induced certain lupus T cells to regain suppressive activity and shut down B cell activity.

One consequence of active SLE, and a product of continuous immune stimulation, is elevated IL-10 production (278 ,279). IL-10 inhibits T cell function by blocking the effects of APCs on T cell function. Among the cytokines that are downregulated by IL-10 are IL-2, TNF-α, and IFN-ß (83 ,280 ,281 ,282 ,283). Each of these cytokines has been considered to have an important role in the generation of cytotoxic T cells and those that downregulate antibody production. Even though under certain conditions IL-10 can be stimulatory (284), high levels of this cytokine strongly inhibit the expression of costimulatory molecules by antigen-presenting cells and thereby interfere with T cell function. IL-10 also makes T cells more sensitive to activation induced cell death (146).

In conclusion, the apparently contradictory functional defects described in SLE may be due to the multifactorial abnormalities in SLE that include persistent T cell activation, accessory cell defects, humoral factors, and ineffective feedback regulatory mechanisms. As a result of the failure to shut down autoimmune T cell reactivity, the reactivity of other T cells is impaired.

Antigen Recognition by T Cells in SLE

Tolerance Induction

In SLE tolerance to antinuclear antigens and many cytoplasmic antigens has broken down with the production of a wide variety of autoantibodies. This loss of tolerance is not a result of a general immune defect. Studies of mouse models of SLE suggest that ability to delete autoreactive T cells with high affinity for self is generally intact. Clonal deletion of self reactive T cells is normal in two models of SLE (285 ,286 ,287 ,288). Deletion of T cells stimulated with superantigen is also intact (287). T cell tolerance induction in B/W mice carrying a transgene encoding beef insulin was also normal (289). Rather, the breakdown in tolerance to nuclear autoantigens and autoantibody production is because of multiple inherited cellular abnormalities. These include abnormalities of antigen-presentation, clearance of apoptotic bodies and immune complexes, T cell activation and death, T cell regulation, and B cell defects. Increased apoptosis of mononuclear cells and a failure to clear them, results in persistent T cell exposure to nucleosomal antigens (290 ,291). Defects in T cell activation result in a decreased threshold for T cells to respond to antigen (217). DC and B cells have a heightened capacity to present nucleosomal autoantigens (292). Increased expression of B7.1 (CD86) on B cells (293) and CD40L on T cells (215 ,216) contributes to this increased reactivity. In autoimmune mice breaking of self-tolerance requires signaling via both the CD28/B7 and CD40/CD40L pathways (294).

In human SLE, short term T cell lines were resistant to anergy induction. This resistance was associated with increased expression of CD40L and persistent activation of the mitogen-activated protein kinase ERK. (295), abnormalities that result in upregulation of cyclooxgenase 2 (296, see below). These multiple factors result in the activation and clonal proliferation

of T cells with low avidities for nuclear autoantigens. These cells are not deleted by central mechanisms in the thymus.

Persistent Nuclear Autoantigen Availability Because of Increased Numbers and Decreased Clearance of Apoptotic Cells

There is increased apoptosis of T cells, neutrophils, monocytes, and even endothelial cells in SLE patients (145 ,146 ,148 ,179 ,297 ,298 ,299 ,300 ,301 ,302). Activated cells are more susceptible than resting cells to the induction of apoptosis (303 ,304), and evidence has been reviewed earlier indicating increased numbers of activated T cells in patients with SLE. Lymphoblasts from patients with other inflammatory rheumatic diseases and infections are also more susceptible to apoptosis, but not to the same extent of SLE. Increased apoptosis in SLE may be related to disease activity (145 ,297 ,301). Apoptosis of lymphoblasts from lupus patients with high erythrocyte sedimentation rates and elevated levels of Th1 cytokines was especially pronounced (298). Others however, have reported increased apoptosis unrelated to disease activity (148).

Apoptotic cells are the principal source for the nuclear autoantigens that are immunogenic in SLE. These products are derived from chromatin and small nuclear ribonucleoproteins (snRNPs). As cells die many of these autoantigens are redistributed to the cytoplasm and accumulate in membrane blebs. Nucleosomes, which are complexes of DNA and histone proteins from chromatin, are the major products of apoptosis. In the early process of apoptosis, there is extranuclear accumulation of the nucleosomal histones H2A, H2B, H3, and H4 (305) elements which are immunogenic in SLE (306). Nucleosomal particles in the serum of SLE patients correlate with disease activity (307).

While apoptotic cells are normally cleared rapidly, this function is defective in SLE (308 ,309 ,310). Mononuclear phagocytes in SLE have decreased expression of Fc receptors II and III, and have a decreased capacity to clear IgG-sensitized erythrocytes (311). In SLE, monocytes that should be clearing apoptotic bodies are killed by autoreactive $CD4^+$ cells. These T cells express increased levels of pro-apoptotic ligands, tumor necrosis factor family proteins FasL, TWEAK, TRAIL (312).

Hyperactive Antigen-Presenting DC and B Cells in SLE

Apoptotic cells that are not cleared become necrotic, and when taken up by antigen-presenting cells in this inflammatory form, these cells become highly immunogenic. Activation of the innate immune system by apoptotic and necrotic cells and complexes of nucleic acids and IgG result in the production of large amount of IFN-α. Products of DNA and RNA released from apoptotic cells complex with lupus IgG and bind TLR and FcR receptors expressed by monocyte-derived plasmacytoid dendritic cells (313 ,314). The triggering of these receptors results in strong DC activation and the production of IFN-α and other cytokines. TLR9 dependent and independent mechanisms of activation have been reported (315). Immune complexes with other proteins were less effective in activating DC. Serum from lupus patients and IFN-γ isolated from lupus serum can induce monocytes to become autoreactive DC that express high levels of B7 and other costimulatory molecules (316). The splenic dendritic cells DCs from the lupus prone NZB/W F1 mice spontaneously stimulate nucleosome-specific T cells to a much greater degree than both DCs from normal mice (317).

In addition to their role as the precursors of antibody-forming cells, activated autoreactive B cells present cognate antigen to T cells (318). B cells have been postulated to break tolerance to ignorant or anergic T cells. Alternatively, they can further stimulate T cells that have been activated by dendritic cells (292). Interestingly, lupus-prone MRL/Faslpr mice deficient in CD80 or CD86 develop lupus similar to B7 sufficient mice (319).

Antigen Specificities of Autoreactive T Cells

Although SLE is characterized by anti-DNA antibodies, native mammalian DNA is a poor immunogen. Even purified denatured DNA that is complexed to an immunogenic carrier protein does not induce antibodies to native DNA (320). Bacterial DNA, however, differs from mammalian DNA in the frequency and methylation of CpG sequences (321). These CpG sequences have adjuvant effects that can alter and enhance the immogenicity of native DNA. Moreover, the apoptotic nucleosomes have abnormally methylated GC-rich regions (322). As stated above, CpG-dinucleotides that bind to intracellular TLR9 in DC would markedly enhance the antigen-presenting properties of these cells. In this manner, DNA-protein complexes can trigger pathogenic anti-DNA antibodies in SLE. DNA that is bound to histone or complexed to other proteins is, in fact, a common target of autoantibodies in SLE (322 ,323).

It is now evident that nucleosomes are a major immunogen for autoantibodies that cause lupus nephritis (306 ,324 ,325 ,326). Conformational epitopes on native chromatin and the (H2A-H2B)2-DNA subnucleosome induce specific antibodies, which then spread in a stepwise manner to include IgG antihistone and anti-native DNA antibodies (5 ,326), which may be complement fixing. Nucleosomes typically express cationic residues that bind to complementary-charged domains of TCR that are expressed by autoreactive T cells (327 ,328). Thus, the epitopes that T cells recognize are peptide fragments of the proteins that are complexed with DNA or histones in nucleosomes.

Five major auto-epitopes from the core histones of the nucleosome particle that stimulate autoreactive helper T cells in human SLE have been identified (306). $CD4^+$ T cells from lupus patients recognized peptides from histone regions H2B, H4, and H3. At least two peptides from the H2A and H4 were recurrently recognized by autoreactive T cells from different lupus patients (329). Since lupus T helper cells do not respond to free histones, the immunogenic peptides are generally not processed and presented by antigen-presenting cells. To identify these “cryptic” peptides, 154 candidate peptides spanning the

entire length of core histone were tested. The peptides that stimulate human helper cells overlapped with the major epitopes for the T helper cells that induce anti-DNA antibodies in lupus-prone mice (329). Another group also found that histone peptides could induce autoreactive Th clones (330).

Nonnucleosomal peptides can also stimulate the autoreactive lupus T cells that provide help for pathogenic anti-DNA antibodies. Peptides from a pathogenic anti-DNA antibody VH region also have this property. Immunization of NZB/W F1 mice with either of three specific VH peptides increased anti-DNA levels, accelerated nephritis, and decreased survival. T cells that are immunized with these peptides produced either a TH1 or TH2 profile of cytokines, but adoptive transfer of either of these T cells accelerated disease (331). These peptides stimulated autoreactive T cells to provide help for a variety of B cells displaying a cross-reactive version of the original immunogen, a form of determinant spreading. This reciprocal T-B cell stimulation spreads until large cohorts of T and B cells have expanded. Presumably, similar spreading occurs in human SLE.

Whether nucleosomal or peptides derived from the VH region of several murine anti-dsDNA antibodies are pathogenic or protective is determined by the route of immunization. It is now evident that both nucleosomal and VH region peptides are tolerogenic when administered intravenously. Strikingly, the protective effects are due to the generation of $CD4^+CD25^+$ and $CD8^+$ regulatory T cells. The mechanism of action of both $CD4^+$ and $CD8^+$ suppressor cells was dependent upon secreted or contact dependent TGF-ß (41 ,42). Thus, lupus-specific autoepitopes can accelerate or ameliorate disease.

As discussed, T cell recognition of and response to both foreign and self-antigens is determined by the class I and II MHC gene products of the host. T cell cytokine production and subsequent helper activity therefore is influenced by the expression of MHC alleles on antigen-presenting cells. For example, expression of HLA-DR3 is associated with decreased production of IL-1 and IL-2 (332); expression of HLA-DR2 and DQw1 correlates with elevated anti-dsDNA autoantibody titers, decreased production of TNF-α in vitro, and lupus nephritis (333); and expression of both HLA-DR3 and DQw2 correlates with detectable anti-Ro/SSA and anti-La/SSB antibodies (334 ,335).

Drugs also can induce lupus syndromes by causing DNA damage and releasing altered nucleosomes (203 ,327 ,329 ,336), in addition to inhibiting DNA methylation (94 ,95 ,96). Studies of apoptotic keratinocytes have revealed blebs containing nucleosomes and spliceosomes, which bear most of the predominant SLE autoantigens (336 ,337 ,338). These structures are subject to oxidative modification. Following phagocytosis and processing by antigen-presenting cells, the altered epitopes may be rendered strongly immunogenic for nontolerant $CD4^+$ T cells.

T Cell Lines and Clones

Unlike most peptide antigens, the nucleosomal epitopes do not obey the rule of MHC restriction. They can be presented and recognized in the context of diverse MHC alleles. As stated above, the immunogenic peptides and the lupus TCRs bear reciprocally charged residues which result in high-affinity interactions between the α chain of lupus TCRs and the APC. Approximately one half of cloned human lupus T helper cells responded to nucleosomal antigens that contained cationic residues (326). The CDR3 loops of TCR α chains contained a recurrent motif of anionic residues, whereas the TCR ß chains contained both anionic and cationic residues in their CDR3, suggesting that these pathogenic clones probably recognize autoantigens with epitopes of mixed charges (328).

Cytokines produced by autoreactive SLE T helper cell lines or clones stimulated with immunogenic histone peptides have been identified. Some peptides preferentially induced a strong Th1 (IFN-γ) response, while others favored Th2 (IL-10 and/or IL-4) production (329). Another group found most Th clones secreted IL-2, IFN-γ and IL-4, whereas others produced predominantly IL-2 and IFN-γ (330). This group also reported that the histone peptides could induce T cells from healthy subjects to become similar autoreactive clones.

Human T cell clones generated from the peripheral blood mononuclear cells (PBMCs) of patients with SLE or mixed connective tissue disease (MCTD) were found to react against uridine-rich, RNA-snRNP antigen. As with the histone peptides, these snRNP clones could be produced from MHC genotype-matched normal controls. These were oligoclonal $CD4^+$ memory cells (339). Further studies have revealed that these autoreactive T cells can provide help for autoantibody production (340). This group has also described immunogenic epitopes derived from the Smith antigen (341). A proliferative response to a ribosomal P fusion protein has been reported (342), notwithstanding the impaired response of SLE T cells to soluble antigens.

The Response of SLE T Cells to Antigen

SLE T Cells Have a Low Threshold for Activation

T cells with low avidity receptors for self-antigens are not deleted by the thymus and are present in the periphery. Their persistence throughout life suggests that they are continuously being stimulated by self antigens (343) but at subthreshold levels for activation. In normal animals, these low levels may be sufficient to induce them to become suppressor cells (344). In SLE, however, these cells are activated and become pathogenic.

There is evidence of polyclonal T cell activation in SLE. Increased numbers of activated T cells are present in both human and mouse models of SLE (168 ,345 ,346). One strain of lupus prone mice bear a genetic locus on chromosome 7 that contributes to a lower threshold of T cell activation and resistance to activation-induced cell death (347). Several inherent defects of T cell receptor signaling in SLE result in abnormal signaling (see below). Using TCR transgenic

animals, one group demonstrated that T cells derived from an SLE background proliferated faster and made more IL-2 in response to peptide than nonautoimmune controls (167). Finally, lupus T cells express higher levels of costimulatory CD40L than normal T cells (216 ,217 ,218 ,295). Thus, lupus mice develop an accelerated disease when stimulated by pathogenic peptides, whereas in normal mice autoantibodies appear only transiently (348).

Increased Resistance to Activation-Induced Cell Death

SLE T cells are resistant to activation-induced apoptosis, a homeostatic mechanism that should eliminate self-reactive T cells that may have been stimulated by cross-reactive antigens. One group repeatedly stimulated normal and SLE T cells, and after resting these cells attempted to induce them to undergo apoptosis. The lupus T cells, however, were resistant to activation-induced cell death. To explain this result, these workers reported decreased phophorylation of Cbl-b, an adapter protein that downregulates critical kinases in T cells signaling pathways that include Zap70, Lck, phospholipase 1, protein kinase C, and the p85 subunit of phosphatidlinositol 3-kinase (217 ,295). Cbl-b is an ubiquitin kinase that results in the proteosomal degradation of targeted proteins (349). Lupus T cells with impaired Cbl-b function are resistant to anergy because of persistent activation of the extracellular-regulated kinase (ERK) (295). In turn ERK may stabilize CD40L mRNA and result in hyperexpression of this costimulatory molecule. The result of decreased levels of Cbl-b would be sustained IL-2 production, a finding reported in both human and murine lupus. Others have described a mouse model of lupus with T cells that are resistant to anergy induction and increased levels of IL-2 (350). T cells from newly diagnosed, untreated lupus express increased levels of IL-2 mRNA (166).

Since certain strains of mice with defects in T cell expression of Fas or Fas Ligand develop an SLE-like disease, there has been a considerable interest in Fas expression in SLE. Fas-mediated cytotoxicity represents a major pathway leading to cell death (351 ,352 ,353 ,354) and is an important mechanism in peripheral tolerance. Mice that are homozygous for either lpr, a mutation in the fas gene (354) or for gld, a point mutation resulting in defective or absent Fas ligand expression, develop generalized lymphadenopathy in association with lupus-like features (355 ,356 ,357 ,358 ,359 ,360 ,361). These mice have impaired deletion of self-reactive B cells and expansion of autoreactive T cells (288). Conversely Medical Research Laboratory (MRL)-lpr/lpr mice that are transgenic for the intact fas gene under the control of a T cell–specific CD2 promoter and enhancer do not develop the lymphadenopathy, glomerulonephritis, or clinical autoimmunity that their nontransgenic littermates do (362). Although Fas expression is not decreased in human SLE and actually may be increased (363 ,364), the potential ramifications of the observations in murine lpr and gld mice for human disease have been highlighted by an association in humans between fas mutations and clinical autoimmunity and/or lymphadenopathy (365 ,366 ,367). Moreover, soluble Fas protein, which can inhibit apoptosis of stimulated cells under appropriate conditions, has been reported to be elevated in the serum of many patients with SLE (368 ,369), although this finding has been challenged (370 ,371).

T Cell Signaling Pathways in SLE

The molecular basis for T cell hyperactivity and their resistance to apoptosis is beginning to be understood (Table 9-5). In response to T cell receptor (TCR) stimulation intracellular calcium increases and there is phosphorylation of signaling proteins in the immunologic synapse. In SLE both of these events are enhanced and prolonged. This ultimately results in “rewiring” of the TCR with replacement of the TCR chain signaling molecule with Fc receptor chain. The result is a lower activation threshold for SLE T cells (372).

The increased calcium fluxes also contribute to the prolonged expression of CD40L on lupus T cells. As stated above, CD40L is a very potent costimulatory molecule only transiently expressed by normal T cells following activation. Persistent expression of CD40L, in turn, contributes to the resistance of lupus T cells to anergy induction. Antagonism of CD40L by a pharmacologic agent restores the ability of lupus to cells to become anergic (295).

In an attempt to explain anergy resistance in SLE, one group looked for differences in the phosphorylation of signaling proteins in anergic T cells. T cells become anergic following ligation of TCR without costimulation. This study

revealed that there was a lack of phosphorylation of cbl-b, a critical T cell silencer in SLE T cells. This was an especially important observation since a defect in this silencer could explain the exaggerated phosphorylation of adapter proteins in SLE and enhanced expression of the ERK signaling pathway, which should be shut down in anergic cells (295).

Table 9-5: Defects of Signal Transduction in SLE T Lymphocytes

Exaggerated increase in intracellular free calcium and increased phosphorylation of signaling proteins following T-cell receptor stimulation.
Decreased expression of CD3/T cell receptor ζ chain
Decreased expression of protein kinase C
Decreased activity of protein tyrosine phosphatase activity of CD45
Decreased protein kinase A type I and type II isoenzyme activity
Decreased levels of the p65-RelA subunit of the NF-κB nuclear transcription factor
Increased binding of the transcriptional inhibitor pCREM (cyclic AMP response element modifier) to the IL-2 promotor
Defective phosphorylation of Cbl, an adaptor protein that negatively regulates transmembrane-signaling; correlates with increased expression of CD40 ligand and resistance to tolerance induction
Reduced levels of the intracellular signaling protein, LCK in lipid rafts

Cyclic AMP, 3, 5 8-cyclic adenosine monophosphate.

Although some T cells in patients with active SLE are IL-2 producing cells, SLE T cells generally produce decreased levels of this cytokine following TCR stimulation. Progress has been made in understanding the molecular basis of this cytokine defect. Decreased transcription of the IL-2 gene is a result of decreased enhancer and increased repressor activity (296). The activity of nuclear factor-κ B a gene that has a central role in immune responses and inflammation is decreased in SLE (373). This transcription factor not only controls IL-2 production, but also many other cytokines and other immune response genes. Normally, IL-2 activity is downregulated by a transcriptional adaptor protein called CREM (cyclic AMP response element modifier) (374). CREM binds to the IL-2 promotor and suppresses its activity and expression of this adaptor protein is increased in SLE T cells (375).

The reasons for increased CREM expression in SLE are complex. CREM is regulated by $Ca2^{+}$calmodulin-dependent kinase, a protein found to be increased in the nucleus of SLE T cells. Although the increased TCR-mediated free intracytoplasmic $Ca2^{+}$ complexes observed in SLE can account for the increase in $Ca2^{+}$calmodulin-dependent kinase, this kinase by itself cannot account for increased CREM. Overexpression of $Ca2^{+}$calmodulin-dependent kinase in normal mice could not reproduce the effect (268). Protein kinase A (PKA), protein kinase C (PKC) and ERK also regulate CREM expression and defects of each of these kinases have been reported in SLE (152 ,376 ,377 ,378 ,379 ,380 ,381 ,382 ,383 ,384 ,385 ,386). Abnormalities of both type I (PKA-I) and type II (PKA-II) isozyme activities have been described in SLE (386 ,387 ,388).

Although genetically inherited traits probably account for some of the signaling abnormalities, it has become clear that the host response to chronic antigenic stimulation strongly contributes to the defects described in SLE. For example, stress related oxidants contribute to the downregulation of TCR ζ chain expression in SLE. Resting SLE T cells in the presence of anti-oxidants reversed this defect (389). Moreover, anti-TCR/CD3 autoantibodies in lupus serum have been reported to increase expression of CREM and increase the binding of CREM to the IL-2 promotor. Thus, anti-CD3/TCR antibodies present in SLE sera activate a kinase that facilitates the binding of a transcriptional repressor or to the IL-2 promoter (268). This finding is in agreement with previous studies that revealed that the inhibitory effects of lupus serum on T cells from SLE patients and healthy controls was more striking than intrinsic defects of lupus T cells (169 ,254 ,255).

Defective expression of the lymphocyte-specific protein kinase (LCK) is also associated with disease activity of SLE (390). LCK has a critical role in maintaining the resting state of T cells and for initiating the activation of signaling cascades. Again resting lupus T cells in vitro reversed defects in LCK expression and other alterations in lipid rafts where TCR signaling is taking place (391). This defect, therefore, can be attributed to uncontrolled, persistent T cell activation in SLE.

The Role of T Cells in the Initiation of SLE

Table 9-7 outlines a proposed sequence of events leading to the various SLE syndromes.

Genetic Factors

SLE results from the interaction of several genetic loci, which by themselves cannot induce clinical disease (392). In mice one or more loci have been described on 15 different chromosomes that affect T cell activation, differentiation and cell death. SLE 1 on chromosome 1 is associated with loss of tolerance to nuclear antigens. A recent study of SLE 1 mice illustrates many of the points discussed above. T cells from these mice have a decreased activation threshold and $CD4^{+}$ cells from these mice can provide help to antichromatin B cells. Moreover, levels of $CD4^{+}CD25^{+}$ regulatory cells decrease just prior to appearance of autoantibodies. This finding provides strong evidence that $CD4^{+}CD25^{+}$ cells have an important role in controlling autoimmunity. Although there is a loss of tolerance to nuclear antigens, SLE 1 $CD4^{+}$ cells had a limited ability to provide help for other autoantigens, and these mice do not develop lupus (393). Thus, genes localized to a single locus can have major effects on both T helper and regulatory cells, but cannot induce full blown disease.

SLE3 is a lupus susceptibility locus expressed on murine chromosome 7 (347). Congenic recombination has resulted in mice with antinuclear autoantibodies. DC and macrophages appeared to be more mature, more resistant to apoptosis, more pro-inflammatory, and better at costimulating T cells in vitro (394). These mice also do not develop lupus. However, mice that express both SLE1 and SLE3 develop full blown lupus, a result indicating the genetic interaction of these two loci. In human SLE, a genome wide scan has also revealed linkage with SLE susceptibility in at least nine chromosomal loci (395).

As stated earlier, $CD8^{+}$ lymphocytes in SLE have an impaired ability to become killer cells (220 ,221 ,224 ,225). Indeed, the CTL defect in SLE is independent both of disease activity and of immunosuppressive medications (221). Moreover, as discussed, in monozygotic twins who are discordant for SLE, the defect often is detectable in the clinically healthy co-twins (225), raising the possibility that the CTL defect in SLE may be inherited. These individuals may have an increased risk of developing SLE if they are exposed to one or more inciting environmental factors.

Inciting Factors

The ultraviolet radiation from sunlight can generate the autoantigens that precipitate SLE. UVA and UVB in sunlight induce keratinocytes to undergo apoptosis and necrosis,

and reactive oxygen species alter nucleosomal DNA, Ro, La, and snRNPs. These altered structures appear as blebs on the cell surface of apoptotic cells where they can serve as autoantigens (280 ,324 ,396 ,397 ,398). The chemokines produced by keratinocytes in response to UVB irradiation can attract interferonγ producing plasmacytoid dendritic cells to the skin and increased numbers of these antigen-presenting cells have been reported in the skin of patients with lupus. These cells in turn can recruit other autoimmune T cells and IFN-γ producing DC to the skin to amplify and perpetuate cutaneous lupus (398).

Activated cells are more susceptible than resting cells to the induction of apoptosis (303 ,304). Thus, because of apoptosis of various cells and decreased clearance of the fragmented nuclei, plasma nucleosome levels may be increased in SLE patients (325) and various epitopes are recognized by self-reactive T cells.

Infectious agents can act as the trigger factors to induce polyclonal B cell activation and autoimmunity. A compelling argument for microbial superantigens has been offered in triggering polyclonal T cell helper activity, which may result in SLE (399). Microbial superantigens, like anti-CD3 monoclonal antibodies, activate T cells via surface CD3/TCR. Certain bacteria such as staphylococci, streptococci, and mycoplasmas bear structures called superantigens that simultaneously bind to specific structures on the variable (V) region of the TCR chain and to the class II MHC molecules of antigen-presenting B cells. Therefore, these structures bring $CD4^+$ cells into close contact with B cells. Such bridging of T and B cells by microbial superantigens can induce polyclonal IgM and IgG formation. Moreover, specific autoantibodies may be produced if there also is concurrent crosslinking of the B cell receptor by autoantigen. In addition, it has been reported that superantigens and TLR ligands interact with each other. Superantigens synergize with LPS in an IFN-γ–dependent pathway and prime the innate immune system to a subsequent challenge with endotoxin (400).

This finding is another example of interactions between the innate and adaptive immune system. EBV infection has been considered to be important in the pathogenesis of SLE. A peptide from the latent viral protein EBV nuclear antigen (EBNA) 1 cross-reacts with a 60 kDA Ro epitope, an initial autoantigenic epitope for some patients positive for these antibodies. It has been proposed that humoral autoimmunity in human lupus arises through molecular mimicry between EBNA 1 and lupus autoantigens (401). As discussed above, lupus $CD8^+$ cells have an impaired ability to clear this virus (226).

Failure of Feedback Control Mechanisms

Disruption of normal immunologic homeostasis provides the opportunity for the activation of autoreactive T cells. Decreased clearance of apoptotic cells, the persistence of infectious agents, certain drugs, and the loss of regulatory T cells are examples of conditions that can lead to breakdown of immune tolerance. Here also genetic factors are important since the same immunogenic peptides that can trigger lupus in susceptible mice only cause transient autoimmunity in resistant strains (348).

T cells have multiple molecular feedback regulators of activation to control activation of autoreactive T cells. These include the negative regulatory cell surface molecules CD30 and PD-1 (402 ,403). Deletion of PD-1, a transmembrane protein containing an ITIM (immunoreceptor tyrosine-based motif) in normal mice results in a lupus-like syndrome (404). A regulatory genetic polymorphism in PDCD-1 is associated with increased susceptibility to human SLE (405). PD-1 is expressed by $CD4^+CD25^+$ regulatory cells (406). A deletion of the cell cycle regulator p21also leads to a lupus syndrome in normal female mice (407). In mice deletion of the genes that encode TGF-ß, CTLA-4 and FoxP3 result in a similar T cell driven fatal lymphoproliferative disease with multiple organ pathology shortly after birth (242 ,243 ,244).

In SLE, decreased macrophage phagocytosis (308 ,311 ,408), decreased levels of the chromatin-binding C-reactive protein (CRP), and decreased levels of the early complement components (409 ,410) result in persistent high concentrations of potentially pathogenic autoantigens. Treatment of NZB/W F1 mice with CRP decreases autoantibody formation and increases survival (411). As a result of decreased clearance of apoptotic debris, increased enriched guanine plus cytosine (GC)-containing DNA fragments are found in the sera of SLE patients. Moreover, abnormal DNA methylation of GC-rich regions in apoptotic nucleosomes further increases the immunogenicity of these autoantigens (322).

Drugs that Inhibit DNA Methylation of $CD4^+$ Cells can cause lupus-like Syndromes Procainamide and hydralazine are capable of converting anergic, autoreactive T cells to immunocompetent ones through this mechanism. T cells from patients with active lupus have hypomethylated DNA. Mouse T cells have been treated in vitro with drugs that modify DNA methylation and then injected into syngeneic female mice. These mice develop a lupus-like disease (203 ,336).

Breakdown of Peripheral Tolerance

The continuous presence of chromatin and snRNPs resulting from decreased clearance of apoptotic cells, paired with hyperactive T cells and antigen-presenting cells set the stage for a breakdown of T cell tolerance and generalized autoimmunity. Because B cells that are reactive to nuclear antigens are not fully deleted, these cells also are prime candidates for being antigen-presenting cells that contribute to the breakdown of self-tolerance. Considerable evidence has been accumulated indicating that B cells have an important, if not critical role, as antigen-presenting cells in autoimmune diseases, including SLE (292 ,412 ,413 ,414 ,415 ,416 ,417 ,418). Since B cells generally lack the costimulatory molecules to trigger T cell activation, presentation of chromatin autoantigens by self-reactive B cells should result in T cell anergy. Like plasmacytoid dendritic cells, however, B cells express TLR9 (418), which enable them to bind

unmethylated deoxycytosine-deoxyguanosine (CpG) motifs (419). In this manner they can be activated by CpG stimulation (420). Moreover, the combination of CpG and IFN-α produced by plasmacytoid DC have been reported to trigger polyclonal B cell expansion and B cell differentiation toward Ig-producing plasma cells without T cell help (421). These hyperactive SLE B cells, therefore, may have the capacity to induce autoreactive T cells to become fully responsive to self-antigens. This effect of the innate immune system is analogous to experimental graft-versus-host disease where donor activated $CD4^+$ cells provide the costimulatory signal than permits B cell activation and an autoantibody–mediated lupus-like disease (422 ,423 ,424).

Initially, the T cell response to nuclear autoantigens is probably controlled by $CD4^+$ and $CD8^+$ suppressor cells. In lupus-prone mice $CD4^+CD25^+$ cells decrease shortly before the antibodies appear (393). The numbers of these cells is also decreased in patients with SLE (251 ,252). Moreover, $CD8^+$ cells in SLE provide B cell help instead of inhibiting antibody production (121). They also inhibit IL-2 production, a cytokine required for the development of $CD4^+$ $CD25^+$ regulatory T cells (425 ,426). Dysfunctional $CD8^+$ cells in SLE, therefore, probably contribute to the pathogenesis of this disease (201 ,221 ,224 ,241).

Thus, a combination of genetic and environmental factors ultimately results in a loss of tolerance to certain nuclear and cytoplasmic antigens. The factors include persistent exposure of immune cells to pathogenic autoantigens, hyperactive antigen-presenting cells, self-reactive T cells with a low threshold of activation and an inadequate number of functional suppressor/regulatory T cells to interrupt this response. The autoantigen–specific T cells that emerge have the ability to provide B cell help for a panoply of autoantibodies. Although a single cryptic peptide presented by B cells may be the antigen that is recognized by T cells, the phenomenon of epitope spreading will broaden the response to include many nucleosomal antigens. Recruitment of other nontolerant self-reactive T cells will broaden the response even further and lead to generalized autoimmunity. Thus, pathogenic Th1 cells provide help for IFN-related IgG complement fixing dsDNA autoantibodies associated with nephritis and other autoantibodies that contribute to other lupus syndromes. It is important to note that a breakdown of immune tolerance, by itself, is probably insufficient to trigger clinical disease (393). Appropriate alleles of other susceptibility genes that regulate the inflammatory response to autoantibodies are also required for disease onset. While high titers of anti-dsDNA autoantibodies are generally associated with lupus nephritis, studies reporting a lack of correlation of autoantibodies and disease have also been reported (427 ,428).

T Cells in the Perpetuation of SLE

Genetically inherited elements that control T cell function, T cell abnormalities secondary to persistent activation, the cytokine milieu, certain autoantibodies, regulatory T cell defects, and the consequence of disease activity all contribute to the perpetuation of SLE. Polymorphisms of the negative regulators PD1 and CTLA-4 contribute to the perpetuation, as well as the initiation of SLE (405 ,429). Since most of the various T cell signaling defects listed do not change with disease activity (Tables 9-5 and 9-6), these probably reflect inherited traits (Table 9-7). Table 9-8 shows the correlations of T cell abnormalities that correlate with disease activity and could, therefore, contribute to the perpetuation of disease. The defects that do not correlate with disease activity are also indicated.

As stated earlier, the costimulatory element, CD40L is upregulated in SLE and persistent ligation of CD40 with CD40L may result in chronic T cell help for antibody and autoantibody production (125 ,215 ,216 ,217). The interaction between CD40 expressed by B cells and CD40L expressed by activated T cells is a critical signal for B cell differentiation (207 ,208). A brief treatment of lupus mice with a monoclonal antibody against CD40 ligand greatly decreased the onset of lupus nephritis (430). As stated above, hyperexpression of CD40L is associated with a defect in anergy induction (295). Interestingly, $CD8^+$ T suppressor cells directly inhibit the CD40 signaling pathway (280), and the activity of these cells is decreased in SLE.

Sustained, high levels of IL-10, discussed in the following chapter, directly sustain B cell proliferation and differentiation. This cytokine also contributes to enhanced T cell apoptosis in SLE (144). Moreover, IL-10 downregulates IL-2, TNF-α, and TGF-ß (36 ,280 ,281 ,282), cytokines that are needed for feedback regulation of B cell activity. TNF-α has a protective effect in lupus mice (431), and the treatment of rheumatoid arthritis with a monoclonal antibody that antagonizes TNF-α leads to the appearance of anti-DNA antibodies in approximately 10% of the patients (432).

As reviewed above, suppressor/regulatory T cell function is decreased in SLE and both IL-2 and TGF-ß induce $CD4^+$ and $CD8^+$ cells to develop this function (28 ,29 ,35 ,36). Insufficient levels of these cytokines probably contribute to decreased $CD4^+CD25^+$ cells in SLE and why $CD8^+$ cells support rather than suppress B cell activity in SLE (121). The transfer of T cells from young lupus-prone mice to older mice that had developed SLE reverses the disease (433). This is probably because cytokine production is intact in young mice and they have functional regulatory T cells (393).

Several autoantibodies contribute to impaired T cell function in SLE and perpetuate the disease. IgG anti-CD3/TCR antibodies trigger signaling pathways to lead to impaired IL-2 production (268). Anti-Brn autoantibodies correlate with increased expression of heat shock protein 90 in SLE (434). Besides their housekeeping and cytoprotective functions, heat shock proteins are now believed to regulate the immune response (435).

Finally, the effects of active disease can have negative effects on T cell function. For example, increased levels of interferon alpha correlate with disease activity (52 ,53). As stated above, this cytokine has negative effects on the number and proliferative ability of $CD4^+$ cells, negative effects on suppressor

activity, but has positive effects on the on the number of HLA-DR+ T cells and the antigen-presenting ability of DC. A correlation with disease activity, T cell function and inhibitory IgG has been reported previously (254). Table 9-6 shows the correlations with disease activity and abnormalities of T cell function.

Table 9-6: Relationship of T Cell and Related Defects to Clinical Activity of SLE

Correlation	No correlation
Elevated levels of the anti-apoptotic Brn-3 family members with autoantibodies to these molecules	Decreased threshold for T-cell activation
Serum levels of IFN-γ	Resistance to activation-induced apoptosis
Levels of antilymphocyte antibodies	Decreased clearance of apoptotic cells
Lymphopenia	Impaired response to mitogenic stimulation (Most studies)
Decreased CD4+ cells	Decreased production of IL-2 and active TGF-ß
Increased HLA-DR+ T cells	IgG antibodies to CD3/TCR
Non-responsiveness to skin test antigens	**T-cell signaling abnormalities**
Levels of soluble costimulatory molecules	Enhanced and prolonged rise in intracellular calcium following CD3/TCR stimulation
Decreased T-cell cytotoxicity	Increased intracellular phosphorylation of signaling adaptor proteins
Decreased CD8+ cell suppressive activity	Decreased phosphorylation of the signal silencer Cbl-b (correlates with increased expression of CD40 ligand and resistance to tolerance induction)
Decreased NK cell activity (Some groups)	Decreased expression of TCR ζ chains
Decreased antibody-dependent cytotoxicity	Increased binding of the transcriptional inhibitor pCREM to the IL-2 promotor
Activated CD8+ granzyme B and perforin positive cells	Decreased Protein Kinase C activity
Serum inhibition of T-cell proliferation	Decreased Protein Kinase A type I and type II isoenzyme activity
Decreased production of total TGF-ß	Decreased amounts of MAPK signaling proteins
Decreased Varicella Zoster-specific CD4+ cells	Decreased levels of p65-RelA subunit of the NF-κB nuclear transcription factor factor
Decreased Fc receptor expression by monocytes	
T-cell signaling abnormality	
Decreased LCK in lipid rafts	

Table 9-7: Initiation of Systemic Lupus Erythematosus

1. Genetic predisposition	Genes that decrease the activation threshold of T and B cells
	Genes that result in increased generation and decreased clearance of apoptotic cells, the source of pathogenic nucleosomal autoantigens.
	Genes that increase the production of IL-10, and decrease the production of TGF-ß.
	Genes that regulate the production of inhibitory receptors and T-cell signaling molecules
	Major histocompatibility complex class II susceptibility alleles (for autoantibodies)
	Resistance genes such as C1, C4, or C2 complement components that clear immune complexes
2. Triggering events	Female sex hormones
	The adjuvant effect of infectious agents that stimulate cells of the innate immune system to produce large amounts of interferon α and γ
	Sunlight injury that results in cell death and the release of immunogenic nucleosomal autoantigens.
	Drugs that decrease T-cell methylation of DNA and thereby enhance their activation by autoantigens can induce a lupus-like syndrome.
3. Breakdown of peripheral tolerance (nonresponsiveness)	Presentation of nucleosomal autoantigens by hyperactive antigen-presenting cells to naive autoreactive T cells that havea low activation threshold.
	Stimulation of naive autoreactive naive T cells and their transition to the activated or memory phenotype
4. Failure of fail-safe, feedback control mechanisms	Failure of a regulatory cell network consisting of CD4+, CD8+ and probably NKT cells to block the response of self-reactive T cells to autoantigens, to inhibit the migration of activated Tregs to inflammatory sites, and to prevent their effector functions.
	Failure of expression and/or function of receptors that inhibit T-cell responsiveness
5. Onset of clinical disease in genetically susceptible hosts	T-cell help to selfreactive B cells
	Pathogenic autoantibodies and immune complexes
	Systemic inflammatory disease

Table 9-8: Perpetuation of SLE

Continuous presence of immunogenic nucleosomal autoantigens
Continuous stimulation of clonally expanded, autoreactive T and B memory cells
Production of cytokines such as IL-10 that sustain B-cell activity and also inhibit T-cell function
Decreased production of IL-2 and TGF-β, the cytokines required for the generation of CD4+ and CD8+ regulatory
T cells needed to control antibody production.
IgG autoantibodies that perpetuate T-cell hyperactivity in SLE
Depressed cell-mediated immunity that enhances susceptibility to infections

A principal difference between human and mouse lupus is the regularity of remissions and exacerbations of the human disease in contrast to the progressive disease in mice. This finding suggests that feedback regulatory mechanisms persist in humans, but are not strong enough to induce remission. Long term improvement in SLE patients has been observed in patients that have received autologous stem cell transplantation (436) or rituximab therapy (437). There is now evidence that stem cell transplantation restores the regulatory T cell network. Thus the immune system can be reset in a manner that allows normal homeostatic mechanisms to be reestablished and autoimmunity can be controlled.

Chapter 10
Cytokines and Interferons in Lupus

Mary K. Crow

Kyriakos A. Kirou

Introduction

The immunopathology of systemic lupus erythematosus (SLE) has traditionally been attributed to the deposition in tissues and organs of immune complexes or autoantibodies with specificity for or crossreactivity with locally expressed antigens. These mechanisms are likely to account for an important component of the inflammation that generates tissue damage in this disease, but accumulating data suggest that additional mechanisms should be considered. The complement of soluble mediators, particularly cytokines and chemokines, that are produced in the context of innate and adaptive immune system activation in patients with lupus is likely to be a product of whatever endogenous and exogenous triggers are inducing autoimmunity, as well as the efforts of immune system cells to gain control over its activated components. These molecules may shape the character of the immune system dysfunction and organ system involvement. In SLE, given the heterogeneity of the disease, distinct cytokine pathways may operate in different patients and those pathways may, in part, determine the different organ systems affected. In addition, different cytokine pathways may be important at different stages of the disease. Understanding the balance of cytokines that are expressed in a given patient may ultimately guide medical management as new approaches to modulating cytokine pathways therapeutically become available.

Properties of Cytokines and Their Receptors

Cytokines are small soluble proteins that are produced by immune system cells and mediate activation or functional regulation of nearby cells by binding to cell surface receptors (1). Cytokines act in an autocrine or paracrine manner, in close proximity to their source, and have been considered to serve a similar function to neurotransmitters in the nervous system. Basal production of most cytokines is negligible, and activation of the producer cells, through nonspecific or antigen-specific receptors, results in either new gene transcription or translation of pre-existing cytokine mRNAs and protein secretion. Cytokine protein is typically not detected in serum from healthy individuals, but in patients with SLE, elevated levels of some cytokines are measurable and some vary with disease activity (Table 10-1).

The level of cell surface expression of the receptors to which cytokines bind is also highly regulated and contributes to the impact of the cytokine on immune system activity. Once the receptors are engaged, complex multi-component molecular pathways transduce a signal from cell surface to nucleus, resulting in new gene transcription. The Janus kinase (Jak)-signal transducer and activator of transcription (STAT) pathways are common mediators of cytokine-cytokine receptor interactions (2). The strength of these signaling pathways can be affected by the state of activation of the target cell and the additional signals that it has received, with the mitogen-activated protein (MAP) kinase and other signaling systems modulating the function of the Jak-STAT pathway. In addition, negative regulators of cytokine signals, such as the suppressors of cytokine signaling (SOCS) proteins, further modulate the strength of target cell response to the cytokine (3).

The degree of expression of individual cytokines or activation of their pathways is also regulated based on genetic differences among individuals that translate into variable efficiency in cytokine production or response (4). The extent of genetic polymorphisms that contribute to SLE has not been fully characterized. However, variable sequences in the promoter region of tumor necrosis factor (TNF) may contribute to other autoimmune diseases, including juvenile diabetes mellitus, and IL-6 polymorphisms have been associated with SLE (5 ,6 ,7 ,8). Genetic variability can be localized to regulatory regions of genes, potentially modifying the level of expression, or can be in coding sequences, sometimes resulting in an altered amino acid sequence and modified conformational structure. More complete study of the genetic variants that are associated with disease activity and clinical disease subsets is likely to provide new understanding of the basis of the immune system alterations that contribute to autoimmune disease and inflammation.

Assessment of Cytokine Production

The expression of cytokines and the capacity to produce cytokines in an individual can be assessed using numerous distinct and complementary approaches (9). The identification of genetic polymorphisms that modify expression or function of cytokine gene products, along with understanding the role of those cytokines in immunopathogenesis, may permit assignment of disease susceptibility to an individual.

Measurement of mRNA encoding a cytokine can be used to provide a reasonable indication of the amount of cytokine protein produced. However, the variable stability of one or another mRNA must be considered, and the presence of mRNA may not necessarily indicate that the mRNA is translated and the corresponding protein generated.

Table 10-1: Role of Cytokines and Interferons in Lupus Pathogenesis

Mediator	Role in Pathogenesis
Products of the Innate Immune Response	
Type I Interferon	Increased in active SLE
-IFN-α, IFN-β, IFN-ω	Mediates multiple immune system alterations, including dendritic cell maturation, immunoglobulin class switching, and induction of IL-10, interferon-γ, and other immunoregulatory molecules. IFN-α being targeted by new therapeutics in clinical trials.
Tumor Necrosis Factor	Role in SLE not clear.
Interleukin-1	Increased levels associated with active SLE.
Interleukin-10	Complex role in SLE.
Promotes B cell expansion and immunoglobulin class switching. Pro-B cell effects may dominant its anti-inflammatory effects.	
BLyS/BAFF	Increased levels in SLE.
Promotes B cell survival and may contribute to immunoglobulin class switching.	
Interleukin-6	Increased levels in active SLE.
Promotes terminal B cell differentiation. Being targeted by new therapeutics in clinical trials.	
Interleukin-12 and -18	Support expansion of Th1 cells and NK cells.
Interleukin-8, IP-10, MIG, MCP-1, fractalkine	Chemokines that may be increased in active SLE and may recruit inflammatory cells to sites of organ inflammation, particularly in lupus nephritis
Products of the Adaptive Immune Response	
Interleukin-2	Decreased production in SLE in in vitro studies. Mediates T cell proliferation and activation induced cell death.
Interferon-γ	Produced by Th1 cells and NK cells.
Implicated in lupus nephritis in murine models and human SLE.	
Interleukin-6 and -10	Produced by T and B lymphocytes, as well as monocytes.
TGFβ	Produced by multiple cell types.
Role in SLE not clear, but may contribute to T regulatory cell function and renal scarring.	

Direct measurement of protein, as by enzyme-linked immunoabsorbent assay (ELISA), is a fairly reliable indicator of the presence of that protein, but issues of protein degradation and variable detection, based on the antibodies used and the availability of their corresponding epitopes, suggest that confirmation of protein concentration using alternative approaches can be valuable. While ELISA determines quantity of protein per volume of fluid, usually serum or plasma, intracellular staining for cytokine protein and the enzyme-linked immunospot assay (ELISPOT) determine the percentage of cytokine-producing cells in a cell preparation and permit identification of those cells (10 ,11 ,12 ,13 ,14). The latter approach provides important information, as some of the pathogenic cytokines are products of multiple cell types. Knowing the major cell source can assist in development of therapeutic strategies to inhibit (or augment) production of the cytokine.

Because some cytokines may be short-lived, in some cases measurement of the activation of signaling molecules induced by a cytokine or expression of the target genes regulated by a cytokine may be a more sensitive measure than assay of the cytokine itself. For example, phosphorylation of components of the Jak-STAT pathway of signaling molecules can indicate recent binding of the relevant cytokine to its receptor (15). A more “downstream” target, gene transcription, can also be measured as a readout of recent cytokine activity. For example, recent use of micro-array technology has indicated that a set of genes regulated by interferons (IFNs), the first-described cytokine family, is activated in patients with SLE, based on increased relative expression of mRNA corresponding to those target genes (16 ,17 ,18 ,19 ,20). As any given gene target can usually be induced by multiple triggers, inhibition of gene expression with an antibody that neutralizes activity of a specific cytokine can

be used to demonstrate the relevance of that cytokine to the induction of the target mRNA (or protein) being measured.

Use of Microarray to Study Cytokine Effects

Micro-array analysis, a system in which thousands of oligonucleotide sequences are spotted on a solid substrate, usually a glass slide, and RNA-derived material from a cell population is hybridized to the gene array, is an innovative technology that permits a global view of the profile of genes expressed in a cell population at a point in time, including genes in the cytokine pathways (19). Applying micro-array analysis to heterogeneous cell populations in peripheral blood of patients with autoimmune diseases raises technical challenges. The variable proportions of different cell populations in each individual, each making variable contributions to the mRNAs in the blood sample, adds complexity to the comparison of study groups. Additionally, the statistical analysis of thousands of gene sequences studied in multiple individuals is daunting. Recent investigations have demonstrated that in spite of these technical challenges, significant and useful micro-array data can be derived from complex cell samples, including peripheral blood mononuclear cells stimulated in vitro and peripheral blood preparations from patients with autoimmune disease. The view that IFN-α might play a central pathogenic role in SLE has only recently gained momentum with the completion of several large-scale studies of gene expression profiling using micro-array technology (16 ,17). At least four groups have used this powerful technology to demonstrate that mRNAs encoded by IFN-regulated genes are among the most prominent observed in peripheral blood cells of lupus patients (Fig. 10-1) (16 ,17 ,18 ,19 ,20).

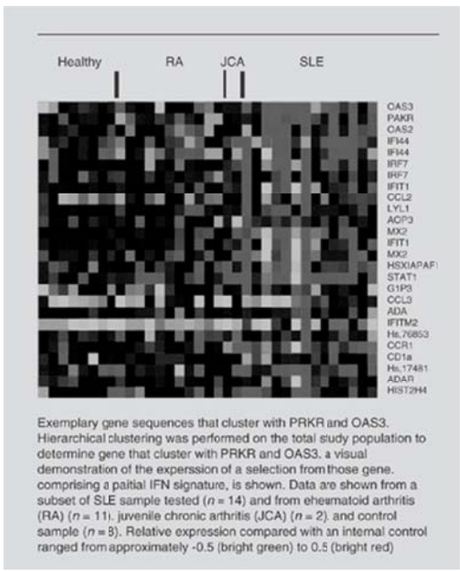

Figure 10-1. (See color plate.) Exemplary gene sequences that cluster with PRKR and OAS3. Hierarchical clustering was performed on the total study population to determine genes that cluster with PRKR and OAS3. A visual demonstration of the expression of a selection from those genes, comprising a partial IFN signature, is shown. Data are shown from a subset of SLE samples tested (n = 14) and from rheumatoid arthritis (RA) (n = 11), juvenile, chronic arthritis (JCA) (n = 2) and control samples (n = 8). Relative expression compared with an internal control ranged from approximately -0.5 (bright green) to 0.5 (bright red). (From Crow MK, Wohlgemuth J. Microarray analysis of gene expression in lupus. *Arthritis Res* Ther 2003:5: 279-287. Used with permission.)

It should be emphasized that microarray is a screen to identify genes potentially altered in expression in a cell preparation or disease state. Micro-array data should be confirmed using more quantitative techniques, such as real-time polymerase chain reaction (PCR), and data derived from patient samples should be confirmed in additional patient cohorts.

Activation of the Immune Response in SLE

The mechanisms that account for aberrant production of autoantibodies, cytokines, and other soluble mediators in SLE can be modeled in parallel to the production of antibodies and mediators in a productive immune response to microbial pathogens in a healthy individual. The initial encounter with the microbe is mediated by cells of the innate immune response. While those cells have traditionally been considered to initiate an immune response through nonspecific cell surface receptors, the recent elucidation of the Toll-like receptor (TLR) family has altered that picture (21 ,22). Although the innate immune response does not have the fine level of specificity that characterizes the adaptive immune response generated by T and B lymphocytes, the members of the TLR family do recognize classes of stimuli with characteristic structural features. Among the TLR ligands are nucleic acids, including hypomethylated CpG DNA and single-stranded or double-stranded RNA. These nuclei acids are typical components of viruses and bacteria but might also be a product of apoptotic or necrotic host cells. Whether microbe-derived in the setting of infection or self-derived, these oligonucleotides provide an adjuvant-like stimulus that can initiate a heightened level of immune system activity, including the production of cytokines.

It is the production of cytokines in the context of innate immune response activation that permits the activation and maturation of antigen-presenting cells (APC), such that T cells of the adaptive, highly specific, component of the immune response can become engaged. Whether the antigenic target is a viral or bacterial protein or a self-antigen

concentrated in the cell surface blebs of apoptotic cells, antigen-specific T cell receptors and T cell surface costimulatory molecules, such as CD28, interact with the antigenic peptide-major histocompatibility complex and the costimulatory ligand, CD80 or CD86, on the surface of an APC and stimulate biochemical signals, new gene transcription, and cell activation. The activated T cell is then able, through expression of new cell surface molecules that mediate cell-cell interactions with B cells and other target cells, along with production of cytokines, to drive the humoral immune response and activate effector cells. It is the nature of the cytokines produced by the APC, T cells and B cells that shape the quality of the adaptive immune response to a microbe. It is likely that parallel mechanisms account for the induction of immune responses to self-antigens, although genetic factors must be important in setting a threshold for lymphocyte activation that favors an immune response to stimulation by self-antigens in a lupus-susceptible individual. In both innate and adaptive immune responses to foreign and self-antigens, the antigens determine the specificity of the response but cytokines determine the quality of the response. The isotype of antibodies produced and the extent of amplification of an inflammatory response by chemokines and cells will be determined by the particular cytokines generated.

Cytokines of the Innate Immune Response

Cells of the innate immune system—macrophages, neutrophils, and dendritic cells (DC)—are among the first cells to encounter pathogens in the setting of infection and are likely to be early players in the lupus autoimmune response. In either case, the cells respond to their stimuli with production of soluble mediators, including cytokines. Recent studies support a contribution of signals through TLRs to the activation of the innate immune response in lupus (23 ,24 ,25 ,26). Among the documented triggers relevant to SLE are immune complexes containing DNA or RNA, along with specific antibodies (25 ,26 ,27). A consequence of TLR ligation is production of type I IFN, predominantly IFN-α, that then mediates numerous functional effects on immune system cells. Plasmacytoid dendritic cells, a rare cell type that is enriched in skin lesions of lupus patients, are presumed to be active producers of IFN-α (28 ,29 ,30 ,31 ,32 ,33 ,34 ,35). Interaction of IFN with widely expressed cell surface receptors activates intracellular signaling pathways and induction of transcription of a large number of IFN-responsive genes, including those associated with maturation of myeloid dendritic cells (36 ,37). The result is predicted to be increased antigen presenting cell function and augmented capacity to trigger self-reactive T cells (38).

In addition to plasmacytoid and myeloid dendritic cells, mononuclear phagocytes are essential for the inactivation of pathogenic infectious organisms and for the clearance of potentially pathogenic immune complexes and senescent or apoptotic cells. These cells are also important in SLE. Impaired clearance of apoptotic cells has been supported in some studies, and IFN-mediated maturation of monocytes into effective APCs has been shown in another study (38 ,39). Macrophages bind, process and present antigenic peptides to T cells; they physically interact with T cells, delivering secondary activation signals through cell surface adhesion and costimulatory molecules; and they secrete a panoply of soluble products, including TNF, IL-1, IL-6, IL-10, IL-12, and B-lymphocyte stimulator (BLyS), that provide important accessory and regulatory signals to both T and B cells. The role of these products of innate immune system cells will be highlighted, with a particular emphasis on the type I IFNs.

Type I Interferons (IFN)

Productive infection of host cells by a virus, leading to synthesis of RNA or DNA molecules of viral origin, induces production of host proteins, including the IFNs (40). The function of these proteins is to inhibit viral replication and to modulate the immune response to the virus, with the aim of controlling infection. The type I IFN locus on chromosome 9p21 comprises genes encoding 13 IFNα isoforms, as well as IFN-ß, IFN-ω, IFN-κ, and IFN-ε, the latter mostly restricted to trophoblast cells and produced early in pregnancy (41 ,42). The IFN-α gene complex is likely to have been generated by repeated gene duplications and recombinations. While the need for and function of each of the IFN-α genes is not clear, specific virus infections are associated with induction of one or another IFN-α isoform (43 ,44). Recent data from two groups have identified additional IFNs that are encoded by a gene family related to the classic type I IFNs (45 ,46). IFN-λs (IL-28 and IL-29) have only moderate sequence similarity to IFN-α, bind to a distinct receptor, yet induce genes similar to those induced by IFN-α. The relative functional roles of IFN-λ and the chromosome 9p-encoded IFNs are under study (47).

IFN-α can probably be produced by all leukocytes, but plasmacytoid dendritic cells (PDC) are the most active producers. Rapid progress in study of type I IFN regulation indicates that cell type (PDC vs. fibroblast), stimulus (dsRNA, single-stranded RNA, DNA), and signaling pathway used (TLR3 vs. TLR7/8 vs. TLR9) all contribute to determining the specific IFN isoforms that are produced (47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59). The TLR family of innate immune system receptors and their downstream signaling components play a central role in mediating activation of type I IFN gene transcription (Fig. 10-2). The details of these pathways are now being elucidated; TLR3 is triggered by dsRNA, TLR7 and 8 are triggered by ssRNA, and TLR9 is triggered by CpG DNA (21). TLRs 7, 8, and 9 signal through the MyD88 adaptor. IFN regulatory factors and additional transcription factors, including nuclear factor of kappa light polypeptide gene enhancer in B cells (NF-κB) and ATF-2, bind to and activate an IFN stimulated response element (ISRE) present in the IFN-α and IFN-ß gene promoters (49 ,50 ,51). Although the details of these complex pathways are being modified on a weekly basis, with new publications providing new insights into the complex regulation of the IFN

system, what is clear is that tracking the specific intracellular factors that mediate transcription of specific IFN isoforms can provide clues to the innate immune system receptors and the relevant triggers that drive production of those IFNs.

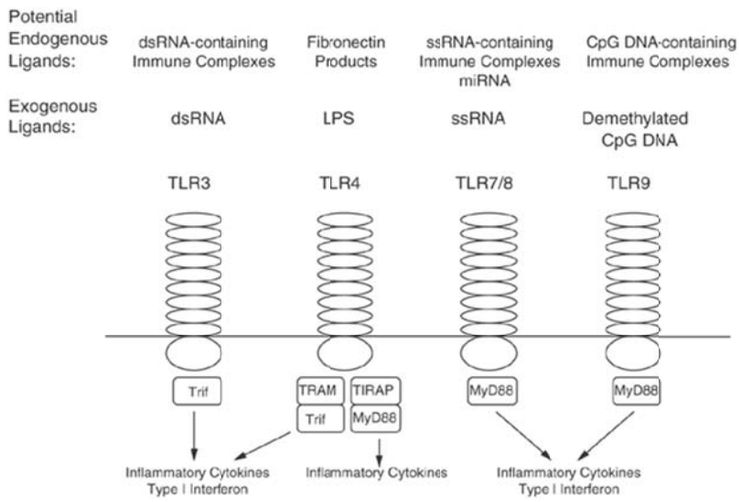

Figure 10-2. Induction of the type I interferon pathway through toll-like receptors. Both exogenous and endogenous stimuli can induce TLR activation, resulting in new gene transcription. Among potential endogenous ligands are immune complexes containing DNA or RNA or matrix-derived components. TLR ligands trigger activation of intracellular adaptors (including Trif, TIR domain-containing adapter inducing IFN-ß; TRAM, Trif-related adaptor molecule; TIRAP, TIR-domain-containing adapter protein; or MyD88, myeloid differentiation primary response protein 88) and induce transcription of type I interferons or inflammatory cytokines.

Type I IFN production represents the first line of defense in response to viral infection. Following invasion of the host by a virus, IFN-α is secreted by PDC, along with other immune system cells, and binds its receptor on many target cells, resulting in engagement of intracellular signaling molecules and induction of a gene transcription program (60). The IFNs were used as model cytokines when Darnell et al. defined the requirements for cytokine-mediated signal transduction (61 ,62 ,63). Binding of IFN-α to its cell surface receptor was shown to activate Jak1 and then STAT1. Subsequently, it was shown that Tyk-2, also a Jak kinase, is constitutively associated with the α subunit of the type I IFN receptor (IFNAR), while Jak-1 is associated with the ß subunit of the receptor. Cytokine binding leads to activation of Tyk-2 and Jak-1 and phosphorylation of the α receptor subunit and part of the ß subunit. Subsequent events include activation of STAT1, 2, and 3, the insulin receptor substrate proteins 1 and 2 (IRS-1 and IRS-2) and vav (64). STAT1-to-STAT1 and STAT1-to-STAT2 dimers bind to the pIRE element and ISGF3, including STAT1, STAT2, and a third protein, p48, binds the ISRE element (49 ,62). The Jak-STAT pathway seems to be sufficient to mediate the antiviral effect of IFN-α, while the IRS proteins, as well as other undefined factors, are also required for the antiproliferative effect of IFN-α (64).

Activation of the type I IFN pathway has diverse and numerous functional effects on immune system cells. IFN-α matures DC by inducing ICAM-1, CD86, MHC class I, and IL-12p70 expression, and promotes expression of some T cell activation molecules (65 ,66 ,67). However, IFNα has anti-proliferative effects on T cells, and it is generally described as a suppressor of T cell immune activity. IFN-α inhibits expression of some pro-inflammatory cytokines, including IL-8, IL-1, and GM-CSF, and it preferentially promotes Th1 responses, by decreasing IL-4 and increasing IFN-γ secretion (68 ,69). In the setting of coculture of monocytes with lipopolysaccharide (LPS) or CD4+ T cells with anti-CD3 and anti-CD28 monoclonal antibodies, IFNα augments IL-10 production (68 ,70). IFN-γ does not have these effects and in fact inhibits IL-10 production. Although IL-10 has important suppressive effects on T cell proliferative responses, its capacity to promote B cell proliferation and immunoglobulin class switching suggests that IFNα may favor antibody production (71 ,72 ,73 ,74 ,75 ,76 ,77). Finally, IFN-α leads to increased NK- and T cell–mediated cytotoxicity (78 ,79 ,80). This effect on CTL function has been exploited in the treatment of several malignancies with IFN-α in order to augment tumor lysis, although the mechanism that accounts for the increased killing has not been elucidated fully. At least one such mechanism is the induction of FasL expression on NK cells and increased Fas-mediated apoptosis (80). IFN-α can also promote an inflammatory response. Among IFN-α–inducible gene targets are several chemokines, soluble mediators that attract lymphocytes and inflammatory cells to

tissues. In brief summary, IFN-α helps to initiate an adaptive immune response that results in increased cytotoxic T- and NK-cell activity, increased Fas-mediated apoptosis, increased antibody production and inflammation but decreased T cell proliferation. Many of these immune system effects are reminiscent of those observed in patients with SLE (Fig. 10-3).

Several sets of compelling data suggest an important pathogenic role for IFNs in SLE. Papers published as early as 1979 described increased serum levels of IFN in patients with SLE, particularly those with active disease (81 ,82 ,83 ,84 ,85). At that time, the distinct type I and type II IFNs had not yet been documented, but within several years, IFN-α was cloned and it became clear that IFNα was present in particularly high levels in SLE blood. This IFN was said to be “acid-labile,” a characteristic that is still not fully understood but may relate to its glycosylation state (85 ,86 ,87). Soon after, it was observed that tubuloreticular-like structures in the renal endothelial cells of SLE patients and in murine lupus models were associated with IFN-α and that in vitro culture of cell line cells with IFN-α–induced similar intracellular structures (88). These observations suggested that IFN-α was not only increased in concentration in SLE blood but also that it might have a functional impact on cells and perhaps contribute to disease. Another key observation was first reported in 1990 and has been noted many times subsequently. Therapeutic administration of IFN-α to patients with viral infection or malignancy occasionally results in induction of typical lupus autoantibodies and, in some cases, clinical lupus (89 ,90 ,91 ,92 ,93). This demonstration of induction by IFN-α of SLE in some individuals indicated that given the appropriate genetic background and perhaps in the setting of concurrent stimuli, SLE could be induced by IFN-α. Twenty percent to 80% of patients treated with IFN-α have been noted to develop autoantibodies specific for thyroid or nuclear antigens, including anti-DNA autoantibodies (94). Clinically apparent disorders include autoimmune thyroiditis, inflammatory arthritis, and SLE. Hints regarding possible mechanisms of these IFN-α toxicities come from an animal model of autoimmune diabetes (95). Expression of IFN-α by pancreatic islets correlates with development of type I diabetes, and transgenic mice overexpressing IFN-α acquire diabetes. These mice develop autoreactive CD4 T cells that are Th1 and can kill islet cells. Blanco et al. recently showed that IFN-α is one component in lupus serum that can promote maturation of blood monocytes to have increased antigen-presenting activity (38). These data are consistent with the demonstration that IFN-α is one of several maturation factors for immature DC, permitting efficient antigen presenting function to T cells (96 ,97). Generation by IFN-α of an antigen-presenting cell functional phenotype competent for activation of autoantigen–specific T cells could be an important immune mechanism that incorporates many of these findings (98). Murine studies have supported a role for type I IFN in SLE. Both NZB lupus mice and B6/lpr mice deficient in the IFN-α/β receptor show significant improvement in some manifestations of autoimmunity as well as improvement in clinical disease (99 ,100).

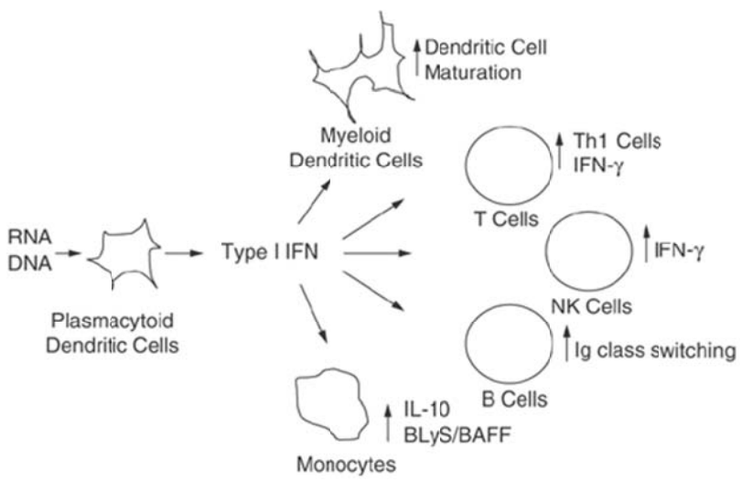

Figure 10-3. Regulation of the immune response by type I interferons. Activation of plasmacytoid dendritic cells through Toll-like receptors, perhaps triggered by endogenous DNA or RNA, results in production of type I interferon. Actions of type I interferon on the immune system include dendritic cell maturation; increased Th1 cytokine production, particularly IFN-γ; activation and IFN-γ production by NK cells; augmented immunoglobulin class switching by B cells; and increased IL-10 and BLyS/BAFF expression by monocytes. Many of these functions are among the features of the altered immune system that have been described in SLE.

In the early 1990s, the major cellular source of IFN-α had not yet been identified, but Ronnblom et al. were able to demonstrate that immune complexes containing lupus autoantibodies and cellular material could induce production of IFN-α by peripheral blood mononuclear cells in vitro (23 ,28 ,29 ,101 ,102). With the assignment of PDCs as the major source of IFN-α, lupus immune complexes were shown to be active inducers of IFN-α by those cells, while additional recent data implicate TLR9 and FcγRIIa in the induction of IFN-α by some of those complexes (27 ,30 ,31 ,32). A similar scenario has been demonstrated in a collaboration between the Marshak-Rothstein and Shlomchik laboratories in another system relevant to rheumatic diseases, the activation of rheumatoid factor producing B cells by DNA enriched in CpG immunostimulatory sequences opsonized with anti-DNA antibody (24 ,25). Means et al. recently reported similar data using lupus immune complexes (26). PDC appear to be somewhat reduced in the blood, but they have been demonstrated in the skin lesions of lupus patients (33 ,34 ,35). It is possible, or likely, that the IFN-α–producing cells have also been recruited to other sites of active disease, including lymph nodes and kidney. Monoclonal antibody to BDCA-2, a cell surface C-type lectin that may contribute to internalization of immune complexes, has been used to identify PDC (103).

Several previous reports documented increased expression of IFN-α–induced genes in SLE, including dsRNA-dependent protein kinase (PRKR) and oligoadenylate synthase (OAS), as well as Mx1, present in lupus-involved skin (104 ,105 ,106). Recently, microarray studies have reproducibly demonstrated that in SLE, IFN-induced genes are the most significantly overexpressed of all those assayed on the microarray (16 ,17 ,18 ,19 ,20). While these data could have initially been interpreted as

attributable to either type I IFN (IFN-α) or type II IFN (IFN-γ), recent experiments have used quantitative real-time PCR analysis of SLE PBMC to show that those genes that are increased in expression in SLE are those that are preferentially induced by IFN-α, not those induced by IFN-γ (107 ,108). With the description of the new type III IFN gene family (IFN-λ), its gene products can also be considered candidate inducers of the genes overexpressed in SLE. High expression of IFN-inducible genes is seen in approximately 40% of adult SLE patients. These patients are characterized by autoantibodies to RNA-binding proteins (Ro, La, Sm, and RNP) and frequent renal involvement (108).

Genetic contributions to variability among individuals in production and signaling of IFN have been suggested by a recent study. Data document an association of a single nucleotide polymorphism in one of the TLR pathway transcription factors, IRF5, with SLE in Swedish and Finnish populations (109). This observation draws attention to the pathway that utilizes IRF5, the TLR7 and 8 pathway, but also suggests that genomic variations in additional innate immune system pathways could potentially impact efficiency of induction of IFN production.

Given all of the described observations, there is strong support for the hypothesis that inhibition of the type I IFN pathway may benefit lupus patients, particularly those with increased expression of IFN-inducible genes. However, IFN pathway blockade might weaken the innate and adaptive immune responses to viral infection. Potential approaches to inhibit the type I IFN pathway could include antibodies specific for the IFN-α receptor or for one or more of the various IFN subtypes noted above. Other approaches might include inhibition of upstream (e.g. TLR pathways) or downstream (e.g., Jaks or STATs) signaling molecules (110). Humanized monoclonal antibodies to IFN-α are currently available and clinical studies are eagerly awaited (111).

Tumor Necrosis Factor

Tumor necrosis factor (TNF), the prototype member of the TNF family, is expressed as a trimer on the cell surface and in soluble form after activation of innate immune system cells, including macrophages and dendritic cells, through TLRs, Fc receptors, and receptors for other cytokines. Like type I IFN, TNF is produced early during immune responses to microbes and is particularly effective in promoting influx of inflammatory cells into sites of microbial invasion and in stimulating granuloma formation. The important role of TNF in controlling microbial infections is demonstrated by the reactivation of *Mycobacterium tuberculosis* that can occur in the setting of TNF blockade.

The role of TNF as a central upstream inducer of inflammation has been clearly shown in rheumatoid arthritis based on in vitro studies and on the impressive clinical response experienced by some patients treated with TNF inhibitors. The importance of TNF in lupus is still being debated. In murine lupus models it has been described as both protective and as harmful, depending on the mouse strain and stage in disease development (112 ,113 ,114 ,115). In SLE patients, data are variable, but at least some studies show high levels of TNF in sera and kidneys (116 ,117 ,118 ,119 ,120). The observation that anti-TNF agents can sometimes induce anti-dsDNA antibodies and occasionally clinical lupus raises interesting questions regarding the mechanisms by which reducing TNF might promote autoimmunity, as well as concern about treatment of SLE patients with TNF inhibitors (121 ,122). Nevertheless, an open-label safety study with infliximab has been carried out in SLE and documented efficacy with regard to arthritis and proteinuria in 6 patients (123). Urinary tract infections occurred in three patients of whom one had *Escherichia coli* bacteremia. Interestingly, anti-dsDNA and anticardiolipin titers increased transiently but without concomitant complement level depression or clinical flare.

A potential mechanistic relationship between TNF and type I IFN has been suggested with some experimental support (124). In some in vitro and in vivo settings, TNF can inhibit synthesis of type I IFN and vice versa (125). It is possible that when availability of TNF is reduced by anti-TNF agents, negative regulation of IFN production is abrogated, allowing increased activation of the type I IFN pathway and augmented immune system capacity to develop autoimmunity. Addition investigation will be required to address this hypothesis.

IL-1

IL-1 and its physiologic inhibitor IL-1 receptor antagonist (IL-1ra) are produced by monocytes and macrophages in the early stages of an immune response and are also demonstrated at local sites of inflammation. High serum IL-1 levels have been associated with active SLE and correlate with serum C-reactive protein levels (126). Interestingly, low serum IL-1ra levels correlated with renal flares of the lupus (126). Only limited clinical experience is available for therapy with recombinant IL-1ra in SLE. In one study of 3 patients, arthritic symptoms but not myositis improved (127). Moreover in another study of 4 SLE patients with arthritis, IL-1ra therapy resulted in improvement in all (128). However, two relapsed despite continued therapy. At this time, there is neither strong rational nor experimental support for a central role for IL-1 in SLE.

IL-10

IL-10, a pleiotropic cytokine produced by monocytes and lymphocytes, is considered to have anti-inflammatory effects in that it inhibits activation of APC, reduces expression of costimulatory molecules on their cell surface, thereby blunting T cell activation, and inhibits TNF production. However its functional effects are complex, since when it binds to activated monocytes, as may occur in autoimmune disease, IL-10 may not effectively generate intracellular signals. For example, in the presence of IFN-α, it can mediate pro-inflammatory effects on target monocytes (129). Additionally,

IL-10 augments B cell proliferation and immunoglobulin class switching, resulting in increased secretion of antibodies with the capacity to enter extravascular compartments and promote inflammation and disease in SLE (130).

Immune complexes, present at increased levels in many SLE patients, can stimulate production of IL-10 after binding to FcγRII (CD32) (131). Indeed, IL-10 levels are increased in the serum of active lupus patients (132 ,133). Disease activity in lupus has been shown to correlate with an elevated ratio of IL-10-secreting to IFN-γ–secreting cells (134). Increased IL-10 has also been associated with increased activation-induced apoptosis of SLE T cells, an effect reduced by anti-IL-10 antibodies (135). Increased burden of apoptotic cells could potentially contribute to increased load of self-antigens that are ultimately targeted by autoantibodies.

When considering the diverse activities of IL-10 in a host with an otherwise activated immune system, its overall effects may contribute to disease, based on its less efficacious inhibition of activated, compared with unstimulated, monocytes and its positive actions on B cells (130 ,131).

In animal models of lupus there is evidence that therapy with anti-IL-10 mAb (136 ,137), or IL-10 itself, might be beneficial (138). In humans, treatment of six SLE patients with a murine anti-IL-10 monoclonal antibody resulted in significant improvement in cutaneous lesions, joint symptoms, and SLEDAI, even 6 months after the 21-day therapy (139). Although this study showed benefit, additional studies with humanized reagents will be needed to assess the value of this therapy in SLE.

BLyS

B lymphocyte stimulator (BLyS; also called B cell-activating factor, BAFF) and a related molecule, a proliferation inducing ligand (APRIL), belong to the TNF ligand superfamily, and like TNF they can exist in a soluble trimeric form (140). These molecules are produced by myeloid lineage cells and act exclusively on B cells through several receptors, transmembrane activator and CAML interactor (TACI), BAFF receptor and less so through B cell maturation factor (BCMA), to induce B cell maturation and survival (140). BLyS supports survival of transitional and mature B cells and also supports immunoglobulin class switching to mature immunoglobulin isotypes, although with less activity than that provided by CD40 ligation (141). In mice, BLyS is overexpressed in NZB × NZW F1 and MRL/lpr lupus mice, and BlyS inhibition ameliorates disease (142). SLE patients express high levels of BLyS as well (143 ,144). In a recent phase II study, LymphoStat-B (or belimumab, a humanized monoclonal antibody to BLyS) was apparently well tolerated and showed clinical effect, although it did not meet the predetermined efficacy endpoints of the study (reported at: http://www.hgsi.com/news/press/05–10–05_LSB_Phase_2_Results.htm). The publication of this study is awaited to better assess the role of this agent in SLE management.

IL-6

IL-6 is a pleiotropic cytokine that is secreted mainly by monocytes, fibroblasts, endothelial cells and also by B cells and T cells. It is induced by inflammatory signals (such as LPS) and cytokines (such as TNF and IL-1), as well as by anti-dsDNA antibodies (145). Among the many properties of IL-6 is its ability to activate and mediate terminal differentiation of B cells to secrete immunoglobulin, as well as the induction of acute phase protein synthesis, including C-reactive protein (146). Interestingly, although IL-6 is primarily thought of as a pro-inflammatory cytokine, it can inhibit TNF and IL-1 synthesis. With regard to kidney function, IL-6 can induce mesangial cell proliferation.

IL-6 has been implicated in lupus, both in animal models and in human disease (146). Blockade of IL-6 ameliorates murine lupus and inhibits anti-dsDNA production (147 ,148). Moreover, IL-6 has been noted to be present at increased levels in SLE sera and has been associated with active disease in some but not all studies (149 ,150 ,151). Indeed in one large recent cross-sectional study IL-6 levels were associated only with hematologic disease activity (mainly reflected in an inverse correlation with hemoglobin levels) but not with any other organ disease activity as measured by the BILAG index (152). High levels of IL-6 have also been noted in the urine of active nephritis patients.

Inhibition of IL-6 by a humanized monoclonal antibody to IL-6 receptor (IL-6R) has been attempted in other autoimmune diseases, including rheumatoid arthritis and juvenile idiopathic arthritis, with good responses (153 ,154). The therapy was tolerated well, but significant hypercholesterolemia was noted in many patients, while one patient died of reactivation of chronic EBV infection. The antibody, called tocilizumab or MRA, binds soluble and membrane bound IL-6R, blocking its binding to IL-6 and thereby inhibiting IL-6–mediated signaling. Signaling by other IL-6-like cytokines, such as IL-11, is spared (155). In summary, there is some evidence that anti-IL-6 therapy could decrease anti-dsDNA levels and ameliorate disease activity, including renal disease, in SLE patients. An ongoing randomized controlled trial with MRA may provide additional data on these points.

Other Cytokines

In addition to the cytokine products of the innate immune response discussed above, IL-12, IL-18, and IL-8 have also been found to be high in sera of active SLE patients (156 ,157 ,158 ,159). Both IL-12 and IL-18 are produced by activated macrophages and can promote the differentiation of IFN-γ–secreting T cells and NK cells. Inhibition of IL-18 in MRL/lpr lupus mice reduced renal damage and mortality, suggesting that the cytokine plays a pathogenic role in that model (160). IL-8 is a chemokine with potent chemoattractant activity. IL-8, along with the chemokines IP-10, MIG, MCP-1, and fractalkine have been observed at high levels in SLE sera and are candidate markers of increased disease

activity (156 ,161). Although some of these may be attractive candidates to therapeutically target in patients with active end-organ disease, such as nephritis, there is as yet no significant clinical experience with inhibitors of those mediators in lupus patients.

Cytokines of the Adaptive Immune Response

SLE is characterized by production of autoantibodies, and abundant data indicate that those autoantibodies are both antigen-driven and depend on T cell help. The T cell–derived signals that drive B cell expansion and immunoglobulin class switching to produce the potentially pathogenic isotypes IgG and IgA comprise those delivered by cell contact, such as those mediated by the CD154 (CD40 ligand)/CD40 pathway, as well as signals delivered by T cell–derived cytokines (162). The degree of activation of T cells as well as the effector pathways to which T cell differentiation is directed depend on many factors, including the avidity of the interaction between antigenic peptide-major histocompatibility complex antigen and the T cell antigen receptor, the level of expression of costimulatory ligands and receptors on APC and T cells, and the cytokines produced by those APC. Inherent features of T cells, including structure and expression of cell surface molecules, intracytoplasmic T cell signaling pathways and transcription factors, show variability among individuals based on genetic polymorphisms. These differences can contribute to variable T cell function, including cytokine production. The nature of the cytokines produced by T cells has an important impact on the character of the B cell immune response, particularly with regard to selection of immunoglobulin isotypes, and on induction or control of inflammation, through effects on mononuclear phagocyte Fc receptor expression, phagocytic activity, and production of effector cytokines.

Cytokines Generated in the Adaptive Immune Response: T Cell–Derived Cytokines

The Th1/Th2 Paradigm

The concept that T lymphocytes differentiate along one of two possible vectors, termed T-helper-1 (Th1) and T-helper-2 (Th2), was presented by Mossman et al. (163). Each of these T cell types was characterized by production of distinct cytokines (IL-2 and IFN-γ for Th1 and IL-4,-5,-6,-9,-10, and -13 for Th2). Subsequent studies elucidated some of the determinants of differentiation along one or the other pathway, including cytokines to which T cells were exposed (IL-12 supporting Th1 and IL-4 supporting Th2 development) and transcription factors expressed in the T cell (T-box expressed in T cells, T-bet, in Th1 cells and GATA3 in Th2 cells) (164 ,165 ,166). The two T cell types have been generally associated with distinct functions, with Th1 cells viewed as promoting cell-mediated immunity and inflammation by supporting T cell expansion and monocyte activation, and Th2 cells considered to support humoral immunity, including immunoglobulin class switching to produce some IgG subclasses as well as IgE.

Although the classical Th1/Th2 paradigm might suggest that Th2 cytokines would predominate in SLE, as Th2 cytokines are thought to drive B cell differentiation and production of pathologically significant autoantibodies is a central feature of lupus, in fact the cytokine picture in SLE is complex (167). In murine lupus models, the IgG subclasses that make up a substantial proportion of the autoantibodies that are found in serum are IgG2a, a subclass supported by the Th1 cytokine IFN-γ (168). Moreover, IFN-γ deficient lupus mice are protected from nephritis, suggesting an important role for that cytokine in end-organ inflammation and tissue damage (169 ,170 ,171). On the other hand, IL-10, a product of Th2 cells, is elevated in SLE as discussed. Careful measurement of T cell, monocyte, and DC–derived cytokines, as well as definition of the cells that produce those cytokines, will be important for more complete characterization of the pathogenic mechanisms that contribute to disease in SLE and other autoimmune syndromes.

Interleukin-2

IL-2, a classic Th1 cytokine, is produced by T cells after activation through the T cell antigen receptor and the costimulatory molecule CD28. The regulation of IL-2 occurs through activation of signaling pathways and transcription factors that act on the IL-2 promoter to generate new gene transcription, but also involves modulation of the stability of IL-2 mRNA. IL-2 binds to a multi-chain receptor, including a highly regulated α chain and ß and γ chains that mediate signaling through the Jak-STAT pathway. IL-2 delivers activation, growth and differentiation signals to T cells, B cells, and NK cells. IL-2 is also important in mediating activation-induced cell death of T cells, a function that provides an essential mechanism for terminating immune responses. Perhaps because IL-2 was among the first cytokines to be studied in detail by immunologists investigating basic mechanisms of T cell and general immune function, the level of expression and functional role of IL-2 in the cellular alterations that characterize SLE were the focus of numerous studies over the past 25 years.

In general, the consistent observations were that IL-2 production by T cells stimulated in vitro was low in SLE (172 ,173 ,174). However, when studied in vivo, there are some reports of increased serum IL-2 protein, and IL-2 mRNA transcripts have been documented in unstimulated SLE peripheral blood cells (175). Regarding IL-2 receptors, in vitro studies have indicated impaired induction under conditions of cell activation, but serum levels of soluble IL-2 receptor are increased in patients with active disease (176). Taken together, the data are most consistent with in vivo activation of CD4 T cells in SLE, with the additional possible interpretation that chronic or repeated exposure of those cells to self-antigens

presented by mature APC in vivo alters their capacity to demonstrate normal activation responses when studied in vitro. At this time there is not strong support for therapeutically manipulating the IL-2 pathway in SLE.

Interferon-γ

IFN-γ is the sole type II IFN. Early in an immune response, IFN-γ is mainly generated by NK cells, and once the adaptive immune response is engaged, it is a major product of Th1 cells activated by APC that produce IL-12 or IL-18. IFN-γ implements a broad spectrum of effects on immune responses, including activation of monocytes, and when produced in excess can promote tissue injury (177). Among its activities are the induction of other pro-inflammatory cytokines such as TNF and induction of apoptosis in renal parenchymal cells. The relationship between IFN-α and IFN-γ is complex (178). IFNα inhibits the induction of IFN-γ by NK cells in the presence of STAT1. In contrast, in the absence of STAT1 IFN-α can stimulate production of IFN-γ by T cells. Like IFN-α, IFN-γ signals cell activation through STAT1 but can also utilize a poorly defined STAT1-independent pathway (179).

The role of IFN-γ in the pathogenesis of SLE has been best illustrated in studies of murine lupus. Experiments using IFN-γ–deficient mice have demonstrated a requirement for IFN-γ in development of significant nephritis and for expression of IgG2a anti-dsDNA antibodies in MRL/lpr and NZB × NZW F1 mice (168 ,169 ,170 ,180 ,181 ,182 ,183). However, in pristane-induced lupus, the pristane treatment was sufficient to induce some IgG2a anti-Sm/RNP autoantibody, even in the absence of IFNγ (184). Additional approaches supporting a requirement for IFN-γ for most manifestations of lupus include administration of anti-IFN-γ antibody, soluble IFN-γ receptor, and study of IFN-γ receptor deficient mice. Nephritis appears to be particularly dependent on IFN-γ (168 ,185). It is likely that the different murine models will show variable dependence on either type I or II IFN for development of autoimmunity and disease, perhaps based on their baseline relative expression of those cytokines. While murine studies support important roles for both type I and II IFN in lupus, support for IFN-γ in human lupus is less well documented. Gene expression studies of peripheral blood cells do not show increased levels of CXCL9 mRNA, a gene product that is highly induced by IFN-γ (107). However, IFN-γ may be more highly expressed in kidneys of patients with lupus nephritis and could play an important role in augmenting expression of chemokines that contribute to recruitment of inflammatory cells and tissue damage.

Th2 Cytokines in SLE

As described above, IL-6 and IL-10, typical Th2 cytokines, are increased in the serum of active lupus patients, but the production of those cytokines is more likely to be attributable to monocytes and B cells than to T cells (186 ,187). IL-4 and IL-5 are additional Th2 cytokines, but the role for these mediators in SLE is less well supported than for others discussed. Increased production of IL-4 has not been consistently demonstrated in SLE. A recent report suggests that Th2 cytokines may actually be protective from lupus nephritis (188).

TGF-ß

TGF-ß is a pleiotropic and multifunctional cytokine. While produced by many cell types, it is included among the Th2 cytokine family. TGF-ß is produced as a latent molecule that is then activated by plasmin-mediated cleavage and release of the biologically active fragment. When TGF-ß binds to its receptor, SMAD proteins translocate from cytoplasm to nucleus and promote generation of new mRNAs. TGF-ß plays an important role at each stage of an immune response and in the context of wound healing (189). Early in an immune response, TGF-ß promotes activation of innate immune system cells. Once an adaptive immune response is well underway, it inhibits activation and proliferation of T cells to provide regulation of cellular immunity. Finally, TGF-ß is a central mediator of tissue repair (190).

A role for TGF-ß in the inhibitory activity of Tregulatory cells (Tregs) has been recently investigated (189). Regulatory T cell function is now felt to reside in the CD4+CD25+ T cell population and is associated with production of TGF-ß and IL-10, as well as expression of a transcription factor, FOXP3 (190 ,191 ,192). TGF-ß also appears to contribute to induction of Tregs from precursor T cells.

As is the case for other T cell-derived cytokines, interpretation of data addressing the expression and function of TGF-ß in SLE is challenging, particularly in view of the fact that most of the cytokine present in serum is present in the latent form. Most data indicate that production of TGF-ß in peripheral blood cells is decreased in SLE which would be consistent with impaired regulation of T cell activation (193). However, TGF-ß may be expressed at sites of inflammation, such as the lupus kidney, and potentially contribute to renal scarring (194). Intracellular pathways activated by TGF-ß are well known to target genes, such as those encoding collagen and fibronectin, that are implicated in tissue fibrosis.

Additional T Cell–Derived Cytokines

IL-16 is produced by CD8 T cells and mediates chemotaxis of CD4 T cells and monocytes. IL-16 serum levels are increased in patients with severe disease and the serum levels showed correlation with measures of disease activity (195 ,196).

Cytokines Generated in the Adaptive Immune Response: B Cell–Derived Cytokines

B lymphocyte function in SLE is most simply characterized as hyperactive. A high proportion of peripheral blood B cells are activated by morphologic criteria. SLE B cells in vitro proliferate and differentiate to antibody-secreting cells spontaneously, without the addition of traditional mitogens (197).

The spectrum of B cells that secrete antibody in patients with SLE represents a polyclonal assortment, but characteristic of SLE is the selective and high-level secretion of a restricted population of autoantibody specificities including those reactive with nucleic acids and nucleic acid-associated proteins.

Studies of B lymphocytes have focused on their exclusive role in generating antibody-producing plasma cells, with some additional emphasis on the capacity of activated B cells to effectively present antigen to T cells. Current thinking has expanded the function of B cells to include production of soluble mediators, including cytokines. Most of the products of B cells are not exclusive to those cells, but are also expressed by monocytes and T cells. Among those, IL-6 and IL-10 have been discussed. As noted, these cytokines have been demonstrated to be expressed at high levels in patients with active SLE, and both contribute to B cell expansion and differentiation. While it is likely that multiple cell types produce these cytokines in lupus, activated B cells may be particularly active in this function.

