Chapter 52

The Fetus in Systemic Lupus Erythematosus

Rodanthi C. Kitridou

T. Murphy Goodwin

A variety of fetal and neonatal problems is associated with lupus. This chapter will deal with fetal loss, its pathogenesis and treatment, prematurity, intrauterine growth restriction (IUGR), their causes, and management recommendations. For a definition of terms used, please see Chapter 51 . Over the last 55 years there has been an enormous interest in the subject with a plethora of studies documenting that practice has evolved toward earlier disease detection and more aggressive therapy. In the series antedating 1980, the outcome of pregnancy in patients with systemic lupus erythematosus (SLE) was characterized by higher fetal loss than the general population, with increase in spontaneous abortions and stillbirths. There had been little change in the 30 years between 1950 and 1980 (1 ,2 ,3 ,4) (Table 52-1). However, in the 1980s, 1990s, and 2000s, there is better understanding of the causes of fetal loss and better fetal survival through improved pregnancy management (5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 , 41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53).

Fetal Outcome in Systemic Lupus Erythematosus

A pregnancy may result in live birth, full-term, or premature (preterm) delivery, or in fetal loss. A neonate may be of normal weight for age, or small for gestational age, the latter also known as IUGR. Fetal loss may be a result of spontaneous abortion (before the 20th week of pregnancy), or of intrauterine fetal death (stillbirth, after the 20th week of gestation).

The factors responsible for overall fetal loss in lupus include antiphospholipid (APL) antibodies, disease activity, and lupus nephritis, discussed later.

It is increasingly recognized that the death of a fetus of normal appearance on ultrasound after 10 weeks' gestation has a much stronger association with autoimmune mechanisms than earlier loss. The common very early pregnancy loss is most often chromosomal or hormonal in nature. Therefore, the International Congress on Antiphospholipid Antibodies (APL Congress) included both pre-embryonic, embryonic losses, and the fetal-neonatal complications in their 1999 criteria, distinguishing three categories of pregnancy loss (54):

- One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation
- One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe preeclampsia or severe placental insufficiency
- Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation

In practice, this means that we look for evidence of APL antibodies, or subclinical SLE or APL syndrome (APS) as a cause of pregnancy loss in the above settings.

The older data dividing spontaneous abortions and stillbirths by 20 weeks' gestation are still needed for comparison and trends, especially for regional and national statistical comparisons.

Spontaneous Abortions

The prevalence of spontaneous abortions (SABs) in SLE pregnancy (Table 52-1) was reported as 11.6% for the decade 1950 to 1959, 19.5% for the years 1960 to 1969, and 19.4% for the period 1970 to 1979. All these figures are derived from retrospective studies. In most studies that compare pregnancy outcome before and after lupus onset, fetal loss was found to be increased even before disease onset (2 ,3 ,4 ,5 ,6 ,7 ,8). SABs ranged from 14% to 35%, with general population rates reported as 7% to 12.5%. Full-term deliveries ranged from 64% to 86% (average 72.5%).

After onset of SLE, there was usually an increase in SABs, reported in 4% to 40%. In the study by Fraga et al. (3), 23.1% of 183 pregnancies before SLE onset ended in SABs, with 12.5% in 288 control pregnancies (4). After SLE onset, SABs rose to 40.5%. An exception is a study from Greece, where no increased fetal loss prior to disease onset was found (8).

Between 1980 and 1989, 17 reports on 724 lupus pregnancies appeared (4,5,8–22), three of them were prospective (16,18,22), and five addressed SLE nephritis and pregnancy (4,5,12,15,20). The mean prevalence of SABs in 543 pregnancies (excluding most of the nephritis pregnancies), was 13.7% (Table 52-1). The highest prevalence was 30% in a patient questionnaire study from Vancouver (17), whereas the lowest rates are 0% and 6% (8,9). In the prospective study from Mexico City by Mintz, the frequency of SABs was 16.6% (17 of

102 pregnancies), significantly higher than 6.7% in their controls (18).

Table 52-1: Fetal Outcome of Systemic Lupus Erythematosus Pregnancies, Exclusive of Elective Abortions

[†]227 pregnancies are discussed under Lupus Nephritis, Table 52.2
[‡]128 pregnancies
[a]395 pregnancies
[b]147 embrya (1 twin pregnancy)
[c]64 embrya (3 twin pregnancies)

Of 21 studies from the 1990s (23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,56), 10 are prospective (24 ,28 ,29 ,30 ,33 ,34 ,35 ,36 ,38 ,39), 2 are prospective and controlled (24 ,28), and the rest retrospective, with a total of 1,780 reported pregnancies. Three studies specifically addressed SLE nephritis and pregnancy and are discussed later (26 ,27 ,56). Spontaneous abortions ranged from a low of 5.4% (39) to a high of 30% (37), with a mean of 14.8% (Table 52-1). The reasons for the variations are not apparent, but, aside from lupus activity and APL antibodies, may include socioeconomic, educational, and cultural diversity parameters. Overall pregnancy loss is lower than previous decades, 19.1%, with a corresponding increase in live births to 80.4%.

Of the 18 studies from 2000 to 2005, reporting 1859 pregnancies, 11 address SLE in general (43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53), 6 address pregnancies with nephritis (57 ,58 ,59 ,60 ,61 ,62), and 1, SLE pregnancies after renal transplantation (63). In the first 11 series the trend of the 1990s continues: pregnancy loss is the lowest ever, 17.9%, with 14.6% SABs, 4.7% perinatal loss and further increase in live births (82.1%) (43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53). SAB rates varied widely and ranged from a low of 7.1% in the Johns Hopkins Lupus Cohort (53), to a high of 29.3% in a study from India (50). In the latter study, women with active SLE during pregnancy lost over half of their fetuses to SABs (55.6%) (Table 52-1). Women with nephritis had high losses as well and will be discussed later.

Overall, the last 25 years show a reduction and then stabilization of SABs below 15%, which is an improvement from the 19.5% rates of the 1960s and 1970s, and much closer to normal population values.

Perinatal Death (Table 52-1)

Perinatal death is the sum of stillbirth (intrauterine fetal death) and neonatal death, approximately 10/1000 in the general population. Intrauterine fetal death (IUFD) or stillbirth is the death of the fetus after the 20th week of gestation. The rate is approximately 5 per 1,000 in the general population. Neonatal death is defined as death occurring in the first 28 days after birth. The background rate is 5 per 1,000. In lupus, IUFD is the major component of perinatal loss. Perinatal loss was 10-fold that of the general population in the 1950s (10.3%), and has been decreasing over the last 55 years to 6.8% in the 1960s, 8.5% in the 1970s, 7.4% in the 1980s, 4.3% in the 1990s, and 4.7% in 2000 to 2005 (Table 52-1).

Of the 21 studies of the 1990s, reporting 1,780 pregnancies, perinatal loss was the lowest ever, 4.6%, excluding most nephritis patients (1,652 pregnancies, 23–25,28–42), and ranged from 0% (24 ,28) to 12% in women with lupus nephritis and APL antibodies (27). In the 11 studies from 2000 to 2005, perinatal loss was seen in 4.7% of 1466 pregnancies (43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53), essentially the same as in the 1990s. There were no stillbirths or neonatal deaths reported in a study from Israel (51), whereas the highest rate was encountered in severely active SLE, 16.7% and 15.8% (50 ,53) and in lupus nephritis, 31.6% and 38.5% (47 ,58).

Neonatal deaths are excessive in SLE pregnancies, with the highest prevalence of 20% in the 1965 study by Estes and Larson (2), and of 25% in the 1978 study by Thomas et al. (55). In the 1950s there were 5.8% neonatal deaths (9 of 155 uninterrupted pregnancies), in the 1960s, 0.7% (2 of 307), and in the 1970s, 0 of 505 pregnancies (1). Among the 16 series published in the 1980s, there were 15 neonatal deaths in 724 pregnancies (2.07%) (4 ,11 ,12 ,16 ,18). In the 21 reports from the 1990s, there were 18 neonatal deaths in 1,780 pregnancies (1.01%) (26 ,30 ,31 ,33 ,39). Some of these were due to extreme prematurity, or to congenital heart block (39 ,44). In 2000 to 2005, there were 21 neonatal deaths in 1859 pregnancies, 1.13%, over double the general population rate (44 ,45 ,50 ,52 ,58 ,61). Most neonatal deaths occur in very premature and growth-restricted neonates.

Pregnancy (fetal) loss is the sum of spontaneous abortions and perinatal deaths. Excluding elective (induced, therapeutic) abortions, the prevalence of pregnancy loss in lupus patients remained stable in the three decades between 1950 and 1980, at 27% to 27.9%. From 1980 to 1989, fetal loss prevalence was 22.3%, and six series showed, for the first time, a decrease to under 20% (8 ,9 ,10 ,11 ,14 ,19). This trend continued into the 1990s, with the mean pregnancy loss at 19.1%, with 12 of 20 series showing loss under 20% (23 ,24 ,25 ,26 ,28 ,29 ,30 ,34 ,35 ,39 ,41 ,42). In the last 5 years, pregnancy loss decreased even further to 17.9%, with most studies (8 of 12) under 20% (43 ,45 ,46 ,48 ,49 ,52 ,53 ,62) (Table 52-1). An analysis of pregnancy outcomes over 40 years (1960 to 2000) in 5-year increments has also shown that pregnancy loss has decreased from 43% in 1960 to 1965 to 17% in 2000 to 2003 (68). The decrease is attributed to better disease management and perinatal monitoring.

Etiology of Pregnancy Loss

The activity of maternal lupus, of SLE nephritis, and APL antibodies have been incriminated as etiologic factors for total perinatal loss in lupus.

Activity of Lupus

In early pregnancy studies, lupus activity was determined by experienced clinicians; more recently, it is assessed by validated lupus activity instruments (Systemic Lupus Erythematosus Disease Activity Index [SLEDAI], Systemic Lupus Activity Measure (SLAM), Lupus Activity Index [LAI], British Isles Lupus Assessment Group [BILAG], European Consensus Lupus Activity Measure [ECLAM]) (65 ,66). In recognition of differential diagnostic dilemmas between SLE activity versus preeclampsia, which have certain symptoms and findings in common (headache, hypertension, proteinuria, seizures, red blood cells in urine), and versus pregnancy-associated problems (fatigue, edema, alopecia), certain modifications have been developed in the above activity measures for use in pregnancy (67 ,68).

In certain studies, pregnancy loss seems independent of lupus activity, for example, in the prospective study by

Mintz et al. there was no significant difference between spontaneous abortions or stillbirths in active (13.7% and 6%) versus inactive lupus (19.6% and 3.9%) (18), and, in their study of 108 pregnancies, Lima et al. concluded that flares during pregnancy did not increase the risk of fetal loss (35). On the other hand, a prospective study from Johns Hopkins has assessed definitively the impact of lupus activity on all aspects of fetal outcome (53) (Table 52-1). Among 267 pregnancies there were 210 low-activity, and 57 high-activity pregnancies, as defined by a physician's estimate of lupus activity. With high activity in the first trimester, spontaneous abortions tripled, 29% versus 9% in low-activity pregnancies. Perinatal mortality in the high-activity pregnancies was also threefold that of the low-activity group, 15.8% versus 4.8%. Similarly, a study from India found inactive lupus pregnancies to have a much lesser rate of SABs, perinatal death, and pregnancy loss than active lupus pregnancies (8.7% vs. 55.6%, 8.7% vs. 16.7%, and 17.4% vs. 72.2%) (Table 52-1) (50).

Lupus Nephritis (Table 52-2)

Several studies associate severe nephritis flares with adverse pregnancy outcomes, including pregnancy loss. In the 1980s, 5 studies addressed SLE nephritis and pregnancy (4 ,5 ,12 ,15 ,20). Overall spontaneous abortions were 22% in these 227 pregnancies, versus 13.7% in the remaining 543 pregnancies (Tables 52-1 and 52-2). It should be noted that there were nephritis patients among the 543 pregnancies, without adequate data to distinguish their outcome (8 ,9 ,10 ,11 ,13 ,14 ,16 ,17 ,18 ,19 ,21 ,22). Perinatal loss was similar, at 7.3% and 7.4%, and pregnancy loss was higher with nephritis 29.5%, than without, 22.3%. Gimovsky et al. reported 40% spontaneous abortions and 12.5% IUFDs in women with lupus nephritis, with 28% and 2.5% respectively without (4). These patients were socioeconomically disadvantaged, with a great proportion of illegal aliens (as much as 60% to 70%). In the Hayslett study, of 55 pregnancies with active lupus or nephritis at conception, live births were at 56% with nephrotic syndrome, 64% with active SLE, and 88% with quiescent SLE (12). Fetal loss was seen in one of 10 pregnancies with serum creatinine less than 1.5 mg/dL, and in 50% with creatinine more than 1.5 mg/dL. Hence, in the 1980s, severe lupus nephritis tended to be associated with greater fetal loss and pregnancy was discouraged.

In the 1990s, three studies with 128 pregnancies addressed the role of active nephritis in the outcome of pregnancy: Overall, SABs were 10.1%, perinatal loss was 4.7% with a pregnancy loss of 14.7% (26 ,27 ,56). Of 47 pregnancies in 25 women with mostly stable lupus nephritis, overall fetal loss was 19%, but was double in hypertensive patients than normotensive patients (29% vs. 13%), and all SABs occurred with nephritis class III, IV and V (26). In the above study, there was no determination of APL antibodies. In the study of 57 pregnancies with lupus nephritis by Packham et al., fetal loss was slightly greater with class III and IV glomerulonephritis, than with membranous nephropathy. Nevertheless, the majority of fetal loss (3 of 5 SABs, all 5 stillbirths, and 2 of 5 neonatal deaths) occurred in mothers with the lupus anticoagulant (LAC) (27).

Five more studies from the 1990s merit attention: In a study of 121 pregnancies, active nephritis predicted fetal loss (13.4% live births with active nephritis, vs. 33% with inactive nephritis), and hypertension predicted prematurity and IUGR (23.8% preterm and IUGR babies with hypertensive mothers, vs. 6.6% with normotensive mothers) (38). In this study, fetal loss with and without APL antibodies did not differ. In a study from Spain, hypertension occurred in 5 of 10 pregnancies with nephritis versus 11.6% of 43 pregnancies without nephritis, and nephritis was significantly associated with lower gestational age at delivery, 35.9 versus 37.3 weeks (39). Three additional studies related poor fetal outcome to nephritis flares (34 ,37 ,40), and one study linked small-for-date neonates to hypocomplementemia, even without flare (41).

In 2000 to 2005, 6 studies specifically addressed SLE nephritis and pregnancy (57 ,58 ,59 ,60 ,61 ,62), 2 SLE pregnancy studies gave pertinent data on the nephritis patients included (47 ,49), and 1 study reported on lupus pregnancies after renal transplant (63). These 9 studies include 395 pregnancies, where the SAB rate is 21.6%, versus 14.6% in patients without nephritis (Table 52-1), perinatal loss is 7% (vs. 4.7%) with all pregnancy loss 27.7% versus 17.9%. Active nephritis or new-onset nephritis during pregnancy, proteinuria, hypertension, and hypocomplementemia had the highest pregnancy loss with 57.9%, 38.5%, and 52.6% (47 ,58 ,61) (Table 52-2). On the other hand, well controlled, quiescent nephritis at conception had a very low pregnancy loss, 6% (49). In a study of 101 pregnancies from Barcelona, pregnancy loss was similar in 38 pregnancies with class III and IV nephritis (18.4%), 11 pregnancies with class II and V nephritis (18.2%), and 52 pregnancies without nephritis (17.3%) (62). Hypertension, preeclampsia, and the need for cesarean section (43.7%) were significantly more frequent in pregnancies with class III and IV, and mean birthweight was lower by more than 500 grams, whereas cesarean section was needed in only 18.6% in the group without nephritis (62). Pregnancies with inactive lupus nephritis had the best outcome, with up to 94% live births (49).

In the 54 SLE pregnancies after kidney transplantation, pregnancy loss was 20.5%, hypertension was present in 45% of pregnancies, and cesarean sections were needed in 30% (63). Overall, the pregnancy loss of SLE patients was similar to kidney transplant patients without lupus.

Antiphospholipid Antibodies

Since Nilsson et al. in 1975, Firkin et al., and Soulier and Boffa (69 ,70 ,71) suggested a link between the lupus anticoagulant (LAC) and recurrent abortions, a tremendous body of knowledge has been amassed.

The spectrum of obstetric problems associated with APL includes the following (72):

- Recurrent pregnancy loss, especially second or third trimester loss

Table 52-2: Fetal Outcome in Lupus Nephritis, Exclusive of Elective Abortions

* 65 embrya (1 twin pregnancy).
**52 embrya (1 twin pregnancy).
†Babies in III and IV were smaller than babies with no maternal nephritis x, mothers had SLE with kidney transplants y, birth weight <2,500 g and birth weight <1,500 g, respectively

- Fetal growth restriction, especially severe, early onset
- Oligohydramnios, otherwise unexplained
- Placental abruption
- Placental infarction
- High midpregnancy maternal serum alpha-fetoprotein (MSAFP) and human chorionic gonadotropin (hCG), otherwise unexplained
- Pregnancy-induced hypertension (PIH), especially severe and of early onset
- Pregnancy-related thrombosis, venous or arterial

Any of the above problems, especially if severe, of early onset, and otherwise unexplained, should prompt investigation for APL, even if the clinical picture does not point to lupus and the history does not include intravascular thrombosis.

Table 52-3 shows the fetal outcome in SLE and SLE-like illness in the presence or absence of antiphospholipid antibodies. In 15 retrospective studies of 1,249 pregnancies, there were 479 pregnancies in APL-positive women, and 770 pregnancies in APL-negative women (31 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85). In the APL-positive pregnancies, there was a mean fetal loss of 37% (range, 14% to 68%). In the APL-negative pregnancies, there was a mean loss of 18% (range, 3% to 43%) and the difference was not statistically significant. Kutteh et al. have determined the prevalence of multiple abortions in lupus (2 or more) as 27% among anticardiolipin (ACL)-positive women and in only 3% of ACL-negative women (85). These authors showed that the percentage of fetal loss correlated with the level of ACL antibody: at 10 phospholipid units, fetal loss was 10%; at 10 to 20, 20%; at 21 to 80, 32%, and at 80 units, 60% (85). In their study of 70 lupus nephritis pregnancies, Moroni et al. reported 76% fetal loss in APL-positive, vs. 13% fetal loss in APL-negative pregnancies, an odds ratio of 17.8 (58).

APL, antiphospholipid antibodies.

In seven prospective studies of 892 lupus pregnancies, 301 occurred in APL-positive, and 591 in APL-negative women. In the APL-positive pregnancies, mean fetal loss was 48% (range, 4% to 100%), and in the APL-negative, 9% (range, 0% to 20%) (86 ,87 ,88 ,89 ,90 ,91 ,92). Despite the large range, the significance of positive APL as a cause of fetal loss seems irrefutable. APL positivity has been linked more to midpregnancy and late fetal loss (27 ,77 ,93 ,94), but is also emerging as an important factor in early loss (95).

Risk factors for fetal loss include the LAC (27 ,91), high-level IgG anticardiolipin, alone (76 ,81 ,85 ,86 ,89 ,93), or in combination with the LAC (96 ,97), and a history of prior fetal loss (76 ,84 ,86). In lupus patients with both LAC and ACL (about 16% of 349 lupus patients), fetal loss was the highest, at 89% (97). APL levels may fluctuate, especially when low positive (82 ,98 ,99 ,100 ,101).

Another antiphospholipid, antibody to $ß_2$-glycoprotein I ($ß_2$GPI), is often found in association with ACL antibody and uncommonly alone. Although initially it was thought that testing for anti-$ß_2$GPI did not identify additional patients at risk for recurrent abortion or fetal loss (102), several recent studies support the value of testing for anti-$ß_2$GPI, suggesting that as many as 10% of patients with features of APS may not be identified with LAC and ACL alone (103 ,104 ,105).

High APL level was predictive of fetal distress, manifested by abnormal fetal heart deceleration and preceding fetal death (86). Two subsequent studies further confirmed the association of high levels of IgG ACL, or lupus anticoagulant with fetal death: with IgG ACL of over 40 GPL international units, the proportion of fetal deaths was 46% to 65%, and with 0 to 39 GPL it was 17% to 19% (98); similarly, in women with high-positive APL (lupus anticoagulant, or more than 19 IgG binding units of ACL), fetal death was 27%, whereas with negative APL, IgM anticardiolipin only, or low-positive IgG ACL (<20 binding units), fetal death was 3% to 8% (99).

“Unexplained” high MSAFP, or hCG are considered markers of a “leaky” placenta in which the fetal-maternal barrier is damaged by intervillous, decidual, or villous thrombosis. Two studies have addressed the significance of elevated MSAFP levels: in 13 of 60 pregnancies with APL antibodies, elevated second-trimester MSAFP in the absence of fetal anomalies was associated with significantly increased fetal death and perinatal loss over pregnancies with normal maternal AFP (62% vs. 6%, and 77% vs. 15%, respectively) (106). MSAFP was prospectively determined in 54 lupus, and 1,001 control pregnancies at the 16th to 31st week of gestation (107): elevated MSAFP was significantly more frequent in lupus pregnancies than in controls (7.4% vs. 2.6%), and was associated with high ACL, preterm delivery, and higher prednisone dose. Patients with “unexplained” high MSAFP or hCG, whether associated with SLE or not, are followed with serial ultrasound examination for fetal growth and antepartum testing after 34 weeks of gestation.

The pathogenesis of APL-related fetal loss involves vascular insufficiency, intravascular clotting of the placenta, and fetal hypoxia, has been discussed in Chapter 51 , and will be briefly reviewed later.

Other potential causes of intravascular clotting include interference with the natural anticoagulant system of protein C and protein S, factor V Leiden mutation (G1691), alone or in combination with APL (108). Decrease in free protein S occurs in nephrotic syndrome (109). IgG anti-protein S antibodies were found in 31% of 184 SLE patients, more frequently with venous thrombosis, prematurity, preeclampsia, and IUGR (110). There was no interference, however, with plasma free protein S, hence the antibody significance is unclear at this time.

Antiphospholipid Antibodies and Fetal Loss without Lupus and with in vitro Fertilization-Embryo Transfer

Investigators have been searching for causes of fetal loss without lupus or APS, of infertility, and failure of in vitro fertilization. APL was found in 5.3% of 7,278 normal obstetrical patients, 20% of 2,226 women with recurrent fetal loss, 24% of 3,343 women undergoing in vitro fertilization, and 37% of 1,579 women with SLE (72).

Five large studies tested 6,631 normal pregnant women, mostly consecutive patients in obstetric services, for APL (111 ,112 ,113 ,114 ,115). Lupus anticoagulant was rather rare, 0.27% to 0.07% and overall prevalence of positive APL varied from 1.25% (of >5 SD IgG ACL) (113) to 24.4% (115). Fetal loss in these patients varied from 0% (112) to 50% in women with high-positive IgG ACL (113). APL-positive pregnancies had a 60% prevalence of preterm birth (111) and there was IUGR in 18% of neonates whose mothers had prolonged APTT (114). Routine testing for APL in the absence of recurrent fetal loss, SLE, or APS is not recommended (112).

The prevalence of APL was determined in 1,698 women with pregnancy loss and had a wide range. In women with 3 or more fetal losses, APL ranged from 5.5% to 31% (77 ,91 ,116 ,117 ,118 ,119 ,120 ,121); with 2 or more, it was 10.7% and 15% (118 ,122); with <2 losses, 4.8% (116), and with one loss, APL were present in 0% to 11% (77 ,123 ,124). Eroglu and Scopelitis reported strictly on first trimester losses (120). Control subjects had 0% to 10% APL and no fetal loss (117 ,119 ,120).

Of 41 infertile women 17% had APL in addition to other autoantibodies, versus 6% of 351 normal pregnant women (125).

Several studies have addressed APL in women with implantation failure in the process of in vitro fertilization-embryo transfer (IVF-ET). Overall prevalence of APL in women failing IVF is 18% to 34% and some investigators have instituted treatment with heparin and aspirin, or intravenous immunoglobulin (126 ,127 ,128 ,129 ,130). A controlled, nonrandomized study showed the prevalence of APL in 191 women undergoing IVF as 18.8%, 5.5% in 200 normal controls, 26% in 200 women with recurrent pregnancy loss, and 32% in 200 women with SLE (128). There was no difference in pregnancy rates between the heparin and ASA-treated IVF group versus the group on standard treatment for IVF (25% vs. 19.4%). A randomized controlled trial also showed that heparin and aspirin did not improve pregnancy or implantation rates for patients undergoing IVF (129).

The Practice Committee of the American Society for Reproductive Medicine has addressed whether the presence of APL affects the outcome of IVF-ET, by examining 16 studies, 7 of which have data on IVF patients with or without APL with no treatment for APL. The clinical pregnancy and live birth rates were comparable, 57% and 46% in APL-positive, and 49.2% and 42.9% in APL-negative women. Therefore, the American Society for Reproductive Medicine has concluded that APL do not affect IVF success, testing for APL is not indicated, and treatment is not justified in this situation (131).

Treatment for Prevention of Antiphospholipid-Related Fetal Loss

Since 1983, several publications have addressed the prevention of fetal loss associated with APL antibodies. In 34 studies reporting 10 or more pregnancies, there has been improved fetal outcome (91 ,132 ,133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,150 ,151 ,152 ,153 ,154 ,155 ,156 ,157 ,158 ,159 ,160 ,161 ,162 ,163 ,164 ,165). Fetal loss in the over 1,310 untreated pregnancies was 76.2% to 100%, with only 7.9% mean live births (range, 0% to 23.8%). All treatments have resulted in some increase of live births, to a mean of 70.8% (range, 28.6% to 100%). A total of over 1,403 pregnancies were treated: the initial therapy with low-dose aspirin (75 to 100 mg/day) and 40 to 60 mg of prednisone per day for 1 to 2 months was effective but is no longer used because of serious maternal side effects, including diabetes mellitus and hypertension. The most effective treatment regimen is heparin, low molecular weight (LMWH) or unfractionated (UFH), plus low-dose aspirin, LDA (139 ,141 ,142 ,143 ,144 ,153 ,154 ,155 ,156 ,157 ,163 ,164). For details, please see Table 51.5 in the preceding chapter.

Comparison of low-dose (up to 12,000 IU/day) versus high-dose UFH (up to 30,000 IU per day) showed no advantage of the latter (76% vs. 80% live births) (154). LMWH is safe in pregnancy, can be given once a day and showed a decided advantage over historical placebo controls (83.9 vs. 55.9 live births (156)). A recent prospective, controlled study of 50 women with APS suggests that the LMWH enoxaparin is equivalent in safety and efficacy to unfractionated heparin (160). Low-dose enoxaparin (40 mg/day) was equally effective as high-dose (40 mg BID) in 51 women with APL and recurrent pregnancy loss, without heparin-induced thrombocytopenia or bleeding (164). Heparin and LMWH are category B drugs, do not cross the placenta, and are not harmful to the fetus, LWMH causes less heparin-induced thrombocytopenia (HIT) and osteoporosis than UFH. Low-dose aspirin therapy alone is not nearly as effective as the aspirin-heparin combination (42% to 44% live births, versus 71% to 80%, respectively) (153 ,154 ,155).

The efficacy of intravenous immunoglobulin (IVIG) has been reported in three prospective, controlled studies (158 ,161 ,162). Heparin plus LDA and IVIG was compared to heparin plus LDA and albumin in 14 patients: live births were 100% with both regimens (158). In another study, 40 women with APS were randomized to heparin and LDA versus IVIG as primary treatment. The live birth rate was higher (84%) in the heparin group than in the IVIG group (57%) (161). In the third study, of 82 recurrent aborters, 29 were treated with prednisone and LDA and 53 with IVIG: there was no difference in live births, at 78% and 76%, but birth weight was higher in the IVIG group (162).

A possible role for IVIG may still be found in failures of the ASA and heparin regimen. Of interest is a three-phase case-control study of 687 APL-positive women undergoing IVF-ET (130), concerning IVIG in addition to heparin and aspirin. When the women underwent IVF under heparin and ASA treatment, there were 46% live births in treated IVF cycles, versus 17% in untreated cycles. Of 322 women with a single APL subtype treated with ASA and heparin, there were 17% live births with IVF in those with antiphosphatidylethanolamine (anti-PE) or antiphosphatidylserine (anti-PS), versus 43% in women with other APL specificities. Of the women with anti-PE and anti-PS, 121 who did not achieve live births despite ASA and heparin, were given these plus IVIg: this treatment resulted in a 41% birth rate (130). This study suggests that, in specific situations, addition of IVIg to ASA and heparin may provide further pregnancy success. The conclusion is supported by a recent review (165).

A pilot study of 22 pregnancies treated with fish oil (eicosapentaenoic acid and docosahexanoic acid, 5.1 gram/day) resulted in 95.5% live births (149), but a subsequent prospective controlled study of 30 APS pregnancies showed that fish oil was as effective as aspirin (live births 73.3% vs. 80% respectively) (159).

A study on early fetal loss associated with APL compared aspirin 75 mg per day versus placebo and found no difference, with 80% and 85% live births, respectively (166).

There are two sets of treatment recommendations for prevention of fetal loss in APL-positive women, developed by the 7th conference of the American College of Chest Physicians (ACCP) on Antithrombotic and Thrombolytic Therapy (167), and the 10th International Congress on Antiphospholipid Antibodies (APL Congress) (168). Most recommendations are similar and all details can be seen in Table 51.6 of the preceding chapter.

Essentially, as soon as pregnancy is confirmed, women with prior APL-related pregnancy complications, but no thrombosis, should start subcutaneous (SC) enoxaparin 0.5 mg/kg (or other LMWH) daily, calcium supplementation at 1.5 g daily, and axial weight-bearing exercise, or unfractionated heparin, 5,000 to 10,000 U subcutaneously twice daily, calcium, and exercise.

For women who have clotted previously, SC enoxaparin 1 mg/kg every 12 hours, or adjusted dose of unfractionated heparin subcutaneously; all regimens are accompanied by daily low-dose aspirin.

For more details see Pregnancy Management for Optimal Fetal Survival , below, and the corresponding section in Chapter 51 .

In summary, there is a substantial prevalence of spontaneous abortion, stillbirth (IUFD), and overall pregnancy loss in lupus patients, which is linked mainly to active maternal lupus, active severe nephritis, and APL antibodies. There is a diminution of fetal loss during the 1990s, and 2000s, accompanied by significant increase in live births in these high-risk pregnancies, through better SLE management and treatment with antiplatelet and anticoagulant agents.

Anti-Ro/SSA Antibodies

It is well known that anti-Ro/SSA antibodies are responsible for complete congenital heart block in children of positive mothers (169). Additionally, four studies have implicated anti-Ro positivity in fetal loss (170 ,171 ,172 ,173), and two have found no such a relationship (46 ,174). In a retrospective study of 50 anti-Ro positive women, 20 with SLE, 34 had

84 pregnancies with 28% fetal loss, which was far more pronounced in African-American women, 71% (171). No information was given about the APL status of these patients. In a retrospective cohort study, recurrent pregnancy loss was associated with anti-Ro in women with Sjögren syndrome or rheumatoid arthritis (23.7%), but not with SLE (172). The same investigators found that antibodies to Ro52, Ro60, p57, and thyroglobulin, were independent predictors of recurrent pregnancy loss in women with autoimmune diseases (173). Two more studies failed to find a relationship between anti-Ro positivity and pregnancy loss in 47 SLE women (174) and in 100 women with a variety of autoimmune diseases, including 53 with lupus (46). The last study was prospective. Apart from congenital heart block, the effect of anti-Ro on fetal death is unclear.

Other Observations

In the study by Nossent and Swaak, the male-to-female ratio of offspring of lupus patients (male babies per 100 female babies) was 72.7 before, and 78.9 after onset of SLE, lower than the normal of 105 for the Dutch population (23). This implies greater fetal loss of male offspring. In an attempt to explain the high female-to-male ratio in SLE, Oleinick examined the family histories of 198 lupus patients and their 581 siblings. He found that the ratio of male to total siblings born within 4 years of the birth of lupus patients was lower and suggested that excessive male fetal loss may explain, in part, the female preponderance in SLE (175). In a later investigation, the author found that there was no excess mortality risk in early life for male siblings or offspring of lupus patients (176).

Elective (Induced, Therapeutic) Abortions

Elective (induced or therapeutic) abortions in lupus pregnancies are reported as high as 34% from Hong Kong (24), 25% from Toronto (9), 21% from Vancouver (17), and as low as 0% from Mexico City (18). In the U.S. series, the prevalence ranges from 10% to 24% (14 ,16). These worldwide variations are probably a result of different local legislation regarding elective abortion, patient attitudes and socioeconomic setting, and physician attitudes, sophistication, and level of comfort with lupus pregnancy.

Elective abortion may be followed by severe SLE flare, fails to induce remission, and, in earlier studies, was at times followed by death of the mother (13 ,177 ,178). More recently, the experience has been that patients tolerate the procedure, and disease activity improves with corticosteroid or other treatment. Pistiner et al. reported 106 elective abortions in 634 pregnancies (16.7%) among 227 women with lupus, without ill effects (25). Vigorous steroid treatment, rather than induced abortion, is medically indicated for suppression of lupus flares during pregnancy. If an elective abortion is indicated for psychologic or social reasons, a careful evaluation of SLE activity should be undertaken, and steroid dosage adjusted accordingly before the procedure.

Prematurity (Preterm Birth) (Table 52-1)

Prematurity or preterm birth is defined as birth before the 37th week of gestation and prematurity rate is the percentage of premature infants among all neonates (live births). Preterm birth in lupus women was virtually fivefold that of control women in a study of 555 SLE deliveries, 21% in SLE, versus 4.2% in controls (45). Before 1980, the prematurity rate was 15.3%, but preterm births were not always reported (Table 52-1). The lowest rate was 6% (179), and the highest, 30% (180).

Ten of the 13 series in the 1980s, with 362 pregnancies (excluding nephritis, see below) contained adequate data on prematurity (4 ,8 ,9 ,10 ,11 ,13 ,14 ,16 ,18 ,19): 21.9% of 362 pregnancies resulted in preterm birth, which ranged from a low of 4% (11) to a high of 63% (18).

In the 1990s, 14 of 20 series contained information on prematurity (23 ,24 ,28 ,29 ,32 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42): preterm birth ranged from a low of 16.7% (41) to a high of 64% (42), with a mean of 36.4%.

In the twelve series of 2000 to 2005, excluding the eight studies on nephritis, prematurity data are given on all 1,464 pregnancies (the twelfth study concerns 52 pregnancies without SLE nephritis used as controls in (62)): preterm births have a wide range, from 4.2% (50) to 63.6% in patients with high SLE activity (53), with the mean at 23.2% (Table 52-1).

Given the large numbers of pregnancies reported in the 1990s and the first half of the 2000s, the reduction of preterm deliveries from 36.4% to 23.2% is very credible and a most welcome improvement in the outcome of lupus pregnancies.

Etiology of Preterm Births-Maternal Lupus Activity, Nephritis, Hypertension, Corticosteroids, Preterm Premature Rupture of Membranes, and Antiphospholipid Antibodies

The etiology of premature birth is multifactorial, and many of the invoked factors coexist. Several authors have associated preterm births with active maternal lupus, lupus nephritis, APL antibodies, preeclampsia, steroid therapy, and preterm premature rupture of membranes.

Lupus activity during conception and/or during pregnancy was held responsible for premature births in several studies (2 ,5 ,10 ,20 ,28 ,29 ,34 ,43 ,47 ,49 ,52 ,53 ,181 ,182). A recent study of 267 SLE pregnancies over 16 years from Johns Hopkins showed definitively the impact of lupus activity in pregnancy on fetal outcome (53): 28 of 44 live births (63.6%) were premature in high-activity pregnancies, compared to 55 of 185 (29.7%) preterm births in low-activity patients. Similar findings were reported earlier by the same group (28), by Georgiou et al. (43), Mok et al. (49), and Chakravarty et al. (52). If hypocomplementemia and steroid therapy are considered surrogates for increased SLE activity, then more studies ascribe premature births to

lupus activity (41 ,51 ,182). Certain authors have considered prematurity unrelated to SLE activity (12 ,18 ,23 ,24 ,31).

Maternal hypertension was cited as a factor for prematurity in several studies (18 ,28 ,32 ,34 ,38 ,47 ,51 ,60). In a study of 121 pregnancies, hypertension predicted prematurity and IUGR (23.8% preterm and IUGR babies with hypertensive mothers, vs. 6.6% with normotensive mothers) (38). Proteinuria was associated with prematurity in three studies (49 ,58 ,60).

Nephritis, especially when active or newly diagnosed during pregnancy, has been associated with preterm births (Table 52-2). Of the ten preterm births in Oviasu's series, nine occurred in patients with the more severe forms of nephritis (26). In a study from Spain, hypertension occurred in 5 of 10 pregnancies with nephritis versus 11.6% of 43 pregnancies without nephritis, and nephritis was significantly associated with lower gestational age at delivery, 35.9 vs. 37.3 weeks (39). During the last 5 years, premature births in 395 pregnancies with nephritis were 42.3% versus 23.2% in the overall lupus series, with a range from 12.9% (49) to 77.8% (60) (Tables 52-1 and 52-2). Pregnancies with active nephritis had almost twice the preterm deliveries than pregnancies with inactive nephritis, 70% versus 40% (61). Patients with proliferative nephritis, WHO classes III and IV, had almost twice the premature birth rate of women without SLE nephritis, 34.6% versus 18.6%, although the difference was not statistically significant (62). Furthermore, the relationship between prematurity and SLE nephritis activity appears to be mediated through superimposed preeclampsia, which necessitates prompt delivery for maternal well-being.

In 66 lupus pregnancies reported by Johnson et al., preterm premature rupture of membranes (PPROM) occurred in 39% of premature deliveries, and PROM in 30.3% of term deliveries, and was the major cause of prematurity (181). PPROM was responsible for 16 of 29 preterm births (55.2%) in a recent study (52). It should be clear that PPROM precedes spontaneous preterm birth, as distinguished from induced preterm birth, by medical means or by cesarean section.

The role of steroid therapy alone in the cause of prematurity has been clarified by Laskin et al. (156): of 202 women with unexplained recurrent fetal loss, positive autoantibodies and no lupus, 101 were randomized to received ASA 100 mg/day and steroid, 0.5 to 0.8/mg/kg/day, and the remaining 101 patients, placebo. In the steroid treatment group, preterm delivery was significantly greater, 62%, compared to 12% in the placebo group. Similar findings were reported by Silver et al. (183).

Several reports have found increased preterm births in pregnancies of APL-positive women, including studies from the last 5 years (36 ,47 ,58 ,60 ,111 ,146 ,182 ,184 ,201). Clark et al. found ACL IgG in 55.5% of preterm deliveries versus 19.4% in term deliveries, a significant difference (182). Cortes-Hernandez et al. noted the association of prematurity with any APL antibody, including ACL, LAC, and anti-β_2GPI, in addition to maternal hypertension and steroid treatment (47). In two studies, there was no correlation of preterm birth with maternal APL (27 ,31).

In summary, although there is no complete unanimity in the reported series, premature births are commonplace in lupus and are associated with maternal disease activity, hypertension, nephritis, preeclampsia, preterm premature rupture of membranes, steroid therapy, and antiphospholipid antibodies.

Intrauterine Growth Restriction

Both birth weight and fetal weight are normally a function of the gestational age of the newborn or fetus, and growth curves have been developed to show this relationship (185). When weight is below the norm for gestational age, the condition has been alternatively called IUGR, fetal growth restriction (FGR), intrauterine malnutrition, or small newborn for gestational age (SGA). By convention, IUGR means that weight is below the tenth percentile for gestational age. Very often, premature babies have low birth weight or IUGR.

Not all reports of SLE pregnancy have this information. From 1980 to 1989, four studies offered IUGR information (4 ,13 ,14 ,18): overall IUGR was present in 31% of pregnancies, with a range of 23% to 35%. In the 1990s, 7 of 20 studies found overall 18.2% IUGR in 446 pregnancies (range, 7.1% to 31%) (24 ,29 ,35 ,38 ,39 ,40 ,41). Of the twelve studies from 2000 to 2005, IUGR data are given in 11 (43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53): IUGR ranged from 4.1% (43) to 50% (51), with a mean of 18.1%, almost identical to that of the 1990s.