Summary

The scope of immune system alterations in SLE is so extensive that it has been difficult for investigators to determine which of those altered functions is a primary contributor to lupus pathogenesis. The recent resurgence of interest in the type I IFN system and documentation of a prominent and broad activation of the IFN pathway in cells of lupus patients, along with rapid progress in the elucidation of the TLR system, has helped to reformulate the view of lupus pathogenesis to include an important role for innate immune system activation, by either exogenous or endogenous adjuvant-like triggers, in generating type I IFN and many of its downstream effects on immune function (110). As in immune responses to microbes, the adaptive immune system is engaged subsequent to activation of the innate immune system, but in SLE it is focused on self-antigens. Activation of T and B lymphocytes results in production of a diverse complement of cytokines, along with autoantibodies, that contribute to the character of the disease. IFN-γ produced by T cells and NK cells is a potent inducer of chemokines that attract inflammatory cells to involved tissues and organs. BLyS/BAFF, IL-6 and IL-10 are products of the innate immune response but promote survival and differentiation of B cells, amplifying their production of pathogenic autoantibodies. Each of these cytokines represents a rational therapeutic target. With some good fortune, we can look forward to the opportunity to evaluate data from clinical studies of potentially therapeutic cytokine inhibitors, allowing new insights into lupus pathogenesis and new hope for patients.

Chapter 11

B Cells in Systemic Lupus Erythematosus

Stamatis-Nick C. Liossis

George C. Tsokos

The hallmark of immune cell dysregulation in systemic lupus erythematosus (SLE) is B cell overactivity. B lymphocytes in SLE produce a spectrum of autoantibodies (autoAb) against soluble and cellular constituents. Although all cellular constituents represent potential targets of the lupus autoAb response, the most characteristic, as well as the most common autoAb in SLE, are those targeting the macromolecular complexes of the cell nucleus, the antinuclear antibodies (ANA). While the spectrum of autoAb specificity in SLE may seem unrestricted, it is only a handful of those that have been shown to contribute convincingly to disease-related tissue injury. The latter are best represented by the anti-blood cell antibodies that activate complement and cause cytopenias and the cationic anti-dsDNA autoAb that are thought to contribute to the expression of nephritis (1 ,2). The presence of some autoAb correlates with clinical subsets of the disease and is used in disease diagnosis. Besides patients with SLE and patients with a variety of autoimmune and nonautoimmune diseases, normal individuals have autoAb in their sera albeit transiently and in low concentrations (3). In this chapter we will review pertinent human data and we will refer to and integrate useful information produced from the study of B cells in different murine lupus models.

Autoreactive B Cells

Older theories portrayed the view that normally autoreactive B cells do not exist because their presence would provoke overt autoimmunity and they are, therefore, eliminated during the maturation process. Nevertheless, it is currently well established that such B cells do exist in the normal person. Moreover, while the naturally autoreactive B cell pool was initially thought to be rather small, novel studies have presented evidence that this is an underestimation. B cells often respond to autoantigens for which they have such small affinities that cannot be detected with the use of older, conventional assays (4).

Under normal conditions or in disease states ranging from viral infections to malignancy, normal, autoreactive B cells produce a variety of natural autoAb that do not cause autoimmune disease or tissue damage. Natural autoAb usually belong to the IgM isotype, and do not undergo isotype switching and affinity maturation. They are poly- and cross-reactive with auto- and alloantigens, their appearance may be helpful for the host in order to efficiently eliminate an invader, and finally, natural autoAb usually appear in the circulation for a short time because of tight regulatory mechanisms imposed on their existence. Natural antibodies are also expected to “dispose” dying or dead cells, but when tissues are exposed to stressors such as ischemia, then they may bind to newly revealed antigens, activate complement, and confer extensive tissue damage. The nature of the antigen(s) natural antibodies bind may represent proteins or phospholipids (5 ,6 ,7 ,8). The above characteristics contrast with those of the autoAb response in SLE where isotype switching and affinity maturation occur, their presence is not helpful for the host since they can cause tissue damage, their production is continuous and their presence is long-lived, indicating that regulatory mechanisms governing their appearance and/or elimination are profoundly defective.

Autoreactive antibodies arise from autoreactive B cells, but the mechanisms involved in the preservation of autoreactive B cells are unclear. One view favors that immature B cells having autoreactive potential are eliminated by negative selection so the mature B cell population contains a few, or, no autoreactive cells. Escaping the negative selection process may thus represent a mechanism of nonelimination of immature autoreactive B cells. The generation of the hen-egg lysozyme (HEL) transgenic mouse model improved our understanding on the preservation of autoreactive B cells and the appearance of autoimmunity. Data derived from the study of this model indicate that all B cells inherently exhibit a certain level of autoreactivity. Thus, it may be dangerous for the host to eliminate too many developing immature B cells that bear autoimmune potential because it may restrict severely the spectrum of the normal immune response repertoire. It may be equally dangerous to eliminate too few, because this may cause overt autoimmunity. Such a dynamic equilibrium between immunity and autoimmunity is maintained at the stage of the pre-immune B cell and is driven by specific selection processes. These selection functions include the strength of B cell antigen receptor (BCR)-generated intracellular signals (the stronger the BCR-initiated signal, the more likely the rapid elimination of the preimmune B cell) and the interclonal competition. In the presence of a normal B cell repertoire, the autoantigen weakly-binding B cells cannot compete for entry into the follicles of the lymph nodes and spleen in

order to receive cell-survival signals. The nonautoimmune B cells are arithmetically superior and they enter and occupy the follicles rather easily. The follicle-excluded B cells deprived of important survival signals die. When the B cell repertoire becomes compromised, the autoantigen–binding B cells face less competition, so they eventually enter the follicles, receive survival signals and become long-lived cells (9 ,10 ,11 ,12 ,13 ,14). The increased occurrence of autoimmunity in conditions of immunodeficiency is in agreement with this theory (15 ,16). Further supporting the above are data produced in high- and low-affinity anti-Sm autoAb producing transgenic mice. High-affinity anti-Sm producing B cells enter lymphoid follicles and differentiate appropriately into B1 cells, while low-affinity anti-Sm producing B cells still enter the follicles but become partly anergic long-lived B2 cells (17).

Circulating B cells in patients with SLE are not present in increased numbers, have increased rates of proliferation, and spontaneously secrete increased amounts of immunoglobulin consisting of natural antibodies, natural autoantibodies and autoantibodies reactive with nuclear, cytoplasmic, and cell-membrane self antigens (18 ,19). The number of B cells spontaneously releasing immunoglobulin correlates rather accurately with disease activity (20 ,21). Significantly increased telomerase activity, an indication of increased activation and proliferation, is also found in B, but not in T cells, from patients with SLE (22).

If we consider that detection of autoAb indicates the presence of autoreactive B cells, it is currently understood that such cells exist in patients with SLE several years before the development of clinically evident disease. A recent study conducted using serum samples obtained from previously healthy individuals that subsequently developed SLE (*n* = 130) disclosed that autoAb were present in 115 (88%) of them as early as 9.4 years (mean: 3.3 years) before diagnosis was made. AutoAb were present in 3.8% of sera obtained from healthy control individuals. It is of interest to note that autoAb were present in the first available serum samples obtained from many patients suggesting that autoreactive B cells were present and functional even earlier (23).

Autoreactive B cells in SLE arise early in B cell ontogeny, and a significant number of antigen-inexperienced naïve B cells are capable of producing autoAb. As shown from the exhaustive analysis of different early B cell subpopulations in three patients with juvenile-onset SLE the two discrete tolerance checkpoints imposed during B cell ontogeny are violated although to a different degree in different patients. The first checkpoint is at the immature B cell stage in the bone marrow where the majority of polyreactive and ANAs are lost. The second checkpoint is in the periphery before maturation of new emigrant B cells into naive immunocompetent lymphocytes. Single B cell analysis in the B cell compartment newly emigrated from the bone marrow and in the mature naïve B cell compartment disclosed that the two tolerance checkpoints in patients with SLE are compromised. Twenty five percent to 50% of the mature naïve B cell compartment is autoreactive in this limited number of patients with SLE before they encounter autoantigen(s) while in healthy individuals 5% to 20% of such B cells are capable of producing self-reactive autoAb (24). The differential development and fate of specific autoreactive B cells in patients with SLE and healthy individuals was addressed in another study. B cells producing natural autoAb bearing the VH4.34 heavy chain were followed from immaturity to terminal development into plasma cells. In healthy donors the naïve VH4.34 B cells are numerous and follow a sequence of specific steps of positive and negative selection into secondary lymphoid organs. Negative selection forces in the normal host predominate in such a manner that progression into terminal stages of differentiation is efficiently blocked resulting in underrepresentation of VH4.34 B cells in the memory B cell pool. This block can be violated ex vivo following culture with IL-2, IL-10 and CD70 in the normal host; in patients with lupus this ex vivo step was not necessary since VH4.34 B cells readily progress in vivo to the final plasma-cell stage. It is therefore suggested that tolerance checkpoints in SLE are malfunctioning (25). Despite the striking B cell overactivity challenging SLE patients with standard immunizations or stimulating lupus peripheral B cells with polyclonal activators in vitro can result paradoxically in substantially decreased amounts of specific Ab production compared to the responses of B cells obtained from normal individuals (26 ,27).

B Cell Subpopulations

B-1 cells are phenotypically distinguished from the conventional B cells (B-2 cells) because they bear the T cell surface marker CD5 in humans (Ly-1 in mice). B-1 cells, the majority of B cells during fetal life, predominate in cavities such as the peritoneum; nevertheless, their numbers in the circulation progressively decrease following birth until they become no more than 20% of the circulating B cell pool in the adult. B-1 cells have interesting and distinct properties because they are self-reconstituting and long-lived and because they produce highly cross-reactive and low-affinity antibodies that usually belong to the IgM class (28 ,29).

B-1 cells may be involved in the pathophysiology of some human and murine autoimmune diseases such as Sjögren syndrome and rheumatoid arthritis because they produce IgM rheumatoid factor (30 ,31). Moreover, B-1 cells are expanded in certain murine lupus-prone models where they contribute significantly to the production of important autoAb. While this may be the case for autoimmunity models such as the NZB, the (NZB × NZW) F1 and the motheaten mouse where B-1 cells produce anti-erythrocyte and anti-DNA antibodies, it is not the case for other experimental animal lupus models (29 ,32 ,33). In other murine lupus models B-1 cells are not expanded in the circulation, and their induced expansion in nonautoimmune backgrounds does not correlate with autoimmunity (32 ,34). The potential pathogenic role of B-1 cells in human lupus is questionable principally because in patients with SLE both B-1 and

B-2 cells contribute to the production of pathogenic autoAb such as anti-dsDNA (35).

A detailed analysis of circulating B cells in patients with SLE disclosed that there are major disturbances in the different peripheral B cell compartments. A recently described B cell subpopulation representing immature transitional B cells (generated in the bone marrow but not having undergone final maturation steps in peripheral lymphoid organs) named type I transitional (T1) B cells were reportedly increased in the circulation in patients with SLE (36). In patients with active but not in those with inactive SLE there was a marked reduction in the numbers of naïve ($CD19^+CD27^-$) B cells and an enhanced representation of the $CD27^{high}CD38^+CD19^{dim}sIg^{low}CD20^-CD138^+$ plasma cells in the periphery (37). A naïve B cell–specific glycoform of the surface molecule CD45 was recently shown to be the target of IgG VH4.34 autoAb produced by the VH4.34 B cell subpopulation, which is greatly expanded in SLE patients. This CD45 glycoprotein in memory B cells has a different glycosylation pattern from that of naïve B cells and does not bind VH4.34 autoAb (38). Immunosuppressive therapy, commonly used in lupus patients, induces changes in the different B cell subsets: it reduces significantly the numbers of $CD27^{high}$ plasma cells and of $CD27^-$ naïve B cells but does not affect the population of $CD27^+$ B cells (37). In one study, increased numbers of CD27 high plasma cells correlated with increased disease activity more accurately than a combination of clinical and serologic parameters, suggesting that this may be of value in monitoring disease activity (39). In another study of pediatric patients with SLE it was found that both naïve and memory peripheral B cells were reduced by 90% and that plasma-cell precursors were expanded threefold. The predominant B cell subpopulation in such young patients with SLE was a novel B cell subset with pregerminal center phenotype. These B cell subset alterations were independent of disease activity (40).

The Abnormal Immunoregulatory Environment

The features of the autoAb (isotype switching and affinity maturation) indicate that the lupus autoAb response is a T cell dependent, (auto)antigen-driven immune process. But is the T cell compartment responsible for B cell hyperreactivity? If this is correct then B cells should be under either decreased T cell–mediated suppression or under excessive, unopposed T cell–derived help or both. In the past it was considered that autoreactive B cells in SLE are not properly controlled by suppressor T cells (41 ,42 ,43). There is evidence supporting the opinion that increased T cell help is responsible for the increased production of antibody and autoAb in SLE. Apart from $CD4^+$ helper T cells, other T cell subpopulations can provide help to SLE B cells to produce pathogenic autoAb such as $CD8^+$, or $CD3^+CD4^-CD8^-$-TCRαß + or $CD3^+CD4^-CD8^-$-TCRγδ+ cells (44 ,45 ,46). Increased, nonspecific help to autoreactive B cells can also lead to autoimmunity. When anti-dsDNA heavy chain transgenic B cells were generated in a nonautoimmune background and alloreactive T cell help was provided in the setting of chronic graft-versus-host disease, such transgenic B cells were specifically expanded (70%) and secreted high titers of anti-dsDNA autoAb. Analysis of these autoAb disclosed that they had undergone receptor editing evidenced by the detection of light-chain rearrangements (47).

The recent interest in the role of T regulatory cells in the development of autoimmune diseases (48) has rekindled interest in the role of these cells in the pathogenesis of human SLE. Indeed, a study showed decreased numbers of T regulatory cells in the peripheral blood on SLE patients (49) but it has not been shown yet whether they control B cell function also.

The above studies conclude that B cell overactivity and the production of autoAb are a result of factors exogenous to the B cell and lie within the T cell compartment. While the previously mentioned data clearly document the contribution of the T cell compartment to the production of autoAb, there are functional as well as genetic studies challenging the view of an entirely T cell–dependent process. Studies of murine and human lupus have produced direct or indirect evidence that B cells in SLE are not innocent bystanders but that their contribution to disease initiation and perpetuation may be central.

The Intrinsically Abnormal B Cells in SLE: Functional Studies

A number of studies have concluded that the B cell in lupus may contribute in a T cell independent manner to the production of autoAb. These studies cumulatively have shown that:

- The immunologic tolerance of B cells can be violated rather easily in vitro under conditions that could be readily reproduced in vivo (50). B cell tolerance can be broken during viral infections, during immunizations, and upon stimulation with polyclonal activators (51 ,52 ,53 ,54 ,55 ,56). Polyclonally triggered B cells are found in the circulation of patients with SLE and Sjögren syndrome (57 ,58). Additionally, chronic polyclonal B cell stimulation may lead to autoimmunity in mice (59). Nevertheless, polyclonal activation is not the principal cause for the production of autoAb (60). Bretscher and Cohn have proposed the two-signal hypothesis suggesting that contact with (self) antigen in the absence of T cell–derived help tolerizes B cells (61). Initial B cell contact with a self antigen and T cell–derived help at the same time results in B cell tolerance breakdown (62 ,63). Nevertheless, experimental data support that this rule can be violated, and B cell tolerance can be broken without the support of T cell–mediated help (64).
- Lupus-prone murine strains genetically manipulated to have no T cell antigen receptor (TCR)$αß^+$ (and no $CD4^+$) T cells were still able to produce significant amounts of pathogenic IgG autoantibodies (65).

MRL/lpr mice congenitally deficient in TCRαß T cells develop autoimmunity characterized by hypergammaglobulinemia, autoAb to native DNA and to small nuclear ribonucleoproteins and also manifest immune-complex mediated nephritis (66).

- Finally when pre-B cells obtained from the embryonic liver of (NZB × NZW) F1 mice were transferred to mice with severe combined immunodeficiency (SCID), they were able to produce anti-dsDNA autoAb and to sustain a lupus-like disease in the SCID recipients (67). These data are in contrast with previous studies reporting that the transfer of autoreactive B cells into nonautoimmune animals caused the production of relatively small amounts of autoAb (68). In contrast, transfer of normal B cells into autoimmunity-prone recipients was associated with autoantibody production within a month from the transfer (69 ,70).

The former studies underscore that B cells of lupus-prone experimental animals are able to produce autoAb and to cause lupus-like disease even in host environments where they receive no $CD4^+$ - mediated T cell help. This ability is preserved in the absence of αß T cells and even in the total absence of T cells, and hence in the total absence of either T cell–mediated increased help or decreased suppression. But is it the presence of B cells that is causally related to the development of disease, or the presence of autoAb that results from B cell overactivity? A study elegantly approached this question. Lupus-prone MRL/lpr mice genetically manipulated to express B cells bearing sIg BCR but unable to secrete any antibody were employed. A proportion of these mice still developed autoimmunity characterized by nephritis with cellular infiltrates, indicating autoimmune B cells themselves without the production of autoAb and immune complexes, contribute directly to disease pathogenesis (71). The absolute dependence of the expression of SLE on either direct or indirect interactions of B cells with either hyperactive or autoreactive T cells is therefore questionable under certain experimental conditions.

The expression of B cell antigen receptor (BCR) on bone marrow cells limits subsequent rearrangements of Ig by downregulation of the expression of recombination activating genes (RAG) 1 and RAG2. If those B cells re-express RAG activity then autoreactive receptors may be eliminated or, nonautoreactive ones may acquire significant self-reactivity (72). Data from one lupus patient failed to show aberrant Ig editing (73) but the jury may be still out on this issue.

The lupus B cell is an efficient autoantigen-presenting cell.

Other investigators taking into account the particularly efficient antigen presenting capacity of the B cell have produced data indicating that the B cell in lupus may represent the central pathogenic cell that triggers other immune cells toward hyperactivity. Studies from the MRL/lpr lupus murine model have shown that when these mice undergo genetic manipulations in order to have no B cells, they do not display autoimmune manifestations, lack circulating autoAb and deposits of immune-complexes in tissues. These animals do not have circulating activated T cell that appear in the MRL/*lpr* animals and inflamed tissues with infiltrating T cells. While the vast majority of the circulating T cells in the unmanipulated animal have a particular activated/memory phenotype, the vast majority of the T cells in the manipulated animals are naïve T cells. It is thus proposed that the abnormal B cells of the $MRL/^{lpr}$ model are not only responsible for the production of pathogenic autoAb, but also mediate the activation of the T cell compartment (74 ,75 ,76). More specifically, this T cell activating power of B cells has been shown for $CD8^+$ T cells in the MRL/*lpr* mouse (77). In the above models the presence or the absence of B cells was the one and only determinant of the appearance or not of the autoimmune murine syndrome. In the absence of B cells these autoimmune mice had neither activated T cells nor lupus. It is thus possible, that under certain circumstances, lupus B cells are not restricted to the production of autoAb only, but also mediate abnormal T cell activation.

Patients with SLE treated with anti-CD20 antibody the clinical effect was associated with decreased numbers of circulating T cells expressing CD40L (78), suggesting that, as in mice, in human lupus B cells are involved in the generation of activated T cells.

Genetic Studies

The description of functional aberrations in lupus B cells suggest a potentially intrinsic defect and that such a defect(s) may reflect the product of genetic alteration(s). Studies of the genetic composition of lupus-prone mice began several years ago. Three independent research groups analyzing the whole genome of the (NZB × NZW) F1 mouse mapped genetic loci that contribute to development of murine lupus (79 ,80 ,81). It is currently thought that these disease-predisposing genetic loci work in an additive manner; the more disease-predisposing loci an animal inherits, the higher the likelihood it will develop the full-blown lupus-like illness. Three independent groups reached similar conclusions during mapping of such disease-susceptibility loci (82 ,83).

One lupus-prone strain analyzed was the NZM2410 mouse. This is a substrain of the (NZB × NZW) F1 strain characterized by highly penetrant and early onset lupus-like illness. In the NZM2410 model disease-susceptibility maps to a few genetic intervals named *Sle1, Sle2, Sle3*, and so on (84). The other two groups also mapped disease susceptibility loci; one lupus-related genetic locus called nba-1 by one group and the one called by others *Lbw-2/Sbw-2* was identified as the locus with a particularly strong pathogenetic contribution (79 ,81). *Nba-1, Lbw-2/Sbw-2* as well as *Sle2* map in a 9cM-spanning region of murine chromosome 4, possibly within the context of a single gene. Crossing experiments produced a new strain expressing *Sle2* only, that developed a clinical picture characterized by hypergammaglobulinemia and IgM class autoAb, which could be attributed to dysfunction of the B cell compartment only. Nevertheless, *Sle2*-only expressing

mice did not develop full-blown lupus, nor did the other strains that expressed other isolated disease-susceptibility genetic intervals. Such experiments propose that *Sle2* may represent a “lupus B cell overactivity genetic locus” (85).

Equally interesting are the data stemming from the novel *Sle1* expressing murine models. *Sle1* maps on murine chromosome 1 and is associated with the production of anti-histone autoAb in lupus mice. Histones are T cell dependent autoantigens and the production of antihistone autoAb is a well-characterized T cell dependent autoimmune-response. *Sle1* expressed in a lupus-resistant background led to the production of IgG anti-H2A/H2B/DNA autoAb. It is now understood that *Sle*1 is expressed in both B and T cells. When expressed in B cells in the absence of T cells it mediates a break of tolerance and the production of autoAb and when expressed in T cells in the absence of B cells it mediates the abnormal production of cytokines and activation markers. Expression of glomerulonephritis requires the expression of *Sle1* in both B and T cells (86). Isolated expression of the genetic interval *Sle3* that maps on chromosome 7 was associated with low-grade polyclonal T- and B cell activation and mildly penetrant glomerulonephritis (87). However, the simultaneous presence of *Sle1* and *Sle3* was associated with an aggressive autoimmune phenotype, particularly in female mice. *Sle1* and *Sle3* bi-congenic mice developed splenomegaly, significantly expanded B- and $CD4^+$ T cells with activated phenotypes, widespread humoral autoimmunity including pathogenic autoAb, and a highly penetrant glomerulonephritis (88).

Based on their elegant studies the Wakeland group propose an epistatic model for the development of autoimmunity, where a combination of multiple defects in the genome allow for the expression of autoimmune aberrations culminating in the expression of lupus-like disease. To complicate things further, the same group identified autoimmunity–suppressing modifiers. One of these, designated *Sles1* was shown to specifically suppress the autoimmune features that should ensue because of the presence of *Sle1*, but not of *Sle2* or *Sle3* loci (89). It is thus the presence of autoimmunity–promoting and/or the absence or loss of autoimmunity–suppressing genetic elements that integrate into the development of overt autoimmunity in experimental models.

The *Sle1* interval has been further divided into *Sle1a, b,* and c. Chapter 7 lists further details about the major genes contributing to murine SLE.

The Deranged Cytokine Environment

The production of and the response to cytokines such as IL-6 and IL-10 is abnormally increased in SLE B cells. Both IL-6 and IL-10 are B cell stimulatory cytokines, while IL-10 also inhibits type-1 cytokine responses (90 ,91). Patients with active SLE have elevated serum levels of IL-6 (92 ,93), increased numbers of IL-6 secreting cells (94) and increased IL-6 mRNA content in their peripheral blood mononuclear cells (95). B cells from patients with SLE express constitutively cell-surface IL-6 receptors, but normal B cells do not (96). IL-6 generates an in vitro increase in the lupus B cell output of IgG and an increase of IgG anti-DNA autoAb, and the addition of anti-IL-6 mAb inhibits the IL-6 induced effects (92 ,96). The autocrine action of IL-6 has been shown clearly in B cells from (NZB × NZW) F1 and from MRL/*lpr* mice (97 ,98 ,99).

Similarly to IL-6, patients with SLE have elevated serum levels of IL-10 (100), increased numbers of IL-10 secreting cells (94) and increased IL-10mRNA content in their peripheral blood mononuclear cells (95). Interleukin-10 overproduction was shown to have functional significance since an anti-IL-10 mAb used in that study suppressed the in vitro production of autoantibodies from B cells obtained from patients with SLE but recombinant human IL-10 promoted it (101). In support of the above is that continuous administration of anti-IL-10 mAb delays the onset of autoimmunity in (NZB × NZW) F1 mice (102). It could be proposed that increased production of IL-10 may represent a product (rather than a cause) of a hyperproliferating B cell population. Because the degree of B cell proliferation parallels closely the activity of the disease and the overproduction of IL-10 was disease activity-independent, these data point toward a putative intrinsic B cell defect in SLE. In agreement with this hypothesis are reports that increased production of IL-10 is found in B cells from relatives of SLE patients. The mRNA of IL-10 was found in lupus B cells but was undetectable in control B cells. Using flow cytometry it was reported that circulating, unmanipulated lupus $CD5^+$ B cells spontaneously produce IL-10, an effect not seen in healthy individual B cells (103). Additional in vitro studies have shown that IL-10 producing B cells from patients with SLE express the surface marker CD40L (104).

Phenotypic Changes of the Lupus B Cell

The “ectopic” expression of CD40 ligand (CD40L, CD154) was first described on the surface membrane of lupus B cells (105). In the peripheral blood of patients with active SLE $CD40L^+$ B cells were 20.5-fold more when compared to healthy donors. In patients with inactive SLE the numbers of CD40L+ B cells were comparable to those of the controls. Nevertheless, activation-induced CD40L expression on the surface of lupus B cells was 17-fold the baseline levels, compared to a 7.6-fold increase recorded in control subjects. CD40L expressed on the surface of lupus B cells is functional because the addition of a neutralizing anti-CD40L mAb in in vitro cell-culture settings decreased the production of cationic anti-dsDNA. Because not only T cells, but also B cells from SLE patients express functional CD40L on their cell surface, and because both kinds of lymphocytes express CD40, a bidirectional cognate stimulatory loop may function between lupus T and B cells (106). Moreover, it was reported that CD40L expressed on the surface of B cells costimulates other B cells (107). CD40L-expressing circulating

B cells from patients with active SLE were also shown to express the recombination activating genes 1 and 2. These two genes are not expressed by circulating B cells of healthy volunteers (108). In lupus-prone mice continuous administration of anti-CD40L ab resulted in decreased IgG anti-dsDNA autoAb production and delayed the onset of autoimmunity. Nevertheless, autoreactive IgM-producing B cells were still detected and following cessation of treatment such cells underwent a series of activation events and became again fully competent ab-secreting cells (109). The role of CD40L-expressing B cells in the production of autoAb in patients with SLE was supported by a study analyzing the fate of such cells and the production of autoAb in a few patients with active SLE and nephritis treated briefly with anti-CD40L mAb. The frequency of IgG- and IgG anti-DNA autoAb-producing lupus B cells was markedly reduced for months. This effect was also seen in EBV-transformed B cell lines established from the patients with SLE (110). Finally, the transgenic expression of CD40L on the surface of B cells in a nonautoimmune murine background correlated with the development of autoimmune manifestations in some of the ageing animals. Several different autoAb were detected in their sera and half of the animals developed immune-complex mediated nephritis, underscoring a potentially crucial role for CD40L-expressing B cells in the appearance of autoimmunity (111). Another costimulatory pair of molecules, the inducible costimulator (ICOS) and its ligand (ICOS-L), is also aberrantly regulated in lupus lymphocytes. While the expression of ICOS on the surface of circulating lupus T cells was increased, the expression of ICOS-L on the surface of circulating memory B cells was significantly decreased. The authors inferred that this effect was a result of recent contact between B and ICOS+ T cells in patients with SLE (112).

In addition to CD40L, CD80 and CD86 are also aberrantly expressed on the surface of lupus B cells. Fresh, small, resting, peripheral B cells but also large, activated B cells from patients with SLE were studied for the expression of CD80 and CD86. While CD80 expression was only slightly increased on the surface of large, activated lupus B cells, the expression of CD86 was 2.5- and 7-fold increased on the surface of activated and resting lupus B cells respectively, when compared to B cells obtained from patients with allergic disorders (113). Although all patients studied were in remission, and the functional integrity of the costimulatory molecules was not assessed, this study provided evidence that B cells from patients with SLE overexpress molecules that belong to the B7 family of costimulatory molecules. Expression of B7-family molecules has been shown to be a prerequisite for the disruption of immune tolerance toward self antigen (114). A recent study disclosed that both CD80 and CD86 were significantly upregulated on the surface of circulating B cells from patients with SLE. CD86 was not found on the surface of normal B cells but was induced following coculture with CD40L-expressing T cells. In the presence of anti-CD40L mAb the expression of CD86 on B cells from patients with lupus was inhibited. In the presence of anti-CD86 but not of anti-CD80 mAb the production of polyclonal Ig and of antisingle-stranded DNA was inhibited, suggesting a functional role for the abnormally expressed CD86 molecule on B cells from patients with lupus (115). Another group of investigators reported aberrant expression of the B cell surface molecule RP105. In patients with SLE there is an over-representation of RP105-negative B cells; such cells are reportedly responsible for the production of autoAb. When cultured in vitro with IL-6 RP105-, but not RP105+ B cells from patients with SLE were capable of secreting anti-dsDNA autoAb (116) (Table 11.1).

Table 11-1: Molecules Abnormally Expressed on the Surface of B Cells in SLE

Molecule abnormality	Normal Function
CD40L (CD154) ↑	Costimulation
ICOS-L ↓	Costimulation
CD80 Slightly ↑	Costimulation
CD86 ↑	Costimulation
RP105 ↓	Unknown
CR1 ↓	Complement receptor
CR2 ↓	Complement receptor EBV receptor

Aberrant B Cell Antigen Receptor Signal Transduction

The studies discussed above present evidence supporting the view that B cells from patients with SLE have functional as well as phenotypic abnormalities that are at least in part independent of the activity of the underlying disease. It is thus possible that such aberrations represent intrinsic lupus B cell defects. It is also possible that the heterogeneous defects described above may have a common underlying central biochemical abnormality. Crucial aspects of lymphocyte function, such as activation, proliferation, cytokine production, effector functions, and apoptosis are determined by the signaling biochemical pathway initiated following ligation of the surface antigen receptor (117 ,118 ,119 ,120 ,121 ,122 ,123). Physiologically, the ligand for BCR is the relevant antigen, and for the autoreactive B cell it is the autoantigen.

We have addressed the question of possible antigen-receptor-mediated signaling aberrations in B cells of lupus patients using anti-Ig antibodies (124). Stimulation of circulating B cells from patients with SLE through their sIgM or sIgD BCR produced significantly higher fluxes of free intracytoplasmic $Ca2^{+}$ when compared to similarly induced responses of B cells from patients with other systemic rheumatic diseases, or to the responses obtained from normal B cells. The elevated $Ca2^{+}$ responses come primarily from the intracellular calcium stores. Nevertheless, the production of inositol 1,4,5-trisphosphate (the principal mediator of free

calcium release from the intracellular compartment) was only slightly elevated, raising the possibility of either a hypersensitive $Ca2^+$ release machinery or of dominant, and as yet incompletely understood, inositol triphosphate-independent pathway(s) of $Ca2^+$ release.

The earliest known BCR-mediated signaling event is the activation of protein tyrosine kinases, which results in tyrosyl phosphorylation of cellular proteins (125 ,126 ,127). The tyrosyl phosphorylation reaction has numerous substrates; only a few of these substrates have been identified. In lupus B cells, the overall level of IgM-initiated protein tyrosyl phosphorylation was significantly enhanced and correlated with the augmented BCR-mediated free calcium responses. More specifically, at least four cellular proteins with molecular sizes between 36 and 64 kD were significantly hyperphosphorylated in anti-IgM-treated lupus B cells compared to the response of B cells from normal controls (124). The aberrant BCR-mediated signaling process was detected in approximately three quarters of the studied patients and did associate with disease activity, treatment status or specific clinical manifestations. Moreover, enhanced tyrosyl protein phosphorylation was disease-specific, implying a possible intrinsic lupus B cell defect, which may have pathogenic impact. Furthermore, the increased $Ca2^+$ responses could represent a biochemical and molecular basis for the enhanced expression of CD40L on the surface of lupus B cells upon stimulation. It has been previously reported that CD40L upregulation on the cell-surface is predominantly NFAT-, and hence $Ca2^+$-dependent (128). Moreover, strikingly similar abnormalities of antigen-receptor signaling have previously been reported from the study of fresh T cells, T cell lines and autoantigen–specific T cells from patients with SLE (129 ,130), pointing towards a potentially unifying Ag-receptor-mediated signaling defect(s) in lupus lymphocytes. It has been proposed that the signaling abnormalities encountered in SLE lymphocytes may provide a biochemical and molecular background for such diverse functions as lymphocyte activation, anergy, and cell death (131).

It is interesting that BCR-initiated signaling abnormalities similar to those in human lupus were encountered in a study of experimental murine lupus. Feuerstein et al. (132) induced systemic lupus-like autoimmunity by inducing graft-versus-host disease in a background of double-transgenic sIg/sHEL murine tolerance model. Induction of autoimmunity correlated with phenotypical as well as with signal-transduction changes of B cells similar to the human disease. B cell surface expression of CD21 (part of the complement receptor 2, CR2, complex) was significantly decreased in the autoimmune state. Additionally, changes in the BCR-mediated protein tyrosyl phosphorylation pattern in B cells developed following the induction of autoimmunity. In the autoimmune but not in the tolerant state, two substrates with apparent molecular masses of 78 and 60 kD were hyperphosphorylated following BCR crosslinking. The similarity of BCR-induced signaling in patients with SLE and in this particular autoimmunity model underscore the potentially central pathogenic role of aberrantly functioning B cells in both conditions.

Estrogens and the Lupus B Lymphocyte

Estrogens are indisputably involved in the pathogenesis of SLE in humans as well as in murine models. Hormonal manipulations dramatically alter the expression of SLE in lupus-prone mice and women of child-bearing age are afflicted more commonly than men. The mechanisms involved in the contribution of estrogens to the pathogenesis of SLE are unknown.

A recent study elegantly showed that estrogens, estradiol in particular, can break B cell tolerance and cause a lupus-like disease in a previously nonautoimmune mouse that transgenically expresses the heavy chain of a pathogenic anti-DNA autoAb (133). Estradiol induced high titers of anti-DNA autoAb, and glomerulonephritis. Estradiol-induced autoimmunity in the above murine model was associated with increased expression of the antiapoptotic molecule Bcl-2 by such autoreactive B cells. The same group of investigators reported that sustained elevation of estradiol levels produced changes in B cell subpopulations because a subset of autoreactive marginal zone B cells were significantly expanded and activated (134).

Abnormalities of BCR-Signaling Regulatory Molecules

When B cells encounter antigen other B cell surface molecules are also engaged and some of them provide regulatory control over the intensity, the duration, and the fate of the biochemical signal generated by the interaction of BCR with the antigen. Engagement of signaling regulatory molecules triggers separate intracytoplasmic biochemical cascades; the net sum of these signals may result in an increased, or attenuated, or a qualitatively different BCR-initiated signal outcome (135) (Fig. 11-1).

Complement Receptors on Lupus B Cells

The most important signal-augmenting B cell surface molecule is the complement receptor type 2 (CR2). This heterooligomeric complex (the CR2 complex) is contributed by CD21 (CR2), CD19 (the signaling molecule of the complex), and CD81. Physiologically, CR2 binds iC3b, C3dg, or C3d. The cytoplasmic signal produced when antigens decorated with the aforementioned complement fractions bind to B cells, represents the sum of co-crosslinking BCR and CR2 and is several orders of magnitude higher when compared to the signal produced by the same antigens via the BCR alone (reviewed in (136)). The effects of CR2-BCR co-crosslinking in B cells from patients with SLE were directly addressed recently. A construct made of anti-IgD ab conjugated to the Epstein-Barr virus (EBV) protein gp350 was employed to stimulate fresh, unmanipulated B cells from patients with SLE and it was shown that despite a significant decrease in the expression of cell surface CR2 the free

cytoplasmic $Ca2^{+}$ responses recorded were significantly enhanced compared to normal B cells (137).

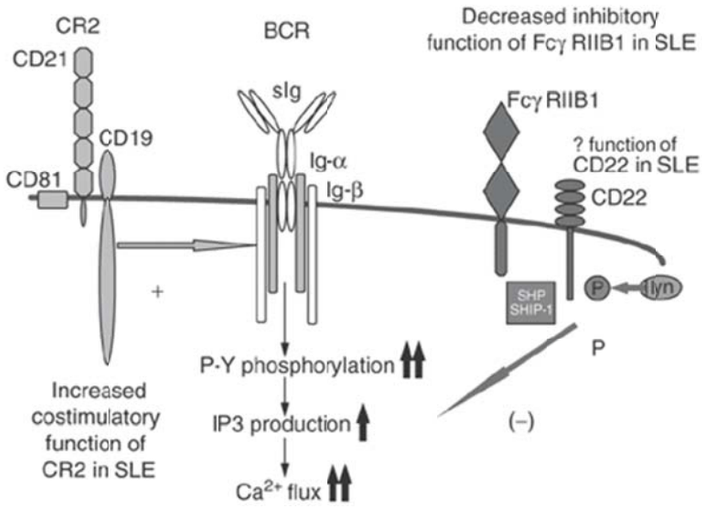

Figure 11-1. An outline of the AgR-mediated signal transduction aberrations encountered in lupus B cells, and possible contributions from B cell surface coreceptors.

BCR (sIgM or sIgD)-triggered early signal transduction events in lupus B cells leads to significantly enhanced production of tyrosine-phosphorylated cellular proteins and to increased formation of inositol triphosphate, when compared to B cell responses from either normal or disease-control individuals. These events are followed by a significantly increased free Ca2+ flux in the cytoplasm, which is contributed primarily by the intracellular calcium stores. Free Ca2+ is an important second messenger for numerous cellular functions.

B cell surface coreceptors regulate the magnitude of BCR-generated signals. Complement receptor type 2 (a complex of CD21, CD19, CD81) is a signaling enhancer. CR2 and BCR co-crosslinking significantly lowers the threshold for B cell activation. In lupus sera, ligands of CR2 (C3d, C3dg and iC3d) are commonly found in abundance.

Of the negative regulatory coreceptors, FcgRIIB1 is functionally characterized best. BCR and FcgRIIB1 co-crosslinking (i.e., when Ag is presented to B cells in the form of immune complexes) causes an early termination of BCR-initiated signals. Lyn, a tyrosine kinase phosphorylates inhibitory motifs on the intracytoplasmic domains of FcRgIIB1 and CD22 to which the tyrosine phosphatases SHP and SHIP-1 bind. This results in suppression of the signaling process initiated by BCR.

In SLE, the function of Fc receptors is defective, and abnormalities in other types of Fcg receptors have been characterized at the molecular level. The functional status of other regulatory B cell-surface molecules (CD22, CD5, CD72) in human lupus is unknown.

Previous studies have shown that expression of both CR2 and of complement receptor type 1 (CR1, an alternatively spliced product of the CR2 gene) is decreased on the surface of B cells from patients with SLE. Because this defect was also present in healthy relatives of patients with SLE it was proposed that it may be a genetically determined alteration (138). Decreased expression of B cell surface complement receptors is also seen on MRL/lpr B cells during the development of autoimmunity (139). When the expression of CR1/CR2 was partially or totally disrupted in the MRL/lpr background, survival and development of nephritis were not altered. Decreased expression of CR1/CR2 correlated with decreased levels of total IgG3 and IgG3 rheumatoid factors and significantly higher levels of IgA deposition in the glomeruli, suggesting that CR1/CR2 expression plays a role in autoAb production and/or clearance (140). According to a more recent study decreased CR2 expression levels correlate well with increased disease activity (141).

CR2 also represents the B cell surface receptor for EBV. A recent epidemiologic study disclosed that young patients with recent onset SLE had evidence of EBV infection more commonly than their healthy counterparts (99% vs. 70%) (142). A previous in vitro study reported that in circulating lymphocytes, EBV infection of lupus B cells cannot be contained by lupus T cells (143). This potentially defective T cell–mediated EBV control in patients with SLE was also reported in a recent study (144). Blood cells infected with EBV were detected in abnormally high frequencies in patients with SLE along with aberrant EBV-gene expression and correlated with disease activity (145). Additionally, EBV causes hyperactivation of B cells in SLE and decreases their apoptotic death because it induces overexpression of the anti-apoptotic molecule bcl-2 in the cytoplasm (146).

CR2 deficiency on the surface of lupus B cells does not help to explain the pathophysiology of the overactive lupus B cell. Nevertheless, a novel concept on CR2 (and CR1) function supported by recently produced experimental data proposes that complement receptor-mediated signaling maintains B cell immune tolerance to self antigens (147). This view may provide a molecular background to understand how lupus B cells, expressing low amounts of membrane complement receptors (a result of genetic or acquired defects), display deranged immune self-recognition. It has been proposed that complement participates in the early stages of B cell negative selection. According to this proposal, circulating natural autoantibodies identify highly conserved self-antigens and activate the classical pathway of complement. Such complexes bind to the BCR and complement receptors of autoreactive immature B cells arising daily in the bone marrow; this process represents an efficient means to delete these highly autoreactive B cells. In the case of early complement factor (or complement receptor) deficiencies, autoreactive immature B cells are not efficiently removed, and lupus-like autoimmunity develops (148). In support of the above it was recently reported that B cells from mice that partially or totally lack C4 produce anti-DNA autoAb. It is of interest that production of autoAb can be triggered in vitro months earlier, before their detection in the sera of the experimental animals (149). Finally, complement activation products can trigger B cell signaling events. The membrane-attack complex (C5b-9) found in the serum at sub-lytic concentrations may induce activation of the B cell kinases Ras, Raf-1, and extracellular regulated kinase (ERK) 1 in a B cell line via a mechanism involving G proteins (150). Circulating sub-lytic C5b-9 complex concentrations are reportedly increased in the serum of patients with SLE (151).

Stimulatory B Cell Surface Molecules

B lymphocyte stimulator (BLyS) and a proliferation-inducing ligand (APRIL) represent two novel members of the TNF-superfamily (152 ,153). They are distinct but closely related and they can stimulate B cells both in vitro and in vivo (152 ,154), APRIL being a weaker B cell stimulator compared to BLyS. Apart from similarities in their structure and function APRIL and BLyS also share common cell-surface receptors, i.e., the B cell surface receptors TACI and BCMA. TACI is an important inhibitory receptor found on the surface of B cells; TACI(-/-) murine models develop autoimmune glomerulonephritis and autoantibodies and fatal lymphoproliferation (155). So far, while the function of BCMA has been characterized as redundant (156), the receptor BAFFR is thought to be the principal B cell stimulating receptor that mediates the action of BLyS (157 ,158 ,159). Therefore, BlyS can bind to BCMA, TACI, and BAFF, whereas APRIL can bind only BCMA and TACI. Much attention has been focused on BLyS because it has clearly been shown that BLyS protein is vital and indispensable for normal B cell development. Use of soluble fusion proteins composed of BLyS receptors (BCMA and TACI) and the Fc fragment of IgG resulted in inhibition of both T cell dependent and T cell independent antibody responses (154 ,160 ,161). BLyS-knockout mice are B cell lymphopenic and have reduced antibody responses to T cell dependent and independent immune responses (162 ,163). Genetically manipulated mice expressing the TACI-Ig construct display a similar phenotype (162 ,164).

Administration of recombinant BLyS to mice induces polyclonal hypergammaglobulinemia (152). Lupus-prone mice like the NZB × NZW (F1) and the MRL-*lpr/lpr* mice display increased serum levels of BLyS during the onset and progression of their lupus-like disease, and genetically manipulated mice overexpressing BLyS develop lupus-like autoimmunity (165). Some patients with SLE have increased levels of BLyS protein in their sera, and the titers of BLyS correlated well with the titers of anti-dsDNA autoAb but not with disease activity (166 ,167). The biologic activity of circulating BLyS in patients with SLE was higher compared to normal controls (167). Nevertheless, there is a heterogeneity in BLyS levels among different lupus patients, and there are patients with SLE that have normal or even lower than normal levels of circulating serum BLyS (166).

Based on the central role of BLyS in the B cell immune response, different groups evaluated the effects of BLyS blockade in experimental lupus. Treatment of NZB × NZW (F1) and MRL-*lpr/lpr* lupus-prone mice with the soluble construct TACI-Ig delayed disease progression and improved survival (165). Treatment with adenovirally encoded TACI-Ig diminished polyclonal hypergammaglobulinemia and autoAb production in lupus-prone mice (168). Anti-BlyS is currently in phase 2 clinical trials in patients with SLE.

B Cell Surface Receptors That Provide Negative Regulation

There are several B cell surface signaling inhibitory receptors (169). Among them, the functions of CD5, CD22, and FcγRIIB1 are best understood. The ligand for CD5 was recently shown to be CD72 (170). The role of $CD5^+$ B cells in SLE and in experimental animal lupus is discussed above. The role of coreceptor CD22 as a signaling inhibitory molecule was clarified in CD22-knockout mice. Young CD22-knockout mice display autoimmunity, increased BCR-initiated cytoplasmic calcium responses, hypergammaglobulinemia, and circulating IgM autoAb (171). Adult CD22-knockout mice display glomerulonephritis, circulating IgG anti-dsDNA and anticardiolipin autoAb (172). This is an interesting model of systemic lupus-like autoimmunity, because it is monogenic, and because one B cell molecular defect created an autoAb response that included isotype switching and affinity maturation of the autoantibody, features reminiscent of a T cell–dependent immune response. Nevertheless, CD22 expression on the surface of B cells from patients with either active or inactive SLE is similar to that of normal controls (173 ,174). Expression of CD22 ligand on the surface of B cells has not been addressed in humans but has been studied in lupus-prone mice. Different lupus-prone strains were analyzed and it was reported that B–cell expression of CD22 ligand increases in parallel with the progression and severity of the autoimmune disease, but it could not be concluded if this was a primary or secondary effect (175).

Another B cell surface inhibitory receptor is the one for the Fc fraction of IgG type IIB1 (FcγRIIB1, CD32). When antigen bound to IgG is presented to the BCR, then BCR and FcγRIIB1 are co-crosslinked resulting in a net signal of smaller magnitude than the signal generated by antigen alone (176 ,177). The cytoplasmic free $Ca2^+$ response is of shorter duration and the resulting B cell response is incomplete activation and proliferation. Previous studies have reported that the system of receptors for the Fc fraction of IgG is overall malfunctioning in SLE resulting perhaps in the production of excess antibodies and the accumulation of immune-complexes (178). Genetically manipulated mice having B cell surface FcγRIIB1 deficiency manifested hypergammaglobulinemia (179). In NZB as well as in (NZB × NZW) F1 mice, the B cell surface expression of FcγRIIB1 was reported to be decreased in follicular germinal center B cells of adult (autoimmune) mice, but not in the circulating B cell pool. The NZB allele for FcγRIIB1 was found to have two deletion sites that included transcription factor-binding sites, increasing thus the likelihood that such deletions have a functional impact (180). This defect was correlated with IgG hypergammaglobulinemia. Additionally, a single-nucleotide polymorphism (a G-C substitution at position -343) in the human *FCGR2B* promoter was recently identified; homozygosity for this polymorphism was overrepresented in European-American patients with SLE. The -343

G/C polymorphism results in decreased binding of the AP-1 transcription factor to the FCGR2B promoter and hence to decreased transcription, providing thus a molecular explanation for the dysregulation of FcγRIIB1 in some patients with SLE (181).

The role of FcγRIIB1 as a suppressor of autoimmunity was demonstrated when the Fas(lpr/lpr) phenotype was crossed with FcγRIIB1-sufficient and FcγRIIB1-deficient B6 mice. Fas mutations were not sufficient to cause autoimmunity in wild-type B6 mice but in FcγRIIB1-/- animals an aggressive autoimmune lupus-like systemic disease developed characterized by multiple autoAb, glomerulonephritis, arthritis, and a markedly shortened life span (182). More recently data stemming from the study of FcγRIIB1 deficient IgG anti-DNA autoAb producing mice suggested a novel role for FcγRIIB1 as a potential distal peripheral checkpoint limiting the accumulation of autoAb-producing plasma cells (183). In B cells from patients with SLE the surface expression of FcγRIIB1 was similar to controls but the inhibitory function of this molecule was impaired. Co-crosslinking the BCR and FcγRIIB1 resulted in a significantly defective suppression of the free cytoplasmic $Ca2^{+}$ response in circulating B cells from patients with SLE compared to B cells from disease-control or healthy individuals (184).

The coreceptors CD22 and FcγRIIB1 bear a signaling inhibitory domain in their cytoplasmic tail called immunoreceptor tyrosine-based inhibitory motif (ITIM) (185 ,186 ,187). ITIM become functional when their tyrosyl residues become phosphorylated under the influence of protein tyrosine kinases (188). Tyrosyl phosphorylated ITIMs become the docking and activating sites for SH2-domain containing protein tyrosine phosphatases, particularly SHP-1 and SHIP (189 ,190 ,191). It is interesting that SHP-1 is absent or dysfunctional in another autoimmunity model, the motheaten and the viable motheaten mouse respectively (192).

The phosphorylation of ITIM tyrosyl residues is accomplished by protein tyrosine kinases. The ITIM lying in the cytoplasmic tail of FcγRIIB1 and CD22 coreceptor undergoes tyrosyl phosphorylation by the src-family kinase lyn (193). In the absence of lyn the CD22-initiated signaling inhibitory pathway is not triggered, despite adequate amounts of B cell surface CD22 expression (194). Until recently, lyn was considered as an integral part of the BCR-initiated B cell activation machinery (195 ,196). Yet, knockout experimental models disclosed that lyn is redundant in its stimulatory mediator role. In lyn-/- animals immature B cells developed normally but mature B cells were decreased. Rather unexpectedly it was shown that BCR-initiated signaling events were not only propagated but in fact they were enhanced. The lyn-/- mice develop autoimmunity with features quite reminiscent of lupus; they have hypergammaglobulinemia, increased sensitivity to IL-4, and develop autoAb and glomerulonephritis (197 ,198 ,199 ,200).

Lyn is crucial for the phosphorylation of CD22 and FcγRIIB1, and phosphorylation of CD22 and FcγRIIB1 are crucial for the activation of SHP-1 and SHIP respectively. Based on recent experimental animal studies, it appears that lyn, CD22 and SHP-1 are present in limiting quantities in B cells. A reduction in the quantity of each of the above mediators promotes a state of B cell hyperreactivity that eventually correlates with the development of autoimmunity (201).

Furthermore, it also appears that the signaling inhibitory coreceptor CD22 and the signaling enhancer CD19 molecule (part of the CR2-complex) are interrelated and form a regulatory feedback loop that tunes BCR-initiated signaling (202). CD19-deficient B cells are hyporesponsive but B cells expressing even slightly increased CD19 levels are hyperresponsive and develop autoimmunity (203 ,204). CD19 amplifies src-family protein tyrosine kinase activity and has been shown to allow for optimal CD22 function (205). Similarly, CD22 expression negatively regulates CD19-mediated functions. There are several pieces of experimental data suggesting that CD19 amplifies the activity of lyn that in turn phosphorylates CD22. CD22 ITIM phosphorylation recruits SHP-1 that negatively regulates the activity of CD19 by tyrosyl dephosphorylating it (203). A study recently investigated the expression of CD22 and lyn in B cells from patients with SLE (206). Preliminary data disclose that while CD22 expression is comparable to control B cells, the content of lyn in lupus B cells is significantly decreased in two thirds of patients with SLE examined (207). Although the function of the CD22/lyn signaling inhibitor was not addressed, it is likely that decreased lyn in SLE B cells contributes to B cell overactivity by deficiently regulating the BCR-initiating response.

Summary

The single most characteristic abnormality of immune cells encountered in both patients with SLE and in animal lupus models is B cell overactivity (Fig. 11-2). The pathogenic contribution of factors exogenous to the B cell itself, be it an aberrantly functioning T cell compartment or the local cytokine environment are well established. Recent data support a more central pathogenic role for the lupus B cell itself. It is revealed that lupus-like autoimmunity can ensue with either minimal or no contribution from T cells. Genetic as well as functional studies support a role for lupus B cell as an independent contributor to the appearance of the disease, apart from the well-known contribution of potentially harmful autoAb production. Studies unraveling the biochemistry of lupus B cell function reveal that there are disease-specific signal transduction aberrations that may represent a common background for other disturbed effector functions. The contribution of signal transduction regulators is appreciated using well-characterized genetically manipulated experimental models. Improving our understanding of the lupus B cell physiology and pathophysiology will ultimately improve our understanding of the disease and may provide us with useful tools to deal with SLE more rationally.

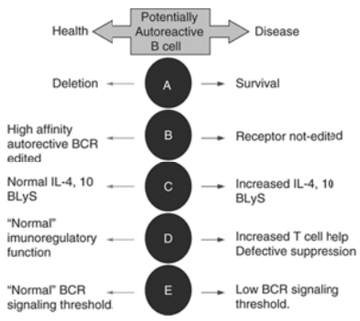

Figure 11-2. Processes that may lead to B cell-mediated autoimmune response. Any of the indicated processes, A through E, alone or in any possible combination can lead to B cell-mediated autoimmune response and autoimmune disease.

A. B cells with "proper" affinity for autoantigen are expected to be deleted in the bone marrow. Inability to delete autoreactive cells may lead to expansion of certain B cell subsets as recorded in the peripheral blood of lupus patients. Genetic defects of molecules involved in B cell apoptosis can limit cell deletion.

B. Once a BCR has been selected it can be edited to adjust for autoreactivity. Escaping autoreactive BCR can be edited to lower affinity or autoantigen. Although this process has been shown to be important in the regulation of the BCR repertoire, it has not been shown operative in human SLE.

C. Genetic, hormonal or environmental factors can cause increased production of cytokines that promote B cell function and in a proper background the expansion of autoreactive cells.

D. Increased T cell help and possibly diminished T regulatory function can promote excessive autoimmune B cell function.

E. Genetic, hormonal and possibly environmental factors can lower the excitation threshold for B cells through several distinct processes. First, gain of function or loss of function changes in the expression of enhancing and repressive signaling molecules can lead to increased B cell signaling responses as recorded in SLE patients. Defects (numerical or functional) in the expression of coreceptors (see Fig. 11-1) can alter the BCR excitation threshold.

Chapter 12

Abnormalities in Immune Complex Clearance and Fcγ Receptor Function

Jane E Salmon

Systemic lupus erythematosus (SLE), the prototype human disease mediated by immune complexes, is characterized by circulating antigen/antibody complexes that may be removed by the mononuclear phagocyte system or deposited in tissues. The fate of circulating immune complexes depends on the lattice of the immune complexes (i.e., number of antigens and antibody molecules in a given complex), the nature of the antigen and antibodies composing the immune complexes, and the status of the mononuclear phagocyte system. The efficiency of mononuclear phagocyte system immune complex clearance depends on the function of Fcγ receptors, receptors recognizing the Fc region of immunoglobulin, and the complement receptors. In SLE, inadequate clearance results in tissue immune complex deposition, detected by immunofluorescence and electron microscopy, that initiates release of inflammatory mediators and influx of inflammatory cells. If sustained, this leads to tissue damage with resultant, clinically apparent disease, such as glomerulonephritis. Through in vivo and in vitro studies of patients with SLE, there clearly are both FcγR-dependent and complement-dependent mononuclear phagocyte dysfunction in SLE that have inherited and acquired components. This chapter reviews the role of the mononuclear phagocyte system in immune complex clearance, describes abnormalities in the mononuclear phagocyte function in SLE, and discusses mononuclear phagocyte system Fcγ receptor dysfunction as a mechanism for abnormal immune complex clearance in SLE.

The Role of the Mononuclear Phagocyte System in the Clearance of Immune Complexes

Early studies of the blood clearance of bacteria in mice, rabbits, and guinea pigs demonstrated that the mononuclear phagocyte system (previously known as the reticuloendothelial system) performed this function for opsonized particles. Infused bacteria were internalized by hepatic and splenic phagocytes (1). The rate of clearance of bacteria from the blood and the site of their clearance depended on the level of antibodies to the bacteria in the serum of the animal. Rapidly cleared, well-opsonized bacteria were principally phagocytosed in the liver, while the more slowly cleared, less efficiently internalized bacteria (and presumably less opsonized) were removed by splenic phagocytes. These observations are remarkable for their similarity to the models of immune complex clearance in animals and humans that are described later.

The role of the mononuclear phagocyte system in the clearance of soluble immune complexes infused into the circulation has been defined in several experimental animal models. In mice and rabbits a major proportion of infused immune complexes formed with rabbit antibodies is taken up by the liver, indicating that the mononuclear phagocyte system serves an important role as a site for complex removal (2 ,3). This system may be saturated with increasing amounts of infused immune complexes, resulting in glomerular deposition of immune complexes (4). These early studies suggested that modulation of mononuclear phagocyte system function regulates the localization of immune complexes.

Several lines of evidence support this model and demonstrate that defective mononuclear phagocyte system clearance of immune complexes may be important in the development of immune complex diseases, especially glomerulonephritis. Increased glomerular deposition of immune complexes is found when the clearance rates of infused immune complexes are decreased by blockade of the mononuclear phagocyte system with colloidal carbon (5), by cortisone treatment (6), or by reduction and alkylation of antibodies (7 ,8). In mouse strains with intrinsically lower clearance rates, there is a high degree of immune complex glomerular deposition (9); in contrast, decreased deposition of immune complexes in the kidney is found when mononuclear phagocyte system clearance is enhanced by pretreatment with *Corynebacterium parvum* (10) or zymosan (11).

While impaired immune complex clearance leads to increased tissue deposition, the absence of activating FcγR on phagocytes prevents an inflammatory response at the sites of immune complex deposition. Mice with targeted deletions of stimulatory FcγR are protected from fatal antigen-antibody Arthus reactions and immune complex-mediated glomerulonephritis. In contrast, mice lacking inhibitory FcγR have exaggerated responses to immune complexes (12 ,13 ,14).

Animal models of endogenous immune complex deposition also support the relationship between depressed mononuclear phagocyte system clearance and the genesis of glomerulonephritis. In chronic serum sickness, there is decreased clearance of aggregated albumin (15) and aggregated human immunoglobulin G (IgG) (16). Decreased clearance of heat-aggregated IgG in murine nephritis (associated with lymphocytic choriomeningitis virus infection) (17) and of polyvinyl pyrrolidine in New Zealand black/white (NZB/W) mice (18) has been observed, although some studies of endogenous immune complex-mediated disease have not found dysfunction of the mononuclear phagocyte system. Studies of Heyman nephritis (19) and NZB/W nephritis (20) have concluded that mononuclear phagocyte system function is either normal or supranormal. These results are not in conflict, however; rather, they highlight the importance of the mononuclear phagocyte system probe, the site of clearance, and the timing of the study in relation to the genesis of disease (discussed later).

The principle to be derived from these animal models of immune complex disease, whether from infused immune complexes or endogenous disease, is that immune complex deposition is influenced by the efficiency of mononuclear phagocyte system clearance. Specifically, impairment of mononuclear phagocyte system clearance is associated with tissue deposition of immune complexes and the potential for local organ damage.

Mechanisms of Immune Complex Clearance

A number of factors govern the physical characteristics of immune complexes and, hence their biologic properties (Table 12-1). These include the nature of the antibody in the complex, the nature of the antigen, and the antigen-antibody interaction. Antigen and antibodies in the circulation may rapidly form immune complexes, but the immunochemical properties of these circulating immune complexes determine their ultimate fate, either removal by the mononuclear phagocyte system or deposition in tissues. The potential of immune complexes to interact with FcγRs, to fix complement, and to react with complement receptors influences their rate of clearance. Immune complexes without complement will be cleared primarily by FcγRs on fixed tissue macrophages. Complexes that are opsonized with sufficient complement may bind to the receptor for C3b on circulating erythrocytes and subsequently be removed by FcγRs and complement receptors. Thus, two classes of receptors, the FcγRs on phagocytes and the complement receptors on both erythrocytes and phagocytes, participate in the clearance of immune complexes (Fig. 12-1).

Complement Mechanisms: Immune Adherence and Erythrocyte CR1 System

Complement component 3 and the receptor for C3b on erythrocytes are important in processing and transporting large immune complexes (21) (see Chapter 13). Incorporation of complement components, C3b in particular, modifies the solubility of large immune complexes (22 ,23) and mediates the binding of immune complexes to human and other primate erythrocytes. Although both the liver and spleen are the major sites of immune complex uptake, erythrocytes in primates (21 ,24), and platelets in rodents (25 ,26) are important in clearing/processing immune complexes from the circulation. It has long been known that large complement-opsonized immune complexes bind to human erythrocytes (27). Termed immune adherence, this reaction has recently been shown to participate in the handling of nascent circulating immune complexes in primates (28).

Human erythrocytes express complement receptor type 1 (CR1), which permits binding of complement-fixing immune complexes. CR1 on erythrocytes can be conceptualized as having three main functions, which are not mutually exclusive: buffering, transporting, and processing (Fig. 12-1). The role of immune complex buffer has been suggested because erythrocyte-bound immune complexes are unavailable for tissue deposition, whereas nonbound complexes can deposit in the tissues. Bound immune complexes are transported to the liver or spleen where fixed tissue phagocyte FcγRs and complement receptors strip the immune complexes from the erythrocytes, which then return to the circulation to continue this process, thus performing the transporting function. Finally, CR1 promotes degradation of captured C3b on immune complexes, thereby modifying their subsequent handling.

The human CR1 (the complement receptor for C3b/C4b and, to a lesser degree, iC3b) is a single-chain, intrinsic membrane glycoprotein expressed on several different cells, including erythrocytes, granulocytes, monocytes, and macrophages (see Chapter 13). There are four codominantly expressed alleles of CR1, with molecular weights of 220,000, 250,000, 190,000, and 280,000 d (29 ,30 ,31 ,32). This structural polymorphism reflects differences in the number of long homologous repeat units comprising the receptors (33). Inherited and acquired differences in the numeric expression of CR1 on erythrocytes also have been described and associated with SLE (34 ,35 ,36 ,37 ,38).

Two alleles with codominant expression determine erythrocyte CR1 number in healthy individuals (37 ,39). Although the CR1 number expressed on erythrocytes is low compared with that on leukocytes, approximately 90% of total circulating CR1 is on erythrocytes, because there are far more erythrocytes than leukocytes in the circulation (40 ,41).

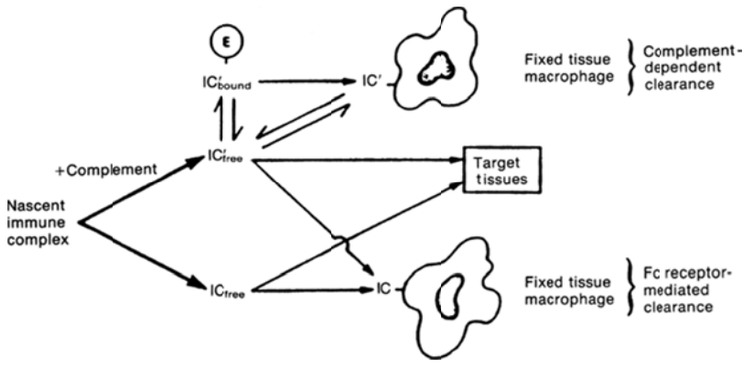

Figure 12-1. Framework for immune complex handling. Nascent immune complexes (ICs) that fix complement efficiently are rapidly bound by erythrocytes (E). ICs containing complement may cycle between E-bound and unbound; they usually are rapidly taken up in the liver. Unbound complexes also may deposit in the tissues, and with impaired complement-dependent uptake, they may be taken up by Fc receptor-dependent mechanisms. ICs that do not bind complement are either taken up by Fc receptor-dependent mechanisms or deposited in tissues. (Reprinted with permission from Elsevier from Kimberly RP. Immune complexes in rheumatic diseases. In: Pisetsky DS, Snyderman R, eds. Immunology of the Rheumatic Diseases, vol. 13. *Rheum Dis Clin North Am* 1987:583–596.)

The binding of immune complexes to CR1 occurs rapidly in vivo, and it represents multivalent binding between multiple C3b molecules on the complex and clusters of CR1 on erythrocytes (28 ,42 ,43 ,44 ,45). In vivo studies have demonstrated that immune complexes preferentially bind to circulating erythrocytes that express multiple CR1 clusters, and that the capacity of each erythrocyte for binding correlates with the density of cell surface CR1. Because CR1 on erythrocytes tends to cluster more than that on resting neutrophils, most immune complexes that are bound to circulating cells are bound to erythrocytes (22 ,24 ,40 ,41 ,46 ,47 ,48 ,49 ,50). A reduction in the number of functional CR1 limits the capacity of erythrocytes to transport and buffer immune complexes, and in vivo studies have demonstrated that repeated administration of antigens in immunized humans and primates with immune complex formation results in a decrease in erythrocyte CR1 levels (46 ,51). Studies with primates have suggested that circulating immune complexes that are not bound to erythrocytes are more easily trapped in the microvasculature and can be recovered in the lungs and kidneys (50 ,52). Taken together, these findings have obvious implications for immune complex-mediated diseases.

The efficiency of immune complex binding to erythrocytes via CR1 relates to the nature of the immune complex, particularly the ability to activate complement and capture C3b, the spatial organization of the captured C3b, and the final size of the complex (53). Several models have been used to analyze the characteristics of immune complexes interacting with the erythrocyte CR1 system, including DNA/human anti-DNA, bovine serum albumin (BSA)/anti-BSA, tetanus toxoid/human antitetanus toxoid, and hepatitis B surface antigen/human antihepatitis B surface antigen (24 ,28 ,48 ,50 ,54). In each system, large immune complexes bind to erythrocytes better than do small immune complexes. The antigen and antibody also influence this reaction, because the capacity to fix complement varies with antibody class and certain antigens alone may capture C3b. Erythrocyte CR1 immune complex binding is avid but reversible, and the rate of dissociation also varies according the particular immune complex, which dictates the nature of C3b capture (43 ,55).

The erythrocyte CR1 system also may have a second physiologic function: providing a processing mechanism for immune complexes (56). In addition to being a carrier for opsonized immune complexes, CR1 has a potent inhibitory function in the complement cascade, which may enhance clearance. It participates in the inactivation of C3b and may alter the size of complexes, thus affecting their subsequent handling. Specifically, CR1 is a cofactor for factor I in the cleavage of C3b to iC3b and then to C3dg (57 ,58). Therefore, the binding of immune complexes containing C3b to erythrocyte CR1 facilitates proteolytic cleavage of the C3b to iC3b and C3dg, which do not bind to CR1. This reaction is the basis for the degradation of complement on immune complexes with their subsequent release from the receptor (59), and its rate varies with the physicochemical properties of the individual complexes (55). If the immune complex can again activate complement and bind C3b, it can rebind to CR1 (60). Although

repeated cycles of binding and release are likely, these immune complexes are not constantly bound to erythrocytes and thus are available for either deposition or (enhanced) removal by the mononuclear phagocyte system. The fraction of immune complexes in whole blood that is erythrocyte bound depends on several dynamic processes: complement fixation and C3b capture, erythrocyte binding, and C3b degradation and immune complex release.

Fcγ Receptor Mechanisms

Immune complexes are removed from the circulation by the mononuclear phagocyte system of the liver and spleen through engagement of FcγRs and complement receptors. The interaction of immune complexes with the phagocyte involves a qualitatively different process than that with erythrocytes (47). The relative contribution of each receptor system depends on the immunochemical properties of the complex. The liver, which is much larger than the spleen, is the principal site for the uptake of immune complexes (52 ,61 ,62); however, immune complexes that escape clearance by hepatic macrophages, which may be smaller and of lower valence, are taken up by the spleen (61). The role of FcγRs in immune complex clearance of both soluble and particulate immune complexes is shown by studies wherein blockade of FcγRs by an infusion of aggregated IgG into the portal venous system (40) or of antibodies against FcγRs (47) suppresses uptake of these immune complexes (Fig. 12-2). Supporting the pivotal role of FcγRs in handling certain immune complexes, studies of complement depletion show no effect on the efficiency of uptake of immune complexes by the liver or spleen and actually show an acceleration in the rate of removal of complexes from the circulation, presumably resulting from trapping in the microvasculature (50).

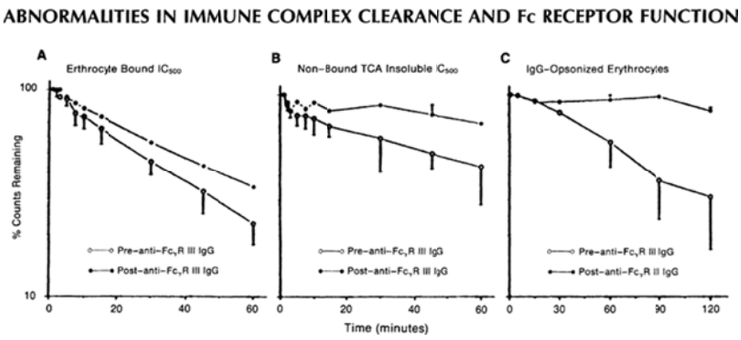

Figure 12-2. Effect of anti-FcγRIII monoclonal antibody (MAb) on the handling of soluble immune complex (IC). The effects of anti-FcγRIII MAb infusions on the handling of several different radiolabeled model IC probes in chimpanzees are presented with data expressed as the percentage counts remaining relative to the counts infused. A: Following intravenous infusion of soluble radiolabeled IC, clearance of erythrocyte (E)-bound IC was measured and found to be slowed by treatment with anti-FcγRIII MAb IgG. B: After intravenous infusion of soluble IC, clearance of non-E-bound IC was slowed more by anti-FcγRIII MAb IgG. C: Clearance of IgG-opsonized E was most markedly slowed by anti-FcγRIII infusions. (Reprinted with permission from Kimberly RP, Edberg JC, Merriam LT, et al. In vivo handling of soluble complement fixing Ab/dsDNA immune complexes in chimpanzees. *J Clin Invest* 1989;84: 962–970.)

FcγRs appear to play a key role in the transfer and retention of immune complexes by mononuclear phagocytes. Studies of DNA/anti-DNA complexes that are bound to radiolabeled erythrocytes and injected into chimpanzees show that while immune complexes are removed by the mononuclear phagocyte system, the erythrocytes are not sequestered; rather, they are stripped of immune complexes and promptly recirculated (24). Although the mechanism of this stripping is not well defined, the involvement of complement proteases has been implicated (63). In this model of immune complex clearance, infusion of erythrocyte-bound DNA/anti-DNA complexes after treatment with anti-FcγR monoclonal antibody results in a significant amount of nonerythrocyte-bound circulating immune complexes, documenting the participation of FcγRs in the retention of immune complexes by phagocytes (Fig. 12-2B) (47).

In addition to stripping erythrocyte-bound complexes, FcγRs as well as CR3/CR4 are responsible for the clearance of those complexes that are unable to bind to erythrocyte CR1 because of inadequate C3b capture or degradation of C3b. This interpretation is supported by experiments in primates that were treated with anti-FcγR monoclonal antibodies and showed impaired clearance of infused immune complexes, which was most pronounced in the fraction of complexes that did not bind to erythrocytes (47). It has been shown that immune adherence is not a prerequisite for the efficient handling of immune complexes by the mononuclear phagocyte

system (51), but immune complexes that do not fix complement or that fix complement poorly cannot be cleared if FcγR function is impaired (Fig. 12-1).

Abnormal Immune Complex Clearance in SLE

Human Models of Immune Complex Clearance

Probes that have been used to assess the efficiency of immune complex clearance in humans are: (a) autologous erythrocytes sensitized with IgG antibodies that are directed against the D antigen of the Rh system, (b) preformed immune complexes or aggregated IgG, and (c) antigen infused into passively immunized subjects. Because each of these probes has distinct immunochemical properties, they interact differently with the complement and FcγR systems, as expected. Thus, the results of in vivo studies comparing immune clearance in patients with SLE and in healthy individuals vary depending on the probe used.

Analysis of the Clearance of IgG-Sensitized Autologous Erythrocytes

The technique introduced by Frank et al. (64) to measure mononuclear phagocyte system function employs autologous 51Cr-radiolabeled erythrocytes that are sensitized with IgG anti-(Rh)D antibodies and injected into study subjects, and clearance or removal of these cells from the circulation is determined by serial bleeding. External surface counting of sensitized radiolabeled erythrocytes shows initial rapid sequestration in the liver, followed by splenic accumulation of most of the injected cells. The semilogarithmic plot of mean data for the clearance of sensitized cells in normal control subjects is curvilinear, with a rapid initial loss of radiolabeled cells followed by a slower, sustained loss of radioactivity (Fig. 12-3) (65 ,66 ,67).

Although originally conceptualized as a measure of FcγR capacity, kinetic analysis of in vivo clearance studies and in vitro studies with IgG anti-(Rh)D-coated erythrocytes suggests that complement also plays a role in clearance of this probe. Further support comes from studies of C4-deficient patients, who show delayed clearance relative to healthy individuals (68). A proposed model to describe the series of steps in handling of IgG anti-(Rh)D-sensitized erythrocytes is as follows: Circulating cells initially sequestered by a complement-dependent process are deactivated and released back into the circulation or are phagocytosed. Released cells are sequestered and phagocytosed by an FcγR-mediated process. Circulating cells also may be directly sequestered and phagocytosed by FcγRs (66 ,67 ,68).

The role of complement in the clearance of anti-(Rh)D-sensitized erythrocytes is a function of the level of antibody sensitization (69). Erythrocytes that are prepared with a low density of surface anti-(Rh)D are cleared primarily by splenic FcγRs, while at higher-density sensitizations, hepatic complement receptor-mediated clearance becomes increasingly important. This observation is highlighted in studies of splenectomized patients, which show that the clearance of erythrocytes sensitized with low levels of anti-(Rh)D antibody is more markedly prolonged than that of more densely opsonized erythrocytes, which fix complement and may be cleared by hepatic C3b receptors. Because the density of opsonization determines the relative contribution of FcγRs and complement mechanisms in clearance, the results of in vivo clearance studies in patients with SLE must be interpreted in the context of the sensitization of the probe.

In Vivo Studies of IgG-Sensitized Autologous Erythrocytes in SLE

Abnormal mononuclear phagocyte system function in patients with SLE has been demonstrated in several studies performed with IgG anti-(Rh)D-sensitized erythrocytes (64 ,70 ,71 ,72 ,73). Clearance half-times for radiolabeled autologous IgG-sensitized erythrocytes were prolonged in these patients compared with normal individuals and were longer in patients with renal disease than in those without renal disease (Figs. 12-3 and 12-4). In these studies, the prolongation of clearance half-time of erythrocytes (low-density sensitization) was attributed to impaired splenic FcγR function. At this low level of sensitization, hepatic complement-mediated clearance is negligible, and the rate of clearance indeed reflects the efficiency and capacity of FcγRs. The abnormality in clearance is

receptor specific, because clearance of heat-damaged erythrocytes and aggregated albumin was not prolonged in these patients with SLE (64 ,74).

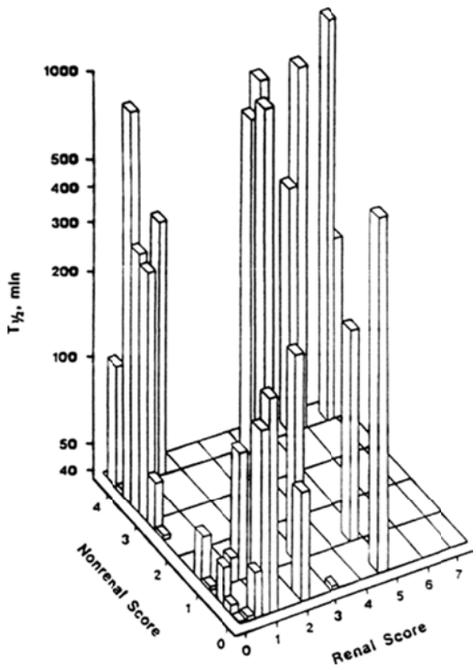

Figure 12-4. Relationship of clinical activity and FcγR-mediated mononuclear phagocyte system dysfunction. Clinical activity was assessed in terms of both renal and nonrenal manifestations. Longer (taller) clearance half-time values represent greater degrees of dysfunction. Patients with active renal and nonrenal disease showed the greatest degree of FcγR-mediated clearance impairment. (Reprinted with permission from Kimberly RP, Salmon JE, Edberg JC, et al. The role of Fc receptors in mononuclear phagocyte system function. *Clin Exp Rheum* 1989;7(Suppl):S130–S138.)

In a contrasting study, clearance of more heavily sensitized erythrocytes in patients with SLE was similar to that of normal controls (75). At this higher level of sensitization, clearance half-times are primarily a measure of hepatic complement receptor function rather than splenic FcγR function (69). Because complement-dependent clearance often is normal in patients with SLE but without renal involvement (discussed later), the overall clearance of heavy opsonized erythrocytes may be normal despite marked FcγR dysfunction.

When clinical activity in patients with SLE was assessed, there was a significant but independent association between impaired FcγR clearance and the level of both renal and nonrenal disease activity (72). Increased activity along either parameter was associated with more impaired clearance. As shown in Fig. 12-4 , patients with active renal and nonrenal disease are most likely to have the highest degree of clearance dysfunction. Longitudinal studies in patients with SLE showed that mononuclear phagocyte system function changed concordantly with changes in clinical status, indicating that clearance dysfunction is dynamic and closely related to disease activity (70 ,71).

Semilogarithmic plots of the mean data for clearance in patients with SLE, grouped according to disease activity and the presence or absence of renal involvement, show differences in slope and duration of the initial, rapid loss of radiolabeled cells from the circulation (predominantly complement-dependent clearance) and in the slope of the slow, sustained clearance reaction (predominantly FcγR-mediated clearance) (Fig. 12-3B). Rate constants governing the FcγR- and complement-dependent steps of the clearance process were derived from kinetic analysis of these curvilinear clearance data. Rate constants were evaluated for four steps: (a) complement-dependent sequestration, (b) C3b deactivation and release, (c) complement-mediated phagocytosis, and (d) FcγR-mediated sequestration and phagocytosis. Such analysis of the studies of patients with SLE grouped by disease activity revealed both FcγR-and complement-dependent dysfunction (67). Impaired FcγR function was evident in all patients except those with neither renal involvement nor any other manifestation of activity. Complement-mediated phagocytic dysfunction was seen only in patients with renal disease. These data suggest that altered complement-mediated phagocytosis in combination with abnormal FcγR-mediated phagocytosis by fixed tissue macrophages contributes to the pathogenesis of lupus nephritis.

In hypocomplementemic patients with SLE, examination of clearance rate constants revealed a good correlation between disease activity and FcγR-mediated clearance function (68). With decreased complement levels, there may be deficient complement opsonization of complexes, impaired binding and processing by erythrocytes, and reduced clearance by hepatic complement receptors. Such circulating immune complexes with little or no complement must be cleared by FcγRs. While rapid hepatic complement-dependent clearance appears to be the first line of defense against immune complex deposition, FcγR-mediated clearance becomes pivotal when this mechanism fails. In disease processes that are associated with hypocomplementemia, tissue immune complex deposition and increased disease activity occur when there is a concomitant defect in FcγR clearance. Similar to human SLE, studies in four murine models of lupus demonstrated an early progressive defect in FcγR-mediated clearance of IgG-sensitized erythrocytes, whereas the efficiency of complement-mediated clearance varied among the murine strains (76). The consistent finding of impaired FcγR-specific clearance in patients with active SLE emphasizes the potential importance of the mechanism for immune complex disease.

Given the role of immune complex deposition in the pathogenesis of SLE, circulating immune complex levels in patients were measured by a series of different assay systems (i.e., C1q binding, staphylococcal protein A binding assay,

Raji cell assay) at the time of in vivo erythrocyte clearance in many studies. There was a relationship between the levels of immune complexes and FcγR dysfunction in some, but not all, groups of patients with SLE. The lack of direct correlation between mononuclear phagocyte system function and immune complex level in all studies is not surprising, however, given the complexity of immune complex handling and the range of variables determining net complex levels (70 ,72).

Although partly acquired and related to disease activity, the FcγR mononuclear phagocyte dysfunction also may have a genetic component. Normal individuals with a human leukocyte antigen (HLA) haplotype containing either DR2 or DR3, which are some gene products found with increased frequency in SLE populations (see Chapter 6), are more likely to have an abnormally prolonged FcγR-mediated clearance of IgG-sensitized erythrocytes than their normal counterparts without these haplotypes (77 ,78). While the magnitude of the FcγR dysfunction is substantially larger in patients with SLE and has a large dynamic component associated with disease activity (64 ,70 ,72), individuals with an immunogenetically associated decrease in FcγR function might be more susceptible to the secondary FcγR abnormalities associated with SLE. Allelic polymorphisms of FcγR also are potential inherited factors influencing immune complex clearance (discussed later). Thus, basal genetically determined mononuclear phagocyte clearance in normal individuals may contribute to the predisposition and pathogenesis of SLE.

Analysis of Clearance of Infused Soluble Immune Complexes

As another measure of mononuclear phagocyte system function, the clearance of preformed, large, soluble, complement-fixing immune complexes has been studied in humans. Radiolabeled tetanus toxoid/anti-tetanus toxoid, hepatitis B surface antigen/antibody, or aggregated human IgG are infused and then sequential blood samples obtained and analyzed for whole blood and erythrocyte-bound radioactivity to monitor clearance (48 ,54 ,79). Clearance of these preformed immune complexes (free or erythrocyte bound) from the circulation of humans has been shown to involve the activation of complement with capture of C3b, binding to erythrocyte CR1 receptors, uptake by complement, and FcγR tissue mononuclear phagocytes as described earlier. Factors that cause the erythrocyte transport system to fail, such as hypocomplementemia or CR1 deficiency, are associated with an initially more rapid disappearance of immune complexes, presumably caused by trapping in capillary beds outside the mononuclear phagocyte system. For example, clearance of injected hepatitis B surface antigen/antibody complexes in patients with essential mixed cryoglobulinemia is accelerated compared with that in normal subjects, presumably because of immune complex deposition in tissues outside the liver and spleen as a result of impaired immune adherence. The basis for defective erythrocyte transport and buffering of complexes in these patients appears to be a result of complement depletion and monoclonal rheumatoid factor inhibition of immune complex opsonization and binding (54).

Because the relevance of these large, preformed complexes (40S) to human SLE is not entirely clear, studies of the clearance of smaller (19S) complexes formed in vivo have been performed. Patients with ovarian cancer were infused with murine antitumor antibodies followed by human anti-murine IgG (46). In this model, complexes were cleared rapidly by the liver, although the role of erythrocyte CR1 was unclear. In vivo immune complex formation was associated with systemic complement activation, reduction in erythrocyte CR1, and increased erythrocyte C3 and C4 (similar to the findings in SLE described later), which could predispose to less efficient handling of further complexes.

Given the different kinds of information obtained from each of these in vivo probes, examination of multiple models of immune complex clearance is necessary to define the mechanisms of immune complex deposition in SLE.

In Vivo Studies of Infused Soluble Immune Complexes in SLE

In vivo studies of infused soluble immune complexes complement the sensitized erythrocyte model of clearance and demonstrate multifactorial mononuclear phagocyte dysfunction. Abnormalities in erythrocyte CR1 system, the early buffer for circulating immune complexes, are described in patients with SLE, and for these models it is important to recognize that such patients tend to have an acquired, decreased numeric expression of CR1 on erythrocytes that correlates with disease activity (80 ,81) and may result from repeated immune complex/erythrocyte CR1 interactions (48 ,51). There also is evidence of an inherited deficiency of CR1 in some patients (36 ,38).

Diminished CR1 resulting in impaired immune adherence is one of the mechanisms for abnormal clearance of infused soluble complexes in SLE. For example, patients with SLE who were infused with radiolabeled aggregated human IgG showed decreased binding of the probe to erythrocytes and a more rapid initial distribution phase compared with that in normal controls (62 ,78). Similarly, complement-mediated binding of tetanus toxoid/antitetanus toxoid immune complexes to erythrocytes was decreased in SLE, and this correlated with erythrocyte CR1 number (48). With these model immune complexes, a rapid first phase of elimination was noted in patients with low complement, low CR1, and low immune adherence, which was ascribed to inappropriate tissue deposition of complexes (49).

The second, slower elimination phase of infused aggregated IgG also is abnormal in SLE, presumably because of impaired splenic uptake as well as generalized mononuclear phagocyte dysfunction. Whereas studies in normal individuals show preferential hepatic uptake of aggregated IgG and those who are splenectomized show hepatic compensation for splenic loss with normal elimination half-times, patients with SLE have both minimal splenic uptake and prolonged clearance half-times (62 ,78 ,82). Studies of the infusion of large, soluble

immune complexes (hepatitis B surface antigen/antibody) in patients with SLE reveal both impairment of hepatic clearance and retention of complexes as well as impairment of splenic clearance and retention of complexes (83). With this probe, the dysfunction is related to hypocomplementemia and decreased number of erythrocyte CR1 receptors. Similarly, in a patient with hereditary homozygous C2 deficiency, treatment with fresh frozen plasma to normalize classical pathway complement activity normalized the binding of hepatitis B surface antigen/antibody complexes to erythrocytes and corrected defects in splenic clearance and retention (84). Regardless of the mechanism, however, abnormalities in both splenic and hepatic clearance function allow for a spillover of complexes beyond the mononuclear phagocyte system in SLE.

Blockade of FcγRs by elevated levels of IgG interferes with this key mechanism for the elimination of soluble circulating immune complexes (85 ,86). That serum concentrations of IgG are an important factor predicting the rate of aggregated IgG clearance in SLE (78) emphasizes the importance of FcγR mechanisms in this model and supports the conclusions derived from the sensitized erythrocyte model of immune complex clearance. Specifically, FcγR-mediated clearance efficiency is crucial in SLE because of the defects in complement-dependent function.

Biology of Human Fcγ Receptors

With evidence for both the genetic and acquired components of FcγR-mediated clearance defect, further information about FcγR structure and function should enhance our understanding of immune complex handling and provide novel therapeutic options. Human FcγR structure is much more varied than simply being one type of receptor for IgG, as assumed in many of the early studies cited in this chapter. Recent, dramatic growth in our knowledge of FcγRs has revealed extreme diversity accompanied by great complexity. The nomenclature for FcγR follows that proposed by Ravetch and Kinet (87): uppercase letters refer to genes, and lower case letters refer to proteins (i.e., gene products).

Structure and Distribution

FcγRs are an essential receptor system that is engaged by immune complexes as they trigger internalization, release of inflammatory mediators, cytokines and degranulation. In contrast to complement receptors, FcγR recognize ligand in its native form. In humans, there are three distinct but closely related classes of FcγR—FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16)—that are identified by immunochemical and physicochemical properties, cellular distribution, and complementary DNA (cDNA) sequences (88 ,89 ,90 ,91 ,92). There are eight FcγR genes, each of which may lead to unique protein products. Extensive structural diversity among FcγR family members leads to differences in binding capacity, distinct signal transduction pathways, and cell specific expression patterns (Fig. 12-5). This chapter considers structure-function relationships in the context of each receptor family and provides a framework for understanding how FcγR may contribute to susceptibility, pathogenesis, and therapeutic intervention in SLE.

FcγR on surface of hematopoetic cells are often expressed as stimulatory and inhibitory pairs. Given the protean and potent reactivity initiated by stimulatory FcγR, cell activation must be modulated to respond appropriately to variations in environmental stimuli. Studies have suggested that inhibitory FcγRs, which modulate thresholds for activation and terminate stimulating signals, are a key element in the regulation of effector function (13 ,14). When co-aggregated with stimulatory receptors on the cell surface, inhibitory FcγRs can abolish cellular signaling, whereas when self-aggregated, they do not trigger effector functions. Inhibitory FcγRs play a central role in afferent and efferent immune responses as negative regulators of both antibody production and immune complex-triggered activation.