IUGR is often associated with preterm birth: 66% of premature neonates had IUGR, compared to 28% of term neonates (4). In the study by Mintz et al., 30% of preterm newborns had IUGR, compared to only 14% of term neonates (18). This difference is statistically significant, and was associated with better survival of the term neonates. In the study by Le-Thi-Huong, IUGR correlated with pregnancy of short duration, hypertension, and low serum C3 or C4 (34).

Several publications point out the association of IUGR and low birth weight with maternal APL antibodies (51 ,72 ,138 ,139 ,140 ,146 ,186). Caruso et al. found that birth weight was significantly lower when three tests were positive for APL (LAC, ACL, and Venereal Disease Research Laboratories [VDRL]) (146). In a study of 22 patients with IUGR and 43 healthy pregnant controls, ACL was significantly higher in the former, especially with severe IUGR (186). Out et al. found significantly lower birth weight in the APL-positive patients, but no difference in prevalence of IUGR between APL-positive and APL-negative women (24% vs. 21%) (91).

Treatment of APL-related recurrent pregnancy loss with antithrombotic therapy is associated with increased birth weight and reversal of IUGR: when Semprini et al. treated 14 recurrent aborters with heparin and prednisone, achieving a 64% rate of live births compared to 3.7% before treatment, the prevalence of low birth weight was reduced from 44% to 12% (138). Wallenburg and Rotmans treated 24 women with prior IUGR with low-dose aspirin and dipyridamole after 16 weeks' gestation, with reduction of fetal growth restriction to 13% in treated versus 61% in untreated pregnancies (187).

Other associations with IUGR include SLE activity 6 months before and at conception (49), nephritis (48), hypertension, low C4 and maternal age older than 35 years (47), hypertension, pregnancy-induced hypertension (PIH) (61), and proliferative lupus nephritis, classes III and IV (62).

In summary, APL antibodies have emerged as an important factor in poor fetal outcome, including pregnancy loss, preterm birth, and growth restriction.

Live Births

The overall proportion of live births in systemic lupus pregnancies has varied over the last 55 years, is increasing, and can be seen on Table 52-1 . In the 1950s mean live births were 72.5%, in the 1960s, 73%, in the 1970s, 72.1%, in the 1980s, 75.1%, in the 1990s, 80.4%, and, in 2000 to 2005, 82.1%. Clark et al. have analyzed meticulously live birth and preterm birth data in lupus pregnancies from 1960 to 2003, grouped in 5-year periods and weighted according to sample size (68). The authors showed that pregnancy loss has diminished very significantly, from 43% in 1960 to 1965 to 17% in 2000 to 2003 (see Table 52-1). Because of inadequate data on induced vs. spontaneous preterm birth, the authors could not group studies, but showed a trend for decrease in preterm births from 37.3% in 1980 to 32% in 2003 (68).

Live births vary widely, even in the last 5 years, depending on lupus activity, origin of the study, socioeconomic setting of patients, and other factors.

The rate of cesarean sections in lupus births varies from 18% to 44% and to 89% (26 ,29 ,45 ,62 ,188). In the study of 555 lupus pregnancies, cesarean sections were needed in 38.2% of these patients versus 19.7% of controls (45). The major indications for cesarean section are fetal distress and maternal preeclampsia.

Pathogenesis of Adverse Fetal Outcome

The pathogenetic mechanism of APL-associated fetal outcome is multifaceted, involves expression of β_2GPI in the placenta, attachment of APL, involvement of the complement cascade, interference with annexin V, inhibition of trophoblast differentiation and invasiveness, and is discussed in the previous chapter (Chapter 51). We will discuss here certain data about placental immunopathology in SLE and APS.

Placental Studies

There are at least 17 reports concerning placentae of patients with lupus or APS (88 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 ,201 ,202 ,203 ,204 ,205). The largest studies were reported by Out et al. (195), Magid et al. (200), Ogishima et al. (201), and Van Horn et al, (205) comprising 47, 40, 47, and 81 placentae, respectively. The majority of these studies concern patients with SLE and APL or just with APL syndrome (APS).

Common findings in most studies include low placental weight, infarction, thrombosis, ischemic-hypoxic change, hemorrhage, decidual vasculopathy with fibrinoid change and atherosis, and chronic villitis. Magid et al. distinguished the following clinical outcomes in SLE without APL: abortions, prematurity, and fetal growth restriction (IUGR), and in SLE with APL, there was fetal death in addition to the above (200). Placental changes were qualitatively similar: decreased weight, infarction, ischemic-hypoxic change, decidual vasculopathy, decidual and fetal thrombi, and chronic villitis of implied unknown etiology. Extensive infarction (>20%) of placenta and diffuse, moderate or marked ischemic-hypoxic change were significantly more frequent with APL-positive placentae. Placental changes and adverse fetal events were not deemed to correlate with maternal SLE activity. Similar changes were described in the studies by Out et al. (195), Van Horn et al. (205), and Nayar et al. (203). The last study reported acute atherosis in a placenta from a first trimester abortion. Ogishima et al. noted that the most severe placental infarctions, decidual vasculopathy, thrombosis, and fetal death were associated with double APL positivity for ACL and LAC (201). In a controlled study, placental histopathology was similar in 44 antiphospholipid and 37 antiphospholipid-like syndrome specimens (negative APL tests, similar clinical pregnancy problems) (205).

IgG is normally found in trophoblast basement membranes (189). Granular IgG, C3, and fibrinogen deposits on placental vessels and stroma were found in several studies of SLE placentae (190 ,191 ,194 ,197 ,202). In one patient with lupus nephritis and high DNA binding, anti-DNA was eluted from the placenta (190), and another placental eluate had antinuclear antibody (ANA) activity. Large IgG, massive vascular IgM, and C3 deposits were found in decidual vasculopathy areas (191). Guzman et al. described ANA-like nuclear staining by IgG in five placentae, C3 in two, and IgG deposits along the amniotic membranes in a lupus band-like pattern (194). Erlendsson's two patients with SLE, LAC, ACL, and false-positive VDRL had pregnancies with severe IUGR and fetal death with very small, infarcted placentae with immunoglobulin deposits and necrotizing arteritis; after treatment with low-dose ASA and 40 mg prednisone/day, they had successful pregnancies with minimal placental changes on biopsy (196). In La Rosa et al.'s study, β_2GPI was found increased on the trophoblast surfaces of patients with persistently high APL titers, along with IgG deposition (197). This is consistent with recent findings about the mechanism of APL-related fetal loss, that trophoblast cell membrane anionic phospholipids bind β_2GPI, which in turn binds anti-β_2GPI antibodies (206).

Two studies reported elution of APL from placentae of women with recurrent fetal loss (198 ,199). Chamley et al. eluted IgG ACL, ANA, and β_2GPI from placentae of four women with high serum ACL (198); β_2GPI was localized in syncytiotrophoblast. Katano et al. eluted five types of APL from seven placentae of patients with IgG APL (three also had IgM APL) and a history of at least two fetal losses (199). One patient had SLE, and all were treated with prednisolone and aspirin. IgG APL were eluted from four of seven placentae, most commonly antiphosphatidyl inositol and antiphosphatidyl serine. Cord blood was negative for

APL. Fetal outcome was one IUFD, four IUGR, and two neonates of normal weight. Infarcts and fibrinoid deposits were present in six of seven placentae, degeneration necrosis in four, and thrombosis in three. The number of pathologic findings seemed to correlate inversely with placental and fetal birth weight (199).

In placentae from SLE and APL syndrome, the distribution of cell-adhesion molecules was the same as in controls, and included intercellular adhesion molecule-1 (ICAM-1) in placental vascular endothelium and the placental villous stroma, platelet endothelial cell adhesion molecule (PECAM) in the placental vascular endothelium, whereas P-selectin was mildly expressed in the stem vessel endothelium only (204).

The deposition of immunoglobulins, complement, anti-DNA, and ANA in the placenta, and in areas of vasculopathy/vasculitis, and chronic villitis suggest that bland clotting is not the only mechanism of placental hypoperfusion and ischemia, and, hence, fetal ischemia, and that an immune-mediated inflammatory mechanism is be at play as well.

Pregnancy Management for Optimal Fetal Survival

The value of multidisciplinary care, careful maternal and fetal monitoring, and judicious use of surgical delivery were amply demonstrated in the studies from Mexico City, where fetal wastage was reduced by almost half, from 40.5% in the retrospective, to 22.5% in the prospective study (3 ,18). Modern perinatology (high-risk obstetrics) and neonatology offer tremendous advantages in fetal surveillance. Fetal ultrasound, Doppler studies of blood flow of the uterine and umbilical arteries (146 ,188 ,207 ,208 ,209 ,210 ,211), and fetal echocardiography (213 ,214), have added to conventional antepartum testing for fetal well-being—the modified biophysical profile (212 ,215). Early in the pregnancy, fetal ultrasound is used for accurate gestational dating, and for assessment of the growth of the fetus. Throughout pregnancy, ultrasound is used to assess fetal growth. Evaluation and monitoring of the uterine and umbilical arterial blood flow by Doppler velocimetry or waveforms has an important place in the early (146), and the third trimester evaluation of lupus pregnancies (211).

The diagnostic accuracy of the Doppler is limited to bilateral uterine artery notches at 22 to 24 weeks, especially in the subgroup of women with positive lupus anticoagulant. Bilateral notching of the uterine artery Doppler at 22 to 24 weeks is a useful screening test in predicting preeclampsia and SGA infants: bilateral notching was associated with a 12- to 14-fold increased likelihood of preeclampsia or IUGR, whereas normal flow was associated with an 80% decreased likelihood of the same outcome (211).

The biophysical profile consists of real-time ultrasonography, during which the fetal tone, movements, breathing movements, and amniotic fluid volume are scored; a nonstress test follows and a score of zero to 10 is assigned, 10 being optimal (212). At our institution, the modified biophysical profile is performed (216), which includes the nonstress test and amniotic fluid index, with the full biophysical profile as a back-up (215).

Fetal echocardiography is important for the follow up of bradycardia or heart block, which is almost always detected on simple auscultation; the mainstay of antepartum fetal heart testing is the nonstress test. During normal intrauterine fetal movement, the fetal heart accelerates. Failure to accelerate constitutes a nonreactive, or abnormal nonstress test. The earlier the gestational age, the greater the percentage of nonreactive nonstress tests: nonstress test is most meaningful after the 28th week of gestation. Fetal heart rate decelerations during the nonstress test are associated with fetal distress during labor (213), and nonperiodic fetal heart decelerations at 20 to 28 weeks may identify the fetus at risk for intrauterine death (217). The contraction stress test is cumbersome and has been abandoned.

Recommendations

The following are recommendations for management of lupus pregnancy to optimize fetal survival and diminish loss.

Mother

- As recommended in Chapter 51 , maternal disease should be assessed carefully for activity and severity at the outset of pregnancy, which ideally should be planned after 6 to 12 months of remission. The mother should be watched carefully for SLE flares.
- Maternal flares should be diagnosed early and treated aggressively, depending upon severity, with appropriate steroid dose and route (i.e., intravenous large doses for severe flares. Unless there is a dire emergency, i.e., acute anuric renal failure, cytotoxic drugs should be avoided during the first trimester. Mothers with nephritis at risk for hypertension and preeclampsia should be treated with low-dose aspirin (60 to 81 mg/day) until the 36th week of gestation, or until 1 week prior to delivery. The risk of abnormal bleeding is theoretical, but discontinuation may remove impediments to regional anesthesia.
- The mother's status in terms of APL, and anti-Ro/SSA, anti-La/SSB positivity should be known; the former, because of predisposition to fetal loss, preeclampsia and IUGR, and the latter two because of the small risk for congenital heart block in the child.
- Joint follow-up by the rheumatologist and obstetrician-perinatologist should be done every month for the first half of pregnancy, and more frequently thereafter (every 1 to 3 weeks), with repeat of CBC, urine, chemistry, quantitation of proteinuria in patients with nephritis, complement C3 and C4 levels, anti-dsDNA, and a measure of circulating immune complexes every 1 to 3 months depending on disease activity. Blood pressure should be monitored very carefully.
- In the event of high-positive APL antibody, especially of the IgG class, or with a “double positive” for APL (both

ACL and LAC positive, or/plus anti-β2GPI-positive), the option of an antithrombotic agent should be discussed with the patient, even in the absence of a prior thrombus or pregnancy complication. See also Chapter 51 and Table 51.6 for antithrombotic therapy recommendations (167 ,168).

Unless there is concomitant lupus activity, high-dose prednisone for APS is not recommended.

- Steroid stress doses should be given at the time of delivery, be it vaginal or by cesarean, if steroids have been employed during pregnancy.

Fetus

- Accurate gestational dating is important because of the frequent IUGR and premature births in SLE. Menstrual dating should be confirmed by ultrasonography at the first prenatal visit.
- Ultrasound evaluation of the growth of the fetus should be performed monthly after 20 weeks' gestation. At the baseline growth scan, uterine artery Doppler is used to identify the fetus at high risk for IUGR and superimposed preeclampsia. Delayed growth indicates an increased risk of fetal death in utero and should prompt a search for evidence of increased disease activity, or developing superimposed PIH. Doppler of the umbilical artery and middle cerebral artery is employed liberally at the time of the ultrasound for fetal growth to detect placental dysfunction and central redistribution of fetal blood flow associated with growth restriction.
- In the event of positive anti-Ro/SSA and/or anti-La/SSB, fetal heart tones should be checked for 1 minute at every visit after the 16th week of gestation. Any abnormal heart rhythm should prompt a detailed fetal echocardiography to rule out developing heart block.
- Antepartum testing for fetal well-being should be initiated between 24 and 34 weeks' gestation. In patients at highest risk, such as those with a history of fetal compromise, active SLE, or positive for both ACL and LAC, testing should be initiated near the cusp of viability, at 24 weeks. In women with quiescent lupus who are APL and anti-Ro/SSA negative, testing may start at about 34 weeks with the modified biophysical profile (216). Umbilical artery Doppler is used whenever fetal growth restriction is suspected or low amniotic fluid volume is encountered. Decreased amniotic fluid may presage IUGR or cord accidents leading to stillbirth.
- An abnormal fetal heart tracing or an amniotic fluid index less than 5 cm is almost always an indication for prompt delivery, usually by cesarean. When delivery is planned before 34 weeks' gestation, long-acting steroids (dexamethasone or betamethasone) should be administered to enhance fetal maturity, if the delivery can be safely delayed (217).

Other drugs should be used with great care. Maternal thiazide diuretic therapy is generally safe in late pregnancy and has rarely been associated with severe neonatal thrombocytopenia (218). Angiotensin-converting enzyme (ACE) inhibitors should not be used in pregnancy because fetal and neonatal hypotension, anuria, and even renal failure may occur (218). For more information on antirheumatic drugs in pregnancy and lactation, see the section on use of medications in Chapter 51 . As mentioned in that chapter, prednisone, prednisolone, and methylprednisolone are oxidized by placental enzymes, whereas dexamethasone and betamethasone are not; the latter are utilized to treat the fetus in utero.

Under dire circumstances, unconventional therapeutic interventions may be appropriate during pregnancy such as intravenous cyclophosphamide for maternal anuric renal failure, or intravenous gamma globulin for severe maternal SLE.

It is reassuring to note that in over 5,330 lupus pregnancies reported in the last 55 years (Table 52-1), there were very few cases of congenital malformations, with the exception of congenital heart block (see Chapter 53). These figures include infants whose mothers were on cytotoxic medications, mainly azathioprine and cyclophosphamide. Details are discussed in Chapter 51 .

Chapter 53
Neonatal Lupus

Jill P. Buyon

Robert M. Clancy

Introduction

Although physicians counseling prospective mothers with SLE appropriately focus attention on the clinical status of the mother, accumulating evidence supports that injury to the developing fetus and neonate can occur independently of maternal health. Following the seminal observation in the late 1970s that sera from nearly all mothers of children with isolated congenital heart block (CHB) contain specific autoantibodies (1 ,2), this disease, previously of interest only to the disciples of cardiology, became an important model of passively acquired autoimmunity. Over the next three decades the association solidified. Identification of heart block (first-, second-, or third-degree) before or at birth, in the absence of structural abnormalities, predicts in more than 85% of cases that the mother will have autoantibodies to SSA/Ro and/or SSB/La ribonucleoproteins, regardless of whether she has SLE, Sjögren syndrome (SS), or is totally asymptomatic (3 ,4). Cardiac injury occurs in a previously normal fetus and is presumed to arise from the transplacental passage of maternal IgG autoantibodies that result from an autoimmune process in the mother (5). Autoimmune-associated CHB does not occur randomly during fetal development but rather is most often detected between 16 and 24 weeks of gestation (6). In some cases there may be an associated myocarditis/endocarditis (7 ,8). One of the most intriguing aspects of CHB is that it is an injury unique to some phase(s) of development. Despite the presence of identical antibodies in the maternal circulation, conduction defects have not been reported in the maternal heart, with a single recent exception (9). Because CHB carries a substantial mortality [~20% (10 ,11)] and morbidity [100% eventual need for permanent pacing (12)], understanding the biology of disease and bringing this knowledge to the clinic is critical. Other abnormalities affecting the skin, liver, and blood elements are also linked with anti-SSA/Ro-SSB/La antibodies in the maternal and fetal circulation and are now grouped under the heading of neonatal lupus syndromes (NLS) (13 ,14 ,15 ,16). Neonatal lupus was so termed because the cutaneous lesions of the neonate resembled those seen in SLE (15 ,16). Disease in the offspring parallels the presence of maternal antibodies in the fetal and neonatal circulation and disappears, except for CHB, with the clearance of the maternal antibodies by the sixth to eighth month of postnatal life. The transient hematologic abnormalities and skin disease of the neonate reflect the effect of passively acquired autoantibodies on those organ systems that have the capacity of continual regeneration. In contrast, these regenerative processes apparently do not occur in cardiac tissue; to date, third-degree block is irreversible.

NLS, albeit infrequently encountered by those caring for pregnant patients with SLE, presents a unique challenge to the clinical team of rheumatologist, perinatologist, neonatologist, pediatric cardiologist, and dermatologist. For the basic immunologist, the study of these syndromes may yield important insights into the mechanism by which an autoantibody directly or indirectly causes tissue injury, whereas the embryologist may uncover relevant milestones in fetal antigen expression. The study of NLS exemplifies not only translational research, which inherently draws upon clinical observations and explores them in the laboratory, but “integrational” research which attempts to fit critical clinical and basic observations together, even those seemingly at odds.

Passively Acquired Heart Block: an Irreversible Manifestation of NLS

Pathogenesis: Laying the Groundwork for Discovery

This model of passively acquired autoimmunity offers an exceptional opportunity to examine the effector arm of immunity and define the pathogenicity of an autoantibody in mediating tissue injury. A molecular scenario in which maternal anti-SSA/Ro-SSB/La antibodies convincingly contribute to the pathogenesis of cardiac scarring has yet to be formulated. One difficulty in identification of a pathogenic effect of an autoantibody is accounting for the heterogeneity of that effect. CHB is a stellar example in that not only is the injury seemingly rare, but the degree of injury varied, with the spectrum inclusive of clinically inconsequential first-degree block as well as third-degree block and an associated cardiomyopathy that is often fatal.

The necessity of anti-SSA/Ro-SSB/La antibodies is supported by their presence in more than 85% of mothers whose fetuses are identified with conduction abnormalities in a structurally normal heart (4). However, when Brucato et al. (9) prospectively evaluated 118 pregnancies in 100 patients with anti-SSA/Ro antibodies, the frequency of CHB in a fetus was only 1.7%. Although recurrence rates exceed the 2% risk

for a mother who has never had an affected child by five- to tenfold, the risk is not 100%. Moreover, the concordance rate in genetically identical twins is also not 100%. Accordingly, it is likely that antibody specificity alone cannot account for cardiac injury and that fetal factor(s) and/or the in utero environment must amplify the effects of the antibody, which may be necessary but insufficient to cause disease. Notably, one mother in the series reported by Brucato et al. (9), who gave birth to two healthy children, developed complete heart block herself, raising the possibility that her heart had acquired “fetal factors.” Clearly, this is a unique situation and one that needs to be further studied, because it is likely to contribute important clues to pathogenesis.

Another challenging aspect of the pathogenicity of this disease is that the candidate target antigens are normally sequestered intracellularly. This suggests several possibilities: (a) the proposed target is not correct, (b) there is a cross-reactivity of the true target with an antigen normally found on the cardiac surface, and/or (c) the target becomes available to maternal antibody following a change in the cell that results in translocation to the membrane.

The sections that follow address several of the challenges posed by trying to fit the clinical clues with pathogenesis.

Cardiac Histopathology

Histopathologic studies constitute a major basis for formulating hypotheses regarding the pathogenesis of CHB. It appears logical to assume that the time of death relative to initial immune attack may influence the pathologic findings. Evidence of a cellular infiltrate might be present if death occurs close to the time a bradyarrhythmia is first detected, but calcifications may be the sole pathologic finding if death has occurred months later. An inflammatory component is supported by the finding of a mononuclear cell infiltration in the myocardium of a fetus dying in utero at 18 weeks of gestation (17) and the demonstration of patchy lymphoid aggregates throughout the myocardium of an infant delivered at 30 weeks and dying in the immediate postnatal period (18). Moreover, immunofluorescent studies have shown deposition of IgG, complement (including C1q, C4, C3d, C6, and C9), and fibrin (18 ,19). The first cardiac lesion may be a global pancarditis with inflammation of the pericardium, myocardium, and endocardium, resulting in subsequent fibrosis of the conducting system clinically manifest as permanent heart block. Litsey et al. identified IgG deposits in the epicardial, myocardial, and endocardial tissue of the right atrium on postmortem analysis of a neonate with CHB (19). Although published literature on serial echocardiograms in mothers at high risk of a pregnancy complicated by CHB is limited (albeit the PRIDE study, discussed below, will address this), it has been the general experience that the first clinically apparent abnormality in cardiac function is bradycardia, and only very rarely myocarditis (i.e., effusions, ventricular dysfunction). This implies that early inflammation is not clinically detectable and/or that atrioventricular (AV) nodal injury occurs independent of an inflammatory pancarditis.

Specific vulnerability of the conducting system is unexplained (20). Ho et al. described the histopathology of seven hearts with CHB and associated maternal antibodies to the SSA/Ro polypeptide. In all of these hearts there was atrial-axis discontinuity: the AV node was replaced by varying degrees of fibrosis or fatty tissue (20). The distribution of the distal conducting system was normal.

In five cases of CHB compiled by Carter there was disruption of the AV conduction system by a process of uncertain cause (21). In all five instances the presence of microscopic crystalline structures was associated with the conduction system and with fibrous structures of the heart. These deposits have been designated as products of connective tissue degeneration resulting from an intrauterine inflammatory process. Hogg has reported hematoxylin bodies in the AV node (22). Further support for an inflammatory process is demonstrated by the findings of calcification along ventricular portions of the conducting system and area of the sinoatrial (SA) node (19 ,23). The diffuse fibroelastosis reported in some of these affected babies is considered to result from dilatation of the cardiac chambers secondary to the compensatory increased stroke volume present in CHB (22). However, Nield et al. (7) have recently reported 13 CHB patients with endocardial fibroelastosis (EFE), six diagnosed in utero and seven in the postnatal period, despite ventricular pacing of all but one infant. EFE is associated with significant mortality and morbidity: nine (70%) of these 13 patients died, and two (15%) required heart transplants.

Given the importance of histologic data to infer pathogenic mechanisms, medical records of all families enrolled in the U.S. Research Registry for Neonatal Lupus (RRNL; established in September 1994) were reviewed to determine the incidence and timing of death, with emphasis on the pathologic findings in the affected fetal hearts (24). Complete autopsy reports were available in 11 cases. The mean time from detection of CHB to autopsy was 11 weeks. Although in three cases there were various lesions of the tricuspid valve, the pathologic descriptions were more suggestive of an imposed injury than a true developmental defect. These included nodularity, dysplasia, hypoplasia and fusion of valve leaflets, and fibrosis. The pulmonary valve was abnormal in two: one was described as stenotic dysplastic, and the other nodular and dysplastic. Aortic valve insufficiency and stenosis and hypoplasia of the mitral valve leaflet were observed in one. Endocardial fibroelastosis of the right and left ventricles (RV, LV), with or without calcification, was present in seven. Chronic changes in the myocardium were documented in ten, and included biventricular hypertrophy and increased RV and LV walls, thickened but hypoplastic RV, and hyperchromatic nuclei of the myocytes. Abnormalities of the AV node or vicinity were noted in eight with involution, fibrosis, fatty infiltration or calcification. However, in two the AV node per se appeared normal: in one there was calcification in adjacent tissue, and in another there was an atrophic His bundle with replacement by dense focally calcified fibrous tissue and scarring of the left and right bundle branches. Although previously unappreciated, autopsies obtained from the RRNL revealed a high incidence of valvular

abnormalities. Although there were sufficient changes in the AV node to account for CHB in most cases, clinical conduction abnormalities may have been secondary to a functional exit block in a normal-appearing node. SA nodal disease expands the spectrum of conduction dysfunction (as addressed below in the discussion of arrhythmogenicity and perturbation of L-type calcium channels).

These studies leave little doubt that the signature lesion of autoantibody-associated CHB is fibrosis, which can clearly extend beyond the conduction system. Consequently, the cascade leading to fibrosis is a major focus of investigation.

CHB Occurs in an Anatomically Developed Heart and Coincides with Placental Transport

The presence of maternal immunoglobulins in the fetal circulation is directly related to the normal physiology of antibody traffic across the placenta (25). Maternal antibodies interact with Fc receptors on the trophoblastic cell surface in a specific transport process. Each Fc receptor has a different ligand specificity and affinity for the IgG subclasses but all receptors bind IgG1 and IgG3 with greater affinity than IgG2 or IgG4 (26). IgG1, IgG2 and IgG3 are transported relatively early with detectable levels noted at 6 to 11 weeks of gestation. In contrast, IgG4 is present in the fetal circulation after 19 weeks (27). The resultant fetal concentrations of total IgG are marginally detectable in the first trimester (<100 mg/dL) and remain low until after 17 weeks, at which time they steadily increase, reaching 400 mg/dL by 24 weeks and 800 mg/dL by 32 weeks as placental transfer becomes more efficient (28). IgM and IgA antibodies do not cross the placenta, suggesting that CHB may occur in offspring of mothers whose antibodies are of IgG1 and IgG3 subclasses, whereas those whose antibodies are predominantly IgG2 and IgG4 are protected. However, no significant differences in subclass distribution have been observed between mothers with anti-SSA/Ro and/or -SSB/La antibodies who had pregnancies complicated by CHB or those who had normal pregnancies (29). For both groups of mothers, IgG1 antibodies were significantly increased over the other three subclasses in the anti-52kD and 60kD SSA/Ro responses. IgG1 and IgG3 were the major subclasses represented in the 48kD SS/La responses. All subclasses, including IgG2 and IgG4, were observed in one-third to one-half of the maternal serum with anti-52kD and 48kD responses. In contrast, anti-60kD antibodies were, with rare exception, confined to IgG1. Accordingly, the IgG subclasses of anti-48kD SSB/La, 52kD, or 60kD SSA/Ro antibodies do not account for the susceptibility of one fetus versus another for the development of CHB.

The stage of cardiac ontogeny that coincides with the initiation of transplacental passage of maternal autoantibodies into the fetal circulation may influence the extent of tissue injury and permanent dysfunction. The human heart attains most of its adult characteristics by 6 to 8 weeks of gestation (30). Parasympathetic innervation of the heart occurs very early in fetal development whereas sympathetic innervation develops much later and is completed some months after birth. The SA node can be recognized in the first trimester and by 10 weeks of fetal age attains its own artery. Landmarks of the three internodal pathways from SA to AV nodes appear in the second month of gestation, although the septal course of these pathways does not become fully developed until the closing of the foramen ovale cordis, shortly after birth. The AV node arises separately from the bundle of His and is joined to it at 8 weeks. The human His bundle undergoes extensive postnatal remodeling to achieve its adult form. Clearly the fetal conduction system has reached functional maturity before maternal antibodies gain access to the fetal circulation.

To support a pathogenic role of maternal autoantibodies in the development of CHB, the onset of bradycardia would be predicted to coincide with heightened placental transport and occur in a previously normal heart. As expected if the hypothesis is correct, Deng et al. reported the lack of immunoglobulin deposition in cardiac tissue from 10-week fetuses of two mothers with anti-SSA/Ro antibodies (31). There is likely to be a “window of vulnerability” when maternal antibodies gain access to the fetal circulation and recognize an antigen unique to the developing heart that is absent or otherwise inaccessible in the maternal heart.

Review of data obtained from the RRNL revealed that in 71 (82%) of 87 fetuses, bradycardia was identified before 30 weeks of pregnancy (11). Detection was most frequently clustered between 20 and 24 weeks. Fourteen (16%) cases were first identified in the third trimester, five of which were noted at the time of delivery. The median time of in utero detection was 23 weeks. Of the 85 fetuses diagnosed with CHB during pregnancy, 15 were born between 1970 and 1987, eight of whom were diagnosed before 30 weeks of gestation. Seventy pregnancies occurred between 1988 and 1997, in which 63 were diagnosed with CHB prior to 30 weeks (P <0.003, earlier detection of CHB in pregnancies after 1988 compared to pregnancies before 1988).

Classification of Heart Block

There still exists some confusion regarding the assignment of “congenital” heart block. Webster defines congenital as that “existing at or dating from birth.” Data from Hübscher et al. strongly suggest that postnatally “acquired” heart block (even without structural abnormalities) is not associated with maternal antibodies to SSA/Ro or SSB/La (32) and is probably best categorized as a separate entity.

Again, the issue of “complete” versus “incomplete” heart block warrants clarification. Initially, heart block was operationally defined as third-degree or congenital complete heart block (CCHB) although it was hypothesized that heart block might progress through various stages. Of 187 children in the RRNL with CHB associated with anti-Ro/La antibodies in the mother, nine had a prolonged PR interval on EKG at birth, four of whom progressed to more advanced AV block (33). A child whose younger sibling had third-degree block was

diagnosed with first-degree block at age 10 years at the time of surgery for a broken wrist. Two children diagnosed in utero with second-degree block were treated with dexamethasone and reversed to normal sinus rhythm by birth, but ultimately progressed to third-degree block. Four children had second-degree block at birth: of these, two progressed to third-degree block. Accordingly, the general abbreviation “CCHB” is not precise and CHB (congenital heart block) has been adopted.

When CHB is associated with major structural abnormalities such as transposition of the great vessels, maternal autoantibodies are generally not present. This defect of cardiogenesis occurs prior to the 10th week of gestation and results in the disruption of the development of the AV conducting system. Such cases should be considered as a distinct classification of CHB secondary to abnormal cardiac embryogenesis and not likely the result of passively acquired autoimmunity. Examination of a heart from a child with this type of CHB, whose maternal serum did not contain autoantibodies, revealed nodoventricular discontinuity, with the AV node well formed and normally situated (34). Similarly, mass lesions developing in the conducting system, such as mesotheliomas of the AV node, would constitute another distinct type of CHB.

Arrhythmogenicity of Maternal Autoantibodies and Perturbation of L-Type Calcium Channels

Two earlier publications, both in animal models, indirectly invoked arrhythmogenic effects of anti-SSA/Ro-SSB/La antibodies. Alexander et al. reported that superfusion of newborn rabbit ventricular papillary muscles with IgG-enriched fractions from sera containing anti-SSA/Ro-SSB/La antibodies specifically reduced the plateau phase of the action potential consistent with an alteration of calcium influx (35). Garcia et al., using isolated adult rabbit hearts, showed that IgG fractions from women with anti-SSA/Ro-SSB/La antibodies induced conduction abnormalities and reduced the peak slow inward calcium current (I_{Ca}) in patch-clamp experiments of isolated rabbit ventricular myocytes (36). Because conduction in the AV node is essentially dependent on calcium electrogenesis, AV block would be expected to result from treatments leading to reduction of the I_{Ca} in ventricular myocytes. The L-type calcium channel is mainly responsible for I_{Ca} in ventricular myocytes and for the propagation of the action potential in the AV node.

These intriguing publications led to a collaborative effort with Dr. Mohamed Boutjdir (Brooklyn VA Medical Center, Brooklyn, NY) in which attention focused on the human fetal heart (37). To assess the effect of IgG fractions and affinity-purified antibodies on conduction and heart rate, electrocardiogram (EKG) recordings were obtained from whole human fetal hearts, aged 18 to 24 weeks. Baseline EKGs were recorded after a stabilization period of 30 to 45 minutes. Perfusion of the heart for 27 minutes with purified anti-52kD SSA/Ro antibodies from three mothers of children with CHB resulted in bradycardia associated with widening of the QRS complex that could represent bundle branch block or an intraventricular defect in the conducting system. The average increase in R-R and P-P interval corresponded to 32% and 30%, respectively. At 33 minutes of perfusion, complete AV block was diagnosed with the presence of only P waves and missing QRS complexes. Reperfusion of the heart with antibody-free Tyrode solution for 48 minutes resulted in partial and slow recovery. In contrast, IgG from four control mothers did not have any measurable effect on AV conduction. These findings were further characterized by studying the effects of IgG fractions and affinity-purified anti-52kD SSA/Ro antibodies on whole cell L-type I_{Ca} recorded by the patch clamp technique (38). IgG from two CHB mothers, but not from three control mothers, inhibited peak I_{Ca} at all voltages tested. The average inhibition at 0 mV was 59%. Similarly, affinity-purified anti-52kD SSA/Ro antibodies from three CHB mothers inhibited peak I_{Ca} by 56% at 0 mV. Accordingly, inhibition of I_{Ca} by the autoantibodies in isolated myocytes further supports the contribution of Ca^{2+} channels to the conduction abnormalities observed in the whole heart.

The biophysical properties by which the autoantibodies inhibited whole cell I_{Ca} were then investigated at the single channel level using the cell-attached configuration of the patch-clamp method (38). Barium currents were recorded through Ca^{2+} channels as described (39). Bath application of affinity-purified anti-52kD SSA/Ro antibody from two CHB mothers produced a significant decrease in the Ca^{2+} channel activity and the ensemble average current. The ensemble average currents decreased from 0.23 pA to 0.13 (-43%, $P < 0.02$). Similar inhibition was obtained with IgG from two CHB mothers, but no significant effect was observed with IgG from three control mothers. Analysis of single channel kinetics indicated that this inhibition was the result of shorter open times and longer closed times, which could also explain the basis of the whole cell I_{Ca} inhibition by the autoantibody. The effect of the affinity-purified antibody and IgG from CHB mothers was less pronounced in the cell-attached than the whole-cell recordings, suggesting involvement of a diffusible cytosolic constituent in mediating the response to autoantibodies. Boutjdir et al. have extended this work and recently reported a direct interaction of maternal anti-SSA/Ro-SSB/La antibodies with the pore-forming α(1)-subunit of Ca channels using transfected *Xenopus* oocytes (40), a finding of interest that remains to be confirmed.

Given the data in the rabbit and human heart, it is tempting to conclude that inhibition of L-type Ca^{2+} channels explains the pathogenicity of anti-SSA/Ro (perhaps anti-SSB/La) antibodies in the development of CHB. Several facts are highly supportive of this conclusion. AV nodal electrogenesis is dependent on L-type Ca^{2+} currents. Ca^{2+} channel density is lower and sarcoplasmic reticulum less abundant in fetal compared to adult cardiac cells, increasing the dependency on transsarcolemmal Ca^{2+} entry (41). Prolonged exposure of fetal Ca^{2+} channels to the maternal anti-SSA/Ro-SSB/La antibodies may lead to internalization and degradation of the channel, cell death, and ultimately fibrosis. Inhibition of

ventricular Ca^{2+} channels may result in decreased contraction and congestive failure. Alternatively, antibody binding to the channel may result in opsonization and phagocytosis by macrophages with inflammatory/fibrotic sequelae (similar to the apoptosis theory described above).

SA nodal electrogenesis is also dependent on L-type Ca^{2+} currents (42). Interestingly, detailed evaluation of autopsies done on children in the RRNL revealed pathology in some cases at the SA node (as described earlier in this chapter) (24). Mazel et al. observed sinus bradycardia in a murine model of passive immunity with anti-SSA/Ro antibodies (43). Highly relevant to these histologic and functional observations is Brucato's identification of sinus bradycardia in four of 24 EKGs from otherwise healthy newborns born to the cohort of mothers with SSA/Ro antibodies (9). Of 187 cases in the RRNL (33), atrial rates from postnatal EKGs were available for 40 neonates; the mean rate was 137 bpm ± 20 standard deviations (SD), range 75 to 200. The single slow rate of 75 bpm was obtained during sleep and increased to 140 bpm when awake. In an additional child, the records stated sinus bradycardia; however, no EKG was available and subsequent records were not sent to the RRNL. In both our review and the study by Brucato (9) the sinus bradycardia was not permanent. Although this suggests that the nature of the initial insult and/or the subsequent reparative processes may be different for the SA and AV nodes, normal atrial rates may reflect the functioning of other pacer foci in the atria.

Accounting for Accessibility of Intracellular Antigens to Circulating Maternal Autoantibodies

A mechanism whereby antibodies might interrupt critical intracellular events in fetal cardiomyocytes or specialized Purkinje cells is largely unknown. As previously stated by Tan, “the question is whether autoantibody reacts with intrinsic antigens to perturb the biologic function of normal cells” (44). For anti-SSA/Ro and -SSB/La antibodies to be causal in the development of NLS, three basic requirements should be satisfied. First, the candidate antigens must be present in the target fetal tissues; second, the cognate maternal autoantibodies must be present in the fetal circulation; and third, these antigens must be accessible to the maternal antibodies.

Earlier studies have firmly demonstrated reactivity of anti-SSA/Ro antibodies with fetal cardiac tissues, including the conduction system (31 ,45 ,46). The preferential vulnerability of the fetal versus the adult heart is addressed by a study demonstrating that a 23-week fetal heart contained a greater quantity of SSA/Ro per mg protein than 18-to-22-week hearts or an adult heart (47). The presence of SSA/Ro and SSB/La antigens in the fetal heart is well established and therefore satisfies the first requirement. Similarly the second requirement has been fulfilled by studies demonstrating anti-SSA/Ro-SSB/La antibodies in the fetal circulation as assessed by measurements in cord blood (29 ,48).

The third requirement, accessibility, has been more difficult to establish. It has been suggested that autoantibodies can penetrate living cells, subsequently alter function, and cause cell death (49), but this notion still remains controversial. Alternatively, if the antibody cannot cross the cell membrane, then is the antigen trafficked to the cell surface? Finally, anti-SSA/Ro-SSB/La antibodies could crossreact with other surface cardiac antigens.

Several lines of evidence have been advanced to support the possibility that otherwise sequestered intracellular autoantigens can be expressed on the cell surface. Baboonian et al. have demonstrated the sequential expression of the SSB/La antigen from the nucleus through the cytoplasm and ultimately on the cell surface of HEp-2 cells infected with adenovirus (50). There is now accumulating data supporting surface expression of SSA/Ro in keratinocytes, after exposure to ultraviolet light (51 ,52 ,53) or following incubation with TNF-α (54).

Reichlin et al. have bolstered support for the accessibility of the candidate antigens to the respective maternal antibodies by the finding of antibodies to native 60kD SSA/Ro and denatured 52kD SSA/Ro in acid eluates of a heart from a fetus with CHB who died at 34 weeks' gestation (55). The enrichment was apparently selective, because these antibodies were not detected in eluates from the brain, kidney, or skin. Furthermore, Horsfall et al. have demonstrated maternal IgG-bearing anti-SSB/La idiotypes on the surface of fetal myocardial fibers on autopsy of a neonate with CHB (56).

Apoptosis has been traditionally conceptualized from an immunologic point of view as either a means of maintaining B- and T-cell tolerance (57 ,58) or as a mechanism for providing accessibility of intracellular antigens to induce an immune response (59). Casciola-Rosen et al. have demonstrated that autoantigens are clustered in two distinct populations of surface blebs on keratinocytes (59). The larger blebs, so-called apoptotic bodies derived from the apoptotic nucleus, contain both SSA/Ro and SSB/La proteins with SSB/La detected at the cell surface surrounding large blebs in the later stages of apoptosis. The 52kD protein was not specifically identified, but rather deduced, because evaluation was done with a patient serum considered “monospecific” for 52kD SSA/Ro antibodies. The smaller blebs, arising from fragmented rough endoplasmic reticulum and ribosomes, contain SSA/Ro presumably of cytoplasmic origin. SSB/La was not contained in these blebs.