FcγRs belong to the immunoglobulin supergene family and are encoded for by multiple genes, which have been mapped to the long arm of chromosome 1q21-23 (93 ,94 ,95). Within the three FcγR families, the presence of multiple distinct genes (arising from gene reduplication) and alternative splicing variants leads to a variety of receptor isoforms that are most strikingly different in transmembrane and intracellular regions, whereas they share similar but not identical extracellular domains (Fig. 12-5).

FcγRs capable of triggering cellular activation possess intracellular activation motifs, termed immunoreceptor tyrosine-based activation motifs (ITAMs), similar to those of B cell receptors, and T cell receptors (96 ,97). Inhibitory FcγRs have extracellular domains that are homologous to their activating counterparts, but their cytoplasmic domains contain an immunoreceptor tyrosine-based inhibitory motif (ITIM). Stimulatory FcγRs are typically multichain receptors composed of a ligand-binding α subunit, which confers ligand specificity and affinity, and associated signaling subunits with ITAMs in the cytoplasmic domains (Fig. 12-5). FcγR α chains are transmembrane molecules that share the structural motif of two or three extracellular immunoglobulin-like domains, but vary in their affinity for IgG and in their preferences for binding different IgG subclasses (IgG1, IgG2, IgG3, and IgG4). There are also allelic variations in the ligand-binding region of specific FcγR that influence the ability to bind certain IgG subclasses and alter the responses of phagocytes to IgG-opsonized antigens (98 ,99 ,100). The transmembrane domains of the α subunits contain a basic residue to mediate the physical interaction with associated signaling chains required for efficient expression and signal transduction. The two multichain FcγR isoforms are termed FcγRI, a high affinity receptor for IgG that binds monomeric IgG, and FcγRIIIa, an intermediate affinity receptor, that binds only multivalent IgG. Homodimeric γ-chains are transducing modules for FcγRI and FcγRIIIa (Fig. 12-5). Heterodimers of γ-ζ chains or homodimers of ζ chains can also transduce signals through FcγRIIIa in human natural killer (NK) cells. The other isoform, FcγRIIIb, has neither an ITAM nor

a transmembrane domain, but is maintained in the plasma membrane outer leaflet by a glycosyl phosphatidylinositol anchor (Fig. 12-5). In addition to multichain receptors, there are two other types of activating FcγR and one inhibitory receptor with two different splice variants. FcγRIIa and FcγRIIc are single-chain receptors that include an extracellular ligand-binding domain and ITAM in the cytoplasmic domain. Inhibitory FcγRs, FcγRIIb1 and FcγRIIb2, are single-chain receptors with extracellular domains highly homologous to their activating counterparts and cytoplasmic domains with ITIMs (Fig. 12-5) (101).

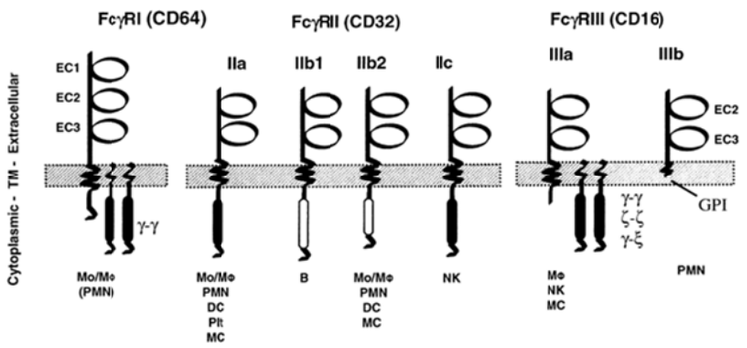

Figure 12-5. Schematic representation of the human Fcγreceptor family members. FcγR α chains contain two or three disulphide-linked immunoglobulin-like extracellular domains (ellipses) that mediate binding to IgG. All FcγRs, except the glycosyl phosphatidylinositol-anchored FcγRIIIb, have a transmembrane region (TM), some of which can interact with accessory chains to yield a multichain signaling complex. The cytoplasmic domains of FcγR or their associated subunits are responsible for signal transduction. FcγRIIIb is the only FcγR that lacks a cytoplasmic tail. FcγRI and FcγRIIIa are multichain receptors that associate with immunoreceptor tyrosine activation motif (ITAM)-containing γ- or ζ~- chain dimers (black cylinders) to mediate positive signaling. FcγRIIa and FcγRIIc are single chain stimulatory receptors containing ITAM motifs in their cytoplasmic tails. FcγRIIb (isoforms FcγRIIb1 and FcγRIIb2) are single chain inhibitory receptors containing immunoreceptor tyrosine inhibitory motif (ITIM) in their cytoplasmic tails (white cylinders). The cellular distribution of FcγRs is listed below each receptor: monocytes (Mo), macrophages (MΦ), dendritic cells (DC), mast cells (MC), B lymphocytes (B), platelets (Plt), natural killer cells (NK) and polymorphonuclear leukocytes (PMN). (Adapted from Salmon JE, Pricop L. Human receptors for immunoglobulin G: key elements in the pathogenesis of rheumatic disease. *Arthritis Rheum* 2001;44:739–750, with permission.)

FcγRI (CD64) is distinguished by its relatively high affinity for IgG (102). It is the only FcγR that is capable of binding monomeric IgG; other FcγRs require multivalent ligands. In contrast to the low-affinity FcγRII and FcγRIII, which have only two immunoglobulin-like domains homologous to the first two extracellular domains of FcγRI, FcγRI has three extracellular immunoglobulin-like domains, the last of which is postulated to confer high affinity (103 ,104 ,105) (Fig. 12-5). FcγRI is encoded for by at least three different genes, thus suggesting the possibility of the expression of different isoforms. Only FcγRIa has been detected on the cell surface. FcγRIa, a heavily glycosylated 72-kd protein, associates with homodimers of the γ-subunit of the high-affinity receptor for IgE (106) (Fig. 12-5). FcγRIa is present on monocytes, macrophages, and dendritic cells (107). Monocyte expression of FcγRI is markedly enhanced by interferon-γ (IFN-γ) (108 ,109), and neutrophils that do not constitutively express FcγRI can be induced to express this receptor by IFN-γ and granulocyte colony-stimulating factor (G-CSF) (110 ,111).

The FcγRII (CD32) family contains 40-kd receptors with low affinity for IgG, interacting only with IgG in complexes. They are the most widely expressed FcγR, and this family has the greatest range of structural heterogeneity. FcγRII family members are present on nearly all cells that bear FcγRs, including most leukocytes and platelets (112 ,113 ,114). Density of expression varies with cell type but generally is higher than that for FcγRI (115). The structural heterogeneity of FcγRII has a complex genetic basis with at least three genes (FcγRIIA, FcγRIIB, and FcγRIIC) and alternative splicing, resulting in the expression of six different isoforms (89 ,90 ,91 ,92 ,116) (Fig. 12-5). The three genes are nearly identical in their extracellular and transmembrane domains but differ in their cytoplasmic domains. The divergence in cytoplasmic tails determines the effector functions that are mediated by each isoform. FcγRIIA, FcγRIIB, and FcγRIIC represent single-protein gene products (α-chains) that are competent for ligand binding (extracellular domain) and signal transduction

(cytoplasmic domain incorporating structural motifs essential for signaling). This contrasts with the other FcγRs that assemble in multimolecular signaling complexes (Fig. 12-5). Among the FcγRII family members, there are activating and inhibiting receptors which differ mainly in the signaling motif in the cytoplasmic domain. FcγRIIA and FcγRIIC contain ITAMs and they are preferentially expressed on cells of myeloid lineage, monocytes, neutrophils, platelets and dendritic cells. FcγRIIC has recently been identified on NK cells (117).

FcγRIIB is the only FcγR gene encoding for an inhibitory receptor. It encodes for single-chain low-affinity receptors with extracellular domains highly homologous to FcγRIIA and FcγRIIC, but with cytoplasmic domains containing an ITIM (101) (Fig. 12-5). Alternative splicing generates two isoforms, FcγRIIb1 and FcγRIIb2, which differ only in their intracytoplasmic regions (116). FcγRIIb1 contains an insertion of 19 amino acids that significantly alters receptor function. FcγRIIb is widely expressed on hematopoetic cells: FcγRIIb1 on B lymphocytes and FcγRIIb2 on myeloid cells. Neither isoform can trigger cell activation. Instead, both isoforms of FcγRIIb, when coaggregated with ITAM-bearing receptors, are negative regulators of activation. In addition, FcγRIIb2 participates in endocytosis of multivalent ligands by phagocytes and antigen presenting cells while the intracytoplasmic insertion in FcγRIIb1 inhibits internalization (118). FcγRIIb can modulate cell activation by stimulatory FcγR, as well as responses triggered by B cell receptor (BCR), the T cell receptor (TCR), and Fc receptors for IgE (119). However, to inhibit cell activation, FcγRIIb must be co-aggregated with ITAM-expressing receptors by a multivalent ligand, and cell activation must be triggered by the receptors that are co-aggregated with FcγRIIb (120). For example, FcγRIIb co-aggregation with FcγRIIa by IgG-opsonized particles blocks phagocytosis, and FcγRIIb coligation to BCR by antibody-antigen complexes inhibits B cell proliferation and antibody production (121 ,122). Thus, FcγRIIb-mediated negative regulation of ITAM-dependent cell activation endows IgG-containing immune complexes with the capacity to regulate B cells and inflammatory cells. Because FcγRs are often expressed as activation/inhibitory pairs, the balance between stimulatory and inhibitory input determines cellular response.

In addition to different isoforms, there are two allelic forms of FcγRIIA (R131 and H131), resulting in further polymorphism in this receptor class. The FcγRIIA alleles differ functionally because of a single base difference that encodes for the amino acid position 131 in the second extracellular domain (arginine and histidine, respectively). These alleles are expressed codominantly on neutrophils, monocytes, and platelets and have differing IgG subclass-binding specificities (discussed later) (90 ,98 ,99). For FcγRIIb, allelic polymorphisms have been described in the promoter region which alter receptor expression (123).

The FcγRIII (CD16) family of low-affinity receptors for IgG contains two members, each of which is encoded for by different but highly homologous genes (FcγRIIIA and FcγRIIIB), and each is selectively expressed in specific cell types (90 ,91 ,124). FcγRIIIa is the most abundant class of FcγR on macrophages and thus is a key receptor of the mononuclear phagocyte system. It is present at high density on Kupffer cells in the liver and on macrophages in the spleen, both important areas for immune complex clearance binding and internalization. Additionally, it has been described on a subpopulation of monocytes (125) and on mesangial cells (126). One source of diversity between isoforms of FcγRIIIa is differences in glycosylation, which may account for the variations in receptor affinity noted for NK versus macrophage forms of FcγRIIIa and for FcγRIIIa versus FcγRIIIb (127). FcγRIIIa associates with members of a family of signal transduction molecules that bear ITAMs within their cytoplasmic domains (Fig. 12-5) (128). These molecules also are used by FcγRI and the high-affinity receptor for IgE and the T cell receptor/CD3 complex. These accessory molecules form disulfide-linked dimeric complexes (homo- or heterodimers) that noncovalently associate with the transmembrane region of FcγRIIIa to enable cell surface expression and signal transduction. FcγRIIIa also has the capacity to associate with the γ-subunit of the high affinity IgE receptor (129).

FcγRIIIb is the most densely expressed FcγR on neutrophils and therefore is the most abundant FcγR in the circulation. The major difference between the two subclasses of FcγRIII is that FcγRIIIa, which is the form expressed on macrophages and NK cells, is a conventional transmembrane protein, whereas FcγRIIIb, which is the form expressed exclusively on neutrophils, is anchored to the outer membrane leaflet by a glycosyl phosphatidylinositol moiety (130 ,131) (Fig. 12-5). Further diversity in FcγRIII structure is provided by an allotypic variation in FcγRIIIb. The two recognized allelic forms of the glycosyl phosphatidylinositol-anchored neutrophil isoform of FcγRIIIb, termed NA1 and NA2, differ by several amino acids and N-linked glycosylation sites (132 ,133). The alleles are inherited in a classic mendelian manner and are expressed in a codominant fashion. In addition to different isoforms, there are two allelic forms of FcγRIIIA (F176 and V176), which differ in one amino acid at position 176 in the extracellular domain (phenylalanine or valine, respectively) (100 ,134 ,135). These alleles differ in binding capacity for IgG1 and IgG3 (discussed later).

Another potentially important form of FcγR in the context of immune complex handling is circulating soluble receptor. Normal sera contain soluble FcγRII and FcγRIII (136 ,137). These soluble FcγRs lack transmembrane domains and presumably derive from alternative splicing or release from circulating leukocytes (136 ,137 ,138). The physiologic significance of these circulating IgG-binding proteins is not yet clear, but a proposed biologic function of plasma FcγRs is to suppress IgG production by B cells (139). The role of plasma FcγRs in immune complex clearance is open to speculation. Certainly, they may influence the clearance of immune complexes by blocking the ligand-binding site for FcγRs and thereby inhibiting both FcγR-mediated clearance and FcγR-triggered inflammation at sites of tissue deposition. Immune complex binding of plasma FcγR also has the potential to affect clearance by changing the size of the complexes, altering their solubility, modifying their capacity

to activate complement and capture C3b, and shifting binding from macrophage FcγRs to complement receptors.

Ligands

Ligand specificity for FcγRs is relative rather than absolute, and it depends on the valence or degree of opsonization of the study probe. Table 12-2 shows the binding specificity of human FcγRs for human IgG subclasses. The IgG subclass of the antibody in immune complexes and the valence of the complex influence the efficiency of the interaction with FcγRs (140). Further, a single immune complex may bind simultaneously to different classes of FcγR. FcγRI, the high-affinity receptor and the only FcγR capable of univalent binding of IgG (89 ,90), and FcγRII and FcγRIIIb, which are lower-affinity FcγRs, preferentially bind IgG1 and IgG3. There is differential binding affinity for allelic variants of FcγRIIIa (100). While the affinity of FcγRIIIa-expressed on macrophages and NK cells is higher than that of FcγRIIIb on neutrophils, the pattern of specificity for subclasses is similar for all FcγR (127). For all three classes of FcγR, IgG2 is the ligand with lowest affinity (Table 12-2), although studies have shown efficient binding to IgG2 by the H131 allele of FcγRIIa (discussed later) (98 ,99 ,141).

In addition to classic IgG-FcγR interactions, FcγR may bind ligands through lectin-carbohydrate interactions. The internalization of nonopsonized *Escherichia coli* bearing mannose-binding lectin requires neutrophil FcγRIIIb, which has high mannose oligosaccharides (142). Monocyte FcγRs also participate in lectin-carbohydrate interactions (143). These observations suggest that nonclassic engagement of FcγRs through lectin-carbohydrate interaction, perhaps by antigens in complexes, can affect clearance by phagocytes. Additionally, recent studies have shown that FcγRI and FcγRIIa are critical receptors for C-reactive protein (CRP) and that FcγRIIa is the main receptor on human phagocytes for CRP, which raises the possibility that FcγRs are important for the clearance of nucleosomes bound to CRP, which may also be influenced by allelic polymorphisms (144 ,145 ,146).

FcγR Signal Transduction

Effector cell activation is initiated when FcγRs are clustered at the cell surface by multivalent antigen-antibody complexes. Monovalent ligand binding is insufficient to generate a signal. Signal transduction by FcγR following aggregation involves a number of early cellular biochemical changes that lead to cellular activation. Like many other immune system receptors, such as the TCR and BCR, FcγR initiates tyrosine phosphorylation as a critical early signaling event (96 ,97). Stimulatory FcγRs have no intrinsic enzymatic activity, but are associated with membrane anchored src family kinases. The presence of two YxxL motifs separated by seven variable residues in the signaling subunit (γ-chain) of activating FcγRI and FcγRIIIa, or 12 residues in the case of FcγRIIa and FcγRIIc, is necessary for docking the protein tyrosine kinase syk and for initiation of positive signaling. Tyrosine kinases phosphorylate many intracellular substrates, including phospholipid kinases, phospholipases, adapter molecules, and cytoskeletal proteins. Activation of phospholipase C and phosphatidylinositol-3 (PI3) kinase by syk leads to the production of phosphoinositol messengers and a sustained increase in cytoplasmic Ca^{2+} (147). Recruitment of the adaptor protein shc allows signals triggered by FcγR to reach the nucleus via the ras pathway, leading to phosphorylation of mitogen-activated protein (MAP) kinase, activation of transcription factors, and induction of gene expression (148).

Table 12-2: FcγR Affinity and IgG Subclass Specificity

	MW(kD)	Genes	Affinity for IgG (Ka)	IgG Specificity
FcγRI	72	FcγRI	10^{8}–10^{9} M^{-1}	1, 3 > 4 ≫ 2
FcγRII	40–50	FcγRIIA-R131	<10^{7} M^{-1}	1, 3 ≫ 2, 4
		FcγRIIA-H131	<10^{7} M^{-1}	1, 3, 2 > 4
		FcγRIIB, C,	<10^{7} M^{-1}	1, 3 ≫ 2, 4
FcγRIII	60–70	FcγRIIIA	10^{7} M^{-1}	1, 3 > 2, 4
	50–80	FcγRIIIB	<10^{7} M^{-1}	1, 3 ≫ 2, 4

IgG, immunoglobulin; MW, molecular weight.

FcγRIIb isoforms are important negative regulators of ITAM-dependent activation and establish the threshold for effector cell activation. Inert when self-aggregated, inhibitory FcγRIIb abolishes cellular signals when co-ligated with stimulatory receptors. The ITIM motif (V/IxYxxL), contained in a 13-amino acid sequence present in the intracytoplasmic domain of both FcγRIIb1 and FcγRIIb2, is essential for the negative regulatory properties of FcγRIIb and other inhibitory receptors (reviewed in (149 ,150 ,151)). Like ITAMs, ITIMs are phosphorylated by protein tyrosine kinases and then recruit SH2-containing cytoplasmic molecules. Inhibitory function requires the recruitment of phosphatases to the phosphorylated ITIM. Although the protein tyrosine phosphatases SHP-1 and SHP-2 bind to FcγRIIb-phosphorylated ITIM motifs, the inositol polyphosphate 5′-phosphatase SHIP has been shown to be preferentially recruited to FcγRIIb and appears to play the predominant role in FcγRIIb-mediated inhibition by preventing Ca^{2+} influx (152 ,153 ,154).

Since most cells express more than one FcγR isoform, it is likely that antigen-antibody complexes coaggregate more

than one type of receptor. Coclustering of stimulatory FcγR represents a mechanism where different FcγR cooperate to amplify signals and produce more efficient activation of effector cells. FcγR that act synergistically transphosphorylate each other, leading to activation of tyrosine kinases and downstream substrates and initiation of $[Ca^{2+}]i$ transients, with subsequent cytoskeletal changes and transcriptional activation. In contrast, the regulation of ITAM-dependent cell activation by inhibitory FcγR is a mechanism for negative cooperation. Coclustering of inhibitory FcγRIIb with ITAM-bearing FcγR prevents the influx of extracellular Ca^{2+} and attenuates effector cell activation (149 ,150). By providing activated protein tyrosine kinases to phosphorylate the ITIM of FcγRIIb, stimulatory FcγRs play a role in their own inhibition. In cells that express both stimulatory and inhibitory receptors for IgG, the relative levels of these two types of receptors determine the state of cell activation after interaction with immune complexes.

FcγR-Mediated Effector Functions

The multivalent interaction of phagocytes with immune complexes leads to internalization of the complex, generation of reactive oxygen intermediates, and release of inflammatory mediators, including prostaglandins, leukotrienes, hydrolytic enzymes, and cytokines (e.g., IFN-γ, interleukin-6 [IL-6], tumor necrosis factor-α [TNF-α], and so on) (155 ,156 ,157 ,158 ,159). The role of individual isoforms of FγcRs in initiating these effector functions has been investigated in experiments using anti-FcγR monoclonal antibodies, cell lines with limited expression of FcγRs, and transfectants. There is significant overlap among the biologic activities mediated by each family of FcγR, and the relative contribution of each receptor family depends on the nature of the ligand, the state of phagocyte activation, and the effector function being assessed.

Binding and internalization are the most important effector functions for immune complex clearance. Experiments using erythrocytes coated with Fab fragments of anti-FcγR monoclonal antibodies show that in cultured human monocytes (a model system for fixed-tissue macrophages), FcγRI, FcγRIIa, and FcγRIIIa mediate phagocytosis (160). FcγRI is a key receptor on monocytes involved in the binding of IgG anti-(Rh)D-sensitized erythrocytes and small complexes in vitro (161). A role for FcγRIIIa is evident from studies showing that blockade of FcγRIII by infusion of anti-FcγRIII monoclonal antibody in humans and nonhuman primates inhibits clearance IgG anti-D-sensitized erythrocytes as well as clearance of soluble and erythrocyte-bound DNA/anti-DNA immune complexes, but to a lesser extent (Fig. 12-2) (47 ,162 ,163). Studies revealing an altered distribution of the allelic variants of FcγRIIa and FcγRIIIa in patients with lupus nephritis compared to control subjects without SLE highlight the importance of these receptors as inherited risk factors in the pathogenesis of SLE, presumably related to altered immune complex handling associated with the genotypes (discussed later). Taken together, these studies underscore the crucial role of each FcγR family in particulate and soluble immune complex handling by mononuclear phagocytes.

On neutrophils, while FcγRIIa mediates phagocytosis, the capacity of FcγRIIIb to independently mediate internalization is minimal (160 ,164 ,165). Although FcγRIIIb, the glycosyl phosphatidylinositol-anchored molecule, independently generates intracellular signals and initiates several other effector functions, it is conceptualized by some as a trap for circulating immune complexes that focuses IgG ligand for more efficient recognition by other FcγR species on neutrophils (91 ,160 ,166). Recent studies suggest a far more significant role for FcγRIIIb in triggering neutrophil responses—as a potentiator of other receptors on the cell. Crosslinking of FcγRIIIb enhances the amount of FcγRIIa-specific internalization, and coligation of FcγRII and FcγRIIIb results in a synergistic phagocytic response: internalization that is greater than the sum of the FcγRII and FcγRIIIb (165 ,166 ,167). This synergistic capacity of FcγRIIIb also enables complement receptor-mediated phagocytosis.

Regarding the intact phagocyte, the mechanisms triggering individual receptor-mediated function as well as engagement of multiple families of receptors in an interactive framework must be considered. In this context, studies of the ligation of individual receptor species (discussed earlier) demonstrate the functional potential of a given receptor. Alternatively, engagement of two receptors may lead to quantitatively, and perhaps qualitatively, distinct cell functions in relation to the engagement of either receptor alone. With engagement of mononuclear phagocyte FcγRs by immune complex, there are both heterotypic and homotypic receptor clusters, resulting in intracellular interactions between the signals that are generated by each receptor family. In monocytes, FcγRI and FcγRIIa cooperate in triggering activation, presumably by heterotypic clustering. In neutrophils, FcγRIIIb acts synergistically with FcγRIIa to mediate phagocytosis (166 ,167). Coaggregation of activating FcγR with inhibitory FcγRIIb alters the threshold and magnitude of effector functions. Interactions between FcγRs and other leukocyte receptors modulate FcγR-initiated functions; for example, engagement of complement receptor type 3 enhances FcγR-mediated phagocytosis by monocytes. In the interaction of immune complexes with leukocytes, effector function capacity is a consequence of positive and negative cooperation among FcγR families and between FcγRs and other receptors, all of which may be simultaneously engaged.

Cytokines elaborated during an immune response alter FcγR expression and functional capacity. For example, IFN-γ and G-CSF upregulate FcγRI on monocytes and induce its expression on polymorphonuclear cells (PMNs), whereas IL-4 inhibits the expression of all ITAM-bearing FcγR (168 ,169 ,170). Granulocyte-macrophage CSF (GM-CSF) specifically increases FcγRIIa, and transforming growth factor-β (TGF-β) increases FcγRIIIa (170). In contrast to their effects on stimulatory receptors, IFN-γ decreases and IL-4 increases the expression of the inhibitory receptor, FcγRIIb2, on human monocytes (171). It has been proposed that FcγRIIb functions to modulate inflammatory response by establishing the threshold

of immune complex-stimulated activation of macrophages. That IFN-γ (a prototypic T-helper-1 [Th1] cytokine) and IL-4 (a prototypic Th2 cytokine) differentially regulate the expression of FcγR isoforms with opposite functions provides a mechanism for regulation of activating and inhibitory signals delivered by FcγRs on phagocytes. Cytokines released within an inflammatory milieu thus act in an autocrine and paracrine manner to modulate effector cell function.

Inherited Differences in FcγRs

Mechanisms for the diversity of FcγR within an individual were discussed earlier. Inherited or acquired differences in FcγR structure, expression, or function provide the basis for differences in FcγR function between individuals, and these differences may contribute to disease susceptibility and pathogenesis. Heritable differences include gene deletions, promoter polymorphisms, and allelic forms. Individuals with the rare deficiency of FcγRIa1 are free of clinical disease, circulating immune complexes, and increased susceptibility to infection (172). The initial report of FcγRIIIb deficiency in a patient with SLE focused attention of the genetics of FcγR and immune complex disease (173). Defects in the expression of FcγRIIIb as a consequence of alterations at the genomic level have been identified in multiple unrelated individuals completely lacking FcγRIIIB alleles (174 ,175 ,176), but they have no consistent clinical pattern of increased infections or immune complex-mediated diseases (177). Although a second report of SLE in FcγRIIIb deficiency raises the possibility that this receptor functions in immune complex handling, perhaps as a carrier for circulating complexes, more extensive population and family studies are required (178).

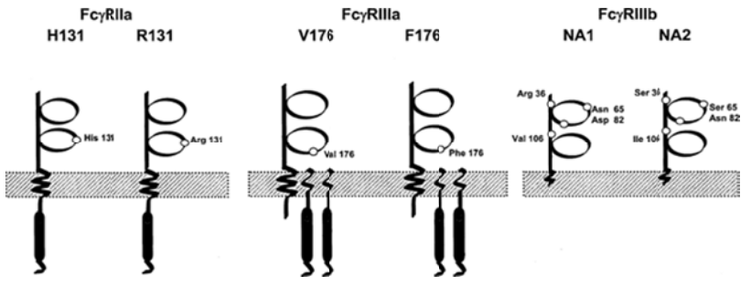

Figure 12-6. Allelic variants of activating human FcγR. Left: The FcγRIIa polymorphism is a consequence of an arginine (R131) to histidine (H131) substitution at amino acid position 131 in the extracellular domain, which causes differences in binding affinity for human IgG2 and C-reactive protein (CRP). Middle: The FcγRIIIa polymorphism is the consequence of a valine (V176) to phenylalanine (F176) substitution at position 176, leading to changes in binding affinity for human IgG1 and IgG3. Right: The NA1 and NA2 polymorphism of FcγRIIIb reflects four amino acid substitutions with consequent differences in N-linked glycosylation sites and quantitative differences in phagocytic function. (Adapted from Salmon JE, Pricop L. Human receptors for immunoglobulin G: key elements in the pathogenesis of rheumatic disease. *Arthritis Rheum* 2001;44:739–750, with permission.)

The concept that the balance of stimulatory and inhibitory FcγR is a determinant of the susceptibility to and severity of immune complex-induced inflammatory disease has been validated by data from murine models (12 ,13 ,14). Descriptions of deletions in the promoter region of FcγRIIB in all major autoimmune-prone mice strains have underscored these findings. These deletions are associated with a reduction in the expression and function of the inhibitory FcγRIIb on macrophages and activated B cells, defects that would be expected to promote autoimmunity (179 ,180 ,181). Furthermore, mice with targeted deletions of FcγRIIB develop autoantibodies and autoimmune glomerulonephritis in a strain-dependent fashion, related specifically to deficiency of FcγRIIb on B cells (182). As yet, there have been no reports of deficiency of inhibitory FcγRIIb function in antibody-mediated human disease. However, it is possible that differences in the relative expression of ITAM- and ITIM-containing FcγR influence an individual's risk of developing autoimmune disease. Indeed, polymorphisms in the promoter region of FcγRIIB which alter receptor expression are associated with alterations in cell function and enhanced autoimmunity (123 ,183).

Genetically determined alterations in FcγR structure provide a basis for inherited predisposition to disease. Allelic variants of human FcγR profoundly influence phagocyte biologic activity. Single amino acid substitutions within the extracellular domains of some stimulatory FcγR alter the capacity of these receptors to bind IgG and have been associated with risk for and phenotype of autoimmune and infectious disease (Fig. 12-6). Allelic polymorphisms have been identified in four FcγR family members: FcγRIIa, FcγRIIb, FcγRIIIa, and FcγRIIIb. Inherited variants of FcγR have differential binding avidity for different IgG subclasses.

FcγRIIa, expressed on mononuclear phagocytes, neutrophils, and platelets, has two codominantly expressed alleles, H131 and R131, which differ at amino acid position 131 in the extracellular domain (histidine and arginine, respectively), an area which strongly influences ligand binding (Fig. 12-6). The allelic variants differ substantially in their ability to bind human IgG2 (98 ,99 ,118 ,184). FcγRIIa-H131 is the high binding allele and R131 is low binding, while heterozygotes have intermediate function. Because IgG2 is a poor activator of the classical complement pathway, FcγRIIa-H131 is essential for handling IgG2 immune complexes. Even with model immune complexes containing IgG2 in combination with other IgG subclasses, there is differential handling in PMNs from homozygous individuals related to host FcγRIIA genotype (11). The genotype distribution of FcγRIIA in Caucasian and African American populations is approximately 25% homozygous for H131, 50% heterozygous, and 25% homozygous for R131. Among Asians the frequency of the R131 allele is much lower, and less than 10% of the population is homozygous for R131 (reviewed in (185)).

FcγRIIa has substantial clinical importance for host defense against infection with encapsulated bacteria known to elicit IgG2 responses, such as *Neisseria meningitidis*, *Hemophilus influenzae*, and *Streptococcus pneumoniae* (186 ,187 ,188). There is an increased frequency of homozygosity for FcγRIIa-R131 among otherwise healthy children who suffer from recurrent respiratory tract infections or fulminant meningococcal sepsis. FcγRIIa-R131 has also been shown to be a risk factor for invasive pneumococcal infection in patients with SLE (189). Like IgG2, CRP binds to several encapsulated bacteria. The recent report of a reciprocal relationship between the binding affinities of IgG2 and CRP for FcγRIIa suggests a mechanism for partial protection from invasive infection in individuals homozygous for FcγRIIa-R131 (145). That FcγRIIa is the main receptor for CRP raises the possibility that handling of nucleosomes bound to CRP may also be influenced by allelic polymorphisms (146).

FcγRIIIa, expressed on mononuclear phagocytes and NK cells, also displays codominantly expressed biallelic variants, F176 and V176, which differ in one amino acid at position 176 in the extracellular domain (phenylalanine or valine, respectively) (100 ,134 ,135) (Fig. 12-6). FcγRIIIa alleles differ in IgG1 and IgG3 binding; V176 homozygotes bind IgG1 and IgG3 more avidly than F176. These differences in IgG binding have implications for antibody-mediated immune surveillance, (antibody-dependent cell-mediated lytotoxicity toxicity [ADCC]), antibody-mediated host defense against pathogens and autoimmune disease. The distribution of genotypes of FcγRIIIA in disease-free Caucasian and African-American populations has been reported to be 40% to 50% homozygous F176, 40% to 50% heterozygous, and 8% to 18% homozygous V176 (185).

Two common allelic variants of FcγRIIIb, a receptor exclusively expressed on neutrophils, have been characterized and shown to alter neutrophil function. The allotypes, known as neutrophil antigen (NA) 1 and NA2, were identified as a consequence of their involvement in blood transfusion reactions and alloimmune neutropenias. They differ by five nucleotides, which results in a substitution of four amino acids in the membrane-distant first extracellular domain (133) (Fig. 12-6). Although binding of IgG does not seem to be affected, the NA1 and NA2 allelic forms do have different levels of quantitative function (99 ,167 ,190 ,191). Neutrophils obtained from NA1 homozygous donors have a more robust FcγR-mediated phagocytic response as compared to cells from NA2 donors, despite equivalent receptor density (190 ,191). Functional differences between the NA1 and NA2 alleles appear to have clinical significance. Homozygous NA1 individuals may be more resistant to bacterial infection, especially when FcγRIIa cannot be effectively engaged, as suggested by the finding of increased *Neisseria meningitidis* infection among hosts with complement component 6 or 8 deficiency who are homozygous for FcγRIIIb-NA2 and FcγRIIa-R131 (192).

Polymorphisms in FcγRIIb that alter signaling and variations in the promoter region that alter gene expression have recently been described. A single amino acid substitution in the transmembrane domain of FcγRIIb, replacement of 232 isoleucine with threonine (Fcγ RIIb232 I/T), leads to attenuated function (193). Fcγ RIIb-T232 is excluded from lipid rafts and is thus unable to inhibit activatory receptors resulting in the unopposed proinflammatory signaling thought to promote SLE (194 ,195). In addition to its expressions of mononuclear phagocytes and dendritic cells, FcγRIIb is present on B cells and plays crucial role in the maintenance of self-tolerance. Less potent inhibition of B cells receptor signaling associated with Fcγ RIIb-T232 alleles may favor autoimmunity and thus contribute to susceptibility for lupus. Single nucleotide polymorphisms in the promoter of FcγRIIB have also been identified which correlate with altered gene transcription and surface expression of Fcγ RIIb (123 ,183 ,196).

Studies of the allelic polymorphisms of FcγR demonstrate functional consequences of subtle structural differences, and these models suggest the potential impact of the rich structural diversity in FcγRs on immune complex handling.

Abnormalities in Fcγ Receptors in SLE

FcγR saturation by circulating immune complexes with decreased receptor availability was initially proposed as a potential mechanism for defective FcγR-mediated clearance (64). The complexity of FcγR structure was not appreciated at the time of these studies, however. Support for this hypothesis was derived from in vitro induction of loss of surface FcγRs in monocytes by culture with immune complexes (197 ,198) and in vivo production of mononuclear phagocyte blockade by infusion of immune complexes (4). Even so, several different studies of blood monocytes from patients with SLE demonstrated an increase rather than the predicted decrease in FcγR binding (199 ,200 ,201). In experiments quantitating the binding of monomeric IgG, oligomeric IgG, and IgG-sensitized erythrocytes to monocytes, there was an increase in the levels of binding in patients with SLE compared with the levels in controls. The observed increase in FcγR binding correlated with SLE disease activity in some studies and thus was highest in the population most likely to

have the greatest abnormality in FcγR-mediated clearance (199). In other studies, FcγR binding directly correlated with levels of immune complexes (202). Whether the increased binding capacity is specific to one class of FcγR or generalized is not known. The basis for the observed increase in patients with SLE is speculative, but this increase may result from exposure to cytokines and cellular activation (143 ,202 ,203).

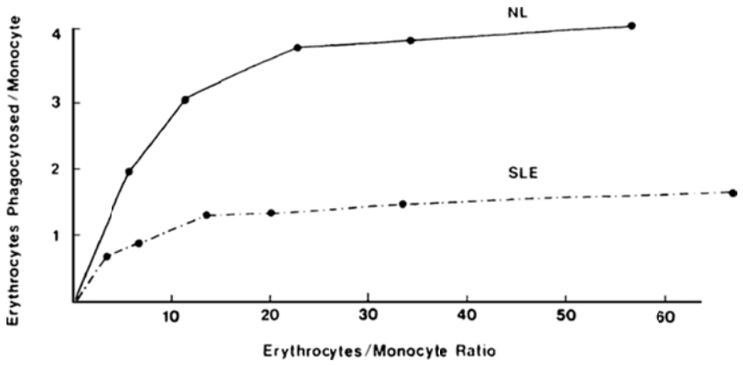

Figure 12-7. In vitro phagocytosis of 51Cr-labeled IgG sensitized erythrocytes (EAs) by monocytes from normal volunteers ("-") and patients with SLE ("- • - ") was measured at various ratios of erythrocytes to monocytes. Phagocytic capacity was dependent on the ratio of erythrocytes to monocytes in the incubation mixture. At all ratios, the patients with SLE had lower FcγR-mediated internalization. (From Salmon JE, Kimberly RP, Gibofsky A, et al. Defective mononuclear phagocyte function in systemic lupus erythematosus: dissociation of Fc receptor-ligand binding and internalization. *J Immunol* 1984;133:2525–2531, with permission.)

Despite enhanced binding of FcγR ligand in vitro, FcγR-mediated phagocytosis of IgG-sensitized erythrocytes was markedly impaired in monocytes derived from patients with SLE (201) (Fig. 12-7). The defect in phagocytosis in vitro was most profound in those patients with the most significantly impaired in vivo mononuclear phagocyte system clearance. These observations, along with those from other studies demonstrating a correlation between in vivo clearance and in vitro FcγR phagocytosis, support the role of defective phagocytosis as an important component of altered FcγR-mediated clearance (77 ,86). The dissociation of FcγR-mediated binding and FcγR-mediated internalization suggests relative receptor-effector uncoupling. Because the probes used in these studies could not discriminate among the FcγR expressed on monocytes, the contribution of a given class (or classes) of FcγR to this dysfunction is not yet known.

The net FcγR-mediated phagocytic capacity in SLE is a result of at least two factors. The first is inherited, such as that associated with allelic polymorphisms of FcγR; the second is disease acquired and may be related to disease activity. It has been hypothesized that low binding FcγR alleles are susceptibility factors for SLE. Association studies indicate that FcγRIIa-R131 and FcγRIIIa-F176 alleles are highly enriched in some groups of patients with SLE (204 ,205 ,206 ,207 ,208 ,209). In the initial studies with African Americans, a group with a high prevalence and severity of SLE, an association between FcγRIIA alleles and lupus nephritis was described (204). There was an increased frequency of FcγRIIA-R131 gene in the patients with SLE and a corresponding decrease in FcγRIIa-H131, the only human FcγR with the ability to efficiently recognize human IgG2 in black patients with lupus (Fig. 12-6). The skewing in FcγRIIA gene distribution was most marked in the nephritis group as compared with control subjects without SLE. The H131/H131 genotype was uncommon among patients with nephritis, suggesting that FcγRIIA-H131 plays a protective role in the homozygous state, an idea that is supported by in vitro experiments showing that the FcγRIIa-R131 gene product is characterized by deficient IgG2 handling in both homozygotes and heterozygotes. Thus, it appears that FcγRIIa-R131/R131 homozygotes and R131/H131 heterozygotes, who have the potential for less-efficient immune complex clearance, are at a greater risk for immune complex deposition. Similar results have been observed for FcγRIIIA. There is a strong association of low binding F176/F176 genotype (Fig. 12-6) with SLE, especially nephritis, and a corresponding under-representation of the homozygous high binding V176/V176 genotype (100). As a consequence of these studies, FcγR were considered the first non-major histocompatibility complex (MHC) genes associated with SLE. Indeed, there is evidence from a genome-wide scan of linkage of the region of the FcγR gene cluster on chromosome 1 with SLE (210).

Although homozygosity for low binding alleles at either the FcγRIIA or the FcγRIIIA locus can lead to impaired binding of immune complexes, an association between low binding alleles of FcγR and lupus, and especially lupus nephritis, has not been demonstrated in all ethnic groups studied (100 ,204 ,211 ,212 ,213). Nonetheless, one meta-analysis of studies seeking to establish a relationship between SLE and FcγR variants showed that FcγRIIa-R131 is associated with SLE, especially in African Americans, and that FcγRIIIa-F176 is associated with SLE in Caucasians and in other groups (182). More recent meta-analyses (comprising more than 3000 patients) suggested that FcγRIIa confers a risk for SLE, but not for nephritis and that the population attributable fractions of SLE cases because of FcγRIIa-R131 were 13%, 40%, and 24%, in subjects of European, African, and Asian descent, respectively (214). In contrast, FcγRIIIa low binding alleles confer a risk for lupus nephritis in these populations, but is not a significant susceptibility factor in the absence of nephritis (215). Even within ethnic groups where associations have been demonstrated, there have been conflicting results. Such lack of uniformity has been ascribed to population admixture, lack of appropriate internal controls, differences in disease phenotype, and the confounding influence of other inherited susceptibility factors.

An alternative explanation for these inconsistencies is that the role of specific loci varies with the qualitative nature of the immune response. Differences in the IgG subclass of pathogenic autoantibodies have a profound effect on the relative importance of FcγR alleles in disease. For example, in the presence of anti-C1q antibodies, which correlate with severe renal disease and are largely of the IgG2 subclass, FcγRIIA genes appear to play a crucial role in determining disease severity (216 ,217). Two studies have found that FcγRIIa-R131 alleles were associated with renal disease among Caucasian lupus patients with anti-C1q antibodies, whereas analysis of

the population as a whole revealed no significant difference in the frequencies of FcγRIIa-R131 and -H131 alleles compared with controls (216 ,217). Indeed, IgG2 is a predominant IgG subclass found in glomeruli of patients with proliferative nephritis. In a recent study, the frequency of genotypes containing the low-binding IgG2 allele, FcγRIIa-R131, was significantly greater than expected in patients with class III or class IV nephritis and in patients with intense IgG2 deposition. CRP, a ligand with particular affinity for FcγRIIa-R131, was consistently present in the renal immune deposits of lupus nephritis specimens (218). Thus, with precisely defined phenotypes, FcγRIIa variants have been identified as disease modifiers, in this example, conferring inherited risk for nephritis.

The finding that other autoantibodies associated with nephritis, specifically antidouble-stranded DNA (dsDNA) and antinucleosome antibodies, are predominantly IgG1 and IgG3 supports the importance of FcγRIIIA variants as disease modifying genes (219 ,220). For both FcγRIIa and FcγRIIIa, optimal handling of pathogenic immune complexes is provided only in the homozygous state for high binding alleles; heterozygotes at either locus have intermediate-binding capacity. Low affinity for IgG2-containing immune complexes by FcγRIIa-R131 and for IgG1 and IgG3 by FcγRIIIa-F176 results in impaired removal of circulating immune complexes, increased tissue deposition, and accelerated organ damage. An alternative explanation for the association of FcγRIIA and FcγRIIIA with lupus is that these genes are in linkage disequilbrium with other candidate proteins. The fact that IgG2 and IgG3 subclasses are present in immune deposits of proliferative glomerulonephritis, however, supports a role for both FcγR genes in conferring risk for SLE and the possibility that these receptors act additively in the pathogenesis of disease (221 ,222 ,223).

The relative importance of interactions between alleles and the potential role of linkage disequilibrium between two FcγR genes within the same cluster on chromosome 1q21-23 is not yet established. However, in a cohort of Hispanic patients with a high prevalence of lupus nephritis there was selection for haplotypes containing both FcγRIIa-R131 and FcγRIIIa-F176 (224). Given that the distance between any of the low affinity FcγR genes is less than 300 kilobases (kb), linkage disequilibrium of haplotypes might be expected (94 ,95). Studies in multiplex SLE pedigrees have demonstrated linkage disequilibirum between adjacent genes within the FcγR cluster on chromosome 1 (225). Furthermore, subtle variations in genes controlling immune function, which may have little or no effect in the general population, can assume greater significance in individuals with autoimmune diatheses.

Allelic polymorphisms in inhibitory FcγRIIb have also been associated with SLE in population studies. The FcγRIIb232I/T substitution in the transmembrane domain affects the localization and function of FcγRIIb and the less inhibiting 232T/T genotype occurs more commonly in Japanese, Thai and Chinese lupus patients than in ethnically similar controls, pointing toward FcγRIIB as a common susceptibility gene in the Asian populations (193 ,226 ,227). There is no evidence of skewing of the distribution of these alleles in European Americans of African American SLE patients (228 ,229). Promoter variants have also been described for FcγRIIB. An uncommon polymorphism (G-C substitution at position –343 relative to the start of transcription) leading to decreased FcγRIIb expression and function in activated B cells has been associated with SLE in Caucasians (196). According to the linkage disequilibrium analysis and conditional tests of association within the FcγR cluster, the association of FcγRIIB with SLE does not represent disequilibrium with FcγRIIA or FcγRIIA (123).

The physiology of stimulatory and inhibitory FcγR alleles provides a new framework within which the interplay between humoral immune response and host genotype may be defined and heritable risk factors for disease susceptibility and disease severity may be identified.

In addition to FcγR dysfunction, there is impaired phagocytosis of other probes in SLE monocytes. Internalization of apoptotic cells is decreased in SLE which may promote autoimmunity (230). Additionally, reduced uptake of nonopsonized particles and complement-opsonized particles has been clearly demonstrated in SLE monocytes (196 ,231). Thus, as predicted by the in vivo clearance studies, there are bipartite defects in internalization by SLE monocytes, dysfunction of FcγRs and complement mechanisms (67 ,68).

Collectively, in vivo clearance data and in vitro monocyte data indicate that FcγRs play a central role in immune complex handling. Regarding conditions with decreased complement-dependent immune complex uptake by fixed tissue macrophages, such as hypocomplementemia or deficiency in erythrocyte CR1 receptors, both of which are seen in SLE, it has been proposed that FcγR-mediated clearance mechanisms can handle both complement- and noncomplement-fixing complexes. In contrast, even in the face of intact complement mechanisms, immune complexes that do not fix complement, or that fix complement poorly (e.g., such as IgG2 containing complexes), are cleared less efficiently if there is abnormal FcγR-mediated function (Fig. 12-1). In this context, the observations that normal subjects with HLA haplotypes associated with SLE handle an erythrocyte-bound FcγR ligand probe less efficiently and that allelic variants of FcγR have distinct functional capacities provide a compelling argument that certain individuals may be at higher risk for the development of immune complex disease (232). In contrast to the complement system, the defect in FcγR function in SLE is not associated with decreased receptor number or saturation, but rather with a dissociation of receptor-ligand binding and internalization superimposed on possible inherited differences in FcγR function (199 ,200 ,201).

Strategies for Modulating FcγR-Mediated Immune Complex Clearance

The emerging picture of the extensive structural diversity of human FcγRs, the importance of FcγRs in immune complex clearance, and the evidence for FcγR dysfunction in SLE presents the opportunity for novel treatment strategies.

A variety of cytokines can regulate total receptor expression, modulate relative isoform predominance, and modulate receptor function (115). For example, in vivo and in vitro studies have shown that IFN-γ and G-CSF upregulate FcγRI expression (108 ,115 ,233 ,234) and that TGF-ß, IFN-γ, and M-CSF upregulate FcγRIIIa on monocytes (170 ,235) while IL-4 and IL-13 downregulate expression of all three classes of stimulatory FcγRs (189 ,236). In contrast, IL-4 increases the expression of FcγRIIb2 on monocytes (171). The identification and utilization of cytokines that increase the ratio of expression of inhibitory and stimulatory FcγR represents a new approach for the treatment of autoimmune diseases. Similarly, targeted pharmacologic manipulation of protein kinases or phosphatases may yield effective treatments.

Steroid hormones also have major effects on FcγR expression and function. Estrogens augment and progesterones inhibit (237 ,238), but steroid effects may vary with the level of activation of the mononuclear system (239). For example, glucocorticoids enhance the IFN-γ-induced augmentation of monocyte FcγR function, whereas alone they are inhibitory for normal donors (240 ,241 ,242 ,243 ,244). Interestingly, for monocytes from patients with SLE, which may be primed in vivo with IFN-γ (245 ,246 ,247), glucocorticoids enhance function. Patients with active SLE who are treated with high-dose intravenous pulse methylprednisolone have improved clearance of IgG-sensitized autologous erythrocytes, enhanced monocyte FcγR expression and phagocytosis, and decreased levels of circulating immune complexes (203). These data raise the possibility that pharmacologic therapies can act synergistically with endogenous cytokines to achieve the desired outcome.

Endogenous and pharmacologic agents also modify FcγR function either directly or as consequence of interacting with cytokines to alter net FcγR function (203 ,248). Released at sites of tissue injury, adenosine interacts with two classes of cell surface receptors on macrophages. Occupancy of high-affinity adenosine A1 receptors enhances FcγR-mediated internalization, whereas ligation of low-affinity adenosine A2 receptor is inhibitory (249). The rapid and potent modulation of FcγR-mediated function suggests that adenosine is an important local regulator of the inflammatory response, and that receptor-specific adenosine analogues may provide novel therapies for immune complex disease.

The complement split product C5a, which is generated at sites of immune complex-triggered inflammation, upregulates activating FcγRIIIa expression and downregulates inhibitory FcγRIIb expression on macrophages, providing a mechanism beyond its anaphylatoxin activity, to augment immune-mediated tissue damage (250). By altering the balance of activation/inhibitory FcγR, C5a, TNF, and IFN-γ lower the threshold of activation of effector cells. In contrast, the antiinflammatory property of intravenous gamma globulin (IVIG), a therapy for some autoimmune diseases, induces increased surface expression of FcγRIIb on macrophages in mouse models of antibody-mediated tissue injury. Disruption of inhibitory FcγRIIb either by genetic deletion or with a blocking monoclonal antibody reversed the therapeutic effect of IVIG (251). Taken together these studies indicate that modulation of inhibitory signaling, thereby raising the threshold required for immune complexes to trigger activation, is a potent therapeutic strategy for attenuating autoantibody–triggered inflammatory diseases.

Soluble FcγR may be novel anti-inflammatory agents. Circulating forms of FcγRII and FcγRIII are present in normal individuals (136 ,137). In animal models, infusion of soluble FcγR inhibits immune complex-mediated activation of phagocytes by blocking access to FcγR on effector cells (252). Circulating FcγR have also been shown to suppress IgG production by B cells and may therefore be immunosuppressive (253). With the development of soluble TNF receptors and soluble complement receptors as therapeutic modalities, one can envision the use of soluble FcγRs to block antibody-mediated tissue injury (254 ,255). The unique properties of different FcγRs—affinity and IgG subclass preference—could be exploited to target specific pathogenic antibodies with specific soluble FcγR variants.

With our increasing recognition of the role of FcγRs in the pathophysiology of SLE and such a range of receptor-modulating agents, successful therapeutic intervention will be feasible and form the basis of further advances in the treatment of SLE.

Summary

- Properties of antigens and antibodies are important in determining the fate and pathogenic potential of immune complexes.
- Efficiency of mononuclear phagocyte system immune complex clearance depends on the function of Fcγ receptors (receptors recognizing the Fc region of immunoglobulin) and the complement receptors.
- SLE is characterized by impaired Fcγ receptor-dependent and complement-dependent mononuclear phagocyte function resulting in inadequate clearance and tissue deposition of immune complexes.
- Genetic variations in Fcg receptors influence antibody binding and pathologic effects of immune complexes.

Chapter 13

Complement and Systemic Lupus Erythematosus

Chau-Ching Liu

Joseph M. Ahearn

Historical Overview

The complement system is arguably linked more intimately to systemic lupus erythematosus (SLE) than to any other human disease. This association has been recognized for decades and, until recently, was viewed as inexplicably paradoxical. Two seemingly irreconcilable early observations formed the foundation for this conundrum. First, in 1951, Vaughan et al. were the first to assay serum complement in cases of SLE (1). They determined from four cases that diminished CH_{50} correlated with disease activity. Elliott and Mathieson confirmed this and noted complement depression to be particularly associated with “albuminuria” (2). Lange et al. discovered complement to be diminished in virtually all cases of acute, but not in chronic, glomerulonephritis, while low complement was characteristic of SLE whether or not there was renal involvement (3). Schur and Sandson, in the largest study to that time, found CH_{50} to be below 50% of normal in 24% of patients with active SLE, and in 46% of those with renal involvement, but in only 4% with inactive disease (4). Schur suggested that complement levels were of particular value in following and evaluating patients with SLE, especially those with nephritis. These seminal observations were followed by a large body of work from many laboratories demonstrating that complement activation, reflected by diminished serum levels of C3, C4, and CH_{50}, plays a major role in the tissue inflammation and organ damage that result from lupus pathogenesis.

Seemingly paradoxical to these findings was a second set of observations that demonstrated a strong association between hereditary homozygous deficiency of the classical pathway components and development of SLE (5 ,6 ,7). In fact, inherited complement deficiency is still recognized as conferring the greatest known risk for development of SLE. Thus, for decades this paradox has been pondered. How is it that complement deficiency may be causative in SLE, yet activation of this same inflammatory cascade is detrimental in patients who already have the disease?

Discoveries made during the past several years have begun to explain this perplexing link between complement and SLE and have concomitantly identified potential strategies and opportunities for mining the complement system for lupus genes, biomarkers, and therapeutics. In this chapter we will review the biology of the complement system in relation to SLE, summarize common methods for measurement of complement, revisit the utility of complement assays in clinical management of SLE, and consider the potential for targeting the complement system for therapeutic intervention.

Biology of the Complement System

The complement system comprises more than 30 plasma and membrane-bound proteins that form three distinct pathways (classical, alternative, and lectin) designed to protect against invading pathogens (8 ,9 ,10 ,11) (Fig. 13-1). Many of the complement proteins exist in plasma as functionally inactive pro-proteins until appropriate events trigger their activation. Once activated, the proteins within each pathway undergo a cascade of sequential serine protease-mediated cleavage events, release biologically active fragments, and self-assemble into multimolecular complexes. In general, activation of the complement system can be viewed as a two-stage process. The first stage, unique to each of the three activation pathways, involves the early complement components that lead to the formation of the C3 convertases. The second stage, common to all three pathways once they converge, results in the formation of a lytic complex consisting of the terminal complement components (Fig. 13-1).

Complement Activation Pathways

The classical pathway of complement activation, which is responsible for executing a major effector mechanism of antibody-mediated immune responses, is thought to play an important role in SLE pathogenesis. There are five proteins specific to activation of the classical pathway: C1q, C1r, C1s, C4, and C2 (Fig. 13-1). Activation of this pathway begins when C1q binds to the Fc portion of IgG (particularly IgG1 and IgG3) or IgM molecules that are bound to an antigen. The binding of C1q to an antigen-antibody complex (immune complex) leads to activation of C1r (a serine protease), which, in turn, leads to activation of C1s (also a serine protease). C1s enzymatically cleaves the other two classical pathway proteins, C4 and C2, generating and releasing two small soluble

polypeptides, C4a and C2b. At the same time, this proteolytic cleavage leads to the formation of a surface-bound bimolecular complex, C4b2a, which functions as an enzyme and is referred to as the classical pathway C3 convertase. Recent studies have shown that in addition to immune complexes, a variety of other molecules can also initiate activation of the classical pathway by interacting with C1q. These include C-reactive protein (12), amyloid P component (13), ß-amyloid protein (14 ,15), and DNA (16).

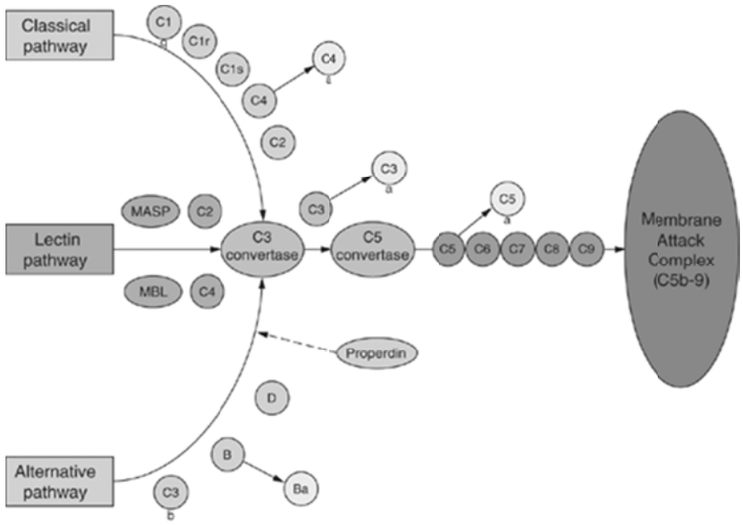

Figure 13-1. Overview of the complement system and activation pathways.

Activation of the alternative pathway is not dependent on antibodies or other specific recognition molecules. Three plasma proteins are unique to the alternative pathway: Factor B, Factor D, and properdin (Fig. 13-1). Normally, native C3 molecules undergo a so-called “C3 tickover” process, a continuous, low-rate hydrolysis of the thioester group that generates iC3* (hydrolyzed C3) and subsequently C3b fragments (17). A fraction of these spontaneously generated C3b fragments may covalently attach to the surface of microbial pathogens and host cells via thioester bonds. The bound C3b molecules are capable of binding Factor B. Once bound, Factor B is cleaved into Ba and Bb fragments by Factor D (a serine protease). While the small, soluble Ba fragment diffuses away from the activation site, the Bb fragment remains associated with C3b. Similar to the C4b2a complex in the classical pathway, the surface-bound C3bBb complex serves as the alternative pathway C3 convertase. The C3bBb complexes, if bound to mammalian cells, will be rapidly degraded by several regulatory proteins, thereby preventing self-damage of the host cells and tissue. However, the C3bBb complexes associated with microbial pathogens, which do not generally express these regulatory proteins, will remain intact and can be further stabilized by the binding of properdin.

The lectin pathway shares several components with the classical pathway (Fig. 13-1). Initiation of the lectin pathway is mediated through the binding of mannose-binding lectin (MBL; also known as mannose-binding protein [MBP]) to a variety of repetitive carbohydrate moieties such as mannose, *N*-acetyl-D-glucosamine, and *N*-acetyl-mannosamine, which are abundantly present on a variety of microorganisms (18 ,19). MBL, a plasma protein composed of a collagen-like region and a carbohydrate-binding domain, is structurally similar to C1q. As in the case of the C1qC1rC1s complex, MBL forms complexes in the plasma with other proteins such as mannose-binding protein-associated serine proteases (MASPs) (20 ,21 ,22). Under physiologic conditions, MBL does not bind to mammalian cells, probably because these cells lack mannose residues on their surface. Once bound to microbial pathogens, MASPs can cleave C4 and initiate the complement cascade. Alternatively, MBL, in place of C1q, may trigger the activation cascade by activating C1r and C1s. At this point, the lectin pathway intersects with the classical pathway and a C3 convertase, i.e., the C4b2a complex, is eventually generated.

C3 convertases, generated during the first stage of complement activation, cleave C3, the central and most abundant component of the complement system. This proteolytic cleavage gives rise to a smaller C3a fragment and a larger C3b fragment. The C3b molecules associate with C4b2a or with C3bBb complexes to form the classical and alternative C5 convertases. The C5 convertases cleave C5 and initiate activation and assembly of the terminal components, C5, C6, C7, C8, and C9, into the membrane attack complex (MAC; C5b-9) on the surface of foreign pathogens.

Effector Functions of Complement

The complement system is traditionally thought to have four biological functions in protecting against invasion by pathogens: (1) opsonization, (2) activation of

inflammation, (3) clearance of immune complexes, and (4) osmotic lysis of invading microorganisms (8 ,9 ,10 ,11). During SLE pathogenesis, complement activation and its inflammatory consequences are generated by self-antigens and autoimmune complexes rather than by foreign microbes.

The soluble proteolytic fragments, C3a, C4a, and C5a, are highly potent pro-inflammatory molecules. They attract and activate leukocytes by binding to specific receptors (e.g., C5a receptor) expressed on those cells. The larger fragments, C3b, C4b, and their derivatives (e.g., iC3b and iC4b), can remain bound to the surface of microbial pathogens (or autoantigens) and facilitate recognition and uptake of the opsonized particles by phagocytic cells. This function is mediated through the binding of these complement-derived fragments to complement receptor 1 (CR1) (for C3b and C4b), CR3 (for iC3b), and CR4 (for iC3b) expressed on phagocytes.

The binding of C4b and C3b to immune complexes also prevents their aggregation into insoluble complexes and enhances their clearance. The clearance of C3b/C4b-opsonized immune complexes is mediated by erythrocytes that express CR1 and are capable of transporting immune complexes to macrophages of the reticuloendothelial system in the spleen and liver (23 ,24). In addition, C3b/C4b-opsonized immune complexes may bind to B lymphocytes, monocytes, and neutrophils. Phagocytosis of opsonized immune complexes by neutrophils and monocytes is often accompanied by release of lysosomal enzymes. Finally, the C5b-9 MACs may perturb the osmotic equilibrium and/or disrupt the integrity of the surface membrane of target cells, thereby causing lysis of these cells.

For several decades, the role of the complement system was thought to be limited to these four effector functions. However, there has been a recent explosion in discovery of additional roles for complement, particularly as link between innate and adaptive immunity (25 ,26).

Regulators of Complement Activation and Complement Receptors

In humans and other mammals, complement activation is controlled by a redundant family of regulatory proteins to ensure that this effective machinery is not inappropriately activated by host cells and tissues (Table 13-1). To control the potent consequence of complement activation, soluble or cell-surface regulatory molecules need to act at multiple steps of the activation pathways using different mechanisms, functioning as proteolytic enzymes, cofactors for proteolytic enzymes, or competitive inhibitors of multi-molecular convertases (Fig. 13-2).

Receptors for proteolytic fragments of complement proteins (e.g., C3b, C4b, iC3b, C3d) and, in some circumstances, for complement proteins with altered conformation (e.g., C1q) are expressed by a wide spectrum of cells and serve pivotal roles in executing many of the effector functions of complement described above. Recent studies have led to the identification of at least four receptors for C1q, cC1qR (calreticulin; a collectin receptor), gC1qR, C1qRp, and CR1 (CD35) (27 ,28 ,29 ,30). Binding of C1q-opsonized immune complexes to endothelial cells via C1q receptors has been reported to induce expression of adhesion molecules on endothelial cells and thus enhance leukocyte binding/extravasation (31). On other cell types, C1q binding, presumably via distinct receptors, has been shown to enhance phagocytosis, increase generation of reactive oxygen intermediates, and activate platelets (32 ,33 ,34).

CR1 (CD35) and CR2 (CD21), two major receptors for C3- and C4-derived fragments, belong to the “Regulators of Complement Activation (RCA)” family (35 ,36). CR1 is widely expressed by erythrocytes, neutrophils, monocytes/macrophages, B lymphocytes, some T lymphocytes, and glomerular podocytes (37 ,38 ,39). CR1 binds primarily C3b and C4b. One important function of CR1 expressed on erythrocytes is to bind and clear immune complexes (23 ,24).CR1 also plays a role in regulation of complement activation by serving as a cofactor for Factor I, which is responsible for cleaving C3b and C4b to iC3b and iC4b (40 ,41). CR2 is expressed mainly on B lymphocytes, activated T lymphocytes, and follicular dendritic cells, and binds primarily iC3b, C3dg, and C3d (42 ,43 ,44 ,45 ,46). CR2, together with its cognate complement ligands, is a critical link between the innate and adaptive immune systems (26 ,47). For example, coligation of CR2 (as part of the CD19/CD21/CD81 B cell coreceptor complex) and B cell receptors on the surface of B lymphocytes via the binding of C3d-decorated immune complexes or antigens enhances B cell activation, proliferation, and antibody production (47 ,48 ,49). Antigens and immune complexes opsonized by C3-derived fragments can be retained in the germinal centers of secondary lymphoid follicles via binding to CR2 expressed on follicular dendritic cells (43 ,44); the retained antigens provide essential signals for survival and affinity maturation of B cells as well as for generation of memory B cells (50).

CR3 and CR4 belong to the ß2 integrin family and are composed of two subunits: a common ß chain (CD18) and a specific α chain (CD11b in CR3 and CD11c in CR4). These receptors are expressed on phagocytic cells (e.g., neutrophils, monocytes, and macrophages), antigen-presenting cells (e.g., dendritic cells), and follicular dendritic cells (51 ,52). CR3 and CR4 not only play important roles in phagocytic removal of C3-opsonized pathogens, but also participate in mediating adhesion of mononuclear phagocytes to endothelial cells (53 ,54 ,55).

Complement and SLE

The involvement of complement in the etiopathogenesis of SLE has been scrutinized over the past several decades. Suffice it to say that the role of complement in SLE is both complex and paradoxically intriguing. On the one hand, activation of the complement system is thought to play an important role in tissue inflammation/damage in SLE as a consequence of tissue deposition of immune complexes formed by autoantigens and autoantibodies (56 ,57 ,58). On the other hand, a hereditary deficiency of a component of the

classical pathway (C1, C2, or C4) has been associated with the development of SLE (5 ,6 ,7 ,59 ,60 ,61). These seemingly discordant roles for complement may be reconciled by studies performed during the past several years. Those studies have demonstrated that, while the complement system plays a role in maintaining immune tolerance to prevent the development of SLE (59 ,61 ,62), it also participates in tissue-destructive inflammatory processes once SLE is established in a patient (56 ,57).

Table 13-1: Components of the Human Complement System

Effector Protein	Function/Pathway Involved	Mr (kD)
C1q	Recognition, binding/classical	450 (a six-subunit bundle)
C1r	Serine protease/classical	85
C1s	Serine protease/classical	85
C4*	Serine protease (C4b); anaphylatoxin (C4a)/classical	205 (a 3-chain, αβγ, complex)
C2	Serine protease (C2a); small fragment with kinin-activity (C2b)/classical	102
C3**	Membrane binding, opsonization (C3b); anaphylatoxin (C3a)/terminal	190 (a 2-chain, αß, complex)
C5	MAC component (C5b), anaphylatoxin (C5a)/terminal	190 (a 2-chain, αß, complex)
C6	MAC component/terminal	110
C7	MAC component/terminal	100
C8	MAC component/terminal	150 (a 3-chain, αβγ, complex)
C9	MAC component/terminal	70
Factor B	Serine protease/alternative	90
Factor D	Serine protease/alternative	24
Properdin	Stabilizing C3bBb complexes/alternative	55 (monomers); 110, 165, 220, or higher (oligomers)
MBL	Recognition, binding/lectin	200–400 (2–4 subunits with three 32 KD chains each)
MASP-1	Serine protease/lectin	100
MASP-2	Serine protease/lectin	76
Soluble Regulatory Protein	**Function**	**Mr (kD)**
C1-inhibitor (C1-INH)	Removing activated C1r and C1s from the C1 complex	105
C4-binding protein (C4bp)	Displacing C4b in the C4b2a complex; cofactor for factor I	570 (a 7-subunit complex)
Factor H	Displacing Bb in the C3bBb complex; cofactor for factor I	160
Factor I	Serine protease cleaving C3b and C4b	88
Clusterin	Preventing insertion of soluble C5b-7 complexes into cell membranes	70
S protein (vitronectin)	Preventing insertion of soluble C5b-7 complexes into cell membranes	84
Carboxypeptidase N	Inactivating anaphylatoxins	280 (a multi-subunit complex)
Membrane-Bound Regulatory Protein	**Function**	**Mr (kD)**
CD35 (CR1†)	Binding C3b and C4b; cofactor for factor I	160–250 (4 isoforms)
CD46 (MCP‡)	Promoting C3b and C4b inactivation by factor I	45–70 (different glycosylation forms)
CD55 (DAF§)	Accelerating decay of the C3bBb and C4b2a complexes	70
CD59 (protectin; H19)	Preventing C9 incorporation into the MAC in a homologous restriction manner	18–20
Complement Receptor	**Structure/Mr (kD)**	**Complement Ligand(s){ParaMarks}**
CR1 (CD35)	Single chain; 190–280¶	C3b; C4b; iC3b; C1q
CR2 (CD21)	Single chain; 140–145	C3dg/C3d; iC3b;
CR3 (CD11b/CD18)	2-chain,α/ß; 170/95	iC3b
CR4 (CD11c/CD18)	2-chain, α/ß; 150/95	iC3b
cC1qR (calreticulin)	Single chain; 60	C1q (collagenous tail); MBL
gC1qR	Tetramer; 33/subunit	C1q (globular head)
C1qRP	Single chain; 126	C1q (collagenous tail)
Complement Receptor	**Structure/Mr (kD)**	**Complement Ligand(s){ParaMarks}**
C3a receptor	Single chain; 50?	C3a
C5a receptor (CD88)	Single chain; 50	C5a

*Serum concentration range considered normal: 20–50 mg/dL
**Serum concentration range considered normal: 55–120 mg/dL
†Complement receptor 1
‡Membrane cofactor protein
§Decay accelerating factor
{ParaMarks}Noncomplement ligands (e.g., Epstin-Barr virus for CR2 and fibrinogen for CR3 and CR4) not listed.
¶Four allotypes with different numbers of SCR and displaying distinct Mr under reducing condition: CR1-A (220 kD), CR1-B (250 kD), CR1-C (190 kD), and CR1-D (280 kD).

Immune Complex Abnormalities, Complement Activation, and SLE

Considerable evidence has indicated that many of the clinical manifestations and pathology in patients with SLE can be attributed to immune complex abnormalities (e.g., decreased solubility and impaired disposal of immune complexes) and consequent complement activation. In patients with SLE, decreased serum levels of C3 and C4 (because of genetic or acquired factors, or both) may not permit sufficient binding of C3 and C4 fragments to the antigen-antibody lattice and thereby prevent the formation of small, soluble immune complexes (63 ,64). Furthermore, reduced levels of CR1 on erythrocytes, frequently detected in patients with SLE, may lead to impaired binding, processing, and transporting of immune complexes to phagocytes of the reticuloendothelial system (see further discussion below). Consequently, abnormally large quantities of immune complexes are likely to circulate for prolonged periods of time and form insoluble aggregates that may deposit in various tissues. Deposited immune complexes do not seem to cause tissue damage directly but provide ample binding sites for complement components. The ensuing activation of the complement system causes the release of various mediators, promotes cellular infiltration and interaction, and culminates in tissue damage. The vascular endothelium and glomerular basement membrane appear to be highly susceptible to this mode of inflammatory damage. This pathogenic sequence provides a molecular basis underlying vasculitis and glomerulonephritis, two hallmark manifestations of SLE.

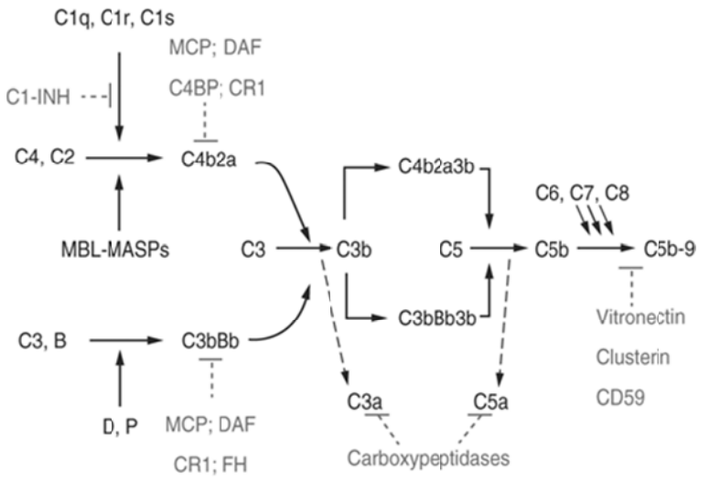

Figure 13-2. Overview of the regulation of complement activation. Regulatory proteins and their action sites are delineated in gray.

Complement Deficiency and SLE

Hereditary Complement Deficiency

Hereditary complement deficiency in humans has been reported for almost every component of the complement system (60 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82). Although the overall incidence of hereditary complement deficiency is low in the general population, a deficiency of any complement component is significantly associated with specific human diseases (Table 13-2). The clinical manifestations associated with the hereditary deficiency of individual complement components vary widely. Patients with homozygous deficiency of the early components of the classical pathway, C1, C4, and C2, are particularly at risk for development of SLE (6 ,7 ,60 ,65 ,66 ,67 ,68 ,75 ,78 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94).

In humans, there are two isotypes of C4, C4A and C4B (95 ,96 ,97). Complete C4 deficiency (homozygous deficiency of both C4A and C4B) is extremely rare. It was first reported in 1974 in a patient who manifested an acute SLE-like disease (5), and a total of 24 cases have since been reported (7). However, homozygous deficiency of C4A alone and heterozygous deficiency of C4A and/or C4B is relatively frequent (7 ,66 ,98). Increased incidence of deficiency of C4A and, less commonly, of C4B, has been reported in patients with SLE (83 ,88 ,89 ,90 ,91 ,92 ,99 ,100 ,101). A review of clinical cases of SLE

associated with complement deficiency revealed a hierarchical correlation between the position of the deficient component within the classical pathway and the prevalence of SLE. It has been estimated that SLE occurs in approximately 90%, 80%, and 30% of patients deficient in C1q, C4, and C2, respectively (7) (Table 13-3). This risk for SLE in complement deficient individuals is greater than concordance of this disease in monozygotic twins (102). This observation indicates that the classical complement pathway loci encode “lupus genes.”

Table 13-2: Complement Component Deficiencies and Associated Diseases

Deficient Component	Functional Defects	Associated Diseases
C1	Impaired clearance of immune complexes and apoptotic cells	SLE*,**; glomerulonephritis; bacterial infections
C2	Impaired clearance of immune complexes	SLE*,**; glomerulonephritis; bacterial infections
C4	Impaired clearance of immune complexes	SLE*,**; glomerulonephritis; scleroderma, Sjogren syndrome; bacterial infections
C3	Impaired opsonization; impaired clearance of apoptotic cells	Bacterial infections*,†; SLE‡
C5	Impaired chemotaxis; absent lytic activity	Bacterial infections†
C6	Absent lytic activity	Bacterial infections†
C7	Absent lytic activity	Bacterial infections†
C8	Absent lytic activity	Bacterial infections†
C9	Impaired lytic activity	Bacterial infections†
Properdin	Impaired alternative pathway activation	Bacterial infections†
MBL	Impaired lectin pathway activation	Bacterial and viral infections*; SLE
C1-inhibitor	Excessive C2 and kininogen activation	Hereditary angioedema*; SLE
Factor H	Excessive alternative pathway activation	Hemolytic uremic syndrome; bacterial infections
Factor I	Excessive alternative pathway activation	Bacterial infections

*Predominant phenotype

**Risk hierarchy for developing SLE: C1 deficiency (~90%) >C4 deficiency (~80%) >C2 deficiency (~30%)

†Most frequently infections with encapsulated bacteria, especially *Neisseria meningitidis*

‡SLE occasionally reported for patients with homozygous deficiency

Clinically, patients with SLE associated with homozygous C1q or C1r/s deficiency usually present with symptomatic disease at an early age (younger than 20), have severe disease with prominent cutaneous manifestations, and do not exhibit the usual female predilection (see (7) for a comprehensive review). Similarly, SLE associated with homozygous C4 deficiency often occurs at an early age and manifests cutaneous lesions more frequently than renal disease (7). Patients with SLE and homozygous C2 deficiency also feature less renal involvement but have more cutaneous involvement (especially photosensitivity) and arthralgia. Serologically, the prevalence of ANA and anti-dsDNA antibodies is often lower in patients with complement deficiency-associated SLE than in patients with idiopathic SLE, but the presence of anti-Ro antibodies appears to be common in SLE associated with C2 or C4 deficiency (7).

Table 13-3: Homozygous Complement Deficiency and SLE

Deficient Component	No. of Patients Reported	No. of Patients with SLE (and SLE-like disease)	Prevalence of SLE (and SLE-like disease) (%)	Sex Ratio (F-to-M)	Reference(s)
C1q	42	39	93	1.3:1	(7)
C1r/s	14	8	57	1.7:1	(7)
C4	26	21	81	2:1	(7,99)
C2	77	24	32	7:1	(7)
C3	24	4	16	3:1	(7,106,107)

In contrast to the high incidence of SLE and SLE-like disease in patients with homozygous deficiency of the classical pathway components, patients with homozygous C3 deficiency seldom develop SLE. Of the reported 24 cases of C3

deficiency, only 4 patients were described to have SLE-like disease and all were negative for ANA (7 ,103 ,104 ,105 ,106 ,107). As for terminal complement components, there have been occasional case reports of patients with SLE and C6 deficiency (76 ,108), C7 deficiency (77), C8 deficiency (72), and C9 deficiency (80). However, the predominant phenotype of homozygous deficiencies of terminal complement components is recurrent infections (Table 13-2).

MBL, the initiating component of the lectin pathway, is structurally and functionally homologous to C1q (18 ,19). Polymorphisms in the promoter and coding regions of the MBL gene that lead to altered serum levels of MBL or encode defective MBL proteins incapable of activating the complement system have been reported (109). Like C1q deficiency, MBL deficiency has been associated with increased susceptibility to SLE (110). Increased frequencies of MBL gene variants encode defective MBL protein (because of changes in amino acid 54 and 57) have been found in SLE patients of different ethnic origins (111 ,112 ,113 ,114). Associations between low serum levels of MBL and SLE have also been reported (112 ,115 ,116). Clinically, MBL deficiency in patients with SLE appears to increase their susceptibility to infections (117).

Acquired Complement Deficiency

Complement deficiency may also occur as an acquired phenomenon. When complement is increasingly consumed during heightened active states of an underlying disease, acquired deficiency can occur and usually involves multiple components simultaneously. For example, patients with hereditary deficiency of C1-inhibitor (C1-INH) suffer from episodes of angioedema (Table 13-2). In these patients, C1-INH deficiency causes unregulated activation of the kininogen system and the complement system (C1r and C1s directly and C4 and C2 consequently). As a result of the unchecked complement activation, patients with C1-INH deficiency have reduced serum levels of C4 and C2. Interestingly, development of SLE in patients with C1-INH-deficiency has been reported (118 ,119 ,120 ,121). These reports not only echo the association between hereditary complement deficiency and SLE described above, but also underscore the notion that early components of the complement classical pathway play a protective role against development of SLE.

Table 13-4: Phenotypes of Mice Deficient in Complement or Complement Receptors

Mouse Model	Phenotype	References
C1q-/- (on 129/B6 hybrid background)	Accumulation of apoptotic bodies in glomeruli; spontaneous development of autoantibodies against nuclear antigens; development of glomerulonephritis; impaired clearance of apoptotic cells in inflamed and noninflamed peritoneum	(129,130,131)
C1q-/-/*lpr*	Similar to the above strain; development of accelerated, severe autoimmune disease	(131)
C4-/- (on 129/B6 hybrid background)	Development of antinuclear autoantibodies; impaired clearance of apoptotic cells by macrophages in inflamed peritoneum	(130,132,133)
C4-/-/*lpr*	Similar to the above strain; development of glomerulonephritis, lymphadenopathy, and splenomegaly	(135,136)
C3-/-	Increased susceptibility to bacterial infections	(134,135)
C3-/-/C4-/-/*lpr*	Similar to those of C4-/-/*lpr* mice	(135)
C2-/-/Factor B-/-	No development of spontaneous autoimmunity	(279)
C1q-/-/C2-/-/Factor B-/-	Development of antinuclear autoantibodies and glomerulonephritis	(280)
Cr2-/-	Abnormal T cell–dependent antibody response; no spontaneous autoimmunity	(185,186)
Cr2-/-/*lpr*	Development of antinuclear autoantibodies, anti-dsDNA autoantibodies, and glomerulonephritis;	(136,187)

In patients with SLE, autoantibodies against complement components have also been found to cause acquired complement deficiency. For example, C3 nephritic factor, an autoantibody capable of stabilizing the alternative pathway C3 convertase BbC3b, can cause consumption of complement proteins via unregulated activation of the alternative and terminal pathways (122 ,123). Another autoantibody reactive with the first complement component, C1q, has been detected at increased frequencies in patients with SLE (124 ,125). A significant portion of patients with SLE also develop functional C1q deficiency secondary to the presence of anti-C1q antibodies (7). Although the pathophysiologic role of anti-C1q in SLE is largely unknown, its presence in patients with SLE has been associated with lupus nephritis (126 ,127 ,128).

Animal Models of Complement Deficiency

Clinical studies of patients with SLE and complement deficiency strongly suggest that early components of the classical pathway play a physiologic role in protecting against the development of SLE, a role that seems to be independent of C3. The observed association between early complement component deficiency and susceptibility of SLE in humans has been corroborated by recent animal studies. Several laboratories have generated mice deficient in individual complement proteins and complement receptors using gene-targeting techniques (Table 13-4). It has been reported

that C1q-knockout (C1q-/-) and C4-knockout (C4-/-) mice on the129/C57BL6 (B6) hybrid genetic background spontaneously developed higher levels of antinuclear autoantibodies (ANA) than strain-matched wild-type mice (129 ,130 ,131 ,132 ,133). Moreover, C1q-/- mice developed histopathologic changes resembling glomerulonephritis by 7 to 8 months of age (129 ,131). The development of autoimmune disease in C1q-/- and C4-/- mice appeared to be dependent on the genetic background of the knockout mice. Neither C1q-/- mice and C4-/- mice on the B6 background nor those on the 129 background exhibited autoimmune phenotypes (131 ,132). C1q-/- mice back-crossed onto the MRL/*lpr* (a mouse model of SLE) background developed accelerated, severe autoimmune disease (131). These findings together suggest that susceptibility genes other than C1q or C4 are required for the expression of SLE-like disease in mice.

In contrast to C1q-/- and C4-/- mice, C3-knockout (C3-/-) mice on the 129/B6 hybrid background were not found to develop autoimmune phenotypes (132 ,134 ,135). In a recent study, *lpr* mice deficient in C4, C3, or both were generated by cross-breeding and were examined for the development of autoimmune phenotype/disease (135 ,136). Autoimmune disease, characterized by marked splenomegaly, lymphadenopathy, high titers of ANA and anti-dsDNA, and glomerulonephritis, were noted to develop in C4-/-/*lpr* as severely as in C4-/-/C3-/-/*lpr* mice, but the disease did not occur in C3-/-/*lpr* mice. These findings suggest that deficiency of C4, but not C3, predisposes to the development of SLE in mice.

In summary, the results of animal studies, in accord with the clinical observations in humans, suggest that the early components of the complement classical pathway, particularly C1 and C4, play a protective role against the development of SLE. The animal studies have also provided insightful clues to the potential mechanisms linking complement deficiency and SLE, which will be discussed in the next section.

Possible Mechanisms Underlying the Complement Deficiency-SLE Association

Currently, there are three non-mutually exclusive hypotheses explaining the intriguing clinical association between complement deficiency and SLE. The first hypothetical mechanism envisions that impaired clearance of immune complexes in the absence of early complement components may trigger/augment the development of SLE. It is interesting to note that of the two isotypes of human C4, C4A has predominantly been implicated in the binding and solubilization of immune complexes (137 ,138 ,139). Consequently, it is not unexpected that the prevalence of C4A deficiency is reportedly higher in SLE patients than in the general population (83 ,89 ,99). Several studies have demonstrated abnormal processing of immune complexes in SLE patients (140 ,141 ,142 ,143). These studies showed that the initial clearance of immune complexes was impaired in the spleen, supporting the concept that impaired clearance of immune complexes may contribute to the development of SLE in the context of complement deficiency.

In 1996, a second hypothetical mechanism was proposed to explain the link between complement deficiency and development of SLE (144 ,145). This hypothesis was based upon the discovery that C1q can bind directly to apoptotic keratinocytes. Subsequent observations in support of this hypothesis demonstrated that endothelial cells and monocytes that are undergoing apoptosis also bind C1q (146) (Fig. 13-3), and this binding can subsequently trigger activation and deposition of C4 and C3 on these apoptotic cells (147 ,148). Thus, apoptotic cells and blebs become opsonized and can be effectively taken up by phagocytic cells via a complement receptor-mediated mechanism (147 ,148). During apoptosis, normally hidden intracellular constituents are often biochemically modified and redistributed/segregated into surface blebs of dying cells (149 ,150 ,151). Impaired clearance of apoptotic cells because of complement deficiency may lead to persistence of such “altered-self” constituents, which may be recognized by the immune system, breach immune tolerance, and trigger autoimmune responses (152). Taken together, these studies suggest that complement is involved in facilitating the clearance of autoantigen-containing apoptotic bodies and therefore plays a pivotal role in maintaining immune tolerance (7 ,59 ,61 ,153).

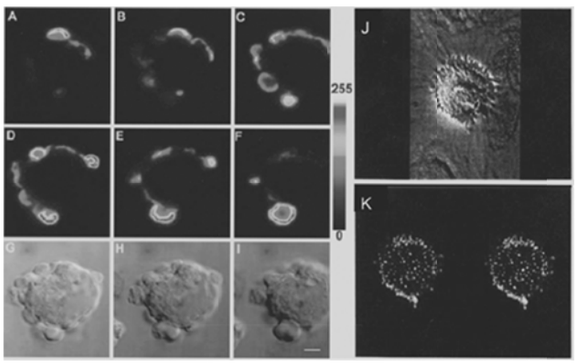

Figure 13-3. (See color plate.) Binding of C1q to apoptotic endothelial cells and keratinocytes. Panels **A–F,** Confocal analysis of C1q present on surface blebs of a human umbilical vein endothelial cell undergoing UVB-induced apoptosis. Shown are six consecutive cross-sections through the cell stained for the presence of C1q by indirect immunofluorescence. The fluorescence intensity is represented by a color scale, with white being the highest intensity and black the lowest. **G–I**, Different interference contrast images of panels **D–F** are shown to visualized morphology of the entire cells and apoptotic blebs. **J** and **K**, Confocal analysis of bound C1q on apoptotic human keratinocytes. Shown are a merged phase and fluorescence image of a single plane of an apoptotic keratinocyte **(J)** and a stereo image of a Z-series of several planes though a single apoptotic keratinocyte **(K)**. and

Navratil JS, et al. The globular heads of C1q specifically recognize surface blebs of apoptotic vascular endothelial cells. *J Immunol* 2001; 166:3231–3239;

Using a mouse model, Botto et al. were first to report accumulation of apoptotic cells in the kidneys and spontaneous development of autoimmune responses to nuclear autoantigens and glomerulonephritis in the absence of C1q (129). Subsequently, Taylor et al. reported similar, but less severe, defects in the clearance of apoptotic cells and spontaneous autoantibody production in C4-deficient mice (130). Results from these animal studies suggest that clearance of apoptotic cells is impaired or delayed in the absence of C1q, and less so in the absence of C4 (Table 13-4). Likewise, the persistence of apoptotic cells may lead to development of autoimmunity and tissue damage in humans. Reduced phagocytic activity of neutrophils, monocytes, and macrophages of SLE patients has previously been observed (154 ,155 ,156). Specifically, a reduced capacity of SLE-derived macrophages to phagocytose apoptotic cells was reported by Hermann et al. (157). Moreover, impaired clearance of iC3b-opsonized apoptotic cells in vitro has been reported using monocyte-derived macrophages prepared from SLE patients (158). Evidence has also been generated in vivo to support impaired clearance of apoptotic cells in human SLE. Bermann et al. reported an abnormal accumulation of apoptotic cells, accompanied by a significantly decreased number of tangible body macrophages (cells responsible for removing apoptotic nuclei), in the germinal centers of lymph nodes in a small subset of SLE patients (159). Collectively, data from both animal and human studies not only substantiate the observed hierarchical correlations between the deficiency of C1, C4, or C2 and the risks for developing SLE, but also provide a strong mechanistic basis linking complement deficiency and SLE.

The third hypothetical mechanism relates to the capacity of complement to determine activation thresholds of B and T lymphocytes, suggesting that complement deficiency may alter the normal mechanism of negative selection of self-reactive lymphocytes (26 ,62 ,136 ,160 ,161). Since coligation of *CR2* and BCR augments B cell activation by decreasing the threshold to antigenic stimulation (47), it has been postulated that self-antigens not opsonized by C4b or C3b are unlikely to trigger sufficient activation of self-reactive B cells, and, as a result, these cells may escape negative selection. The escaped cells may become activated once encountering relevant autoantigens in the periphery, and thus breach self-tolerance to autoantigens.

CR1 Deficiency in SLE

Several investigators have reported reduced levels of CR1 expressed on erythrocytes of patients with SLE (162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174). Whether this deficiency in erythrocyte-CR1 (E-CR1) is genetically determined, acquired, or both has been controversial. Earlier studies performed in the 1980s have led some investigators to conclude that erythrocyte CR1 deficiency is inherited (163 ,165 ,166 ,167). Subsequent studies by other investigators using SLE patients of various ethnic backgrounds, however, have suggested that erythrocyte CR1 deficiency is an acquired phenomenon (162 ,164 ,168 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176). In some studies, reduced E-CR1 levels were shown to correlate with disease activity (162 ,168 ,170 ,174). These conflicting results may originate, in part, from differences in experimental methods and ethnic populations used in different studies.

To elucidate the molecular basis of the observed differential erythrocyte CR1 expression in SLE patients versus healthy individuals, Wilson and colleagues examined E-CR1 levels in SLE patients and their relatives (165). They found that a significant number of patients' relatives had reduced E-CR1 levels, and three patterns of high, intermediate, and low E-CR1 levels could be identified in both SLE patients and controls. Family studies indicated that E-CR1 levels were genetically regulated in a biallelic codominant manner. Subsequently, the same investigators, using DNA probes for the CR1 gene and restriction fragment length polymorphism (RFLP) studies, demonstrated the presence of two HindIII-digested CR1 gene fragments, 7.4 kb and 6.9 kb in length, respectively (177). It was shown that the 7.4 kb fragment (H allele) correlated with high E-CR1 levels, whereas the 6.9 kb fragment (L allele) was associated with low E-CR1 levels. A heterozygous 7.4 kb/6.9kb (H/L) pattern correlated with intermediate E-CR1 levels. These results are consistent with the originally proposed biallelic codominant fashion of inherited E-CR1 expression (165). It should be pointed out, however, that E-CR1 levels were considerably lower in SLE patients than in healthy individuals with the matched HindIII RFLP pattern, suggesting that additional genetic or nongenetic factors may influence E-CR1 expression in SLE patients (166). Although it was initially postulated that increased prevalence of the HindIII L/L genotype may be associated with SLE, subsequent studies have not supported this theory. Several studies have reported that gene frequencies of HindIII H and L alleles do not differ significantly between SLE patients and normal controls (162 ,169 ,172 ,173 ,174), suggesting that the L/L genotype does not increase susceptibility to SLE.

Other lines of evidence that support the possibility of acquired low E-CR1 levels in SLE patients include: (1) normal erythrocytes transfused into SLE patients lost significant amounts of CR1 within a few days after transfusion (178); (2) CR1 levels on reticulocytes (the youngest form of erythrocytes) of SLE patients were equivalent to those on reticulocytes of normal individuals (179); and (3) significantly greater loss of E-CR1 in the peripheral circulation was observed in SLE patients than in normal controls (179).

In summary, experimental and clinical studies strongly indicate that both genetic and acquired factors contribute to the observed deficiency of erythrocyte CR1 in SLE patients. However, the precise nature of these factors remains to be elucidated.

Abnormal Expression of CR2 and CR3 in SLE

Relative deficiency of *CR2* has been observed in patients with SLE. Expression of *CR2* on lymphocytes was found to be approximately 50% to 60% lower in patients with SLE than in healthy controls (180 ,181 ,182). It is unclear whether decreased *CR2* expression correlates with increased activity of SLE and, if so, whether it is a cause or a result. Animal

studies, nevertheless, have shown that decreases in CR1/CR2 expression preceded the development of clinically apparent disease in MRL/*lpr* mice (183). This finding suggests that decreased CR1/CR2 expression may be involved in the initiation or progression of autoimmune disease.

The role of CR2 in the development and pathogenesis of SLE has been investigated using gene-knockout mice. In mice, CR2 and CR1 are encoded by the same gene through differential splicing of the RNA transcripts (184). Therefore, CR2-deficient (Cr2-/-) mice generated by gene-targeting techniques are also deficient in CR1. Initial studies have shown that Cr2-/-mice on the 129/B6 hybrid background did not develop an autoimmune phenotype (185 ,186). However, when back-crossed with B6/*lpr* mice (a mouse model of SLE), Cr2-/-/*lpr* mice on the 129/B6 hybrid background exhibited more aggressive disease at earlier time points than did B6/*lpr* mice (136), featuring marked splenomegaly and lymphadenopathy, increased ANA and anti-dsDNA titers, and increased immune complex deposition in renal glomeruli. In comparison, Cr2-/-/*lpr* mice on the B6 background developed autoantibodies but not other manifestations (187). Recent studies of SLE susceptibility genes using the NZM2410 mouse model further support an important role of CR2 in the development of autoimmune phenotypes (188). Boackle et al. recently identified that Cr2 is a candidate gene within the NZM2410 Sle1c locus (189 ,190). These investigators showed that B6 mice congenic for the Sle1c locus expressed dysfunctional CR1 and CR2 proteins, which are encoded by a defective Cr2 gene with a single nucleotide mutation. Although these mice developed autoantibodies to chromatin, they did not develop glomerulonephritis. Collectively, these results indicate that the Cr2 gene alone is insufficient to induce expression of a full spectrum of autoimmune phenotype/disease in lupus-prone mice, which apparently requires the contribution of additional SLE susceptibility genes.

With respect to CR3, reduced expression of CR3 on lymphocytes of patients with active SLE has previously been reported (191 ,192). Clinical manifestations of these patients included prominent cutaneous changes associated with immune vasculitis and panniculitis, arthritis, serositis, and nephritis. Although congenital deficiency of CR3 (known as “leukocyte adhesion deficiency”) is associated with increased susceptibility to pyogenic bacterial infections (193 ,194), the pathophysiologic significance of decreased CR3 expression in SLE remains to be elucidated. In contrast to the reported decreased CR3 levels on lymphocytes, one study showed increased levels of CR3 on neutrophils of patients with SLE (195). The highest neutrophil CR3 levels were detected in patients with the most severe disease, and in some patients the increased CR3 levels on neutrophils returned to normal when disease flares subsided. Based on these findings, it was postulated that neutrophils of patients with active SLE increase surface expression of CR3 in response to complement activation and these activated neutrophils may contribute to endothelial injury in SLE (195).

Measurement of Complement

During clinical inflammatory states in which complement activation occurs, e.g., flares of SLE, complement proteins would presumably be consumed at a rate proportional to activity of the disease. Thus, measuring complement activation may be useful for diagnosing disease, assessing disease activity, and determining response to therapy. Measuring complement activity and individual component levels is also essential for detecting and diagnosing complement deficiency. Conventionally, the complement system is measured by one of two types of assays. Functional assays measure complement-mediated hemolytic activity: CH_{50} (indicative of the activity of the classical pathway) and APH_{50} (indicative of the activity of the alternative pathway). Immunochemical assays measure serum concentrations of individual complement components and their proteolytic fragments (hereafter referred to as “complemented split products” or “complement activation products”).

Measurement of Complement Functional Activity

Assays that measure complement-mediated hemolysis, such as the CH_{50} and APH_{50} assays, are simple quantitative tests for functional complement components in serum or other fluid samples. Because complement activation in SLE is triggered predominantly by immune complexes that active the classical pathway, it is common to check the CH_{50} in patients with SLE. Complement activity is quantified by determining the dilution of a serum (or other fluid sample) required to lyse 50% of sheep erythrocytes sensitized with anti-sheep IgM (for CH_{50} assays) or unsensitized rabbit erythrocytes (for APH_{50} assays) under standard conditions. The reciprocal of this dilution represents complement activity in units per mL of serum. For example, if a 1:160 dilution of a serum sample lyses 50% of erythrocytes, complement activity in that sample is reported as 160 CH_{50} U/mL. Because some complement components are heat-labile, serum samples, if not used immediately, should be stored at –70°C to optimize the preservation of complement proteins in functionally active forms.

Measurement of Complement Proteins

Measurement of serum levels of individual complement components is commonly used to diagnose and assess disease activity in SLE. These tests also help to identify deficiencies of specific complement proteins.

Traditionally, serum is used for complement measurements. As cautioned above for the functional hemolysis assays, serum samples should be handled promptly and carefully to minimize possible degradation of complement proteins. A number of immunochemical methods, which are generally based on the antigen-antibody reactivity between complement components in the test sample and added anticomplement antibodies, are available for such measurement.

The selection of a proper method depends on several factors such as the level of sensitivity required, the availability of specific antibody, the number of samples, and the types of samples. In most clinical immunology laboratories, nephelometry is routinely used to measure complement components that are present at relatively high concentrations in the serum (e.g., C3 and C4). Other components that are usually present at low concentrations (e.g., C1, C2, C5 through C9, Factor B, Factor D, properdin) can be measured using radioimmunodiffusion (RID) or enzyme-linked immunoabsorbent assay (ELISA). When C3 and C4 concentrations are too low to be measured accurately by nephelometry, i.e., <20 mg/dL and <10 mg/dL, respectively, RID is the alternative method of choice. For other body fluids or cell culture supernatants, in which the levels of complement components may be very low, ELISA is the most practical method to use.

Measurement of Complement Split Products

Measurement of serum concentrations of complement components is essentially a static appraisal of an extremely dynamic process that includes activation, consumption, catabolism, and synthesis of these components. Unlike their parental molecules, which are also acute phase proteins (196 ,197), complement split products are generated only when complement activation occurs, and thus acute phase responses alone do not increase their concentrations. Therefore, direct determination of complement split products is thought to reflect more precisely the activation process of complement in vivo and hence the disease activity. Measures of complement split products in the plasma, yielded from activation of the classical pathway (C1rs-C1 inhibitor complex, C4a, and C4d), alternative pathway (Bb and C3bBbP), lectin pathway (C4a and C4d), and terminal pathway (C3a, iC3b, C3d, C5a, and sC5b-9), are currently performed in many clinical immunology laboratories.

When measuring complement split products, plasma, instead of serum, should be used. Plasma (EDTA-anticoagulated) is used to avoid generating complement split products in vitro. Since only low levels of complement split products may be present in the circulation, even after significantly increased complement activation, ELISA and EIA are the most practical methods for their measurement. Complement split products have different, but commonly short, half-lives in the plasma. Some split products, such as C3a, C4a, and C5a, are quickly converted to more stable, less active forms, such as C3a-desArg, C4a-desArg, and C5a-desArg. In comparison, complement products that form multi-molecular complexes usually have a relatively long half-life in the circulation. Examples of the latter include C1rs-C1 inhibitor complexes (products of classical pathway activation), C3bBbP complexes (products of alternative pathway activation), and sC5b-9 (the ultimate product of complement activation). sC5b-9 is the soluble form of MAC that consists of C5b, C6, C7, C8, poly-C9, and the solubilizing protein, protein S.

Complement as a Source of Biomarkers for SLE Diagnosis and Monitoring

Complement Measurement and SLE Activity

Since Vaughan et al. first reported an association between decreased complement proteins and active SLE five decades ago (1), most patients with SLE are commonly monitored by measures of serum C3, serum C4 levels, and complement hemolytic activity (Table 13-5). Numerous studies have been conducted to evaluate the potential utility of these assays in the diagnosis and monitoring of SLE. A succinct review of noteworthy data and precautions is outlined below.

First, although it has generally been thought that decreased levels of complement components reflect activation of the classical and/or alternative pathway and correlate with clinical disease activity, there is still no consensus regarding the actual value of complement measures in SLE monitoring. Some investigators have found CH_{50} as well as serum C4 and C3 levels to be valuable as markers of SLE activity, while others have found them minimally useful (Table 13-6). Evidence in support of the usefulness of CH_{50}, C3 and C4 measurement include the following observations: (1) significantly decreased levels of CH_{50} and serum C3 and C4 have been associated with increased SLE disease activity manifested by active nephritis and extra-renal involvement (4 ,198 ,199 ,200 ,201 ,202 ,203); (2) an increase/decrease in serum C3 levels has coincided significantly with remission/relapse of lupus nephritis (201 ,202 ,203); (3) a decrease in serum C4 levels has been noted to precede clinical exacerbation (199 ,202 ,204); (4) progressive fall of serum C3 or C4 levels may indicate an impending flare of SLE (205); and (5) serum C3 and C4 levels have frequently normalized on resolution of disease flares (199). On the contrary, the following observations argue against the usefulness of conventional complement measurement: (1) serum C4 and C3 levels have been found to remain normal in some patients during disease flares (206 ,207); (2) persistently low C4 levels have been detected in SLE patients with inactive disease (199 ,200 ,208 ,209); (3) decreases in C3 and C4 have not always been accompanied by increases in the split products (e.g., C3a, C3d, and C4d); and (4) the extent of changes in serum C3 and C4 levels do not correlate quantitatively with disease severity (210 ,211 ,212).

Table 13-5: Common Profiles of Complement Measurement in SLE and Other Inflammatory Conditions

Pathway(s) Involved	CH_{50}	APH_{50}	C3	C4	Factor B
Classical	↓	N	↓	↓	N
Alternative	N	↓	↓	N	↓
Classical/Alternative	↓	↓	↓	↓	↓

Table 13-6: Select Studies of Complement Measures in SLE

Complement Component(s)	Study Design	Results/Conclusions
CH_{50}, C1q, c3, C4	Lloy and Schur (199); prospective study following 27 SLE patients through 47 cycles of clinical activity; serologic tests: CH_{50}, C1q, C3, C4, anti-dsDNA, and immune complex (C1q binding activity) levels	CH_{50}, C3, C4 levels lower in patients with active renal disease than in patients with extra-renal involvement; decreasing C4 levels preceded disease flares
CH_{50}, C1q, c3, C4	Valentijn et al. (200); retrospective study using serial serum samples obtained from 33 SLE patients; serological tests: CH_{50}, C3, C4, immune complexes (C1q binding)	Significant correlation between overall disease activity, decreased C3/CH_{50}, and increased immune complex levels; Low sensitivity, specificity, and predictive value; correlation between C3/C4 levels and organ involvement in subgroups of patients
C3, C4	Ricker et al. (201); retrospective study using serial serum samples obtained from 12 SLE patients with severe nephritis; serological tests: C3, C4	Normal C3 levels observed during disease remission; abnormal C3 levels more frequently detected during flares than C4; Higher specificity and sensitivity of C3 than C4 in monitoring SLE disease activity
C1q, C3, C4, C5, C9	Swakk et al. (281); prospective study of 143 patients; serological tests: C1q, C3, C4, C5, C9, anti-dsDNA	Decreased C4, C1q, and C3, in a sequential order, detected in patients with renal exacerbation; decreasing C4 detectable 20–25 weeks before the flare; decreased C1q and C3 detected during but not before the flare
C3	Abrass et al. (210); prospective study following 48 SLE patients; serological tests: C3, anti-dsDNA, immune complexes	C3 and anti-dsDNA neither associated with nor predictive of changes in disease activity
CH_{50}, C3, C4	Morrow et al. (211); prospective follow up of 35 SLE patients; serological tests: CH50, C3, C4, anti-dsDNA, immune complexes	None of the serologic tests reliably distinguished the three clinical groups
C3, C4	Esdaile et al. (205,282); retrospective analysis of serum samples collected from 202 patients; serological tests: C3, C4, anti-dsDNA, immune complexes	All serologic parameters tested poor predictor of SLE flares; some values of patient-based serial measures in association with specific types of flares (e.g., decreased C3 and renal involvement)
C1rs-C1inh, C3d	Sturfelt et al. (213) Serial (at 6- to 8-wk intervals) samples from 33 SLE patients	Increased C1rs-C1inh consistently found during flares; increased C1rs-C1inh detected before flares, especially extra-renal flares; Increased C3d associated with severe disease flares
C1rs-C1inh, C3(Bb)P, C5b-9	Nagy et al. (227) Plasma samples obtained from healthy controls and 65 SLE patients with active and inactive disease	All 3 activation products elevated in SLE patients with inactive disease compared to healthy controls; C3(Bb)P and C5b-9 but not C1rs-C1inh, distinguishing active disease from inactive disease
C3a, C5a	Belmont et al. (215) Plasma samples of 76 SLE patients with severe, moderate, or inactive disease	C3a significantly elevated in patients with severe or moderate disease activity and quantitatively correlated with disease severity; C5a significantly elevated in patients with severe disease activity
C3a, C5a	Hopkins et al. (216) Serial plasma samples from 23 SLE patients (7 pregnant; 5 CNS involvement)	C3a levels significantly higher in patients with a flare than in those with stable disease; Rising C3a levels predictive of disease flares; Highly elevated C3a and C5a in patients with CNS involvement; C3a levels elevated in most pregnant patients
C3a, C4a, iC3b, C5b-9	Porcel et al. (218) Plasma samples of 61 SLE patients (22 inactive disease; 39 active disease; defined by SLEDAI)	C3a, C4a, and C5b-9 significantly elevated in patients with active disease, with a positive correlation with disease activity scores; C5b-9 most sensitive and specific; iC3b not correlated with disease activity
C4d, C3d	Senaldi et al. (214) Plasma samples of 48 SLE patients (11 inactive, 23 mildly active, 14 moderately/severely active)	Elevated C4d levels correlated with disease activity in a linear fashion; C3d levels elevated but not linearly correlated with disease activity
Ba, Bb, C4d, C5b-9	Buyon et al. (221) 380 serial plasma samples from 86 SLE patients with inactive, stable/moderate, or severe disease	Ba levels significantly elevated and positively correlated with disease activity; Elevated C4 and increased Bb predictive of subsequent flares
Bb, C4d, C5b-9	Manzi et al. (222) 21 SLE patients prospectively followed for 1 year	C4d and Bb sensitive indicator of moderate-to-severe disease activity; C4d and Bb sensitive at predicting increasing disease activity
C5b-9	Falk et al. (224) 108 serial plasma samples from 14 SLE patients	C5b-9 levels significantly elevated in SLE patients, and positively correlated with disease activity

*Adapted from Liu CC, Denchenko N, Navratil JS, et al. Mining the complement system for lupus biomarkers. *Clin Appl Immunol Rev* 2005;5:185–206. Copyright 2005, with permission from Elsevier.)

Second, although direct determination of complement split products, compared to conventional complement measurement, should theoretically reflect more precisely the activation process of complement in vivo and thus more specifically clinically active disease, controversy regarding utility of these assays still remains. Studies arguing in favor of the value of these assays have generally shown that plasma concentrations of complement split products, including C1-C1INH complex, C3a, C4a, C5a, C3d, C4d, C5b-9, Ba, and Bb increased before or during clinical exacerbation (206 ,213 ,214 ,215 ,216 ,217 ,218 ,219 ,220 ,221 ,222 ,223 ,224 ,225), and in some cases, the plasma levels correlated strongly with SLE disease activity scores (214 ,215 ,217 ,218 ,219). However, elevated C1-C1INH and C3d levels have been reported not only in almost all clinically ill patients, but also in a significant fraction of patients with quiescent disease, suggesting that plasma C1-C1INH and C3d levels bear little relationship with clinical activity (211 ,226 ,227 ,228 ,229). Moreover, inconsistent results have been reported for the utility of plasma levels of a given complement split product in differentiating patients with different disease activity/severity (218 ,226).

Drawbacks and Problems Associated with Complement Measurement

The discrepant reports regarding the value of measuring serum C4 and C3 to monitor disease activity of chronic inflammatory diseases such as SLE may originate from several factors that particularly confound measurement of C3 and C4 in disease. First, there is a wide range of variation in serum C3 and C4 levels among healthy individuals, and this range overlaps with that observed in patients with different diseases. Second, traditional concentration measurements reflect the presence of C3 and C4 protein entities irrespective of their functional integrity. Third, acute phase responses during inflammation may lead to an increase in C4 and C3 synthesis (196 ,197), which can counterbalance the consumption of these proteins during activation. Fourth, enhanced catabolism (230 ,231 ,232) as well as altered synthesis of C3 and C4 (233 ,234) have been reported to occur in patients with SLE, which clearly can interfere with static measures of serum C3 and C4 levels. Fifth, genetic variations such as partial deficiency of C4, which is commonly present in the general population and in patients with autoimmune diseases (88 ,98 ,99), may result in lower than normal serum C4 levels in some patients because of decreased synthesis rather than increased complement consumption during disease flares. Sixth, tissue deposition of immune complexes may result in complement activation at local sites in patients with certain diseases; such activity may not be faithfully reflected by the levels of complement products in the systemic circulation. Additional concerns should be raised regarding the measurements of complement split products. As mentioned above, many of the split products have an undefined, most likely short, half-life both in vivo and in vitro. Moreover, complement activation can easily occur in vitro after blood sampling. In combination, these

factors may hamper accurate measures of activation products that are derived solely from complement activation occurring in patients.

Complement Measurement and Organ-Specific Involvement in SLE

Given the numerous confounding factors outlined here, it is not surprising that irreconcilable results have prevailed in the research arena of complement and SLE disease activity. However, complement measures may still be informative if they are performed chronologically in the same patient and interpretation is based on the specific genetic and clinical characteristics of the patient. Complement measures in the blood or other body fluid may also be valuable in assessing disease activity or predicting outcome under particular conditions, such as specific organ involvement and pregnancy.

Lupus nephritis is one of the most serious clinical manifestations of SLE. Nephritic flare has been shown to be a predictor of a poor long-term outcome in SLE patients (235). Measurements of complement components and activation products in the plasma or in the urine may be a useful tool for evaluating the extent of active inflammation in the kidneys. SLE patients with renal involvement were found to more frequently have markedly reduced serum levels of C3 and C4 than patients with extra-renal involvement only (199 ,200). SLE patients with normal C3 and C4 levels were rarely found to have active nephritis (199 ,200). Therefore, the absence of a low C3 or C4 level in a patient with SLE may help to exclude the possibility of ongoing renal disease. Low C3 and C4 levels may also be helpful in predicting long term outcome in SLE, because low C3 levels have been reported to be predictive of persistently active glomerular disease (236) and associated with end stage renal disease (237). In addition to low C3 and C4, very low levels of serum C1q were detected in SLE patients with, but not in those without, active renal disease (199). In patients who had lupus nephritis requiring intense treatment, persistently low C1q levels before and after treatment have been shown to be indicative of continuously progressive damages in the kidneys and hence a poor outcome (238).

Because it seems likely that C3d generated in the kidney at sites of immune complex deposition would pass into the urine, measurement of C3d in the urine has been pursued as a test for specific and accurate estimation of inflammation in the kidney. Kelly et al. (239) and Manzi et al. (222) have reported the detection of C3d in the urine in SLE patients with acute nephritis and in patients without evidence of renal involvement. These results suggest that urinary C3d may also come from nonrenal origins and thus it may not be viewed as a specific marker of acute nephritis or a prognostic indicator of renal disease. Nevertheless, in the study by Manzi et al. (222) urinary C3d was shown to be better than serum C3, plasma C4d, Bb, and C5b-9 in distinguishing patients with acute lupus nephritis from those without such disease activity. Recently, Negi et al. reported that C3d levels were elevated in the urine of patients with active disease, more so in patients with active lupus nephritis (0.87 AU/mL) than in patients with active extra-renal disease (0.31 AU/mL) or in patients with inactive lupus nephritis (0.06 AU/mL) (240). Taken together, these results suggest that increased levels of urinary C3d may reflect active SLE, particularly active lupus nephritis.

In addition to renal disease, low serum C3 and C4 levels have been associated with hematological manifestations. Ho and colleagues reported that decreases in C3 were associated with concurrent decreases in the platelet counts, white blood cell counts, and hematocrit (241). However, they also noted that decreased complement levels were not consistently associated with SLE flares, as had previously been found by other investigators.

Complement levels and CNS disease in SLE has also been investigated. Hopkins et al. reported that plasma C3a levels increased in SLE patients during a disease flare, and were particularly high in 5 patients who had acute CNS dysfunction (216). In 4 of these 5 patients, significantly elevated plasma C5a levels were also detected. Subsequently, Rother et al. reported that SLE patients with CNS involvement had significantly higher levels of plasma C3d than did patients without CNS involvement (223).

Finally, several studies have examined levels of complement proteins in other body fluids. Such investigations have included analyses of synovial fluid (242), pleural fluid (243 ,244), pericardial fluid (245 ,246), and cerebrospinal fluid (CSF) (247 ,248 ,249). Generally, these studies have been too limited to provide conclusive indications regarding the utility of these assays.

Measurement of Cell-Bound Complement Activation Products

Recent reports have explored the hypothesis that cell-bound complement activation products (CB-CAPs) may serve as biomarkers for SLE diagnosis and monitoring (250 ,251). This hypothesis was based upon the following rationale. First, serum C3 and C4 levels have no diagnostic utility and limited monitoring utility, and the inherent flaws in these measurements has been well documented as described above. Second, measurement of soluble complement activation products has been shown to have utility in certain clinical situations; however these assays have not replaced measurement of serum C3 and C4 in clinical practice. Furthermore, the half-lives of these fragments in the circulation is likely to be short. Third, cell surface receptors for complement activation products are present on all circulating cells and may confound accurate and reliable measurement of the soluble activation products. Fourth, C3- and C4-derived complement activation products are capable of covalent attachment to cell surfaces via thioester bonds, and this property of the peptides may increase longevity in the circulation. Fifth, C4-derived complement activation products are known to be present on surfaces of normal erythrocytes, although the physiologic significance of this phenomenon is unknown (252 ,253). Sixth, CB-CAPS on specific cell types might reflect additional disease information by unique

cellular properties such as the life span of erythrocytes and reticulocyte.

Using a flow cytometric assay, Manzi et al. conducted a cross-sectional study to examine erythrocyte-bound C4d (E-C4d) levels in patients with SLE, patients with other inflammatory and immune-mediated diseases, and healthy controls (250). E-CR1 was determined simultaneously in light of the previous reported association of low levels E-CR1 in SLE. The results from this study showed that: (1) significantly higher E-C4d levels occur in patients with SLE than in patients with other diseases and healthy individuals, and (2) abnormally high E-C4d levels, in conjunction with abnormally low E-CR1 levels, is a pattern with high diagnostic sensitivity and specificity for SLE, as compared with healthy individuals (81% sensitive; 91% specific) and patients with other inflammatory diseases (72% sensitive; 79% specific), respectively (250). During investigation of the diagnostic utility of E-C4d for SLE, these investigators also observed significant longitudinal fluctuation of E-C4d with individual patients. This discovery suggested that E-C4d levels might correlate with disease activity in SLE.

Erythrocytes develop from hematopoietic stem cells in the bone marrow and emerge as reticulocytes. Reticulocytes maintain distinct phenotypic features for 1 to 2 days before fully maturing into erythrocytes. Reticulocytes, if released into the peripheral circulation during an active disease state, may immediately be exposed to and bind C4-derived fragments generated from activation of the complement system. Because erythrocytes, which have a life span of approximately 120 days, may bind and retain activation-derived C4d throughout their lifetime, the E-C4d level is likely to be the cumulative result of complement activation and disease activity over a 120-day period. Because of the brief transitional stage of reticulocytes, the levels of C4d attached to reticulocytes (R-C4d) are more likely the result of ongoing activation instead of past events. Therefore, it was hypothesized that R-C4d levels, as opposed to E-C4d levels, may reflect more effectively and precisely the current disease activity in a given SLE patient at a specific point in time, thereby serving as “instant messengers” of SLE disease activity.

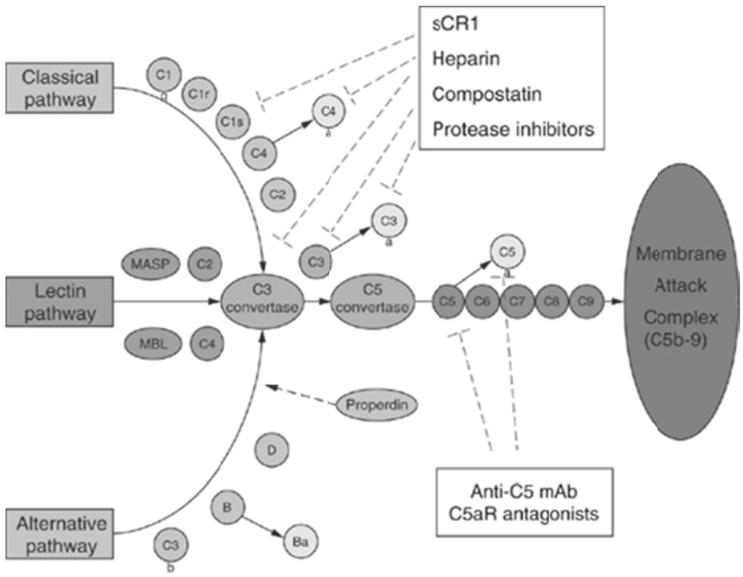

Figure 13-4. Anticomplement therapeutics and potential target molecules

Initial studies indicate that: (1) a wide range of R-C4d is detected in SLE patients, but not in patients with other diseases and healthy controls, (2) the mean R-C4d level of SLE patients is significantly higher than that of patients with other diseases or healthy controls, and (3) R-C4d levels fluctuate and correlate with clinical disease activity as measured using the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and Systemic Lupus Activity Measurement (SLAM) (251). These findings suggest that C4d-bearing reticulocytes may serve as a biomarker for SLE disease activity, providing clues to current and perhaps impending disease flares in patients with SLE.

Anticomplement Therapeutics for SLE

The fundamental role of complement activation in SLE pathogenesis has led naturally to exploration of the complement system as a target for therapeutic intervention. To date, a variety of reagents that inhibit or modulate complement activation at different steps of the cascade have been developed (254). These reagents can be classified into two broad categories: (1) inhibitors of the early steps of complement activation and (2) inhibitors of the terminal pathway that do not interfere with early activation events (254 ,255) (Fig. 13-4). Examples of the first group include: soluble CR1 (sCR1;

capable of regulating the generation of C3/C4 fragments and C3 convertases) (256 ,257 ,258 ,259 ,260), heparin (a polyanionic glycosamine; capable of binding/inhibiting C1, inhibiting C1q binding to immune complexes, blocking C3 convertase formation, and interfering MAC assembly) (261 ,262 ,263 ,264), compstatin (a synthetic peptide capable of binding C3 and preventing its proteolytic cleavage), and protease inhibitors (265 ,266). Prominent among the second group are anti-C5 monoclonal antibodies (mAbs) that can bind C5, block its cleavage and formation of C5a, and abrogate MAC assembly (267 ,268 ,269 ,270 ,271). Synthetic antagonists of C5a receptors also belong to the second group and have been exploited to block the anaphylactic and chemotactic effects of C5a (272 ,273 ,274). Considering that C3b opsonization of pathogens and immune complexes is crucial for host defense and for prevention of immune complex-associated adverse reactions, it is reasonable to postulate that inhibitors of complement activation at a downstream step, such as C5 cleavage, will have therapeutic effects for patients with inflammatory diseases but will less likely increase the risk for infection in these patients.

Eculizumab, a humanized anti-C5 mAb, has recently been studied in the NZB/W F1 mouse model of SLE, and has been shown to improve significantly renal disease and increase survival of treated mice (271). A Phase I clinical trial of Eculizumab in patients with SLE concluded that Eculizumab was safe and well tolerated, without significant adverse effects (275). Heparin, traditionally used as an anticoagulant and known to inhibit complement activation, has recently been demonstrated to prevent antiphospholipid antibody/complement-induced fetal loss in a murine model (264). This seminal observation suggests that heparin at “sub-therapeutic” (nonanticoagulating) doses may be beneficial in pathological situations where excess complement activation is unfavorable, such as ischemia/reperfusion injury, antiphospholipid antibody syndrome, and lupus nephritis.

Conclusion

In 1948, Hargraves reported discovery of the LE cell (276), although the origin and significance of the structure were unknown at the time. For decades the LE cell was investigated scientifically and used for diagnosis and management of patients with SLE, although its clinical utility eventually fell out of favor.

Despite the historical introduction to this chapter, it is now apparent that discovery of the LE cell is likely to have been the first observation to link complement and SLE. Shortly after Hargraves discovered the LE cell, it was determined that in vitro generation of LE cells is dependent on complement activation (277 ,278). Fifty years later, the LE cell is recognized as a neutrophil that has engulfed the remnants of apoptosis, thus linking complement, apoptosis, and SLE.

So consider the LE cell as a lupus biomarker relic and an early icon of the disease. Perhaps it should instruct us to forge ahead with microarrays, proteomics, molecular signatures, and knockout mouse models of lupus, but also to carry with us and occasionally revisit more simple observations of the past. The complement system holds at least one important clue to the mystery of lupus, and recent progress is cause for optimism that a solution to the puzzle may be within reach.

Acknowledgments

We thank our colleagues in the Lupus Center of Excellence and Division of Rheumatology and Clinical Immunology for providing clinical samples, helpful discussion, and skilled technical as well as administrative support. Experimental work from the authors' laboratory are supported by grants from the National Institutes of Health (RO1 AR-4676402, RO1 HL074335, RO1 AR-46588, NCRR/GCRC MO1-RR-00056, K24 AR02213, and P30 AR47372), the Lupus Foundation of Pennsylvania, the Alliance for Lupus Research, the Lupus Foundation of America, Southeastern Pennsylvania Chapter, and the Arthritis Foundation.

Chapter 14

Mechanisms of Acute Inflammation and Vascular Injury in Systemic Lupus Erythematosus

Howard Michael Belmont

Steven B. Abramson

Inflammation in systemic lupus erythematosus (SLE) is mediated by a complex interaction of the cellular and humoral components of the immune system. In contrast to the host immune response to infection that begins with a known inflammatory trigger, the etiologies of connective tissue diseases such as SLE remain undefined. In the absence of known etiologies, treatment strategies rely on the dissection of inflammatory processes into component parts while keeping in mind the complex interaction of these components. This chapter reviews inflammatory mediators released from cells—neutrophils, monocytes, and platelets—as well as humoral activators of these cells, such as chemoattractants, complement components and immune complexes. A particular focus is placed on the pathogenic mechanisms by which inflammatory cells and mediators provoke vascular injury in SLE. Additionally, since endothelial injury and subsequent alteration of endothelial adhesiveness and permeability to leukocytes and platelets are principal mechanisms of both the inflammatory states that characterize exacerbated SLE as well as atherosclerosis, we discuss the relationship between atherosclerosis and autoimmunity.

The Role of Circulating Phagocytic Cells and Platelets in Immune Injury

The activation of phagocytic cells and platelets in response to chemoattractants, immune complexes, and other stimuli provokes the release of inflammatory mediators that account for diverse manifestations of inflammation in autoimmune disease (Table 14-1). The major effector cells and their functions are discussed in the following sections.

Neutrophils

Neutrophils, together with monocyte/macrophages, are the body's “professional phagocytes.” While in the circulation neutrophils are maintained in a resting state, with their wide array of cytotoxic mediators either stored in cytoplasmic granules or separated into plasma membrane and cytosolic compartments. Activation of the cell may be triggered by the engagement of particles, such as invading microorganisms or in the case of autoimmune disease, in response to soluble stimuli that engage specific cell surface receptors (1).

Directed Migration or Chemotaxis

In inflammation, the initial step of neutrophil activation requires movement toward a target. Such directed migration, or chemotaxis, occurs along a chemical gradient originating at the target. Well-described chemoattractants include bacterial products such as formulated peptides, and activated complement components such as C5a. These chemoattractants interact with specific surface receptors that have seven hydrophobic transmembrane domains (2). Ligand/receptor interactions lead to conformational changes of the receptor that allow it to interact with, and activate, heterotrimeric G (guanosine triphosphate [GTP] binding) proteins. Activation of C proteins results in the generation of an intracellular signal that triggers chemotaxis and related functional responses.

Chemoattractants for neutrophils include leukotriene B4, platelet-activating factor, interleukin-8, and the complement split product C5a. At low concentrations, and when distributed in a gradient, these molecules lead neutrophils to migrate toward regions of higher concentrations. At higher concentrations, however (i.e., at the bacterial source of the gradient), these same molecules cause neutrophils to cease migration and become activated, as described below.

Phagocytosis

Following directed migration along a chemoattractant gradient, phagocytosis is initiated by the attachment or binding of target particles to the neutrophil surface. Attachment is followed by enclosure of the particle within a plasma

membrane pouch. Upon closure this pouch becomes a vacuole in the cytoplasm, termed a phagosome. Fusion of the respective membranes permits entry of lysosomal contents into the phagosome and the shielded enzymatic degradation of ingested material, an important aspect of the scavenging function of both neutrophils and macrophages. Thus, phagocytosis can deliver a microbial prey to a sequestered compartment in which the noxious action of host cytotoxins (e.g., degradative enzymes) can be confined.

Table 14-1: Pro-Inflammatory Mediators Released By Neutrophils, Macrophages, and Platelets

Secretory products produced by neutrophils and macrophages
Reactive oxygen intermediates (e.g., superoxide anion)
Proteolytic enzymes
Reactive nitrogen intermediates (e.g., nitric oxide)
Bioactive lipids
Cyclooxygenase products: prostaglandin E2 (PGE2), prostaglandin F2a prostacyclin, thromboxane
Lipoxygenase products: monohydroxyeicosatetraenoic acids, dihydroxyeicosatetraenoic acids, leukotrienes B4, C, D and E*
Platelet-activating factors
(1 O-alkyl-2-acetyl-sn-glycerlyl-3-phosphorylcholine)
Chemokines (e.g. interleukin-8)
Secretory products produced by macrophages
Polypeptide hormones
Interleukin lα and 1β (collectively. IL-1)
Tumor necrosis factor-α (cachectin, TNF)
Interferon-α
Platelet-derived growth factor(s)
Transforming growth factor-β
ß-endorphin
Complement (C) components
Classic path: C1, C4, C2, C3, C5
Alternative path: factor B factor D, properdin
Coagulation factors
Intrinsic path: IX, X. V. prothrombin
Extrinsic path: VII
Surface activities: tissue factor, prothrombinase
Prothrombolytic activity: plasminogen activator inhibitors, plasmin inhibitors
Secretory products produced by platelet
Plasminogen
α2-plasmin inhibitor
Platelet-derived growth factor
Platelet factor IV
Transforming growth factors α and β
Serotonin
Adenosine diphosphate
Thromboxane A2
12 hydroxytetraenoic acid

*Not produced by neutrophils.

Although designed primarily to ingest invading microorganisms, macrophages and neutrophils can be triggered by opsonins to release cytotoxic products in the absence of phagocytosis. This occurs in autoimmune disease where antibodies activate the complement system and where soluble immune complexes with covalently bound (i)C3b can engage neutrophil Fc and complement receptors. While the host has multiple inhibitory proteins in extracellular biologic fluids that inactivate released products, such protective mechanisms can be overcome with resultant tissue injury as observed in necrotizing vasculitis, arthritis, and glomerulonephritis (3).

Release of Toxic Proteolytic Enzymes

Neutrophils contain two morphologically distinct granules (specific and neutrophilic) that contain proteases, which under normal circumstances are sequestered within the granule and the phagolysosome, presenting no threat to the host. However the extracellular release of granule contents may promote inflammation and damage at tissue sites. Phagocytosis is not necessary for neutrophil degranulation, which may be provoked by soluble stimuli (e.g., C5a, interleukin-8). Degranulation is augmented when neutrophils encounter stimuli deposited on a surface: lysosomal release unfolds by a process of reverse endocytosis, or what has been called “frustrated phagocytosis.” This exuberant release of lysosomal enzymes from neutrophils may be relevant to the pathogenesis of tissue injury in diseases characterized by the deposition of immune complexes on cell surfaces or on such extracellular surfaces as vascular basement membranes or articular cartilage (4).

In glomerulonephritis, neutrophil-derived proteases can be demonstrated in urine and are involved in the degradation of the extracellular matrix proteins of the glomerular basement membrane (GBM) and mesangium. The principal proteases that promote GBM degradation appear to be serine proteases, elastase, and cathepsin G, as well as neutrophil collagenase (5). In addition to proteases, neutrophils also release cationic proteins with bactericidal activity, such as lysozyme, bactericidal/permeability increasing factor (BPI), and the defensins, which increase glomerular permeability by neutralizing the anionic components of the GBM.

Production of Toxic Oxygen Radicals

The activation of phagocytic leukocytes results in the production of oxygen free radicals, such as superoxide anion, which have potent microbicidal activity. When released extracellularly, oxygen derived free radicals cause tissue injury and irreversible modification of macromolecules (6 ,7). Superoxide anion is produced by the addition of an extra electron to molecular oxygen by a multiprotein complex that requires membrane-bound cytochrome b558 and key cytosolic proteins (including a ras-related low molecular weight GTP-binding protein). The multiprotein complex is assembled at the plasma membrane in response to cell activation. Stimulated neutrophils also produce hydrogen peroxide, hydroxyl radicals, and possibly singlet oxygen.

Some of the most toxic oxygen metabolites produced by neutrophils are generated by the myeloperoxidase (MPO) hydrogen peroxide-halide system. MPO is a highly cationic enzyme present in the azurophilic granules that catalyzes the reaction of hydrogen peroxide with a halide such as chloride to form hypohalous acids (e.g., hypochlorous acid). These products are capable of killing a variety of microorganisms as well as mammalian cells. There is evidence that the MPO-hydrogen-peroxide halide system plays a significant role in phagocyte-mediated injury in glomerulonephritis (5).

Macrophages

Macrophages as Secretory Cells in Inflammation

Macrophages play multiple roles in inflammation and immunity, serving as both antigen-presenting cells (APCs) that drive adaptive immune responses, as well as primary inflammatory cells in chronic disease. Tissue macrophages derive from circulating monocytes, and differentiate and become activated upon exiting the vasculature. Although the process of macrophage adhesion to, and diapedesis through, blood vessels is similar in many respects to that of neutrophils, the macrophage responds to a different set of chemotactic factors, including the chemokines RANTES, monocyte chemotactic protein (MCP)-1, macrophage inflammatory protein (MIP)-1a and -1b and the growth factors transforming growth factor (TGF)-ß and platelet-derived growth factor (PDGF) (8). Macrophages/monocytes play an important role in immune-mediated tissue injury particularly in nephritis (9). These cells express the three major classes of Fc receptors as well as ß1, ß2, and ß3 integrins, which facilitate phagocytosis of opsonized particles, intercellular adhesion, and adhesion to extracellular matrix proteins. Recruitment requires the expression of adhesion molecules on activated vascular endothelium (e.g., intercellular adhesion molecule-I [ICAM1] vascular cell adhesion molecule [VCAM1]), which are recognized by counter-ligands of the circulating monocyte (e.g., LFA1, VIA4). When monocytes emigrate into tissues they can be transformed into activated macrophages following exposure to cytokines such as interferon-γ (IFN-γ), IL-l, and tumor necrosis factor (TNF-α), Macrophage activation results in an increase in cell size, increased synthesis of proteolytic enzymes, and the secretion of a variety of inflammatory products.

Release of Inflammatory Mediators and Protease

Through ligation of specific surface receptors, macrophages may be activated by IFN-γ, complement components, immune complexes, LPS, and cytokines such as IL-1ß, TNF-α, and IL-6 (8). Once activated, macrophages secrete a variety of pro-inflammatory products, including proteases (e.g., lysozyme, elastase and collagenase), inflammatory cytokines (IL-1ß, TNF-α, IL-6, IL-12, and others), chemokines (including IL-8, MCP-1, MCP-2, RANTES, and others), and several complement cascade proteins (C1, C2, C3, and C4) (8). Indeed, a vigorous acute-phase response, driven by cytokine production and characterized by an increased erythrocyte sedimentation rate and high serum levels of acute phase reactants, is typical of diseases accompanied by extensive macrophage involvement. Activated macrophages also produce reactive oxygen species, inducible nitric oxide, and a number of eicosanoids (primarily PGE2, but also TxA2, prostacyclin, LTB4, and PAF) (10). In addition, activated macrophages produce procoagulant factors such as tissue factor and plasmin inhibitor (11). The procoagulant products include tissue factor (identified as a receptor for factor VII) factor × activator, prothrombin activator, and vitamin K–dependent clotting factors II, VII, IX, and X. Monocytes in rheumatic disease patients display a higher procoagulant producing activity than normal, likely a result of exposure to cytokines and cleavage products of complement. Increased procoagulant activity may contribute to fibrin deposition at sites of inflammation and has been implicated in the formation of crescent formation in glomerulonephritis. Whether such increased macrophage procoagulant activity observed in these conditions also promotes a systemic “hypercoagulable” state in SLE remains unknown.

Production of Cytokines

Macrophages also secrete a variety of polypeptide hormones that regulate immune function and inflammation as well as wound healing and repair (12). Macrophages, for example, produce three cytokines, IL-lα., IL-1ß, and TNF-α, which not only have overlapping functions, but also are capable of inducing each others' release by macrophages themselves (6). Macrophages also produce the cytokine neutrophil-activating peptidel/IL-8, which is a potent neutrophil chemoattractant. The production of IL-8, induced by IL-lα, IL-1ß, and TNF-α has been described in a variety of tissues, including alveolar macrophages renal mesangial cells, and psoriatic skin lesions (13). 1L-8 is now known to be a member of a family of macrophage inflammatory proteins (MIPs) or chemokines.

Nitric Oxide as a Modulator of Inflammation

Macrophages are also among the cellular sources of reactive nitrogen intermediates such as nitric oxide (NO). NO, although originally identified as a product of endothelial cells, which accounts for “endothelium-derived relaxation factor” activity, is now appreciated to be a highly reactive molecule with diverse biologic functions. The exposure of macrophages to cytokines (e.g., IL-1b, IFN-γ) markedly increases NO production. Activities of NO that may be important in the inflammatory response include vasodilation and its capacity to react with superoxide anion to form

toxic peroxynitrite compounds. Consistent with a pro-inflammatory role in SLE, the inhibition of NO synthesis has been demonstrated to reduce the severity of glomerulonephritis in Medical Research Laboratory lymphoproliferative (MRL/pr) mice (14). In human SLE, serum nitrite is elevated during active disease and levels correlated with both SLEDAI and titers of antibodies to double-stranded DNA (15).

NO, constitutively produced by vascular endothelium, may exert anti-inflammatory properties (16). For example, NO inhibits neutrophil and platelet aggregation, inhibits the adhesion of neutrophils to endothelial cells, inhibits neutrophil oxidant production, and thereby may serve as a “Teflon coat” for blood vessel walls against cellular injury (17). Thus, the role of NO in inflammation is complex. The pro or anti-inflammatory properties will depend on (a) whether NO is constitutive (and therefore physiologic) or induced (usually pathologic) and (b) the potential for the formation of toxic derivatives such as peroxynitrite, and (c) the adaptive responses of target cells.

Platelets

Platelets as Inflammatory Cells

Platelets, derived from marrow megakaryocytes, are involved in hemostasis, wound healing, and cellular responses to injury (18 ,19). In addition to its important hemostatic function, the platelet may also act as an inflammatory effector cell. In addition to containing procoagulant factors such as Von Willebrand factor, fibrinogen, and factor V, platelet granules also contain inflammatory mediators, including chemokines (such as RANTES, MCP-3, MIP-1α, and platelet factor 4), growth factors (such as platelet-derived growth factor and transforming growth factor-B), histamine, and serotonin (20). Signaling molecules up regulated on the activated platelet include P-selectin, which adheres to and activates neutrophils, and CD40L, which induces inflammatory phenotypes in many cell lines, including the endothelium (21). Upon activation, platelets also rapidly produce eicosanoids, such as thromboxane A_2, from membrane-derived arachidonic acid, and other lipid membrane-derived inflammatory products, such as platelet-activating factor. Platelets both participate in cell-cell interactions and release micro particles that contribute to leukocyte-leukocyte and leukocyte–endothelial cell interactions; these interactions play a role in inflammation as well. Platelet activation at sites of tissue injury is induced by such hemostatic factors as thrombin, adenosine diphosphate, arachidonate derivates, and exposed subendothelial collagen. There is evidence of platelet activation in immunologically mediated diseases such as asthma, cold urticaria, scleroderma, and SLE (21 ,22 ,23 ,24).

Platelets in Glomerulonephritis

Platelets have been identified in the glomeruli of patients with SLE nephritis where they are believed to play a particularly important role (25). Urinary thromboxane levels are elevated in patients with active lupus nephritis, a finding that has several implications: first, it is a sign of abnormal platelet aggregation in the microvasculature with the potential for thrombosis and endothelial injury; second, the vasoconstrictive properties of TxA_2, would be expected to decrease glomerular filtration rate (GFR) and renal blood flow; and third, the release of growth factors and other mediators by activated platelets could aggravate the proliferative glomerular lesion. Studies of the administration of specific TxA_2 antagonists have shown promise in the improvement of both GFR and renal blood flow in SLE nephritis (26).

Platelet activation in lupus glomerulonephritis has been attributed to a variety of substances, including immune complexes, activated complement components (including C3a and the membrane attack complex, C5b9), PAF, and vasopressin. Additionally, neutrophils may also be able to activate platelets via the release of oxidants and proteases. Platelets may aggravate immune injury in glomerulonephritis via several mechanisms, which include (a) promoting thrombosis; (b) reducing GFR through the production of thromboxane and other vasoactive substances; and (c) releasing products that activate macrophages, neutrophils, and glomerular mesangial cells (5).

Endothelial Cell Activation

In order to localize to extravascular tissue, leukocytes must first exit the vasculature and migrate to the appropriate extravascular space. These processes require a complex sequence of events, beginning with the (micro) vascular response to injury. In response to a bacterial infection or other insult, arterioles vasodilate and endothelial cells contract, exposing the basement membrane; blood flow slows and plasma extravasates. In turn, leukocytes concentrate and gain increased contact with the endothelium. Endothelial cells, activated by mediators such as IL-1ß and TNF-α produced by tissue macrophages, DC, and fibroblasts, express surface molecules that contact and bind leukocytes, permitting their egress from the vasculature (9). Different groups of adhesion molecules sequentially mediate leukocyte rolling, tight adhesion, and passage through the vascular wall, or diapedesis. The first step, leukocyte rolling, occurs via the interactions of the adhesion molecule E-selectin on endothelial cells and L-selectin on leukocytes with mucin-like sialylated glycoproteins on leukocytes and endothelial cells, respectively (27). Selectins are expressed constitutively on both leukocytes and endothelium, and their interactions are strong but short-lived, with the result that a percentage of leukocytes are transiently adherent, or marginated, to the endothelium at all times, moving along with a tumbleweed-like progression. At sites of inflammation, following exposure to stimuli such as IL-1ß and TNF-α, the expression of E-selectin on endothelial cells increases markedly, leading to an increase in the percentage of leukocytes that marginate and roll along the vessel margins. The next step, leukocyte tight adhesion, results from the interaction of leukocyte adhesion molecules known

as integrins (e.g., CD11a/CD18 or LFA-1, CD11b/CD18 or CR3, α4β1 or VLA-4) with counter-ligands on endothelial cells (e.g., the cellular adhesion molecules [CAMs], ICAM-1, and VCAM-1) (28). This process requires de novo expression of CAMs on endothelium and activation of pre-existing integrins on leukocytes, both in response to inflammatory mediators. Important integrin-ligand pairing characterize specific cell-cell adhesion and contribute to the distribution and homing of leukocytes; common integrin-ligand pairs include CD11a/CD18 with ICAM-1 (lymphocytes-endothelium), CD11b/CD18 with ICAM-1 (neutrophils-endothelium) and VLA-4 with VCAM-1 (monocytes-endothelium). Finally, transmigration of leukocytes though the endothelium and basement membrane is mediated by chemokines such as MCP-1, C5a, and IL-8 (29).

Table 14-2: Pathologic and Clinical Spectrum of Vascular Injury on Systemic Lupus Erythematosus (SLE) A

Pathology	Pathogenesis	Clinical Phenomenon
Capillaritis*	Immune complex deposition	**Glomerulonephritis, pulmonary alveolar hemorrhage
Vasculitis*	Activation of complement, neutrophils, and endothelium Modeled by Arthus lesion	†Cutaneous purpura, polyarteritis nodosa-like systemic and cerebral vasculitis
Leukothrombosis	Intravascular activation of complement, neutrophils, and vascular endothelium Modeled by Shwartzman lesion	Widespread vascular injury, hypoxia, cerebral dysfunction, SIRS
Thrombosis	Antibodies to anionic phospholipid-protein complexes interact with endothelial cells, platelets, or coagulation factors Modeled by APS	Arterial and venous thrombosis, fetal wastage, thrombocytopenia, pulmonary hypertension
	Disseminated intravascular platelet aggregation	TTP
Atherosclerosis	Activated endothelium, increased endothelial cell adhesion molecules, increased tissue factor, decreased 27-hydroxylase	MI, CVA

*Capillaritis or microvascular angiitis and lupus vasculitis share a similar pathogenesis but are associated with different clinical phenomena, designated here as ** and †.
APS, antiphospholipid syndrome; CVA, cardiovascular accident; MI, myocardial infarction; SIRS, systemic inflammatory response syndrome; TTP, thrombotic thrombocytopenic purpura.

The Activation of Complement and Inflammatory Cells in the Development of Vascular Injury in SLE

SLE is the autoimmune disease that best exemplifies the consequences of the systemic generation of humoral inflammatory mediators and the activation of the cellular constituents of inflammation as outlined above. Immune complex formation, episodic complement activation, the recruitment of stimulated leukocytes and platelets into tissues, and endothelial cell activation produce vascular injury during SLE exacerbations. Vascular disease in SLE can be classified into two broad categories: inflammatory and thrombotic. The former may be associated with local deposition of immune complexes or result from leukocyte-endothelial cell interactions in the absence of immune complex deposition, and the latter is almost invariably associated with circulating antiphospholipid antibodies (Table 14-2).

Inflammatory Vascular Disease

In most instances, inflammatory vascular disease in SLE involves complement activation and resultant cell-mediated tissue injury.

Complement Cascade

Three distinct complement cascades—the classical, alternative, and lectin pathways—differ in their mechanisms of target recognition and initial activation, but converge at the C3 convertase (30). Many of the complement plasma proteins are zymogens, proteases that become active upon undergoing proteolytic cleavage; thus, these proteins generally circulate in a dormant state. Once active, many of these molecules participate in cleavage or activation of subsequent components. Thus, each successive enzymatic step results in rapid and dramatic amplification. In response to

this potential for explosive activation, a number of complement regulatory molecules exist to dampen the cascades. Given the importance of complement activation to rheumatic disease, a more detailed understanding of the three complement cascades is important for both researchers and practicing rheumatologists.

Classical Pathway

Activation of the classical pathway occurs when the C1q component of the multimeric complement 1 complex (C1) binds to multiple Fc portions of IgG or IgM antibodies complexed to antigen. When at least two of the six globular heads of C1q have bound, the remaining components of the C1 complex (two molecules each of C1r and C1s) undergo a conformational change, which results in the cleavage of soluble C4 and C2 to C4a and C4b and C2a and C2b, respectively (31). C4b and C2b combine to form C4b2b (the C3 convertase of the classical pathway), that cleaves C3 to C3a and C3b. C3b combines with C4b2b to form C4b2b3b (C5 convertase), which in turn cleaves C5 to C5b and C5a (32). Subsequent assembly of the C5b-9 membrane attack complex (MAC) can form a pore in the cell membrane of some pathogens, leading to their death. Additionally, C3b molecules serve as opsonins, which are covalently attached to a single bacterium's surface, facilitating its phagocytosis by macrophages and neutrophils.

Mannose-Binding Lectin Pathway

The mannose-binding lectin pathway is a primitive version of the classical cascade, activated by bacterial surface mannose residues. Since these residues are not accessible on vertebrate cells, the lectin-binding pathway distinguishes “self” from “other” on the basis of a generic pattern, rather than a specific antigen; as such, it represents a bridge between innate and acquired immunity. When the C1q-like mannose-binding lectin (MBL) component of the MBL complex (analogous in form and function to the C1 complex) binds mannose on a pathogen, it activates the mannose-associated serine proteases MASP-1 and MASP-2 (akin to C1r and C1s); thereafter, the MBL complex functions as does activated C1, cleaving C4 and C2 to form C3 convertase (33).

Alternative Pathway

The alternative pathway is unique in that it does not require a pathogen-binding protein for its activation; rather, it is initiated by the spontaneous hydrolysis of C3 in plasma. C3·H20 binds the alternative pathway component factor B, which is then converted by the associated factor D into Ba and Bb. The C3·H20-Bb complex that results is an alternate C3 convertase, and converts fluid-phase C3 into C3a and C3b, the latter of which is quickly inactivated by hydrolysis unless it deposits upon a cell surface. Once covalently bound to a cell surface (or indeed, any surface), however, C3b binds factor B; factor D cleaves factor B, resulting in the formation of the C3 convertase, C3bBb, which is equivalent to the C3 convertase^{C4b2b} of the classical and lectin pathways (32). Others and we have demonstrated that during the course of active SLE, complement is activated via both the classical and alternative pathways, and may be useful in distinguishing disease flare from preeclampsia in pregnant lupus patients (35).

C3a and C5a—Anaphylatoxins

The release of the soluble fragments C3a and C5a, also known as anaphylatoxins, accelerates the inflammatory response in multiple ways: anaphylatoxins engage receptors on mast cells and basophils, triggering release of vasoactive mediators such as histamine and the cysteinyl leukotrienes LTC4 and LTD4. C5a and C3a induce vasodilation and increased capillary permeability; upregulate adhesion molecule expression on leukocytes and endothelial cells; and cause smooth muscle contraction. C5a in particular is also a powerful chemoattractant for, and activator of, neutrophils, and can stimulate both neutrophil degranulation and the respiratory burst (36). Since plasma C3a is a reflection of complement degradation, while plasma levels of total C3 reflect degradation and synthesis of C3, an acute phase protein, measurements of C3a may be more sensitive and specific biomarker of lupus disease activity than C3 (37).

Complement Regulation

When C3bBb binds to host cells, the host complement-regulatory proteins complement receptor 1 (CR1) and decay-accelerating factor (DAF) rapidly bind C3b and displace Bb. CR1 and DAF, in combination with the membrane cofactor protein (MCP), also catalyze the cleavage of C3b by the plasma protease factor I to produce inactive C3b. Bacterial surfaces lack these proteins and instead permit binding of properdin, which stabilizes rather than degrades the alternative C3 convertase.

Other proteins have also evolved to inhibit complement activation. These include fluid-phase proteins, such as C1 inhibitor and the C3 and C5 convertase inhibitors, C4-binding protein and factor H, as well as membrane-bound proteins such as the C3 and C5 convertase inhibitors, and CD59, a glycolipid that prevents insertion of the MAC into plasma membranes (38).

Complement in SLE

Patients with specific complement deficiencies are especially prone to SLE; approximately 90% of C1q-null, 75% of C4-null, and up to 30% of C2-null individuals develop lupus. Why complement deficiency predisposes to autoimmune disease is not entirely clear, but may result from inefficient clearing of apoptotic cells and immune complexes, resulting in either inappropriate exposure to self-antigens or in immune complex deposition (39).

Complement activation plays an important role in the tissue injury observed in many of the manifestations of SLE, including that because of immune complex (IC) deposition, non-IC dependent neutrophil-mediated vasculopathy, as well as injury because of antiphospholipid antibodies. The renewed interest in complement in inflammatory disease has led to the development of pharmacologic complement inhibitors that are currently in development, including humanized monoclonal C5 antibody and a solubilized CR1 molecule, which prevents activation of the C3 convertase (40).

Immune Complex Deposition-Dependent Vascular Inflammation

Vasculitis in SLE is most commonly a result of the local deposition of immune complexes, particularly those containing antibodies to DNA (anti-DNA), in blood vessel walls (41 ,42). This lesion is best modeled by the Arthus reaction and experimental serum sickness. Maurice Arthus reported in 1903 that the repeated cutaneous injection of horse serum into a group of rabbits produced inflammatory reactions characterized by intense polymorphonuclear leukocyte infiltration, hemorrhage, and sometimes necrosis (43). It is now known that this reaction is due the formation of antigen antibody complexes in the vicinity of blood vessel walls, complement activation, and the generation of anaphylatoxins (e.g., C4a, C3a, C5a) and chemotaxins (C5a) (44 ,45). The resulting infiltration of vessel walls by polymorphonuclear leukocytes leads histologically to leukocytoclastic vasculitis and the release of lysosomal enzymes and oxygen radicals to tissue injury (42).

Modifications of the classic active Arthus reaction include immunization by intravenous rather than cutaneous injection of the antigen as well as the local passive Arthus reaction (e.g., simultaneous cutaneous injection of antigen and antibody), direct passive Arthus reaction (e.g., passive transfer of preformed antibody by the intravenous injection of serum from another immunized rabbit), and the reverse passive Arthus reaction (e.g., antibody injected cutaneously and antigen injected intravenously) (46). The necessary elements of these reactions have been examined and require antigen, precipitating antibody, intact complement pathway, and neutrophils (47). One study suggests that the inflammatory response to immune complexes also requires cell-bound Fc receptors with subsequent amplification by cellular mediators and complement (48). A role for C5a receptors has also been established since C5aR blockade abrogates this response (49).

Immune complex disease in SLE can also be modeled by the acute experimental serum sickness or the glomerulonephritis that accompanies chronic serum sickness. In the acute serum sickness model, the injection of antigen is followed by an immune response, with the generation of antibody and clearance of the antigen by the cells of the reticulo-endothelial system. However, during the period of accelerated decay of the antigen the presence of circulating immune complexes produces inflammatory injury involving arteries, glomeruli, and joints (50). Chronic serum sickness requires usually at least 5 weeks of repeated injection of intravenous antigen. The resulting periods of antigen excess leads to circulating immune complexes and glomerulonephritis histologically similar to that observed in patients with SLE (Fig. 14-1) (51).

A major consequence of immune complex deposition in SLE is the activation of complement. The consumption of complement components and their deposition in tissue is reflected by a decrease in serum levels of C3 and C4 in most patients with active disease (52). However, since the synthesis of both C3 and C4 increases during periods of disease activity, the serum levels of these proteins may be normal despite accelerated consumption (53). Conversely, chronically depressed levels of individual complement components, because of decreased synthesis, hereditary deficiencies, or increased extra vascular distribution of complement proteins, has been reported in SLE (54). The decreased serum complement levels in these patients may lead to the mistaken conclusion that excessive complement activation is ongoing. To define more precisely the role of complement activation with respect to clinical disease activity of SLE, circulating levels of complement degradation products during periods of active and inactive disease have been measured (55 ,56 ,57 ,58 ,59 ,60). Levels of plasma C3a, Ba, and the serum complement attack complex, SC5b9, were each shown to be more sensitive indicators of disease activity than either total C3 or C4 level (55 ,56 ,57 ,58 ,60). Elevations of plasma C3a levels may precede other serologic or clinical evidence of an impending disease flare (60). The combination of elevated C3a and anti-dsDNA, as pathogenically anti-dsDNA/DNA immune complexes are complement fixing and more likely to incite tissue injury, can predict flare and may identify patients responsive to preemptive short-term, moderate dose steroid treatment (61).

The pathologic consequences of immune complex deposition in SLE include both a microvascular angiitis (e.g., glomerulonephritis or pulmonary capillaritis with or without pulmonary hemorrhage) and necrotizing vasculitis (e.g., cutaneous purpura, polyarteritis nodosa—like systemic, cerebral).

Immune Complex "Independent" Vascular Injury

Some patients with SLE have small vessel disease and inflammatory vasculopathy in the absence of local immune complex deposition, particularly those patients with central nervous system (CNS) involvement (57 ,62 ,63). Several lines of investigation now suggest yet another mechanism for this complement mediated vascular injury in SLE, one not dependent on immune complex deposition (64 ,65 ,66 ,67 ,68 ,69). This mechanism is best modeled experimentally by the Shwartzman phenomenon. The local Shwartzman lesion requires a preparatory intradermal injection of endotoxin, which is followed in 4 to 18 hours by the intravenous injection of endotoxin (70 ,71). This results in the intravascular

activation of complement triggering the release of anaphylatoxins such as C3a and C5a into the circulation (72). The split products attract and activate inflammatory cells, such as neutrophils and platelets, causing them to aggregate, to adhere to vascular endothelium, to occlude small vessels, and to release toxic mediators. Activation of complement thus leads to an occlusive vasculopathy that may also result in widespread ischemic injury (72).

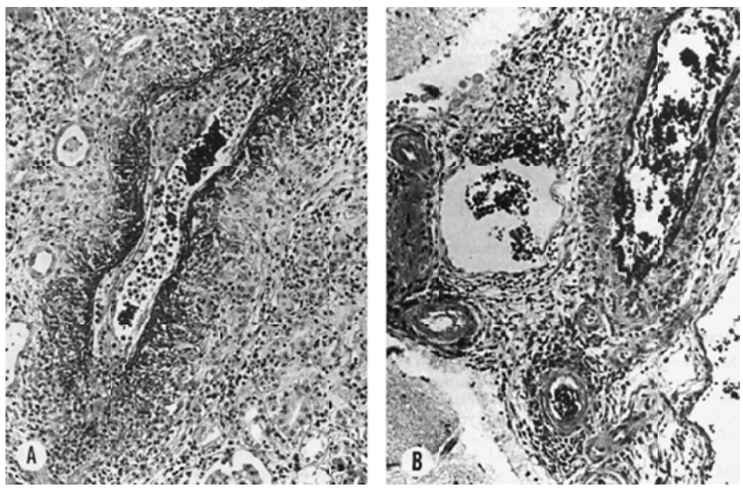

Figure 14-1. A, Polyarteritis-type lupus vasculitis with fibrinoid necrosis in the kidney of a patient with systemic lupus erythematosus (SLE). **B,** Polyarteritis-type lupus vasculitis with fibrinoid necrosis in the brain of a patient with SLE. (H&E, × 160.)

The Shwartzman phenomenon was originally described as a model of meningococcal sepsis but it is now recognized that cytokines such as ILl and TNF-α can substitute for endotoxin (Fig. 14-2) (62). Such agents stimulate the up regulation on the endothelial cell surface of ICAM1 and E-selectin, which are the counterreceprors for the neutrophil adhesion molecule CD 11b/CD 1 8 and SialylLewis X, respectively (74). It had long been established that complement activation in plasma stimulates circulating neutrophils to produce the local Shwartzman lesion, but it has been recognized that the preparatory phase represents a time of ICAM I and Eselectin up regulation (71). The importance of this local endothelial cell activation is supported by the capacity of antibodies to ICAM 1 and E-selectin administered intravenously to prevent the development of the experimental lesion (71).

The episodic, uncontrolled activation of complement proteins is a characteristic feature of SLE. Disease exacerbations are typically accompanied by decreases in total C3 and C4 values in association with elevations in plasma of the biologically active complement split products, C3a desArg and C5a desArg (57 ,58 ,75 ,76). During periods of disease flare, circulating neutrophils are activated to increase their adhesiveness to vascular endothelium, as indicated by the up regulation of the surface ß-2-integrin CD 11b/CD 18 (complement receptor 3) (66 ,67). One study demonstrated that the surface expression of three distinct endothelial cell adhesion molecules, Eselectin, VCAM 1, and ICAM1, is also up regulated in patients with SLE (Fig. 14-3) (63). Endothelial cell activation was most marked in patients with disease exacerbations characterized by significant elevations of plasma C3a desArg, and the activation reversed with improvement in disease activity (63). In these studies, endothelial cell adhesion molecule up regulation was observed in otherwise histologically normal skin and was notable for the absence of local immune complex deposition (63). These data suggest that excessive complement activation in association with primed endothelial cells can induce neutrophil endothelial cell adhesion and predispose to leuko-occlusive vasculopathy during SLE disease flares. This pathogenic mechanism may be of particular relevance to vascular beds, which lack the fenestrations that permit the trapping of circulating immune complexes. Such an example is the CNS, where the blood–brain barrier can prevent the access of circulating immune complexes to the

perivascular tissues. But in the setting of widespread endothelial cell activation, exuberant systemic complement activation can promote diffuse microvascular injury in the absence of immune complex deposition and produce the most common pathologic finding of CNS lupus, microinfarction (Fig. 14-4) (75 ,79 ,80 ,81 ,82).

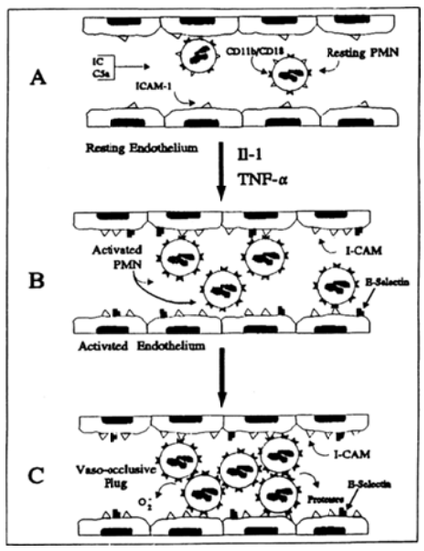

Figure 14-2. Schematic presentation of the Schwartzman phenomenon. **A,** Stimulation of polymorphonuclear leukocytes (PMNs) via engagement of C5a or Fc receptor leads to activation of CD11b/CD18, promoting homotypic and heterotypic aggregation. IC, immune complexes. **B,** Endothelial cell activation by cytokines, such as interlukin-1 (IL-1) and tumor necrosis factor-α (TNF-α), leads to upregulation of constitutive intercellular adhesion molecule-1 (ICAM-1) and induces the expression of E-selectin. **C,** The co-occurrence of PMN and endothelial cell activation results in leukothrombosis and vasoocclusive plugs.

Similar pathologic events may also be present in the mesenteric circulation and produce features of SLE enteritis (62) or produce pulmonary leukosequestration and acute, reversible hypoxemia during disease exacerbations (83).

A role for complement activation and the Shwartzman phenomenon in the setting where antineuronal antibodies may mediate neuropsychiatric lupus is supported by experimental data. Several groups have reported on the prevalence of anti-dsDNA antibodies that cross-react with an epitope on the glutamate/N-methyl-D-aspartate (NMDA) receptor subunit NR2A, which is highly expressed in the human brain, and suggested that their excitotoxic effects can mediate CNS manifestations of lupus (84 ,85). Diamond has studied this mechanism in an animal model immunized by antigen to produce these antibodies, but observed that no neuronal damage occurred until breakdown of the blood-brain barrier occurs. Only following the administration of LPS, the prototypical inducer of the preparatory signals required for the Shwartzman phenomenon, did these antibodies gain access to the brain and it become possible to demonstrate neuronal death with resulting cognitive dysfunction (86). It is likely that some SLE patients with CNS involvement experience a brain capillary leak syndrome or “acute cerebral distress syndrome” resulting either only in reversible leukoencephalopathy or, in the presence of autoantibodies with specificity for brain antigens, the potential for neuronal death (87).

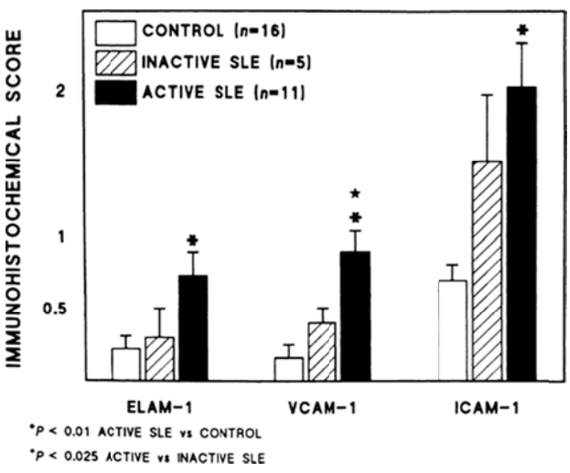

Figure 14-3. Systemic lupus erythematosus (SLE) disease exacerbation is accompanied by endothelial cell upregulation of three adhesion molecules: E-selectin (ELAM-1), vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1). The mean expression of all three adhesion molecules is significantly greater in patients with active SLE versus healthy controls as well as patients with inactive SLE.

The systemic inflammatory response syndrome (SIRS) is a reaction characterized by widespread inflammation primarily affecting vascular endothelium (88). The same cascade of mediators involved in the Shwartzman phenomenon has been invoked in SIRS (89 ,90). The main endogenous mediators of SIRS include TNF-α and Ill (89). A prominent role for PAF vasodilator prostaglandins, complement activation, and upregulation of adhesion molecules on leukocytes and endothelial cells has also been identified (89). A consequence of SIRS is multiple organ failure (MOF) or multiple organ dysfunction syndrome (MODS) with manifestations that include catecholamine unresponsive hypotension, decreased myocardial contractility, cerebral dysfunction, and adult respiratory distress syndrome

(ARDS). Interestingly, mAbs directed against the leukocyte integrin CD 18 can ameliorate the lung injury in experimental models of SIRS (91).

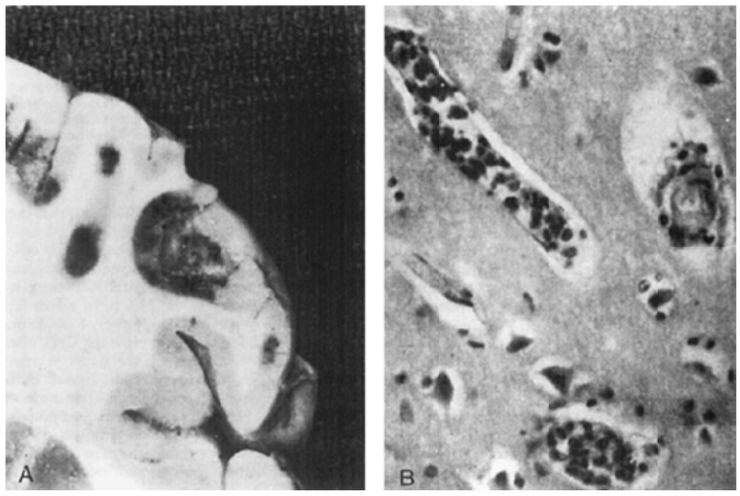

Figure 14-4. Specimen of brain obtained postmortem from a patient with fatal exacerbation of neuropsychiatric lupus without antiphospholipid antibodies. **A,** The frontal lobe reveals multiple small cortical infarcts. **B,** High magnification reveals leukothrombosis, with occlusion of small blood vessels by leukocyte aggregates, as well as acute ischemic changes of the neurons. (Photo courtesy of Dr. Nelson Torre, Buffalo, NY.)

It is now recognized that SIRS may arise both from sepsis and noninfectious causes, such as immune-mediated organ injury (88). Serious exacerbations of SLE can produce a syndrome that is indistinguishable from SIRS and can be accompanied by MOF. Therefore, the Shwartzman phenomenon may serve as a model for both SIRS and the multiorgan dysfunction that can accompany acute lupus crisis.

Inflammatory vasculopathy independent of immune complex deposition may also occur as a result of antineutrophil cytoplasmic antibodies (ANCAs) or lymphocyte responses. A pathogenic role for ANCAs in vasculitis has been suggested by the demonstration of activation of poly-morphonuclear leukocytes and enhanced adhesion to endothelial cells by antibodies to proteinase 3 or myeloperoxidase (92). Lymphocytes directly reacting to antigen may release cytokines that result in tissue damage and a mononuclear inflammatory disease (93). These mechanisms of vascular injury are more typical, however, of Wegener's granulomatosis and Sjögren's syndrome, respectively, than of SLE.

Thrombotic Noninflammatory Vascular Disease

Antiphospholipid Antibody Syndrome

The presence of antibodies to negatively charged phospholipids is associated with recurrent arterial and venous thrombosis, thrombocytopenia, and fetal wastage (94 ,95). Antiphospholipid antibody syndrome (APS) requires the demonstration of an antiphospholipid antibody (e.g., biologic false-positive Venereal Disease Research Laboratory [VDRL] test, lupus anticoagulant, anticardiolipin antibodies) and thrombotic phenomena. It is known that the presence in serum of this family of autoantibodies, perhaps operating through cofactors (e.g., ß2-glycoprotein-1 or prothrombin) can generate a thrombotic diathesis (96 ,97 ,98 ,99 ,100). The mechanism for this hypercoagulable state has not yet been fully understood, although it appears to involve interactions between the antibodies to anionic phospholipid-protein complexes and antigen targets on platelets (101 ,102), endothelial cells (103 ,104 ,105 ,106), or components of the coagulation cascade (107 ,108). Experimental evidence suggests

that increased platelet aggregation, altered endothelial cell function (e.g., decreased prostacyclin or increased thrombomodulin production), or disturbed function of clotting factors (e.g., decreased protein C activation by thrombomodulin, decreased protein S function, as well as decreased prekallikrein and fibrinolytic activity) may explain the predisposition to thrombosis. The role of cytokines in the primary APS or in APS secondary to SLE requires clarification (109). Evidence that antiphospholipid antibodies can activate endothelial cells and increase expression of adhesion molecules suggests another mechanism for the thrombophilia (110).

A critical role for complement and neutrophils in APS, especially in the circumstance of placental vasculopathy that underlies fetal loss, is supported by experimental studies where antibodies that block C5a-polymorphonuclear leukocyte C5a receptor interactions prevent complications in pregnant mice which receive human IgG containing APL antibodies (111 ,112). These findings are further confirmed by experience with using C3 convertase inhibitor complement receptor 1-related gene, gene as well as C3 deficient mice, both of which mitigates fetal loss (113).

A relationship between inflammation and thrombosis in antiphospholipid antibody induced hypercoagulability loss is further supported by the observation that these autoantibodies can induce endothelial cell tissue and monocyte tissue factor (TF) expression. TF, an initiator of the extrinsic coagulation cascade, mRNA and its molecule is increased when murine monoclonal ß2 glycoprotein I dependent anticardiolipin antibodies are incubated with cultured endothelial cells or peripheral blood mononuclear cells (114). That complement activation is proximal to TF production and that blockade of generation of TF can protect pregnancies from aPL antibody induced injury is supported by the finding that in C5aR knock out mice, even after treatment with aPL-IgG, no TF production is observed and the outcomes of their pregnancies are normal (115).

Thrombotic Thrombocytopenia Purpura

SLE exacerbations are infrequently accompanied by secondary thrombotic thrombocytopenia purpura (TTP) with complete or incomplete features of the clinical pentad: fever, microangiopathic hemolytic anemia, thrombocytopenia, renal disease, and neurologic dysfunction (116). In the absence of antiphospholipid antibodies, the characteristic pathology of TTP, eosinophilic hyaline microthrombi, has been identified in patients with SLE. Large multimers of vWF capable of mediating disseminated intravascular platelet aggregation have been demonstrated in patients with chronic, relapsing TTP as well as SLE (117 ,118). A consequence of the endothelial cell activation or injury observed in SLE may be the release of vWF multimers or other mediators of platelet aggregation capable of initiating a TTP-like illness (119). Additionally, evidence suggests that an inhibitor of vWF-cleaving protease (ADAMTS-13) causes the thrombotic microangiopathic hemolytic anemia that characterizes autoimmune associated TTP (120 ,121).

Endothelial Cell Dysfunction and SLE

SLE is increasingly a chronic illness, with rapidly fatal cases now rare and most patients experiencing a long-term disorder with frequent exacerbations and remissions. Therefore, chronic morbidity and late mortality are of greater importance. Urowitz et al. have reported their observations of mortality within the Toronto lupus cohort and described a bimodal distribution of death. Early (within the first year) deaths were most often attributed to active lupus and infection, while late deaths were secondary to atherosclerotic heart disease. Myocardial infarction (MI) accounted for 45% of all deaths. Other studies also document fatal MI in SLE populations but at a significantly lower and constant rate of 3% to 5% of total deaths. In addition to cohort studies of mortality associated with myocardial involvement, the increased prevalence of coronary artery disease in SLE has been documented by case reports and autopsy studies. In 1975, Buckley and colleagues performed autopsies in 36 SLE patients (33 female and mean age of 32 years). Four (11%) experienced MI, while eight (22%) had greater than 50% narrowing in at least one coronary artery. A second autopsy series of 22 patients age 16 to 37 years demonstrated ten (45%) had coronary artery narrowing that exceeded 75%. The Baltimore lupus cohort reported an 8.3% prevalence of cardiovascular events (MI, sudden cardiac death, and angina) in 229 patients. Ginzler et al. from the State University of New York (SUNY) Health Science Center in Brooklyn retrospectively studied 200 patients and found coronary artery disease (CAD) in 30 (15%), MI in 13 (7%), and angina in 24 (12%). Age-specific incidence rates of MI and angina were compared between 498 women with SLE from the University of Pittsburgh Medical Center and 2,208 female controls. Between the ages of 35 and 44 women with lupus were 50 times more likely than controls to experience MI. Most recently studies demonstrate lupus patients on electron beam CT scans have higher calcification scores as compared to controls (Agatston score of 69 vs. 9) and, when controlling for traditional risk factors, increased carotid plaque (37 vs. 15 percent) (122 ,123).

Although coronary artery vasculitis has been described in SLE, it is rare, and the accelerated CAD that is characteristic of SLE is typically otherwise indistinguishable from atherosclerosis that occurs outside the setting of lupus. The pathogenesis of the observed precocious atherosclerosis in SLE includes clustering of traditional risk factors, adverse effects of treatment (e.g., corticosteroids, cyclophosphamide), and vasculopathy that accompanies disease activity (e.g., hypercoagulable state of secondary antiphospholipid syndrome and neutrophil endothelial cell interactions). Endothelial cell injury and dysfunction with subsequent alteration of endothelial adhesiveness and permeability to leukocytes and platelets are principal mechanisms of both the atherosclerosis and the inflammatory state that characterizes SLE.

Endothelial cells line the lumen of all blood vessels and form the interface between the blood and peripheral tissues. Traditionally, the role of endothelial cells was considered to

be that of a gatekeeper. Passive deposition of cholesterol and its metabolites in the artery wall has been thought to be the key step in the pathophysiology of atherosclerosis. In recent years, however, attention has shifted to the role of primary vascular injury. Although many factors cause atherosclerosis, it has become clear now that endothelial cell perturbation and inflammation at the site of vascular injury plays an essential role in the initiation and progression of atherosclerotic disease.

In response to a diverse array of stimuli, activated endothelial cells exhibit a pro-inflammatory phenotype by up regulation of adhesion molecules on their surface, leading to sequential steps in rolling, firm adhesion, and transmigration of leukocytes and monocytes to the site of injury. Formation and accumulation of foam cells in turn promote neointimal proliferation and thinning of endothelium, which result in dysfunction of the endothelial cells, interaction with the platelets, and stimulation of smooth muscle proliferation, leading to fibrous plaque and thrombus formation (124 ,125).

The central role of endothelial cell—leukocyte interaction as an early response in the pathogenesis of atherosclerosis was demonstrated by experiments on the C57BL/6 mice model with homozygous mutations for the ICAM1 gene. This mutation, resulting in a deficiency of endothelial cell ICAM1 expression, is associated with a protective role on the development of atherosclerosis in this animal model (126 ,127). Additionally, SLE, a disease characterized by widespread vascular injury, has a high prevalence of premature atherosclerosis and represents an interesting model to study endothelial perturbation. Table 14-3 gives a summary of the factors altering endothelial cell behavior and specific endothelial responses to these stimuli.

Endothelial Phenotype

Endothelium plays a fundamental role in various physiologic functions, including vasoregulation, hemostasis, inflammation, and adhesion biology. What determines the actual difference between the chronic lesion in atherosclerosis and the acute and sub acute lesions of inflammatory vasculopathy? An understanding of the details of endothelial perturbation in response to stimuli may provide the explanation. Irrespective of the nature of the stimuli (immunogenic or direct mechanical forces), the endothelium responds by up regulating adhesion molecules and recruiting leukocytes, shifting the phenotype to procoagulant by expressing TF or vWF, and/or altering vascular tone.

Prothrombotic Phenotype

By shifting the phenotype to procoagulant in response to stimulation, endothelial cells have a direct role in the mechanism of thrombosis, whether this is at a site of atherosclerotic plaque formation or focal vascular inflammation, or in circumstances characterized by diffuse endothelial activation, such as in SLE, catastrophic antiphospholipid syndrome (CAPS), or SIRS (128 ,129).

Table 14-3: Reviewed Factors Stimulating Endothelial Cells and Endothelial Cells' Phenotypic Responses That Play an Important Role in the Pathogenesis of Atherosclerosis and Inflammatory Vasculopathy

Stimuli	Response
Nonimmunologic	Vascular tone
Mechanical forces: (transmural pressure, tension, hear stress) hypercholesterolemia, oxidized LDL, lysophosphatidylcholine	NO Prostacyclin Endothelin-1
Immunologic	Prothrombotic
Cytokines	Tissue factor
TNF-α	vWF
IL-1 IFN-γ	thrombomodulin
Activated complement products	Pro-adhesive
C3a, C3b, C5a, MAC	ICAM-l
Autoantibodies	VCAM-1
ACL	E-selectin
AECA	
Anti-oxLDL	
CD40/CD40L Interaction	
C1q receptors occupancy	

ACL, AECA, antiendothelial cell antibody; dsDNA, double-stranded DNA; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; LDL, low-density lipoprotein; oxLDL, oxidized LDL; NO, nitric oxide; VCAM, vascular cell adhesion molecule; vWF, von Willebrand factor.

Von Willebrand factor (vWF) is a macromolecular protein complex that plays a pivotal role in hemostasis. It functions as a carrier protein for plasma factor VIII, and mediates platelet adhesion to other platelets and to collagen exposed by damaged endothelium. Vascular endothelium is the major source of plasma vWF under physiologic and pathologic conditions. vWF is stored and released from endothelial cell secretory granules, along with its propeptide vWF-to-AgII. Elevated plasma vWF was found in diabetes and other vasculopathies. Its level and the level of propeptide can serve as a marker of endothelial activation (130). A group from Canada (131) demonstrated decreased peripheral dermal staining for endothelial vWF in SIRS patients, as well as in healthy volunteers after TNF-α injection. This was associated with significantly greater plasma vWF levels, indicating degranulation in response to cytokine stimulation that predisposes to formation of platelet microthrombi, lodging in small capillaries, causing areas of local tissue ischemia.

Cultured endothelial cells in vitro express TF in response to a great variety of stimuli (132). The data in vivo are controversial; one group found an absence of expression of TF by endothelium overlying atherosclerotic plaques by in situ

hybridization (133), but a later study reported endothelial expression of TF by using histochemical assessment (134). Solovey et al. (135) demonstrated expression of TF by endothelial cells of sickle cell anemia patients during the acute vaso-oclusive episode, supported by concurrence between TF antigen and messenger RNA (mRNA) expression.

Proadhesive Phenotype

Adhesion of leukocytes to vascular endothelium is one of the earliest events in acute immunogenic and nonimmunogenic inflammation (124). The initial surface expression of adhesion molecules is the common endothelial response not only to a variety of atherogenic stimuli, but also to complement-mediated vascular injury in SLE (immune complex–mediated, as well as immune complex–independent).

Many cells, including endothelial cells (ECs), constitutively express ICAM1, and its expression is up regulated by ILl or TNF-α. VCAM1 is mainly present on ECs activated by ILl, TNF-α, IFN-γ, or 1L4 (136). ECs activated by ILl, TNF-α, or thrombin transiently express E-selectin, thereby mediating endothelial adhesion of neutrophils or memory lymphocytes (120). Expression of these molecules promotes formation of vaso-occlusive plaques, by interaction of endothelium with activated neutrophils, displaying up regulation of ß2-integrin CD11b/CD18. The importance of this interaction was demonstrated in a model of vascular injury underlying thrombotic stroke (138). Investigators used neutrophil depleted or ICAM 1–deficient mice and demonstrated resistance of this model to focal cerebral ischemia and reperfusion injury provoked by experimental intraluminal occlusion of the cerebral artery. Elkon's group (139) demonstrated in MRL/MpJFAS lpr mice that ICAM 1 deficiency results in a striking improvement in survival. Data from several groups analyzing the level of various adhesion molecules in SLE further support the notion that endothelial cells play a central role in systemic inflammatory response by exhibiting their adhesive properties. Immunohistologic examination of nonsun-exposed skin from SLE patients showed up regulation of the surface expression of all three adhesion molecules—E-selectin, ICAM1, and VCAM1—in patients with active SLE and with otherwise histologically normal skin with no evidence of local immune complex deposition (63). Elevation of soluble adhesion molecules (E-selectin, sICAM1, sVCAM1) also has been reported in active SLE (140). A group from France (136) demonstrated increased level of sVCAM1 in patients with primary antiphospholipid syndrome (APLS), SLE-related APLS, or SLE, compared to healthy controls or thrombosis controls.

Stimuli That Activate Endothelial Cells

Factors that alter the functional status of endothelium can be divided into two major categories: nonimmunologic, such as direct mechanical forces, vasoactive mediators, and products of oxidation; and immunologic, such as cytokines, complement, and autoantibodies.