Apoptosis may be relevant in the pathogenesis of NLS. It is a selective process of physiologic cell deletion in embryogenesis and normal tissue turnover, and plays an important role in shaping morphological and functional maturity (60). Apoptosis is a process that affects scattered single cells rather than tracts of contiguous cells. In the normal adult myocardium, apoptosis has been observed only rarely (61 ,62). In contrast, apoptosis does occur during the development of the heart. In the 1970s, Pexeider extensively characterized the temporal and spatial distribution of cell death in the hearts of chicken, rat and human embryos (63). Major foci included the AV cushions and their zones of fusion, the bulbar cushions and their zones of fusion, and the aortic

and pulmonary valves. Albeit much of the cell death was noted in nonmyocytes, a focus of myocyte death was apparent in the muscular interventricular septum as it grew toward the AV cushions in midgestation. Takeda et al. demonstrated apoptosis in midgestational rat hearts using terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL), an in situ technique that detects DNA strand breaks in tissue sections (64). Although not coincident with the precise timing of CHB, it has also been suggested that apoptosis contributes to the postnatal morphogenesis of the SA node, AV node, and His bundle (65). Perhaps a novel view of apoptosis is that it facilitates the placing of cardiac target autoantigens in a location accessible to previously generated maternal autoantibodies. Tissue damage might be a consequence of being in the right place at the wrong time.

To investigate the hypothesis that apoptosis indeed facilitates accessibility of SSA/Ro and SSB/La in the heart, cultured human fetal cardiac myocytes were incubated with staurosporine or 2,3-dimethoxy-1,4-naphthoquinone (DMNQ) (66). By phase contrast microscopy, morphologic signs of early apoptosis were observed in 40% of the cardiocytes after approximately 4 hours and increased to 95% after 7 hours. The cellular topology of SSA/Ro and SSB/La was evaluated with confocal microscopy and determined in non-apoptotic and apoptotic cardiocytes by indirect immunofluorescence using two previously characterized antisera, one “monospecific” anti-SSB/La, and the other recognizing both 52kD and 60kD SSA/Ro with goat anti-human IgG-FITC as secondary antibody. In nonapoptotic cardiocytes, SSA/Ro was predominantly nuclear with minor cytoplasmic staining, and SSB/La was confined to the nucleus. In early apoptotic cardiocytes, condensation of the SSA/Ro- or SSB/La-stained nucleus was observed accompanied in some cells by a “ring” of bright green fluorescence around the periphery. In the later stages of apoptosis, the nuclear SSA/Ro and SSB/La staining became weaker. Blebs could now be seen emerging from the cell surface, stained with both SSA/Ro and SSB/La. Scanning electron microscopy unambiguously confirmed the surface expression of SSA/Ro and SSB/La on cultured human fetal apoptotic cardiocytes.

Recent studies from our laboratory have focused on the structure/function of extrinsic and intrinsic apoptosis pathways in human fetal and adult heart, and surface accessibility of SSA/Ro-SSB/La antigens to maternal antibodies (67). High levels of Fas-associated death domain protein (FADD) and TNF-α receptor type 1-associated death domain protein (TRADD), key components in the apoptotic machinery, were observed in CHB but not normal cardiac tissues. Fetal cardiocytes readily underwent apoptosis following stimulation with either anti-Fas or TNF-α when plated on pHEMA (a nonadherent condition); however, these same stimuli did not induce apoptosis in adherent cells. Thus, in fetal cardiocytes adhesion to substrate was pivotal to escaping extrinsic pathway activation, whereas adult cardiocytes did not undergo apoptosis via the extrinsic pathway even in the absence of anchorage. However, adult cardiocytes treated with staurosporine underwent apoptosis, suggesting that these cells do have the machinery to execute apoptosis via the intrinsic pathway. Utilizing monoclonal antibodies generated from a chicken phage display library, it was demonstrated that Ro52, Ro60, and La48 are surface accessible on fetal cardiocytes regardless of the method used to induce apoptosis. Accessibility appeared to be restricted to select domains, because not all antibodies that stained permeabilized cells were reactive with intact apoptotic cells. In sum, this study identifies extrinsic activation of apoptosis, differentially operative in fetal compared to adult human cardiocytes, as a mechanism linking autoantibody to subsequent injury.

In vivo studies have confirmed the observations made in vitro. Tran et al. have demonstrated the translocation of SSB/La in apoptotic cardiocytes in the conduction system of the unmanipulated mouse fetal heart (68). Clustering of SSB/La near the surface of apoptotic bodies occurs in vivo under physiologic conditions. To assess proof of concept and examine whether SSB/La and/or SSA/Ro epitopes on apoptotic cells are accessible for binding by antibodies in vivo, these same investigators have exploited a murine passive transfer model in which the fate of human autoantibodies actively transported across the placenta could be traced in fetal tissues known to have high rates of apoptosis (69). Specifically, BALB/c pregnant mice were injected with human anti-SSA/Ro-SSB/La serum, monospecific anti-Ro60 serum, affinity-purified anti-SSB/La, anti-dsDNA, or normal human serum. Apoptotic cells identified in the fetal conducting tissue (present under normal physiologic conditions of remodelling), showed redistribution of SSB/La from the nucleus to the surface of apoptotic bodies. Fetuses from anti-SSA/Ro-SSB/La antibody-injected mothers showed a striking co-localization of human IgG with apoptotic cells in the atrium, AV node, liver, skin (with particulate epidermal deposition), and newly forming bone. The IgG-apoptotic cell complexes were organ-specific and not detected in thymus, lung, or gut. No IgG deposits were identified in fetuses from mothers injected with anti-dsDNA, anti-Ro60, or normal sera. Experiments with affinity-purified anti-SSB/La and anti-SSA/Ro-SSB/La antibodies absorbed with SSB/La confirmed the specificity of deposited IgG as anti-SSB/La.

The demonstration (in vitro and in vivo) of antigen-antibody binding at the cell surface (66 ,68 ,69 ,70) supports the hypothesis that maternal antibodies to components of the SSA/Ro-SSB/La complex are not simply markers of disease, but play an active part in the pathogenesis of CHB. A molecular explanation for subsequent damage to the specialized cells of the conduction system and working myocardium remains speculative. In this context, a mechanism is envisioned whereby unexpected circumstances convert the physiologic process of apoptosis into one in which an inflammatory component is evoked. Perhaps the unexpected event is opsonization. These findings suggest that circulating maternal autoantibodies opsonize cells undergoing physiological apoptosis, which then changes otherwise innocent degradation products into proinflammatory stimuli. This cascade could result in damage and ultimately permanent scarring in those tissues with low regenerative capacity.

To address the functional consequences of opsonization of apoptotic cardiocytes, we designed coincubation experiments with human macrophages (34 ,71). The Th1 cytokine, TNF-α, was chosen as a readout of inflammation. Basal production of TNF-α by the macrophages was 9.7 ± 0.9 SEM pg/mL and decreased to 3.3 ± 0.3 SEM pg/mL after coincubation with apoptotic cells, which was not observed in initial experiments using cardiocytes rendered necrotic after hypotonic lysis. Apoptotic cardiocytes preincubated with normal human IgG acted functionally as nontreated apoptotic cells; TNF-α production by the macrophages was 5.7 ± 0.9 SEM pg/mL. In contrast, when macrophages were cocultured with apoptotic cardiocytes incubated with affinity-purified antibodies to each of the components of the Ro/La complex, TNF-α production was increased by three- to five-fold over basal levels and 10- to 14-fold over that secreted after culture with apoptotic cells alone. Nonapoptotic cardiocytes incubated with medium alone or with serum containing antibodies reactive with 48kD SSB/La, 52kD SSA/Ro, and 60kD Ro did not modify the basal production of TNF-α by the macrophages. In subsequent studies, we have demonstrated that macrophage- derived factors induce phenotypic changes in cardiac fibroblasts supportive of scarring (72).

A potential role for TGF-α in fibrosis of the AV node was supported by additional experiments. Human fetal cardiac fibroblasts exposed to supernatants obtained from macrophages incubated with opsonized apoptotic cardiocytes markedly increased expression of the myofibroblast marker, smooth muscle actin (SMAc), associated with scarring. This effect was blocked by anti-TGF-ß antibodies (72).

In Vitro CHB Model

Immunohistology of the heart from a term male infant (diagnosed with AV block at 24 weeks of gestation and dying shortly after birth) supported macrophage crosstalk despite the 2-month lag time from detection to death (72). The ventricular tissue revealed microcalcification in which a predominant SMAc-positive infiltrate could be readily observed. Macrophages were also seen in areas of scar tissue. Notably, the fibrosis was not bland, but involved an infiltrate of activated myofibroblasts months after the initial insult. Recently, this heart and two others from fetuses with CHB (20- and 22-week fetal deaths) were examined for myofibroblasts, which were found in all specimens, supporting the persistence of the myofibroblast phenotype, because this collection encompassed a spectrum of disease severity and timing of death relative to clinical detection (34).

To evaluate the extent of fibrosis, cardiac sections were stained with picrosirius for detection of collagen. In both the 20- and 22-week CHB hearts, there was extensive fibrosis in the inferior portion of the atrial wall where the AV node is likely to reside. Collagen deposition was absent in the septal tissue of a normal (fetal-age-matched) control heart. In the 20- and 22-week CHB hearts, TGF-ß immunoreactivity was seen in the conduction tissue. In several sections, intense TGF-ß staining was present in the extracellular fibrous matrix between SMAc-positive myofibroblasts concentrated in the adjacent subendocardium and infiltrating CD68-positive macrophages. Double-labeling revealed colocalization of TGF-ß in the cytoplasm of macrophages, including multinucleate giant cells. No fibrosis or TGF-ß immunostaining was seen in conduction tissue or ventricles of control hearts from 22-, 23-week abortuses (34).

Murine Model of CHB

Although clinical data leave little doubt regarding the association of anti-SSA/Ro and/or SSB/La antibodies with the development of CHB, and experimental data are beginning to suggest pathogenicity, efforts to establish an animal model have been limited. Kalush et al. reported that offspring of BALB/c mice immunized with the monoclonal anti-DNA idiotype 16/6 had conduction abnormalities (73). Of 31 pups born to mothers with experimental SLE, eight had first-degree heart block, two had second-degree heart block, two had complete block, ten had bradycardia, and eight demonstrated widening of the QRS complex. None of these disorders could be detected in the 20 offspring of healthy control mice. One of the difficulties in interpreting these findings is that the immunized mothers synthesized a variety of autoantibodies, including antibodies reactive with 16/6 Id, ss/dsDNA, Sm, RNP, cardiolipin, SSA/Ro, and SSB/La. Accordingly, it was not possible to segregate out which specific antibody might be responsible for the arrhythmias detected in these pups. The electrocardiographic data are provocative; however, no histologic data were provided to assess the status of the SA or AV node, or the presence of myocarditis.

To further establish an antibody-specific murine model to correlate arrhythmogenic effects of maternal autoantibodies with the in vivo genesis of CHB, we have immunized female BALB/c mice with 100 µg of one of the following 6 × His human recombinant proteins purified by Ni^{2+} affinity chromatography: 48kD SSB/La, 60kD SSA/Ro, 52kD SSA/Ro (52α full-length), and 52ß (74). Control animals were given the same injections with a Ni^{2+} affinity-purified polypeptide encoded by pET-28 alone. Following primary immunization in complete Freund adjuvant and two boosters (50 µg) in incomplete Freund adjuvant, high titer immune responses to the respective antigens were established by ELISA and immunoblot of recombinant antigens, and immunoprecipitation of [^{35}S]-methionine-labeled in vitro translation products. Sera from mice immunized with either 52α or 52ß immunoprecipitated radiolabeled murine 52kD SSA/Ro, confirming that these mice were specifically reactive with the murine homologue. Moreover, immunoblot of a newborn murine heart demonstrated the presence of 52kD SSA/Ro. Mice were mated and boosters continued every 3 weeks to ensure continued high titer antibody responses. EKGs were performed on all pups using standard limb leads at birth or within 2 days postpartum. Maternal antibodies to the primary immunogens were detected by ELISA in the pups.

Of 54 pups born to six fertile mice immunized with 60kD SSA/Ro, none had CHB; of 27 pups born to three fertile mice immunized with 48kD SSB/La, none had CHB. In contrast, of 78 pups born to five fertile mice immunized with 52α and 86 pups born to five fertile mice immunized with 52β, one and five pups, respectively, had complete AV block. Accordingly, this antibody-specific animal model provides strong preliminary evidence for a pathogenic role of antibodies reactive with 52kD SSA/Ro, particularly the 52β form, in the development of CHB. Moreover, analogous to the frequency of 1% to 5% given for women with SLE who have anti-SSA/Ro and/or SSB/La antibodies (4 ,9), this model suggests that additional factors promote disease expression.

Candidate Antigen-Antibody Systems in NLS

The Target Autoantigens of the SSA/Ro-SSB/La System

Antibodies against SSA/Ro and SSB/La have been discussed in detail by Drs. Reichlin and Harley in Chapter 25 .

Eftekhari et al. recently reported that antibodies reactive with the serotoninergic 5-hydroxytryptamine (5-HT)$_{4A}$ receptor, cloned from human adult atrium, also bind 52kD SSA/Ro (75). Moreover, affinity-purified 5-HT$_4$ antibodies antagonized the serotonin-induced L-type Ca channel activation in human atrial cells. Two peptides in the C terminus of 52kD SSA/Ro, aa365–382 and aa380–396, were identified that shared some similarity with the 5-HT$_4$ receptor. The former was recognized by sera from mothers of children with NLS, and was reported to be cross-reactive with peptide aa165–185, derived from the second extracellular loop of the 5-HT$_4$ receptor. These findings are of particular importance, since more than 75% of sera from mothers whose children have CHB contain antibodies to 52kD SSA/Ro as detected by ELISA, immunoblot and immunoprecipitation (76 ,77).

Given the intriguing possibility that antibodies to the 5-HT$_4$ receptor might represent the hitherto elusive reactivity directly contributing to AV block, we examined whether the 5-HT$_4$ receptor is a target of the immune response in these mothers (78). Initial experiments demonstrated mRNA expression of the 5-HT$_4$ receptor in the human fetal atrium. Electrophysiologic studies established that human fetal atrial cells express functional 5-HT$_4$ receptors. Sera from 116 mothers enrolled in the RRNL, whose children have CHB, were evaluated: 99 (85%) contained antibodies to SSA/Ro, 84% of which were reactive with the 52kD SSA/Ro component by immunoblot. In sum, none of the 116 sera were reactive with the peptide spanning aa165–185 of the serotoninergic receptor. Rabbit antisera that recognized this peptide did not react with 52kD SSA/Ro. Accordingly, although 5-HT$_4$ receptors are present and functional in the human fetal heart, maternal antibodies to the 5-HT$_4$ receptor are not necessary for the development of CHB.

Most recently, Eftekhari's group and ours jointly assessed the role of anti-5-HT$_4$ antibodies (79). Sera from 128 patients (101 anti-SSA/Ro52 positive mothers, of whom 74 had children with CHB; 20 anti-SSA/Ro52 negative patients, of whom one had a child with CHB, six had children with structural HB, five had children who developed HB after birth; 18 healthy donors) were assessed in a single blind test using an ELISA coated with a 5-HT$_4$ receptor-derived peptide. Discrepancies between previous observations in our two groups could be ascribed to small differences in the set-up of the assay. Of the 74 sera from Ro52$^+$ mothers of children with CHB, 11 were reactive with the 5-HT$_4$ peptide. Sera from the Ro52$^-$ mother of a child with CHB, one of six Ro52$^-$ mothers of children with structural HB, three of 35 mothers of unaffected children, and two of 18 controls were also 5-HT$_4$-positive. Although 5-HT$_4$ receptor autoantibodies do not have the predictive value of anti-Ro52 autoantibodies, the presence of these antibodies in a minor subset of mothers whose children have CHB suggests an additional risk factor that may contribute to the pathogenesis of disease.

Fine Specificities of the Maternal SSA/Ro-SSB/La Autoantibody Response

The sensitivity and specificity of anti-52kD Ro, anti-60kD Ro, and anti-48kD La in predicting risk of CHB in an offspring were recently reassessed in sera from 125 mothers of children with NLS, using a commercial line immunoassay that employs natural 60kD Ro protein (Inno-Lia ANA Update, Innogenetics NV, Gent, Belgium) (80). By this method, 96% of the sera had antibodies to 60Ro, 86% to 52Ro, and 78% to 48La. Immunoblot of 65 CHB-mothers showed significantly fewer positive results for anti-60Ro (P <0.001) and anti-52Ro (P <0.05). Sensitivity of the three antibodies was assessed in 78 symptomatic CHB-mothers and 65 disease-matched controls with unaffected children using Inno-Lia ANA Update. The sensitivity of each antibody was compared by multiple logistic regression to adjust for maternal disease. There was no significant difference between the groups for 60Ro or 52Ro antibody. However, there was a significant difference for the anti-La antibody (P = 0.001), with an odds ratio of 3.59. This translates to an increase in risk from a published 2% for CHB in an anti-Ro-positive mother to 3.1% if the woman is also anti-La antibody-positive, and to a decrease in risk to 0.9% if anti-La-negative.

Novel Antigen/Antibody Systems

Although it is not known how maternal antibodies influence the development of cardiac versus cutaneous manifestations of NLS, to date, antibodies to U1RNP in the absence of reactivity to anti-SSA/Ro and/or SSB/La have never been reported in children with CHB. Sheth et al. have added two cases to eight previously reported in which anti-U1RNP antibodies but not anti-SSA/Ro-SSB/La antibodies were present in infants with cutaneous disease alone (81). Furthermore, Solomon et al. describe anti-U1RNP-positive, anti-SSA/Ro-SSB/La-negative dizygotic twins discordant for cutaneous

manifestations of NLS (neither twin had cardiac disease) (82). The segregation of anti-U1RNP antibodies with cutaneous disease may be a useful maternal marker and should guide research efforts in sorting out cardiac versus cutaneous susceptibility to antibody-mediated injury.

Complement Regulatory Proteins

With regard to the mechanism of tissue injury, consideration should be given to the possibility that protective molecules may be diminished on the surface of fetal cells. In adulthood, the organism's cells are protected from complement-mediated damage by membrane-bound proteins such as decay accelerating factor (DAF, CD55), protectin (CD59), and membrane cofactor protein (MCP, CD46) (83 ,84 ,85). DAF regulates C3/C5 convertases and CD59 regulates assembly of the terminal components of the membrane attack complex. MCP patrols cell membranes, inactivating the C4b and C3b that is inadvertently bound by acting as a cofactor for their factor I-mediated cleavage (86). MCP is expressed on a wide variety of cells including those of the epithelial, fibroblast, and endothelial cell lineage (87).

To examine fetal characteristics that might influence autoantibody-mediated diseases acquired in utero, such as heart block in NLS, the tissue expression of MCP was studied (88). Immunoblots of organs from six fetuses (aged 19 to 24 weeks) probed with rabbit anti-MCP antibodies revealed a band at 60kD in addition to the known 65kD and 55kD isoforms that comprise the codominant allelic system of MCP. Five fetuses expressed the most common MCP polymorphism (predominance of the 65kD isoform, upper band α phenotype) in the kidney, spleen, liver, and lung. In contrast, all hearts from these five fetuses demonstrated a different pattern in which there was a marked decrease in the intensity of the 65kD band and accentuation of the lower molecular weight bands. In a sixth fetus, which expressed the second most common polymorphism (equal expression of the 65kD and 55kD MCP isoforms, αß phenotype), the heart was similar to the other tissues. Preferential expression of the MCP ß isoform in five of six fetal hearts, irrespective of the phenotype of other organs, suggests tissue-specific RNA splicing or posttranslational modification. The clinical significance of this tissue-specific phenotype is unknown at present, but may provide an important clue to the susceptibility of the fetal heart to antibody-mediated damage.

Genetic Considerations in the Proposed Pathogenesis of NLS

Fibrosis-Promoting Genes

It is clear that maternal antibodies are not sufficient to directly cause cardiac scarring and that additional maternal and fetal factors, such as genetics, are likely to convert predisposition to clinical expression. At present, no model of inheritance for CHB is known, making this a complex genetic problem. As noted above, CHB occurs in 19% of siblings born subsequent to a CHB-affected infant (11), a rate 3,000 times higher than the population prevalence (1/20,000), implying a strong genetic effect. Driven by the proposed pathologic cascade supported by in vitro and in vivo data, we have begun an initial analysis of TGF-ß and TNF-α polymorphisms.