Nonimmunologic

The endothelium experiences three primary mechanical forces: transmural pressure, tension, and shear stress. Sprague et al. (141) have demonstrated flow-mediated modulation of endothelial activation markers, and Nagel et al. (142) reported up regulation of ICAM expression in cultured human vascular cells in response to shear stress.

Recent studies have supported the view that hypercholesterolemia and oxidative stress are important inducers of atheroma formation. One of the actions of oxidized low-density lipoprotein (oxLDL) is to induce endothelial dysfunction (143). Erl et al. (144) demonstrated activation of endothelial cells by oxLDL via distinct endothelial ligands, promoting adhesion of monocytes. It is speculated that one of the mechanisms is a disruption of signal transduction (145). Other mechanisms may be related to the lysophosphatidyl choline (LPC) moiety, one of the active components of oxLDL particles that induces superoxide endothelial cytotoxic effect via peroxinitrite production (145 ,146). Moreover, LPC is a major factor in the antigenicity of oxLDL (147 ,148). Antibodies against oxLDL were demonstrated both in normal, healthy individuals and in atherosclerotic plaques and were found to correlate with atherosclerosis progression (148). The level of oxLDL antibodies has been correlated with titers for aCL in SLE patients (146 ,149). Several groups (149 ,150) have demonstrated cross-reactivity of aPL and oxLDL underlying the link in development of atherosclerosis and immunologic process.

Immunologic

Cytokines are important mediators of endothelial cell activation. Specifically, TNF-α ILl, and macrophage colony-stimulating factor increase binding of LDL to endothelium and increase transcription of the LDL gene (143). TNF-α, IFN-γ, and ILl stimulate adhesion molecule expression on endothelial cells, and few studies have reported increased levels of these cytokines in the circulation during vasculitis (151). The Shwartzman phenomenon, originally described as a model of endotoxemia, currently is being used as a model of the widespread vasculopathy of SLE. It is recognized now that cytokines such as ILl and TNF-α are the preparatory signals of the inflammatory process (63 ,128). These pro-inflammatory cytokines are capable of promoting atherosclerosis by stimulating the adhesive properties of endothelial cells. Accumulation of TNF-α (152) and ILl (153) was demonstrated in atherosclerotic plaques of coronary arteries. It is also important to note that while endothelial cells are activated by cytokines, they also can produce ILl, 1L6, 1L8 and TNF-α while stimulated (151 ,154). These cytokines can act as autocoids to upregulate adhesion molecule expression. Kaplanski et al. (137) demonstrated induction of 1L8 production in a time- and dose-dependent

fashion by thrombin-activated HUVEC; this effect was inhibited by the specific thrombin inhibitor hirudin.

Complement activation that can be either immune complex–dependent or independent plays an essential role in the mechanism of endothelial injury. This can explain the development of widespread vascular injury in SLE, an example of immune-mediated systemic inflammatory response, even without evidence of immune complex deposition in the tissue. Several products of the activated complement system (C3b, iC3b, and C5a) are known to activate endothelial cells in vitro. More recently, Saadi et al. (155) demonstrated that interaction of complement with endothelial cells and the assembly of MAC leads to expression of P-selectin and activation of a protease that cleaves and releases heparan sulfate proteoglycan from the EC surface, and induces up regulation of TF and cyclooxygenase-2 (COX-2). They concluded that activation of porcine aortic and microvascular ECs on MAC exposure involves the intermediate step of ILl release. By using ECs transgenic for human decay accelerating factor that inhibits complement convertase, these authors demonstrated that complement is required for endothelial activation. The presence of sCRi prevented activation of aortic as well as microvascular ECs (156).

Granular deposits of immunoglobulin and complement components were found within atherosclerotic lesions (157), suggesting that complement dependent endothelial activation could play a role in pathogenesis of atherosclerosis.

Antibodies against endothelial cells and cardiolipin were found in a subset of patients with the clinical and angiographic diagnosis of severe premature atherosclerotic peripheral disease (158). Recent research demonstrated that antibodies might contribute to the derangement of functional status of the endothelial cells, rather than simply displaying cell cytotoxicity. It has been reported that both polyclonal as well as monoclonal antiendothelial cell antibodies (AECAs) induce EC activation in vitro. AECAs have been shown to mediate release of vWF, arachidonic acid metabolites, and ETi from endothelial cells, and to induce a pro-inflammatory and procoagulant phenotype of EC. A statistically significant increase in expression of endothelial ICAM1, VCAM1, and E-selectin was demonstrated on human umbilical vein ECs pretreated with AECA positive sera from a scleroderma patient compared to cells pretreated with AECA negative sera (159). Neutralizing antibodies to ILl, but not antibodies to TNE substantially inhibited or blocked this activation, providing further evidence for the autocrine actions of ILl. Del Papa et al. (160) found that AECA IgG from Wegener's granulomatosis patients upregulates the expression of Eselectin, ICAM1, and VCAM1 and induces the secretion of ILl, 1L6, 1L8, and MCP1. Almost identical results were obtained from analysis of AECA positive sera from Takayasu arteritis patients (161). Another proposed mechanism is that binding of AECAs makes negatively charged phospholipids accessible to antiphospholipid antibodies (162), thereby further enhancing the activation of EC.

Cross-reactivity between anti–dsDNA antibodies, cardiolipins, and AECAs has been observed in earlier studies (163 ,164). By using immunofluorescent staining, Simantov et al. (165) were the first to demonstrate expression of cell adhesion molecules, including E-selectin, VCAM1, and ICAM1 by ECs incubated with purified IgG from patients with high titers of anticardiolipin antibodies, even in the absence of clinical or serologic evidence of SLE. They also established that this mechanism is ß2-glycoprotein dependent.

A direct stimulatory effect of anti dsDNA antibodies on endothelium, as indicated by the release of vWF may have a pathogenic role on expression of adhesion molecules (166 ,167). These data can provide a link between SLE and premature atherosclerosis.

The interaction between CD40 and CD40L is another immune-mediated interaction common to both SLE and atherosclerosis that leads to up regulation of adhesion molecules on endothelial cells (147). CD40 is a type 1 member of the TNF receptor super family of proteins, and is present on a wide variety of cells, including vascular endothelial cells. Ligation of this receptor on endothelial cells is known to increase expression of inflammatory adhesion molecules.

Slupsky et al. (168) demonstrated that platelets express the ligand of CD40 within seconds of exposure to agonist, and interact with endothelial cells to participate directly in the induction of an inflammatory response. The same authors also showed that activated platelets induce TF expression on endothelial cells in a CD40/CD40L dependent manner. Moreover, CD40 ligation on ECs down regulates the expression of thrombomodulin and adhesion molecules, further implicating the procoagulant and pro-inflammatory phenotype of ECs (169). In a genetically modified murine model with hypercholesterolemia, blocking antibodies to CD40 reduced atherosclerotic lesion formation (170).

In SLE Clq immune complexes may be a source of arterial injury initiating atherogenesis. Lozada et al. (171) showed that immune complexes stimulate endothelial cells to express adhesion molecules E-selectin, ICAM, and VCAM in the presence of a heat labile complement component Clq. Clq depletion from serum or Clq protein synthesis inhibition on the surface of ECs blocked the expression of adhesive proteins. Moreover, Reiss et al. (172) were able to demonstrate that occupancy of Clq receptors on ECs by immune complexes down regulated mRNA for sterol 27hydroxylase, the enzyme that mediates peripheral cholesterol metabolism, interfering with the capacity of endothelium to convert cholesterol to antiatherogenic metabolites and therefore enhancing atherogenesis.

In summary, we have described factors leading to endothelial perturbation and overlapping features of endothelial response in autoimmune disorders and atherosclerosis. The conversion of the endothelial phenotype to an adhesive and prothrombotic state and interaction of inflammatory mediators with cholesterol metabolism driven by multiple immunologic and nonimmunologic stimuli are the core of the pathophysiologic link between mechanisms of inflammatory vasculopathy, thrombosis, and atherosclerosis.

The Role of Activated Endothelium in SLE

There is a unifying hypothesis to account for the diverse, episodic, and variably distributed (e.g., widespread versus organ restricted; skin, kidney, or CNS) nature of SLE vascular lesions. Inflammatory lesions would require either circulating immune complexes (e.g., DNA/anti-DNA) or significant complement activation of neutrophils, while thrombotic lesions would require antiphospholipid antibodies. An additional biologic factor, however, is required to explain the waxing and waning nature of disease exacerbations and the limitation of lesions to one or few vascular beds. Immune complexes, activated neutrophils, or antiphospholipid antibodies may be necessary but likely are not sufficient to explain vascular pathology in SLE. Since they may be present in the absence of disease activity and can travel throughout the general circulation, they are incapable of explaining the relapsing and focal nature of vascular injury.

New information regarding the activation of ECs may provide the missing feature. The specificity of vascular injury in SLE may depend on the endogenous capacity of vascular endothelium to respond to stimuli. ECs when activated can express E-selectin, increased ICAMi and an inducible form of nitric oxide synthase (iNOS) (63 ,74). However, there is a restriction to this EC capacity; for example, the up regulation of EC adhesion molecules is limited to postcapillary venules (173). It is therefore possible that the episodic and focal nature of vascular pathology in SLE is dependent on the presence or absence as well as nature of EC activation. EC permissiveness for immune complex deposition or in situ formation can result in colitis. Activation of EC adhesion molecules by cytokines, immune complexes, complement components, antiendothelial cell antibodies, or antiphospholipid antibodies can result in leukothrombosis if there is simultaneous activation of neutrophils and complement (110). Abnormal iNOS synthesis may also have a role in permitting trophil EC interaction and the Shwartzman-like lesion. Additionally, EC activation may lead to the expression of membrane-associated coagulation proteins that are the target of antiphospholipid antibodies.

Additional evidence that activated endothelium contributes to the vasculopathy of exacerbated SLE is the finding that disease flare is accompanied by abnormal levels of circulating endothelial cells (CECs). CEC levels are significantly higher in active SLE patients compared to healthy controls and correlate positively with plasma C3a elevations (174). Furthermore, CECs from patients with active SLE express an activated phenotype, staining for tyrosine. Elevated levels of CEC in active SLE represents a marker for endothelial injury and suggests these cells may further potentiate vascular injury by the production of inflammatory and prothrombotic mediators and by engaging in heterotypic aggregation with neutrophil and platelets. In prior studies, the potential for CECs to participate in micro infarction was suggested by studies reported in sickle cell anemia (175) and acute MI (176). In conclusion, the detection of activated CECs in patients with SLE, particularly with higher SLEDAI scores, provides evidence for widespread endothelial injury. Studies are ongoing to determine whether the presence of CECs predicts or is the result of postcapillary vascular damage and micro infarction leading to organ dysfunction or even premature atherosclerosis. That the endothelial cell perturbations that characterize exacerbated SLE can contribute to both is illustrated by the finding that the mean level of soluble EPCR, endothelial cell protein receptor C, which promotes a thrombotic diathesis when shed, is significantly higher in SLE patients than controls (177). The shedding of sEPCR was increased by IFN-γ and IL-1, but blocked by a metalloproteinase inhibitor, suggesting a role for inflammatory cytokines in the induction of the observed increased sEPCR in the plasma of SLE patients (178).

Vascular injury in SLE may require immune complex formation, complement activation, or antiphospholipid antibody production, but we propose that the EC response is responsible for the clinical character of a disease exacerbation by determining the timing and organ distribution of vascular pathology, which includes vasculitis, leukothrombosis, thrombosis, and atherosclerosis.

Chapter 15
Idiotypes and Idiotype Networks

Bevra Hannahs Hahn

Fanny M. Ebling

Jatinderpal K. Kalsi

History

In 1963, Oudin and Michel (1) proposed the concept of idiotypes (Ids) and anti-idiotypes (anti-Ids) when describing rabbit antibodies that induce antibodies against themselves. In the same year, Kunkel et al. (2) described Ids on human antibodies. In 1974, Jerne (3) suggested that Ids and anti-Ids participate in self-regulatory immune networks. Since then, many investigators have established the importance of Ids in normal immune regulation and in experimental manipulation of cell function and immune responses.

Definitions

Table 15-1 lists terms used in defining Ids and idiotypic networks. Idiotopes are antigenic regions located in the variable regions of immunoglobulin (Ig) molecules or T cell antigen receptors (TCRs). Single Ig molecules can express several different idiotopes; the series of idiotopes is referred to as the idiotype for that molecule. Because the exact structural basis of most idiotopes is unknown, the term idiotype is widely used to describe the entire antigenic region on Igs or TCRs. An antibody produced in response to antigen (Ag) expresses Id and is called Ab1 to define its place in the Id immune network.

Ids are divided into two general classes: private and public. Private Ids are expressed on Igs or TCRs that expand from a single parent clone. Therefore, private Ids define antibodies or T cells that are clonal and relatively specific for a single stimulating Ag. In contrast, public Ids (also called cross-reactive Ids) are expressed on Igs and TCRs deriving from different parental cells. Therefore, Igs and TCRs displaying public Ids bind several different Ags and are likely to appear in many different individuals of the same species. Further, public Ids may be found on antibodies in individuals of different species. For example, public Ids on anti-DNA antibodies derived from certain mouse strains are found on anti-DNA and other Igs in humans (4 ,5).

Because idiotypes are antigenic, they stimulate production of anti-Id antibodies, which are referred to as Ab2. Ab2 molecules are divided into at least two subtypes, depending on whether they mimic Ag (6). Ab2α binds Ab1 but otherwise shares no properties of the initial stimulating Ag. Ab2ß binds Ab1 and behaves in other ways like Ag, and it can stimulate production of more Ab1 and bind to receptors that ordinarily bind Ag. This property was first noted in insulin systems (7). Some Ab2 against antiinsulin Ab1 could bind the insulin receptor on cell surfaces and actually trigger glucose metabolism by those cells. Ab2ß anti-Ids are also called internal image anti-Ids, as suggested by Nisonoff and Lamoyi (8), implying that they share structural similarities with Ag. Some authors refer to them as epibodies or homobodies. Another class of Ab2 is Ab2γ, which contains antiidiotypes that are antigen inhibitable because of steric hindrance with the antigen combining site (9). Ab2ß has been extensively used to generate internal images of infectious pathogens (10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19), tumor antigens (20 ,21 ,22 ,23 ,24), and more recently as mimics of self antigen, for example human interferon (IFN), which has antiviral activity (25). Because Ab2 molecules themselves express Ids, they also stimulate production of anti-anti-Ids (Ab3).

Within the variable region of each Ab1 is a region that binds the epitope of the stimulating Ag. The region on Ab1 that binds Ab2 is called a paratope. If the paratope- and epitope-binding regions of the Ab1 molecule overlap or are located close to each other, binding of either (by epitope of Ag or paratope of Ab2) may inhibit binding of the opposite molecule.

Idiotype Networks

Idiotype networks are complex, and three features are particularly important. First, members of the network regulate each other, thus serving to control immune responses. Second, the network links immune responses to self with immune responses to the external environment. Third, the network links the fetal and newborn repertoires to the adult immune response.

Antigen-Antibody Idiotype Networks

There are at least two major concepts of Id networks. Figure 15-1 illustrates the most widely held view, suggested originally by Jerne (3) and later expanded by him and others (6 ,7 ,8 ,9 ,26 ,27 ,28 ,29). This concept is based on information suggesting that convex epitopes on Ags are bound by concave regions in the Ag-binding groove of Ig molecules, as suggested by x-ray crystallographic studies of an Ag-antibody complex (30). Similarly, convex regions on Ab1 molecules

are bound by concave regions in the binding groove of Ab2; the same process permits binding of Ab3 to Ab2.

Table 15-1: Definitions

1. *Idiotype*. A region on the variable portion of an immunoglobulin molecule or T cell antigen receptor that is antigenic. When present on an antibody molecule, the antibody may be referred to as Ab1.
2. *Idiotype (Id)*. A series of idiotopes on the same molecule.
3. *Private idiotype*. An Id expressed only on the products of a single B- or T cell clone. Antibodies and T cells bearing private Ids will be specific for only one antigen (Ag).
4. *Public idiotype*. An Id expressed on different B- and T cell clones that interrelates them. Antibodies and T cells bearing public Ids are in sum able to recognize multiple different Ags. These also are referred to as cross-reactive or shared Ids.
5. *Antiidiotype*. An antibody directed against the idiotope on immunoglobulin, B cell surface, or T cell antigen receptor. This antibody may be referred to as Ab2.
6. *Anti-Id type 1*. Also called Ab2α, this Ab2 binds to Ab1 but does not otherwise behave like antigen (Ag).
7. *Anti-Id type 2*. Also called Ab2 ß, also called homobody, internal image anti-Id, or epibody. This Ab2 binds Ab1 and behaves in additional ways like Ag. For example, it can bind to receptors for Ag and by so doing can trigger cell activation.
8. *Anti-Anti-Id*. An antibody against Ab2. It also may be referred to as Ab3. Some Ab3 molecules share structural similarities to and behave like Ab1; for example, they may bind the Ag to which the original Ab1 is directed.
9. *Epitope*. The region of an antigen bound by Ab1.
10. *Paratope*. The region of an antibody or T cell receptor bound by anti-Id.
11. *Connectivity*. The property of one Id network influencing the development of another. For example, the Ids on mature immune responses develop in sequence to different Ids, expressed on Ig in fetal mice.
12. *Parallel sets*. A network of Ab1-Ab2-Ab3 that is interactive.
13. *Network antigen*. An Ab2 that can react either with Ag or with Ab1 and therefore can regulate the entire Ag-Ab1-Ab2-Ab3 Id network.

This Id network regulates itself in at least two ways, as shown in Figure 15-1 . First, as discussed earlier, some Ab2 molecules behave like Ag; they stimulate Ab1 production, bind Ag receptors, and can probably trigger cell activation under certain conditions. As illustrated, these Ab2 internal image anti-Ids have sequences or conformations highly similar to those on Ag (31). This property of anti-Id serving as surrogate Ag has been used to isolate and characterize receptors (7) and to stimulate production of neutralizing Ab1, thus using Ab2 as a vaccine (8 ,27). Second, some Ab3 molecules have properties of Ab1, in that they can bind the original Ag. An elegant demonstration of the entire network, from Ag to Ab3, has been reported in a study using the O-specific polysaccharide side chain of Pseudomonas aeruginosa as Ag to raise Ab1 and Ab3 in mice; both Ab1 and Ab3 were opsonizing, protective antibodies that prevented lethal infection (10).

Although experimental results in many Id-anti-Id systems fit the Jerne hypothesis, numerous exceptions have occurred. For example, some Ab2 molecules can serve as surrogate Ags even though their binding to Ab1 is not Ag inhibitable, suggesting that they are not internal image anti-Ids. Such observations have led to another hypothesis of Ag Id-anti-Id interactions, reviewed by Kohler et al. (32). This hypothesis suggests that interactions between Ag, Ab1, Ab2, and so on can occur via side chains/conformations outside the Ag-binding groove of Ig. Some Ab2αs are able to broaden the epitope specificity of the immune response (33). This may be particularly important in situations where a very narrow range of antigenic specificities is recognized by the immune system, for example as in HIV infection. The mechanisms whereby this expansion of response occurs are not clear, but it has been suggested either that Ab2α may bind to both Ab1 and the antigen, thus stabilizing the complex, or that there is formation of a metatope, where new epitopes are revealed through conformational changes that result from the formation of the immune complex (33 ,34). Both hypotheses regarding Id interactions may be correct, and they may occur simultaneously.

The importance of Id networks in SLE has been suggested by several investigators who have demonstrated Ab1 and Ab2 in murine or human SLE; some have detected Ab3 (35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43). In several studies, internal image Ab2 has been shown to bind multiple autoAgs and Ab3 to bind Ab1.

T Cells in Idiotype Networks

The preceding discussion addressed Ag induction of circulating Ab1, Ab2, and Ab3. B lymphocytes secreting the Abs express the same Ids on their surface Ig. In addition, T lymphocytes are involved in Id-anti-Id networks. Several experiments have shown that Ab2 can bind to and, in some cases, activate T cells (44 ,45 ,46). Figure 15-2 illustrates the mechanisms by which B and T-helper (Th) cells interact to activate each other and to upregulate production of Igs bearing certain Ids. Concepts of T cell activation require interaction between antigenic peptides presented by the major histocompatibility complex (MHC) to the TCR of T cells. $CD4^+$ T cells recognize Ag presented by MHC class II; $CD8^+$ T cells recognize Ag presented by MHC class I. Such Ag presentation can be provided by B cells, which can process either surface or cytoplasmic Ig into peptides and present them in surface class I or II molecules (47 ,48 ,49 ,50 ,51 ,52 ,53). Thus, idiopeptides are presented to TCRs. Activation of a Th cell by this method is shown in Figure 15-2 . Ig can probably stimulate both B and T cells; in the reovirus system, a B-cell epitope has been defined in the CDR2 region of the Ig light

chain and a T cell epitope in the CDR2 of the heavy chain (54). Interestingly, in a murine anti-DNA antibody V88, T- and B-cell epitopes were colocated within the same region of the variable region of the heavy chain of immunoglobulin (VH) (55). There is also evidence that idiotypes may interact directly with TCR (56) and thus activate T cells in a non-MHC restricted fashion.

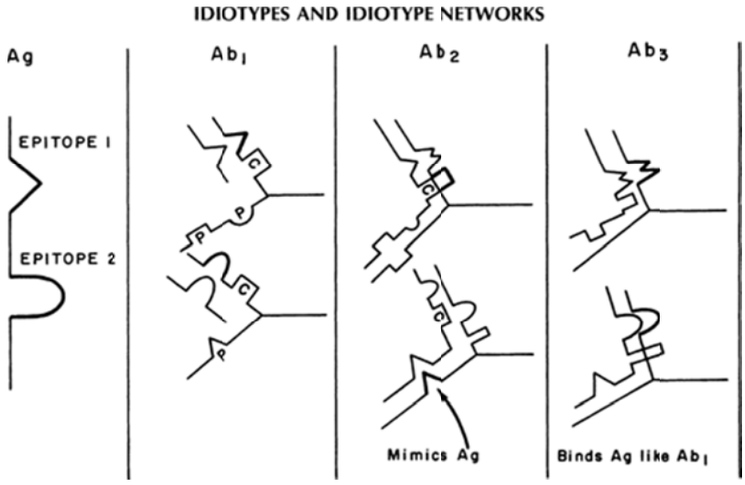

Figure 15-1. The antibody Id network. In the first panel, an antigen (Ag) with two epitopes is shown. In the second panel, two antibodies (Ab1) against the antigen are shown: the top Ab1 recognizes epitope 1, and the bottom Ab1 recognizes epitope 2. Each Ab1 has an idiotope specific to that clone, a private Id (p). Both Ab1s contain an identical sequence or conformational idiotope, designated as a cross-reactive (C) or public Id. Thus, the private Ids identify distinct clonal antibody specific for one Ag, and the public Ids identify related families of antibody that derive from different clones and can recognize different epitopes. In the third panel, two anti-Id antibodies (Ab2) have been induced by Ab1. The upper Ab2 is an alpha type; it binds Ab1 but does not mimic Ag. The lower Ab2 is a beta type; it contains a sequence that mimics an epitope on the original Ag and can behave like Ag (bind receptors for Ag, stimulate Ab1, and so on). It is called Ab2β, internal image anti-Id, or an epibody. In the fourth panel, two antibodies (Ab3) induced by Ab2 are shown. The upper Ab3 binds only Ab2. The lower Ab3 has a sequence or conformation that mimics a sequence/conformation in Ab1; it can bind Ag. Some, but not all, members of the network have the capacity to regulate other members.

Activation of Id-recognizing Th cells is probably necessary for full-scale production of Id-bearing antibodies, as shown in Figure 15-2 . Activation of Th cells releases B-cell growth and differentiation lymphokines, which in combination with cell-cell contact results in B-cell production of Ab1, Ab2, and so on (53).

TCRs can serve as immunogens for developing the Ab1/Ab2/Ab3 network as well as a regulatory T network, as shown in Figure 15-2 . For example, immunization of B10.D2 mice with an anti-Id made against the Id on the TCR of a Th clone specific for Sendai virus was effective in producing virus-specific neutralizing antibody, delayed-type hypersensitivity, cytotoxic T cells, and protection against infection (57). Id-recognizing Th cells may be distinct individual cells, or the recognition of Id may be a property of cells that also can recognize Ag epitopes. In several murine antibody systems, including anti-PC and anti-(T,G)A-L, there is collaboration between Th cells that recognize the Ag and the Id or anti-Id. However, Th cells that specifically enrich Id^+ antibodies have been detected (58).

T cell participation in Id networks is not confined to cells with helper function. Manipulation of the Id network can produce T cells that participate in delayed-type hypersensitivity, suppress Ab1 responses, kill cells expressing surface Ag or Ab2, and suppress proliferation of cells expressing the target Ids on their TCRs (57 ,58 ,59 ,60 ,61). In a pilot clinical trial in multiple sclerosis (MS) patients, antiidiotyic $CD8^+$ T cells were induced following vaccination of patients with irradiated autologous myelin basic protein (MBP)-reactive T cell clones (62). Idiotypic T cells lines were generated from the immunized patients and those reactive against the CDR3 region of the TCR of immunizing MBP-specific clones (63) were able to target and kill autologous MBP-reactive T cells in vitro.

Id-reactive T cells have been identified in both lupus-prone and normal mice (53 ,55 ,64 ,65 ,66 ,67 ,68 ,69 ,70). In the SNF1 model of SLE, $CD4^+$ Id-T cells increase before disease onset

(CD8+ do not), and some CD4+Id-T clones from those mice help production of anti-DNA by syngeneic B cells (71 ,72 ,73). Further, disease can be accelerated by adoptive transfer of CD4+ Id LNF1+ T cell clones in SNF1 mice. Regions of VH in some Id(LN) MAb enriched in positively changed amino acids stimulate these nephritogenic T cells (73). Similarly, CD4+ T cell clones from BALB/c mice immunized with monoclonal antibody (mAb) expressing the 16/6 Id proliferated to that Id and induced autoantibodies and nephritis on transfer to naive BALB/c mice (70). The levels of Id reactive T cells may also vary with disease activity.

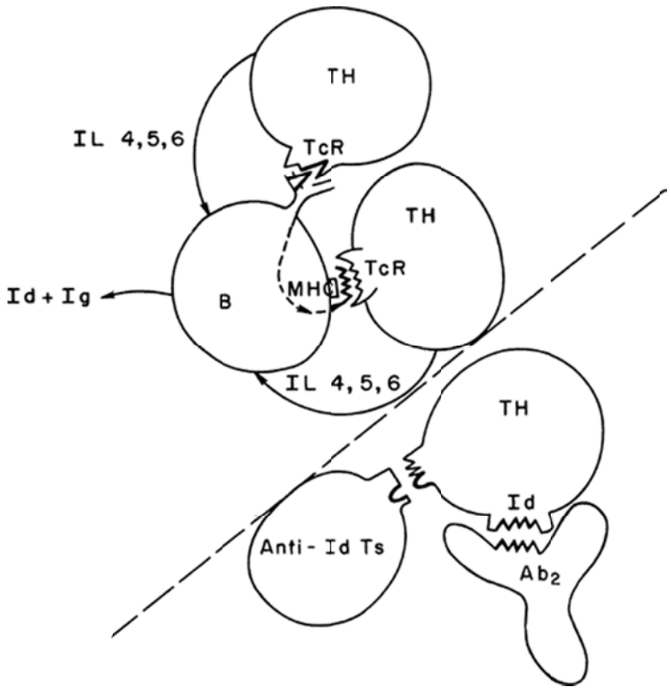

Figure 15-2. The T/B cell Id network. In the upper area, T-helper (Th) cells that augment autoantibody production are shown. They are idiotypic Th cells. The upper Th cell has a T cell receptor (TCR) that recognizes an Id on the surface Ig of an Id+ B cell; the lower Th cell has a TCR that recognizes an idiopeptide processed by the B cell from its surface Ig and presented by a major histocompatibility complex (MHC) class II molecule. Both Id Th cells secrete B cell stimulatory factors (IL-4, -5, and -6) that upregulate production of the Id+ antibody. In the lower area, the Id Th cell recognizes the idiotope on an Ab2 in one region of its TCR; another region of TCR has induced an anti-Id suppressor T cell (Ts), which can suppress the Id Th cell. Thus, both B and T cells participate in cellular and humoral regulatory networks governed by idiotypes.

The Structural Basis of Idiotypes

Apart from a few very well-studied Id systems, for example anti-arsonate CR1A (74 ,75 ,76 ,77) and the T15Id (78 ,79 ,80) associated with the antiphosphocholine response, the structural basis of most Ids has eluded definition. This is partly related to the tools used to define the Id. Classically, most Ids have been defined serologically, using polyclonal antiidiotypic reagents, which has led to problems of reproducibility inherent with such reagents. For many Ids definition has rested solely on whether it is linear (on H or L chain) or conformational (i.e., needs both H and L chain for expression). Delineation of the exact amino acid residues/sequences defining the Id (or their location) has been possible in only a few systems. Some examples are listed below. Within the heavy chain, two amino acids and/or carbohydrates have been defined in the CDR-2 region of the heavy chain (CDR-H2) for antibodies to dextran (81), and D-regions are involved in Id expression in anti-p-arsonate (74 ,75 ,76 ,77) and antigalactan antibodies (82). Id 4B4 found on the Ig of some patients with SLE or Sjögren syndrome (83), Id BH1 on human anticardiolipin antibody (84), and Id cross-reactive idiotype (CRI-EM) described in scleroderma (85) are all associated with the heavy chain. For 16/6Id described in lupus (86 ,87), and related Ids V-88 (88) and WRI-176ß (89), sequences in the FRH2/CDR-H2 (90), CDR-H2/FR-H3 (55 ,91), and CDR-H2 (92 ,93) are reported to carry major idiotopes. Id 9G4, which is expressed by cold agglutinins (94), and by a population of immunoglobulins in SLE (95), is located within the CDR-H1 at positions 23 to 25 as the sequence AVY (94). The trytophan at position 7 in the FR-H1 of 9G4 Id+ heavy chain also contributes to Id expression (96).

Ids associated with the light chain are described in antistreptococcal group A carbohydrate antibodies (97). In lupus autoantibodies the B3Id is located in the CDR-L1 (98); similarly 8.12Id expression is associated with amino acid residues Tyr32 and Asn 33 in CDR-L1 (99 ,100). Id H3 described on anticardiolipin antibodies (101) is also associated with the light chain. Other Ids are conformational. Examples can be found in monoclonal cold agglutinins (102), antithyroglobulin antibodies (103), and Id T15 (78).

Although analysis of the V-region amino acid sequences of Id+~ Igs has greatly facilitated the identification of such residues, mutational evidence confirming their contribution to Id expression has been reported in a very small number of cases (94 ,96 ,100).

An alternative approach to identifying idiotypic determinants has been to use epitope mapping (or pepscan) techniques (104). This method has been used for mapping both B- and T cell idiotopes and has been employed in studies of Id systems in SLE (55 ,64 ,90 ,93). Overlapping peptides of known sequences of VH and/or VL of Id+ Ig are tested against antiidiotypic sera or T cells to determine the sequences of idiotopes contributing to Id expression. In studies of murine and human anti-DNA antibodies expressing public Ids (WRI-176ß, V88, and B3Ids) a large number of B-cell idiotopes were identified using sera from lupus-prone mice and patients with SLE (91 ,93). The idiotopes were located in both the framework regions as well as in the CDRs. Computer models (105 ,106) of the Id+ anti-DNA antibodies revealed that several of the immunodominant sequences identified were located on the surface of the antibody combining site and were therefore accessible, and that others may become accessible upon binding to antigen (105). In addition, the pepscan method detected noncontiguous

epitopes, which in the three-dimensional (3D) binding site structure were situated in close proximity (105) (Kalsi, unpublished data). Descriptions of TCR-related idiotopes are limited, as they require the generation of T cell clones known to participate in idiotypic interactions and a determination of what component of the TCR is responsible for Id expression. However, idiotopes located on the TCR alpha chain CDR3 regions have been identified in murine models of experimental allergic encephalomyelitis (EAE) (107) and in NOD mice models of type 1 diabetes (108). In a recent study of patients with MS, a T cell idiotope was defined in the CDR3 of MBP-reactive TCR (63). Several investigations, however, have concentrated on identifying idiotopes on Id^+ Igs that have the capacity to activate T cells. The earliest such study was reported by Ebling et al. (64). Using T cell proliferation assays, three major sites (p34, p58, and p84) on the VH of nephritogenic murine mAb A6.1 were identified. These idiotopes were reported to modulate disease in young lupus-prone mice. In the murine anti-DNA antibody V88, the immunodominant T cell idiotope was located in the CDR2-FR3 region of the H chain (55). This region also carries at its carboxyl end a major B-cell epitope. Gavalchin and Staines (65 ,73) report on two sequences from the CDR2 and CDR2/FR3 region of the heavy chain of an anti-DNA $IdLNF1^+$ mAb 540, which also carry T cell idiotopes in SNF1 mice.

The definitive proof of the contribution of residues to Id expression (or indeed antigen binding) would derive from studies employing nuclear magnetic resonance or x-ray crystallographic analysis. Very few Ids have been investigated in this manner. To our knowledge there are currently four known crystal structures of idiotype and antiidiotype interaction (109 ,110 ,111 ,112). Mainly these have been generated to determine how closely antiidiotypic antibodies may mimic antigen (112) or not (109 ,110 ,113). In a crystal structure (resolution 1.9 ö) of an antilysozyme Fv fragment and the corresponding antiidiotypic Ab E5.2, Fields et al. (112) reported that essentially the same molecular interactions were observable between the Id and anti-Id as were seen between the antibody and the antigen hen-egg lysozyme (HEL). Thus, mimicry involves similar binding characteristics and is not necessarily a result of exact replication of the antigen. In a more recent study, the structure of the Fab fragment of a mouse anti-anti-idiotypic antibody was solved (114). Fab fragments existed in the crystal as dimers and were found to be self complementary. It is suggested that this may be a means of neutralizing an ongoing idiotypic cascade, and, furthermore, interacting antibodies downstream in the idiotypic cascade may be rendered increasingly similar and self reactive. This is an interesting postulate since it has been found that some autoantibodies may in fact be anti-idiotypic for immunoglobulins (115 ,116).

The composition of an idiotype clearly has a number of components, and the structural feature of the Id which predominates may well depend on the techniques and the tools used in its elucidation. Alongside the structural definition of an Id or a major idiotope there should also be consideration of whether the amino acid residues or sequence being defined as the “structural” idiotope is going to be equivalent in terms of the functional role of the idiotype. For example, when T cell responses to sequences corresponding to the CDR1 and CDR3 regions of a 16/6+ mAb were examined in normal mice, the predominant response in Balb/c mice was to the CDR1 fragment and in SJL and C3H.SW mice to the CDR3 sequence (66). Thus, depending on the strain and therefore the genetic background of the individual, the structural correlate of the major T cell idiotope may be different. Furthermore, since epitope mapping studies show that a number of epitopes within the variable region are “idiotypic,” it is possible that different idiotopes from the same Ig V region have different effects on the immune response.

Idiotypic Regulatory Circuits

Some Ids are regulatory, in that they can be suppressed or upregulated by other members of the circuit and in turn can regulate the other members. Early information regarding regulation suggested that anti-Ids served to suppress expression of their complementary Ids on antibodies to specific Ags (117 ,118). On the other hand, some anti-Ids can upregulate target Ids, even to the extent of activating silent B-cell clones that normally do not express their Id-bearing Ig. For example, BALB/c mice usually do not express the A48Id on their anti-fructosan Abs. However, administration of any of the following can force expression of that Id: (a) A48Id at birth, (b) polyclonal or monoclonal anti-Ids at birth, or (c) keyhole limpet hemacyanian (KLH)-linked polyclonal anti-Id in adults (119). In some systems, certain Ids or anti-Ids are either enhancers or suppressors of Id expression, whereas other Id-bearing mAbs do not regulate the circuit. Furthermore, the nature of the anti-Id (e.g., Ab2ß or γ vs Abα) may determine the ability to regulate idiotypic expression (43).

In many experiments with Ids and anti-Ids, the dose and timing of administration are critical to the results. Generally, administration of small quantities of Ids or anti-Ids upregulates Id expression, whereas administration of large quantities suppresses Id expression. For example, as shown in Figure 15-3 , immunization of young New Zealand black/white (NZB/NZW) F1 (BW) mice with small quantities (200 ng) of anti-IdX (a public Id on anti-DNA in BW mice) in Freund's adjuvant resulted in accelerated appearance of two autoantibodies: IdX^+ anti-DNA, and IdX^+ antihistone (35). In contrast, as shown in Figure 15-4 , repeated administration of large doses of anti-IdX (100 µg every 2 weeks) to adult BW mice suppressed IdX^+ Ig, anti-DNA, and the lupus-like nephritis associated with anti-DNA in this mouse strain (36 ,37 ,120). Thus, the same mAb anti-Id could be used to either enhance or suppress the Id-bearing Ig.

Id-recognizing T cells also can be used to alter immune responses. For example, infusion of T cells that have been sensitized to Ids of $CD4^+$ T cells that recognize alloAgs results in suppression of the ability of Th cells to proliferate to those Ags and prolongs allograft survival (59).

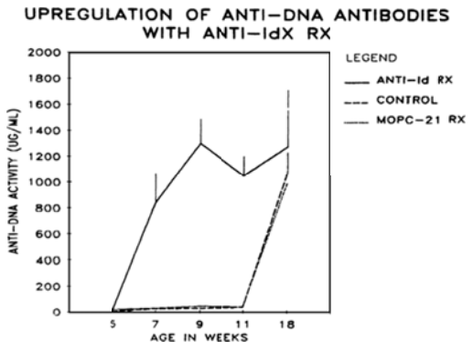

Figure 15-3. Upregulation of Id+ antibodies to DNA by administration of anti-Id antibodies in New Zealand black/white (NZB/NZW) F1 mice. This is an example of an upregulating Id network. Small doses (200 ng) of a monoclonal anti-IdX (made by immunization with an IdX+ antibody to DNA) were injected into young BW mice, and the appearance of anti-DNA in their sera was compared to that of littermates injected with the carrier or with an Id-negative monoclonal antibody (mAb) (MOPC-21). Injections were made at 4 weeks of age. Anti-Id–treated mice developed high titers of antibody to DNA by 7 weeks of age. In the control groups, anti-DNA appeared at 11 weeks (when the mice ordinarily begin to develop antibody); 95 of the anti-DNA in anti-Id–treated mice expressed IdX. The same mice also made IdX+ antihistone antibodies at an earlier age than controls. Thus, the anti-Id activated an Id+ autoantibody network that resulted in production of different autoantibodies expressing the same cross-reactive, public Id. (These experiments were performed by Karen Dunn, MD.)

Although regulatory properties of public Ids can be used to alter in vivo immune responses, the Id network in some systems (e.g., B-cell malignancies) escapes from such regulation (36 ,37 ,121 ,122). One mechanism of escape is somatic mutation of the Id so that it no longer is recognized by anti-Id (122). Because mutation of Ig molecules is common in B cells, whereas it is very uncommon in the TCR of T cells, this escape mechanism probably applies only to Ids on Ig. In NZB/NZW mice treated with anti-Ids, escape of Id^+ antibodies from suppression occurs without evidence of mutation of the Ig (120); this might represent a change in Id-directed T cell help (e.g., a shift from Th1 to Th2 cytokine patterns).

Role of Idiotypes in Maturation of the Immune Response

In adults, the normal B-cell repertoire probably depends on establishment of essential Id networks during fetal life. Studies of B-cell hybridomas obtained from fetal and 1- to 2-week-old normal BALB/c mice have defined early antibody responses in the pre and early immune states (123 ,124). Two properties are clear: (a) many early Ig molecules bind to self Ags, including V regions of Ig; and (b) this pre-immune, natural autoantibody network is highly connected via idiotypy.

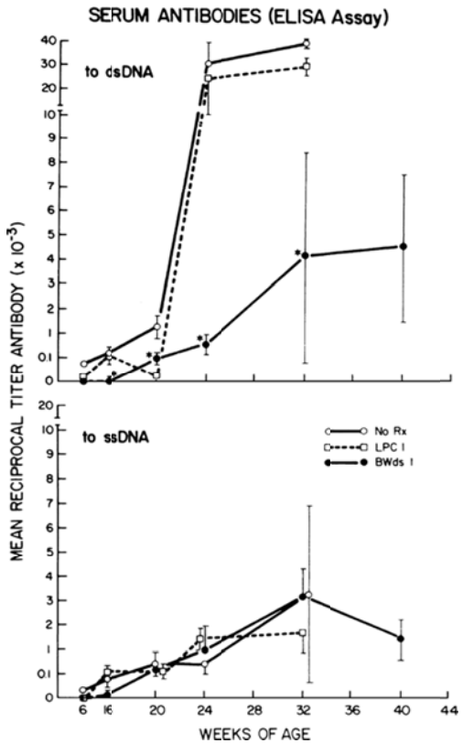

Figure 15-5. Downregulation of autoantibody responses by anti-Id antibodies. The idiotypic system is being studied in these experiments and those shown in Figure 15-3. In this case, high doses of monoclonal IdX (100 µg fortnights), which induce anti-IdX, were given repeatedly to NZB/NZW F1 females beginning at 20 weeks of age. Antibodies to double-stranded DNA (dsDNA) (upper panel) were significantly suppressed in IdX-treated mice (solid line, closed circles) compared with two control groups (open symbols). This is an example of an anti-Id induced by Id downregulating an autoantibody. In contrast, antibodies to single-stranded DNA (ssDNA) were not affected (lower panel). (From ref. 120, with permission.)

Vakil and Kearney (124) have referred to the early multispecific B cell as a superorganizer, influencing many generations of B cells that follow. This early network can be influenced by administration of Id^+ antibodies that do not bind the initiating Ag, so the network is at least partly independent of

Ag and can operate via recognition of Id alone. Any interference with the newborn network (by administration of Ag, Ab1, Ab2, or Ab3) results in impairment of normal antibody responses in adult life, especially if a highly public Id is involved (125). It is interesting that the Id F-423 found in fetal Medical Research Laboratory lymphoproliferative (MRL/lpr) mice occurs on anti–single-stranded DNA (ssDNA) and also appears in adult MRL/lpr and NZB/NZW F1 mice. Administration of IdF-423 accelerates lupus in young MRL/lpr mice and of anti-Id F-423 delays disease onset (126). Similarly, Id D23 on natural autoantibodies of normal mice can be found in the glomerular lesions of NZB/NZW F1 mice with lupus nephritis (127). Thus, some public Ids associated with pathogenic autoantibody repertoires are present in fetal or early postnatal life; SLE might result from their dysregulation.

Several investigators have demonstrated that the maternal idiotypic network has a potent influence in shaping the developing repertoire of the fetus/neonate (124 ,128 ,129 ,130). It has been suggested that to prevent serious infectious diseases of early childhood, immunizations of the mother be utilized to effect immunity in the offspring (130 ,131). Aside from passive immunity there is said to be “immunologic imprinting” by maternal idiotypic networks, which provides molecular information about the external environment and presumably skews development toward those idiotypic networks that would be most useful in dealing with local pathogens (128 ,129). There are a number of examples in the literature reporting the strong association of certain Ids with particular antimicrobial responses (132 ,133 ,134). Furthermore, maternal immunization is reported to alter the kinetics and the quality of the response in successive generations (130 ,135). For example, the F1 generation of mice immunized with respiratory syncytial virus exhibited characteristics of a secondary immune response when challenged with the original immunogen (135). One report (131) has demonstrated the use of engineered Ab2 fragments mimicking the capsular antigen of group B streptococcus for providing immunity transferable to offspring. Thus far, however, anti-Id vaccines remain an interesting but unproven approach to the prevention of infectious diseases in humans.

Idiotypes, Autoimmunity, and SLE

The Role of Idiotypes in Autoimmunity

Id networks play a central role in autoimmune diseases such as SLE. First, most autoantibodies are characterized by public as well as private Ids; therefore, a limited number of networks regulate a substantial proportion of the autoantibody repertoire (88 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147). Second, the Id on any Ab1 that arises may induce internal image Ab2 (epibodies, homobodies), and these internal image anti-Ids can then behave as Ags, thus inducing other Ab1 molecules that react with multiple self-Ags. For example, rabbits immunized with human polyclonal anti-DNA or with monoclonal anti-DNA derived from MRL/lpr mice developed autoantibodies that reacted with DNA, cardiolipin, Sm/RNP, and glomerular extract. All these reactivities were contained in the rabbit anti-Id against the immunizing Ig (38). In fact, some investigators suggest that most autoantibodies are anti-Id responses to antiviral or other protective Ab1 or indeed other autoantibodies (41 ,115 ,148 ,149). Zhang and Reichlin (115) report that some antibodies to Ro and La function as antiidiotypic to anti-dsDNA antibody, mimicking Ag such as p53, and serve to downregulate them. Antibodies able to bind dsDNA antigen, F(ab)2 anti-idiotypes, and idiopeptides from Ids or anti-Ids have also been reported (44 ,55 ,116 ,150 ,151). In susceptible strains of normal mice, certain Id^+ monoclonal anti-DNAs (16/6 and LNF1 for example) or anti-Ids (anti-Id 16/6), when used as immunogens, probably induce a full repertoire of Id network B and T cells, resulting in the appearance of multiple autoantibodies and nephritis (39 ,40 ,42 ,70 ,71 ,72 ,73). Only mice that develop anti-Id responses to Ab1 develop SLE-like disease. (It should be noted that one group of investigators could not repeat the work with Id 16/6 (152).) Third, Id networks are probably defective in patients with active SLE. Anti-Ids are detected in the serum during disease remission but are decreased during periods of disease activity (153 ,154 ,155). In fact, both anti-Ids and Id^+ Ig can be found in human SLE glomerular deposits and may contribute to nephritis (155 ,156 ,157). Ineffective Id networks therefore are among several immunoregulatory abnormalities that contribute to SLE.

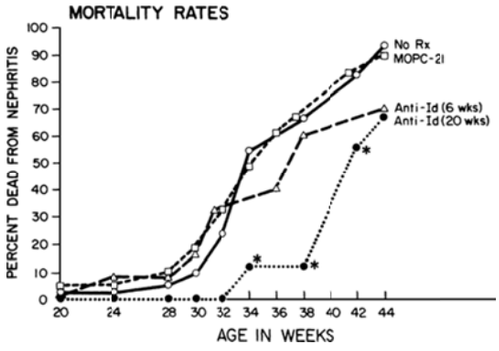

Figure 15-5. Suppression of clinical nephritis in NZB/NZW mice by administration of anti-Id antibody. In these experiments, NZB/NZW F1 females were treated once every 2 weeks with injections of a monoclonal anti-IdX or an Id-negative mAb (MOPC-21). Some littermates were untreated. Mice treated with anti-IdX (dotted line with solid circles) lived approximately 10 weeks longer than other groups. Their production of anti-dsDNA and IdX+ IgG was suppressed during that period but escaped from control. The appearance of IgG anti-DNA in serum was followed within a few weeks by lethal nephritis. Thus, anti-Id therapy was successful, but only as long as the Id network was sensitive to it. (From Hahn BH, Ebling FM. Suppression of murine lupus nephritis by administration of an anti-idiotypic antibody to anti-DNA. *J Immunol* 1984;132(1):187–190, with permission.)

Table 15-2: Mechanisms by Which Idiopathic Networks Participate in the Pathogenesis of SLE

1. Many autoantibodies express public Ids. These Ids may be targets of upregulation, thus keeping the levels of the autoantibodies high.
2. Some public Ids on Ab1 induce anti-Ids (Ab2) that bear internal image of Ags. Those Ab2 molecules in turn induce Ab1 molecules that react with multiple self-Ags. Thus, Id+ anti-DNA can induce Id^+ anti-Sm, Id^+ anticardiolipin, and so on.
3. Certain public Ids are markers of autoantibodies enriched in pathogenic subsets.
4. Idiotypic regulation is skewed toward upregulation of undesirable autoantibodies during periods of disease activity. Restoration of normal Id circuitry might abrogate disease.

Restoration of Id circuitry to normal might suppress active disease, and anti-Ids have been effective in suppressing autoantibody production by murine B cells in vivo (4 ,37 ,38 ,39 ,42 ,126 ,158 ,159 ,160), human B cells in vitro (153), and in patients treated with intravenous immunoglobulin (IVIg) (161). Furthermore, the suppression of target antibodies by administration of anti-Ids or anti-Id T cells, has been highly effective in prolonging survival in murine models of SLE (36 ,73 ,162). Table 15-2 reviews mechanisms by which Ids might participate in the pathogenesis of SLE.

Idiotypes in SLE

Because SLE is considered to be the prototype systemic autoimmune disease, the Id-anti-Id profiles as well as the structure of its most characteristic autoantibody, anti-DNA, have been studied by many investigators (4 ,5 ,35 ,36 ,37 ,38 ,42 ,83 ,86 ,87 ,88 ,99 ,106 ,126 ,127 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,153 ,154 ,155 ,158 ,159 ,160 ,163 ,164 ,165). Although most normal subjects, both human and murine, can make anti-DNA bearing public Ids, and although anti-DNA is part of polyreactive neonatal antibodies, most SLE patients have a different anti-DNA repertoire. For example, when MRL/lpr lupus-prone mice are immunized with Ars-KLH, the anti-Ars response is idiotypically distinct from the Ids of most MRL/lpr autoantibodies (166). In contrast, humans immunized with pneumovax produce anti-PC antibodies bearing Ids typical of anti-DNA in SLE; however, early in the response the Id^+ Ig does not bind DNA (167). Generally, anti-DNA in healthy individuals is composed largely of IgM with low affinity for ssDNA. In contrast, anti-DNA in mice or humans with active SLE is largely IgG with high affinity for both ssDNA and dsDNA. In fact, IgG anti-dsDNA is relatively specific for SLE.

Several laboratories have defined public Ids on anti-DNA antibodies originating either in human or murine systems (Table 15-2). Many such Ids, especially those occurring near the epitope-binding regions of the Ig molecule, occur in both murine and human SLE. Further, they are found in humans with virtually all known connective tissue diseases (most frequently in Sjögren syndrome), in first-degree relatives, and in small proportions of healthy individuals (139 ,168 ,169 ,170). Two groups (171 ,172) have studied Ids in family members of patients with SLE and have found no enrichment in family members or household contacts compared with healthy controls. However, in one study RT-84Id expression was similarly high in patients and their relatives and also occurred more frequently in spouses than in normal healthy controls (170).

Thus, several lines of evidence suggest that many of the public Ids that characterize autoantibodies in SLE are derived from highly conserved germline genes with little or no mutation. That evidence includes the following: (a) presence of the same Id in unrelated people with or without SLE (168 ,170 ,171 ,172), (b) presence of the same Id in mice and humans with SLE (5 ,38 ,143 ,173 ,174), (c) presence of the same Ids in fetal repertoires and natural autoantibodies as on anti-DNA of mature mice with SLE (126 ,127 ,171 ,175), (d) presence of the same idiotypes on different antibodies to self and to nonself (136 ,146 ,176 ,177 ,178 ,179 ,180), (e) ability to induce autoantibodies in normal mice by administering Id from human autoantibodies (42), and (f) inability to correlate the presence or quantity of a nephritogenic Id with MHC class II genes that predispose to nephritis (181). In keeping with this idea that public Ids are constructed from commonly available Ig sequences or conformations, few lupus Ids are confined to anti-DNA; in fact, in healthy individuals the Ids may be found (but rarely on anti-DNA). The 16/6 lupus anti-DNA Id has been found on antibodies to cardiolipin, platelets, cytoskeleton, lymphocytes, brain gangliosides, and mycobacteria (169). With a few exceptions, such as 16/6, 9G4 and 3I, serum levels of the lupus Ids do not correlate well with disease activity, nor do they accurately predict clinical characteristics of a patient (95 ,139).

Sequencing of several Id-bearing anti-DNAs from humans and mice has shown that some are derived from the germline with minimal mutation, whereas others have undergone somatic mutation (see Chapters 18 and 24). These two populations could represent those cases arising from polyclonal activation and those responding to specific antigenic stimulation. Not all anti-DNAs are pathogens; only certain subsets can induce disease directly, especially immune glomerulonephritis (182 ,183). As discussed elsewhere this may be related to the charge, fine specificity, or overall shape of the antigen combining site (184). In studies on antibodies expressing both anti-DNA and anti-F(ab)2 activity, Voss's group (185) showed that the IgG activity was directed toward the hinge region, and suggested that this property may be particularly relevant to immune complex formation and therefore nephritis. Descriptions of unconventional sites within the V regions of some antibodies include the presence of a nucleotide-binding site (186), which may delineate a pathogen in SLE and warrants further investigation.

There is substantial evidence that certain Ids are enriched in pathogenic autoantibody subsets. For example, we found that IdGN2 dominates the Ig in glomeruli of renal biopsy specimens from almost all patients with proliferative histologic forms of lupus nephritis (174); IdGN2 accounted for 28% to 50% of the anti-DNA deposited in glomeruli of patients with diffuse proliferative glomerulonephritis. Other investigators have searched for Id^+ Ig in tissue lesions of mice or humans with active SLE. Ids 16/6, 32/15, 3I, GN2, O-81, RT-72, RT-84, B3, 33C.9, and D5-M have been found in glomerular Ig deposits and/or at the dermal-epidermal junction in patients with SLE (138 ,143 ,144 ,156 ,157 ,169 ,174 ,187) (Table 15-3). It is likely that each of these Ids is enriched in pathogenic antibody subsets. This also is true in animal models of SLE. In NZB × Swiss Webster F1 mice, lupus nephritis with glomerular deposition of IgG anti-DNA, which is highly enriched in a family of Ids designated IdLN (73 ,144). In nephritic NZB/NZW mice, 50% of the glomerular Ig contains IdGN2 and $IdGN1^+$ antibodies. In addition, administration of some (but not all) $IdGN2^+$ monoclonal IgG2 anti-DNA to normal BALB/c mice produces Id^+ Ig deposits in their glomeruli as well as clinical nephritis (183 ,188). In contrast, monoclonal IgG2 anti-DNA bearing another public Id, IdX, does not induce nephritis in normal mice. Ids D23, 3E10, and 4B1 also have been found in glomeruli of mice with lupus (127 ,189 ,190).

As with Ids on antibodies to external Ag, the structural basis of Ids on autoantibodies is known for only a few mAbs. Clearly, the assembly of autoantibodies does not require any special genetic information. They can be constructed from normal germline DNA, with or without somatic mutation;

they can be assembled from different VH and VL gene families, although there may be some bias toward use of certain families; and they can resemble antibodies to external Ag (167 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,188 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 ,201 ,202 ,203 ,204 ,205 ,206 ,207). Expression of public Ids can depend on amino acid sequences on the H or L chains, or both, or may be conformational (76 ,81 ,82 ,83 ,86 ,87 ,88 ,97 ,102 ,103 ,163 ,208 ,209 ,210). Finally, the structural characteristics of an antibody that make it pathogenic, perhaps related in part to Id expression, are poorly understood; they may depend on features such as cross-reactivity, charge, and avidity. (See Chapter 24 for a more complete discussion of the characteristics of pathogenic anti-DNA.)

Table 15-3: Public Idiotypes in Patients with SLE

Id	Source	In Tissue	Location	Special Features	Percent of SLE Patients with Id in Serum	Percent of Normals with Id in Serum	References
GN2	Glomerular	++ (G)	H chain	Dominant Id in glomeruli of pts with DPGN	67	13	(139,174)
X	mAb aDNA BW mouse	0	?	Dominant Id on serum IgG of BW mice; anti-Id suppresses disease in mice	42	0	(138,139)
16/6	mAb aDNA	++ (G, S)	H chain germline VH26 or VH4	Immunization of normal mice may induce autoantibody and SLE-like disease	25-28	7	(39,40,86,87) (137,168) (173,243)
3I	Polyclonal aDNA, SLE patient sera	+ (G)	κ L chain	3I+ aDNA enriched in cationic IgG	50	7	(139,198,244)
8.12	Polyclonal aDNA, SLE patient sera	+ (G)	λ L chain V_λII	May be specific for SLE	50	5	(97,99,163,208)
0-81	mAb a-ssDNA SLE patient	++ (G)	?	Enriched in pts with GN; occurs in BW mice	72 (with GN) 19 (without GN)	0	(147,158,206)
NE-1	mAb a-dsDNA	++ (G)	?	Enriched in pts with GN; occurs on a-dsDNA	33 (with GN) 6 (without GN)	0	(158,206)
B3	mAb IgG anti-dsDNA, SLE patient sera	+ in vivo ANA	λ L chain	Associated with arthritis in SLE patients	20	0	(98)
F4	Polyclonal aDNA, SLE patient sera	?	H chain	Expressed only on IgG; enriched in cationic Ig	35	?	(198,245)
H3	Human mAb from SLE PBC	?	λ L chain	Found on aPL; may be specific for SLE	?	?	(101)
RT84	Human mAb from SLE PBC	?	?	Found on aPL and aDNA	19	42	(246)
3E10	mAb aDNA, MRL/lpr mouse	?	Conformational	Found in sera of patients with SLE and GN	75 (without GN)	25 (without GN)	(187)
KIM4.6.3	mAb IgM anti-ssDNA normal human tonsil	?	L chain	Id from normal on aDNA in SLE patients	90	24	(139,142)
134	mAb aDNA, SLE patient sera	?	?	On SLE Ig in serum	42	0	(139,247)
AM	Polyclonal aDNA in SLE patient sera	?	Conformational	On SLE Ig in serum	25	13	(139,248)
BEG-2	mAb aDNA, human fetal liver	?	L chain	Fetal antibody Id found on aDNA in SLE patients	8	7	(139,249)
8EY	mAb aDNA, patients with leprosy	?	?	Id from antibody of patient with infection occurs on aDNA of SLE patients	25	0	(139,250)
A52	mAb aDNA BW mouse	?	Conformational	Id from BW mice found on human aDNA in SLE patients	>50	?	(5)
Y2	mAb aSm MRL/lpr mouse	?	?	Id from MRL/lpr mouse found on aDNA in SLE patients	41	6	(251,252)
4B4	mAb aSm human	?	H chain	Cross-reacts with Sm and p24 gag protein of HIV-1	52	?	(83,253)
D5-R	mAb IgG aDNA, human SLE	0 (G)	L chain	Found only on IgG	20-30	5	(187)
D5-M	mAb aDNA	++ (G)	Conformational	Found only on IgG	20-30	7	(187)
A24	mAb from normal human cord blood in adults with SLE	?	H chain	Newborn has Id/anti-Id network also found in aDNA network	?	?	(254)

GN, glomerulonephritis; aDNA, anti-DNA; aPL, anti-phospholipid; dsDNA, double-stranded DNA; IgG, immunoglobulin G; mAb, monoclonal antibody; MRL/lpr, Medical Research Laboratory lymphoproliferative mice; ssDNA, single-stranded DNA.

Manipulation of Clinical Disease in Mouse Models of SLE by Altering the Idiotypic Network

Id networks have been manipulated by several investigators through administering Ids or anti-Ids in attempts to alter disease in the NZB/NZW, MRL/lpr, and SNF1 mouse models of SLE. In some experiments, autoantibody production was suppressed, nephritis was delayed, and survival was prolonged (36 ,120 ,126 ,158 ,159 ,160 ,162). In our laboratories, IdGN2, commonly found on glomerular Ig in human lupus DPGN and in nephritic NZB/NZW mice, was downregulated in NZB/NZW mice by administration of a closely related anti-Id (36) (Fig. 15-5). Serum levels of IdGN2 were initially suppressed but escaped from control, and mice died of nephritis with deposits of $IdGN2^+$ and $IdGN1^+$ Ig in their glomeruli. Their lives were prolonged a mean of 10 weeks compared to controls treated with an irrelevant murine mAb. There was no evidence of emergence of mutated or unrecognized Ids in the mice with escape nephritis. It may be that the ability of certain Ids to escape from suppression is a feature that partially explains their enrichment in pathogenic antibody subsets. In a study where NOD mice were immunized with 16/6Id, it was reported that instead of developing insulin-dependent diabetes mellitus (IDDM) the animals developed SLE (211). Thus, in susceptible animals, autoimmunity does not go away but simply reemerges under another guise.

Although much work has focused on attempts to suppress the expression of pathogenic Ids in murine lupus, experiments with the 16/6 Id-anti-Id system have shown that lupus and antiphospholipid antibody syndrome can be induced in normal mice by manipulating this Id network (39 ,40 ,42 ,70). Immunization of some normal mice (BALB/c, C3H.SW, AKR, and SJL, but not C57BL/6 or C3H/He) with Ids or anti-Ids resulted in development of circulating Ids and anti-Ids, multiple autoantibodies (including anti-DNA, anti-Sm, and anticardiolipin), leukopenia, and nephritis. The susceptibility of strains to the induction of disease did not seem to correlate with MHC or Ig allotype genes, but it did correlate with the ability to make immune responses within the Id network. That is, susceptible strains immunized with Id or anti-Id responded by producing high-titer anti-Id or Id, respectively; resistant strains did not. This ability depends on characteristics of bone marrow cells, because BALB/c mice chimeric for C57Bl/6 bone marrow are resistant to induction of SLE by Id or anti-Id immunization (212). Clearly, activation of certain Id networks can induce pathogenic reactivity to self.

Recent work on manipulating the idiotypic networks has centered on the use of idiopeptides derived from the V regions of disease-associated autoantibodies. The peptides used have either been selected from the framework and/or CDR regions of the Id^+ Ig or chosen through epitope mapping studies that have shown these to be immunodominant for T- or B-cell responses (53 ,55 ,64 ,65 ,66 ,67 ,68 ,73 ,213 ,214 ,215 ,216 ,217 ,218 ,219 ,220 ,221 ,222). Since idiotypes are able to enhance or suppress the autoimmune response, it is possible that analyzing the effects different components of the Id have on the autoimmune response may assist in determining what aspects of the idiotypic structure are responsible for stimulation or suppression. In this way motifs pertinent to the reestablishment of regulatory Id networks may be defined. For example, peptides containing the motif KFKGK can stimulate $CD4^+$ T cell responses in BW F1 (64) and SNF1 mice (65 ,73). Studies thus far have demonstrated the following: Immunizations of normal healthy mice with VH peptides from the murine monoclonal anti-DNA antibody V88, $16/6Id^+$, and $IdGN^+$ mAb produced symptoms of SLE (66 ,219 ,223). In lupus-prone mice, immunization with idiopeptides of A6.1 VH, IdLNF1 p62–73, 16/6Id, and V88 64–80 accelerated the disease process and reduced survival time (53 ,65 ,66 ,219 ,223). In contrast,

when a CDR3 peptide was used from a D23Id$^+$ murine monoclonal, immunization was found to have protective effects; up to 50% of lupus-prone mice exhibited prolonged survival times (220). In contrast, using high-dose tolerizing regimens, idiopeptides may also be used to tolerize premorbid lupus-prone mice and delay disease onset (66 ,213 ,224). Furthermore, different idiopeptides derived from the same VH may stimulate the production of different cytokine profiles (Th1 vs. Th2) (53). Anti-idiopeptide antibodies are generated in both spontaneous and induced models of SLE, which not only react with the immunizing peptide and the native Id-carrying Mab, but may also have specificity for DNA (55 ,150). Therefore the anti-DNA response may arise as part of another response simply through sharing of idiotypic determinants. The other response may be to an external or internal antigen (eg pneumococcal lipopolysaccharide, EBNA-1, heat shock protein 90, or tumor suppressing molecule p53 (151 ,177 ,215).

Idiotypes in the Treatment of Human SLE

A number of studies have shown that clinical improvement in SLE patients correlates with the presence of circulating antibodies able to interact with Ig variable regions (153 ,154 ,155). As discussed elsewhere in this volume, there is interest in treating selected patients with SLE using intravenous gamma globulin (IVIG). These preparations are generated from pools of serum from up to 45,000 normal individuals (155). It has been demonstrated that the pools contain anti-F(ab)2 activity, some of which is directed against Ids 8.12, 3I, F4, 4B4, and 16/6 (Ids characteristic of SLE autoantibodies), and many authors have suggested that these anti-Ids account for improvement in clinical disease (162 ,225 ,226). In addition IVIg contains natural antibodies to TCR public Ids (227) which could enhance or suppress help or regulation supplied by TCR-Ids.

Harata et al. (147) reported that affinity columns containing two anti-Ids (D1E2 and 1F5) coupled to sepharose were able to remove 25% to 92% of the anti-DNA antibody repertoire from sera of patients with SLE and could also remove Id$^+$ T cells. In a more recent study of five patients with lupus nephritis, Silvestris et al. (161) compared the effects of using anti-Id (F4 and 8.12) IgG (preparation EL-11) purified from IVIg versus the whole IVIg. In the two SLE patients treated with EL-11 intravenously, a significant improvement was noted. In a larger study of 20 SLE patients, Levy et al. (228) reported decreases in disease activity and autoantibody production. Since M-components express Ids associated with SLE, it has been suggested that they may be used as source material for purification of large amounts of antiidiotypic material for clinical use (229). IVIg have been used to treat a variety of diseases and is thought to operate via a number of mechanisms, reviewed elsewhere (230).

Idiotypic vaccination with murine anti-dsDNA antibody (3E10) of patients with inactive SLE and stable nephritis has been tested in a phase I clinical trial (231). Five of the nine subjects developed anti-idiotypic responses to the murine antibody. In a follow-up lasting 2 years, disease exacerbations did not occur.

A peptide (“Edratide”) from the VH region of an Id16.6-positive human anti-DNA is in clinical trials in SLE patients (214 ,215 ,232). In lupus mice, a similar peptide induces regulatory CD4$^+$CD25$^+$ T cells which suppress autoantibody production and nephritis.

Engineered Idiotypes and DNA Vaccines

Recent technologic advances in molecular biology and protein engineering mean that antibody combining sites and therefore idiotypes can be custom built. This can be achieved in a number of ways. First, it is possible to generate single-chain Fv (scFv) fragments that essentially represent the antigen combining site. These consist of the variable region of the heavy chain and the variable region of the light chain joined together with a short flexible segment referred to as the linker. They are produced by using the genes that encode for the VH and VL regions, respectively. The scFv is expressed in bacteria and more recently on the surface of filamentous phage (210 ,233 ,234). Clearly, the antigen combining site can be modified genetically to generate a product with a higher affinity or different specificity, or can even be used to express antigenic determinants that may not be naturally located within the combining site (235 ,236). All this is possible because first, the structure of the antibody-binding site is well conserved and most of the changes that occur in the combining site happen within the CDRs, especially in the CDR3. Second, specific amino acid sequences can be introduced into the CDRs of the V region without altering the overall shape of the combining site. This process is known as CDR grafting. Since B cells are able to process and present their Ig variable regions (47), these “antigenized” Igs (237) can thus be used to elicit highly specific, what are essentially “anti-Id,” responses to infectious agents, for example. Zaghouani et al. (236) have used this approach to produce antibodies to a principal neutralizing determinant derived from the V3 loop of the HIV-1 envelope protein. Earlier reports demonstrated induction of responses to influenza virus (235) and to malaria (238). Xiong et al. (238) demonstrated that as well as CDR-H3, which is the usual site for grafting, CDR-H2 could also be utilized. Furthermore, the introduction of a T cell epitope into the latter loop enhanced the B-cell response for the malaria antigen. This suggests that idiotypic determinants within the variable region may themselves modulate the “anti-idiotypic” response to other determinants within the same site. ScFv can be used as the classic Ab2 antigen mimic. It can also be altered from the wild type to generate a desirable antibody response (235). Features of anti-DNA binding have also been investigated using scFv technology (210 ,239). Recombinant antibodies also feature in investigations and treatment of tumors. CDR grafting in fact has been used in a number of cases to produce humanized antibodies so as to minimize the effects of using murine antibodies directed against tumor antigens (240).

A more recent development is the use of DNA vaccines (241 ,242). Here the DNA encoding for the VH and VL regions itself can be used as an immunogen. The vaccine essentially consists of the genetic material cloned into a bacterial plasmid that is designed to allow expression in eukaryotic cells. The vaccine also contains CpG motifs that can enhance the immune response. The functional protein (Ab2 mimic or Id) when expressed by the vaccinated individual can then elicit immune responses to the antigen, be this infectious agent or tumor antigen. The vaccine can be made effective by conjugating it another component, for example the fragment C of Clostridium tetani (241).

Engineered Ids have not been used in SLE as far as we are aware. However, it is tempting to speculate that public Ids that have been described in lupus may be engineered and used to purify anti-Id reagents for therapy or be used as inoculi singly or linked in a fusion protein with selected cytokines to re-equilibrate dysregulated idiotypic networks.

Chapter 16

The Importance of Sex Hormones in Systemic Lupus Erythematosus

Sara E Walker

Hormones and the immune system interact through a number of pathways (1 ,2) and understanding the interdependence of these systems is important in order to appreciate the pathogenesis of autoimmune disease. This chapter will discuss the influence of gonads on the thymus and vice versa, as well as the effects of estrogens, androgens, and pituitary and hypothalamic hormones on immune responses and autoimmunity. Identification of the stimulating and suppressive properties of individual hormones affords the opportunity to design effective and relatively nontoxic treatments to change hormone concentrations and thereby affect systemic lupus erythematosus.

Gonadal Hormones

Immune System-Reproductive System Interactions

The interdependence of the thymus, ovaries and pituitary-gonadal axis has been demonstrated in female rodents. A number of thymic peptides, including thymulin, regulate T cell maturation, influence pituitary and hypothalamic structure and act as neurotransmitters. In turn, the production of thymulin is controlled by the anterior pituitary hormones, prolactin and growth hormone (3).

The thymus is required for ovaries to develop and function normally. Congenitally athymic nude mice had small ovaries and premature ovarian failure (4) as well as reduced concentrations of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), estrone, and testosterone (5). Neonatal thymectomy results in sterility and ovarian dysgenesis in rodents. B6A mice thymectomized at 3 days of age responded with diminished ovarian weight, loss of oocytes and lack of corporea lutea. Circulating antibodies to oocytes were identified and the ovaries were infiltrated with lymphocytes. Neonatal thymectomy also resulted in low levels of FSH, LH, growth hormone, and prolactin (6). A preferential decrease in $CD4^+$ lymphocytes occurred after neonatal thymectomy, and reproductive dysfunction was prevented by injecting $CD4^+$ lymphocytes (7) or implanting a normal thymus (8).

The thymus is sensitive to gonadal hormones in rodents, and high doses of estradiol or testosterone depleted lymphocytes in the thymic cortex (9). In contrast, physiologic doses of estrogen stimulate the thymus. It has been proposed that this stimulation is mediated through influences on factors such as thymulin that are secreted by the thymic epithelium. This contention was supported by finding receptors for both thymic hormones and sex hormones on thymic epithelial cells (10) and by the discovery that estrogen stimulated thymulin secretion (11). Erbach (12) found that replacement doses of estradiol increased antibody formation in ovariectomized female rats. Estradiol was effective as long as the rats had an intact thymus or were treated with thymosin factor 5. Mice were “rescued” from thymectomy-induced ovarian dysgenesis if they were treated with estradiol-17ß before the thymus was removed (13).

Effects of Estrogen in Murine Models of Lupus

Sex hormones play an important role in regulating the severity of disease in F_1 hybrid New Zealand Black (NZB) × New Zealand White (NZW) (NZB/NZW) mice, a model of SLE that spontaneously develops antibodies to antidouble-stranded DNA (anti-dsDNA) and immune complex mediated glomerulonephritis. Reports from colonies in different parts of the world verify that disease in NZB/NZW females starts earlier and progresses more rapidly compared to males. Female NZB/NZW mice die of renal failure at 10 to 12 months of age and males die at the age of 14 to 16 months (14). The females have considerably more IgG anti-DNA antibodies compared to males. At 5 to 6 months of age, females switched from autoantibodies of the IgG and IgM classes to primarily IgG autoantibodies. This switch occurred 3 months later in males (15). Of interest, these mice have concentrations of serum estradiol and testosterone that are comparable to mice that do not develop autoimmune disease (16 ,17). Furthermore, the females do not have abnormalities of estrogen metabolism that would alter 2-hydroxylated or 16-hydroxylated products (18).

Treatment with estrogen accelerates disease in weanling NZB/NZW mice. Mestranol, a synthetic estrogen used in oral contraceptives, induced positive tests for fluorescent antinuclear antibodies in male NZB/NZW mice after 6 weeks

of treatment (19). Roubinian (15 ,20) and Steinberg (21) gave castrated NZB/NZW mice crystalline implants that contained high, nonphysiologic doses (6 to 7 mg) of estradiol-17ß. In mice of both sexes, autoantibody levels were stimulated and recipients of implanted estradiol died prematurely compared with untreated castrates and intact animals (15 ,20 ,21 ,22 ,23).

These early studies linked estrogen with the phenotypic expression of severe autoimmune disease in the NZB/NZW model. It was therefore an unexpected finding that surgical oophorectomy did not reduce the severity of lupus in NZB/NZW females (15). In addition, parturition did not lead to immediate postpartum flares of autoimmune disease. When NZB/NZW mice whelped at 10 and 16 weeks of age and the pups were removed within 24 hours, there was no immediate stimulation of anti-dsDNA, serum immunoglobulins, albuminuria, or blood urea nitrogen (24). In NZB/NZW females that had multiple litters, severity of glomerulonephritis and longevity did not differ from virgin controls (25).

The doses of estrogen used in early experiments (15 ,20 ,21) produced extremely high concentrations of circulating estradiol and fatal estrogen toxicity (26). Toxic wasting, bladder distention, endometriosis and pituitary adenomas were observed in NZB/NZW females that had received the high-dose crystalline implants (23 ,26 ,27 ,28). Newer dosing regimes, however, more closely mimicked naturally occurring levels of estrogen in mice. Brick (16) implanted NZB/NZW mice with 1.5 to 2.0 mg of estradiol-17ß and this dose increased antibody responses. Carlsten (29) used biweekly injections of estradiol benzoate 3.2 µg to reproduce physiologic estrogen concentrations. This treatment accelerated renal disease and shortened longevity in first-generation offspring of NZB/NZW × NZB backcross mice that had inherited the $H2^{d}/H2^{z}$ genotype, which is the same genotype as that of NZB/NZW mice.

The MRL/MpJ-Fos^{lpr} (MRL-lpr) mouse model of autoimmunity has variable responses to estrogenic hormones. High estrogen doses accelerated disease, and male castrates that received continuous long-term treatment with a super-physiologic dose died prematurely with renal disease (30). MRL-lpr females injected with complete Freund's adjuvant, followed by 14 daily injections of high-dose estradiol (0.4 mg/kg/day), responded with proteinuria and early mortality (31).

In contrast, longevity is not influenced strongly by gender in MRL-lpr mice (14). A physiologic dose of estradiol did stimulate anti-DNA, but short-term treatment did not affect longevity in castrated males (16). Unexpectedly, physiologic estradiol suppressed postpartum flares of arthritis (31) whereas raloxifene did not accelerate autoimmunity (32).

Of interest, estrogen stimulates expression of autoimmune disease in mice that are considered “not autoimmune.” C57BL/6 mice do not express autoimmune disease at a young age, but the aged animals spontaneously develop anti-DNA antibodies and inflammatory changes in multiple organs (33 ,34). Estrogen implants in C57BL/6 mice stimulated anti-DNA antibodies (34) and increased numbers of spleen and bone marrow cells that secreted IgG and IgM (35).

Gender influences the SLE models developed by Wakeland (36 ,37) in which specific lupus susceptibility genes were introduced into C57BL/6 mice by congenic matings. The *Sle 1* gene leads to breach of tolerance for chromatin, with development of high titers of antinuclear antibodies. The *Sle 3* gene controls glomerulonephritis and has higher penetrance in females than males (36). When both genes were expressed in B6.NZMc1/c7 mice, severe disease developed that was characterized by splenomegaly, expanded populations of activated B cells and $CD4^{+}$ T cells and glomerulonephritis. Female B6.NZMc1/c7 mice had earlier activation of lymphocytes, higher levels of serum IgG and nephrophilic antibodies with stronger glomerular affinity compared to B6.NZMc1/c7 males. These bicongenic females developed very high levels of anti-dsDNA. It therefore appeared that female gender, and possibly female hormones, promoted the pathogenic spread of autoantibody production from anti-nucleosome antibodies to anti-DNA (37).

Lupus that is induced by manipulating “nonautoimmune” strains is stimulated by treating the mice with estrogen before inducing the autoimmune disease. Female C57Bl/10 × DBA/2 F_1 mice injected with DBA/2 lymphocytes are highly susceptible to chronic graft-vs-host disease. When the lymphocyte recipients were treated with estradiol-17ß before induction of the graft-vs-host reaction, there was increased production of multiple autoantibodies including anti-dsDNA (38). BALB/c mice immunized with the 16/6 Id idiotype of human anti-dsDNA will develop anti-DNA, and this autoantibody response is enhanced by estrogen. BALB/c mice of both sexes were implanted with capsules containing 2 to 3 mg of estradiol-17ß and immunized 3 months later with the idiotype. The mice responded with high titers of antibodies to dsDNA and a number of other autoantibodies (39). Treatment of the idiotype-injected mice with either tamoxifen or anti-estradiol antibody decreased severity of proteinuria and protected against immune complex deposits in renal glomeruli (40).

Effects of Testosterone in Murine Models of Lupus

In contrast to estradiol, androgenic hormones are protective in NZB/NZW mice. In female NZB/NZW mice, subcutaneous implantation of Silastic capsules containing testosterone or 5-dihydrotestosterone suppressed SLE and prolonged life spans (23). It was not necessary for the females to be castrated in order to benefit from exogenous androgens, and androgen treatment was effective even if it was started after the onset of clinical disease (23 ,41 ,42). Autoimmune disease in NZB/NZW females is responsive to relatively low doses of androgen. In fact, the low levels of testosterone that are found normally in female mice afford some protection from autoimmune disease. Long-term treatment with flutamide, a specific blocker of androgen receptors, resulted in accelerated mortality in NZB/NZW females (17). The naturally occurring weakly androgenic steroid, dehydroepiandrosterone sulfate (DHEA), delayed the onset of anti-DNA antibodies and prolonged longevity in NZB/NZW females when treatment was started at 2 months of age. In contrast, there was no response

if treatment began at the age of 6 months (43). Treating NZB/NZW mice with DHEA ameliorated imbalances in several cytokines that are associated with progression of autoimmune disease in this model. Circulating levels of IL-10 and IL-6, which are expected to increase with disease onset and exacerbation, were suppressed by DHEA (43 ,44).

In NZB/NZW males, the course of disease was accelerated by castration. Surgical removal of the testicles before puberty was followed by early production of anti-DNA antibodies, early switch from 19S to 7S autoantibodies and early death (41). Early castration was more effective than late castration, and castration of males at the age of 3 months had little effect on anti-DNA antibodies (45).

The rapidly progressive autoimmune disease in MRL-lpr mice does not display marked differences in severity between genders, and high-dose estradiol therapy is required to accelerate disease progression. High doses of androgens do effectively suppress MRL-lpr autoimmunity. Suppression of systemic autoimmune disease in males has been achieved with implants containing 6 to 8 mg of testosterone or 12 mg of 5-dihydrotestosterone, implanted at 2 to 4 weeks of age (46 ,47).

Lacrimal glands of MRL-lpr mice are infiltrated with periductal and perivascular collections of lymphocytes that disrupt acinar tissue, and lacrimal gland involvement in MRL-lpr females is significantly greater compared to MRL-lpr males. Implantation of high-dose pellets that contained 10 or 25 mg of testosterone resulted in dramatic reversal of the inflammatory lesions (48 ,49).

Immunologic Imprinting of the Fetus

Exposure of the fetal mouse to high-dose exogenous estrogen can stimulate autoimmune responses in a strain that does not ordinarily develop autoimmune disease. In C57BL/6 mice, treating the dam with estrogen at 14 to 16 days of gestation resulted in offspring that had sialoadenitis and increased plaque forming cell responses to bromelain-treated erythrocytes (50 ,51).

Immunologic imprinting by naturally occurring gonadal hormones *in utero* can change the severity of autoimmunity in mice that develop autoimmune disease spontaneously. In the maternal-fetal unit composed of the NZB dam and her NZB/NZW F_1, hybrid fetuses production of steroid hormones was regulated differently compared with “nonautoimmune” mice. Male NZB/NZW fetuses are expected to develop into adults that live longer than NZB/NZW females, The male fetuses were found to develop in utero in the presence of abnormally high levels of serum estradiol. In contrast, testosterone concentrations in the testicles and placentae of fetal NZB/NZW males were abnormally low (52).

Estradiol is considered immunostimulatory in young adult NZB/NZW females, Paradoxically, newborn NZB/NZW females benefited from one-shot treatment with high-dose estradiol. Yamaguchi (53) injected NZB/NZW mice with estradiol-17β 200 ng/g within 2 days of birth. Longevity was increased in the females (50% survival at 18 months of age) so that life spans in the estrogen-exposed females resembled life spans in untreated NZB/NZW males.

Testosterone imprinting of the NZB/NZW fetus ameliorated the course of their autoimmune disease after they grew into adults. However, the beneficial effects were manifested only in males. The prenatal effects of androgen were evaluated by treating NZB dams with Silastic implants containing testosterone on days 13 to 18 of gestation. The male NZB/NZW offspring of these dams had therefore been exposed to increased levels of testosterone *in utero* and in adult life these males had extended life spans compared to male NZB/NZW controls (54).

Responses to Estrogen and Androgen in Murine Lupus

Estrogen has powerful effects on the immune system through mechanisms that are regulated differently through two types of estrogen receptors. Mice from nonautoimmune lineages that were knockout for the estrogen receptor α gene spontaneously developed immune complex glomerulonephritis by 1 year of age with proteinuria, destructive infiltration of B cells in the kidney and serum anti-antibodies DNA, The females had increased serum IgG3. Pro/pre-B lymphocytes ($B220^{low}$/IgM-) and mature B lymphocytes ($B220^{high}$/IgM^+) in bone marrow were decreased (55). In contrast, estrogen receptor ß knockout mice had splenomegaly and myeloproliferative disease resembling chronic myeloid leukemia with lymphoid blast crisis (56). Pro/pre-B lymphocytes were increased in numbers and this inhibition of B cell development resembled the changes noted in mice after oophorectomy. Therefore, the ß estrogen receptor appeared to mediate the effects of estrogen on the immune system (55 ,56).

Exogenous estrogen stimulates $CD4^+$ T cell gene and protein expression of surface receptors that regulate T cell homing (57). Furthermore, estrogen stimulates production of the Th1 cytokine, IFN-γ (58), and has the capacity to enhance production of Th2 cytokines (59). These properties could contribute to the enhancing effects of estrogenic hormones in murine models of SLE. Expression of IFN-γ transcripts was very high in unstimulated T cells from female NZB/NZW mice (60 ,61). Furthermore, NZB/NZW females had high expression of IL-6 genes in unfractionated, unstimulated spleen cells (61). Another survey of NZB/NZW females found limited secretion of Th1 cytokines but unfractionated spleen cells produced high levels of IL-3, IL-4, IL-5, and IL-10 (62). Estrogen is capable of stimulating immune responses in both “nonautoimmune” mice and the New Zealand F_1 hybrid. Treatment with estrogen for periods of either 2 or 4 weeks decreased T suppressor cell activity in C57BL/6 mice as well as autoimmune NZB/NZW mice (63).

Estrogen stimulation is not limited to T cells or to cells that produce antibodies directed against a specific antigen. $CD5^+$ B cells, which spontaneously produce polyreactive IgM autoantibodies (49), were increased in nonautoimmune mice and in young NZB/NZW mice that were treated with estradiol-17β (64 ,65).

Immunostimulatory effects of estrogen are expressed in B cells in lupus-prone mice. Murine B cells have both α and ß estrogen receptors (66). BALB/c mice have a genetic background that predisposes to loss of B cell tolerance. Diamond and associates (67) generated transgenic R4A-γ2b BALB/c mice that express the γ2b heavy chain of a nephritogenic anti-DNA antibody. These mice are normally able to maintain tolerance by deleting DNA-reactive B cells that arise in the immature repertoire. When transgenic BALB/c mice were treated long term with implanted estradiol-17ß that provided serum concentrations equivalent to those found in normal estrus cycles, the mice developed a lupus-like phenotype with elevated levels of circulating anti-DNA antibodies and glomerular immune complex deposits.

Estradiol was thought to have stimulated autoimmunity by increasing the resistance of transitional B cells to apoptosis through up-regulation of the anti-apoptotic protein Bcl-2, and the inhibitory signaling molecules CD22 and SHP-1. Estradiol rescued B cells that were capable of producing high affinity anti-DNA so that these cells were not eliminated from the B cell repertoire. Under the influence of estrogen, the cells matured to a marginal zone phenotype. Both follicular and marginal zone anti-DNA producing B cells were increased in estradiol-treated R4A-IgG2b mice. The greatest increase, however, was in marginal zone cells, which were 10 times more common than follicular cells. Furthermore, the marginal zone B cells were activated by estradiol to secrete high affinity and potentially pathogenic anti-DNA antibodies and were not susceptible to regulation by T cells (68 ,69 ,70).

Testosterone clearly suppresses autoimmune disease in NZB/NZW mice of both sexes. Earlier studies of the mechanisms of androgenic suppression suggested that the immunosuppressive effects of androgens were limited to T cells. Testosterone increased T suppressor cell activity (63) and did not affect $CD5^+$B cells (71) in the NZB/NZW model. Detailed studies of “nonautoimmune” C57BL/6 mice demonstrated that surgical removal of the testes was followed by profound changes in B cells and T cells. This reordering of the immune system could explain some aspects of accelerated autoimmune disease in NZB/NZW male castrates. Surgical castration of male C57BL/6 mice at 6 weeks of age was followed by thymic hypertrophy, splenic enlargement because of expansion of B cells and decreased numbers of splenic T cells. Spleen cells had increased production of IL-2 and IFN-γ, and anti-thyroglobulin antibodies and rheumatoid factor production increased (72). $B220^+$ B cells expanded in the bone marrow following castration of C57BL/6J males, and injections of testosterone cypionate 1 mg or dihydrotestosterone 0.2 or 0.4 mg reversed this effect (73).

Diet Therapy for Murine Lupus

The observation that estrogen can stimulate the immune system led to attempts to manipulate lupus activity with diet. Aromatase-knockout mice are unable to make estrogen. Aromatase-knockout mice raised on a phytoestrogen-free diet developed B cell hyperplasia and destructive leukocyte infiltrates in the salivary glands that resembled Sjögren syndrome. The lesions were completely absent if the mice were fed a diet with normal levels of phytoestrogen. These results suggested that endogenous estrogen paradoxically protects against autoimmune exocrinopathy. Furthermore, phytoestrogens that occur normally in food appeared to play an important role in replacing endogenous estrogenic hormones (74).

Indole-3-carbinol is abundant in cruciferous vegetables and can shift estrogen metabolism away from mitogenic 16α hydroxyestrone, which may fuel disease activity, and toward less estrogenic metabolites. When indole-3-carbinol was fed to female NZB/NZW mice soon after weaning, 80% of the treated mice were alive at 1 year of age compared to 10% of controls. Mice that received indole-3-carbinol from the age of 5 months were all alive at 1 year. Treatment was associated with suppressed anti-dsDNA and suppressed renal disease. The ratio of 2- to 16-α-hydroxyestrone in urine was increased, reflecting a shift in estrogen metabolism that favored production of metabolites with less estrogen activity (75).

Hormone Manipulation to Treat Murine SLE

The aromatase inhibitor 4-hydroxyandrostenedione, which inhibits estrogen biosynthesis, suppressed disease in female NZB/NZW mice. Treatment from 11.5 to 15 weeks of age reduced thymus weights and appeared to retard glomerular inflammation (76).

Tamoxifen, a selective estrogen receptor blocker, was highly effective in NZB/NZW females. A dose of 22 mg/kg body weight was injected at 2-week intervals and the mice were sacrificed after 5 months of treatment. Percentages of B cells and $CD5^+$ B cells were decreased, tumor necrosis factor receptor molecules were fewer in number and renal deposition of immune complexes was suppressed in treated mice (77). More intensive treatment with tamoxifen 800 µg twice a week (about 64 mg/kg/week), resulted in significant reduction of antibodies against nuclear extracts of HeLa cells and calf thymus DNA and significant prolongation of life. Serum anti-DNA antibodies of the IgG3 class a class that appears to be pathogenic in murine SLE, were reduced and glomerular deposits were composed primarily of IgG2a (78).

In the estrogen-sensitive transgenic mouse model, R4A-γ2b BALB/c, tamoxifen blocked the appearance of lupus. When tamoxifen was given in conjunction with estradiol, apoptosis was not affected. Autoreactive B cells expanded but were anergic, and the mice did not develop anti-DNA antibodies or glomerular deposits of IgG. This series of experiments illustrated the ability of tamoxifen to abrogate estrogen-enhanced activation of autoreactive B cells, whereas survival of the cells was not affected (79).

Androgens are beneficial in murine models of lupus, and testosterone and 5-dihydrotestosterone produced favorable responses in NZB/NZW (23 ,41 ,42) and MRL-lpr mice (46 ,47 ,48). Female NZB/NZW mice benefited from long term

intraperitoneal injections of DHEA 100 µg twice a week, if the injections were started at 2 months of age before the expected appearance of overt disease. Anti-dsDNA was suppressed and mean longevity was prolonged so that 71% of treated mice were alive at 41 weeks of age compared to 22% of control mice. DHEA treatment that was started at 6 months of age was not effective (43). NZB/NZW females and castrated males also responded favorably to injections of nandrolone decanoate, an androgen with attenuated virilizing properties. Proteinuria and anti-DNA were suppressed and treatment was effective even if it was begun after disease onset (80 ,81).

The 19-nor-testosterone derivatives norethindrone and norgestrel are progestogens used commonly in oral contraceptive pills. Each compound, in Silastic capsules, was implanted separately in 6-week-old and 24-week-old NZB/NZW females in relatively small doses that were calibrated to suppress reproduction (82). Both progestogens suppressed anti-DNA antibodies, and mice that were implanted with norgestrel at the age of 24 weeks had prolonged life spans (83).

Gender Difference in Occurrence of SLE in Humans

Both hormonal and nonhormonal factors predispose to the increased incidence of SLE in women (84 ,85 ,86). Human SLE clearly has a predilection for females of childbearing age (87) and may appear or exacerbate when serum concentrations of reproductive hormones are elevated and when hormones are undergoing rapid change.

The mean age of menarche was delayed significantly in a small group of young women with SLE (13.5 years) compared to healthy adolescents (12.5) but the majority of the adolescents with lupus had normal gonadal function (88). Disease flares were increased in the 2-week period before onset of the menstrual period (89). Flares were fewer in number following natural menopause (90) or ovarian failure induced by cyclophosphamide therapy (91). In the era before corticosteroids were used to treat SLE, improvement was noted after surgical removal of the uterus and ovaries or treatment with testosterone. Irradiation of the ovaries, however, did not change the course of disease (92).

The theory that SLE activity is influenced by reproductive hormones is supported by the finding that disease flares are increased during pregnancy (93 ,94 ,95 ,96 ,98 ,99). The number of pregnancies and live births that occur during a woman's lifetime did not predict an increased probability of developing lupus *de novo* (97). In patients with pre-existing SLE, the risk of increased lupus activity was elevated during pregnancy. Increased flares were observed at the St. Thomas' Lupus Pregnancy Clinic (98). At the Hopkins Lupus Pregnancy Center, flares (defined by a change of 1.0 on a 0 to 3 visual analog scale) occurred in 60% of lupus pregnancies. The rate of flares in pregnancy was significantly greater compared to the same patients after delivery and to nonpregnant SLE patients (96 ,99).

Th1 cytokines, including IL-2, IFN-γ, and tumor necrosis factor (TNF)-ß, are deleterious during pregnancy and may lead to fetal demise. It has therefore been proposed that a shift away from Th1 responses and towards Th2 responses occurs during normal pregnancy and is important in maintaining the intact fetal-maternal unit (100). Are reproductive hormones involved in this shift? Estrogen has the potential to stimulate both Th1 and Th2 responses (58 ,59). It is of interest to speculate that estrogen in the high concentrations found in pregnancy or estrogen acting in concert with other reproductive hormones can stimulate increased Th2 cytokines. This response would be desirable during a normal pregnancy. In the patient with SLE, excessive Th2 responses could cause increased production of antibodies and lead to activation of disease (101).

This theory was not supported by a recent study of adrenal and gonadal hormone levels in 17 pregnant SLE patients. Surprisingly, estrogen concentrations did not increase during the second and third trimesters. This abnormal response was thought to result from damage to the placenta or an abnormality of steroid metabolism in the placenta (102).

Responses of Peripheral Blood Mononuclear Cells to Estrogen in SLE

Peripheral blood mononuclear cells (PBMC) from patients with SLE have abnormal responses to estrogen stimulation. In vitro apoptosis was decreased when lupus patients' PBMC were cultured with estrogen, a response that could permit abnormal cells to survive and perpetuate autoimmune responses (103). In another series of experiments, culturing PBMC from SLE patients with estradiol 17-ß enhanced production of total IgG and IgG anti-dsDNA antibodies. In contrast, PBMC from normal donors responded to estradiol by producing increased IgG but not anti-dsDNA. Adding IL-10 to estradiol had an additive effect on increasing antibody production (104).

Estrogen Receptors

Variations in estrogen receptors have been identified in human lupus. Normal individuals were found to have both wild-type receptors and an isoform which lacks exon V. In contrast, SLE patients had either the wild type or the truncated form of the receptor. It was suggested that the presence of mutated or differentially spliced forms of estrogen receptor accounted for abnormal responses to estrogen in SLE (105). Calcineurin, an enzyme which participates in T cell signal transduction and has the potential to promote activation of IL-2 and other cytokine genes, may serve as a link between estrogen and the immune system in lupus. Estrogen bound to the estrogen receptor evoked a direct, gender-specific increase in calcineurin mRNA expression in T cells from women with SLE (106 ,107). Estrogen also stimulated the amount of surface CD40 ligand mRNA on T cells from lupus patients compared to normal controls (108).

Oral Contraceptives in SLE

The appearance of autoantibodies and overt SLE has been reported in previously healthy women taking combination oral contraceptives with a high content of potent synthetic estrogen (109 ,110 ,111). In contrast, other investigators noted that rheumatic symptoms did not accompany the use of estrogen-containing contraceptive pills (112 ,113). The current practice of using increasingly smaller doses of estrogen (<50 µg) in combination pills probably accounts for the apparent decrease in lupus-like side effects noted in the past three decades. In metropolitan Philadelphia, oral contraceptives were not associated with new-onset SLE in patients diagnosed between 1985 and 1987 (114).

A recent report by Sanchez-Guerrero (115) did suggest that the use of oral contraceptives was associated with a small risk of developing SLE. A cohort of women in the Nurses' Health Study was followed prospectively every 2 years between 1976 and 1990. When those who had used oral contraceptives were compared with those who never used oral contraceptives and a stringent case definition of SLE was used, the relative risk for developing SLE was found to be 1.9.

In women with pre-existing SLE, oral contraceptives with high dose estrogen were reported to stimulate flares in pre-existing SLE in the 1960s and 1970s. Pimstone (116) and Chapel (117) reported lupus flares in women taking combination pills that contained 50 µg of ethinyl estradiol and 100 µg of mestranol, respectively.

Data from the prospective multicenter Safety of Estrogens in Lupus Erythematosus-National Assessment (SELENA) trial showed that triphasic oral contraceptives did not increase lupus flares in selected subjects over a 1-year period. Premenopausal women (*n* = 145, completed follow-up) with either inactive or stable active SLE took either oral contraceptive pills (35 µg ethinylestradiol/0.5–1.0 mg norethindrone) or placebo for 12 cycles. The participants did not have a history of thrombosis, moderate/high titer antiphospholipid antibodies or lupus anticoagulant. Severe flares occurred in 7.7% of oral contraceptive users and 7.6% of the placebo group. Mild to moderate flares were found in 15% of patients taking oral contraceptives versus 16% of those taking placebo (118).

Postmenopausal Estrogen Replacement in SLE

The routine use of hormone replacement therapy after the menopause is not recommended by the US Preventive Services Task Force (119) because “the harmful effects of combined estrogen and progestin are likely to exceed the chronic disease prevention benefits in most women.” A review of earlier reports of women taking estrogen after the menopause is of interest, however, because the question has arisen that these women could be at increased risk to develop SLE. The Nurses' Health Study showed that women who had taken hormone replacement had an increased risk of *de novo* SLE and the risk had a positive relation to duration of the therapy (120). In a separate case-control study, women who used postmenopausal estrogens for 2 or more years were at risk to develop both discoid lupus and SLE (121).

Postmenopausal estrogen replacement has also been associated with flares of SLE. A case has been reported in which a patient with lupus had remission when she became menopausal at 38 years of age. The disease recurred when she was treated with estrogen for osteoporosis at the age of 64 years (122). In contrast, 2 studies of relatively small groups of SLE patients showed no lupus flares associated with conventional hormone replacement (123 ,124). Transdermal estrogen was given without flares to a group of 15 postmenopausal SLE patients for a period of 1 year (125).

The SELENA trial affirmed that postmenopausal hormone replacement therapy could contribute to flares of SLE, but the flares were of mild or moderate severity. In the hormone replacement arm of the study (*n* = 286, women who completed followup), menopausal women with inactive or stable active SLE were enrolled between March 1996, and June 2002, and randomized to take either 0.625 mg of conjugated estrogen for the entire month plus 5 mg of medroxyprogesterone on days 1 to 12 or placebo. Exclusion factors included high blood pressure, history of venous or arterial thromboses or pulmonary emboli or myocardial infarction, high-titer anticardiolipin antibodies or lupus anticoagulant and migraine headaches with neurologic sequelae. The trial was stopped in 2002, after all the patients were enrolled, based upon the reported results of the Heart and Estrogen/progestin Replacement Study (126) and the Women's Health Initiative trial (127). Severe flares were observed in 7.5% of women receiving hormone replacement and 4.5% of the placebo group, but the difference was not significant. In contrast 59% of hormone-treated SLE patients had mild to moderate flares with an overall incidence rate (taking into account multiple flares of any type) of 1.25 flares/person-year. Flares did occur in 50% of patients taking placebo but the incidence rate of flares was significantly lower (0.93 flare/person-year, $p = 0.006$) (128).

Assisted Reproduction and SLE Flares

Ovulation induction increases circulating estradiol to 10 times the concentration found in nonpregnant women, and an increasing number of reports have documented the association of ovulation induction and in vitro fertilization (IVF) with new-onset SLE and flares of SLE (129). Three women who underwent 6 to 10 cycles of ovulation induction developed very high estradiol levels (1,560–2,850 pm/L) and lupus (130). Another presented with acute lupus (butterfly rash, peritonitis, ascites, anti-dsDNA, hypocomplementemia) following 11 cycles of gonadotropin-human chorionic gonadotropin (HCG) ovulation induction (131). A woman who underwent 27 uncontrolled gonadotropin-HCG-stimulated ovulation induction cycles had three pregnancy losses between the ages of 26 and 32 and developed in sequence, insulin-dependent diabetes mellitus, arthralgia, and thrombocytopenia followed by full blown lupus with a photosensitive rash, cells LE, anti-dsDNA, hypocomplementemia, and anticardiolipin antibodies (132).

In women with established SLE, case reports described moderate flares (133) and a fatal exacerbation of SLE in women undergoing ovulation induction (134). Increased lupus activity was observed in 25% of ovulation induction/IVF fertilization cycles in SLE patients and 13% were complicated by the ovarian hyperstimulation syndrome (129). In another series SLE flares appeared after 13 of 62 cycles. The flare rate was higher after gonadotropin induction (27%) compared to clomiphene induction (6%) (135).

Sex Hormones in SLE Patients

Gonadal hormones are abnormal in both women and men with SLE. In women the metabolism of estradiol-17β and estrone is shifted to favor production of 16-hydroxyestrone and estriol and these metabolites are increased significantly compared with normal women. The 16-metabolites are potent mitogens that are thought to have the potential to stimulate inflammation (136 ,137). Women with lupus also have low plasma androgens. Very low levels of circulating androgens have been described in women with active SLE (138). This abnormality could result from increased testosterone oxidation at C-17, or increased tissue aromatase activity (139 ,140 ,141).

DHEA has shown promise as a treatment for SLE. A study conducted in Taiwan enrolled 120 women with active lupus to receive either DHEA 200 mg/day, or placebo for 24 weeks. In the treatment group, testosterone levels increased significantly but overall disease activity measured by the systemic lupus activity measure (SLAM) score did not differ from the control group. Numbers of patients with flares, those with serious adverse events and patient estimates of disease severity were decreased significantly in the DHEA group (142). A multicenter double-blind United States study of women with SLE resulted in improvement in 58.5% of 147 women treated with DHEA 200 mg/day compared to 44.5% of control women, a difference significant at the 0.017 level. Of interest, levels of both testosterone and estradiol increased in the treatment group (143). A significant decrease of circulating IL-10 occurred in DHEA-treated patients (144).

In men with SLE, imbalances in estrogens and androgens could contribute to increased susceptibility to active disease. Estradiol levels have been reported to be increased (145 ,146), normal (147) or low (148) in male SLE patients. Males with lupus had elevated serum 16-hydroxyestrone (136 ,140) and estrone (148) concentrations. Some men with SLE have a state of functional hypoandrogenism with low levels of plasma testosterone (147 ,148) and elevated LH (149).

Prolactin

Effects of Prolactin on the Immune System

Prolactin, a peptide hormone secreted in the anterior pituitary, has the potential to stimulate the immune system and has been implicated as a factor that can activate SLE (150). There is increasing interest in the role of prolactin in SLE and other autoimmune diseases, and the relationship between prolactin and autoimmunity is addressed in several recent reviews (151 ,152 ,153). Prolactin is produced in sites outside the pituitary, including the brain and lymphocytes (154). Prolactin is a cytokine. It has comparable structural motifs, is synthesized in multiple sites including lymphocytes and has similar receptor structures and signal transduction pathways. Prolactin receptors are distributed throughout the immune system (155) and are included in a novel receptor family that includes receptors for IL-2β, IL-3, IL-4, and IL-6 (156). Prolactin can influence the immune system through the thymus (157), inducing IL-2 receptors on lymphocytes (158) and acting as a growth factor for lymphocytes.

Lymphocytes synthesize and release a biologically active form of prolactin (159), which is employed by the cells as an autocrine and paracrine growth factor. It is possible that treatment with corticosteroids affects lymphocyte production of prolactin. Dexamethasone reduces circulating prolactin concentrations and inhibits gene expression of both pituitary prolactin and lymphocyte prolactin (155).

In rodents, prolactin affects the immune system at almost every level and influences T cells, B cells, macrophages and natural killer cells (160 ,161). Prolactin is important in maintaining normal immune function and sustaining life. Rats that were deprived completely of prolactin by hypophysectomy and injections of antiprolactin antibody became anergic and anemic and died within 8 weeks. Replacement injections of either prolactin or growth hormone stimulated expression of the c-myc growth promoting gene and reversed involution of the spleen and thymus (162).

High levels of circulating PRL stimulate immune responses. Hyperprolactinemia that was created in mice by either implanting syngeneic pituitary glands or injecting exogenous prolactin increased primary humoral antibody responses (163), and low levels of prolactin in cysteamine-treated mice were associated with thymic atrophy and immune suppression (164).

Th-1 cytokines are involved in initiating autoimmunity and Th-2 cytokines contribute to production of antibodies by B cells. The transcription factor gene, interferon regulatory factor-1 (IRF-1), which is exquisitely sensitive to prolactin, is an important regulator of T cell and B cell differentiation and maturation. IRF-1 is required for Th1 immune responses. Prolactin, which stimulates IRF-1, has the potential to regulate expression of Th1 cytokines such as IFN-γ and IL-15 (161). The potential of IRF-1 to promote autoimmunity was demonstrated when type II collagen-induced arthritis was induced in mice that were either IRF-1 deficient (-/-) or IRF-1 positive (+/-). Disease was reduced in the IRF-1 -/- mice compared to the +/- mice (165).

Estrogen-Prolactin Interactions

Estrogen is a potent stimulus for production of pituitary prolactin in rodents and estrogen stimulates autoimmunity in the NZB/NZW lupus model. Female NZB/NZW mice treated with either ethinyl estradiol or estradiol-17β developed pituitary adenomas and serum prolactin levels that were up to 91 times greater than controls (26). This secondary elevation of

prolactin could have contributed to the apparent stimulation of autoimmune disease that was attributed previously to estrogen.

The estrogen-sensitive transgenic R2A-γ2b BALB/c mouse model of Bynoe et al. (70) developed lupus-like serology when it was oophorectomized to remove the major source of estrogen and treated with a prolactin dose that caused a twofold increase in circulating prolactin. The T1/T2 ratio was inverted, with more T2 than T1 cells. Bcl-2, was increased and all B cells increased. The autoimmune stimulating actions of prolactin were genetically determined and did not occur in R4A-γ2b C57Bl/6 mice. A second group of lupus-susceptible transgenic BALB/c mice was treated with both estrogen and bromocriptine in order to determine if estrogen could stimulate lupus in the presence of extremely low concentrations of prolactin. Bromocriptine did not block the appearance of DNA-reactive B cells, but these cells were functionally inactive. It therefore appeared that an adequate amount of circulating prolactin was required in the blood stream in order for estrogen to stimulate the lupus phenotype in a lupus-prone mouse with a permissive genetic background (166 ,167).

Effects of Prolactin in Murine Models of SLE

Hyperprolactinemia In NZB/NZW mice resulted in premature death from autoimmune renal disease. Female NZB/NZW mice were made chronically hyperprolactinemic by grafts of two syngeneic pituitary glands and developed premature glomerulonephritis and early mortality. In contrast, mice treated with the prolactin-lowering drug, bromocriptine, had delayed appearance of antibodies to dsDNA and significantly prolonged life spans (168). Neidhart (169) treated mature NZB/NZW females from the age of 36 weeks with a dose of bromocriptine (5 mg/kg/day) that suppressed serum prolactin to undetectable levels. After 12 weeks of treatment, autoantibodies were not suppressed in mice that received bromocriptine, but bromocriptine did suppress the occurrence of proteinuria. No mice treated with bromocriptine had histologic evidence of glomerulonephritis, but glomerulonephritis was found in 70% of the control animals.

The effects of very high levels of prolactin were examined in a group of NZB/NZW females that had 4 transplanted pituitary glands. Twelve weeks after the pituitary glands were implanted, 80% of recipient mice had antibodies to ds DNA and hypergammaglobulinemia (170). Male NZB/NZW mice, which develop an indolent form of SLE, responded to hyperprolactinemia with accelerated disease (171). Another study determined that naturally occurring hyperprolactinemia was detrimental in parous NZB/NZW mice after whelping and suckling 2 liters or after experiencing prolonged pseudopregnancy (172). Elbourne (173) found that mice with high circulating estrogen and high serum prolactin had accelerated albuminuria and premature appearance of antibodies to DNA (75% positive at 16 weeks of age). In contrast, autoimmune disease was retarded in females with high estrogen levels that were treated with bromocriptine. These mice had delayed appearance of albuminuria and antibodies to DNA (10% positive at 16 weeks of age).

Prolactin and Autoantibodies

Disease-associated autoantibodies have been detected in hyperprolactinemic individuals who did not have clinically apparent autoimmune diseases. Women with prolactinomas had antimicrosomal antibodies and antithyroglobulin, each occurring in 21% of subjects. Antithyroglobulin antibodies were found in 19% of hyperprolactinemic men (174). In another survey of 33 women, 82% of whom had pituitary adenomas, antibodies to at least one autoantigen were detected in 76% and 8 had seven or more different autoantibodies. The most common antibody targets were ssDNA and dsDNA, Sm pyruvate dehydrogenase, and SSA/Ro. The subjects did not have clinical evidence of autoimmune disease (175). Anticardiolipin antibodies were found in 22% of hyperprolactinemic women and men (176).

Hyperprolactinemia in SLE

Many surveys have shown that circulating prolactin is increased in SLE patients. Eight series, six of which included both men and women with SLE, reported serum prolactin concentrations above the norm in 20% to 40% of subjects (150). The analyses of McMurray and May (153) found that prolactin values were above normal in 7 of 10 groups of female lupus patients and 2 of 4 groups of males with lupus. Examination of 19 groups comprising a total of 1,149 patients revealed that 21% were hyperprolactinemic compared to 3% of healthy controls. The association between SLE and hyperprolactinemia was supported by the subsequent publication of three reports of elevated prolactin in lupus patients (177 ,178 ,179).

Prolactin concentrations above the norm were found in 12% of serum samples that were submitted to the Antinuclear Antibody Laboratory at the University of Missouri for routine diagnostic testing. High prolactin was most common in women 50 years of age or younger who were diagnosed with SLE and women older than age 50 years who had antibodies to both SSA/Ro and SSB/La. The expected incidence of hyperprolactinemia in normal populations was 1.3% (180).

Elevated prolactin concentrations did correlate positively with active SLE in 7 reports (179 ,181 ,182 ,183 ,184 ,185 ,186 ,187) and in analyses of five published studies (188), whereas six series showed no correlation (178 ,189 ,190 ,191 ,192 ,193). Jara-Quezada (194) reported five pregnant women with SLE whose hyperprolactinemia exceeded that expected during gestation, and the question was raised that excessive increases of prolactin were associated with disease flares during pregnancy. In a larger series, 68 lupus patients were randomized to receive either bromocriptine 5 mg/day for 14 days starting within 12 hours postpartum or no drug. The bromocriptine-treated subjects did not nurse their infants, but 21 of the 44 controls did nurse. Treated mothers had a significantly lower rate of relapses, a lower cumulative dose of prednisone and a lower cumulative dose of cyclophosphamide in 1 year of follow-up (195).

Causes of Hyperprolactinemia in SLE

Why is serum prolactin elevated in some patients with SLE? Hyperprolactinemia can result from stress (196), certain drugs, hypothyroidism or renal insufficiency (180). Prolactinomas have been reported in at least 43 individuals with lupus (197 ,198 ,199 ,200 ,201 ,202), and it has been proposed that the non cycling secretion of abnormally high concentrations of prolactin stimulates autoimmune responses. In six instances, lupus improved with bromocriptine therapy (197 ,198 ,199 ,200 ,202) and 11 patients had flares when bromocriptine was stopped (197 ,198 ,200 ,201). Lymphocytes from SLE patients actively secrete prolactin (203) and may serve as an extrapituitary source of measurable amounts of bioactive circulating 60 kDA prolactin (204). Antiprolactin antibodies have been identified in SLE patients with idiopathic hyperprolactinemia. It is possible that anti-prolactin activity interferes with attachment of prolactin to receptors so that a “false low” level of prolactin is presented to the pituitary and feedback mechanisms involved in regulation of prolactin secretion are disrupted (205). The association between inactive SLE and low levels of circulating homovanillic acid suggests that impaired dopamine turnover and altered dopaminergic tone results in hyperprolactinemia (206). Circulating cytokines that cross the blood–brain barrier in SLE may also stimulate the anterior pituitary to release excessive prolactin (160).

Prolactin-Suppressing Therapy in SLE

Suppression of circulating prolactin controls symptoms and prevents flares in SLE (207 ,208 ,209 ,210). Seven lupus patients with mild to moderately active disease, 6 of whom had normal prolactin concentrations before treatment, responded to bromocriptine. After 6 months, bromocriptine was stopped and 5 patients became hyperprolactinemic. All 7 patients had increased lupus disease activity in the 5 months after treatment was discontinued (207). The double-blind study of Alvarez-Nemegyei (208) showed the potential for daily treatment with a fixed dose of bromocriptine (2.5 mg/day) to reduce lupus flares. In a more recent study, patients with active but not life threatening SLE were randomized to receive either bromocriptine, in a dose designed to suppress serum prolactin to a concentration <1 ng/mL, or hydroxychloroquine 6 mg/kg. Treatment continued for 1 year. In 11 patients who received bromocriptine, the SLE Activity Measure (SLAM) decreased from (mean ± standard error of the mean) 14.0 ± 1.1 at entry to 7.5 ± 0.8 (p <0.05) after 1 year of treatment. In 13 SLE patients who received hydroxychloroquine, the SLAM score decreased from 13.4 ± 1.3 at entry to 9.0 ± 1.4 (p <0.001) posttreatment. Prednisone doses, the numbers of patients who started and stopped prednisone, and numbers of patients who left the study were similar in both treatment groups (209). Hrycek (210) demonstrated that the benefits of prolactin suppressive therapy were not confined to use of bromocriptine. Low-dose quinagolide was given to 20 SLE patients and 17 healthy individuals were the controls. The SLEDAI measure of disease activity decreased significantly during therapy, as did prolactin and IL-6. It was concluded that quinagolide treatment could have a role in managing SLE.

Chapter 17

Neuroendocrine Immune Interactions: Principles and Relevance to Systemic Lupus Erythematosus

Heather E. Gorby

Cherie Butts

Esther M. Sternberg

A large body of both animal and human studies provides evidence for communication between the immune system and the central nervous system (CNS), and for the importance of this communication in susceptibility to inflammatory disease (1). This chapter first outlines the general principles of this communication, its hormonal and neuronal components, and the physiologic role that it plays in autoimmune/inflammatory disease. Subsequent sections define the afferent and efferent limbs of this communication in more detail, the contribution of specific immune cells and their mechanism of action to initiate disease, and evidence from animal and human studies that these mechanisms are operative in systemic lupus erythematosus (SLE).

The immune system and CNS are the body's initial interface with the constant environmental perturbations that threaten homeostasis. These two systems are designed to recognize environmental perturbations and respond, to re-establish homeostasis. Each system recognizes different kinds of foreign stimuli—whether chemical, antigenic, or infectious in the case of the immune system or psychological and physical in the case of the CNS—but both use many of the same transducing systems to translate perturbing signals into stabilizing responses.

These transducing systems can be either hormonal or neuronal and can lead to regulation at the systemic, regional, and local levels. The cytokines of the immune system not only signal other immune cells but also stimulate the CNS through neuronal and hormonal routes. In turn, the hormones of the stress response and neurotransmitter and neuropeptide release from autonomic and peripheral nerves modulate immune and inflammatory responses (Fig 17-1) (1).

These multiple levels of communication between the immune system and CNS represent an important physiologic mechanism for modulating the intensity of immune and inflammatory responses and for controlling susceptibility and resistance to inflammatory disease. Interruptions of this communication, at any point and through any mechanism, lead to enhanced susceptibility to or severity of autoimmune/inflammatory disease. Conversely, reconstitution of the communication reduces autoimmune/inflammatory disease expression. Thus, the degree of inflammation in response to a foreign stimulus depends not only on the nature of the stimulus, its potency, dose, route, and duration of exposure, but also on the intensity of the modulating neuroendocrine and neuronal responses. This principle has important implications for understanding the effects of pharmacologic agents or stress on autoimmune/inflammatory disease. Drugs that are not primarily designed to affect autoimmune/inflammatory disease severity might alter disease course if they alter the communication between the immune system and the Similarly CNS, these principles provide a rationale and potential mechanism for previously anecdotal evidence that “stress” can affect or precipitate autoimmune/inflammatory disease, because hormones of the stress response that are activated by stress have a profound impact on immune responses.

Expression of Cytokines within the CNS

In addition to acting as signals between immune cells and from peripheral immune cells to the brain, cytokines are also expressed within the CNS (2). Such CNS cytokines are produced by neurons as well as by nonneuronal cells, including cerebral vascular endothelial cells, astrocytes, and glia. Oligodendrocytes, astrocytes, and microglia are the support cells of the CNS; neurons are the functional elements of the CNS, which transmit neuronal impulses and synthesize and secrete neurotransmitters and neuropeptides. Oligodendrocytes and astrocytes are derived from neural ectoderm, while microglia are CNS macrophages that are derived from bone marrow. The glial elements produce growth factors, including cytokines, which are important in neuronal cell growth, differentiation, survival, and cell death. Neuronal peptides, which are synthesized in neuronal cell bodies, are transported to neuronal axon terminals, where both peptides and neurotransmitters are stored in vesicles. Upon electrical stimulation and depolarization, these products are released into the synapse.

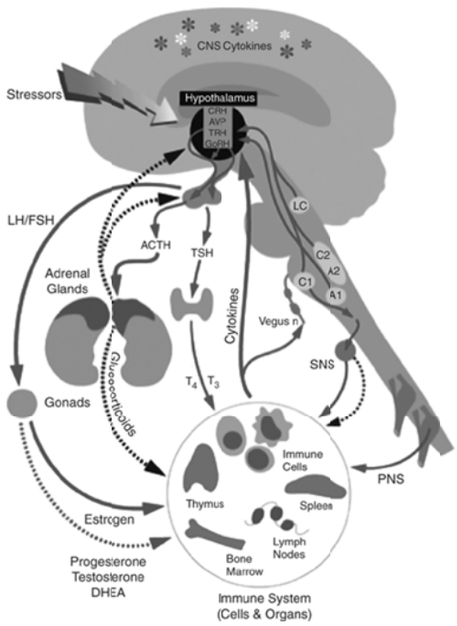

Figure 17-1. Schematic illustration of neural immune connections, including immune signaling of central nervous system via systemic routes and the vagus nerve (Vagus n.) and CNS regulation of immunity via the hypothalamic-pituitary-adrenal (HPA) axis, sympathetic nervous system (SNS) and parasympathetic nervous system and peripheral nervous system (PNS). Cytokine expression within the CNS is represented by asterisks within the brain. Dotted lines represent negative regulatory pathways, solid lines represent positive regulatory pathways. CRH, corticotrophin releasing hormone; AVP, arginine vasopressin; ACTH, adrenocorticotropin hormone, SNS, sympathetic nervous system; PNS peripheral nervous system; LC, locus ceruleus; A1, C1, A2, C2, brainstem adrenergic nuclei. (Reprinted with permission from Marques-Deak A, Cizza G, Sternberg E. Brain-immune interactions and disease susceptibility. *Mol Psychiatry* 2005;10(3):239–250.)

Cytokines can be expressed or induced in CNS resident cells (2 ,3 ,4) and can also be expressed in inflammatory cells invading inflamed cerebral tissue. This latter situation might be likely to occur in diseases such as SLE, in which CNS inflammation occurs. In addition to cytokines themselves, the entire molecular machinery that allows these molecules to be functional is also found within the brain. The best defined of these systems is the IL-1, system, in which all components have been identified in the brain. These include both types of IL-1, (i.e, IL-1α and IL-1ß), both types of IL-1, receptors (i.e, types I and II), the enzyme that activates IL-1ß (i.e, IL-1- converting enzyme), and the endogenous IL-1-receptor antagonist (i.e., IL-1Ra), a molecule that blocks the effects of IL-1.

CNS cytokines perform a different physiologic role than stimulation of the brain by cytokines produced by peripheral immune cells. Thus, central cytokines appear to play an integral role in modulating nerve cell death and survival (3 ,5 ,6), while peripheral cytokine signals to the CNS have a primarily neuroendocrine function. In vitro studies show that IL-1, is toxic to mature neurons but that it prevents the naturally occurring neuronal cell death that takes place in immature neurons (7). Both animal and human studies provide evidence that this growth-and-death effect of cytokines on neuronal tissue is relevant to whole organisms. Neurotoxicity results when cytokines are overexpressed in the brains of transgenic mice, in which cytokine genes are targeted to astroglial cells through a promoter that is specific for astroglia, glial fibrillary acidic protein (8). Such mice develop neuropathology and related neurologic manifestations in areas where cytokines are overexpressed. Thus, mice in which IL-6, is targeted to the CNS develop astrogliosis, inflammation, and angiogenesis in areas of the brain, including the cerebellum. Clinical manifestations in these mice include paralysis, seizures, and ataxia.

In human diseases in which inflammatory cells invade cerebral tissue, molecular techniques that allow visualization of gene expression in situ show overexpression of cytokines in regions of neurodegeneration. In brain tissue from patients who died with AIDS dementia, overexpression of certain cytokines, including IL-1, and TNF, has been shown to be concentrated in areas around invading giant cells (9). This suggests that some of the neurologic features of AIDS may result from the neurotoxicity of cytokines. These findings also suggest the possibility that other inflammatory diseases characterized by involvement CNS, such as SLE, some of the neuropathology and neurologic features might be caused by cytokine overexpression from inflammatory cells as well.

IL-1, also may act in concert with other neuropeptides to regulate neuronal cell death and survival. For example, CRH and IL-1, both are induced in neurons during ischemia. Neuronal damage is diminished by the administration of antiserum against CRH and is enhanced by the administration of IL-1Ra antisera (10). These data suggest that IL-1Ra and CRH both play reciprocal roles as neuroprotective and neurodegenerative agents during ischemia, respectively.

More recently it has also been shown that activated T cells contribute to neuronal repair after injury (11), indicating that immune factors are not only deleterious, but also play an important role in neuronal survival and regeneration. These findings have important implications for new avenues for therapy of spinal cord injury and prevention of paralysis.

Definition of the Neuroendocrine Stress Response

The central anatomic component of the neuroendocrine stress response, the hypothalamus, is located at the base of the brain adjacent to the third ventricle. It responds to a variety of incoming stimuli by synthesizing and secreting the neuropeptide corticotropin-releasing hormones (CRH) from

cells of the paraventricular nucleus (PVN) (12). In turn, CRH is secreted into the rich hypophyseal portal blood supply stimulates the anterior pituitary gland to secrete adrenocorticotropin (ACTH), which in turn stimulates the adrenal glands to synthesize and secrete corticosteroids (13).

Hypothalamic CRH secretion is held under tight regulatory control by several positive and negative neurotransmitter systems that result in regulation of glucocorticoid release from the adrenal glands. The noradrenergic, serotonergic, and dopaminergic systems upregulate CRH via α1-adrenergic receptors (14) 5-HT receptors (15), and dopamine (D1) receptors (16) respectively, while the opiates, gamma-aminobutyric acid (GABA)/benzodiazepine, and glucocorticoid feedback suppress hypothalamic CRH via opiate receptors (17), GABAergic receptors (18), and glucocorticoid receptors (19), respectively (20 ,21).

In addition to its neuroendocrine effects via the pituitary, CRH also acts centrally within the brain as a neuropeptide to induce a set of behaviors that are characterized by cautious avoidance, vigilance, enhanced attention, and suppression of vegetative functions such as feeding and reproduction (22 ,23). Together, this constellation of behaviors is known as the classic “fight or flight” response (14 ,24). Many of these effects are mediated through hypothalamic and extrahypothalamic CRH and interactions of these centers with other neurotransmitter systems, such as the brain stem-noradrenergic system and the sympathetic nervous system (25 ,26).

The hypothalamic CRH system communicates with noradrenergic pathways, which are also activated during the stress response, via anatomic connections between the hypothalamus and the noradrenergic centers in the brain stem (27). In turn, the brain stem-noradrenergic system sends signals to the periphery via the sympathetic nerves. Through such connections, the physiologic components of the stress response, such as increased heart rate, muscle tone, and sweating, are coordinated with behavioral responses to form the generalized stress response. Many studies indicate that the modulation of immune responses by both the sympathetic and the neuroendocrine systems are an important physiologic component of the stress response (28 ,29 ,30 ,31 ,32 ,33).

Afferent Limb Stimulation of the CNS by Signals from the Immune System

Hormonal Signaling of the Brain by Immune Signals: Routes of Communication

The first suggestion that immune signals could stimulate the brain came from animal experiments (34), which showed that after intraperitoneal injection of bacterial lipopolysaccharide, IL-1, could be detected in brain tissue. The next series of experiments (35 ,36 ,37 ,38) that further delineated this signaling between the immune system and the brain showed that IL-1, itself could directly activate the hypothalamic-pituitary-adrenal (HPA) axis cascade of hormones by direct stimulation of the hypothalamus and pituitary. IL-1, directly stimulates secretion of ACTH from cultured pituitary cells, induces CRH mRNA expression in the paraventricular nucleus of the hypothalamus, and induces CRH secretions from explanted hypothalamic tissue in culture (39). Subsequent studies showed that many cytokines stimulate the axis HPA, including IL-6, tumor necrosis factor (TNF), IL-2, and interferon (IFN)-α (40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48).

Cytokines from the peripheral immune system can stimulate the brain, through several routes (49 ,50 ,51 ,52). Cytokines may be actively carried from the blood to the brain across the blood–brain barrier, or they also may cross passively at certain anatomically “leaky” points in the blood–brain barrier, such as the organum vasculosum lamina terminalis or the median eminence. This route may be more prevalent during inflammation or illness, when the blood-brain barrier is more permeable (53). Such conditions are particularly likely to occur in an illness such as SLE, in which inflammation may involve the CNS.

It is not necessary, however, for cytokines to cross into the brain to exert their effects. Cytokines can be expressed in the endothelial cells lining cerebral blood vessels (54) and can stimulate second-messenger release (55) in surrounding brain tissue, thus stimulating neurons in these areas. Thus some cytokine effects, such as fever, are indirectly mediated through second messengers, such as prostaglandins (56). The fact that prostaglandin antagonists such as acetyl salicylic acid and other nonsteroidal anti-inflammatory agents block these effects of IL-1, provides evidence for the importance of this mechanism.

Finally, peripheral cytokines can signal the brain via direct neuronal routes. Intraperitoneal cytokines can activate specific CNS regions via the vagus nerve (51). The brain stem nucleus of the tractus solitarius (NTS) is the first brain region that exhibits electrical and biochemical activity after intraperitoneal injection of IL-1. Cutting the vagus nerve prevents this activity. Thus, signaling via the vagus nerve constitutes the most rapid mechanism by which cytokines activate the brain and may be an important mechanism for IL-1-induced increases in plasma corticosteroids and hypothalamic norepinephrine depletion (57). Intravenous IL-1β also has been shown to activate efferent activity in branches of the vagal nerve that innervate the thymus (58). Indeed, activation of the vagus nerve by pathogen products and cytokines and the subsequent release of ACh that suppresses inflammation is an important route of CNS control of inflammation, that has been termed the “vagal inflammatory reflex” (31).

Behavioral Effects of Cytokines on the CNS

One characteristic set of behaviors induced by cytokines is termed sickness behavior (59). This is characterized by loss of appetite, decreased mobility, loss of libido, withdrawal from social interaction, depressed mood, increased somnolence, and fever. Some of these behavioral and functional effects (i.e., fever) are mediated secondarily through prostaglandins, and others are initially activated via the vagus nerve. The frequent occurrence of depression and suicidality in patients treated with cytokines (e.g., IFN or IL-6) for bone marrow suppression has led to the hypothesis that

some forms of depression may be associated with imbalances in cytokines CNS, Indeed, antidepressant pre-treatment of patients who are about to receive cytokine therapy prevents depression and suicidality in these subjects (60). Although not studied in specifically SLE, these findings suggest that increases in CNS cytokines could contribute to depressive symptomatology in SLE.

Modulation of Immune and Inflammatory Responses by the Neuroendocrine System

Glucocorticoid Modulation of the Immune System

If the stimulation of the CNS by peripheral cytokines is viewed as the afferent limb of the neuro-immune communication, the final end point of the efferent limb of this communication is the glucocorticoid effect on the immune response.

Glucocorticoids modulate immune cell function by acting through glucocorticoid receptors present in immune cells. The molecular structure and mechanism of action of glucocorticoid receptors is described below. The overall functional effect of glucocorticoids on the immune response depends on the preparation, dose (whether pharmacologic or physiologic), and temporal sequence of glucocorticoid exposure in relation to antigenic or pro-inflammatory challenge.

Glucocorticoids have profound effects on the immune/inflammatory response at the molecular, cellular, and whole-organ level. Exposure to stress levels of glucocorticoids results in rapid involution of the thymus, as a result of glucocorticoid-induced thymocyte apoptosis (i.e., programmed cell death). Glucocorticoids also regulate the immune response by inducing apoptosis in proliferating lymphocytes (61). There is evidence to suggest that such glucocorticoid-regulated apoptosis could take place within the thymus through induction of an intrathymic glucocorticoid system, because the enzymatic machinery for glucocorticoid synthesis is present within the thymus (62).

Glucocorticoids also induce redistribution of circulating white blood cells, with neutrophilic leukocytosis, eosinopenia, monocytopenia, and altered ratios of T-lymphocyte subtypes, resulting in decreased peripheral blood CD4, and increased CD8, cells. At the same time that this peripheral redistribution occurs, there is decreased infiltration of neutrophils and monocytes into tissues.

Molecular Mechanism of Glucocorticoid Action

Glucocorticoid receptors are members of a hormone receptor superfamily that are structurally related, including the glucocorticoid receptor (binds corticosterone and dexamethasone), the mineralocorticoid receptor (binds corticosterone and aldosterone), androgen receptor (binds testosterone), estrogen receptor (binds estradiol), progesterone receptor (binds progestins), thyroid hormone receptor (binds thyroxine), and retinoic acid receptors (binds all-trans retinoic acid). All members of the superfamily act by binding to a soluble cytosolic receptor made up of three functional regions: (1) a C-terminal hormone-binding region, (2) a DNA-binding region, and (3) an N-terminal immunogenic region that is involved in transactivation (61 ,63). The unbound receptor located in the cytosol, is folded and inactive, bound to a 90kDa heat-shock protein (64) (hsp90) and immunophilins (Fig 17-2). When the hormonal ligand binds to the receptor, hsp90, is displaced, resulting in a conformational change in the receptor that allows the active ligand-receptor complex to displace to the nucleus and bind to hormone receptor-binding elements (HREs) on DNA either as a homodimer or heterodimer. The hormone receptor complex then acts as a transcription factor, either suppressing or stimulating DNA gene transcription. In addition, the glucocorticoid receptor interacts with over 200, other conuclear factors including NF-κB and AP-1, (65 ,66), inhibiting the stimulatory effects of these transcription factors. The recruitment of either coactivators or corepressor complexes is involved in transcriptional regulation and can determine whether or not a gene is transcribed (67). Other accessory proteins, such as HDAC6, also contribute to transcriptional regulation (68).

The glucocorticoid receptor (GR) binds corticosterone with a lower affinity than the mineralocorticoid receptor (MR). Therefore, GR tends to respond to higher levels of glucocorticoids secreted during stress (i.e., stress levels), while the MR responds to basal or nonstress levels (69). While GRs generally bind to glucocorticoid receptor DNA-binding elements (70) as homodimers, it is also possible for GRs and MRs to form heterodimers (71 ,72). These different mechanisms of binding to DNA response elements confer additional specificity of action to the glucocorticoid and mineralocorticoid receptors.

Further specificity of action of these two receptor types is conferred by tissue distribution of the receptors. The primary glucocorticoid receptor in immune cells is GR, which is consistent with the physiologic role of glucocorticoid regulation of the immune system by stress levels of these hormones (1 ,73 ,74). An additional level of specificity is conferred by the tissue distribution of the corticosterone-metabolizing enzyme 11ß-hydroxysteroid, which metabolizes corticosterone but not aldosterone. Thus, where this enzyme is present (e.g., kidney), the primary ligand that is available for binding to the MR is aldosterone rather than corticosterone (70). Where the enzyme is not present (e.g., brain), the primary ligand for the MR is corticosterone. The MR in the brain plays a role in regulation of basal function HPA, such as circadian rhythm.

Effects of Glucocorticoids on Immune Cells

Glucocorticoids have effects on a variety of immune cells involved in both innate and adaptive immunity, B and lymphocytes T, including natural killer (NK) cells, and dendritic cells (DC). Glucocorticoids suppress NK cell function both in vitro and in vivo in animals as well as humans. Mice treated with glucocorticoids show a reduction in the number of splenic cells NK, and these NK cells have reduced cytolytic activity. In a study of children with asthma, glucocorticoids

were shown to decrease the expression of intracellular adhesion molecule-1, (ICAM-1) and L-selectin, suggesting an inhibition in the ability of these cells to migrate to inflammatory sites (75). Glucocorticoids have also been shown to affect development and function of dendritic cells both in vitro and in vivo. Glucocorticoids, reduce DC production of the TH1, cytokine IL-12, downregulate expression of costimulatory molecules, and strongly reduce allostimulatory capacity in vitro. However, the suppressive effect was not observed with dendritic cells activated with lipopolysaccharide (LPS), indicating that stage of dendritic cell maturation influences the effect of glucocorticoids (76).

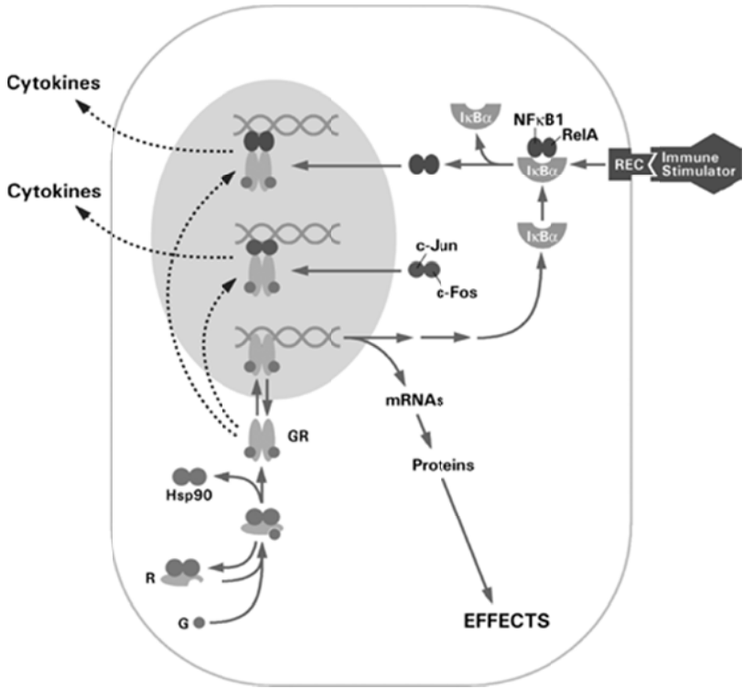

Figure 17-2. Schematic diagram of the molecular mechanism of glucocorticoid receptor regulation of cytokine production. Glucocorticoid hormone (G) binds to the cytosolic glucocorticoid receptor (GR), displacing heat shock protein 90, (HSP90). This allows dimerization, movement into the nucleus and binding of the G-GR complex to DNA, with resultant transcription and translation of proteins, including IkB IkB indirectly suppresses cytokine production by sequestration of NFkB In addition, the G-GR complex can interact with NFkB directly to suppress cytokine production.

Glucocorticoids have been also shown to suppress not only differentiation and maturation of cells T, but also modulate the function of mature effector T cell subtypes, such as cytolytic and helper cells T, In functional assays, a large body of data shows that glucocorticoids suppress mitogen- and antigen-stimulated T- cell proliferation (77). In contrast, some studies indicate that corticosterone in rats can enhance lymphocyte proliferation depending on the conditions of culture (78). While the physiologic relevance of these in vitro studies is not known, this dual suppressing or enhancing effect of glucocorticoids on lymphocyte proliferation underlies their potential physiologic role as immunomodulators rather than pure immunosuppressors.

This modulation is thought to be most critical in T helper cell populations, which are skewed from a TH1, to a TH2, response in the presence of glucocorticoids. This skewing is evidenced by the inhibition of production of TNF-α, IL-2, IL-6, IL-12, and IFN-γ and increase in production of IL-10, IL-4, and IL-13. The effects of glucocorticoids on cytotoxic T cells could be an indirect result of their effect on T helper cells, which do not stimulate cytotoxic T cells in a TH2-type cytokine environment. The suppressive effects of glucocorticoids on B cell proliferation are variable, depending on the stimulus to proliferation and the dose of glucocorticoids used. In general B cell proliferation is suppressed less consistently than T cell proliferation. At the same time, glucocorticoids consistently enhance production of all classes of immunoglobulins.

Thus, while the overall effects of glucocorticoids on immune/inflammatory responses at the cellular level are immunosuppressive, this effect is attained through suppression of many stimulatory components of the immune cascade

and stimulation of some immunosuppressive or anti-inflammatory elements. The relatively greater sensitivity to glucocorticoid suppression of components of cellular versus humoral immunity tends to shift the immune response from a cellular to a humoral pattern (1). Glucocorticoids have also been shown to upregulate IL-6, receptor expression. This would further enhance the action of IL-6, which is a key B cell growth factor (79). In a disease such as SLE, which is characterized by excess or inappropriate antibody production, it is important to delineate whether glucocorticoids may contribute to or exacerbate this shift. Indeed, dexamethasone has been shown to stimulate IL-6, mRNA production in vitro in SLE lymphocytes (80).

Glucocorticoids also downregulate the expression of class II major histocompatibility complex (MHC) antigen expression, thus reducing recognition and binding of antigen. They also inhibit production of pro-inflammatory molecules and mediators (1 ,81), including complement components, arachidonic acid products, histamine, bradykinins, and cytokines. At the same time that many of these immunostimulatory/pro-inflammatory molecules are suppressed, their endogenous suppressors may be enhanced by glucocorticoids. An example of this balance occurs in the complement system, where glucocorticoids suppress C3, while inducing the complement-suppressor factor H Glucocorticoids suppress the production of most cytokines (1 ,82), including IL-1, IL-6, IL-2, IFN-γ, TNF, IL-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Their effects on IL-4, are variable, and in some cases, IL-4, production increases as IL-2, production is suppressed. This pattern of a shift from IL-2, to IL-4, production is consistent with the humoral-, antibody-, and B cell-supportive effects of glucocorticoids and their tendency to shift the immune response from a TH1, to a TH2, pattern (83 ,84). Additionally, while glucocorticoids suppress IL-1, production, they also enhance the expression of IL-1ß receptor (85). Physiologic doses and preparations of glucocorticoids also stimulate delayed-type hypersensitivity (DTH) (74) and induce anti-inflammatory cytokines IL-4, and IL-10.

Taken together these findings indicate that in addition to their suppressive role, glucocorticoids can also stimulate some aspects of the immune or inflammatory response depending on the dose and timing of exposure. Glucocorticoids in this sense may be viewed as physiologic modulators of the immune response (86).

Sympathetic Nervous System Effects on Inflammation and the Immune System

The sympathetic nervous system serves an important role in regional regulation of immunity (87 ,88). Many immune organs, including the spleen, thymus, and lymph nodes, are richly innervated by sympathetic nerves (89). A number of studies, including denervation and ablation studies, indicate that these anatomical connections as well as the neurotransmitters of the sympathetic nervous system play an important physiologic role in inflammatory responses (87). The effects of the sympathetic nervous system are mediated by norepinephrine (NE) released from sympathetic nerve fibers and epinephrine (E) released from the adrenal medulla. Both NE and E exert their actions through adrenergic receptor. The ß2-adrenergic receptor (ß2AR), a G-protein coupled receptor, is the main receptor found on lymphocytes (90). Adrenergic influences on immune cells, including T and B-lymphocytes potently inhibit TH1, cytokines and thereby suppress cell-mediated immune responses. NE and epinephrine also stimulate production of TH2, cytokines, such as IL-10, and could contribute to SLE disease activity (91).

Evidence that the sympathetic nervous system affects the exudation component of peripheral inflammation is provided by sympathetic ablation studies using 6-OH dopamine (6-OHDA) (92) or sympathetic ganglionic blockers such as chlorisondamine (93), or noradrenergic antagonists and agonists (94). Noradrenergic denervation studies have shown differential effects on inflammation depending on the location of denervation. Thus, denervation of the noradrenergic fibers of lymph nodes (95) is associated with exacerbation of inflammation, while systemic sympathectomy or denervation of joints is associated with decreased severity of inflammation (96 ,97). Treatment of neonatal rats with 6-OHDA, which interrupts both central and peripheral systems NA, is associated with exacerbation of experimental allergic encephalomyelitis (EAE) (98). Pharmacologic studies show decreased inflammation in experimental arthritis with beta-blockade (99) and decreased severity of EAE with ß-adrenergic agonists (98).

Peripheral Nervous System Effects on Inflammation and the Immune System

Immune organs and local sites of inflammation are innervated by peripheral nerves that release neuropeptides, such as substance P (SP), that play a role in peripheral inflammation. SP also plays a role in the severity of arthritis (96 ,100) and in the cellular component of inflammation (101). Substance P, which probably is released in retrograde fashion from sensory nerve endings at sites of inflammation, acts as a chemoattractant and stimulator of cellular proliferation and cytokine production. It also plays a role in the early arteriolar changes associated with inflammation (102). Both denervation of SP nerve fivers with local capsaicin denervation of lymph nodes and systemic capsaicin treatment are associated with diminished peripheral inflammation (95 ,96 ,100). Other peripheral neuropeptides that play a role in inflammation include VIP and CGRP, which generally suppress inflammatory responses (103 ,104 ,105 ,106 ,107).

Parasympathetic Nervous System and Immunity

The parasympathetic nervous system both sends immune signals to the CNS through the afferent fibers of the vagus nerve, and also regionally modulates immune responses

through efferent fibers of the vagus nerve. Ganglia outside the spinal cord receive projections from the brainstem, and further innervate visceral organs such as the heart, lungs, gut, liver, and spleen. IL-1, receptors on paraganglia cells located adjacent to parasympathetic ganglia bind IL-1, and activate the vagus nerve, thus signaling the presence of peripheral inflammation to the brain (108). Inflammation in the gut or peritoneum leads to the “inflammatory reflex” which results in the release of acetylcholine from efferent vagus nerve fibers and negative feedback control of inflammation (31). Cutting the vagus nerve prevents immune signaling to the brain and therefore prevents further activation of cholinergic brainstem regions (31 ,108 ,109). Acetylcholine is the primary parasympathetic neurotransmitter, which binds to two receptor subtypes, nicotinic and muscarinic cholinergic receptors, each of which consist of several different subunits which heterodimerize to provide cell and tissue specificity of cholinergic effects. Immune cells contain both of these receptors, but the α7, subunit of the nicotinic receptors specifically mediate cholinergic anti-inflammatory effects in macrophages.

Estrogens and Immunity

Estrogen has a profound influence on immune responses. The two forms of the estrogen receptor, ERα and ERβ (110) are both found in immune cells, including lymphocytes, monocytes, and macrophages (111). Females of all mammalian species have an increased incidence of autoimmune/inflammatory disease compared to males, and the presence of estrogen increases the severity of autoimmune disease. Surgical removal of the ovaries (oophorectomy) in addition to testosterone treatment reduces this tendency in females while estrogen replacement restores it. However, castration (orchidectomy) and estrogen replacement increases autoimmune/inflammatory disease susceptibility in males to levels similar to females. Estrogen has many direct effects in immune cells, which are dose dependent. Estrogen tends to directly enhance immune responses, but may also suppress through indirect effects on the HPA axis (112 ,113).

Prolactin and Immunity

Prolactin is another important endocrine modulator of the immune system. Prolactin, a 200, amino acid peptide hormone, is produced by cells of the anterior pituitary, and other cells including immune cells. Prolactin binds to specific membrane receptors that are members of the cytokine receptor superfamily. Prolactin receptors are expressed on many cells of the immune system such as T cells cells B, monocytes, macrophages, cells NK, and neutrophils. High concentrations of prolactin, similar to levels found during pregnancy, increase the production of pro-inflammatory cytokines IL-12, and TNF in whole blood cultures after LPS exposure in vitro (114).

Physiologic Role of Neural-Immune Communications and Dysregulations in Autoimmune Disease

A multilevel infrastructure exists to allow anatomic, molecular, and functional communications between the immune and nervous systems (115 ,116 ,117). Animal studies in which these communications are interrupted on a genetic, pharmacologic, or surgical basis provide evidence that this interaction plays an important role in regulating susceptibility to and severity of inflammatory and autoimmune diseases. Human studies also provide evidence that dysregulations of such neuroimmune interactions are associated with autoimmune/inflammatory disease, including Sjogren syndrome, SLE, RA, asthma, dermatitis, and irritable bowel syndrome (118 ,119). Some genetic inbred animal strains show a simple association between a relatively blunted HPA axis and autoimmune disease. The obese-strain chicken, which develops spontaneous thyroiditis, and its thyroiditis-resistant counterpart also exhibit relative HPA-axis hypo- and hyper-responsiveness (116). Some, but not all, lupus-prone mouse strains (MRL but not NZB) have a relatively blunted HPA-axis response (120). The concept that an intact HPA axis response protects against inflammatory/autoimmune disease has been shown through intervention studies in disease models including streptococcal cell wall-induced arthritis (121), EAE induced by myelin basic protein (122), and the lethal effects of salmonella (123). Interruptions of the HPA axis in these models surgically, through adrenalectomy or hypophysectomy (i.e., pituitary excision), or pharmacologically, through the glucocorticoid-receptor antagonist RU486, results in enhanced inflammatory disease mortality. Conversely, reconstitution of the axis HPA, surgically or pharmacologically reverses inflammatory disease susceptibility in inflammation-susceptible strains (121 ,122 ,124).

Glucocorticoid Resistance

Impaired glucocorticoid control of inflammation may also result from a lack of responsiveness in cells and tissues that normally respond to circulating glucocorticoids because of impaired receptor function. Glucocorticoid resistance may result from polymorphisms of the receptor or associated cofactors that are necessary for it to function or overexpression of the glucocorticoid receptor-β (GR-β), an inactive form of the GR that binds hormone but does not bind to DNA (1 ,125). Chronic inflammation can itself result in enhanced expression of the GR-β and associated glucocorticoid resistance. Glucocorticoid resistance has been associated with several autoimmune, inflammatory and allergic diseases (see 119).

Together, these studies underline the biologic principle that neuroendocrine responsiveness plays an important modulating role in susceptibility and resistance to autoimmune/inflammatory disease. When the feedback suppression of the immune system by the anti-inflammatory/immunosuppressive effects of the glucocorticoids is interrupted, either by blocking the production of glucocorticoids or by preventing their action

with receptor antagonists, or in the presence of impaired receptor function, enhanced inflammatory susceptibility results. It is likely that in human autoimmune/inflammatory diseases, the HPA axis could be impaired or interrupted at different points in different diseases, or in the same disease in different individuals. Further, neuroendocrine responsiveness varies with time on a circadian basis, in females in relation to the menstrual cycle, and throughout life with aging. Thus, the degree to which neuroendocrine responses modulate inflammatory disease also may vary over time, and this may account for some of the temporal waxing and waning of these illnesses. Understanding the degree to which such hormonal and neuronal inputs control inflammatory disease will provide new insights for future therapeutic approaches in these diseases.

Neuroendocrine Mechanisms in SLE

Neuroendocrine immune interactions could play a role in the pathogenesis of SLE in several ways. As in susceptibility or resistance to other inflammatory illnesses, premorbid neuroendocrine responsiveness might predispose to an increased susceptibility to the development of SLE Once develops SLE, and if the CNS is involved, the local effects of cytokines on neuronal tissue could contribute to some of the specific neuropathologic or neuropsychiatric features of SLE At the effector endpoint of the axis HPA, differences in glucocorticoid receptor number or sensitivity could play a role in the pathogenesis of SLE as well as in clinical response to treatment with steroids. In addition, regardless of the premorbid reactivity of the axis HPA, chronic inflammation itself could alter HPA-axis responses. Studies supporting these possibilities in animal models and in humans, suggest that a variety of neuroimmune mechanisms may be relevant to many features in the pathogenesis of SLE.

CNS Cytokines in Animal Models of SLE

The classic animal models for SLE are (NZB/NZW) F1, mice and mice MRL, These strains of mice develop spontaneous autoimmune disease with many of the characteristic features that are seen in human SLE, including renal disease, vasculitis, and antinuclear antibody production. Neuroendocrine responses and CNS expression of cytokine components have been examined in both these strains. Studies indicate that NZB mice exhibit a profound deficiency of IL-1, receptor expression in the dentate gyrus of the hippocampus (10% of controls) (126), while (NZB/NZW) F1, mice show a 50% deficit and MRL mice show no difference in CNS expression of this receptor as compared with control strains. Although this deficiency is present before the mice develop clinical disease, it is not clear what role it plays in pathogenesis of the syndrome. Differences in expression of the receptor for this cytokine in two strains that both develop lupus-like disease could be interpreted as indicating that the defect is unrelated to the pathogenesis of the disease, or that different molecular mechanisms could lead to the same final disease outcome. Further studies in this area are required to determine which interpretation is correct.

CNS Cytokines in Human SLE

Two clinical aspects of lupus CNS, vasculitis and neuropsychiatric manifestations, could be related in part to the presence of cytokines in the CNS that are released from inflammatory cells. Elevated cytokines have been detected in the cerebrospinal fluid (CSF) of patients with lupus CNS, In one study, IL-6, was increased during clinical exacerbations of CNS lupus and fell to control levels in association with clinical improvements after treatment with methylprednisolone (127). Clinical symptoms in these patients included seizures, organic brain syndrome, nonorganic psychosis, chorea, and focal lesions. In a similar study of lupus psychosis, CSF IFN-α (128) increased and returned to baseline, corresponding with clinical exacerbations and remissions. In both studies, the CSF cytokines were higher than plasma levels, suggesting a CNS source for the cytokines. Further, cytokines were not elevated in patients with seizures from other causes. Although the elevations of CSF cytokines could be viewed as simply a marker for the presence of inflammation, it is noteworthy that in animal models, such as transgenic mice in which IL-6, is specifically overexpressed in brain, clinical features such as focal lesions and seizures are also seen (129 ,130). These transgenic mice also exhibit a reduction in neurogenesis in the dentate gyrus region of the hippocampus, a brain region known to play an important role in learning and memory (131). This suggests that the elevations in IL-6, that are measured in human SLE CSF could play a pathogenic role in development of some of the neuropathologic and clinical features of lupus CNS.

HPA Axis Responsiveness in SLE

Several studies have shown a blunted HPA axis response to a variety of stimuli in human autoimmune/inflammatory and allergic diseases including SLE (Table 17-1). In these

studies, basal cortisol responses do not differ between patients and controls, however patients showed significantly lower cortisol rises in response to stimuli than did controls. Specifically SLE patients showed lower cortisol responses to ovine CRH, compared to controls (132). Studies of HPA axis responsiveness in mouse models of SLE have shown relatively blunted corticosterone responses in MRL, but not NZB/NZW F, mice (133).

Table 17-1: Inflammatory/Autoimmune Diseases Correlated with a Dysfunctional HPA Axis in Humans

Inflammatory/Autoimmune Disease	Reference
Rheumatoid arthritis	(162,163)
SLE	(132)
Sjösgren syndrome	(164)
Dermatitis	(165)
Multiple sclerosis	(152,166)

Evidence for Glucocorticoid Resistance in SLE

In contrast to patients with other autoimmune diseases such as rheumatoid arthritis, patients with SLE often require large doses of glucocorticoids before a therapeutic effect is seen. Furthermore, even during treatment with large doses of steroids, patients with SLE are less likely to develop Cushingoid features. This anecdotal clinical evidence suggests that patients with SLE may display some degree of glucocorticoid tissue resistance (134). The contribution of the glucocorticoid receptor to potential glucocorticoid resistance has been explored in some studies examining the binding number and affinity characteristics of the GR in lupus. Patients who exhibit hormone resistance have been found to have abnormally high levels of GRß (135) or defective, mutated GR (136 ,137). A decrease in GR number in mononuclear cells was also found in lupus patients (136). Patients also had a higher percentage of lymphocytes with high P-glycoprotein activity, a molecule responsible for transporting steroids outside the cell inhibiting their effects (138).

In a study of patients with SLE who had not received steroid treatment within the previous 6, months, glucocorticoid receptor numbers in peripheral blood mononuclear cells were significantly higher than in controls (139). There was no correlation with disease activity, nor was there a difference in affinity of the GR in these patients. In another study, no difference in GR number was found between patients and controls, however, patients who were on low-dose glucocorticoid treatment were not excluded from this study (140). Because exogenous treatment with glucocorticoids suppresses the responsiveness of the axis HPA, the GR numbers measured in glucocorticoid-treated patients may reflect treatment rather than intrinsic factors. Thus, the discrepancy between these studies could be related to differences in exogenous glucocorticoid exposure in these patients, underscoring the inherent difficulty in studying GR binding and number in such patients.

Prolactin and SLE

Hyperprolactinemia is found in 20% of patients with SLE (141 ,142 ,143). These studies suggest that reducing serum prolactin levels may ameliorate disease activity. Inhibiting prolactin secretion with the drug bromocriptine, a dopamine receptor agonist that inhibits prolactin secretion, results in clinical improvement in lupus patients (144). In vitro prolactin also increased secretion of IFN and IL-2, by peripheral mononuclear cells from SLE patients (145), which suggests that elevated levels of prolactin may be pro-inflammatory. Conventional immunosuppressive therapy decreases prolactin levels, and this decrease correlates with a reduction in SLE activity (146). This suggests that prolactin plays an important role in the pathogenesis of SLE, and that therapeutic interventions targeted at modulating prolactin may provide important new therapeutic approaches for management of SLE (see Section VI).

Effects of Stress in SLE

Until recently, studies of the effects of stress on physical illness, including autoimmune diseases such as SLE, were viewed with skepticism. This related in part to the inherent difficulty in accurately defining and quantifying stressful stimuli and response outcomes. However, recent advances in defining and quantifying not only stressors but also neuro-endocrine transducing signals, disease outcomes, and molecular components of the immune/inflammatory response in animals and humans have allowed more accurate assessment of the effects of stress on autoimmune/inflammatory disease and of the mechanisms by which such effects are transduced. While most such studies have been carried out in models of infectious disease (147 ,148), it is clear from such studies that activation of both the HPA axis and the sympathetic system play an important role in modulating immunity during stress. The evidence from animal models that these systems interact provides direction for the future design of human studies to substantiate old or anecdotal claims that stress is associated with exacerbation or precipitation of disease in SLE.

A number of recent studies have suggested that emotional stress might trigger the onset of SLE or worsen its course, and some studies have shown an association between flares of disease and emotional stress or number and severity of daily stressors (149 ,150 ,151).

Chronic inflammation itself can be viewed as a chronic stressor that can alter HPA-axis responses. The effects of chronic inflammation include hypercortisolism and a shift from primarily CRH control of the stress response to primarily vasopressin (AVP) control (152 ,153). The latter shift results from a switch from CRH to AVP expression in hypothalamic neurons (154) and occurs in response to cytokines such as IL-1(155). Studies in another autoimmune disease, multiple sclerosis (MS), have shown both a shift towards an AVP driven stress response (152) as well as glucocorticoid resistance in PBMC in some subsets of multiple sclerosis (MS) patients (relapsing remitting) (156), indicating that an impaired HPA and glucocorticoid responses and glucocorticoid resistance may contribute to its pathogenesis in different subpopulations of patients.

Sympathetic, Parasympathetic, Peripheral Nervous Systems in SLE

In addition to the changes in endocrine function in SLE, other neuronal regulatory systems such as the sympathetic, parasympathetic, and peripheral nervous systems may also

be dysregulated in SLE NE and epinephrine are dysregulated in SLE and may contribute to disease activity (157). Sympathetic nervous system outflow is increased in patients SLE, as demonstrated by increased levels of serum NPY (158). NPY has also been shown to be increased in a mouse model of SLE (159 ,160). The peripheral nervous system can also contribute to disease development in SLE but is considered clinically to be less frequently affected. Peripheral neuropeptides such as VIP, SP, CGRP are increased in SLE (160 ,161). Further investigation of the connection between these systems and SLE is needed.

Summary

It is apparent that neuro-endocrine-immune interactions play an important role in the pathogenesis of many features of SLE at multiple levels, within and outside the CNS, and at the molecular and whole-organ level. This chapter has mainly focused on two aspects of neuro-endocrine interactions with the immune system, HPA and sympathetic immune interactions, as well as on cytokines within the CNS Many additional hormonal systems, briefly reviewed here, also play an important role in modulating immune function, including the female sex hormones estrogen and progesterone as well as prolactin. All of these hormones play an important role in the pathogenesis of SLE and are reviewed in more depth elsewhere in this text.

Acknowledgments

The authors would like to thank Dr. Cherie Butts for her help in the preparation of the manuscript.

Chapter 18
Animal Models of Systemic Lupus Erythematosus

Bevra Hannahs Hahn

Ram Raj Singh

Systemic lupus erythematosus (SLE) is the most heterogeneous autoimmune disease that affects virtually any organ. This heterogeneity in disease expression has posed difficulty in formulating its mechanistic investigations. Consequently, many investigators have turned toward inbred animal models, which spontaneously develop a homogeneous disease recapitulating some of the serological and histopathological features of SLE. Examples of such models include the New Zealand (NZ) strains, Murphy's Recombinant Large (MRL)/MpJ, C57BL/6 × satin beige [SB] (BXSB), Palmerston North (PN), and C57BL/6 × DBA2 (BXD2) strains.

SLE is characterized by the presence of autoantibodies against a variety of ubiquitous self antigens, deposition of autoantibodies and immune complexes in tissues with development of local inflammation, and finally tissue fibrosis and damage in multiple organs (1). Deliberate attempts or serendipitous discoveries have led to identification of animal models that may recapitulate these various steps or stages and individual disease manifestations. For example, BALB/c mice injected with a DNA surrogate peptide develop extensive immune deposition but have no renal inflammation (2), whereas BALB/c mice injected with hydrocarbon oil pristane generally develop immune deposition and a limited kidney inflammation (focal glomerulonephritis) but no kidney failure (3 ,4). In contrast, genetically lupus-prone mouse strains spontaneously develop immune deposition-mediated renal disease which is lethal, with strain dependent variation in disease patterns and severity (5). Numerous single gene knock-out and transgenic strains have also developed autoimmune features (6 ,7) that recapitulate some aspects or stages of SLE disease.

Consistent disease pattern in individual mouse strains and relative ease in testing renal disease have driven extensive investigations into lupus nephritis. Model investigations into lupus involvement of other organs, however, have been limited (Table 18-1), perhaps because of variability in disease expression or lack of appropriate tools to investigate these manifestations. For example, although some forms of neuropsychiatric lupus develop in many lupus susceptible strains, animal investigations have been limited. Similarly, although a few animal strains develop coronary occlusions and myocardial infarction as a result of immune complex deposition, it is unclear whether a similar mechanism characterizes increased cardiovascular disease in human SLE. Other strains develop dermatitis, hemolytic anemia, arthritis, and vasculitis, but their incidence is generally variable. Further, although the animal investigations have helped in understanding some steps in the pathogenesis of SLE, mouse models have not fully recapitulated the waxing and waning nature and the full spectrum of human SLE, suggesting a need for continuing search for additional model systems. In that regard, like human SLE, SLE in dogs is a chronic disease with alternating periods of remission and relapses and manifests with fever, polyarthritis, glomerulonephritis, mucocutaneous lesions, lymphadenopathy, and splenomegaly.

This chapter provides an overview of animal models of lupus highlighting what has been learnt from animal models about the pathogenesis of human SLE. The chapter will also review studies of efficacy of therapeutic interventions in murine lupus that have formed the basis for similar interventions in human disease. Table 18-1 provides an overview of major characteristics of various animals with lupus-like disease.

Clinical Disease, Autoantibodies, Immunologic Abnormalities, and Genetics in Spontaneous Polygenic Murine SLE

Numerous murine models of spontaneous SLE have been studied. This section reviews the principal characteristics of the most extensively studied strains.

New Zealand Mice

NZB/Bl (NZB) Mice

The New Zealand Bielschowsky black (NZB/Bl) mouse was bred by Bielschowsky, who was mating mice by coat color to derive cancer-susceptible strains. In 1959, she reported that NZB mice died early from autoimmune hemolytic anemia (8). Shortly thereafter, her colleagues described a hybrid between NZB and unrelated strains including the New Zealand white (NZW) that were characterized by early death in females from nephritis associated with lupus erythematosus (LE) cells, thus providing the first animal models of SLE (9 ,10).

Tables 18-1 and 18-2 show characteristics of NZB mice. They also are discussed in several review articles (11 ,12 ,13 ,14 ,15).

Table 18-1: Major Characteristics of Animal Strains Developing Systemic Lupus Erythematosus (SLE)

TABLE 18.1.1: Disease Manifestations in Lupus-Prone Animals

Strain	Nephritis	Dermatitis	Arthritis	Neu.-Psy.	Hematol.	Vascular	Other
NZB/Bl	Mild and delayed				Hemolytic anemia		Peptic ulcer 50%
NZB/NZW F1 (BW)	Proliferative, progressive			Yes			Choroiditis 60%-90%, oophoritis 35%
NZM.2410	Early glomerulosclerosis			Yes			
NZM.2328	Proliferative, progressive						Sialoadenitis, dacryoadenitis
NZB/SWR F1 (SNF1)	Proliferative, progressive						
MRL/Mp-lpr/lpr (MRL-l)	Diffuse proliferative; Severe interstitial	Epidermal hyperplasia, ulceration, chronic	75%, Pannus and infiltrate	Yes		Vasculitis 56%	Sialoadenitis 100%, conjunctivitis 85%, band keratopathy 90%, choroiditis 100%, oophoritis 72%
MRL/Mp-+/+	Mild and delayed	Mild and delayed	75%, Pannus and infiltrate			Vasculitis 8%	Milder/later than in MRL-l; sialoadenitis 95%, conjunctivitis 50%, band keratopathy 90%, choroiditis 100%, oophoritis 72%
BXSB	Diffuse proliferative						Neutrophilic infiltrate in joints
BXD2	Diffuse proliferative		Erosive				Splenomegaly
Flaky skin (fsn/fsn)	Glomerulonephritis	Psoriasiform			Anemia		Splenomegaly, hepatitis, lymphadenitis, hyper-IgE, stomach hyperplasia
NZW/BXSB (WBF1)						Ath.*	*Coronary infarct
Hydrocarbon oil-induced	Focal proliferative		Yes				Hepatitis
Anti-DNA Id induced	Yes				Leukopenia	Thrombosis	Elevated ESR
Dog	65%	60%	90%		Thrombocytopenia,	Clotting	Relapsing/remitting disease, Fever, lymphadenopathy, splenomegaly
Heparan sulfate-induced in dog	100%	100%	40%		Anemia		Interstitial pneumonitis

*Ath, atherosclerosis; BXD2, C57BL/6J _ DBA2J; BXSB, Hematol, hematological; MRL, Murphy's Recombinant Large; lpr lymphoproliferative; Neu-Psy, neuro-psychiatric; NZB, New Zealand black mice; NZM, NZW, New Zealand white mice;.

TABLE 18.1.2: Autoantibodies in Lupus-Prone Animals

Strain	dsDNA	Anti-CL	RF	RBC	snRNP	Cryo	Others
NZB/Bl				+			gp70, NTA
NZB/NZW F1 (BW)	100 (4–5 mo), IgG	+	+ (rare)	20–40	0	+	gp70, RNA poly I, RNA, IL-2, ubiquitin, helicase
NZM.2410	IgG						
NZM.2328	IgG						
NZB/SWR F1 (SNF1)	IgG						
MRL/Mp-+/+	100		+	10	83 (9 mo)	+	gp70, albumin, transferrin, La, Ro, ribosome P, S10 RNA poly I
MRL/Mp-lpr/lpr (MRL-l)	100 (4–5 mo), IgG	+	+	10	37 (5 mo)	+	gp70, albumin, transferrin, La, Ro, Su, ribosome P, S10 RNA poly I, laminin, collagen, ubiquitin, mitochondria, CIC
BXSB	IgG, 100 (4–5 mo)			20–40		+	gp70, albumin, transferrin, anti-nucleolar (ref. 703)
BXD2	+		+				
NZW/BXSB (WBF1)		+					
Hydrocarbon oil-induced	+	+	+		+		Su, ribosomal P, tRNA synthetase, helicase
Anti-DNA Id induced	+						
Dog	<30				<30		ANA (90%), histones (90%), <30% Ro, lymphocytes and platelets
Heparan sulfate-induced in dog	0						ANA >1:128 (100%), heparan sulfate

Numbers indicate frequency of specific autoantibodies (at tested age, if known). CIC, circulating immune complexes; cryo, cryoglobulins; dsDNA, double-stranded DNA; RBC, erythrocyte; RF, rheumatoid factors; RNA poly I, RNA polymerase I; snRNP, small nuclear ribonucleoprotein. All strains have ANA (antinuclear antibody) positivity.

TABLE 18.1.3: Genetic and Other Features of Lupus-Prone Animals

Strain	Coat Color	Sex Dominance	Life Span	Age for 50% Mortality (mo)	H-2 Locus	Mls-1 Locus	Vα	Vβ	IgH-C	IgH-V	Ig_

F, female; M, male
*The *Yaa* gene represents a gene copy number polymorphism presenting as the duplication of the *TLR7* gene because of a 4-Megabase expansion of the pseudoautosomal region. Increased expression of TLR7 results in an intrinsic bias of Yaa-containing B cells toward nucleolar antigens.

Clinical Characteristics and Autoantibodies

NZB mice are characterized by hyperactive B cells, which are present in fetal life, that produce primarily immunoglobulin M (IgM) antibodies to thymocytes, erythrocytes, single-stranded DNA (ssDNA), and the gp70 glycoprotein of murine leukemia virus (12 ,13 ,14 ,15 ,16 ,17 ,18 ,19). The first antibody to appear in serum is natural thymocytotoxic antibody (NTA) (20 ,21); by 3 months of age, 100% of mice have this antibody. NTAs are cytotoxic for all thymocytes, 50% to 60% of thoracic duct and peripheral blood lymphocytes (both $CD4^+$ and $CD8^+$ populations), 50% of lymph node cells, 33% of spleen cells, and 5% of bone marrow cells. These figures are similar to the reactivity of anti–Thy-l sera that recognize all T cells. The antigens that are recognized by NTA are varied. Some NTAs react with cell surface molecules on B lymphocytes, granulocytes, and bone marrow myeloid cells; others react with a 55-kd molecule on most T cells. Other reported reactivities include an 88-kd glycoprotein, which is thought to be a T-cell differentiation antigen, and surface molecules of 33- and 30-kd sizes (15 ,22 ,23 ,24).

The primary clinical problem in NZB mice is hemolytic anemia, which is fatal in most at between 15 and 18 months of age (8 ,12 ,15). There is mild disease acceleration in females, with death occurring approximately 1 month earlier than in males. IgM and IgG antibodies to erythrocytes cause the hemolysis (25 ,26 ,27) and can be directed against erythrocyte surface antigens that are exposed by treating the red blood cell (RBC) with bromelein, against erythrocyte membrane protein band 3 (28 ,29 ,30), or against spectrin (31). Early in life, the antierythrocyte antibodies are polyreactive; later, they become more specific for band 3 or spectrin, suggesting antigenic stimulation (31). Anti-RBC appears in the serum by 3 months of age and is found in 100% of mice by 12 to 15 months. Clinical hemolysis begins 1 to 5 months after the antibodies appear. Severe anemia occurs in 56% to 87% of females and 77% of males (32). The expected sequelae of hemolysis occur (i.e., erythrocyte sequestration and extramedullary hematopoiesis in liver and spleen, splenomegaly, hepatomegaly, and deposits of hemosiderin in multiple tissues). The ability to make antibodies to erythrocytes probably depends on up to a dozen genes (33); at least two are major—one designated Aia3 on chromosome 7 and the other in the Nba2 region on chromosome 1, a region that plays a major role in several aspects of NZB/Bl lupus (34).

Table 18-2: Characteristics of NZB/Bl Mice

A. Clinical
   1. Females live a mean of 431 days, males 467 days
   2. Death usually is caused by autoimmune hemolytic anemia
   3. Fifty percent mortality by 15 to 17 months of age

B. Histologic
   1. Glomerulonephritis with immunoglobulin and C3 deposits
   2. Marked thymic atrophy
   3. Mild lymphoid hyperplasia

C. Autoantibodies
   1. IgM NTA
   2. IgM and IgG antierythrocyte
   3. IgM anti-ssDNA
   4. Anti-gp70
   5. ANAs by late life
   6. Modest elevations of circulating immune complexes

D. Immune abnormalities
   1. B cells are unusually mature, hyperactivated, and secrete immunoglobulin spontaneously from a very early age (in fetus and in newborn mice); this abnormality is required for autoimmune disease in NZB mice and in hybrids mated with NZB mice
   2. Numbers of B-1 (CD5+) B cells in spleen and peritoneum are increased; these cells make primarily IgM autoantibodies; however, their elimination by introduction of the xid gene protects from SLE
   3. B cells resist tolerance to T-independent antigens
   4. Older mice develop aneuploidy in B-1 B cells
   5. Thymic epithelium is atrophic by 1 month of age; this is a striking abnormality in NZB mice
   6. Antithymocyte antibodies react with immune T cells and may inactivate/delete precursors of suppressor T populations
   7. T cells are required for maximal autoantibodies formation
   8. A unique form of retroviral gp70 antigen is secreted, and high quantities are found in serum
   9. Clearance of immune complexes by Fc-mediated mechanisms is defective

E. Genetics
   1. Multiple dominant, codominant, and recessive genes participate in the immune abnormalities
   2. One set of genes controls the constellation of polyclonal B cell activation, expression of gp70, and antithymocyte antibodies; another set of genes controls B cell tolerance defects, antibodies to gp70, anti-ssDNA, and anti-RBCs; the gene sets segregate independently; neither of these sets is dependent on H-2
   3. The disease is linked to MHC
   4. Analysis of the NZ genome by microsatellites suggests that NZB donates two to five genes located on different chromosomes, some transmitted in a dominant and others in a recessive fashion, to lupus in mice with NZ backgrounds

ANA, antinuclear antibody; IgM, immunoglobulin M; MHC, major histocompatibility complex; ssDNA, single-stranded DNA.

Clinical glomerulonephritis (GN) may be observed in some NZB mice, but it is mild compared with the nephritis of other lupus murine models, probably because, in contrast to the IgG anti–double-stranded DNA (anti-dsDNA) that arise in the other strains, the IgM anti-ssDNA that dominates the NZB response does not contain many nephritogenic subsets of anti-DNA. However, histologic changes of glomerulonephritis, nephrotic syndrome, and renal insufficiency occur in some mice late in their life span, especially in virgin females (35 ,36). The incidence of antinuclear antibodies (ANAs) in

NZB mice is variable. ANAs are not regularly present in high titers as they are in other lupus-prone strains, but approximately 80% of mice are positive by 9 months of age (12). Some NZB mice exhibit learning disabilities (37), which probably relate both to the cortical ectopias that occur in approximately 40% and to the autoimmune process. Autoantibodies to Purkinje cells of the cerebellum have been found (38), and the numbers of interleukin-1 (IL-1) receptors that are expressed in the dentate gyrus are much lower than in normal mice (39).

Abnormalities of Stem Cells and B Cells

NZB mice are remarkable for inherent abnormalities in their B cells that probably originate in bone marrow stem cells. In comparison to normal mice, there are increased numbers of IgM-secreting cells and increased synthesis of IgM by individual B cells, which are characteristics that may be controlled by different genes (11 ,40 ,41 ,42). This hyperactivation of B cells begins quite early and is detectable in fetal liver. The IgM hypergammaglobulinemia of NZB mice may depend on gene(s) in a region on chromosome 4 that is 70 to 90 centimorgan (cM) distal to the centromere (43). Putative bone marrow pre–B cells exhibit increased growth both in vitro (44) and in vivo (45); this property is lost after 10 months of age (46). The mature B cells are committed to secretion of Ig, particularly IgM. They are resistant to normal control mechanisms involving engagement of the B cell receptor (BCR). Normally, if the BCR is bound, B cells cannot respond to lipopolysaccharide (LPS) stimulation by secreting Ig; NZB B cells in this situation secrete IgM, probably because of abnormal downstream signaling events. Regulation of B cell activation is not completely askew, however; binding of major histocompatibility complex (MHC) class II interrupts signaling by LPS in a normal fashion (47).

Another B cell abnormality that is highly characteristic of NZB mice is the appearance of aneuploidy in B cells, primarily in $CD5^+$ (also designated Ly-1 or B-1) B cells, as the mice age. Hyperdiploid B-1 B cells with additional chromosomes 10, 15, 17, and × are common (48 ,49). Lymphoid malignancies are more common in NZB than in other murine lupus strains, prevalence varying in different colonies between 1% and 20% (20 ,49 ,50 ,51); they may be a model of B cell chronic lymphocytic leukemia (49). Malignant B-1 B cells secrete large quantities of IL-10, which can skew T-cell repertoires away from T-helper-1 (Th1) and toward Th2 phenotypes (52). In young NZB mice, numbers of nonmalignant B-1 B cells are increased in the spleen and peritoneum (11 ,53 ,54); these cells make IgM autoantibodies to RBCs, thymocytes, and ssDNA(11 ,53 ,54 ,55). B-1 cells are also present among marginal zone (MZ) B cells in lymphoid tissues: MZ B cells respond more rapidly to antigen than do other B cells (56). B-2 (CD^5) B cells are more likely to be the source for IgG autoantibodies (57 ,58). However, elimination of B-1 B cells by introducing the X-linked recessive gene, Xid (41), or by lysing the cells with water in the peritoneal cavity (where these cells are renewed) reduces antibodies to RBC and hemolytic anemia (59), thus demonstrating the importance of B-1 cells to NZB disease. Finally, splenic B cells in NZB mice are probably resistant to apoptosis because of the influence of the Ifi202 gene, which is upregulated in this strain and plays a major role in sustained autoantibodies production in hybrids with NZB, and probably in the parent strain as well (60).

Abnormalities of Dendritic Cells

Since the recent recognition of the connections between innate and acquired immunity, there has been great interest in the role of dendritic cells (DC) as mediators of immune tolerance, and as a source of APC that activate T cells. Notably, DC can respond to CpG oligonucleotides (ODNs) derived from bacteria or from nucleosomal DNA in immune complexes, thus becoming activated APC that probably enhance autoimmune responses to DNA. In fact, NZB mice, compared to normal strains, respond to injections of CpG ODN with increased release of IFN-α; the source of that cytokine is DC. Furthermore, cell numbers of DC and mRNA for toll-like receptor 9 (TLR9), which binds ODN in DC, are increased in NZB mice. On the other hand, other features of DC that promote inflammation are abnormally low in NZB DC, including IL-12 production, expression of the homing chemokine CCR7 and the activation surface marker CD62L (61). Whether these abnormalities are primary defects contributing to autoimmunity, or whether they represent an activation stage in DC responding to abnormalities in apoptosis, phagocytosis of apoptotic materials and immune complexes, or intrinsic abnormalities in B and T cells, remains to be determined.

Abnormalities of Thymus and T Cells

Abnormalities of the thymus also are characteristic of NZB mice, and T cells interact with hyperactive B cells to further increase autoimmune responses. NZB mice exhibit dramatic involution of thymic tissue; thymic epithelium is atrophied and immunologically defective by 1 month of age (before the appearance of NTA), with epithelial cell degeneration, accumulation of TdT^+ large immature T cells in the subcapsular region of the cortex, cortical atrophy, and increased lymphoid and plasma cell infiltrates in the medulla (12 ,24 ,62 ,63 ,64 ,65). NZB thymic epithelial cells are functionally defective compared with cells from normal mice, having low expression of surface Ia molecules, low secretion of IL-1, high secretion of prostaglandin E2 (PGE2) and PGE3, and diminished ability to educate nonthymic cells to express Thy-l (63 ,64 ,65 ,66 ,67).