The human gene encoding TGF-ß is on chromosome 19q13 and is highly polymorphic. Awad et al. (89) have identified five polymorphisms in the TGF-ß gene: two in the promoter region at positions -800 and -509, one at position +72 in a nontranslated region, and two in the signal sequence at positions +869 and +915. The polymorphisms at positions +869 and +915, which change codon 10 (T→C, leucine→proline) and codon 25 →G→C, arginine(proline), are associated with interindividual variation in the levels of TGF-ß production. This has clinical relevance, because several animal and human studies have shown that high TGF-ß producers develop significantly more lung fibrosis in response to a number of inflammatory triggers, such as radiation (90), chemotherapy (91) and lung transplantation (92). The Pro^{25} allele is associated with lower TGF-ß synthesis in vitro and in vivo, whereas the Arg^{25} allele is associated with allograft fibrosis in transbronchial biopsies when compared with controls and with nonallograft fibrosis (93). It has been reported that lung allograft recipients with the Leu^{10} allele produced the highest amounts of TGF-ß (89), and chronic rejection after lung transplant is linked with high levels of TGF-ß (93). In parallel with our hypothesis that high levels of TGF-ß permit the development of CHB as a result of enhancement of extracellular matrix and increased fibrosis, patients with cystic fibrosis who develop rapid deterioration in lung function have an increased frequency of the Leu^{10} homozygosity (94).

Codons 10 and 25 of the TGF-ß gene were evaluated in 88 children (40 CHB, 17 rash, 31 unaffected siblings) and 74 mothers from the RRNL (95). The TGF-ß polymorphism Leu^{10} (associated with increased fibrosis) was significantly higher in CHB-children (genotypic frequency 60%, allelic frequency 78%) than unaffected offspring (genotypic frequency 29%, $P = 0.016$; allelic frequency 56%, $P = 0.011$) and controls, whereas there were no significant differences between controls and other NLS groups. For the TGF-ß polymorphism Arg^{25} there were no significant differences between NLS groups and controls.

The rash of neonatal lupus resembles subacute cutaneous systemic lupus erythematosus (SCLE) and is often photosensitive. There is evidence that the release of TNF-α by UV light-exposed keratinocytes contributes to the lesions of SCLE in individuals having the haplotype –308A TNF-α/DRB1*03 (96). The gene encoding TNF-α is highly polymorphic, and a substitution of G→A at position –308 (TNF2) in the promoter region has been associated with increased production of this cytokine (97). The common (wild-type) allele, –308G (TNF1), has a frequency of approximately 80% in Caucasians and 92% in African Americans (97). The link between anti-SSA/Ro antibodies, photosensitivity, and TNF-α promoter polymorphisms extends to HLA class II molecules. In Caucasians, there is a strong linkage disequilibrium

between the –308A allele and HLA-DRB1*03 (98). The presence of DRB1*03 is also common in individuals who synthesize anti-SSA/Ro and SSB/La antibodies.

DNA was isolated from the same RRNL cohort for genotyping of the TNF-α –308 promoter region and HLA-DRB1. There was a significantly higher –308A carrier frequency in children with NLS rash compared to healthy controls (64% vs. 23%; *P* = 0.002) (99). The DRB1 distribution for DRB1*03 was significantly higher in children with rash compared to controls (64% vs. 17%; *P* = 0.014). Interestingly, the carrier frequency of DRB1*03 was also significantly higher than controls for children with CHB (54%) and for mothers (73%) but not unaffected children (39%). Although the carrier frequency was higher in children with rash compared to children without rash, the difference did not reach statistical significance.

In the children with rash, the prevalence of the –308A allele paralleled the prevalence of DRB1*03. When individual subjects were tabulated by the presence or absence of –308A and DRB1*03, the two alleles together were significantly greater in the children with rash, children with CHB, and mothers, compared to controls. In contrast, unaffected children were not significantly different from controls. For children with rash, the association between the –308A allele and DRB1*03 occurred in all but one case (7%) (*P* = 0.012 vs. control). However, for children with CHB and unaffected children the presence of –308A in the absence of DRB1*03 was 25% and 38%, respectively, which did not differ significantly from controls.

Immunogenetics of the Mother and Host

The majority of studies to date have documented the near-universal presence of DR3 alleles in the mothers of affected offspring, frequently associated with the extended haplotype A1, B8 (100 ,101 ,102 ,103 ,104 ,105). In addition to the reports of others, 10 of 11 affected mothers studied at our institution were HLA DR3. The one exception was DR7. For comparison, of 25 women with SLE or SS who gave birth to healthy offspring, 48% were DR3, odds ratio = 16, *P* <0.003. Several investigators have noted an increased frequency of HLA-DR2 in anti-SSA/Ro positive mothers of normal infants (100 ,104). This is not surprising, because sera from the majority of mothers whose offspring have CHB contain both anti-SSA/Ro and -SSB/La antibodies and not anti-SSA/Ro alone (45 ,76 ,106). It is the former subgroup that is more strongly associated with the linked HLA alleles B8,DR3,DRw52,DQw2 and the latter subgroup with DR2,DQw1 (105).

As has been suggested for other HLA-linked diseases, it is possible that several genes within a particular haplotype may contribute to enhanced susceptibility. Arnaiz-Villena et al. found that Class III antigens BS and C4QOB1 are increased together with the A1,B8,DR3 haplotype in SSA/Ro positive mothers whose offspring have CHB (107). Moreover, these class II genes were not significantly increased in a group of SSA/Ro positive mothers whose offspring did not have CHB. Of particular interest was the observation that the most common DR3-bearing haplotype found in the Spanish population for adult SLE (A30,B18,DR3,BfF1,C2C,C4ABQ) was not increased among the mothers of offspring who had CHB. This study did not find an increased frequency of DR2 in the anti-SSA/Ro positive mothers of healthy offspring, i.e., $DR2^+$ = 3/15 (20%) versus 23% in their normal population.

Brucato et al. reviewed the literature and reported that of 28 mothers whose children have CHB, 50% were A1, 62% B8, and 96% DR3 (105). In their own cohort of 15 Italian mothers of children with CHB, Brucato found a significantly increased prevalence of DR3 and DQ2 and B8/DR3, DR3/DQ2, and A1/Cw7/B8/DR3/DQ2 haplotypes (105). In a study of 31 Finnish mothers (all anti-SSA/Ro and/or SSB/La positive) of children with CHB, HLA B8 and DR3 were present in 71% and 74% of the affected mothers, respectively (101). Thus, the genetic background of CHB-mothers is similar in Anglo-Saxon populations and populations from southern and northern Europe (101). The same Finnish study demonstrated that as a group, CHB-mothers were genetically more closely related to primary SS than to SLE (101).

At the present time a role for fetal genetic differences in the major histocompatibility complex influence susceptibility is not firmly established. In five earlier reports of affected neonates, only two were DR3 (100 ,102 ,103 ,104). These data emphasize the passive nature of NLS and the difference between acquiring manifestations of lupus and actually developing the disease. However, continued investigations of larger numbers of affected mothers add complexities to the picture. In the study of Arnaiz-Villena et al., four of five offspring with CHB were DR3-positive compared to two of five unaffected siblings (107).

Perhaps fetal HLA, not as an isolated risk factor, but as it relates to maternal HLA, is a fetal factor contributing to injury. A plausible hypothesis might be that tissue damage occurs either when the HLA relationship between the fetus and mother is bidirectionally compatible or unidirectionally compatible from the child's perspective. Relevant to the hypothesis that macrophage phagocytosis of apoptotic cardiocytes opsonized by autoantibodies initiates and inflammatory cascade leading to CHB, HLA class II compatible maternal Th1 cells would be able to provide help to fetal macrophages. In support of this notion, Miyagawa et al. reported on a limited study on 13 Japanese families in which children with CHB shared both HLA class II alleles with their mothers significantly more often than children without CHB (4/9 CHB vs. 0/12 healthy siblings, *P* <0.02) (108). Furthermore, Stevens et al. (109) have demonstrated maternal cells in the AV node, myocardium, and liver of two infants with NLS who died shortly after birth, possibly representing alloreactive hematopoietic cells that trigger inflammation leading to tissue destruction.

Given two limited studies implicating fetal/maternal class II sharing as contributory to the pathogenesis of CHB, the RRNL was utilized to further expand or refute this notion. DNA was isolated from 65 children (29 CHB, 12 rash, 24 unaffected siblings) and their 62 mothers (anti-SSA/Ro^+, Caucasian) enrolled in the RRNL. HLA-DQB1, DRB1, and

Cw7 alleles were determined by a DNA-based technique, with PCR amplification using sequence specific oligonucleotide primers. Specific HLA alleles were significantly enriched in the mothers: DRB1*03 (79%), DQB1*02 (84%), and Cw7 (92%). No class II allele was enriched in the children with CHB compared to healthy anti-SSA/Ro exposed children or those with rash. Maternofetal compatibility was noted for mother/rash dyads, but no disproportional sharing of HLA molecules was observed between mothers and children with CHB. This is further emphasized by the inclusion of a child with CHB (product of ovodonation) whose HLA molecules were unrelated to the anti-SSA/Ro^+ surrogate mother. In sum, although HLA associations are crucial for cellular immunity leading to maternal autoantibody production, these associations are not likely contributory as fetal factors in the development of CHB but only rash.

Lessons from Twins and Triplets

The study of twin gestations further emphasizes the complexity of NLS. These informative in vivo experiments of nature provide clues to the true relevance of the maternal antibody and host factors. Discordance of disease expression in monozygotic twins would be particularly intriguing, given that the placenta is shared and the fetal genetics are identical. Twins born to mothers with anti-SSA/Ro-SSB/La antibodies provide a unique opportunity to gauge the effect of a specific antibody profile on disease phenotype. Regardless of whether twins share a common placenta or not, it is likely that even if a mother had three types of antibodies (Type A causing CHB, Type B causing skin rashes, and Type C being nonpathogenic) the proportion of these antibodies should be similar in each fetal circulation. Types A and B by definition must be of the correct subclass and isotype (i.e., IgG, subclasses 1–4) to be transported across the trophoblast, whereas Type C might not be transported at all. One might envision quantitative differences in each twin, but it is difficult to conceive of a mechanism to explain why one placenta would transport antibodies more selectively than another unless Fc receptors were differentially expressed.

Of 24 twin pairs and two triplet sets published (1 ,11 ,82 ,102 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125), only six are entirely concordant for disease expression (Table 53-1). Gawkrodger and Beveridge describe disparate disease expression in male twins who were in the same amniotic sac and shared a common placenta (110). The mother had anti-SSA/Ro and anti-SSB/La antibodies. One infant presented at 8 weeks of age with Stokes Adams attack and second-degree heart block, a facial rash and evidence of hemolytic anemia, whereas his twin brother had merely a “peeling” facial rash at 15 weeks of age. Cooley et al. reported two sets of monozygotic twins discordant for CHB (111). Watson et al. performed HLA studies and C4 phenotypes on dizygotic twins discordant for isolated CHB (117). Both infants had identical HLA (DR4, DR7) and C4 phenotypes (C4A3.QOB1.1). Serum from the mother and both cord bloods demonstrated anti-SSA/Ro and SSB/La antibodies with no significant difference in titer noted in the cord blood of either twin when compared with maternal titers. Brucato et al. reported a second pair of HLA identical twins discordant for CHB (118), and a third such pair was reported by Kaaja et al. (119). In our RRNL there were three sets of twins (11). Two sets were dizygotic, with only one twin in each set having CHB. Histologic and genetic analysis of the third set revealed a twin placenta (diamniotic, dichorionic) and monozygosity. One twin had CHB and the other was completely healthy.

Certainly these observations support a fetal contribution to the development of neonatal lupus, but perhaps even more intriguing is that in two sets of twins (110 ,116) and two sets of triplets (120 ,125), all children were affected but with discordant manifestations. Accordingly, even if antibody profile is an important predictor of risk for one manifestation of neonatal lupus versus another, the fetus (perhaps density of calcium channels, impaired healing, exuberant fibrosis) and/or its immediate environment (low oxygen) provide additional factor(s) required to convert susceptibility to overt disease. The logical inference from these reports is that developmental events in utero strongly contribute to the susceptibility of a particular fetus.

The Transient NLS Rash

In striking contrast to the typical late second trimester onset of CHB, the skin lesions generally become manifest several weeks into postnatal life. Less commonly the rash is present at birth. Ultraviolet exposure may be an initiating factor and can exacerbate an existing rash (126). Thornton et al. report that telangiectasia may be a presenting feature and can occur in sun-protected sites independent of “lupus dermatitis” (127). Cutaneous activity, inclusive of erythema and the continued appearance of new lesions, is generally present for several weeks with resolution by 6 to 8 months of age coincident with the clearance of maternal autoantibodies from the baby's circulation. However, hypopigmentation may persist into the second year of life. Lee has observed two children with persistent telangiectasias and one child with a small but persistent patch of hyperpigmentation (126); 11 other children, including several with extensive skin disease, have had complete resolution of the rash.

The rash frequently involves the face and scalp with a characteristic predilection for the upper eyelids. In some instances the rash is present in other locations and can cover virtually the entire body. A review of the corporeal distribution of 57 infants (20 males, 37 females) diagnosed with cutaneous NLS (absent heart disease) enrolled in the RRNL was recently reported (128). All had facial involvement (periorbital region most common) followed by the scalp, trunk, extremities, neck, intertriginous areas, and rarely the palms and soles. In most cases the infant's rash was temporally related to UV exposure; mean age of detection was 6 weeks and duration 22 weeks. The lesions are described as superficial inflammatory plaques resembling subacute cutaneous lupus erythematosus of the adult (129). They are typically annular or elliptical with erythema and scaling.

Hypopigmentation was frequent and may be a prominent feature. The more characteristic lesions of adult discoid lupus such as follicular plugging, dermal atrophy, and scarring were generally not observed in the neonatal skin rash. The lesional histology supports the clinical descriptions of subacute cutaneous lupus with basal cell damage in the epidermis and a superficial mononuclear cell infiltrate in the upper dermis (130 ,131). As observed in subacute cutaneous lupus, immunofluorescence is positive with the finding of a particulate pattern of IgG in the epidermis (126).

Table 53-1: Neonatal Lupus in Twins and Triplets

Study	Maternal Serology	Zygosity	Disease Manifestations		
			Sib 1	Sib 2	[Sib 3]
Gawkrodger (110)	SSA/Ro, SSB/La	monozygotic	CHB/rash/anemia	rash	
Cooley (111)	SSA/Ro	monozygotic	CHB	healthy	
Cooley (111)	SSA/Ro	monozygotic	CHB	healthy

Lockshin (122)	SSA/Ro	dizygotic	rash	healthy	
Solomon (82)	U1RNP	dizygotic	rash	healthy	
Callen (123)	SSA/Ro	dizygotic	rash	healthy	
Lawrence (124)	SSA/Ro, SSB/La	dizygotic	rash	rash	
Stevens (120)	SSA/Ro, SSB/La	trizygotic	CHB (3°)	CHB (1°/2°)	liver
Yazici (125)	SSA/Ro	trizygotic	rash	rash	rash, thrombocytopenia, liver

1, 2, and 3 arbitrarily refer to the twin or triplet siblings but do not imply sequence of birth.
*Both twins had CHB recognized at birth; twin 2 had associated fibroelastosis and was asymptomatic at 1 year of age, twin 1 had L-transposition, ventricular septal defect, coarctation, and hypoplastic right ventricle, and died at 15 days of age.

Less Commonly Encountered Manifestations of NLS

The clinical spectrum of NLS includes hepatic involvement, a manifestation that could well be underestimated since routine neonatal evaluation does not include a liver profile. Permanent sequelae can occur in the liver, but unlike the heart may be clinically insignificant. Laxer et al. have described three living infants and one perinatal death with NLS associated with significant hepatic involvement (13). The living infants presented with neonatal cholestasis as a major component of their clinical picture. Pathologic changes included giant cell transformation, ductal obstruction and extramedullary hematopoiesis. The authors speculated that an inflammatory hepatitis proceeding to hepatic fibrosis may ensue, analogous to the mechanism hypothesized to occur in cardiac tissue. Rosh et al. reported an infant born with CHB in whom severe neonatal cholestasis developed, requiring surgical exploration to exclude extra hepatic biliary atresia (132). The clinical picture included an elevation of the serum glutamic-pyruvic transaminase, glutamic oxaloacetic transaminase, alkaline phosphatase, and gamma-GTP. A percutaneous liver biopsy revealed mild fibrosis, bile ductular proliferation, and a mixed inflammatory infiltrate in the portal tracts. Lee et al. described three infants with hepatic dysfunction; all had laboratory and histologic evidence of significant cholestasis (133). One occurred in the setting of intractable congestive heart failure. At autopsy, immunofluorescence revealed widespread deposits of IgG. A second infant had thrombocytopenia and hepatospleno-megaly at birth, followed at 3 weeks of age by a cutaneous eruption characteristic of NLS. Liver biopsy revealed hepatocellular cholestasis, lobular disarray, and mild pseudoacinar formation. A third neonate developed a typical rash at 2 weeks and transaminitis with jaundice by 8 weeks. Liver biopsy revealed canalicular and hepatocellular cholestasis.

Lee et al. (134) recently investigated the incidence of hepatobiliary manifestations among 219 NLS patients in the RRNL. Nineteen (9%) had probable or possible hepatobiliary disease, appearing as the sole manifestation of NLS in three cases, and in association with cardiac or cutaneous manifestations in 16 cases. Six (including one previously reported by Schoenlebe et al. (135)) of the 19 infants died, either during gestation or within the first few weeks of life. Three clinical variants were observed: (a) severe liver failure present during gestation or in the neonatal period, often with the phenotype of neonatal iron storage disease; (b) conjugated hyperbilirubinemia with mild or no elevations of aminotransferases, occurring in the first few weeks of life; and (c) mild elevations of aminotransferases occurring at approximately 2 to 3 months of life. The prognosis for the children in the last two categories was excellent.

These reports and others (136) suggest that the diagnosis of NLS-related liver disease should be considered in situations in which the liver enzymes and bilirubin levels are most consistent with cholestasis in the absence of a major structural abnormality of the biliary tree. Reassuringly, in babies that survive cardiac manifestations, the general observation is that hepatic disease resolves.

Although the nervous system has not been regarded as an organ characteristically affected in NLS, clinical detection may be a limiting factor. There have been several reports of neurologic sequelae in NLS. Specifically, aseptic meningitis occurred in an infant with CHB and circulating maternal anti-SSA/Ro and anti-SSB/La antibodies (137). There has been one case report of NLS and transient hypocalcemia with seizures (138). Wong et al. observed sonographic evidence of infantile lenticulostriate vasculopathy (LSV) in a case of NLS (139). The authors suggest that sonographic LSV is a nonspecific marker of a previous insult to the developing brain, the clinical significance of which is uncertain. Bourke et al. describe an infant with thrombocytopenia and a generalized annular rash with scattered telangiectases at birth in the setting of antibodies to SSA/Ro and SSB/La (140). At the age of 1 year, the child was found to have an abnormal gait and examination revealed mild spastic diplegia of the lower limbs. The authors appropriately point out that the central nervous system (CNS) abnormalities might have been due to an intracerebral hemorrhage in the neonatal period. This curious observation of late onset lower limb spasticity has been reported in one other infant with antibodies to SSA/Ro and butterfly rash at birth (141). In sum, the mechanism of these neurologic sequelae is entirely elusive and awaits further observation in other neonates born to mothers with anti-SSA/Ro-SSB/La antibodies.

Hematologic abnormalities have been described as a manifestation of NLS. Thrombocytopenia has been observed together with other manifestations of NLS (14). Some of these infants have a petechial or purpuric eruption as the initial feature. Thrombocytopenia was present in 10% of the neonates referred to Lee et al. (129). Gastrointestinal bleeding occurred in one of these infants. In contrast to the cardiac manifestations (which do not parallel disease in the mother) and the cutaneous manifestations (which occasionally occur in the mother but often not in synchrony with her affected offspring), the hematologic manifestations may more closely parallel maternal disease. However, Watson has described thrombocytopenia in offspring of anti-SSA/Ro positive mothers with no apparent history of thrombocytopenia (14). Despite this, the presence of thrombocytopenia raises some questions as to whether antiplatelet antibodies rather than antibodies to SSA/Ro-SSB/La are targeting the surface of fetal cells. These manifestations, while secondary to passively acquired autoimmunity (and therefore part of NLS), may be

more akin to the neonatal thrombocytopenia of idiopathic thrombocytopenic purpura (ITP). The disparate fetal and adult vulnerability appears more pronounced in NLS than in ITP.