As in the B cell compartment, NZB bone marrow contains increased prothymocyte activity, and these prothymoctes have an increased growth advantage when they are transferred to histocompatible recipients (68). T cells probably play a major role in disease, because MHC class II is an important predisposing factor for autoimmunity. The hybrid combination of NZB d/d and NZW z/z or SWR q/q to make d/z or d/q MHC molecules predisposes hybrids to GN that is mediated by IgG anti-dsDNA (69 ,70 ,71 ,72 ,73 ,74 ,75 ,76), which are antibodies that NZB mice do not make. NZB mice that are congenic for H-2b (NZB.H-2b) have less disease than the wild-type NZB.H-2d. However, introduction of a mutated I-A chain (bm12) converts this

animal (i.e., H-2Bbm12) to a phenotype that is similar to the BW hybrid, with high-titer IgG anti-dsDNA and severe clinical GN (77 ,78 ,79 ,80). MHC class II likely plays a role in disease by shaping the repertoires of $CD4^+$ T cells. In fact, $CD4^+$ cells that proliferate in response to the RBC membrane protein band 3 and to spectrin (i.e., the major RBC antigens that are recognized by antierythrocyte Ab) have been isolated from NZB spleens (28). The importance of T cells to autoantibodies formation also is indicated by experiments in which anti-CD4 nondepleting antibody was administered to NZB mice: anti-erythrocyte antibodies were significantly decreased, although anemia was not prevented (81 ,82).

Genetics

NZB mice have a gene(s) located on chromosome 1 (Nba2) linked with elevated serum levels of antibodies to dsDNA, chromatin, histone, and gp70 as well as hypergammaglobulinemia. One gene within the Nba2 region that is particularly important is Ifi202, a interferon type 1-regulated gene which when increased in expression probably renders splenic B cells and non-T non-B cells relatively resistant to apoptosis, thus contributing to sustained autoantibodies production (60). Recent studies have shown Nba2, Nba4 (chromosome 5), Lbw4 (chromosome 6), and Nba5 (chromosome 7) increase antibody responses to chromatin in hybrids with SWR (83). Anti-gp70 responses are increased by genes in the regions Nba2 and Nba5, and gp70 antigen levels are increased by Sgp3 on chromosome 13 in crosses of NZB with C57Bl6 bearing the Yaa lupus-acclerating gene on the Y chromosome (84). There are contributions from the MHC region (H-2d/d) that enhance Nba2 and other gene region influences on autoantibody formation and nephritis (85,86), and from a region on chromosome 4 that predispose NZB/NZW F1 mice to nephritis (GN) (43,85,86). Studies of backcrosses between (NZB × SM/J) F1 and NZW mice, and of (NZB × NZW) F2 intercross mice, have suggested that NZB genes on chromosomes 1, 4, 7, 10, 13, and 19, in various combinations, contribute to GN (69,86). In a preceding paragraph we have noted that a recently discovered locus Aia3 on chromosome 7 along with a locus within Nba2 on chromosome 4, are key in development of anti-RBC and hemolytic anemia (84).

Summary

In NZB mice, the combination of inherent B cell hyperactivity and thymic loss, in addition to expansion and activation of DC in bone marrow, probably results in the abnormal shaping of T- and B cell repertoires. NZB mice are characterized by a fatal hemolytic anemia that is induced by antierythrocyte antibodies. Other autoantibodies in their repertoire include predominantly IgM NTA, anti-ssDNA, and anti-gp70. Their dominant immunologic abnormalities are hyperactivated B cells from fetal life onward, early degeneration of thymic epithelium, and increased numbers of $CD5^+$ (B-1) B cells that develop aneuploidy with age. These manifestations are controlled by multiple different genes. Sex differences are not marked, but disease is slightly accelerated in females.

New Zealand White Mice (NZW)

This strain is of great interest because it is clinically healthy but provides many genes that predispose to SLE in hybrids with other lupus-prone strains (15 ,43 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97). Therefore, the NZW genome must contain controlling or repressor or epistatic genes that protect from SLE, and those controlling genes must be powerful enough to allow the animal to appear normal.

Clinical Characteristics and Autoantibodies

The NZW mouse has a slightly shortened life span and develops largely nonpathogenic autoantibodies, some of which are only intermittently detectable. The autoantibodies pattern is characterized primarily by IgG antibodies to ssDNA and histones (89 ,98).

Genetics

Two groups of genes are clearly important in predisposing hybrid mice of an NZW parent to lupus and nephritis: (a) the MHC class II gene z (probably identical to u), and (b) several non-MHC genes.

Inheritance of the MHC class II z genes from NZW (I-Ez, I-Az, also referred to as I-Eu and I-Au) predisposes hybrid mice to nephritis (89 ,99 ,100 ,101). H-2d/z mice, compared to H-2 d/d mice, have a higher incidence of nephritis; the d/z haplotype increases the risk for nephritis 30-fold (100). These MHC II genes are important in class switching of various autoantibodies from IgM to IgG (89). H-2d/z predisposes to antibodies to ssDNA, dsDNA, chromatin, and histones, but not to gp-70 (99 ,100). Because the MHC region is closely linked to the gene encoding tumor necrosis factor-α (TNF-α) in the same gene region, and low production of that cytokine is a dominant genetic feature of NZW mice (102), it has been somewhat difficult to sort out the role of each gene. This has assumed great importance with the interest in considering TNF-α blockade in the treatment of human SLE. Fujimura et al. (101) made three different H-2 congenic mice of BW bearing distinct haplotypes at class II and TNF-α regions (H-2d/z:A(d/u)E(d/u)TNF-α (d/z), H2(d/u):A(d/u)E(d/u)TNF-α(d/d), and H-2(d/d):A(d/d)E(d/d)TNF-α(d/d); studies of nephritis in each group showed that both the NZW MHC class II and the unique TNF-α allele are important predisposing genes.

Genome scanning has shown regions in several NZW chromosomes outside MHC that increase susceptibility to SLE. These include regions in chromosomes 1, 11, 16, and 19 (which are linked to IgG autoantibody production), with a selective linkage of a region on chromosome 14 with IgG antihistone Ab (89). Additionally, chromosomal regions from NZW parents labeled SLE1, SLE2, and SLE3, have been linked with disease susceptibility in NZM2410 mice (products of matings of NZB/NZW F1 brother/sisters with categorization and further mating of various offspring according to severity of nephritis) and congenics of these mice and the normal strain C57B1/6J (87); see also (88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96)). SLE1 is located in the distal portion of chromosome 1 and promotes breaking of

tolerance to chromatin, with mice developing IgM antichromatin (92 ,94), which sets the stage for production of IgG anti-dsDNA if other permissive genes are present. The presence of the *z* allele of *SLE1* impairs B cell anergy, receptor revision, and deletion, which have been attributed to the lupus susceptibility gene *Ly108* (705). SLE2 is located on chromosome 4 and promotes B cell hyperactivity (91). Identified in NZM2410 mice, SLE2 on a C57Bl/6 background has been divided into SLE2a and 2b from NZW and SLE2c from NZB. The NZW-derived loci increased lymphocyte expansion and renal disease, whereas the NZB-derived locus did not, although it was associated with expansion in B-1 B cells (97). SLE3 is located on chromosome 7 and promotes T-cell hyperactivity (95). If normal mice are made homozygous for SLE1 or SLE3, few develop clinical nephritis. However, if they are made to express either one or two copies of both SLE1 and SLE2, some 85% develop severe nephritis (87 ,103). This illustrates the point that more than one susceptibility gene is required to develop clinical SLE. Another gene, probably located in or near the NZW MHC region, labeled SLE1-s (for "SLE1-suppressor"), when expressed in a normal strain along with SLE1 and SLE3, reduces the incidence of severe nephritis approximately 50% (87 ,103). Therefore, NZW mice appear healthy because their genome contains not only SLE susceptibility genes but also genes that protect from SLE, and the latter dominate in this strain. However, hybrids of NZW in which the other parent also contributes powerful susceptibility genes develop severe SLE. At the time of this writing, the exact gene(s) within these chromosomal regions have not been identified.

Identifiable single gene regions other than MHC/TNF-α, SLE1, SLE2, SLE3, and SLE1-s have been proposed as important to SLE susceptibility in NZW mice (104). For example, a locus designated lbw3, identifed on NZW chromosome 5, is associated with renal disease (69). Recent work (105) suggested that the P2RX7 gene within the lbw3 region contributes to cell death by aponecrosis, which may provide abundant autoantigens such as nucleosomes to the immune systems of mice predisposed to SLE, such as the NZB/NZW F1 hybrid.

The p8.6 gene, encoded upstream of the mouse TCRVa1 gene, contains regions that are consensus motifs for SH2 and SH3 binding motifs known to activate phosphorylation of some molecules. A gene mutation present in NZW (and BXSB) mice is associated with dysregulation in signaling through the BCR or T-cell receptor (TCR), which could play a role in the hyperactive responses or these cells in hybrid mice (106). Additionally, one of two murine Rt6 genes is deleted in NZW mice (107). Rt6 is a T-cell–restricted GPI-anchored membrane protein, a member of the family of mono[adenosine diphosphate(ADP)-ribosyl]transferases, also known as PARP. These enzymes are activated by apoptosis and play a role in DNA repair.

A portion of the TCR, encompassing Db2-Jb2, is deleted in NZW mice (108). Although one genetic backcross study showed lupus-like disease segregating with the abnormal TCRs (74), studies by other groups have not confirmed the importance of this deletion (75).

(NZB/NZW) F1 Mice (BW)

The BW hybrid cross between NZB and New Zealand white (NZW) mice is considered by many to be the murine model that most closely resembles human SLE. The disease is more severe and earlier in females, with high titers of IgG anti-dsDNA, antichromatin, ANA, and LE cells occurring in virtually all females; death results from immune glomerulonephritis (12 ,36 ,109) (Tables 18-1 and 18-3).

Both NZB and NZW parents contribute genetically to the immune abnormalities that cause disease, as discussed in the preceding sections. The B cell hyperactivity that is characteristic of the NZB is inherited by the BW, with abnormally high secretion of immunoglobulin being detectable by 1 month of age (13 ,14 ,15 ,19). However, the T-cell dependence of the response is more striking than in the NZB parent and probably is responsible for the isotype shift from IgM anti-DNA to IgG anti-DNA that precedes clinical disease (110 ,111). The ability to make this shift depends in part on genes located on chromosome 1 from the NZB (Nba2) parent and gene(s) on chromosomes 1 (SLE1), 4 (SLE2) and possibly 7 (SLE3) from the NZW parent.

Clinical Characteristics and Autoantibodies

The large quantities of IgG antibodies that bind both dsDNA and ssDNA, and are widely designated as anti-dsDNA, are striking and can be abrogated by removal of $CD4^+$ (formerly called $L3T4^+$) T cells (70 ,112). IgG antibodies to dsDNA clearly contain subsets that cause nephritis. Transfer of certain monoclonal BW IgG2 anti-dsDNA antibodies to normal BALB/c mice induces nephritis in the recipients (113 ,114). Infusion of anti-DNA into rodent kidneys induces proteinuria (115), and normal mice secreting BW IgG anti-dsDNA encoded by transgenes develop GN (116 ,117). (Chapter 21 discusses in detail characteristics of pathogenic subsets of anti-DNA.)

Anti-DNA and immune complexes containing gp70 and anti-gp70s are the most important autoantibodies made by BW mice that contribute to nephritis (118 ,119). ANAs are detectable in most females by 2 to 3 months of age; they include antibodies that bind subnucleosomes, nucleosomes, chromatin, dsDNA, ssDNA, dsRNA, transfer RNA (tRNA), polynucleotides, and histones (111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119). IgM anti-DNAs arise in females between 3 and 5 months of age; by 5 to 7 months, IgG anti-DNAs appear (12 ,110 ,111). The IgG2a and 2b subclasses are most frequent, which is important because these subclasses fix complement well. The IgM to IgG switch and the dominance of IgG2a and 2b thereafter occur in BW females responding not only to DNA but also to other thymic-independent and -dependent antigens (120). Shortly after the switch to IgG, IgG and complement deposit in the mesangia of BW glomeruli, spreading later to capillary loops and interstitial tubular regions (12). Proteinuria appears between 5 and 7 months; azotemia followed by death occurs at 6 to 12 months of age. Approximately half of the females are dead by 8 months and 90% at 12 months (12 ,14 ,114). With regard to immune complexes containing gp70, that antigen is an endogenous

retroviral glycoprotein produced by hepatic cells that is found in all mouse strains. However, lupus-prone mice (MRL-Fas(lpr), BXSB, NZB, NZW, NZB/NZW F1) all have high serum levels. It is likely that past integrations of murine leukemia viruses into the mouse genome account for production of gp70. DNA/anti-DNA complexes are difficult to detect in mouse sera, whereas gp70/anti-gp70 complexes are found more frequently than free antibody to gp70. It may be that many antibodies to DNA cause nephritis by direct attachment to planted or cross-reactive glomerular and tubular antigens, whereas passive trapping of gp70/anti-gp70 immune complexes is important in inducing nephritis. Both anti-gp70 and anti-nucleosome bind to endogenous xenotropic virions; immmunization of BWF1 mice with such virions induced stronger antibody responses than did immunization with chromatin. Therefore, the gp70 response may be very important as an indicator that pathogenic antinucleosomal antibodies can be made (121). NZB chromosome regions Nba2 (on chromosome 1, contains the Ifi202 gene) and H2 (on chromosome 17) are linked to high levels of gp70/anti-gp70 immune complex production, as they are linked to high titers of IgG anti-DNA. In contrast, the ability to make high levels of gp70 antigen is linked to regions on chromosomes 4 and 13 (119).

Table 18-3: Characteristics OF NZB/NZW F1 Mice

A. Clinical
   1. Females live a mean of 280 days, males 439 days
   2. Death usually is caused by immune glomerulonephritis
   3. Fifty percent mortality by 8 months in females and 15 months in males

B. Histologic
   1. Glomerulonephritis with proliferative changes in mesangial and endothelial cells of glomeruli, capillary basement membrane thickening, and chronic obliterative changes; mononuclear cell infiltrates in interstitium
   2. Glomerular immune deposits of IgG (predominantly IgG2a) and C3; similar deposits in tubular basement membrane and interstitium
   3. Thymic cortical atrophy by 6 months of age
   4. Myocardial infarcts with hyaline thickening of small arteries
   5. Mild lymph node hyperplasia and splenomegaly

C. Autoantibodies
   1. IgG anti-dsDNA (also binds ssDNA), enriched in IgG2a and 2b
   2. ANA and LE cells in all
   3. IgG antibodies bind chromatin, nucleosomes, and phospholipids
   4. Antithymocyte in most females and some males
   5. Renal eluates contain IgG anti-dsDNA concentrated 25 to 30 times greater than in serum; IgG2a isotype usually is dominant
   6. Modest elevations of circulating immune complexes; these include gp70–anti-gp70
   7. Low serum complement levels by 6 months of age in females

D. Immune abnormalities
   1. Polyclonal B cell activation
   2. B cells are resistant to tolerance to some antigens
   3. Strict dependence on T cell help for formation of pathogenic IgG anti-DNA, $CD4^+CD8^-$ and $CD4^-CD8^-$ α/ß TCR cells, as well as $CD4^-CD8^-$ γδ TCR cells, can provide help
   4. IgG repertoire becomes restricted with age to certain public Ids; there is some restriction of B cell clonality in the IgG anti-DNA response
   5. Thymic epithelial atrophy by 6 months of age; medullary hyperplasia; effect of thymectomy on disease varies
   6. Clearance of immune complexes by Fc- and complement-mediated mechanisms is defective
   7. Disease and autoantibody production is sensitive to sex hormone influences

E. Genetics
   1. The expression of high-titer IgG anti-dsDNA requires heterozygosity at MHC, namely $H\text{-}2^{d/z}$
   2. Additional complementary non–H-2-linked genes are required from both NZB and NZW parents to permit full expression of the IgG anti-DNA response; by microsatellite analysis of DNA, there are approximately 10 genes on as many chromosomes, with multiple genes required for early mortality, glomerulonephritis, antichromatin, and splenomegaly; this suggests a multigenic inheritance, with certain groupings predisposing more strongly than others to disease, rather than a simple additive model
   3. The large deletion in the ß chain of the TCR of the NZW parent probably does not predispose to disease

---

dsDNA, double-stranded DNA; TCR, T cell receptor.

Antibodies eluted from glomeruli are composed predominantly of IgG anti-DNA; 50% of the total IgG is anti-DNA according to some reports (122 ,123). In colonies in our laboratory, anti-DNA accounts for as much as 85% of the total glomerular IgG (124). IgG2a is the dominant isotype in glomerular deposits, suggesting a role for Th1 cells, because production of IgG2a is dependent on interferon-γ (IFN-γ). Other antigens and antibodies have been reported in glomerular eluates, including gp70, antihistones, anti-C1q, and anti-RNA polymerase (125 ,126 ,127). The high serum levels of IgG anti-DNA occur at about the same time as hypocomplementemia, and levels of circulating immune complexes are elevated (12).

Histologic changes in kidneys include chronic obliterative changes in glomeruli, mesangial, and peripheral proliferative changes, capillary membrane thickening, glomerular sclerosis, tubular atrophy, infiltration by mononuclear lymphocytes and monocyte/macrophages, and vasculopathy

(primarily degenerative, occasionally inflammatory) (12 ,36) (Fig. 18-1). Additionally, messenger RNA (mRNA) encoding several molecules that contribute to proliferation, inflammation, and sclerosis is increased in the kidneys of BW mice with GN; those molecules include platelet-derived growth factor (PDGF), MHC class II, insulin-like growth factor-1 (IGF-1), IFN-γ, and basic fibroblast growth factor (bFGF) (128 ,129 ,130 ,131). Other autoantibodies also occur in BW mice. Antibodies to erythrocytes are found in 35% to 78% of BW females, but they rarely cause hemolytic anemia (14). Approximately 50% develop NTAs by 6 months of age. Because the genes governing NTA, anti-DNA, and antierythrocyte antibodies probably segregate separately (13 ,15 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,102 ,103 ,104 ,106 ,107 ,132 ,133 ,134 ,135), New Zealand mouse strains have been bred that have high-titer NTAs but no autoimmune disease. However, NTAs may serve as an accelerator of the disease process that occurs in mice with IgG anti-DNA, because NTAs may alter T-cell function. Both IgM and IgG antiphospholipid antibodies have been detected and obtained as monoclonal antibodies from BW mice (136). Some have anticardiolipin activity and others lupus anticoagulant properties.

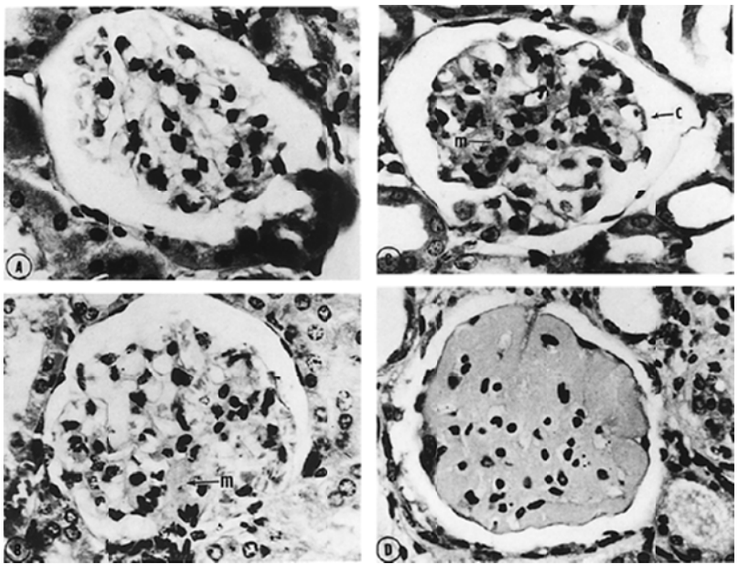

Figure 18-1. Glomerulonephritis in New Zealand mice. Each sample is from a kidney section of NZW mice. **A,** Normal mouse glomerulus. **B,** Mesangial proliferation and thickening (m). **C,** Proliferative glomerulonephritis with thickened glomerular capillaries (c). **D,** End-stage glomerulopathy; the glomerulus is obliterated.

IgG1 antibodies have been eluted from the neurons of BW mice (137); it is not known whether they cross-react extensively with lymphocytes, as do some human lupus antineuronal antibodies. Antibodies to histones, ubiquitin, chromatin, and fibrillarin have been reported, as have cryoglobulins (138 ,139 ,140). Some antibodies to DNA, chromatin, and nucleosomes can bind to and/or penetrate living cells; some of these subsets make glomerular cells proliferate and impair cellular production of protein (141 ,142 ,143 ,144 ,145).

The lymphoproliferative features of NZB mice occur in BW hybrids, which exhibit mild lymphadenopathy and splenomegaly (12 ,14). Lymphoid neoplasia is far less common in BW than in NZB mice. Some investigators have reported a relatively high incidence of thymoma, from 1% to 5% (146), but that has been rare in our colonies unless mice are treated with cytotoxic agents (147). Extrarenal lesions occur in BW mice, including lymphocytic infiltration of salivary glands, mild inflammation around bile ducts in the liver, pancarditis, vasculitis (less common than in MRL-Fas(lpr) and BXSB mice), myocardial infarcts, and deposits of DNA and anti-DNA in the dermoepidermal junction of skin and in the choroid plexus (12 ,148 ,149).

Sex Hormone Influences on Lupus in BW Mice

The femaleness of spontaneous BW disease has been studied extensively. Most BW males develop ANAs, including antibodies to DNA, but they are predominantly IgM. The IgM to IgG switch occurs relatively late in life, usually after 12 months. Histologic evidence of nephritis can be found in males, and most die of slowly progressive chronic nephritis by 15 to 20 months of age (12 ,14).

The BW mouse is particularly sensitive to the effect of sex hormones on disease. Generally, androgens are protective and suppress the expression of autoantibodies and disease, and estrogens are permissive. Castrated male BW mice (and other hybrids of NZB) develop high titers of IgG autoantibodies as early in life as do females (13). Males that are castrated and/or treated with estrogens or testosterone antagonists assume a female pattern: early IgM-to-IgG switch of anti-DNA antibodies and early, fatal nephritis (150 ,151 ,152). Females that are treated with castration and androgens, or with antiestrogens, have prolonged survival, with suppression of IgG anti-DNA and nephritis (153 ,154 ,155 ,156). In old females, androgens can suppress disease without altering the elevated levels of IgG anti-DNA. Addition of exogenous estrogens cause early death in females, but this may result largely from toxic effects rather than from enhancement of immune responses (152). Hyperprolactinemia occurs in some women with SLE. In BW mice, SLE is accelerated in pseudopregnant females in which cyclical increases of prolactin occur, and administration of prolactin to BW mice accelerates disease, while bromocriptin suppresses it (157 ,158 ,159). Manipulations of BW mice that produce both high levels of estrogen and high levels of prolactin shorten survival about 8 weeks (159).

The effects of sex hormones on immune responses are complex and poorly understood. There are receptors for estrogens, progestogens, and prolactin on lymphocytes (157). The administration of estradiol in vivo dramatically suppresses NK cell function, and NK cells downregulate activated B cells (160). Additionally, normal mice transgenic for a murine IgG antibody to DNA show defective B cell tolerance if they are treated with exogenous estradiol (161). Such mice fail to delete B cells producing anti-DNA from unmutated germline genes. In addition to their effects on sex tissues and lymphocytes, sex hormones may regulate the expression of certain genes.

Abnormalities of Stem Cells and B Cells

BW mice exhibit the hyperactivated B cell phenotype of their NZB parent, except that defects appear later in life. BW mice have abnormally elevated secretion of IgM by 1 month of age. Stem cells of the pre-B lineage can partially transfer disease: severe combined immunodeficiency disease (SCID) mice (a mutant strain that lacks most T cells) that are inoculated with BW bone marrow pre–B cells develop autoantibodies (including IgG anti-dsDNA), and approximately 25% develop clinical nephritis (162). These studies suggest that both B and T cells are required for the full expression of BW disease. The B cell repertoire that expresses anti-DNA is somewhat restricted. Public idiotypes (Ids) that are expressed on total serum IgG become increasingly restricted as the mice age (163). Although many different V genes can be used to assemble antibodies that bind DNA (164), most BW monoclonal antibody anti-DNA belong to one of approximately 12 families (165 ,166 ,167 ,168). This type of restriction is seen in normal, antigen-driven antibody responses. B-1 B cells and marginal zone B cells are increased in number. Depleting some of these cells by administering a B cell superantigen (protein A from *Staphylococcus aureus*) delays appearance of serum IgG anti-DNA and reduces proteinuria, confirming participation of these cells in autoimmunity in this mouse strain (169).

Abnormalities of Thymus and T Cells

The degeneration of thymic epithelial cells that is characteristic of NZB mice occurs in BW mice, but at 6 months of age in contrast to 1 month of age in the NZB parent (15). Responses to thymectomy have been variable; there are reports of thymectomy failing to alter disease or even accelerating it (63). Full-blown BW lupus depends on the presence of $CD4^+$ helper T cells; T-cell lines from nephritic mice can accelerate disease in naive young syngeneic mice (170 ,171). Elimination or inactivation of $CD4^+$ T cells prevents the onset of disease and can even partially reverse established nephritis (112 ,172). As BW mice age, the numbers of $CD4^+$ T cells increase fivefold, and these cells are polyclonal (173 ,174). T cells from nephritic BW mice can drive B cells from young normal mice to make pathogenic autoantibodies (170 ,171), whereas B cells from old mice will not secrete anti-DNA when they are cocultured with T cells from premorbid young normal mice (170 ,175).

Pathogenic T cells must receive second signals after TCRs are engaged to develop into activated effectors of disease. Interruption of second signals with blockade of the CD28/CTLA4 T-cell surface molecule's interactions with CD80/CD86 (B7–1/B7–2) on antigen-presenting cells (APCs) prevents disease. Experiments showing this include the administration of cytotoxic T-lymphocyte antigen-4 (CTLA-4)–Ig, which binds B7.1 and B7.2, thus preventing interaction with CD28 (176), and the administration of antibodies to CD80 and CD86 (177). Additionally, blocking second signals that activate B cells (CD40 interacting with CD40 ligand) by administration of antibody to CD40L prolongs survival in BW and other New Zealand-background lupus mice (178 ,179). Blocking both CD28/B7 and CD40/CD40L interactions is probably more effective than blocking either one alone (180).

Because $CD4^+$ T cells of the Th1 phenotype (secreting IL-2 and IFN-γ) generally support cell-mediated reactions, whereas $CD4^+$ cells of the Th2 phenotype (secreting IL-4, IL-5, and IL-6) give help to B cells for antibody production, there has been great interest in the possibility that a skewing toward Th2 plays a major role in the SLE of BW mice. Such skewing has been suggested by the well-known fact that T cells from BW mice secrete less and less IL-2 as the mice age, with a diminution in IL-2 receptors on T-cell surfaces (14 ,175 ,181). One study (181) showed a concomitant decline in IL-2 and IFN-γ, with an increase in IL-4 secretion by 6 to 8 months of age that would support a shift to Th2. Another study, however, showed a decrease in IL-2 and IL-4

and an increase in IFN-γ as mice aged (175). In our colonies, dramatic increases in plasma levels of IFN-γ and IL-4 occur at the time high quantities of IgG anti-DNA appear. Because the dominant isotype that is eluted from glomerular lesions is IgG2a, which depends on IFN-γ for its synthesis, Th1 cells (or Th0 that secrete IFN-γ) are important in inducing disease. Additionally, our laboratory has accelerated disease in young BW mice by the transfer of either Th1 or Th2 cell lines, implying that both subsets play important pathogenic roles. IL-6, which is secreted by Th2 cells and B cells, potentiates autoantibodies formation (182). Administration of IL-6 accelerates disease, and antibodies to IL-6 delay it (183). IL-10, which is made predominantly by monocyte/macrophages, also is important, is increased in SLE, and shifts repertoires from Th1 toward Th2, probably by suppressing IL-6. Thus, administration of anti–IL-10 delays disease in BW mice (184).

Transforming growth factor-ß (TGF-ß) can mediate suppression, which is critical to controlling SLE-like immune responses (185). TGF-ß a is essential for the suppression by some $CD4^+CD25^+$ regulatory T cells (186) and by $CD8^+$ T cells (187), which delay autoautoimmunity in BW mice tolerized with histone or Ig peptides. However, late in disease TGF-ß contributes to glomerular scarring and thus to shortened survival (1). IL-1 and TNF-α are both pro-inflammatory and may be abnormally elevated in BW lupus (188 ,189). The role of TNF-α in murine and human lupus has been debated for several years. NZW mice have an unusual gene that may encode abnormally low levels of TNF-α, and short-term administration of TNF-α to BW mice delays disease (190). However, mRNA for TNF-α is increased in the glomerular tissue of BW mice (189), and chronic administration of the cytokine worsens disease (191 ,192).

Abnormalities of Monocytes/Macrophages

Monocyte/macrophages are primary sources of IL-1; production of that cytokine is reduced in BW and other murine lupus strains (188 ,193). Macrophages also produce IL-12, the major cytokine stimulating Th1 responses. The ability of CRP treatment to delay disease onset in BW mice may relate to the fact that CRP reduces IL-12 production by macrophages following ingestion of apoptotic materials; those macrophages have reduced ability to activate T cells (194 ,195 ,196 ,197).

The Role of Defective Regulatory Cells in BW Lupus (CD4+CD25+, CD8+, NKT cells, B-1 B cells)

Finally, the possibility that regulatory cells that ordinarily suppress activated T and/or B cells are defective or missing from BW repertoires should be considered. $CD8^+$ T cells, which usually are cytotoxic or suppressive, behave abnormally in BW mice. As the mice age, $CD8^+$ T cells fail to expand while $CD4^+$ T and B cells are increasing greatly in numbers, and very few $CD8^+$ cells express surface markers of activation and memory. Furthermore, activating $CD8^+$ T cells from old BW mice results in apoptosis rather than the activation characteristic of normal mice and young BWs (174). Infusing $CD8^+$ T cells from young BW mice suppresses murine lupus (180). Recent studies showed that tolerizing regimens with autoantibodies– or histone-derived peptides induce both suppressive $CD8^+$ T cells and classical $CD4^+CD25^+$ regulatory T cells, each of which can prolong survival in BW or NZB/SWR Fl mice, indicating that regulatory T-cell defects can be “repaired” in vivo (186 ,187 ,198). However, the systemic autoimmunity in NZM2328 mice is not associated with a global deficiency in functional $CD25^+$ Treg cells (199). CD1-restricted NKT cells prevent the development of autoimmune manifestations if activated in early stages of disease in BW (nephritis), pristane-injected BALB/c (nephritis) and MRL-lpr (dermatitis) mice (1 ,3 ,200), but not in late stages of BW disease and in pristane-injected SJL mice (201 ,202). As BW mice age, the numbers of NKT expand and become hyperactive; they can actually increase production of IFN-γ—a major cytokine that enhances SLE in this strain (203).

Regulation provided by B-1 (CD5+) B cells also may be abnormal in BW mice. B-1 B cells can downregulate autoantibody production under normal circumstances; BW mice have large numbers of these cells. B-1 B cells derived from normal CBA/J bone marrow and transferred with BW marrow into chimeric mice, suppressed disease (204). In contrast, mixtures of BW and CBA/N bone marrow (CBA/N carries the xid gene, which eliminates B-1 B cells) transferred BW lupus to recipients (204). Thus, BW B-1 cells increase autoimmunity instead of suppressing it. Monocytes/macrophages, which are defective in IL-1 production in BW mice, also may serve as downregulators in normal circumstances; it is not clear that they serve this function in the BW model.

Abnormalities of DC in BW Mice

DC, which connect innate and acquired immunity, and can be activated by oligonucleotides produced by bacteria and by SLE patients, are abnormal in BW mice. As mice age, DC expand in numbers and acquire ability to attract B cells and to present antigen (205). This activity is particularly brisk in the spleen, where DC stimulate nucleosome-reactive T cells to a much greater extent than normal (206). In BW mice, splenic DC are potent adjuvants for induction of autoantibodies to apoptotic materials (207). Furthermore, DC are a major source of type 1 interferons. High production of these interferons is characteristic of BW mice and of humans with SLE (6). Increased expression of the Ifi202 gene (interferon-inducible) from the Nba2 gene region of NZB mice is important in predisposing to disease (60). Deficiency of the type-I interferon receptor protects NZB mice from disease (208), and administration of IFN-α accelerates disease in BW mice (209). Therefore, abnormal DC play a critical role in promoting lupus-like disease in BW mice.

Genetic Predisposition

Genetic predisposition is discussed fully in Chapter 7 and was reviewed briefly in the preceding sections on NZB and NZW mice. In BW mice, genetic contributions to disease are provided by both NZB and NZW parents. The most important contributors are probably MHC genes (heterozygosity for H-2 d/z) and the Ifi202 gene from NZB encoding

a transcription factor that inhibits lymphocyte apoptosis (6 ,60). Additionally, multiple non-MHC genes on at least eight different chromosomes contribute to disease susceptibility (43 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,95 ,96 ,99 ,100 ,101 ,102 ,103 ,104 ,106 ,107 ,108).

Summary

BW mice develop fatal glomerulonephritis, mediated primarily by IgG antibodies to dsDNA and immune complexes of gp70 and anti-gp70, that occurs earlier and is more severe in females and can be modulated by sex hormones. Multiple genes inherited from both NZB and NZW parents, both MHC and non-MHC, are required for the development of high-titer IgG anti-dsDNA and clinical nephritis. Abnormalities in B-1 and marginal zone B cells, in $CD4^+$ helper T cells and $CD4^+CD25^+$ regulatory T cells, in $CD8^+$ and NK-T suppressor cells, and in DC are all required for the disease to be fully manifest.

(SWR × NZB) F1 (SNF1) Mice

The SNF1 mouse is a model of lupus nephritis that is produced by mating the normal SWR mouse with the autoimmune NZB mouse (210 ,211 ,212 ,213 ,214 ,215); it does not matter which parent is female and which is male (Table 18-4). In contrast to NZW mice, SWR mice are completely healthy, with normal life spans, low levels of serum gp70, and no evidence of autoimmune disease (210 ,211). Their B cells can produce Igs bearing the same public Ids that dominate serum Ig in MRL-Fas(lpr) mice (215 ,216 ,217).

Table 18-4: Characteristics of NZB × SWR F1 (SNF1) Mice

A. Clinical
1. Mean survival in females is 297 days; mean survival in males is 531 days
2. Females die from immune glomerulonephritis between 5 and 13 months of age

B. Histologic
1. Glomerulonephritis with proliferative and obliterative lesions

C. Autoantibodies
1. IgG anti-dsDNA is made by all females
2. Anti-dsDNA is dominated by IgG2b cationic populations with restricted idiotypes
3. ANAs in all females

D. Immune abnormalities
1. B cells are hyperactivated
2. The development of nephritis depends on the presence of T cell help for production of IgG anti-DNA
3. Cationic IgG anti-dsDNA may use the allotype of either the NZB or healthy SWR parent
4. Anti-dsDNA deposited in glomeruli cluster into two main groups defined by their Ids
5. $CD4^+CD8^-$ and $CD4^-CD8^-$ T cells can provide help for the synthesis of cationic IgG anti-dsDNA

E. Genetics
1. Probably similar to BW mice

Clinical Characteristics and Autoantibodies

SNF1 mice are similar to BW mice. Females are dead by 10 to 12 months of age (50% mortality at 6 months) from an immune glomerulonephritis that is mediated primarily by IgG2b antibodies to dsDNA (212 ,214). This model has been of particular interest because of the oligoclonality of the IgG anti-DNA that is deposited in glomeruli (213 ,215). Activated B cells of NZB mice make anti-DNAs that are predominantly IgM, bind ssDNA rather than dsDNA, and are anionic in charge (214). In contrast, B cells of SNF1 mice make predominantly IgG2b anti-dsDNA that is cationic (214 ,215). Cationic charge probably is important in initiating nephritis, because cationic antibodies (or antigens or immune complexes) can bind to polyanions in glomerular basement membranes. IgG in glomerular eluates from BW mice also is enriched in cationic subpopulations (118 ,124), and it is those populations that bind directly to glomeruli when they are infused into old BW mice (218).

The presumed pathogens, IgG2b cationic anti-dsDNA, also are restricted in Id expression. The IgG in the glomeruli of SNF1 mice can be grouped into two families of Ids (213 ,215). The first, Id564, is composed entirely of cationic IgG, and most members bear the Igh allotype of the SWR parent. The second Id cluster, Id512, contains immunoglobulin of anionic, neutral, and cationic charge; the allotypes expressed are both SWR and NZB derived. Id564 is unique to SNF1 mice and is not found in either parent. This Id restriction is similar to that reported by our group in BW mice, where only two public Ids (IdGN1 and IdGN2) dominate the glomerular immunoglobulin deposits (163).

Sequence data show that the expression of Id564 depends on the VH region of the immunoglobulin molecule; $Id564^+$ monoclonal antibodies are closely related structurally and probably derive from a germline gene that is unique to the SNF1 mouse (216). One family of Ids, designated as $IdLNF^+$, has been used to track reciprocal T- and B cell functions that are connected by idiotypy. SNF1 mice also make antihistone antibodies, which are characterized by some clonal restriction and by somatic mutations, as are most autoantibodies in the mouse models (219).

Abnormalities of Stem Cells and B Cells

It is assumed that SNF1 mice inherit hyperactivated B cells from their NZB parent, but there are few data on the subject. The interesting features of this model include the demonstration that a nephritogenic anti-DNA subset can be constructed from the allotype of a normal parent given the appropriate additional genetic background. Idiotypic connectivity between B and T cells also has been particularly well described in this model (220 ,221 ,222). $IdLNF^+$ immunoglobulin does not contain much antibody to DNA, but nephritis and early death correlate with high serum levels of $IdLNF^+$ immunoglobulin and glomerular deposits of the Id, thus illustrating the role of non–DNA-binding immunoglobulin in the glomerular disease. Suppression of $IdLNF^+$ immunoglobulin by the administration of a specific anti-Id does not

downregulate serum levels of IgG anti-DNA, but nephritis is delayed and survival prolonged (222).

Abnormalities of T Cells

Studies suggest that the T-cell abnormalities of BW mice are reiterated in the SNF1 model. B cells from SNF1 spleens (or BW spleens) secrete IgG anti-dsDNA (including cationic subsets) only when they are stimulated by T cells in culture (223 ,224). Those T cells may bear the classic $CD4^+CD8^-$ phenotype of helper T cells, or they may be $CD4^-CD8^-$ (223).

As mice age, their $CD4^+$, $IdLNF^+$-specific repertoire expands greatly. There is little TCR restriction in the expanding $CD4^+$ cells. Transfer of a few T-cell clones that are specific for the Id increased the Id^+ immunoglobulin production in young SNF1 mice (220 ,221). Some of the T cells that help anti-DNA production recognize a small number of peptides in the histones found in nucleosomes (225); autoantibodies production and disease can be dramatically delayed by administration of some of those peptides in very small quantities (186).

Genetics

As in the BW mouse, genes contributed from both parents are necessary for disease in the SNF1. Some genes clearly are linked to H-2. However, one study suggests that nephritis also is influenced by the TCR-ß chain (which contains a large deletion similar to the NZW) as well as by the I-A-chain genes of the SWR parent (224).

Summary

The SNF1 mouse is another example of female-dominant, T-cell–dependent lupus nephritis in a hybrid mouse with an NZB background. The nature of the antibodies that deposit in glomeruli has been particularly well studied and is somewhat oligoclonal, thus providing important information about the characteristics and genetic control of pathogenic subsets of autoantibodies.

(NZB × SJL) F1 (NS) Mice

The female predominance of lupus-like disease was also demonstrated in another NZB-based strain, where the female, but not male, offspring of NZB crossed with SJL mice developed proteinuria and Ig deposits in the renal glomeruli and at the dermo-epidermal junction of the skin at 12-months of age (226). Female NS mice died faster and exhibited ANA, anti-dsDNA antibody and circulating immune complexes earlier in life and in greater amounts than male NS mice. The disease development in female NS mice is associated with thymic pathology characterized by the intrathymic accumulation of mature T and B cells (227). Ovariectomy of NS females reduced but did not prevent the accumulation of T and B cells in the thymus indicating that estrogen plays a minimal role in the thymic pathology of this strain. In contrast, chronic dihydrotestosterone (DHT) treatment of female mice, started at 4 weeks of age, inhibited the development of thymic lesions. Consistently, orchidectomy of NS males induced the appearance of “female-like” thymic lesions that could be prevented by DHT treatment. This demonstrates that the absence of thymic disease in NS males probably reflects an inhibitory action of androgens (228).

New Zealand Mixed (NZM) Mice

In 1993, Rudofsky et al. (73) reported a new strain of mice with SLE. They performed selective inbreeding of the progeny of one cross between NZB and NZW mice, selecting for severity of nephritis and coat colors. They derived 27 strains and studied 12, determining homozygosity for NZB and NZW polymorphic gene markers at H-2, Hc (i.e., a polymorphism for C4 on chromosome 2), and coat-color loci on chromosomes 2, 4, and 7. Most NZM strains have IgG anti-dsDNA antibodies. Some strains develop early onset nephritis in males and others in females similar to the BW F1, and some strains have little nephritis. These initial studies showed that there is not a strict requirement for H-2d/z heterozygosity to develop nephritis, but such heterozygosity increases susceptibility.

Subsequently, selected NZM strains were used to study the segregation of genes with manifestations of lupus. For example, the NZM/Aeg2410 line (i.e., more rapid and severe GN than in BW) was backcrossed to normal C57B1 mice for interval mapping of susceptibility loci (229). Three chromosomal intervals containing strong recessive alleles predisposing to GN were found on chromosomes 1, 4, and 7. All of these are contributed by the NZW parent: they have been designated SLE1, SLE2, and SLE3. Studies in single and double congenic mice have shown that SLE1 allows a mouse to break tolerance to chromatin, SLE2 permits B cell hyperactivity, and SLE3 permits T-cell (and some B cell) hyperactivity. Normal C57Bl/6J mice expressing SLE1 or SLE3 do not develop nephritis, but C57 mice expressing both chromosome regions develop nephritis. See the discussion of genetics of NZW mice above, and Chapter 7 for a more detailed discussion. In SNF1 mice, heterozygosity at H-2 correlates strongly with GN; the MHC alleles seemed to confer susceptibility independently and were additive (229). Subsequent studies in other strains have identified similar regions of chromosomes that contribute to GN, but as more and smaller segments of the mouse genome have been analyzed, the inheritance pattern has looked more like polygenic gene combinations without a strictly additive pattern of inheritance (see Chapter 7). Chapter 7 summarizes the genetics in the NZM and other strains, which are also available in many excellent reviews (230 ,231 ,232 ,233 ,234).

B cells in this strain are abnormal (like the NZB and BW) in that ligation of the BCR does not modulate LPS signals in a normal way (47).

NZM2328 mice, another New Zealand Mixed strain, develop autoantibodies and acute and severe chronic glomerulonephritis with female predominance similar to NZB/NZW F1 and humans with SLE (235). Chronic GN with glomerular sclerosis and tubular atrophy but not acute GN was correlated with severe proteinuria. Using a backcross analysis of (NZM2328 × C57L/J) F1 × NZM2328, Fu et al.

identified loci that could be linked to either autoantibodies production or to acute or chronic glomerulonephritis. Further, in this model adoptive transfer of $CD4^+CD25^+$ cells can suppress anti-DNA antibody production, but do not influence the development of glomerulonephritis (199). These authors further showed that the male NZM2328 mice that normally do not develop glomerulonephritis experience an accelerated onset of acute glomerulonephritis after day 3 thymectomy, but this acute glomerulonephritis does not progress to chronic glomerulonephritis.

When compared to MRL-lpr and BW mice, NZM2410 mice develop an accelerated onset of chronic glomerulosclerosis that can be suppressed by in vivo blockade of IL-4 by monoclonal antibody treatment or by genetic deletion of transcription factor Stat6 that inhibits production of and responsiveness to type 2 cytokines such as IL-4 (236). In fact, levels of IL-4 are markedly elevated in NZM.2410 mice, as determined using an in vivo cytokine assay. Germline deletion of Stat6 in NZM2328 mice has a similar ameliorating effect on glomerulosclerosis (237). Strikingly, antibody blockade or Stat6 deletion has no effect on IgG anti-dsDNA antibody levels and on renal IgG deposition in NZM2410 and NZM2328 strains. Thus, IL-4 effects on lupus nephritis in NZM2410 and NZM2328 models appear to be independent of IL-4 effects on autoantibody production. On the other hand, the germline deletion of Stat4, a transcription factor for type 1 cytokines, suppresses anti-dsDNA antibody production, but does not suppress the incidence of glomerulonephritis in NZM2410 and NZM2328 models (236 ,237).

These observations suggest that anti-DNA autoantibodies production and development of acute and chronic glomerulonephritis can be uncoupled in some models, raising the question of the direct cause-effect relationships between the presence of autoantibodies and lupus nephritis in some of the NZM strains.

MRL/Mp (MRL+/+) and MRL-Fas(lpr) Mice

The MRL-Fas(lpr) strain and the congenic MRL/Mp (MRL/+/+) (also called MRL/n) were developed by Murphy and Roths in 1976 (238). They were derived from LG/J mice crossed with AKR/J, C3HDi, and C57B1/6. By the 12th generation of inbreeding, the MRL-Fas(lpr) which is characterized by marked lymphadenopathy and splenomegaly, large quantities of antibodies to DNA, antibodies to Sm, and lethal immune nephritis, was derived. Lacking the lpr gene, MRL/+/+ mice share over 95% of the genetic material of the MRL-Fas(lpr) (14). The lpr (i.e., lymphoproliferation) trait occurred as a spontaneous mutation in a single autosomal recessive gene; the mutation results in a defective Fas molecule (239 ,240 ,241 ,242 ,243). Interactions of Fas and Fas ligand (FasL) are required for the initiation of apoptosis in activated B and T lymphocytes under normal immunoregulatory conditions (244). Therefore, mice that are homozygous for the lpr mutation (i.e., Fas (lpr), formerly designated lpr/lpr) develop massive lymphoproliferation, large quantities of IgG autoantibodies, and autoimmune disease (245 ,246 ,247). Table 18-5 lists features of this strain.

Table 18-5: Characteristics of MRL/lpr Mice

A. Clinical
1. Massive lymphadenopathy with expansion of $CD4^+$ and Thy1 + B220 + $CD4^-CD8^-$ TCR αß + (double negative or DNT) cells
2. Early death in males and females (50% mortality at 6 months)
3. Congenic strain MRL/++ lacks lpr; 50% mortality at 17 months
4. Deaths usually result from immune glomerulonephritis
5. Approximately one half develop acute necrotizing polyarteritis
6. In some colonies, approximately 25% develop destructive polyarthritis

B. Histologic
1. Subacute proliferation of mesangial and endothelial cells, occasional glomerular crescents, basement membrane thickening; deposits of immunoglobulin and C3 in glomeruli, especially in capillary walls; marked mononuclear cell infiltrate in interstitium
2. Acute polyarteritis of coronary and renal arteries
3. Proliferative synovitis, pannus formation, and destruction of articular cartilage—usually detected microscopically, not grossly
4. Thymic atrophy
5. Massive hyperplasia of all lymphoid organs, sometimes with hemorrhage and cystic necrosis

C. Autoantibodies
1. Monoclonal paraproteins in approximately 40%; IgG3 cryoglobulins are common
2. Most marked elevations of serum IgG, IgM, and immune complexes of all murine SLE models
3. ANAs at highest levels of all murine SLE models
4. IgG and IgM anti-dsDNA and anti-ssDNA
5. Anti-Sm in 10% of females and 35% of males
6. IgM and IgG rheumatoid factors in 65%; some IgG–IgG complexes
7. gp70–anti-gp70 complexes
8. IgM and IgG antibodies to DNA, snRNP particles, and phospholipid often are cross-reactive, suggesting that any of the antigens can activate the entire repertoire
9. Hypocomplementemia

D. Immune abnormalities
1. Lymphoid hyperplasia primarily results from expansion of unusual $CD3^+CD4^-CD8^-$ B220 + α/ß$^+$ T cells; they probably derive from activated $CD8^+$ cells that fail to undergo apoptosis
2. Appearance of these T cells and of early disease is strictly dependent on the lpr gene and also is thymus dependent; thymectomy prevents disease
3. High numbers of hyperactivated B cells appear just before onset of clinical disease
4. Autoantibodies, nephritis, arthritis, and CNS disease are prevented by elimination of $CD4^+$ cells; lymphoproliferation is not
5. Lymphoproliferation is prevented by elimination of $CD8^+$ cells; autoantibodies, nephritis, and arthritis are not affected
6. Defective Fc-mediated phagocytosis and clearance of immune complexes
7. Monocytes/macrophages are abnormal, with low expression of IL-1ß; and defective function

E. Genetics
1. Accelerated disease is produced by a single autosomal recessive gene, lpr; this mutation encodes a defective Fas molecule, so that very low levels of Fas are expressed on cell surfaces; engagement between Fas and FasL is infrequent, making Fas-mediated apoptosis defective; Fas/FasL interaction delivers a major signal for deleting activated T cells by apoptosis; mice homozygous for lpr develop lymphoproliferation on most backgrounds, but clinical autoimmune disease primarily appears in permissive backgrounds, such as MRL/++ and NZB
2. The congenic MRL/++ has a B cell repertoire that makes anti-DNA, anti-Sm, and rheumatoid factors; these autoantibodies probably are controlled by multiple genes, as in the NZB

Clinical Characteristics and Autoantibodies

MRL/+/+ mice are abnormal and develop late-life lupus. They make anti-DNA, anti-Sm, and rheumatoid factors, but serum levels are lower than those of MRL-Fas(lpr) mice. Male and female MRL/+/+ are similarly affected; most develop clinical nephritis with advancing age and are dead by 24 months (12 ,14 ,238).

In MRL-Fas(lpr) mice, the quantities of antibodies that are provided by the MRL/+/+ background are greatly amplified by T-cell help delivered by the $CD4^+$ cells expanded by lymphoproliferation (248 ,249 ,250 ,251 ,252 ,253 ,254 ,255 ,256 ,257 ,258), probably resulting from delayed/defective apoptosis because of the abnormal Fas gene. The most numerous cells that pack lymph nodes and spleen are not $CD4^+$; they bear the surface phenotype $CD3^+CD4^-CD8^-$ $B220^+$. They bear α/ß TCRs and therefore are part of the T-cell lineage. Presumably in normal mice the double negative cells are rapidly eliminated by apoptosis, and they accumulate in MRL-Fas(lpr) mice because of defects in this process. These mice die at 3 to 7 months of age.

Both male and female MRL-Fas(lpr) mice develop high serum levels of immunoglobulins, monoclonal paraproteins, ANAs, and immune complexes (the highest of all murine lupus strains) (12 ,14). They make IgM and IgG anti-ssDNA and anti-dsDNA, and they die from immune nephritis at a young age (90% dead by 9 months of age). Other autoantibodies in their repertoire include IgG antibodies that bind chromatin, histone, nucleosomes, nucleobindin (i.e., a DNA-binding protein), cardiolipin, erythrocyte surfaces, thyroglobulin, lymphocyte surfaces, Sm, Ul snRNP, Ro, La, Ku, Su, proteoglycans on endothelial cell membranes, neurons, ribosomal P, RNA polymerase I, C1q, and heat shock proteins (256 ,257 ,258 ,259 ,260 ,261 ,262 ,263 ,264 ,265 ,266 ,267 ,268 ,269 ,270 ,271 ,272 ,273 ,274 ,275 ,276 ,277). Additionally, they have gp70/anti-gp7O immune complexes (119). A substantial portion of MRL-Fas(lpr) mice develop IgG3 cryoglobulins, some containing rheumatoid factor activity (140 ,278 ,279). Many of these antibodies are closely related; that is, many antibodies to Sm, La, C1q, and nucleobindin also bind DNA. Anti-DNA, anti-Sm, and anti-La frequently use highly similar VH genes. The following features are found in MRL-Fas(lpr) and never, or rarely, in NZB mice and their hybrids: (a) massive lymphoproliferation, (b) inflammatory erosive polyarthritis (usually detected microscopically rather than grossly), (c) IgM rheumatoid factors, (d) severe necrotizing arteritis, and (e) antibodies to snRNP particles (12 ,14 ,238 ,257 ,269 ,270 ,271 ,272 ,273 ,280 ,281 ,282). In addition to the development of fatal nephritis, most MRL-Fas(lpr) mice develop lymphocytic infiltration of salivary glands, pancreas, peripheral muscles and nerves, uvea, and thyroid (283 ,284 ,285 ,286 ,287). In fact, they develop clinical thyroiditis with hypothyroidism, abnormal electrical transmission in muscles and nerves (suggesting clinical polymyositis and polyneuritis), learning disabilities, sensorineural hearing loss, and band keratopathy (285 ,286 ,287 ,288 ,289).

In females, anti-DNA is detectable in the circulation by 6 to 8 weeks of age, proteinuria begins at 1 to 3 months, and death associated with azotemia occurs at 3 to 6 months (12 ,14). Males lag behind females by approximately 1 month. IgG2a antibodies to DNA deposit in glomeruli, as do IgG1 and IgG3. The IgG3 cryoglobulins may be associated with either wire-loop, membranous-type lesions or with focal proliferative glomerular disease (140 ,278 ,279). The IgG anti-DNA repertoire is dominated by a public Id.H130 (217). Such dominance is reminiscent of the nephritis of BW and SNF1 mice. As for BW mice, there is some evidence that the first stimulating autoantigen is DNA linked to protein, such as chromatin or nucleosomes (274 ,275). After these antibodies mutate, specificities for other autoantigens could develop (e.g., ssDNA, dsDNA, phospholipid, Sm, La, and so on) (266 ,269 ,270). Antibodies to small nuclear ribonucleoprotein (snRNP) antigens, such as Sm, Ro, and La, occur in the MRL-Fas(lpr) and MRL/+/+ lupus-prone strains (12 ,14 ,267 ,268 ,269 ,270 ,276), and not in New Zealand strains. However, antibodies to snRNP have been found in the Palmerston North lupus-prone strain, discussed below (290). In MRL mice, antibodies to snRNP antigens are found in approximately 25% of animals. The reasons why some MRL-Fas(lpr) mice express anti-Sm and others do not is unclear; there are no demonstrable genetic or environmental factors that account for these differences (291). There may be a role for antibody specificities, however. The D epitope of Sm may contain helper epitopes that permit antibody expression, and the B epitope may contain suppressor epitopes (267). Antigen specificity for components of the polypeptides/nRNP complex is similar to the specificities of human anti-Sm. The anti-Sm response is dominated by public Ids (e.g., Y2), which can be found on human anti-Sm and on other human and murine autoantibodies (292 ,293). The ability to make anti-Sm does not correlate with clinical nephritis.

Histologic examination of the kidneys shows proliferation of mesangial and endothelial cells in glomeruli, occasional crescent formation, and basement membrane thickening, as well as interstitial infiltration by lymphocytes. IgG, C3, and anti-DNA are deposited in glomeruli; the presence of gp70 is variable and less constant than in NZB and related strains (294). Antibodies to RNA polymerase I also may contribute to nephritis (259). Renal failure is the primary cause of death.

Polyarthritis occurs in some MRL-Fas(lpr) mice with a prevalence between 15% and 25% (12 ,14 ,280 ,281). Years ago, these mice were reported to develop swelling in the hind feet and lower legs; today, most studies are done examining histology rather than observing gross evidence of inflammation (281). By 14 weeks of age, there is synovial cell proliferation with early subchondral bone destruction and marginal erosions. Cartilage is intact in this early lesion, and the synovial stroma is devoid of inflammatory cells. By 19 weeks of age, there is destruction of cartilage and subchondral bone that is associated with proliferating synovial lining cells and pannus formation. Mild inflammation occurs in synovial stroma but is remote from areas of cartilage damage. Focal arteriolitis can occur. By 25 weeks of age, the inflammatory response in synovium is more marked, but proliferating synovial lining cells continue to be present. Additionally, joint destruction has progressed to the development of periarticular fibrous scar tissue and new bone formation. The animals have rheumatoid factors and antibodies to collagen type II (12 ,14 ,280). There also is a correlation between the presence of IgM rheumatoid factor and arthritis. The rheumatoid factors in MRL-Fas(lpr) mice differ from those in MRL/+/+ and C57Bl6-lpr/lpr in that they are more likely to bind IgG2a than to bind other IgG isotypes (279 ,282). All of these features raise the possibility that MRL-Fas(lpr) mice are a model of spontaneous, genetically controlled arthritis, albeit arthritis that is relatively subtle. It is particularly fascinating that the initial destructive lesions are formed by proliferating synovium without inflammatory cells.

Acute necrotizing arteritis, primarily of coronary and renal arteries, is found in over half of MRL-Fas(lpr) males and females (12 ,14). Many have myocardial infarctions, but these seem to be more related histologically to small vessel vasculopathy than to inflammation of medium-sized arteries. The degenerative vascular disease consists of periodic acid-Schiff–positive eosinophilic deposits in the intima and media of small vessels without inflammation. Ig, C3, and occasionally gp70 can be found in the walls of medium and small arteries, venules, and arterioles.

T Cells, B Cells, Stem Cells, and the Thymus

Lymphoproliferation is the hallmark of MRL-Fas(lpr) mice. In both males and females, lymphadenopathy begins by 3 months of age (12 ,14). Nodes can reach 100 times their normal size and may develop hemorrhage and necrosis. Lymphoid malignancies are rare. Normal mouse strains onto which the Fas (lpr) gene is engrafted yield homozygotes with lymphoproliferation. Most of these develop anti-DNA, and varying proportions develop nephritis (not as universal or severe as in MRL-Fas(lpr) mice) (14 ,249). Therefore, the lpr gene encoding a defective Fas molecule with resultant diminished apoptosis creates a T-lymphocyte population in which highly autoreactive cells are not eliminated in a normal fashion. Other T cells, and probably B cells as well, also proliferate in the absence of some of the usual control mechanisms.

The development of lymphoproliferation may depend on $CD8^+$ cells, which are precursors of the double negative (DN) cells, or some DN cells may be a separate autoreactive lineage that is usually deleted in mice with normal tolerance mechanisms. MRL-Fas(lpr) mice that are treated with antibodies to CD8 or genetically engineered to fail to express CD8 or MHC class I molecules do not develop lymphoproliferation (295 ,296 ,297). The unusual $CD3^+$, $B220^+$, $CD4^-CD8^-$TCR- α/β cell that is so greatly expanded may derive from activated $CD8^+$ T cells that do not undergo the usual apoptosis following activation (244 ,247 ,298). On the other hand, the DN cell may be an independent lineage capable of certain functions. On in vivo transfer to chimeric mice, MRL DN cells did not develop into single positive cells (although the experiment did not strictly rule out the possibility) and their survival was short-lived (299). In other experiments (primarily in vitro), activation of DN cells caused them to express perforin and become cytolytic (300). However, the high levels of TGF-ß in serum of MRL-Fas(lpr) mice after immunization might suppress the cytolytic capacity of the DN cells in vivo (301). The DN T cells also may play a role in nephritis; this is the best evidence that they are active in vivo. Some T cells cloned from kidney infiltrates have the DN surface phenotype and are autoreactive and kidney-specific, proliferating to renal tubular epithelial and mesangial cells (302 ,303). When activated in vitro, they induce MHC class II and intracellular adhesion molecules (ICAM-1) on cultured tubular epithelial cells; the cytokines encoded by mRNA in the T-cell clones include IL-4, TNF-α, and IFN-γ. Tubular epithelial cells may play an important role in MRL nephritis, because they can process antigen and act as APCs (304).

The autoantibodies, vasculitis, arthritis, and Ig-induced nephritis of MRL-Fas(lpr) mice depend largely on $CD4^+$ cells. Studies of mice (a) after the administration of antibodies to CD4, (b) in which MHC class II is knocked out (thus preventing development of $CD4^+$ T cells), or (c) that lack CD4 molecules show that these disease features do not develop (251 ,295 ,296 ,305 ,306). The presence of the lpr gene causes marked expansion of $CD4^+$ cells at the same time that the DN population is increasing. In fact, T-cell help for syngeneic B cells is more marked in MRL-Fas(lpr) than in NZB or BXSB mice (14). T cells probably are not entirely incapable of undergoing apoptosis; the protein kinase C–dependent pathway for apoptosis is intact (307). The genes that are used to assemble the TCRs on MRL-Fas(lpr) cells are diverse (252). There may be some restriction in clonality at the onset of disease; TCR-Vß8 families were abundant in lymphoid or salivary glands in some studies (308). As disease progresses, however, multiple different clones are involved (252 ,309). T cells in the periphery have other abnormal features. The ability of MRL-Fas(lpr) T cells to cap, proliferate, and express IL-2 surface receptors and to

secrete IL-2 after antigenic or mitogenic stimulation is impaired (254 ,310). This may result from deficient signaling via the phosphoinositide pathway (311). There is increased tyrosine phosphorylation of p561ck in splenic T cells of MRL-Fas(lpr) mice with increased levels of intracellular polyamines (312). In lymph nodes, quantities of mRNA encoding IL-6, IL-10, and IFN-γ are increased (313), suggesting the participation of both Th1 and Th2 cells in disease. Cytokine gene therapy has been studied (314), and monthly intramuscular injection of cDNA expression vectors encoding for TGF-ß or IL-2 altered MRL-Fas(lpr) disease. TGF-ß prolonged survival, decreased autoantibodies and total IgG, and suppressed histologic damage to kidneys. IL-2 decreased survival and increased autoantibodies and IgG production.

The Fas-defective T cells of MRL-Fas(lpr) mice can be destructive in non-lpr backgrounds. When T cells are transferred to MRL/+/+ or SCID mice, graft-versus-host wasting disease occurs, probably because there is little Fas on the donor T cells to engage FasL on hepatocytes and other cells in the recipients. Therefore, the donor T cells, when activated, do not enter apoptosis but survive and mediate perforin-induced cytotoxicity of the target recipient organs (315 ,316 ,317).

There is debate regarding the role of B cells in the pathogenesis of MRL-Fas(lpr) lupus. The hyperactivation of B cells and abnormalities of pre-B stem cells that clearly are present in NZB mice, their hybrids, and BXSB mice are far less dramatic in the MRL background. However, MRL-Fas(lpr) B cells that are isolated from T cells are hyperactivated (318). They hyperrespond to stimulation with LPS or IL-1 (319 ,320 ,321), display increased quantities of IL-6 receptors on their surfaces (322), and do not undergo anergy or receptor editing (two mechanisms of B cell tolerance) as efficiently as B cells in normal mice (323). Perhaps all of these qualities reflect the importance of normal Fas/FasL interactions in B cells, or the influence of the large populations of helper T cells to which the B cells are exposed. There is restricted B cell clonality to several autoantigens, such as rheumatoid factor that binds IgG2a, but this is similar to the situation in both BW and normal mice making antibody responses after stimulation by specific antigens (324). In MRL-Fas(lpr) mice the contribution of the MRL background apparently provides B cells with appropriate antibody repertoires to cause autoimmunity.

Stem cells in these mice may be less abnormal than stem cells in other SLE mouse models. One group has reported significant delay in disease onset after syngeneic bone marrow transplantation (325). MRL-Fas(lpr) mice underwent immunoablation with high-dose cyclophosphamide and then received syngeneic bone marrow that was depleted of Thy1.2 cells. Mean survival was 350 days, compared with 197 days in untreated controls, and lymphadenopathy did not develop. This is a curious finding, because all background genes, as well as the lpr gene, would be transferred with the marrow. It suggests that removing T cells can reset the thermostat for autoimmunity, and many weeks are required for disease to begin again.

The thymus is structurally abnormal in MRL-Fas(lpr) mice, as it is in all strains that develop spontaneous SLE (326). Thymic cortical atrophy is severe and medullary hyperplasia common, as in NZB and BW mice (62 ,63). The numbers of epithelial cells in the subcapsular and medullary regions are decreased, and there are cortical holes in which no epithelial cells can be seen. Total cortical thymocytes are decreased in number. Levels of DN cells are high, while levels of single-positive cells are low, thus suggesting the inability of activated DN cells to undergo apoptosis. Studies with superantigens have suggested that early intrathymic deletion of autoreactive T cells is normal in MRL-Fas(lpr) mice (327 ,328), but that this may be impaired at older ages (329 ,330). Both thymic and peripheral deletion mechanisms for T cells likely are affected profoundly by the defect in apoptosis, which eliminates highly autoreactive activated T cells from the repertoire (244 ,245 ,246 ,247 ,329 ,330). In fact, SLE in MRL-Fas(lpr) mice may be more thymus dependent than in other strains. Thymectomy of newborn MRL-Fas(lpr) mice prevents development of lymphoproliferation and autoimmune disease (13 ,14 ,331), and MRL-Fas(lpr) thymus engrafted into MRL/+/+ mice causes lymphoproliferation and early death from autoimmune nephritis (14).

Abnormal cell functions also extend to populations other than lymphocytes. Neutrophils from MRL-Fas(lpr) (but not MRL/+/+) mice have a marked defect in Fc-receptor–mediated phagocytosis, which develops at the time of onset of autoimmune disease; this may result from elevated levels of TGF-ß in the serum. Their ability to access areas of inflammation also may be impaired (332). Macrophages make abnormally small quantities of IL-1 (188 ,333), and immune complexes are not cleared as efficiently as in normal mice (334).

Genetics

The role of the lpr gene (and of the defective Fas molecule it encodes) as a disease accelerator is fairly well understood. The lpr allele on chromosome 19 is a mutation in the Fas gene resulting from an early retroviral transposon insertion in the intron between exons 2 and 3, which results in abnormal RNA splicing with a frame shift and premature termination of the mRNA (239 ,240 ,241 ,242 ,243). Mice that are homozygous for lpr express very small amounts of Fas on their cell surfaces. Normal mice express high levels of Fas on activated T and B lymphocytes and on $CD4^+CD8^+$ thymocytes, and lower levels on proliferating cells in the thymus, gut, skin, heart, liver, and ovary. Fas in concert with the FasL transduces signals, which usually results in stimulation via activation of protein tyrosine kinase, which phosphorylates a nuclear RNA-binding protein TIA-1, a ceramide-mediated apoptosis pathway, IL-1–converting enzyme (ICE), cysteine proteases, and protein tyrosine phosphatase 1C gene (PTP1c) to promote apoptosis. On the other hand, Fas/FasL interactions can activate the Abl kinase to inhibit apoptosis (335 ,336 ,337 ,338 ,339 ,340 ,341 ,342 ,343 ,344 ,345).

Presumably, mice that are homozygous for lpr are unable to delete highly autoreactive T (and possibly B) cells in the periphery, which accounts in part for their high production of multiple autoantibodies. Activation-induced cell death (AICD) has been shown to depend in part on Fas/FasL interactions in

$CD8^+$, Th0, and Th1 $CD4^+$ T cells, and B cells (346 ,347 ,348). Lpr B cells resist apoptosis (349). Fas/FasL also is essential for killing by $CD4^+$ Th1 cells and is one of two pathways that are used by $CD8^+$ cytotoxic lymphocytes (350 ,351). Anergic autoreactive B cells are normally eliminated by $CD4^+$ T cells; in the absence of normal Fas/FasL interactions, the B cells are activated rather than killed (352). The genetic defect in Fas also accounts for the accumulation of $B220^+$, $CD4^-CD8^-$, and TCR^+ T cells that cause the massive lymphadenopathy associated with lpr/lpr. MHC class II knockout MRL-Fas(lpr) mice that lack $CD4^+$ cells do not develop SLE despite massive lymphadenopathy (305). MRL-Fas(lpr) mice that are transgenic for the gene encoding normal Fas molecules do not exhibit the acceleration of disease characteristic of the wild strain (353). The introduction of Fas(lpr) into any mouse strain results in lymphadenopathy of various degrees and production of autoantibodies; only strains that are genetically susceptible to SLE develop high-titer autoantibodies and full-blown clinical autoimmune disease.

MRL+/+ background genes are essential for the development of full-blown SLE. As in NZB and NZB hybrid mice, backcross studies have shown that the abilities to secrete large quantities of immunoglobulin and to make several different autoantibodies segregate independently of each other. More recent analysis of the MRL-Fas(lpr) mouse genome by microsatellite methods has identified two regions that associate with nephritis, one on chromosome 7, and one on chromosome 12. Interestingly, no linkage was found with the region on chromosome 17 that encodes the MHC (240). This is different from other murine models of spontaneous SLE. Genome scanning of MRL-Fas(lpr) and C57B1/6-Fas (lpr) mice (354) showed that lymphadenopathy and splenomegaly are linked to regions on chromosomes 4, 5, 7, and 10, designated Lmb l–4. Lmb l, 2, and 3 were also linked to anti-DNA but not nephritis; in contrast, Lmb4 was linked to nephritis. Lmb 1 was derived from the C57B1 background; Lmb 2, 3, and 4 were from MRL. These loci appeared to be additive. At the time of this writing, the single gene(s) within these chromosomal regions have not been identified.

Summary

MRL-Fas(lpr) mice are particularly interesting as a model of the accelerating factor for autoimmunity that can be provided by a single gene being added to a susceptible host. The massive lymphoproliferation that is associated with the autosomal-recessive lpr gene almost surely results from defective apoptosis. The resultant expansion in $CD4^+$ T cells drives predisposed MRL B cells to make the largest array of autoantibodies that occurs in murine lupus. The production of pathogenic autoantibodies and the presence of cytolytic DN cells and of $CD4^+$ T cells in target organs such as kidneys and salivary glands result in accelerated autoimmunity and early death from lupus-like nephritis. Some MRL-Fas(lpr) mice develop destructive polyarthritis, which often is associated with IgM rheumatoid factors. MRL mice are the only strains that spontaneously make anti-Sm. They also develop vasculitis, which can be severe.

BXSB Mice

The BXSB strain was developed by Murphy and Roths (355 ,356). BXSB is a recombinant inbred (RI) strain; RI mice are derived by brother/sister matings within each generation, usually extending for 12 to 20 generations. The RI technique is used to produce strains with high frequencies of homozygosity at many loci to see the expression of recessive genes. The initial mating was between a C57BI/6 (B6) female and a satin beige (SB/Le male), hence the designation BXSB.

The unique features of BXSB mice are that disease is much worse in males than in females, and the disease-accelerating gene that is responsible for this difference is located on the Y chromosome. The gene is called *Yaa,* for Y chromosome-linked autoimmunity accelerator. The female BXSB mice develop late-life lupus; therefore, additional genes contribute to disease, as in all other models of spontaneous lupus studied to date (Table 18-6).

Clinical Manifestations and Autoantibodies

BXSB mice make an autoantibodies repertoire that includes IgG antibodies to ssDNA and dsDNA, chromatin, C1q, ANA, and antibodies that are directed against brain cells (12 ,14 ,357 ,358). Additionally, a small proportion make antierythrocyte, NTA, monoclonal paraproteins, and gp70anti-gp70 immune complexes (12 ,14). By an early age (3 months), they have elevated levels of circulating immune complexes and hypocomplementemia (12). Serum levels of C4 diminish as clinical disease appears (359).

Death is caused by immune glomerulonephritis (12 ,14 ,358). Histologically, the disease is more exudative than in other mouse models. That is, there are neutrophils invading glomeruli along with IgG and C3 deposition, proliferative changes in mesangia and endothelial cells, and basement membrane thickening (12). The progression from nephritis to death is rapid, with 50% of males dead by 5 months of age (12 ,14 ,358 ,359).

T Cells, B Cells, Stem Cells, and the Thymus

Lymphoproliferation occurs in BXSB mice; it is more marked than in BW but less dramatic than in MRL-Fas(lpr) (12 ,14). In contrast to MRL-Fas(lpr) mice, the hyperplastic nodes contain predominantly B cells (13 ,14), and for some time it was thought that B cell defects were the primary abnormality in BXSB mice. As in the other models, B cells are hyperactivated, higher portions are mature (expressing IgD and IgM on their surfaces), higher proportions display CD40L on their surface, and secretion of IgG and IgM is increased (13 ,14 ,360 ,361). The B cells are resistant to tolerance with human gamma globulin; the resistance is a property of the B cell itself and does not reflect abnormalities in APCs or T cells (362). Studies in Yaa^+Yaa-double bone marrow chimeric mice show that Yaa^- T cells can activate Yaa^+ B cells to make autoantibodies (or increased antibodies to foreign antigens), but Yaa^+ T cells cannot drive Yaa- B cells to make autoantibodies (363 ,364).

This probably indicates that Yaa+ B cells present antigen to T cells and the two cells cross-activate each other. However, BXSB T cells play an important role in disease (365 ,366) by providing help for autoantibodies formation. As mice age, they develop the typical T-cell defects of SLE mice (i.e., abnormally low proliferative responses to antigens/mitogens, reduced production of IL-2). Elimination of CD4+ T cells (but not CD8+) suppresses autoantibodies, monocytosis, and nephritis (366). Production of mixed chimerics in BXSB mice created by lethal irradiation followed by transfer of bone marrow from nonautoimmune BALB/c mice plus congenic marrow depleted of T cells prolongs survival, prevents nephritis, and restores normal primary immune responses (which are abnormal in mice receiving only allogeneic cells). Depletion of BXSB T cells is essential to the success of this approach (367). In sum, it is clear that T cells are required for development of full-blown disease. Disease is delayed by the prevention of second signal-mediated T-cell activation after administration of CTLA41g (368). As BXSB males age, their T cells acquire a memory phenotype and secrete lymphokines that are characteristic of both Th1 and Th2 cells (369 ,370). Recent experiments showed that BXSB disease is not altered in mice deficient in IL-4 (371).

Table 18-6: Characteristics of BXSB Mice

A. Clinical
1. Males die early of lupus (50% mortality at 5 months; 90% at 8 months)
2. Females have late-onset lupus (50% mortality at 15 months; 90% at 24 months)
3. Major cause of death is immune glomerulonephritis

B. Histologic
1. Males show severe acute to subacute glomerulonephritis, with proliferation and exudation of neutrophils into glomeruli
2. In males, IgG and C3 deposit in mesangium and glomerular capillary walls by 3 months of age; deposits in tubular basement membranes and interstitium also occur
3. Lymph node hyperplasia (10–20 times normal size) in males
4. Myocardial infarcts in 25%, without arteritis
5. Thymic cortical atrophy with medullary hyperplasia; thymic epithelial cells contain crystalline inclusions

C. Autoantibodies
1. All males develop ANAs and IgG anti-dsDNA and anti-ssDNA
2. Less than one-half of males develop monoclonal paraproteins, antierythrocyte antibodies, gp70–anti-gp70, and thymocytotoxic antibodies
3. Hypocomplementemia in males by 3 months of age; low C4 levels
4. Elevated levels of circulating immune complexes
5. Defective monocyte/macrophages

D. Immune abnormalities
1. B cell is the most frequent cell in hyperplastic lymph nodes
2. B cell hyperactivation and advanced maturity
3. B cells are resistant to tolerance with some antigens
4. Male bone marrow transferred to female BXSB mice produces accelerated disease; female marrow confers late lupus when transferred to males; mature male B cells do not accelerate disease; abnormality is contained in marrow stem cells
5. Monocytosis occurs
6. Elimination of CD4+ T cells diminishes anti-DNA, monocytosis, nephritis, and mortality
7. Disease is not influenced substantially by thymectomy
8. Disease is not influenced substantially by sex hormone therapies and/or castration
9. Defective Fc-mediated immune complex clearance

E. Genetics
1. A single gene that accelerates disease, Yaa, is present on the Y chromosome; Yaa is probably overexpression or duplication of the Tlr 7 gene
2. Additional genes that behave as X-linked recessives confer susceptibility to disease; they may account for late-life SLE in females

The thymus shows cortical atrophy and defects similar to those in other SLE strains (326 ,372). Crystalline structures have been described in the thymic epithelial cells of BXSB males; they are thought to represent abnormal storage of thymic hormones (373). Apoptosis of thymic cells is delayed in all SLE strains studied, including BXSB. Thymectomy has accelerated disease in some studies and has not altered it in others (13 ,374). The effects are not as consistent and dramatic as the protection from disease that is conferred by thymectomy in MRL-Fas(lpr) mice(13 ,14 ,331).

An additional feature of BXSB mice is monocytosis. By 2 weeks of age, BXSB males have increased numbers of monocyte colony-forming units in spleen and lymph nodes (375). Further, the monocytes/macrophages are abnormal; they make unusually large quantities of procoagulants, which might contribute to the rapid damage of glomeruli that characterizes lupus in this strain (376).

Studies of lymph nodes show dramatic increases in mRNA for IL-1, with some increase in IL-10 and TGF-ß, all of which probably come from monocytes. IFN-γ also is increased, suggesting simultaneous increase in monocyte/macrophage and T-cell activity (313).

There is good evidence that a stem cell abnormality is crucial to the development of disease in BXSB mice (14 ,377), because male BXSB bone marrow can transfer disease and normal marrow grafted into male BXSB mice can prevent disease (14 ,377 ,378 ,379). This stem cell defect may lead to a single abnormality that affects both B and T cells, or there may be multiple genes influencing multiple responses leading to hyperactivity in each type of lymphocyte and in monocytes.

Manipulations such as castration and androgen therapy do not dramatically alter outcome (13 ,14 ,380), in contrast to mice with New Zealand backgrounds.

Genetics

Multiple genes predispose to SLE in BXSB mice, as in the other models. There is an inherent tendency toward autoimmune disease in BXSB mice of both sexes; that tendency is dramatically accelerated by the introduction of the *Yaa* gene on the Y chromosome. This accounts for the earlier, more severe disease in males. If normal mice are generated that bear the *SLE1* gene

from NZW mice (a gene associated with ability to break tolerance to nucleosomes) and the *Yaa* gene, fatal autoimmune nephritis occurs (87). *Yaa* has recently been shown to be overexpression (or duplication) of the *TLR7* gene (703 ,706). The *Yaa* gene alone is not sufficient to permit the development of autoimmunity: MHC and other genes play important roles (381 ,382 ,383 ,706). The *Yaa* gene represents a duplication of the *TLR7* gene because of a 4-megabase expansion of the pseudoautosomal region (703). This results in increased expression of TLR7, a single-stranded RNA-binding innate immune receptor, which appears to cause an intrinsic bias of Yaa-containing B cells toward nucleolar antigens. Thus, the Yaa locus represents an example in which qualitative phenotypic differences in disease pathology are derived from a copy number polymorphism, a genetic event that has been shown to be common both in mice and humans (704). Mice of the H-2b haplotype (BXSB is H-2b) do not express MHC class III-E molecules; introduction of the I-Eα chain into BXSB males permits the mice to display I-E on cell surfaces and prevents disease (384 ,385 ,386). This effect is controlled by MHC and occurs only in mouse strains with “permissive” MHC such as H-2b (387). The I-A molecule in the transgenic mice contains peptides from I-E, and it is possible that those peptides prevent the presentation of other peptides that induce and sustain pathogenic autoantibodies production (387). Susceptibility to autoimmunity is transmitted as an autosomal dominant trait in some F1 hybrids that are derived from BXSB (381 ,382 ,383), and in others susceptibility behaves as if it were controlled by autosomal-recessive genes (14).

Results of genome scans of backcrosses between BXSB and B10 mice have been published (388 ,389). Three to four regions on chromosome 1 and a region on chromosome 3 are linked to nephritis. One publication reports linkage with a region on chromosome 13, the other with regions on chromosomes 4 and 10. The regions on 1 that are telomeric have been linked to SLE in other strains; the other regions may be unique to BXSB.

Summary

In summary, BXSB mice are unique in that lupus nephritis is more severe and occurs earlier in males than in females; this is from the accelerating effect of a single gene, Yaa, which excludes enhanced expression of TLR7 which is located on the Y chromosome. Disease develops rapidly in BXSB males, with 50% dead of immune glomerulonephritis by 5 months of age.

B cells, T cells, and monocytes all have abnormal functions, most of which suggest hyperactivation. The autoantibodies repertoire is directed primarily against nucleosomal and DNA antigens. Multiple genes participate, some of which are shared in other lupus mouse strains and some of which are probably unique to the BXSB background.

The BXD2 (C57BL/6J × DBA2J) Model of Spontaneous Erosive Arthritis and Glomerulonephritis (“Rhupus”)

The BXD2 strain of mice is one of approximately 80 BXD recombinant inbred (RI) mouse strains that were generated originally by Dr. Benjamin A. Taylor at the Jackson Laboratory (Bar Harbor, Me, USA) by inbreeding the intercross progeny of a cross between C57BL/6J and DBA/2J strains for more than 20 generations (390). During the course of a survey to discover genetic loci that influence T-cell senescence by using a set of 20 of the BXD RI strains, Mountz and colleagues observed the development of spontaneous arthritis in the BXD2 strain in specific pathogen-free conditions (391). The adult mice spontaneously develop generalized autoimmune disease, including glomerulonephritis (GN), increased serum titres of rheumatoid factor (RF) and anti-DNA antibody, and a spontaneous erosive arthritis characterized by mononuclear cell infiltration, synovial hyperplasia, and bone and cartilage erosion. The arthritis affects 50% of female mice by 8 months and 90% at ages >12 months. There is a female predominance, as the incidence of arthritis in male mice is lower than that in female mice. The mice also exhibit splenomegaly, but lymphadenopathy is not a pronounced feature.

The features of lupus and arthritis developed by the BXD2 mice segregate in F2 mice generated by crossing BXD2 mice with the parental B6 and D2 strains. Genetic linkage analysis of the serum levels of anti-DNA and RF by using the BXD RI strains shows that the serum titers of anti-DNA and RF were influenced by a genetic locus on mouse chromosome (Chr) 2 near the marker D2Mit412 (78 cm, 163 Mb) and on Chr 4 near D4Mit146 (53.6 cm, 109 Mb), respectively. Both loci are close to the B cell hyperactivity, lupus or GN susceptibility loci that have been identified previously. Thus, the BXD2 strain of mice is a novel polygenic model for complex autoimmune disease that spontaneously develops both generalized autoimmune disease, including renal disease, and chronic erosive arthritis (391).

The (NZW × BXSB)F1 Model of Antiphospholipid Syndrome and Coronary Artery Disease

Disease Characteristics and Autoantibodies

Male hybrid (NZW × BXSB)F1 mice have been particularly interesting as models of autoimmunity linked to accelerated degenerative coronary artery disease, a combination seen in some patients with SLE. In these mice, 50% of the males are dead by 24 weeks of age, usually with extensive MI, with occlusive disease and intimal thickening in small coronary arteries but not extramyocardial coronary arteries. These mice also develop high serum levels of anti-DNA and immune complexes, with antibodies against both platelets and phospholipids. Some monoclonal anticardiolipin antibodies also bind platelets and DNA, similar to some antibodies from BW mice. Most of the antiphospholipids bind β_2-glycoprotein I; such subsets may be more likely to be associated with clotting than subsets without that characteristic (392). The males also develop glomerulonephritis, hypertension, leukocytosis, gastrointestinal vasculitis, and thrombocytopenia (392 ,393).

Abnormalities in Stem Cells, T Cells, and B Cells

All these cells are abnormal, as in BXSB parents. Serum levels of IFN-γ and IL-10 increase as mice age. Treatment with antibodies to CD4 delays disease, whereas treatment with antibodies to CD8 accelerates it (394). Lethal irradiation of (NZW × BXSB)F1 mice followed by transfer of bone marrow from normal C57B1 mice prevents nephritis, coronary artery disease, and thrombocytopenia, suggesting that all of these manifestations result from immune and inflammatory processes (394). On the other hand, treatment with the calcium channel blocker ticlodipine prolongs survival and lowers the prevalence of myocardial infarction without affecting nephritis (395). Similarly, treatment with nifedipine lowers blood pressure and prolongs survival, protects partially from coronary artery stenosis and myocardial infarction, and reduces the amount of histologic nephritis (396). Therefore, the final expression of disease has immune, inflammatory, and degenerative components.

Genetics

One genome scan has shown linkage between various disease features and different chromosomal regions. Antibodies to cardiolipin, platelet-binding antibodies, thrombocytopenia, and myocardial infarction were each controlled by independently segregating dominant alleles. Regions on chromosomes 4 and 17 are linked to anticardiolipin, on chromosomes 8 and 17 to antiplatelet antibodies and thrombocytopenia, and on chromosomes 7 and 14 to MI (397). This suggests that there is not a simple direct association between antiphospholipid and myocardial infarct or thrombocytopenia; the antibodies and disease expression have complex genetic requirements.

Gld/Gld Mice with Absence of functional Fas Ligand (FasL)

In 1984, Roths et al. (398) reported a spontaneous autosomal-recessive mutation that occurred in the inbred mouse strain C3H/HeJ, which they called gld (for generalized lymphoproliferative disorder). It now is known that the mutation is a single base change in the C-terminal extracellular domain of the FasL molecule, which is encoded on mouse chromosome 6 (399 ,400 ,401); functional FasL molecules are not generated. FasL is expressed on cell surfaces, but the mutation interferes with its ability to bind Fas. Therefore, apoptosis does not proceed normally, highly autoreactive T and B cells persist instead of dying, and SLE results.

FasL plays a major role in apoptosis. Clinically, C3H/gld/gld mice of both sexes develop lymphadenopathy and splenomegaly by 13 weeks of age. Lymphoid organs contain increased numbers of B, T, and DN lymphocytes. The $B220^{+}CD4^{-}CD8^{-}TCR^{+}$ T cell that expands so dramatically in MRL-Fas(lpr) mice probably is identical to the major expanded population in gld/gld mice, since both strains have major defects in apoptosis mediated by Fas/FasL interactions. Recent evidence suggests that these DN cells require MHC class I expression for expansion, and contain populations with high avidity for self antigens such as endogenous retroviral superantigens; such a dangerous population is deleted in normal mice (402). C3H/Gld/gld mice have a shortened life span compared with wild-type C3H/HeJ, with male C3H/gld/gld mice living a mean of 396 days and females 368 days, compared with 688 days in females that are not homozygous for gld. Lymphoid cells and macrophages infiltrate the interstitium of lungs extensively, but other organs rarely are involved. Vasculitis does not occur. Most of these mice do not develop histologic lupus nephritis, although all mice older than 22 weeks have immunoglobulin deposits in glomeruli (primarily confined to the mesangium). By that age, serum levels of gamma globulin are approximately five times normal; this increase occurs in all isotypes but is most dramatic in IgA and IgG2b. ANAs begin to appear at 8 weeks of age, and all C3H/gld/gld mice are positive by 16 weeks. By 20 weeks, all have antibodies to thymocytes and antibodies to dsDNA (398 ,403). The primary cause of early mortality probably is the pulmonary disease. In C3H/gld/gld and BALB/gld/gld mice that live to 1 year of age, B cell malignancies are common (usually $CD5^{+}$ malignant plasmacytoid lymphomas) (404). As in other lupus models, genetic backgrounds in addition to the single point mutation determine the extent of disease: B6/gld/gld mice have milder disease than C3H/gld/gld.

The gld mutation has greatly increased our understanding of the importance of Fas/FasL interactions and of apoptosis in maintaining normal immune homeostasis. For example, lethally irradiated mice reconstituted with stem cells from Fas-deficient MRL/lpr mice develop chronic graft-versus-host disease (GVHD), but stem cells deficient in both Fas and FasL do not produce GVHD, showing that FasL is an important effector in this syndrome. Interestingly, these double-deficient T cells can induce normal B cells to produce autoantibodies (405). In pristane-induced murine lupus, lpr and gld mutations affect some autoantibody production but not others, suggesting that autoantibodies differ in their dependence on Fas and FasL expression by T cells (406). B6/gld/gld mice can clear cytomegalovirus after infection, but they cannot downregulate the resultant inflammatory responses (407). Nonobese diabetic (NOD) mice spontaneously develop autoimmune diabetes resulting from immune destruction of pancreatic ß cells. NOD/gld/gld mice are protected from disease, showing the dependence of the process on FasL-mediated apoptosis (408). Interestingly, lupus-like disease in C3H/gld/gld mice also requires TNF-α; mice deficient in that cytokine or treated with antibodies to TNF-α have milder disease (409). C3H/gld/gld disease can be prevented by lethal irradiation followed by reconstitution with a mixture of normal and gld bone marrow, as long as the normal marrow is not depleted of $Thy1^{+}$ cells, suggesting that T cells expressing FasL can correct the gld defect; $CD8^{+}$ $FasL^{+}$ cells are primarily responsible for suppression of lymphoproliferation (410).

In summary, autoiminune–permissive strains with defective production of FasL develop lymphoproliferation,

autoantibodies, and infiltration of organs with lymphocytes that cannot be deleted normally. Their disease has similarities to human SLE, as does disease associated with production of a defective Fas molecule in lpr-bearing strains.

Palmerston North Mice (PN)

PN mice are descendants of albino mice that were purchased from a pet shop in 1948 and raised at the Palmerston North Hospital in New Zealand. Inbreeding began in 1964, with animals being selected for ANA positivity. Autoantibodies and nephritis were characterized by Walker et al. (411) in 1978.

Clinical Characteristics and Autoantibodies

Fifty-percent survivals are 11 months for females and 15 months for males. The mice develop two main pathologic lesions: (a) necrotizing vasculitis of small and medium arteries; and (b) proliferative glomerulonephritis with fibrinoid necrosis, crescent formation, and glomerular deposits of IgG and C3. Arteritis occurs in spleen, thymus, kidneys, ovaries, and lungs, with sparing of the aorta. Lymph nodes are hyperplastic in some mice, and malignant lymphoma occurs. Thymic cortical atrophy occurs late (at approximately 11 months).

Anti-DNA and ANAs may be present at birth in some PN mice, and both increase with age until most animals are positive. By 1 month of age, all female PN mice have IgM anti-dsDNA and ssDNA, and the majority also produce IgM antibodies to cardiolipin. By 3 months of age, approximately 90% have IgG anti-ssDNa and -dsDNA. By 6 to 12 months, all females have IgG antibodies to cardiolipin and other phospholipids and the majority have IgG antibodies to erythrocytes (411). LE cells have been reported. As the mice age, the proliferative responses of their T cells tends to diminish, as in other lupus strains (412).

The most remarkable finding in PN mice is vasculitis. A recent report detailed the types of cells and cytokines in perivascular and vascular infiltrates. Perivasculitis dominated in arteries and veins in kidney, liver, brain, and lung; vasculitis dominated in veins and venules. The infiltrates were composed mainly of an unusual cell type with T-cell and B cell markers, in addition to $CD4^+$ expression. The predominant cytokines in lesions were IL-4, IL-6, and IL-10 with little to no IL-2, IFN-γ, TGF-β, or TNF-α. Therefore, these T-cell populations are mostly Th2 with little participation of monocytes/macrophages at the time the lesions are full-blown (413).

In summary, the PN mouse is a model of spontaneous autoantibodies, including antibodies to phospholipid, with impressive vasculitis and glomerulonephritis. The genetics are not yet well understood.

“Flaky Skin” (fsn) Mutant Mice

The autosomal recessive mutation “flaky skin” (fsn) causes pleiotropic abnormalities in the immune and hematopoietic systems accompanied by psoriasiform dermatitis, anemia, anti-dsDNA autoantibodies, glomerulonephritis accompanied by immune complex deposition in the kidneys, elevated IL-4 production by spleen cells, increased serum IL-4, and hyper-IgE (414 ,415). Additional systemic lesions include splenomegaly, granulomatous lymphadenitis, mixed inflammatory cell infiltrates and fibrosis around portal triads in the liver, progressive and massive papillomatosis of the stratified squamous epithelium of the forestomach, hyperplasia and dysplasia of the glandular stomach, increased apoptosis of cecal enterocytes and testicular degeneration (415).

The fsn mutation that was mapped to chromosome 17 (416) has recently been identified as a mutation in the tetratricopeptide repeat domain 7 (Ttc7) gene (417). This mutation is due to the insertion of an endogenous retrovirus (early transposon class) into intron 14 of the Ttc7 gene. The insertion leads to the reduced levels of wild-type Ttc7 transcripts in fsn mice and the insertion of an additional exon derived from the retrovirus into the majority of Ttc7 mRNAs. The Ttc7 is expressed in multiple types of tissue including skin, kidney, spleen, and thymus, but is most abundant in germinal center B cells and hematopoietic stem cells, suggesting an important role in the development of immune system cells.

Induction of Lupus in Normal Mouse Strains

In the previously discussed models of spontaneous SLE, multiple genetic factors likely provide the major if not the only important risk factors. Mutations in Fas (Fas-lpr) and FasL (gld) accelerate autoimmunity in these susceptible strains. However, there are several examples of the induction of SLE-like disease in mice that are otherwise healthy, with genetic backgrounds that do not predispose to autoimmunity. These include (a) induction of chronic GVHD; (b) alteration of expression of single molecules (either upregulation via transgene insertion or deletion in knockout mice); (c) transfer of pathogenic autoantibodies or the B cells that secrete them; (d) forced expression of pathogenic autoantibodies via the introduction of transgenes; (e) activation of idiotypic networks that result in the production of pathogenic autoantibodies; (f) inoculations of DNA, DNA/protein, other autoreactive proteins or oligopeptides, and (g) injections of hydrocarbon oils such as pristane. In most of these models, some strains of mice are more susceptible than others, again suggesting that most if not all murine genetic backgrounds contain genes that permit autoimmunity.

Chronic GVHD

GVHD is produced in mice by injecting lymphocytes from a parent into an F1 hybrid differing at one MHC locus from that parent. It is caused by T cells recognizing foreign MHC antigens (418). Acute GVHD is runting disease with failure to thrive, diarrhea, wasting, and early death (419). T cells that are defective in Fas expression (caused by the lpr gene) can cause acute GVHD in recipients with identical MHC class II

molecules, because they do not undergo apoptosis after activation (420). Acute GVHD is not lupus-like. If lymphocytes are injected after the recipient F1 animal has reached at least 6 weeks of age and if certain H-2 gene interactions occur between parent and F1, chronic GVHD results. Chronic GVHD resembles SLE (418 ,419 ,421 ,422 ,423 ,424). Several IgG autoantibodies are made, including anti-dsDNA, anti-ssDNA, and antihistone (418 ,421 ,424). In some combinations, fatal lupus-like nephritis mediated by the IgG anti-DNA occurs.

$CD4^+$ effector cells provided by the donor are required for induction of chronic GVHD (418 ,419); they must be activated by appropriate MHC class II gene products on the surface of the recipient cells (422 ,423). One combination that results in fatal nephritis of chronic GVHD is H-2d donor lymphocytes into an H-2b recipient (423 ,424). In contrast, most recipient H2k haplotypes are resistant. The development of clinical nephritis and of autoantibodies can be separated. Many parental hybrid combinations result in the ability of the recipient to make high-titer IgG anti-DNA, but class II genes I-A and I-E (equivalent to human HLA class II DR and DQ) must contain a susceptible haplotype, such as b, for severe nephritis to result (424). Animals without nephritis confine renal deposits of IgG to mesangial regions of glomeruli; animals with nephritis have IgG deposits along the capillary loops (424).

This model provides an excellent example of lupus nephritis resulting from interactions between $CD4^+$ T-helper cells, $CD8^+$ cytotoxic/suppressor cells, and APCs of a host that differs from the donor at MHC. Disease is initiated by donor $CD4^+$ cells activated by host APC to secrete IL-4, and B cell stimulation with autoantibodies production begins. Ability of the host to mount $CD8^+$ cells that kill the B cells determines whether acute or chronic GVHD will occur. Both acute and chronic GVHD may begin as a Th2 cytokine-mediated B cell stimulation; transition to acute GVHD depends on the education in the host thymus of donor-derived pro-T and pre-T cells to develop into double-positive cells and ultimately $CD8^+$ T cells that terminate the B cell hyperactivity by eliminating activated B cells (both perforin-mediated cytotoxicity and Fas/FasL killing occur). Activation of $CD8^+$ T is promoted by IFN-γ secretion by donor $CD4^+$ T cells. If thymic education does not occur, IL-4 secretion continues and B cells are not downregulated; sustained autoantibody production and lupus-like chronic GVHD result (425 ,426 ,427 ,428). Mice with severe chronic GVHD usually have high levels of IgE and IgG1 in their serum, confirming the important role of Th2 cells in disease. Antibodies to IL-4, or infusion of soluble IL-4 receptor, prevents or suppresses disease (429).

Genetic Alteration of Expression of Single Molecules: Increased Expression in Transgenic Mice

See Chapter 7 for a detailed discussion of genes in murine lupus. In Table 18-7 , various gene-targeted strains are grouped according to potential mechanisms by which over-expression or deficiency of certain genes causes humoral autoimmunity and lupus-like disease. Studies in which single genes are overexpressed in transgenic mice, or single genes are deleted in knockout mice, have all suggested that strategies that permit extended lifetimes for autoreactive lymphocytes or for autoantigens promote the development of SLE-like disease in normal mice. For example, overexpression of bcl-2 (which protects cells from apoptotic death) in normal mice transgenic for that molecule causes them to develop mild autoimmunity (430). Bcl-2 transgenic C57B1/6-lpr mice have lymphadenopathy but no abnormal autoantibodies (431). In C57B1/6-lpr mice transgenic for Pim-l (a cytoplasmic serine/threonine protein kinase that also inhibits apoptosis), lymphoproliferation resulting from the accumulation of $B220^+$ T cells also occurs (432). A molecule that stimulates the growth of B lymphocytes, which is variously named BlyS (B lymphocyte stimulator), BAFF (B cell activating factor belonging to the TNF-α family), THANK (TNF-α homologue that activates apoptosis, nuclear factor [NFI]-xB, c-Jun NH2-terminal kinase), TALL-1 (TNF-α and apoptosis ligand-related leukocyte-expressed ligand 1), and zTNF4, can induce autoimmunity when overexpressed. BLyS is a monocyte-specific TNF-α family cytokine that is a potent costimulator with anti-immunoglobulin M in vitro and with CD40L in vivo for B cell proliferation. BLyS enhances the humoral responses to T-cell–independent and T-cell–dependent antigens by protecting antigen-activated B cells from apoptosis (433 ,434 ,435).

Genetic Alteration of Expression of Single Molecules: Deleted Molecules in Knockout Mice

Table 18-7 summarizes various gene knockout strains that develop lupus-like disease. Two general categories of single gene deletion have led to generation of lupus-like disease in otherwise healthy mice: (a) removal of genes that downregulate accumulation and/or activation of B or T lymphocytes; and (b) deletion of genes that regulate normal degradation and clearing of DNA, immune complexes, or apoptotic cells and bodies. In the first category, normal mice with deletion of Lyn have a marked increase in IgM-secreting B cells and develop high levels of immune complexes and anti-DNA, along with a glomerulonephritis similar to SLE (436 ,437). Lyn is a Src protein tyrosine kinase associated with the BCR that participates in an inhibitory signal after BCR activation; Lyn phosphorylates the BCR coreceptor CD22, a process that recruits the tyrosine phosphatase SHP-1 to the BCR/CD22 complex and controls B cell activation. In the absence of Lyn, B cells exhibit spontaneous hyperreactivity, which doubtless contributes to their lupus-like phenotype (438). Motheaten mice (so called because of patchy alopecia) have spontaneous deletion of a single residue in the N-terminal SH2 domain of the protein tyrosine phosphatase 1C gene (PTP1c). PTP1c activity is absent, which may remove an inhibitory signal for the activation of Lyn and Syk, with resultant B cell

hyperactivation. IgM levels are high, B-1 B cells are abnormally activated, and high-titer ANAs develop, with immune complex deposition in many tissues (439 ,440). On the T-cell side, deletion of PD-1, an immunoglobulin superfamily member bearing an immunoreceptor tyrosine-based inhibitory motif (ITIM) that affects primarily $CD4^-CD8^-$ thymocytes also results in lupus-like disease (441). Similarly, expression of the cell-cycle regulator p21 prevents accumulation of $CD4^+$ memory cells; deletion of that molecule in normal mice results in loss of tolerance for nuclear antigens. Interestingly, female mice with a p21 deletion are particularly prone to develop SLE; they develop IgG antibodies to dsDNA, lymphadenopathy, Ig-mediated glomerulonephritis, and shortened survival (442).

Table 18-7: Gene Targeted Strains with Lupus-Like Phenotypes

Potential Mechanism	Targeted Genes*	References
Impaired apoptosis and cell cycle	Bcl-2Tg, Bim, CD95DIT, CDK, E2F2, Fas, Fas ligand, GADD45, IEX-1Tg, PtenHet, PtenT cell-CKO	(6,7,694,695)
Defective clearance of DNA, apoptotic cells, and immune complexes	C1q, C4, DNase, IgM (secreted), Mer, MFG-E8, SAP	(696,697)
Dysregulated lymphocyte activation caused by mutations in cell receptors and their ligands	BAFFTg, CD22, CD21/CD35, CD45PMt, CD152, FcγRIIB, G2A, IL-2Rß;, PD-1, TACI, TCR-α, TGFßRIIDNT or T cell-CKO	(5,6,698,699)
Dysregulated lymphocyte activation caused by intracellular signaling molecule mutations	Aiolos, Cbl-b/Vav-1, E2F2, Fli-1Tg, Gadd45a, LIGHTTg, Lyn, PKC-d, P21, Rasgrp1, SHP-1, SOCS-1, Stra13, TSAd	(5,6,699)
Cytokine production abnormalities	IFN-γTg, IL-4Tg, IL-10, TGFß	(6,700,701)
Defective hormone signaling	ERα	(702)

*Gene-targeted mice are conventional knockout mutations unless marked as Tg (transgenic overexpression), DIT (dominant interfering transgene that cause deficiency of the targeted molecule), Het (heterozygous for the targeted gene), CKO (conditional knockout), PMt (A point mutation in CD45 prevents dimerization and negative regulation of phosphatase activity), and DNT (dominant negative transgene).

In the second category—gene deletions that influence clearing of DNA, nucleosomes, apoptotic cells, and apoptotic bodies—several single gene deletions have produced lupus-like phenotypes in normal mice. Humans with homozygous deletions of C1q have a very high prevalence of SLE. Similarly, among mice in which the C1q gene was deleted, approximately half developed high-titer ANAs and 25% had clinical nephritis by the age of 8 months; glomeruli showed unusually abundant deposits of apoptotic bodies (443). C1q probably plays a role in clearance of immune complexes, of apoptotic cells, and of apoptotic bodies (444). Serum amyloid P component (SAP) binds to DNA and chromatin, displaces H-1 histones, and solublizes native long chromatin. SAP also binds to apoptotic cells (surface blebs contain chromatin) and to nuclear debris following cell necrosis. It is probably important in the disposal of these materials. Mice with deletions in the SAP gene developed autoantibodies, including anti-DNA, and severe glomerulonephritis (445). Mice deficient in DNAse1 also developed ANA, Ig deposition in glomeruli, and clinical nephritis (446).

In summary, these single gene knockout mice show that one alteration permitting B- or T-cell hyperactivation, or interfering with the elimination of DNA/nucleosomes or apoptotic and necrotic cells that provide stimulatory nucleosomes and other self antigens, is powerful enough to produce lupus-like phenotypes in mice that otherwise are resistant to clinical autoimmunity.

Lupus Induced by Direct Transfer of Pathogenic Autoantibodies or B Cells That Secrete Those Antibodies

See Chapter 21 for a detailed discussion of this topic. Briefly, our laboratory demonstrated that transfer of B cell hybridomas secreting pathogenic IgG anti-dsDNA to normal BALB/c mice resulted in the development of SLE, with circulating IgG anti-dsDNA and immune complexes and severe Ig-mediated glomerulonephritis (113 ,114). In some cases, mice were injected repeatedly with purified IgG rather than with hybridoma cells, with the same results. Injections of the immunoglobulin into C57B1/6 mice did not produce any disease, suggesting that background susceptibility genes, perhaps influencing the composition of the kidney, must be present for this approach to induce disease. SCID mice that were populated with BW pre–B cells developed SLE with the expected secretion of autoantibodies by their adopted B cells (162). Similarly, some human monoclonal antibody anti-DNA inoculated into SCID mice deposited in glomeruli and induced proteinuria (447).

Lupus in Mice Transgenic for Pathogenic Autoantibodies

Transient lupus nephritis developed in normal mice that were transgenic for an IgG2b anti-dsDNA derived from a nephritic BW female (116). The gene construct permitted only small

quantities of the transgenic IgG2b to be expressed on B cell surfaces, thus bypassing early tolerance mechanisms. Therefore, the transgenic mice secreted IgG2b anti-dsDNA for several weeks and, during that time, developed proteinuria. Later, B cell receptor editing occurred, with resultant elimination of the ability of the immunoglobulin to bind DNA; the proteinuria disappeared and the mice lived a normal life span. Mice carrying transgenes encoding anti-DNA from MRL-Fas(lpr) mice have also been generated and studied for B cell tolerance. In MRL-Fas(lpr) mice, anti-dsDNA B cells undergo receptor editing, while anti-ssDNA B cells are functionally silenced (448). In the lupus mice compared to normal BALB/c mice, developmental arrest of autoreactive B cells does not occur; in the presence of the Fas/lpr mutation anti-dsDNA, B cells find their way to lymphoid follicles, along with CD4 T cells, so that T-B interactions continue to drive clinical autoimmunity (323 ,449). To summarize, if normal mice express the transgene-encoded immunoglobulin on B cell surfaces, the cells are developmentally arrested, deleted, anergized, or receptor edited; cells do not reach T-B interaction sites in lymphoid organs, and secretion of the anti-DNA is short-lived if it occurs at all. If the transgenic mouse has an lpr background, these mechanisms of tolerance degrade over time, pathogenic B cells reach follicles where they can interact with T cells, and ANAs encoded by the transgene are secreted with steadily increasing titers. In another model using mice transgenic for the R4A-γ 2b heavy chain of an anti-DNA monoclonal antibody (mAb) (which can combine with multiple light chains to made a DNA-binding Ig), nonautoimmune hosts display a high-affinity population that is anergic, another high-affinity population that is deleted, and a third population that produced germline-encoded antibodies with low affinity for dsDNA that escaped normal regulation (450). Perhaps these low-affinity cells that normally escape regulation undergo activation and receive T-cell help in mice predisposed to SLE and thus become pathogenic anti-DNA–secreting B cells.

Lupus Following Activation of Id/Anti-Id Networks

Chapter 15 discusses the role of Id/anti-Id networks in SLE. Immunization with an Id induces anti-Id; immunization with an anti-Id induces anti-anti-Id and/or Id. This principle has been used to study murine models of SLE and of antiphospholipid syndrome. After immunization of BALB/c or other susceptible strains (again, C57B1/6 is resistant) with Id 16/6 (i.e., a frequently occurring Id in patients with SLE) or anti-Id 16/6, a full Id/anti-Id network appeared in the mice along with autoantibodies to DNA, to phospholipids, and to snRNP particles. The mice developed leukopenia, elevated sedimentation rates, and immunoglobulin deposits in glomeruli (451 ,452 ,453). Normal mice that were immunized with a monoclonal antiphospholipid IgM with lupus anticoagulant activity also developed an Id/anti-Id network, along with thrombocytopenia, lupus anticoagulant, and fetal loss (454 ,455). These models also have been used to test multiple therapeutic interventions (456 ,457 ,458 ,459 ,460 ,461). Both $CD4^+$ and $CD8^+$ cells may be necessary for the development of full-blown disease (460 ,462). It should be noted that C57B1/6 mice are not completely protected from SLE; when mated with a substrain of NZM/Aeg, some hybrids develop severe immune complex GN (73).

Lupus Induced by Immunization with DNA, DNA/Proteins, RNA/Proteins, or Oligopeptides

There has been great debate regarding the nature of the inciting antigens in SLE. Most investigators agree that DNA/protein and RNA/protein molecules and particles likely are the true immunogens in mice or humans who are predisposed to SLE. In general, naked mammalian DNA is a weak immunogen and does not induce SLE in normal mice unless it is bound to a protein (78 ,463 ,464). In contrast, bacterial DNA used to immunize normal mice can induce IgG antibodies to DNA (almost exclusively to ssDNA rather than dsDNA), and some animals develop immune complex nephritis (465). Whether this DNA acquires protein after immunization is unknown. Mammalian DNA used as an immunogen also can induce IgG anti-DNA and nephritis in normal mice if it is bound to protein. Thus, immunization with nucleobindin, which probably combines with nucleosomes that are released from the thymus and other tissues, can induce anti-DNA in normals (261), as can DNA that is combined with a fusion protein (463). Nucleosomes are particles in which DNA is wrapped around histones; they likely are direct immunogens that induce many of the autoantibodies characteristics of SLE.

Immunization of rabbits, mice, and baboons with protein or oligopeptide autoantigens (from Sm B/51, Ro 60-kd peptides, and La/SS-B) have induced epitope spreading, antinuclear antibodies, and proteinuria in a proportion of animals (466 ,467 ,468 ,469). However, one group of investigators found more limited epitope spreading in rabbits and mice after immunization with a peptide of Sm B/B8, less ANA production, and no clinical disease (470). This may reflect differences in environmental stimuli to which animals are exposed in different laboratories.

Lupus Induced by Injection of Hydrocarbon Oil

Chronic inflammation may induce autoantibodies in susceptible mice. Satoh et al. (471) injected pristane into the peritoneal cavities of BALB/c mice. Approximately half of these mice developed IgM anti-ssDNA, IgM antihistone, IgG anti-Sm, and IgG anti-Su. IgM, IgG, and C3 were found in glomeruli, predominantly in mesangial areas. This is excellent evidence that inflammatory stimuli can provoke autoantibodies production; whether that leads to disease, however, probably depends on concurrent immune responses and genetic susceptibility.

A single intraperitoneal injection of 2,6,10,14-tetramethylpentadecane (pristane) induces lupus-like autoantibodies in several inbred strains of mice (472). Pristane-injected BALB/c mice develop autoantibodies to nRNP/Sm, Su, and dsDNA, whereas similarly treated SJL/J mice produce anti-ribosomal P autoantibodies. Associated with

these autoimmune responses, mice of both strains experience an immune-complex-mediated glomerulonephritis (3 ,471). IgM, IgG, and C3 are found in glomeruli, predominantly in mesangial areas. The finding that BALB/c, CBA, and DBA mice develop an inflammatory joint disease after two intraperitoneal injections of pristane further increases interest in this animal model. The pristane-induced arthritis occurs between 100 and 200 days after the initial pristane injection (473). It preferentially involves ankle and wrist joints and presents several similarities to rheumatoid arthritis. A variety of autoantibodies, including rheumatoid factor, autoantibodies to collagen type II, and antibodies to stress proteins, are detected in the serum of affected mice. Contact with environmental microorganisms is necessary for the induction of pristane-induced arthritis, which reportedly does not develop in specific pathogen-free mice maintained in isolator cages. Interestingly, pristane-induced murine lupus is associated with marked hypergammaglobulinemia that is also influenced by microbial stimulation.

Because pristane selectively induces lupus-specific autoantibodies in virtually any strain of mouse regardless of its genetic background (474), this model is increasingly being used in testing the role of various genes on lupus manifestations using transgenic and knockout mice that are generally generated in normal mouse backgrounds. The use of hydrocarbon model in these experiments saves time and resources that would be required to backcross the null mutation from the stock (usually C57BL/6-Sv129) onto genetically lupus-prone strains. Further, pristane injection broadens the spectrum of lupus-like autoantibodies produced in genetically lupus-prone mice. For example, it induces anti-nRNP/Sm and Su antibodies that are not generally detected in genetically lupus-prone NZB/NZW F1 mice. Pristane injection also enhances anti-chromatin/DNA antibodies in these mice and dramatically accelerates lupus nephritis (475). Thus, environmental influences can trigger and exacerbate autoimmunity in genetically lupus-prone animals. Furthermore, injection with adjuvant mineral oils, such as Bayol F (Incomplete Freund's adjuvant: IFA) and squalene (MF59), also induces lupus-like autoantibodies production in otherwise normal BALB/c mice (476).

A Brief Overview of the Pathogenesis of Murine Lupus

Chapter 5 summarizes current concepts regarding the pathogenesis of SLE. Here, the information from murine lupus is briefly synthesized (Table 18-8).

Spontaneous murine lupus results primarily from genetic predisposition (almost always involving multiple genes in certain pathogenic combinations), from environmental stimuli, or both. It is likely that a susceptible genetic background is always required, because no single environmental trigger that accounts for disease induction or flare in all patients has been identified. However, the relative importance of genes and environmental triggers may vary.

Table 18-8: Pathogenesis of Autoimmunity in Murine Models of SLE

A. Genetic susceptibility
1. MHC genes (NZ and BXSB)
2. Multiple genes on different chromosomes, not linked to MHC
3. Single accelerating genes: lpr, Yaa, me

B. Immune abnormalities
1. Excessive T cell help by $CD4^+$ and $CD4^-$ $CD8^-$cells
2. Excessive B cell activation, partially independent of T cells, including B-1 and marginal zone B cells.
3. Defective generation of regulatory/inhibitory T cells, including $CD8^+$
4. Defects in bone marrow stem cells (NZ and BXSB mice)
5. Abnormal architecture and function of the thymus, with marked cortical atrophy
6. Defective clearance of apoptotic materials and immune complexes

C. Production of autoantibodies
1. Antibodies against DNA/protein and RNA/protein antigens
2. Antibodies against cell surface molecules including erythrocytes, lymphocytes and neurons
3. Antibodies against phospholipids

D. Infiltration of target organs by T cells capable of damaging the organ

E. Activation of dendritic cells by oligonucleotides from bacteria, viruses and DNA/anti-DNA complexes: DC then activate T cells

F. Environmental factors influencing disease
1. Diet
2. Sex hormone status
3. Infections
4. Neuroendocrine system

Examples of Spontaneous and Induced Mouse Models of SLE Illustrate These Points

In mice, multiple genes are required for the development of spontaneous SLE. Addition of accelerator genes to these backgrounds makes the disease appear earlier, such as Fas/1pr, gld and Yaa, each of which is discussed above. In most if not all strains MHC class II genes are critical, probably because they shape the $CD4^+$ T-cell responses that drive abnormal B cells, which already are prone to secrete large quantities of IgM and autoantibodies. Microsatellite analysis of DNA in the mouse genome has shown that multiple genes on different chromosomes are required for development of all SLE manifestations that are known to develop in NZ hybrids. There may be at least two or three genes that influence each manifestation (e.g., anti-DNA, early mortality, glomerulonephritis, and so on). In most strains, there is a region on the telomeric portion of chromosome 1 that contains at least one gene that significantly increases susceptibility; a syntenic region on human chromosome 1 has been

associated with SLE in several human populations. In total, there may be ten or more genes in each strain that in combination cause all of the manifestations that are associated with murine lupus, with some providing a higher proportion of susceptibility than others. (These concepts are discussed in detail in Chapter 7 .)

Additionally, there are several single genes that can be knocked in or knocked out of the genome of normal mice that result in lupus-like clinical disease. Most of them alter B- or T-cell survival and/or affect apoptosis.

The Role of Stem Cells, Thymus Cells, B Cells, and T Cells in Murine Lupus

Most investigators think that abnormalities occur in B and T cells of NZB, NZ hybrids, and BXSB mice. Therefore, a defect (or, more likely, multiple defects) in stem cells may underlie the disease. Transfer of bone marrow cells likely to be stem cells from NZ and BXSB mice have transferred the ability to make autoantibodies and develop disease to otherwise normal recipients (45 ,136 ,367 ,378 ,379). There is evidence that activation of both T and B cells is abnormal in that cells are too sensitive to stimulation, not eliminated properly after activation, or both. If there are one or a few abnormalities in cell activation that characterize any one strain, however, they have eluded detection thus far.

Thymic architecture is abnormal in all mice with spontaneous SLE (10 ,62 ,63 ,64 ,326 ,372). Basically, cortical atrophy occurs in all, and medullary hyperplasia may be seen. The function of thymic epithelial cells is abnormal. There must be profound effects on positive and negative selection of T-cell repertoires in these thymuses, but again, a basic functional defect that is common to all lupus mice remains to be identified. Thymectomy prevents development of disease in MRL-Fas(lpr) mice, but probably not in NZ strains or BXSB mice.

B cells are abnormal in NZ and BSXB mice. They are easily activated and increase in numbers over time (15 ,18 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,52 ,53 ,54 ,55 ,57 ,58 ,59 ,162 ,204 ,212 ,318 ,320 ,321 ,323 ,364). The IgM antibodies they make spontaneously probably are the origin of the pathogenic IgG autoantibodies that mediate tissue damage. All that it takes is the addition of T-cell help, and the disease becomes florid. B cells from MRL mice also may be abnormal, although the evidence for this is weaker than in the other strains. After all, the MRL-Fas(lpr) mouse makes far more autoantibodies than any other strain, both in terms of antigens that are recognized and total quantities of each antibody. Does this simply mean that any B cell has the capacity to make all of the autoantibodies that are characteristic of SLE? Or does the MRL B cell have characteristics that allow it to recognize a greater number of self antigens?

Finally, the T cell is required for full-blown SLE to develop in all strains with spontaneous disease. In all of the strains tested, depletion or inactivation of $CD4^+$ cells is a very effective intervention to prevent the appearance of disease and even to at least partially reverse established lupus (81 ,82 ,112 ,172 ,176 ,177 ,251 ,295 ,305 ,306 ,366 ,369). Recent studies have shown that murine lupus can be prevented by interrupting T- and B cell activation at the level of second signals. After TCR engagement by MHC/peptide, second signals through CD40-CD40 ligand (gp39), through CD28/CTLA4B7-1/B7-2 ligands, or through BlyS-TACI/BCMA are required for the production of cytokines by T cells and of immunoglobulin by B cells. Interruption of these second signals by the administration of antibodies or soluble receptors that prevent ligand interactions, or by knocking out one of the ligands, prevents development of high-titer IgG anti-dsDNA and of nephritis (176 ,177 ,368 ,433 ,434).

Role of Monocytes/Macrophages and Neutrophils in Murine Lupus

Monocytosis and increased cytokine production by monocytes/macrophages are features of the full-blown autoimmune syndrome in BXSB and MRL-Fas(lpr) mice (188 ,313 ,333 ,362 ,375). Monocytes/macrophages probably play important roles in disease. The glomeruli of MRL-Fas(lpr) mice are infiltrated with monocytes/macrophages (477). Expression of IL-1 and thromboxane (which is induced by IL-1), and of TNF-α, are greatly increased in the glomeruli of MRL-Fas(lpr) mice (189 ,477 ,478). Kupffer cells from the livers of MRL-Fas(lpr) mice also secrete high levels of TNF-α (479). Monocytes/macrophages from BXSB mice also release increased quantities of procoagulants (362). The combined effects of these cytokines would contribute to glomerular damage and accelerate disease.

Defects in Clearance of Immune Complexes and Apoptotic Cells

As in humans with SLE, the clearance of circulating immune complexes, and of cells coated with antibodies, and of apoptotic cells is abnormal in murine lupus. The Fc-mediated clearance of radiolabeled, Ig-sensitized RBCs is delayed in NZB, BW, MRL-Fas(lpr), and BXSB mice by the time they reach 6 months of age. Complement receptor-mediated clearance was delayed in MRL-Fas(lpr) mice but not in the other strains (328 ,480). Clearance of heat-aggregated IgG is reduced in old MRL-Fas(lpr) mice, but not old MRL/+/+, BXSB, or BW mice (481).

Abnormalities in Target Organs

It is possible that certain mouse strains are susceptible to SLE in part because the organs that are exposed to immunoglobulin and T cells are predisposed to injury. For example, renal tubular cells in MRL-Fas(lpr) mice probably process antigens (likely to be self) and act as APCs that activate T cells to induce injury (303 ,304). Mesangial cells from these mice also proliferate more vigorously than mesangial cells from nonlupus mice when exposed to growth factors (482).

The Role of Environmental Factors

The micro-environment is important in some strains, especially with relation to sex hormones. In all murine lupus strains except BXSB, disease occurs earlier in females than in males (12). In NZB and MRL-Fas(lpr) mice, the difference in disease onset is only 1 to 2 months. In BW and SNF1 mice, the difference is several months, and the female predominance in these two strains is striking. Disease in BW mice can be dramatically altered by sex hormone manipulation, with estrogens accelerating disease and androgens delaying it (150 ,151 ,152 ,153 ,154 ,155 ,156 ,157 ,158 ,159 ,160 ,161).

Regarding exogenous stimuli, there is evidence that infections can accelerate murine lupus (119 ,173 ,319). This probably results from the formation of additional immune complexes that can add to the immunoglobulin deposits in glomeruli and blood vessels. Polyclonal activation by in vivo administration of LPS (similar to the effects of endotoxin) also can accelerate disease in MRL-Fas(lpr) mice (319); however, these effects are probably minor. Lupus in mice is almost entirely a genetic disease.

Abnormalities of Immune Regulation

All of the abnormalities in murine lupus, whether spontaneous or induced, likely depend on abnormal regulation to persist and cause disease. In some induced models, regulation simply is overwhelmed by providing huge quantities of pathogenic autoantibodies or by making most B cells express a pathogenic antibody that is encoded by a transgene. In other induced models, regulation is dysregulated by activating undesirable idiotypic circuits. The Fas/lpr gene is an excellent example of a single gene that alters the normal regulation of apoptosis, with catastrophic results for the MRL mouse destined for mild, late-in-life lupus. Some regulatory mechanisms, including B cell tolerance, are influenced by sex hormones in some genetic backgrounds; in those mice, disease can be profoundly influenced by the manipulation of hormones. There is evidence that $CD8^+$ inhibitory T cells become dysfunctional as NZB/NZW F1 mice age, but both $CD4^+CD25^+$ regulatory T and inhibitory $CD8^+$ T cells can be induced by tolerizing regimens, and when so induced can prevent or suppress autoantibodies and disease. The complex interactions that are required to regulate autoimmune responses will continue to be identified in the future.

Summary

Multiple abnormalities are required for a mouse to develop lupus-like disease. These include disturbances in the function of hematopoietic stem cells, DC, B lymphocytes, T lymphocytes, and phagocytic cells. In spontaneous SLE, the abnormalities are determined primarily by genetic influences; most require multiple genes, which are provided by both parents of a susceptible strain. Three accelerating genes, lpr, gld, and Yaa, are not sufficient to cause disease unless they are engrafted onto a host that is genetically susceptible to autoimmunity. The most important results of the abnormalities are production of pathogenic subsets of autoantibodies and immune complexes, which depend on both abnormal B cell repertoires and unopposed T-cell help. Environmental factors may accentuate these abnormalities but are of minor importance.

Therapeutic Interventions in Murine Lupus

A major advantage of each mouse model of SLE is its availability for studies of therapeutic interventions. These interventions are strategies to (a) provide general immunosuppression, (b) eliminate or inactivate helper T cells, (c) inactivate pathogenic B cells, (d) activate suppressor networks, (e) kill autoreactive B cells, (f) activate DC, (g) alter cytokines, (h) replace stem cells, (i) alter generation of eicosanoids, (j) alter immunoregulation via sex hormones, and (k) alter tissue damage in target organs. Table 18-9 summarizes interventions.

All successful interventions are most effective when they are introduced before the development of full-blown clinical lupus. The most interesting ones also are effective in mice with established disease.

Strategies That Are Widely Immunosuppressive

Cytotoxic and immunosuppressive drugs that are standard in the management of SLE in patients have been studied in murine models of lupus. These include glucocorticoids, azathioprine, cyclophosphamide, methotrexate, cyclosporine, and newer cytotoxics such as mycophenolate mofetil, rapamycin, and others not yet available for human therapy (e.g., 15-deoxyspergualin and dimethylthiourea), and total lymphoid irradiation. Glucocorticoids suppress hemolysis and prolong life in NZB mice (483). In BW mice, murine chronic GVHD, and MRL-Fas(lpr) mice, immunosuppressive agents suppress IgG anti-dsDNA, proteinuria, glomerular immunoglobulin deposits, and nephritis, with resultant prolonged survival (131 ,358 ,483 ,484 ,485 ,486 ,487 ,488 ,489 ,490 ,491 ,492 ,493 ,494 ,495 ,496 ,497 ,498 ,499 ,500 ,501 ,502 ,503 ,504 ,505 ,506 ,507 ,508 ,509 ,510 ,511). They are effective even in animals with established nephritis although better when introduced before clinical disease appears. Figure 18-2 shows the effects on survival of strategies from comparable studies.

Azathioprine as a single agent does not prolong survival in NZB, BW, or chronic GVHD mice. Added to glucocorticoids and/or cyclophosphamide, however, the combination is more effective than any single drug alone (486 ,487 ,489).

As a single drug intervention, cyclophosphamide is superior to glucocorticoids or azathioprine in suppressing nephritis and IgG autoantibodies, and it prolongs life in NZB, BW, and chronic GVHD mice (147 ,486 ,490 ,491 ,492 ,493 ,494 ,495 ,496). It is equally effective whether given daily or intermittently (Fig. 18-3). In combination with glucocorticoid, it suppresses disease in

MRL-Fas(lpr) mice (490); combinations of cyclophosphamide and another immunosuppressive drug such as glucocorticoid or FK506 are more effective than either drug alone (490 ,498). Administration of cyclophosphamide in any regimen is associated with substantial increases in malignancies, and in some colonies azathioprine also has this effect (147 ,489 ,495). Any combination therapy that includes cyclophosphamide suppresses lupus nephritis effectively (490).

Table 18-9: Therapeutic Interventions in Murine Lupus

Intervention	Strains Studied	Effects
Immunosuppressive regimens		
1. Glucocorticoids	NZB, BW, MRL/lpr, BXSB, chronic GVH	Prolong survival Suppress GN Suppress autoantibodies Suppress T abnormalities
2. Cyclophosphamide	Same as 1	Same as 1
3. Azathioprine	BW, chronic GVHD	Not effective as single drug; effective in combination
4. Combinations 1–3	BW	More effective than one drug alone
5. Mycophenolate mofetil	BW, MRL/lpr	Decreases autoAb and nephritis, including glomerulosclerosis
6. 15-Deoxyspergualin	MRL/lpr, BXSB	Suppresses B activity Suppresses lymphoproliferation Suppresses CIC, anti-DNA Suppresses GN
7. Cyclosporin A	MRL/lpr, BXSB, BW	Suppresses lymphoproliferation No suppression of anti-DNA, CIC Suppresses GN, arthritis Prolongs survival
8. FK506	MRL/lpr	Prolongs survival Suppresses lymphoproliferation Suppresses anti-DNA Suppresses nephritis
9. Total nodal irradiation	BW	Prolongs survival No suppression of anti-DNA Suppresses GN Reduction of T cell help for months, suppression for weeks
Inhibition of T cells		
1. Anti-L3T4 (anti-CD4)	BW, MRL/lpr, BXSB	Prolongs survival in pre-dz and post-dz mice Depletes or inactivates $L3T4^+$ T, suppresses accumulation of $CD8^+$ T, B, and monocytes in lymphoid organs and kidneys Suppresses anti-DNA Suppresses GN
2. CTLA4-Ig	BW	Suppresses autoAb and GN if given before disease begins. Effective after nephritis onset if combined with cyclophosphamide or anti-CD40L
3. Anti-CD40L	BW	Suppresses autoAb and GN with reduced expression of TGF-b, IL-10 and TNF-α in kidneys, better effects combined with CTLA4-Ig
4. Anti-CD137	BW	Suppresses autoAb and nephritis
5. Anti-Ia	BW	Anti-IAz-prolongs survival Suppresses anti-DNA Suppresses GN Anti-IAd less effective
Inhibition of B Cells		
1. Anti-idiotypes	BW, MRL/lpr	Prolong survival Suppress anti-DNA Suppress GN
2. Deplete/diminish B-1 B cells	BW	Suppress anti-DNA and GN (introduce Xid gene, give B cell superantigen)
3. TACI-Ig	BW. MRL/lpr	Suppresses anti-DNA and GN (or ad-encoded TACI)
4. Ig peptide minigenes	BW	Induce $CD8^+$ T cells that ablate anti-DNA B cells and suppress GN
Induction of Immune Tolerance in T and/or B cells		
1. LJP394 (Riquent)	BXSB	Suppresses anti-DNA and GN
2. Peptides from Ig	BW	Suppresses autoAb and GN: Induces $CD4^+CD25^+$ and $CD8^+$ regulatory/inhibitory T cells
Id-induced lupus		
3. Peptides from histones	SNF1	Suppresses autoAb and GN: Induces $CD4^+CD25^+$ and $CD8^+$ regulatory/inhibitory T cells
4. Peptide	BW	Suppresses anti-DNA, induces $CD4^+$ IL-10 secreting regulatory T cells from D1 protein of Sm antigen
Manipulation of Cytokines:		
1. Inhibit IFN-γ	BW, MRL/lpr	Suppresses autoAb and GN
2. Inhibit IL-4	BW, NZM.2410, NZM.2328	Decreases glomerulosclerosis
3. Inhibit IL-10	BW, MRL/lpr	Decreases autoAb and GN (including with CRP)
4. Inhibit IFN-α	NZB	Decreases autoAb and GN
5. Inhibit TNF-α	BW	Mixed results—see text
6. Inhibit TGF-ß	BW	supress chronic renal lesions
Replace bone marrow stem cells with Allogeneic or T-depleted syngeneic cells:	MRL/lpr, BW, BXSB	Diminishes disease
Reduce Eiconasoids (low calorie/fat diet, PGE, omega-3 fatty acid enriched):	NZB,BW,MRL/lpr,BXSB	Delays and diminishes disease
Sex hormone therapies		
1. Estrogens, castration	BW, MRL/lpr, BXSB	Accelerate male dz Increase IgG anti-DNA Increase nephritis Decrease survival Dramatic in BW, modest effects in MRL/lpr, no effect in BXSB males
2. Androgens	BW, MRL/lpr	Suppress female dz plus castration or antiestrogens Prolong survival Delay IgG anti-DNA Delay nephritis Dramatic in BW, modest effects in MRL/lpr females
3. Anti-sense nucleotides	BW	Diminish anti-DNA and GN for G proteins
4. Indole-3-carbinol	BW	anti-estrogen effect, prolongs survival

Methotrexate delayed the appearance of proteinuria and prolonged survival (without decreasing anti-DNA) in BW and MRL-Fas(lpr)mice, but it did not affect disease in NZW × BXSB F1 males (497). A different antifolate, MXX-68, was as effective as methotrexate in delaying nephritis in MRL-Fas(lpr) mice (499).

The effects of cyclosporin A (Cy-A) in MRL-Fas(lpr), BXSB, and NZB mice also have been studied. Cy-A is highly effective in suppressing lymphoproliferation; the DN T cells that are associated with Fas/lpr do not expand (500 ,501 ,502 ,503). Cy-A in high doses can suppress the synthesis of anti-DNA in vitro (503). However, B cell hyperactivation with production of high levels of Ig, circulating immune complexes, rheumatoid factors, and anti-DNA was not suppressed when the drug was given in vivo (501 ,502). The effects on nephritis were variable. One group reported no suppression of nephritis and no improvement in survival for either MRL-Fas(lpr) or BXSB mice (501), whereas others reported reduction of nephritis and prolonged survival (502). Apparently, renal damage can be suppressed without diminishing B cell

activation and autoantibody synthesis, suggesting that autoantibodies alone may be necessary, but not sufficient, for the development of lethal lupus nephritis. FK506 was given to young MRL-Fas(lpr) mice; it prevented lymphoproliferation and nephritis and also reduced titers of anti-dsDNA (504); in another study FK506 was more effective in combination with cyclophosphamide (498).

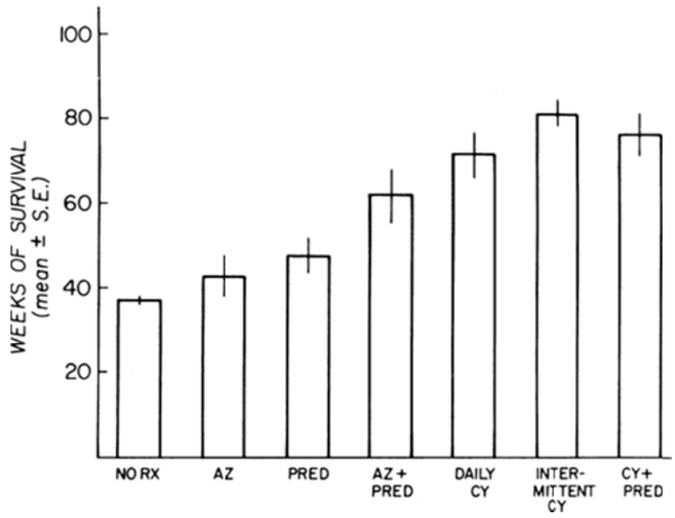

Figure 18-2. Survival in (NZBxN2W) F1 female mice treated from 6 weeks of age with daily oral doses of azathioprine (AZ), prednisolone (Pred), cyclophosphamide (Cy), or combination therapies. Bars indicate mean weeks of survival; vertical lines are 1 SEM. Survival was significantly better in Pred vs. No Rx, AZ plus Pred vs. AZ alone, Pred alone, or no RX, and best in all groups receiving Cy, whether daily or intermittent. (From Hahn BH, Shulman LE. Autoantibodies and nephritis in the white strain (NZW) of New Zealand mice. *Arthritis Rheum* 1969;12(4):355–364.)

A recently developed cytotoxic drug, 15-deoxyspergualin, suppresses immune complex formation, anti-DNA, nephritis, and lymphoproliferation in MRL-Fas(lpr) and male BXSB mice (358 ,505). It has been administered primarily to mice before onset of florid disease. It was also effective in treating the immune thrombocytopenia characteristic of (NZW × BXSB)F1 mice (506). Another newer cytotoxic drug, dimethylthiourea, has been used to treat BW mice (507). When given before disease onset, it is effective at preventing nephritis.

Mycophenolate mofetil has been studied in BW and MRL-Fas(lpr) mice. Mycophenolate is an inhibitor of inosine monophosphate dehydronase, thus inhibiting guanosine nucleotide synthesis. T and B lymphocytes depend on this pathway for their purine synthesis, whereas other types of cells have alternate pathways. Therefore, mycophenolate is relatively specific for suppression of lymphocytes, in contrast to the other drugs discussed above. In both murine lupus strains development of nephritis was suppressed (and in most levels of autoantibodies and total numbers of lymphocytes were also suppressed). In comparison to cyclophosphamide, the numbers of cells infiltrating renal tissue was less with cyclophosphamide (508 ,509 ,510 ,511). Mycophenolate has benefits other than reducing autoantibodies levels (it is particularly effective at reducing IgG2a) (512). In particular, administration of mycophenolate suppresses oxidative damage in kidneys: it decreases renal cortical expression of iNOS and urinary nitrite production, along with reducing glomerular sclerosis (513). In support of this idea, a study in which mycophenolate was combined with a cyclooxygenase-2 inhibitor to reduce thomboxane A2 production (an eiconosoid that promotes ischemia), survival of lupus mice was better with combination therapy (514).

Administration of paclitaxel to BW females resulted in significantly prolonged survival, reduced levels of anti-DNA, and delayed onset of nephritis (515).

Several Asian herbal preparations act as general immunosuppressants. Some of these have been effective in suppressing various manifestations of lupus in MRL-Fas(lpr) mice (516 ,517).

Total nodal irradiation has been studied in murine as well as human SLE(496 ,518 ,519 ,520 ,521 ,522). Irradiation of BW or MRL-Fas(lpr) mice, even after clinical disease is established, results in prolonged survival and markedly diminished nephritis, which is associated with decreased serum levels of anti-DNA. In MRL-Fas(lpr) mice, lymphoproliferation is reduced (520 ,522). Both suppressing and enhancing cell circuits are suppressed for a few weeks after therapy is stopped, but helper circuits return to supernormal, with increased antibody production and proliferation to antigens and mitogens. However, the mice are protected from recurrent high levels of ANA production and from disease for several months after this help appears, despite the fact that suppressive circuits cannot be demonstrated. In one study comparing total node irradiation to cyclophosphamide therapy in BW mice, irradiation was superior in prolonging life, because the incidence of malignant tumors was lower (521).

In summary, immunosuppressive regimens that include glucocorticoids and/or cyclophosphamide, or total nodal irradiation, are impressive in their ability to reverse established nephritis at least partially. The other approaches, such as interfering with synthesis of IL-2, are either more effective when done before clinical organ damage appears or have not been adequately studied in established disease.

Strategies That Deplete or Inactivate T Cells

Because $CD4^+$ helper T cells amplify autoantibodies production and are required for the development of full-blown SLE in all SLE mouse models that have been studied to date, elimination or inactivation of those cells is highly effective in preventing disease, and even in partially reversing it once clinical nephritis is manifest. Administration of antibodies to CD4 prolongs survival, suppresses IgG anti-dsDNA and other autoantibodies, and suppresses nephritis and lymphoproliferation in NZ-derived, MRL-Fas(lpr), and BXSB mice, and even in normal mice that have been induced to express antiphospholipid antibodies (81 ,82 ,112 ,172 ,251 ,295 ,306 ,366 ,460). Anti-CD4 prolongs survival in BW mice with established nephritis (172). Long-term benefits require continual, repeated treatments throughout the lifetime of the mouse.

Apparently, $CD4^+$ cells are not entirely eliminated, or their numbers are repopulated (even in the absence of a thymus), so that autoantibodies and disease eventually appear if the treatment is stopped (523).

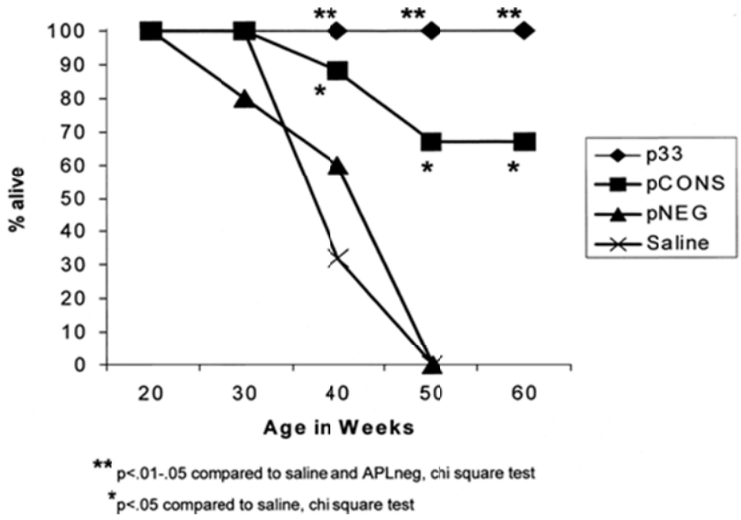

Figure 18-3. Effect of immune tolerance to peptides from autoantibody molecules on survival in (NZB/NZW) F1 mice. BW females were treated from the age of 12 weeks with saline (-×-), a negative control peptide that binds major histocompatibility complex (MHC) class II I-Ed but does not cause T cell activation (pNEG: -Δ-), a wild Ig peptide stimulatory for BW T cells, (p33: -◊-), or a synthetic peptide based on T cell stimulatory Ig sequences (pCONSENSUS or pCONS: -□-) until 60 weeks of age. Peptides were administered as tolerogens, high doses intravenously once a month. Each group contains 5 to 15 mice. Note that all mice in the saline and pNEG groups were dead by 50 weeks of age, whereas 70% to 100% of mice tolerized with peptides that are stimulatory for T cells were still alive. Survival was significantly longer in the effectively treated groups, p <0.01 to 0.05 in the p33 group compared to saline and pNEG by chi square test, p <0.05 comparing pCONS to saline. Autoantibodies and cytokine increases in interferon-γ (IFN-γ) and interleukin-4 (IL-4) were all significantly delayed in the tolerized groups. These mice mounted normal T and B cell responses to immunization with HEL, an external foreign antigen. This illustrates a new approach to achieving specific immune suppression of undesirable autoantibodies.

The monoclonal antibody used in all of these studies is a rat antimouse L3T4 (CD4); it has the advantage of inducing tolerance to itself in the recipient by preventing antibody responses that require T-cell help (112 ,524 ,525). In earlier studies using antibodies against lymphocytes or thymocytes or $Thy\text{-}1^+$ cells ($CD2^+$ in humans), results were often obscured by the development of inactivating antibodies and of serum sickness nephritis caused by the immune response to the antilymphocyte globulin (526 ,527 ,528 ,529). The rat anti-L3T4 monoclonal antibody is cytotoxic to helper T cells and deletes them from the repertoire. The F(ab)2 fragment of the monoclonal antibody is not cytotoxic, because it cannot fix complement, but it inactivates $L3T4^+$ T cells and is as effective as the whole antibody molecule in preventing the development of anti-DNA and nephritis in BW mice (524). In addition to the predictable effects of anti-L3T4 on diminishing T-cell help and autoantibodies formation, non-$L3T4^+$ cells that infiltrate renal and lymphoid tissue as lupus evolves also are influenced. $CD8^+$ T cells and $B220^+$ B cells, as well as $CD4^+$ T cells, are all diminished (525). This suggests a central role for $CD4^+$ T cells in the evolution of activated $CD8^+$ and B cells. In contrast to the benefit of anti-CD4 in (NZW × BXSB)F1 mice, administration of anti-CD8 worsened disease (394).

Anti-CD4 therapy of MRL-Fas(lpr) mice is particularly interesting, because the lymphoproliferative component of their disease is dominated by $B220^+$ $CD4\text{-}CD8^-$ TCR α/ß cells. However, the autoantibodies, arthritis, nephritis, and central nervous system (CNS) disease depend on $CD4^+$ cells (295). Treatment of MRL-Fas(lpr) with a combination of anti-CD4 and anti-CD8 abrogates most disease manifestations. However, treatment with anti-CD4 alone suppresses autoantibodies, proteinuria, histologic nephritis, arthritis, and CNS disease, but does not affect lymphocytic proliferation and actually worsens lacrimal gland destruction (283 ,295 ,306). Nonmitogenic anti-CD3 also reduces mortality and adenopathy in MRL-Fas(lpr) mice (530). The BW mouse has a predictable response, because its disease depends primarily on $CD4^+$ cells: administration of anti-CD8 to tolerized BW mice

depleted $CD8^+$ cells but did not influence autoantibody titers, nephritis, or survival (531). Although anti-CD4 therapy is remarkably effective in murine lupus, its use in the human disease has produced disappointing results. Perhaps by the time a patient is diagnosed, desirable immune regulation has developed and is dependent in part on $CD4^+$ cells, so eliminating T-cell help also eliminates T-cell regulation.

BW mice also have been bred with nude mice to produce BW-nu/nu offspring. Nu/nu homozygotes are athymic and develop T-cell repertoires that are small in number and uneducated in the thymus. Without T-cell help, BW-nu/nu mice have prolonged survival that is associated with decreased levels of IgG anti-DNA and little development of nephritis or lymphoproliferation (532 ,533). However, the animals are not completely disease-free and develop some autoantibodies.

To disable activated $CD4^+$ T cells rather than all $CD4^+$ cells, there has been recent interest in interfering with second signals. T cells receiving only one signal (binding of their TCR) usually undergo activation only if they receive second signals via CD28/CTLA-4 interacting with B7–1 and B7–2 (CD80 and CD86), or CD40 interacting with gp39 (CD40L, CD154). Several groups have investigated the effect of disabling B7–1 and/or B7–2. Antibodies to B7–1 plus B7–2 (or to gp39) interrupt signaling, as does soluble CTLA-4–Ig, which binds B7–1 and B7–2 so they cannot interact with CD28 and deliver a second signal. Such treatments are effective in delaying disease in BW and BXSB mice (176 ,177 ,534). Gene deletion of B7.1 worsened nephritis in MRL-Fas(lpr) mice, whereas deletion of B7.2 reduced kidney pathology: disabling both molecules by treatment with antibodies to both B7.1 and B7.2 suppressed disease (535). In BW mice, one dose of adenovirus containing CTLA-4–Ig reduced numbers of activated T cells and affected disease as long as the protein was present. B cells requiring T-cell help were impaired, although there was no effect on intrinsic B cell abnormalities (536). Blockade of CD28-B7 interactions with soluble CTLA-4-Ig fusion protein has been beneficial in other, nonlupus animal models of autoimmunity. For example, gene therapy with adenovirus containing CTLA-4-Ig prevented induction of collagen-induced arthritis (537). Recent work in which CTLA4-Ig was administered to lupus mice showed that it delayed autoantibodies production if given prior to disease onset, but was less effective in established disease. However, when combined with anti-CD40L (anti-CD154), TACI-Ig, or cyclophosphamide, there was dramatic suppression of autoantibodies and healing of renal lesions. Induction therapy with the combination of CTLA-4Ig and cyclophosphamide arrested the progression of murine lupus nephritis and precluded the need for additional therapy—an experiment very exciting for its potential implications in the therapy of human lupus nephritis (180 ,538 ,539 ,540).

Impairment of CD40/gp39(CD40L) interactions has also been studied in murine lupus. BW mice treated with anti-CD40L had reduced anti-DNA levels, reduced proteinuria, and prolonged survival (178). Treatment with anti-CD40L also prolonged survival in SNF1 mice even if started after nephritis was clinically evident (179). However, anti-CD40L is effective in a higher proportion of mice if administered before nephritis begins, but it can suppress established renal disease in subsets of older mice which repond with rapid reductions in renal mRNA for TGFbeta, IL-10, and TNF-α (541). One group reported that better clinical results are obtained in BW mice by blocking both CD28/B7 interactions using CTLA-4–Ig, and CD40/gp39 interactions using anti-gp39. In fact 10 months after a 2-week course of both therapies, 70% of mice were alive compared to 0% to 18% of mice treated with only one of the agents (180). It is likely that combination therapy will be more useful in human disease as well, since there are several routes to B cell production of autoantibodies.

Finally, inhibition of MHC class II (thus blocking the first signal to $CD4^+$ T cells) has been effective in treating murine lupus. One group studied the efficacy of antibodies to I-A in murine lupus (542). NZB/NZW F1 mice express I-A and I-E MHC class II molecules with two alleles, d and z. Administration of antibodies directed against Az suppressed production of anti-DNA and development of nephritis in BW mice. Anti-I-Ad was somewhat immunosuppressive, but less effective than anti-I-Az. Knockout of MHC class II in MRL-Fas(lpr) mice prevented the development of autoantibodies and nephritis, but not of lymphoproliferation (305). A safer strategy to block MHC-peptide activation of TCR is to provide tolerizing peptides in MHC class II molecules, which is discussed below. A report of methimazole treatment benefiting BW mice speculated that the effectiveness depended on downregulation of MHC class I molecules by the drug (543), suggesting that class I activation of $CD8^+$ cells is also important in development of full-blown murine lupus.

In more recent work, anergy was induced in BW $CD4^+$ T cells by administation of anti-CD137 (4-IBB), which blocks another costimulatory molecule required for sustained T cell help, and autoimmunity was dramatically suppressed (544).

Strategies That Prevent B Cell Activation

Many interventions that interrupt B cell development or activation also prevent murine SLE. Introduction of the Xid gene into NZB or BW backgrounds results in near-deletion of B-1 B cells resulting in inability to synthesize normal levels of IgM. In that setting, NZB.xid and BW.xid mice do not develop their characteristic early life, severe lupus (41 ,545 ,546). They are not disease free, however; a few animals develop autoantibodies and nephritis late in life (545). Xid is a mutated nonreceptor tyrosine kinase (BTK); the kinase promotes activation of NF-κB via activation of the B cell receptor, resulting in IgM production (547 ,548). The hyperactivity of SLE B cells is prevented by Xid. In addition, normal B cells may serve a regulatory function that is defective in lupus B cells. Transfer of MHC-matched normal B cells (but not Xid B cells) into nonirradiated BW mice decreases serum IgG autoantibodies levels, delays proteinuria, and prolongs life (549). Direct inhibition of NF-κB by administration of a p50 antisense nucleotide inhibited NF-κB expression, reduced total IgM and IgG synthesis, and reduced antibodies to dsDNA by 90% (550).

If the IgD or IgM molecules on a B cell surface are ligated, that cell cannot undergo class switch to produce IgG. When MRL-Fas(lpr) mice were treated with multivalent anti-IgD that was conjugated to dextran, development of glomerulonephritis was delayed and survival prolonged (551). Interestingly, removing a major antigen, DNA, that delivers first signals to B cell receptors in mice with lupus was not effective. DNAse treatment of BW mice reduced numbers of anti-DNA–secreting B cells for 1 month but did not alter cytokine production, glomerulonephritis, or survival (552).

Manipulation of the idiotypic network by administration of Id or anti-Id can have profound effects on the immune system, and those effects can result in either upregulation or downregulation of autoantibodies. Administration of carefully chosen Ids or anti-Ids in proper doses at the correct time can suppress Id^+ anti-dsDNA and delay the onset of nephritis in BW mice (553 ,554 ,555 ,556 ,557), MRL-Fas(lpr), and SNF1 mice (222 ,558). Treatment with anti-Ids conjugated to cytotoxic compounds such as neocarzinostatin also is effective in suppressing autoantibodies and nephritis in BW mice, particularly if multiple anti-Ids are included in the regimen (556 ,557). Anti-Ids also can suppress in vitro synthesis of autoantibodies by human B cells (559). There are limitations to Id/anti-Id therapies, however. Some anti-Ids upregulate autoantibodies (560), and variations in dose and time of administration to lupus mice can profoundly influence whether immune responses are enhanced or suppressed. Some anti-Ids do not affect antibody synthesis (561). Beneficial responses can be short-lived, abrogated either by the escape of pathogen-enriched Ids from suppression or by the emergence of pathogenic autoantibodies bearing different Ids (553 ,555). Finally, pathogenic autoantibodies can express different Ids, so that suppression of multiple public (and possibly some private) Ids may be required for prolonged efficacy. The efficacy of anti-Id therapy in mouse SLE is established. A phase I study in nine patients with SLE suggested that anti-Id can be induced by immunizations with a selected idiotype (3E10) without adverse effects (562). Treatment of SLE with intravenous gamma globulin may benefit individuals with SLE by suppressing certain Ids, depending on the anti-Ids in each preparation (563). Mice with induced antiphospholipid syndromes have benefited from the administration of intravenous gamma globulin (456).

Interruption of the B cell growth cytokine IL-4 by administration of soluble IL-4 receptor suppresses autoantibodies production in murine lupus (429).

MRL-Fas(lpr) B cells respond to IL-1 by secreting Ig, and the level of IL-1 mRNA is elevated in the kidneys of MRL mice with nephritis. Infusion of human recombinant IL-1 receptor antagonist into mice with nephritis suppressed circulating IL-1 but did not change the disease (564). Perhaps earlier treatment would be more effective.

Recently, a new member of the TNF-α family has been described that is a coreceptor for second-signal B cell activation following BCR ligation. That molecule, BlyS (also called BAFF, TALL-1, and zTNF4) is secreted by monocytes and binds its receptors TACI, BCMA, and BAFF-R on B cells (435 ,565 ,566 ,567). Since elimination of activated B cells is a reasonable therapeutic goal in murine and human SLE, a phase II trial of anti-BLyS is in progress in human SLE at the time of this writing. Therefore, we will review some information about this molecule. BLyS and a related molecule, April, are made by myeloid cells, stromal bone marrow cells, and T cells. BlyS (also called BAFF) and April are released as soluble molecules and can bind to receptors on B cells. Three such receptors have been defined: TACI, BCMA and BAFF-R. The first two receptors can bind both BlyS and April; BAFF-R binds only BlyS. The consequence of binding to TACI and BCMA is that B cells have longer survival and prolonged activation. B cells in the marginal zone of spleen (which can activate naïve T cells in the absence of antigen) are particularly expanded. In approximately half of patients with SLE, rheumatoid arthritis, or Sjogren syndrome, Blys levels in the circulation are high. A fusion protein of TACI, soluble TACI-Ig, has been used in vivo in mice to bind soluble BlyS and April. This therapy has been effective in delaying onset of autoimmunity in BW mice (566). Administration of adenovirus-encoded soluble TACI reduced glomerulonephritis and proteinuria in MRL/lpr mice but was ineffective in BW mice because of appearance of antibodies to TACI (568). In contrast, in the presence of T cell blockade with CTLA4-Ig, TACI-Ig was highly effective in BW mice: it depleted B cells past the T1 stage, decreased numbers of activated and memory $CD4^+$ T cells, and delayed proteinuria in spite of high titers of autoantibodies that appeared after therapy was stopped (540). Interesting experiments introducing the BlyS/BAFF gene into congenic mice with C57Bl/6 background expressed with the lupus-promoting gene regions Sle1 or Nba2 suggested that BAFF contributed to severe glomerular disease (but not tubulointerstitial), probably unrelated to anti-DNA, antinucleosome and anti-gp70. Whether other autoantibodies are promoted by BlyS/BAFF, or whether there is another mechanism that damages glomeruli remains to be determined (569).

Induction of Tolerance in T and B Cells

There are several mechanisms of immune tolerance: ignorance, anergy, deletion, receptor editing (in B cells), and active suppression. One can induce tolerance in T or B lymphocytes in lupus mice by inhibiting the first activating signal (i.e., binding the TCR or BCR with the peptide or antigen it recognizes), without a second signal (via CD28, CD40, CD137 or BlyS/BAFF), thus inducing anergy. Or, tolerance results by inducing apoptosis in autoreactive cells (deletion). Finally, one can induce regulatory cells to control autoimmunity. Induction of tolerance to autoantigens in either helper T or B cells in individuals with SLE would abrogate production of pathogenic antibodies. Several laboratories have developed strategies to tolerize mice with lupus to DNA and related antigens (570 ,571 ,572 ,573 ,574 ,575). Mice so treated have significant delays in the appearance of autoantibodies and nephritis. For example, intrathymic inoculation of Hl-stripped chromatin into BXSB males significantly reduced T-cell proliferation to nucleosomal antigens, and production of IgG

antichromatin, anti-dsDNA, and anti-ssDNA, for 8 to 10 weeks (574).

Recently there has been success in both human and murine SLE in tolerizing B cells to a molecule containing short nucleotides displayed on a tetrameric scaffold—a compound called LJP 394, or Riquent (575 ,576). BXSB mice treated with this tolerogen have delayed appearance of IgG anti-dsDNA and nephritis, as well as significantly prolonged survival. In some patients with SLE who have antibodies to DNA that bind LJP394 with high avidity, there is good clinical response to repeated intravenous injections of LJP394. Quantities of anti-DNA drop significantly, and there are fewer flares of renal disease compared to a placebo-treated control group (577). Another strategy for cross-linking B cells to inactivate them is to administer DNA/anti-DNA soluble immune complexes. That has been effective in improving survival of MRL-Fas(lpr) mice (578).

In BW mice, repeated tolerization with monthly intravenous doses of a synthetic peptide based on T helper determinants in the VH region of murine antibodies to DNA, or of combined wild immunoglobulin-derived peptides, produced dramatic delays in nephritis and prolonged survival (579 ,580 ,581). Figure 18-3 shows results of one series of experiments. Similarly, tolerization to helper-T-cell–activating peptides from the histone moieties of nucleosomes reduces autoantibodies formation and delays Ig deposition in glomeruli in (SWR × NZB)F1 mice (582). In all these studies, peptides that are both T-cell and B cell epitopes, and induce tolerance to first signals in both T and B cells, were the most effective in delaying clinical disease. One group has reported that repeated oral administration of low doses of whole kidney extract reduced IgG1 and IgG3 anti-dsDNA antibody levels, reduced numbers of inflammatory cells and expression of IL-4 and Il-10 in kidney tissue (while increasing expression of IL-1, IFN-γ, and TNF-α), and prolonged survival (583). This is interesting and may depend on timing of the oral preparation, since aged BW mice have low intestinal IgA levels and are quite resistant to oral tolerance, which usually depends on the production of regulatory and inhibitory T cells in the mucosa-associated lymphoid tissue (584).

Strategies That Activate Suppressor Networks

Most experts suspect that one of the defects in murine and human SLE is an absence of normal suppressive immunoregulatory networks. In normal mice, regulatory T cells develop in both thymus and periphery; they can be $CD4^+$, $CD8^+$, or double negative; some secrete TGF-ß, others IL-10, and still others suppress effector cells by contact (585). These cells have the capacity to prevent autoimmunity and probably function to do so in most normal individuals. Vaccination of mice with disease-inducing T cells, or with certain peptides, can activate suppressive networks, with at least some of the regulatory cells ($CD4^+$) recognizing the TCR of the disease-upregulating T cells. De Alboran et al. (586) inoculated young MRL-Fas(lpr) mice with irradiated cells from the diseased lymph nodes of older MRL-Fas(lpr) mice; peripheral T cells were obtained that protected against disease in adoptive transfer experiments. Normal B cells may also serve a regulatory function; transfer of MHC-matched normal B cells into nonirradiated BW mice decreased serum IgG autoantibodies levels, delayed proteinuria, and prolonged life (549). It is likely that attempts to induce regulatory networks in SLE will be successful in the near future.

Based on these observations, there is currently great interest in devising strategies to induce regulatory/inhibitory T cells to prevent autoimmunity and to control cancers. In the tolerance therapies discussed above, there are multiple simultaneous processes that suppress autoimmunity. For example, in the tolerance induced in BW mice by administration of a soluble 15-mer artificial peptide based on T-cell epitopes in anti-DNA, $CD4^+$ T cell help is anergized, but at least two subsets of regulatory/inhibitory T cells are induced—$CD4^+CD25^+CTLA4^+$ antigen specific cells that suppress B cells making anti-DNA by direct contact, and $CD8^+$ supressors which prevent proliferation of $CD4^+$ helper T cells via secretion of TGF-ß (187 ,198). Similarly, administration of nanomolar quantities of histone peptides which contain T cell epitopes suppress disease in SNF1 mice, at least in part by inducing $CD4^+CD25^+$ regulatory and $CD8^+$ inhibitory cells—each of which depends on secretion of TGF-ß for activity (187). Administration of human Ig CDR1-derived peptide (also containing T-cell epitope) to BW mice also suppresses autoantibodies and nephritis and induces regulatory $CD4^+CD25^+$ T cells (587). A different regulatory T cell was induced in BW mice by IV injection of the D1 protein from Sm antigen; those cells were $CD4^+$ and secreted IFNgamma and IL-10 (but not TGF-ß); they suppressed helper T-cell proliferation and B cell synthesis of anti-DNA (588). The classical $CD4^+CD25^+$ regulatory T cells are characterized by expression of Foxp3, a DNA-binding protein, which may contribute to protection of the regulatory/inhibitory cells from apoptosis (187 ,198). Strategies to induce such cells are in progress for control of many autoimmune diseases.

Fan and Singh used a minigene vaccination approach to elicit cytotoxic/regulatory $CD8^+$ T cells (589). They showed that the impairment in the activation of $CD8^+$ regulatory T cells can be overcome in BW mice by administering plasmid DNA vectors that encode MHC class I-binding peptides. These minigenes encoding single or multiple peptides preferentially induced $CD8^+$ T cells that can kill anti-DNA B cells and suppress glomerulonephritis in BW mice.

Therapeutic Strategies Employing Cytokines

Manipulation of cytokines that affect T cells, B cells, or target tissue alters murine lupus. T cells from virtually all SLE mice develop defects in the production of IL-2 and the presentation of IL-2 receptors on their surfaces. Consistently, treatment of MRL-lpr mice with the human IL2 gene delivered via live vaccinia recombinant viruses or with the murine IL2 delivered via Salmonella typhimurium suppresses glomerulonephritis, autoantibodies production and lymph node enlargement (590 ,591). However, intramuscular injections with cDNA

expression vectors encoding Il2 gene increased autoantibody production in MRL-Fas(lpr) mice (314), and treatment with drugs that inhibit IL-2, such as cyclosporine and FK506, are beneficial (discussed earlier). Rapamycin has some effects that are similar to those of Cy-A and FK506—it prolongs life and reduces lymphoproliferation and nephritis in MRL-Fas(lpr) mice (592).

Interleukin-4 (IL-4) is a multifunctional cytokine. Although most studies have focused on the B cell stimulatory and Th2 promoting properties of IL-4 in the development of autoantibodies and autoantibody-mediated diseases, a few reports suggest a T-cell suppressor role for this cytokine in lupus. Since these properties of IL-4 may sometimes result in opposing outcomes, amplifying or inhibitory, on overall B cell functions, it is not surprising that a few studies have found no role for IL-4 in the development of autoantibodies and lupus. Evidence for a more novel role for IL-4 in the development of lupus nephritis comes from recent studies, which suggests that IL-4 may directly promote extracellular matrix deposition in the glomeruli. Consistent with this idea, blockade of IL-4 by antibody or drug treatment or of its signaling by inactivation of the Stat6 gene ameliorates glomerulosclerosis and delays or even prevents the development of end-stage renal disease, despite the presence of high levels of IgG anti-dsDNA antibodies (236 ,593). Thus, IL-4 may serve multiple roles in the development of lupus: it may enhance autoantibodies production via its direct B cell effects, protect against autoimmunity via its T-cell suppressor effect, or perpetuate tissue damage via its direct effects on target organs (594).

Studies of cytokine mRNA in BW and MRL-Fas(lpr) mice with established clinical lupus suggest that both Th1 and Th2 subsets are activated. In BW mice, the largest population of pathogenic anti-DNA are IgG2a, an isotype that depends on IFN-γ (from Th1 cells) for its synthesis. There are high levels of mRNA for both IFN-γ (i.e., a Thl cytokine) and IL-10 (i.e., a promoter of Th2-cell development) in lymphoid tissues. Inhibition of IL-10 by continuous administration of anti–IL-10 significantly delays the onset of lupus in BW mice (184), probably by interfering with the generation of IL-6 (i.e., a B cell growth factor), because simultaneous administration of anti–IL-6 abrogates the benefit of anti–IL-10 and administration of IL-6 worsens disease (183). In MRL-lpr mice, however, IL-10 deficiency exacerbates lupus manifestations, whereas administration of rIL-10 reduces IgG2a anti-dsDNA autoantibodies production presumably through inhibition of pathogenic Th1 cytokine responses (595). In addition to increases in Th1 and Th2 cytokines in lupus mice, pro-inflammatory cytokines, including IL-1 and TNF-α, that are derived primarily from monocyte/macrophages are increased (313). IFN-γ is a cytokine of central importance in several strains of murine lupus. Administration of this cytokine worsens murine SLE in BW mice; administration of antibodies to IFN-γ or of soluble IFN-γ receptors to BW mice before disease begins significantly prolongs survival and diminishes immunoglobulin deposition and lymphocytic infiltration of kidneys (130). In MRL-Fas(lpr) mice, antibodies to IFN-γ do not alter disease (596), but lowering serum levels of IFN-γ with IFN-γ R/Fc molecules was effective (597). Gene therapy of MRL-Fas(lpr) mice with intramuscular injections of plasmids containing complementary DNA (cDNA) encoding IFN-γ R/Fc molecules resulted in reduced serum levels of IFN-γ, and reduced levels of autoantibodies, lymphoid hyperplasia, and glomerulonephritis, with prolonged survival. Treatment after mice had established nephritis was also effective (597). Genetic deletion of IFN-γ receptor significantly delayed nephritis in BW mice, although the mice developed lethal lymphomas at 1 year of age (598).

Other cytokines have been studied as therapeutic agents in murine lupus. The response of MRL-Fas(lpr) mice to granulocyte colony-stimulating factor (G-CSF) was complex: chronic administration of low doses accelerated nephritis, whereas high doses prolonged survival and prevented inflammation in glomeruli even in the presence of Ig deposits (599). Inhibition of IL-4 in mice transgenic for IL-4 prevented the glomerulosclerosis that occurs in those transgenics (600). Another strategy for changing regulation is to provide large quantities of cytokines. Gene therapy in which cytokines in vectors were injected intramuscularly into MRL-Fas(lpr) mice once a month showed that IL-2 accelerated disease, whereas TGF-ß suppressed it (314). TGFbeta, a cytokine required for generation of regulatory/suppressive T cells early in immune responses, but also involved in promoting glomerular sclerosis in later disease, was inhibited by administration of the angiotensin-converting enzyme (ACE) inhibitor, captopril, to BW or MRL/lpr mice either before or after proteinuria appeared. Treatment delayed proteinuria in pre-morbid mice and reduced chronic renal lesions in older mice, without affecting autoantibodies production. Expression of both TGF-beta1 and TGF-beta 2 isoforms were reduced in the kidneys and IL-4 and IL-10 were reduced in spleen cells (593). It is likely that timing and quantities of TGF-ß are critical in obtaining either immunosuppression or suppression of sclerosis. TNF-α plays a major role in inflammation and immune responses (192). BW mice produce abnormally low quantities of TNF-α, which is a defect that correlates with an unusual restriction fragment length polymorphism in the TNF-α gene (190 ,601). Initial studies reported that administration of normal recombinant TNF-α delayed the development of nephritis (190). The ability of the recombinant molecule to suppress established nephritis and prolong survival in BW mice was shown, but the benefit was lost after a few months. Another study reported that low doses of TNF-α accelerated nephritis (191). Treatment of normal mice with TNF-α reduced the ability of monocytes to support lymphocyte proliferative responses to mitogens, and it inhibited both T-cell cytotoxicity and NK cell activity (192). Such effects, if they occur in autoimmune mice, should confer substantial benefit. Bindarit is a propanoic acid derivative that inhibits the chemokine monocyte chemotactic protein-1 (MCP-1) as well as TNF-α production by activated monocytes and macrophages. Treatment of BW mice with bindarit did not reduce autoantibody titers but delayed proteinuria and prolonged survival, even better than did treatment with cyclophosphamide (602 ,603).

Recently there has been great interest in the role of type I interferons, particularly IFN-α, in promoting SLE, and therefore great interest in strategies that inhibit that cytokine. Evidence that IFNalpha is important in SLE includes: (1) a major lupus-promoting gene in the Nba2 region from NZB mice, Ifi202, is regulated by interferons and once upregulated probably protects B cells from apoptosis (60), (2) peripheral blood cells from patients with SLE display a genomic signature with striking upregulation of genes controlled by IFN types 1 and 2 (604), (3) administration of IFN-α to young BW mice accelerates disease (209), and 4) type I interferon receptor deficiency reduces autoimmunity in NZB mice (208). It is possible that IFN-α is the “boss” cytokine in SLE, in the same manner that TNF-α is the “boss” cytokine in rheumatoid joints. Important advances in this area can be expected between now and the next edition of this text.

New strategies that alter cytokines in BW mice involve administration of C-reactive protein (CRP) or suppressive oligonucleotides. There is a discussion of them in the section on cytokines, but they have effects on the interactions between innate immunity and adaptive immunity that may be equally important. CRP interaction with apoptotic materials facilitates their phagocytosis and clearance (194). It is likely that this process must be intact to reduce the quantitative level of autoantigen presentation by apoptotic cells and bodies that can stimulate autoantibody formation. Suppressive oligonucleotides expressing TTAGGG motifs impair the activation of DC and macrophages and therefore their release of interferons, TNF-α and IL-12, all of which are pro-inflammatory. Administration of CRP to BW mice delayed proteinuria but not anti-DNA formation; the benefit depended on IL-10 (196). BW mice transgenic for human CRP expressed the protein primarily in renal tissue; deposition of IgM and IgG and glomerular damage were reduced (197).

In summary, cytokines appear to have multiple effects on the development of lupus disease. Some cytokines, such as TGF-β and IL-4, appear to have suppressor effects in early stages of disease by modulating immunity, whereas the same cytokines might exacerbate late stages of disease by promoting local tissue repair and remodeling. This is clearly represented in manipulations in which autoantibodies production persists, but renal damage is diminished, thus separating these as two disease manifestations. Doses and timing of cytokine manipulation are critical to outcome, and may be achieved by many different mechanisms.

Strategies to Replace Stem Cells

An important question in SLE is whether replacement of bone marrow stem cells with allogeneic cells from MHC-compatible normal mice (378), or with syngeneic cells that have been depleted of T cells (325), will prevent (or at least delay) disease. Immunoablated MRL-Fas(lpr) mice receiving bone marrow from MRL+/+ or other H-2–matched strains developed mild rather than the usual marked lymphoproliferation; survival was prolonged (605). Interestingly, immunoablation with radiation or high-dose cyclophosphamide followed by transfer of T-cell–depleted syngeneic MRL-Fas(lpr) marrow also prolonged survival (325). In BW mice, transfer of bone marrow–derived pre–B cells from normal donors also suppressed autoantibody production (204). Such stem cells can even be provided from human cord blood (606). Bone marrow stem cell transfer also has benefited BXSB mice (607). These data provided background for the recent studies of immunoablation followed by autologous stem cell transplantation in patients with SLE, several of whom had impressive improvement (608).

Strategies to Alter Generation of Eiconasoids: The Role of Diet

Because inflammation in murine SLE is mediated by multiple molecules, including products of arachadonic acid (AA) metabolism, there has been interest in deviating the products of AA toward less proinflammatory metabolites than the leukotrienes and thromboxanes. This can be done by giving PGE or analogues, or by altering diets. The administration of PGs to BW mice influences their SLE. Repeated injections of PGE1 suppress nephritis and prolong survival (609 ,610 ,611). Two days of treating MRL-Fas(lpr) mice with a PGE analogue, misoprostol, reduced renal cortical IL-1 mRNA levels but not leukotrienes (612).

Dietary factors have a major influence on murine lupus. Calorie reduction alone, to approximately 40% of the usual laboratory mouse dietary intake, significantly prolongs survival and suppresses lymphoproliferation, autoantibody production, increases in Thl and Th2 cytokine production, and nephritis in NZB, BW, MRL-Fas(lpr), and BXSB mice (148 ,613 ,614 ,615 ,616 ,617). Restriction of dietary fat seems to be more important than restriction of protein. Diets that are rich in unsaturated fats and in omega-3 fatty acids, such as fish oil, flaxseed, menhaden oil, and eicosapentanoic acid, are associated with improved survival and markedly less lymphoproliferation, autoantibodies production, nephritis, and vasculitis in NZB, BW, and MRL-Fas(lpr) mice (613 ,615 ,618 ,619 ,620 ,621 ,622 ,623 ,624 ,625 ,626 ,627 ,628). In contrast, diets that are enriched in saturated fats and in omega-9 and omega-6 fatty acids are associated with reduced survival, enhanced oncogene expression, and severe lymphoproliferation (613 ,615 ,618 ,625 ,629).

The most likely explanation for the profound effects of diet in murine lupus relate to the conversion of dietary fats to various AA metabolites (i.e., PGs and leukotrienes). Presumably, the omega-3 fatty acids are precursors of molecules that are less inflammatory and/or immunostimulatory than the products of omega-9 and omega-6 fatty acids. Omega-3–rich diets lower the production of leukotriene B4 and tetraene peptidoleukotrienes by peritoneal macrophages, presumably reducing inflammation (628). Additionally, they increase antioxidant enzyme gene expression and decrease tissue levels of proinflammatory cytokines such as IL-6 and TNF-α (148 ,629).

Dietary factors that are unrelated to lipids also influence murine lupus. BW mice that are raised on a casein-free diet have diminished anti-DNA and nephritis and improved

survival (630). The mechanism of this effect is not known. Alfalfa seeds fed to cynomolgus macaque monkeys were associated with the development of autoimmune hemolytic anemia and ANA (631). When the seeds were autoclaved before administration, however, the disease did not occur (632). Several investigators have attributed this phenomenon to the presence of L-canavanine, which is a nonprotein amino acid, in alfalfa. L-Canavanine is immunostimulatory and increases the proliferation of lymphocytes to mitogens and antigens (633 ,634). The importance of this finding in human SLE, however, is unknown.

Strategies That Manipulate Sex Hormones

The influence of sex hormones on murine lupus is highly variable, depending on the strain. Hybrid mice that are derived from NZ backgrounds, especially BW mice, are exquisitely sensitive to the effects of sex hormones. Females are protected from severe early life lupus by castration plus androgenic hormone, or by antiestrogens(150 ,153 ,154 ,155 ,156 ,635). Estrogens worsen their disease, probably through toxic effects as well as immunostimulation (152). Males develop early-onset severe SLE rather than their usual late-onset disease if they are castrated and treated with estrogenic hormones or antiandrogens (150 ,155 ,156). Whether this relates to the modification of immune responses by sex hormone receptors in immune cells or to modification of gene expression is unclear. In contrast, male BXSB mice develop rapid-onset, early-life lupus whether or not they are castrated or receive sex hormones (156). MRL-Fas(lpr) mice are intermediate between BW and BXSB; that is, estrogenic hormones tend to worsen and androgenic hormones to suppress disease manifestations, but the effects are less dramatic than in BW mice (156). In fact, the effects of estrogen in MRL-Fas(lpr) mice are to worsen renal disease but to lessen vasculitis and sialadenitis (636). This could result from the simultaneous stimulation of antibody responses and suppression of T-cell– and NK-cell–mediated immunity (160), but the effects of sex hormones are doubtless more complicated than that. Studies in normal mice transgenic for Ig genes that encode anti-DNA show that estrogen affects B cell tolerance and permits survival of autoreactive B cells (161). Administration of tamoxifen to MRL-Fas(lpr) mice and to BW mice reduces renal damage and prolongs survival (637). Prolactin administration worsens lupus in BW mice, whereas bromocriptine suppresses it (157 ,158 ,159 ,638). New strategies that reduce sex hormone levels include administration of antisense oligonucleotides to Galpha(Q/11) which inhibits the G proteins required to transmit the effect of gonadatropin-releasing hormone. BW mice receiving the anti-sense oligonucleotides had reduced levels of autoantibodies and proteinuria, with inhibition of IL-6 production (639). A diet enriched in indole-3-carbinol, an anti-estrogen abundant in cruciferous vegetables, was given to BW mice, and resulted in lower levels of anti-DNA, less severe nephritis, and dramatic improvement in survival (640). Studies in this interesting area are likely to expand in the next few years.

Strategies That Protect Target Organs from Damage after Immunoglobulin Deposition

Protecting tissue from damage induced by deposition of immunoglobulins, rather than altering immunoglobulin production, is another strategy for treating lupus. For example, administration of NG-monomethyl-l-arginine, which suppresses nitric oxide production, reduces the severity of arthritis and nephritis in MRL-Fas(lpr) mice (641). High quantities of inducible nitrous oxide synthetase (iNOS) are expressed in kidneys of MRL-Fas(lpr) mice after nephritis begins; administration of linomide significantly decreases iNOS mRNA levels and prevents development of nephritis (642). Similarly, administration of aminoguanidine reduced glomerular expression of both iNOS and TGF-ß mRNA in BW mice: this effect was associated with less glomerulosclerosis (643). Antibody MEL-14, which blocks the homing of lymphocytes to lymph nodes, suppressed adenopathy in MRL-Fas(lpr) mice; it did not alter autoantibody production (644). Combined treatment with antibodies to LFA-1α and ICAM-1 reduced Ig and C3 deposition in glomeruli and prolonged survival in mice treated after induction of chronic GVHD (645). Inhibition of thromboxane A and endothelin receptors reduced histologic renal damage, hypertension, and proteinuria in BW mice (646 ,647). Administration of antibodies to ICAM-1 protected MRL-Fas(lpr) mice from skin vasculitis and behavioral abnormalities that occurred in the controls (648). Administration of heparin or a heparinoid prevented binding of nucleosome/antinucleosome immune complexes to glomerular basement membrane of BALB/c mice and delayed proteinuria and histologic glomerular damage in MRL-Fas(lpr) mice for several weeks (649). Another method to prevent damage is to inhibit development of activated terminal components of complement proteins. Administration of a monoclonal antibody specific for the C5 component of complement blocks cleavage of C5 and generation of C5a and C5b-9. Continuous therapy with anti-C5 for 6 months reduced nephritis and increased survival in BW mice (650). Finally, deposition of immune complexes in glomeruli can be prevented by administration of a soluble peptide selected from a peptide display library for reaction with a mouse monoclonal pathogenic anti-DNA (but not with nonpathogenic monoclonals) (651).

Miscellaneous Interventions

Several additional strategies that affect murine lupus should be noted. Exposure of BW mice to ultraviolet (UV)A light, especially if the mice are shaved to maximize the exposure, was associated with prolonged survival, reduced lymphoproliferation, and suppression of anti-DNA antibodies (652). In contrast, exposure of BXSB mice to UV light that included UVA and UVB, and was reproduced with UVB alone, exacerbated disease (653).