Kanagasegar et al. (142) reported an infant with neutropenia and mildly abnormal liver functions, but no cardiac or cutaneous manifestations of NLS, born to a mother with anti-SSA/Ro-SSB/La antibodies. The child's neutropenia improved as maternal antibody was metabolized. Sera from this child and mother, as well as sera from two RRNL mothers who had given birth to infants with CHB and neutropenia, were shown to bind the cell surface of intact neutrophils (142). Binding to neutrophils was then inhibited (>80%) by incubating the sera with 60kD Ro antigen, suggesting that anti-60kD SSA/Ro is directly involved in the pathogenesis of neutropenia.

Wolach et al. extend the hematologic spectrum of NLS (143). They describe a 5-month-old infant with anti-SSA/Ro antibodies and typical cutaneous involvement in the setting of complete marrow aplasia, who recovered at 8 months with the disappearance of anti-SSA/Ro antibodies. However, before this complication is added to the “official list” of manifestations, it is curious that the mother herself was said to have “tested negative” for anti-SSA/Ro antibodies. The child died at 16 months from gram-negative sepsis.

Maternal Disease at Identification of Neonatal Lupus and Progression

In 1987, McCune et al. assessed the health status of 21 mothers and their children with NLS (144). This study suggested that all mothers eventually developed symptoms of a rheumatic disease but larger series have not reached similar conclusions (77 ,145 ,146 ,147).

To date we have evaluated 110 mothers of children with CHB enrolled in the RRNL; at the time CHB was identified, 39 mothers were asymptomatic, 17 had an undifferentiated autoimmune syndrome (UAS), 20 had SLE, 24 had SS, five had SLE/SS, and for five the diagnosis is unknown. At a mean follow-up of 8.4 years, 14 (36%) of the 39 initially asymptomatic mothers had developed symptoms of a rheumatic disease: one developed UAS, five SLE, two SS, and one SLE/SS. Twenty-five (64%) remained asymptomatic. Of the 17 mothers initially diagnosed with UAS, one developed SLE and four SS. Three mothers with SS at the birth of the affected child progressed to SLE/SS at follow-up.

Similar results were reported by Julkunen et al. (77). Fifteen (48%) of 31 mothers whose children had CHB were asymptomatic before the index delivery, seven of whom remained asymptomatic after a mean follow-up of 8 years. Two mothers had SLE, one mother had definite primary SS, one had probable SS, one had autoimmune hypothyroidism, and one had Grave disease. Six (19%) gave a self-reported diagnosis of a chronic autoimmune disease antedating the index delivery. Of two mothers who died, one subsequently developed SLE and died of a fatal cardiac arrhythmia 5 years after the birth of the affected child. The other died of alcoholic liver disease and had developed SLE after 11 years. No patient with SLE had nephritis. Importantly these authors noted that as a group, mothers of CHB children had clinical and immunologic characteristics more closely related to primary SS than SLE.

In a study of 64 CHB-mothers from Toronto, 42 (66%) were asymptomatic, two (3%) had SLE, two (3%) had linear scleroderma, two (3%) had RA, three (5%) had a history of rheumatic fever, one (2%) had SS, and 12 (2%) had UAS (145). Three of the 12 mothers with UAS progressed to SLE and two developed SS. Thirty-six of the 42 initially healthy mothers remained well, one developed SLE, one hyperthyroidism, one ankylosing spondylitis, and three UAS. Unlike the other larger studies, not all mothers included in this cohort were documented to have anti-SSA/Ro-SSB/La antibodies.

Taken together, it can be concluded that asymptomatic mothers do not invariably become ill (at least over 8 years or more of follow-up) and if an asymptomatic mother does develop SLE, it is not likely to be life-threatening. Although more formal epitope analysis of the autoantigens has not been done with regard to clinical outcome, the fine specificity of anti-SSA/Ro-SSB/La antibodies as assessed by immunoblot is highly stable for years, independent of the maternal clinical status (145).

Maternal health status may also be of interest with regard to the discordant clinical manifestations of neonatal lupus. A link between the health status of the mother and child might aid in defining risk for a given mother, an enormous benefit to the practitioner faced with family counseling, and in identifying a pathogenetic mechanism of injury. Maternal disease might reflect the fine specificity of an antibody response, which in turn could account for the preferential vulnerability of one particular organ versus another. Lawrence et al. compared a cohort of 24 women with anti-SSA/Ro-SSB/La antibodies whose children have only cutaneous manifestations of neonatal lupus (146) to their previously published cohort of 32 mothers with similar antibodies whose children have only cardiac manifestations (145). Maternal health status was considered as either symptomatic (inclusive of varied rheumatic diseases such as systemic lupus erythematosus, Sjögren syndrome, and undifferentiated autoimmune diseases) or completely asymptomatic. A significantly greater number of mothers whose children had CHB were asymptomatic (75%) compared to mothers of children with NLS rash alone (42%). At follow-up, mothers of children with CHB were more likely to remain asymptomatic (59%) than were mothers of children with NLS rash (25%).

This same question was also addressed by review of data in the RRNL; included were 105 mothers whose children had only CHB and 47 whose children had only NLS rash (148). All mothers had documented antibodies to SSA/Ro and/or SSB/La. Initially, 37% of the “CHB-mothers” and 28% of the “rash-mothers” were asymptomatic and, after at least 5 years of follow-up, 24% and 13%, respectively, remained symptom-free. There was a trend to more symptomatic disease in the mothers whose children had cutaneous manifestations, but the differences between rash-mothers and CHB-mothers in the RRNL did not reach statistical significance. These data are not completely in accord with those of Lawrence et al.

(147), the difference being in the distribution of maternal disease in the CHB groups. There was a significantly greater proportion of symptomatic CHB-mothers in the RRNL than in Toronto. Interestingly, when Fisher's exact test was used to compare the rash-mothers, the proportion of symptomatic individuals did not differ significantly between the Toronto and RRNL databases. The referral patterns of the two studies could plausibly explain their divergent findings with regard to the health of CHB-mothers. All subjects in the Toronto database are from within a single city, not from outside sources; the RRNL, in contrast, includes the entire United States. Although the referral source for the Toronto patients is not included in the report by Lawrence et al., in the RRNL 42% of CHB and 54% of rash cases were referred by rheumatologists (*P* = NS, CHB vs. rash). Data from two separate studies suggest that mothers who have children with cutaneous disease are more likely to be symptomatic than asymptomatic. However, this could be explained by the fact that recognizing a neonatal rash as NLS is more likely in a mother with rheumatic disease. Whether maternal health status (i.e., absence of clinical disease) is a marker for heart disease remains to be established.

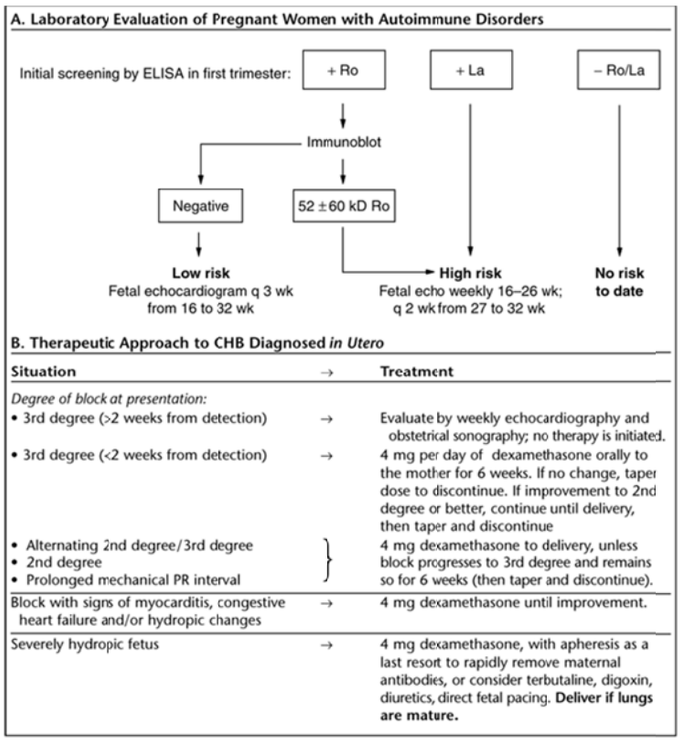

Table 53-2: Current Laboratory Evaluation and Clinical Management of Neonatal Lupus

Clinical Management of NLS

Identification and Management of the High-Risk Pregnancy

Table 53-2 presents an overall schema for management. These recommendations are considered experimental,

based on the author's experience, and have not been tested in a controlled trial.

Prenatal Considerations

Ideally, since CHB is most often identified from 18 to 24 weeks of gestation, intrauterine therapy should eventually be possible. The clinical approach to cardiac manifestations of NLS includes obstetric and rheumatologic management of (a) the fetus identified with CHB and (b) the fetus with a normal heart-beat but at high risk of developing CHB.

To address the treatment of identified CHB one needs to know if the presence of bradycardia represents an irreversible fibrotic process and if continued autoimmune tissue injury will cause progressive damage. McCue has reported a neonate described with first-degree heart block at birth, which resolved at 6 months (115). In contrast, Geggel et al. report an infant born with second-degree heart block, which progressed to third-degree block by 9 weeks of age (149). Data from the RRNL also emphasize that incomplete AV block is not always fixed and the degree of block is variable (11 ,33). There is a spectrum of conduction abnormalities even at the time of initial detection and in utero injury can have continued sequelae in some cases despite clearance of maternal antibodies from the neonatal circulation.

The rationale for treatment of identified heart block and prevention of potential heart block is to diminish a generalized inflammatory insult and reduce or eliminate maternal autoantibodies. Accordingly, several intrauterine therapeutic regimens have been tried including dexamethasone, which is not metabolized by the placenta and is available to the fetus in an active form, and plasmapheresis. Although there is not yet documentation in the literature regarding the reversal of third-degree heart block (complete fibrosis of the AV node would not be reversible) by maternal treatment with dexamethasone alone, the potential for diminishing an inflammatory fetal response attacking the myocardium is plausible. This would be an effect independent of a decrease in antibody titer. Precedent for this therapeutic rationale is the resolution of associated pleuropericardial effusions and ascites reported in separate investigations (17 ,46 ,150). In the largest retrospective study published to date it was observed that fluorinated glucocorticoids ameliorated incomplete atrioventricular block and hydropic changes in autoimmune-associated congenital heart block but did not reverse established third-degree block (151). Specifically, the data included 47 mothers whose sera contain anti-SSA/Ro-SSB/La antibodies, and their 50 children diagnosed with isolated CHB in utero and in whom at least four echocardiograms were performed thereafter. In 28 pregnancies, the mothers were treated with dexamethasone 4 to 9 mg/day for 3 to 19 weeks or betamethasone 12 to 24 mg/wk for more than 6 weeks (group A). In 22 pregnancies, fluorinated steroids were not used (group B). Third-degree block was present in 21 fetuses in group A and 18 fetuses in group B; none were reversible despite steroids. Three fetuses in group A and two in group B progressed from alternating second-degree/third-degree block to permanent third-degree block at birth and postnatally. Notably, of four fetuses in group A with second-degree block at presentation, all reverted to first-degree by birth. Of two fetuses in group B with second-degree block at presentation, both progressed to permanent third-degree block postnatally. Initial echocardiographic evaluation revealed pericardial effusions in 13 group A versus four group B (P = NS), pleural effusions in two group A versus none in group B (P = NS), ascites in eight group A versus none in Group B (P <0.007), hydrops in eight group A versus none in Group B (P <0.007), and intrauterine growth restriction (IUGR) in one group A versus one group B (P = NS). Pericardial effusions resolved and reappeared in both groups. Steroid therapy was most effective in the sustained resolution of pleural effusions (2/2), ascites (6/8), and hydrops (5/8). Oligohydramnios ensued in nine group A and two group B (P = NS). Although fetuses in group A had more associated complications at initial presentation than those in group B, there were no significant differences between the groups in the duration of pregnancy (35.7 vs. 37.0 wk), number of deaths (4 vs. 1), final degree of block, or requirement for permanent pacing (14 vs. 11).

In our experience and that of others, apheresis in addition to dexamethasone has not reversed third-degree heart block (17 ,152 ,153), although titers of maternal anti-SSA/Ro-SSB/La have been profoundly decreased (152). Maternal risks of dexamethasone are similar to any glucocorticoid and include infection, osteoporosis, osteonecrosis, diabetes, hypertension, and preeclampsia. Fetal risks include oligohydramnios, intrauterine growth retardation, and adrenal suppression. Intervention with glucocorticoids might decrease acute inflammation, but not necessarily prevent subsequent fibrosis.

Available data support serial cardiac monitoring of all fetuses with any bradyarrhythmias detected in utero and of neonates with incomplete blocks at birth whose mothers are previously known or currently identified to have anti-SSA/Ro-SSB/La antibodies. Fetal echocardiogram is essential to diagnose and follow the course of disease, and may suggest the presence of an associated myocarditis by the finding of decreased contractility in addition to the secondary changes associated with myocarditis such as an increase of cardiac size, pericardial effusions, and tricuspid regurgitation. The obstetric management should be guided by the degree of cardiac failure noted on the ultrasound images. The in utero environment is preferred as long as possible because of the low resistance circulatory pathways, thereby affording minimal work to maintain cardiac output.

The initiation of dexamethasone or plasmapheresis as a preventative measure has been considered. With regard to prophylactic therapy of the high-risk mother (documentation of high titer anti-SSA/Ro and SSB/La antibodies, anti-48kD SSB/La and 52kD SSA/Ro on immunoblot, and a previous child with NLS), administration of prednisone, dexamethasone, or plasmapheresis is not justified at the present time. Maternal prednisone (at least in low and moderate doses) early in pregnancy does not prevent the development of CHB (154). This might be anticipated, because prednisone given to the mother is not active in the fetus (155) and levels of anti-SSA/Ro and anti-SSB/La antibodies remain relatively constant

during steroid therapy. However, Shinohara et al. recently published uncontrolled data suggesting that prenatal use of maternal glucocorticoids has prophylactic merit (156). This recommendation was based on the finding that 15 of 61 infants born to 40 mothers with anti-SSA/Ro antibodies who did not receive glucocorticoids had CHB. The unexpectedly high prevalence may be explained by the retrospective nature of the study and potential referral bias. Conversely, CHB did not occur in any of 26 fetuses whose mothers were given steroids prior to the 16th week of gestation. If one accepts the rate of 2% then at least 40 mothers with anti-SSA/Ro antibodies may need to be followed to find one infant with complete block.

With regard to plasmapheresis as a prophylactic therapy, Barclay et al. initiated plasmapheresis during the late second trimester in a woman with anti-SSA/Ro antibodies and a history of four unsuccessful pregnancies, including a 32-week stillbirth with unexplained antenatal bradycardia. The pregnancy resulted in a healthy birth, and the titer of anti-SSA/Ro antibodies was decreased by 75%, although detectable antibodies were present in the cord blood (157). We similarly utilized “prophylactic” plasmapheresis in a pregnant woman with SS and a previous child with CHB (152). In this case, the fetus, despite having circulating levels of these antibodies detectable at birth, was exposed to only 10% of the potential maternal antibody load during the second and third trimesters. The child, now 8 years of age, never had any manifestations of NLS. In the absence of controlled studies, which may never be feasible given the rarity of CHB, plasmapheresis should be considered highly experimental and only reserved for those cases where the fetus is in a life-threatening situation with hydrops and deteriorating cardiac function.

The best approach for a mother with a previous offspring with CHB is unknown. We suggest that all mothers with anti-SSB/La antibodies or antibodies to components of SSA/Ro (particularly the 52kD) on immunoblot should have serial fetal echocardiography done by an experienced pediatric cardiologist weekly from 16 to 26 weeks and every other week until about 34 weeks. Thereafter, auscultation should be sufficient. In the last few years there have been major advances in fetal echocardiography. Until recently, the in utero detection of first-degree block was not technically feasible. However, the EKG equivalent of the PR interval can now be measured by echocardiography (158). A prospective NIH-supported multicenter study, PR Interval and Dexamethasone Evaluation (PRIDE) in CHB is underway to examine the mechanical PR interval weekly in pregnant woman with anti-SSA/Ro and/or anti-SSB/La antibodies. One of the goals of this trial is to identify the prevalence of first-degree block and to determine whether it is a marker for more advanced destruction of the conducting system. Such information will provide the optimal opportunity for reversibility. It is strongly recommended that all neonates born to mothers with anti-SSA/Ro-SSB/La antibodies have an EKG at birth to detect first-degree block.

Breastfeeding

Mothers often ask about the risks of breastfeeding. Askanase et al. (159) have addressed whether human breast milk contains antibodies to components of the SSA/Ro-SSB/La complex and, if so, whether breastfeeding might be associated with the postnatal manifestations of neonatal lupus. To accomplish these goals, breast milk from nine mothers with serologic evidence of anti-SSA/Ro and/or SSB/La antibodies was examined by ELISA and immunoblot for the presence of these same antibodies. Five of these breastfed infants were healthy without any manifestations of neonatal lupus, one had an isolated cardiomyopathy and died, two had cutaneous manifestations of neonatal lupus, and one had both CHB and rash. IgA and IgG antibodies to all components of the SSA/Ro-SSB/La complex were present in breast milk. Not unexpectedly, the antibody profiles of the breast milk paralleled those observed in the serum.

Of 237 mothers enrolled in the RRNL as of September 2000, 129 mothers answered a questionnaire regarding breastfeeding of their 266 children. Neonatal lupus was present in 149 of the children (55 with NLS rash alone, 72 with CHB alone, and 22 with both manifestations) and 117 were unaffected. The frequency of breastfeeding in the mothers enrolled in the RRNL was slightly lower (51%) than the national average (60%) of mothers breastfeeding upon leaving the hospital (160). This might be explained by the fact that mothers with anti-SSA/Ro-SSB/La antibodies are discouraged from breastfeeding by their physicians or in some cases might be too ill or on other medications. Overall, a total of 136 children (51%) were breastfed. Of 55 children with NLS rash, 33 were breastfed. Of 22 with both rash and CHB, 12 were breastfed. For the unaffected siblings, 60 of 117 were breastfed. The Fisher exact test revealed no significant differences between the breastfed and nonbreastfed children with isolated NLS rash, or those with associated CHB, compared to the unaffected children. Although there was a trend for the children who were breastfed to have the cutaneous manifestation of neonatal lupus appear at a later age than those who had rashes and were formula-fed, the difference in mean age of presentation of the rash did not reach statistical significance: 9.69 weeks vs. 7.55 weeks (*P* = NS). The duration of the rash was not influenced by breastfeeding: 14.7 weeks in the breastfed group versus 19 weeks in those not breastfed (*P* = NS). Not unexpectedly, of 72 children with isolated CHB, 31 were breastfed, which did not differ significantly from the unaffected children. Of seven infants in whom cardiomyopathy was detected after birth, four were breastfed.

Accordingly, the available data do not suggest that breastfeeding has pathologic consequences. Specifically, children with skin rashes were not breastfed more frequently than those who remained healthy. Furthermore, prematurity was not a factor contributing to the development of NLS rash in breastfed infants. There was a trend toward later presentation of the rash in the children who were breastfed, but there was no increase in duration compared to children who received formula. Because maternal antibodies transferred to the fetus during gestation would still be present for several months postpartum, the additional contribution of antibodies from breast milk may be inconsequential even if intestinal transport is effective. Mothers should be advised that autoantibodies are present in their breast milk but reassured that, at least within

the limits of published literature, breastfeeding is not associated with neonatal lupus. Given the potential for intestinal transport of the maternal antibodies, in the unusual circumstance of a worsening rash or developing cardiomyopathy consideration should be given to discontinuation of breastfeeding.

Treatment of Cutaneous Manifestations

Infants with CHB should be protected from excessive sun exposure since they are at risk for developing skin lesions until 8 to 12 months of age. In the absence of precise information regarding specific pathogenicity of the maternal antibody response, it is reasonable to consider all offspring of mothers with antibodies to components of the SSA/Ro-SSB/La ribonucleoproteins at risk for cutaneous disease in the first few months of postnatal life. Topical steroids, preferably those that are nonfluorinated, have been recommended for babies who develop lesions (126). High potency topical steroids to the skin of an infant can result in systemic effects. Because the lesions are transient and generally benign, systemic therapies such as antimalarials, which have a low toxic-to-therapeutic ratio in young children, have not been recommended (126).

Neiman et al. (128) reported on therapy and outcome of 57 infants (20 males, 37 females) diagnosed with cutaneous NLS (absent heart disease) between 1981 and 1997. Thirty-four (60%) were treated. Thirty-one were given only low to medium potency topical corticosteroid preparations. Three children were initially given topical antifungal agents and then subsequently treated with topical steroid preparations. None received systemic glucocorticoid therapy. The active rash resolved in all children regardless of treatment. In 51 children for whom reliable follow-up data were available, 37 rashes completely resolved without sequelae, of which 21 were treated and 16 received no therapy except avoidance of sun exposure. However, in 14 there were residual skin abnormalities: ten had telangiectasias, two had hyperpigmentation of the affected areas, ten had what was described as pitting, scarring or atrophy after at least 2 years of follow-up. Of these 14 children, ten were treated and four untreated. Although there was no significant difference in outcome between treated and untreated children by the Fisher exact test, firm conclusions are limited by the small number of cases.

Recurrence Rates

In the RRNL as of December 2005, 100 mothers have had pregnancies (lasting longer than 6 months) subsequent to the birth of child with CHB. In 73 (73%) of these pregnancies there were no AV conduction abnormalities or reported cutaneous manifestations of NLS in the children. Eighteen (18%) next pregnancies resulted in a second child with CHB, three in association with a rash. In seven (7%) next pregnancies, the offspring had cutaneous manifestations alone. Thus, the probability of having a second affected child with any manifestation of NLS was 25%. In one (1%) subsequent pregnancy, fetal demise occurred at 30 weeks, but with no apparent conduction abnormalities. Another subsequent pregnancy (1%) resulted in the birth of a boy who died at age 2 months. Although there were no documented conduction abnormalities, severe aortic stenosis and cardiomyopathy were present, which on biopsy was found to be associated with immunoglobulin deposition (24).

It is also important for the clinician to consider the outcomes of pregnancies subsequent to the birth of a child with NLS rash. Among RRNL mothers, as of December 2005, there have been 46 pregnancies (lasting longer than 6 months) following the birth of a child with NLS rash. In 17 (37%) of the offspring, there were no cardiac or cutaneous manifestations of NLS; 15 (33%) had NLS rash alone. It is striking that 13 (28%) next pregnancies resulted in a child with CHB, five in which there was also an associated rash. Although these recurrence rates from rash to CHB are disturbing, one caveat to consider is that many of these women entered the RRNL because of a child with CHB, but request for photos of younger siblings revealed characteristic NLS rashes.

Fetal Outcome

Data published from the RRNL reveal that 22 (19%) of the 113 offspring with CHB whose mothers were documented to have anti-SSA/Ro and/or SSB/La antibodies have died (12 boys, 10 girls). Six of these deaths occurred in utero. Ten neonates died in the first 3 months of life. Six children died between 3 months and 3 years of age. None of the 67 children between 3 and 10 years old remaining in the cohort have died. Twenty-two children are older than 10 years. However, the mortality is markedly reduced in those children born at later gestational ages. Specifically, only 8 (9%) of 86 children born at or after 34 weeks have died (11). Those infants who survive the neonatal period have an excellent prognosis. The cumulative probability of survival at 3 years is 79%.

With regard to the morbidity of CHB, 67 (63%) of the 107 children born alive have required pacemakers, 35 within the first 9 days of life. Fifteen additional children have been paced in the first year, and 17 after 1 year. One infant has had a cardiac transplant at 8 months of age, because of intractable cardiomyopathy. Moak et al. (8) recently underscored the need to recognize late-onset cardiomyopathy as a sequela of CHB with their report of 16 cases that developed despite adequate pacing.

In a study of 15 CHB patients followed by Silverman et al., there were three neonatal deaths, two late deaths due to pacemaker failure, and six who have required pacemaker therapy (106). Similarly, McCune reported a follow-up of 14 neonates with CHB, of whom five required pacemakers (144).

Long Term Follow-Up of Children with Varied Manifestations of NLS

Given the rarity of the disease, little information is available on the health outcome of children with neonatal lupus and their unaffected siblings. This is of interest from several perspectives. There is a genetic susceptibility for the

development of SLE (161 ,162 ,163), and relatives of SLE patients can have autoantibodies in the absence of clinical disease (164). Perhaps in addition to autoantibodies, the expression of SLE in the mother increases the risk of autoimmune disease in her offspring independent of whether the child has neonatal lupus or not. This generates the hypothesis that children with neonatal lupus, as well as their unaffected siblings, whose mothers have SLE might be at greater risk for the development of subsequent disease than children whose mothers are asymptomatic. Perhaps vulnerability to neonatal lupus is a marker for susceptibility to, or protection from, the development of actively acquired autoimmunity.

Martin et al. (165) report on the health of children 8 years of age or older who had manifestations of neonatal lupus (affected group) and their unaffected siblings (unaffected group). Questionnaires were sent to mothers (with anti-SSA/Ro-SSB/La antibodies) enrolled in the RRNL, and a control group composed of children of healthy mothers referred by the RRNL enrollees. Responses to the questionnaires were confirmed and expanded by review of medical records. Fifty-five mothers enrolled in the RRNL returned questionnaires on 49 children with neonatal lupus and their 45 unaffected siblings. Six children were identified with definite rheumatologic/autoimmune diseases: two with juvenile rheumatoid arthritis, one with Hashimoto thyroiditis, one with psoriasis and iritis, one with diabetes mellitus and psoriasis, and one with congenital hypothyroidism and nephrotic syndrome. All had manifestations of neonatal lupus and their mothers have manifestations of autoimmune diseases: four Sjögren syndrome, one systemic lupus erythematosus/Sjögren syndrome, and one undifferentiated autoimmune disease. Four of 55 sera tested were positive for ANA (two of 33 affected children and two of 22 unaffected children). No serum contained antibodies reactive with SSA/Ro or SSB/La antigens. These data suggest that children with neonatal lupus require continued follow-up, especially prior to adolescence and if the mother herself has an autoimmune disease. Although there was no apparent increased risk of SLE, the development of some form of autoimmune disease (systemic or organ-specific) in early childhood may be of concern. During adolescence and young adulthood, individuals with neonatal lupus and their unaffected siblings do not appear to have an increased risk of developing systemic rheumatic diseases.

In one small series, Brucato et al. (105) found that, at a mean follow-up of 18 years, none of 13 children with CHB developed clinical symptoms or serologic abnormalities suggesting immune disease.

Despite these encouraging results, other authors have reported seven cases in which an autoimmune disease developed in a child with manifestations of neonatal lupus. All the children were female, and in each instance except one the mother had SLE. Specifically, Esscher and Scott (166) reported a female with CHB who developed SLE at age 15 years. Jackson and Gulliver (167) reported an infant with cutaneous neonatal lupus who developed SLE at age 13, and Fox et al. (168) described a similar patient who developed SLE at age 19 years. In a patient described by Waterworth (169), CHB was identified at age 6 years and SLE diagnosed at age 13 years; no information was provided on the mother. Lanham et al. (170) reported two children with CHB; one subsequently developed primary SS at age 23 years, and the other arthritis, positive ANA and antibodies to dsDNA at age 19 years. Hübscher et al. (171) reported the development of a scleroderma of the face, puffy hands, and Raynaud phenomenon in a 13-year-old girl with CHB. At age 15 she was found to be seropositive for anti-SSA/Ro and U1RNP. It should be emphasized that maternal anti-SSA/Ro-SSB/La antibodies were not actually documented for any of these mothers.

Conclusions

The presence of antibodies reactive with several components of the SSA/Ro-SSB/La ribonucleoprotein particle, notably the 48kD SSB/La and the 52kD SSA/Ro antigens, is to date a near-universal characteristic of all mothers giving birth to offspring with NLS. Although NLS is rare, its discussion is an integral part of all pregnancy counseling of women with SLE, SS, and UAS. Overall studies suggest that there is an unacceptable morbidity and mortality. A major clue to defining the pathogenesis of antibody-mediated damage is the selective vulnerability of the fetal heart. Vulnerability could relate to a direct or indirect antigen target differentially expressed in the developing human heart. Alternatively, but not mutually exclusively, biologic events operative during fetal life, such as apoptosis, could facilitate accessibility of intracellular antigens to the extracellular environment. Opsonization of apoptotic cardiocytes might alter the normal events of cell removal by macrophages. Inadvertent activation of the macrophage and subsequent dysregulation of the fibroblast may lead to permanent injury. Perturbation of L-type calcium channels, which propagate the action potential in the AV node, provides a clue to a definable pathogenetic effect of anti-SSA/Ro antibodies. How apoptosis and calcium channel dysfunction relate, if at all, is not intuitive; there may be more than one mechanism involved in pathogenesis. A reproducible murine model of CHB would be a critical tool to define antibody pathogenicity at the histologic and molecular level with subsequent application for testing prophylactic and therapeutic interventions. The availability of a research registry devoted to neonatal lupus should continue provide an invaluable resource for basic and clinical research. The reporting of recurrence rates, mortality and morbidity, and maternal outcomes in a large number of patients has greatly facilitated family counseling. We eagerly await the results of the PRIDE study in the hope that with more detailed echocardiographic data, risk can be better defined and reversibility of early injury, a reality.

Acknowledgments

Chapter 54

Reproductive Issues in Women with Autoimmune Disease

T. Flint Porter

D. Ware Branch

Introduction

The human physiologic process that protects pregnancy from interruption by the maternal immune system remains a mystery. In recent years, investigators have theorized that breeches in this system may result in either infertility or recurrent pregnancy loss (RPL). Numerous immunologic mechanisms for so-called “reproductive failure” have been proposed and several immunomodulating treatments have been suggested as infertility therapy. This chapter will examine the evidence pertaining to proposed mechanisms and treatment regimens relating to immunologic reproductive failure.

Embryologic Development of the Immune System

The development of the immune system begins at conception and continues throughout pregnancy and into the newborn period. During weeks two and three of gestation, pluripotential yolk sac stem cells form the precursors for all the blood cell series. The thymus develops in the human embryo at week six of gestation, and lymphocyte differentiation proceeds in the absence of foreign antigens. Small lymphocytes appear in the peripheral blood at week seven and around lymphocyte plexuses by week eight. As early as 13 weeks of gestation, T cells that can respond to mitogens and recognize histoincompatible cells begin to appear. By 20 weeks of gestation, the human fetus has the ability to respond to congenital infections by producing plasma cells and antibodies.

The presence of an intact trophoblastic cellular barrier prevents the movement of large numbers of immunocompetent cells into or out of the fetus during pregnancy. In contrast, maternal IgG, by virtue of its Fc fragment, is specifically selected for placental transfer. Fetal IgG concentrations are about 10% of adult levels by the middle of the first trimester. Adequate humoral immunity in the neonatal period depends on the circulating immune globulins that have crossed the placenta, and fetal blood levels of IgG reflect maternal levels. The specific antibodies depend on the mother's own antigenic experience and function primarily to protect the neonate from infection. Additionally, maternal autoimmune disorders characterized by production of IgG antibodies may result in the transplacental passage of potentially antibodies to the fetus and newborn.

Maternal–Fetal Immunology

The normal relationship between mother and fetus appears to be growth promoting rather than the usual allogeneic model of destruction (1). Although incompletely understood, several immunologic mechanisms have been suggested. Gleicher (2) noted a generally higher prevalence of autoantibodies in women than men, speculating that selectively regulated autoantibodies have evolved in women as a compensatory mechanism to combat the excessive autoantigen load imposed by pregnancy (3 ,4). The implication is that autoantibodies may be considered normal and perhaps essential for normal reproduction.

Circulating blocking factors have been theorized to attenuate maternal immunologic reaction. These suppressor or blocking antibodies are measured using maternal-paternal mixed lymphocyte reactions (MLR) or flow cytometric cross-match (5). One progesterone-induced blocking factor suppresses production of lymphocytes and pro-inflammatory cytokines. Additionally, so-called blocking antibodies may prevent lymphocytic destruction by binding to receptors on fetoplacental tissues. Alternatively, blocking antibodies may be directed against antigen-specific combining sites (idiotypes) on maternally produced antibodies that prevent them from assisting lymphocytes in targeting cells on the conceptus. The concept of protection by blocking antibodies is indeed intriguing. However, their relevance remains unsettled. They are not universally present in the sera of women with normal pregnancies (6), but are often present in patients with RPL (7). Second, there is no evidence they are the cause of inhibition in the mixed lymphocyte response which is nonspecific and may be a result of factors other than immunoglobulins (8). Not only do

agammaglobulinemic women without antibody production have normal pregnancies (9), antibodies do not frequently appear until late in the first or second trimester of the first pregnancy.

Immunotolerance during pregnancy is probably a local phenomenon at the maternal-fetal interface rather than from generalized immunosuppressive state. Before conception, endometrial stromal cells transform into decidual cells that contain T cell subtypes with immunosuppressive activity. One T helper cell subset secretes cytokines that are beneficial or neutral to the presence of the fetus. Another is thought to prevent colonization with microbial pathogens. Additional evidence suggests that some subsets of the decidual T cells promote growth of the placenta through the secretion of cytokines that suppress inflammation. Hormones, enzymes, growth factors, and endometrial proteins within maternal decidual tissue also have potent immunomodulatory properties that promote a favorable interaction between the conceptus and the mother.

The presence of large granular lymphocytes in luteal phase and early to midpregnancy deciduus has generated considerable interest among reproductive immunologists (10). Under normal circumstances, these nonspecific innate immune effector cells, similar to natural killer (NK) cells, kill standard NK cell-targets with the notable exception of trophoblastic cells (11). Their absence or alteration has been associated with pregnancy loss.

The placenta also plays an active role in protection of the fetus from maternal immune responses. Villous cytotrophoblasts and syncytiotrophoblasts escape destruction because both express nonclassic MHC antigens that prevent trophoblast destruction through inhibition of lysis by activated NK cells, limitation of leukocyte cytotoxic activity, suppression of proinflammatory cytokine production, and induction of T cell death. Nonclassical MHC antigens also promote trophoblast proliferation and invasion. Altered expression of nonclassical MHC antigens has been linked to recurrent miscarriage and preeclampsia.

Placental expression of a protein known as the Fas ligand may also play a role in pregnancy success through selective deletion of antifetal T cell clones. In animal studies, binding to the Fas ligand causes death and removal of autoreactive T cells. The placenta may also inhibit T cell proliferation by sequestering nutrients. Placental indoleamine 2,3 dioxidase (IDO) inactivates the amino acid tryptophan that is essential for the proliferation of T cells. The role of IDO in recurrent pregnancy loss in humans has not yet been widely investigated.

Recurrent Pregnancy Loss

Background

Most pregnancy losses are sporadic, nonconsecutive spontaneous abortions that occur as an isolated event in the reproductive career of a woman with other successful pregnancies. Approximately 10% to 20% of pregnant women experience sporadic loss of a clinically recognized pregnancy (12). By comparison, only 2% of pregnant women experience two consecutive pregnancy losses. The diagnosis of recurrent pregnancy loss (RPL) is traditionally reserved for women with three or more consecutive losses and is estimated to occur in 0.5% to 1% of couples (13). Etiological categories include genetic, uterine pathology, endocrine, immunologic, thrombophilia, and environmental factors. Unfortunately, a cause for RPL is identified in only about 50% of affected couples (14).

Pregnancy loss prior to 20 weeks' gestation (menstrual dates) has traditionally been termed miscarriage or spontaneous abortion with fetal death thereafter considered a stillbirth. This oversimplified classification scheme ignores precepts of developmental biology as well as the clinical realities of pregnancy loss. In reality, the development of the conceptus from fertilized egg to live born infant involves numerous complex, inter-related steps. The pre-embryonic period lasts from conception through the fourth week from the first day of the last menstrual period (3 weeks after fertilization). During this period, the early trophoblast differentiates from the tissue destined to become the embryo (the inner cell mass) and accomplishes implantation into the maternal endometrium (days 6 to 7 after fertilization). The pre-embryo develops into a bilaminar and then trilaminar disk of cells and microscopically observable alterations of the cell disk define the cranial end central neural axis of the pre-embryo. Oxygen and nutrient needs are met by diffusion across maternal tissues.

The embryonic period is thought to begin around the fifth week of gestation, lasting through the ninth week of gestation during which time the trilaminar disk folds to become cylindrical, the head and tail regions become recognizable as cranial and caudal folds, definite segmentation is seen, and all organs form (organogenesis). The fetal period begins at the tenth week of gestation and extends through pregnancy until delivery. This period is characterized by substantial growth and differentiation of previously formed structures with relatively little organogenesis.

There are also distinct phases in the development of the placenta and the maternal-fetal circulation. Careful histologic examination (15) and evidence from Doppler ultrasound (16) indicates that normal pregnancies are characterized by obstruction of uteroplacental arteries by invading trophoblastic cells, which severely limits maternal blood flow into the intervillous tissue during the first 10 to 12 weeks. During this time, the intervillous space is relatively hypoxic (17) and is filled with an acellular fluid (15 ,18). Trophoblastic regression and dislocation of arteriolar trophoblastic plugs are thought to begin around 10 weeks' gestation allowing the initiation of true intervillous blood flow and an increase in intervillous oxygen tension. Until then, oxygenation of the embryonic tissues is presumed to occur largely through diffusion across adjacent tissues, rather than an organized circulatory delivery.

Accurate dating of pregnancy loss is often difficult because of the nature of its clinical presentation. The

symptoms of early loss, typically uterine bleeding and cramping, usually occur several days after the demise of the conceptus so that a pre-embryonic or embryonic loss may not become clinically apparent until 10 to 12 weeks' gestation. In other cases, fetal death may not occur until shortly before or even after clinical symptoms appear, as in the case of cervical insufficiency.

Epidemiology of Recurrent Pregnancy Loss

Approximately 50% of conceptions are thought to end in failure (19); the vast majority going unrecognized because they occur prior to or with the expected next menses (20). In one study of 232 early pregnancies of which 13% ended in failure, 90% occurred prior to 12 to 14 weeks' gestation (from last menses) and only 2% between 14 and 20 weeks' gestation (21). Miscarriage was infrequent between 8.5 to 14 weeks' gestation with no embryos alive at 8.5 weeks' gestation dying before 14 weeks' gestation, suggesting that pregnancy loss is somewhat biphasic in its distribution. Including both fetal deaths and early neonatal deaths, approximately 5% of all pregnancies end in pregnancy loss from 14 weeks' gestation through term (22 ,23 ,24). It is not clear whether failure of so-called “chemical pregnancies,” diagnosed solely by sensitive human chorionic gonadotropin assays, should be considered pregnancy losses.

Most cases of RPL take place in the pre-embryonic/embryonic period. Primary RPL refers to consecutive losses without any live births, whereas secondary RPL refers to losses following a live birth (25 ,26). The prognosis for a successful pregnancy is better after secondary RPL (Paukku, 1999). Women with three successive pre-embryonic or embryonic losses have a recurrence risk of approximately 25% to 30% (13 ,27 ,28 ,29). The recurrence risk is thought to increase with the number of successive losses. Other risk factors include tobacco and moderate alcohol use (30 ,31). Advanced maternal age also increases the likelihood of both sporadic and RPL. Even so, 70% of untreated couples with a history of RPL loss will have a live birth in a subsequent pregnancy. The risk of recurrent fetal death is less well understood. When one fetal death has occurred, the risk increases substantially, the magnitude depending on the gestational age at which it occurred (32 ,33). The risk increases 20-fold if fetal death occurs between 16 to 27 weeks but only fivefold if it occurs after 28 weeks' gestation (32).

Immunologic Recurrent Pregnancy Loss

The immunologic nature of otherwise unexplained RPL has generated considerable controversy in recent years. Both antibody-mediated and cellular-mediated mechanisms have been proposed. An association between systemic lupus erythematosus (SLE) and RPL is uncertain. In a recent retrospective study, women with SLE were about twice as likely to have spontaneous miscarriage or choose elective termination as controls (34). However, the authors noted that race and cultural background were more predictive of family size than the presence of SLE or even the number of miscarriages. To date, the only scientifically validated humoral cause for RPL remains antiphospholipid antibodies (APA), particularly the lupus anticoagulant (LA) and anticardiolipin antibodies (aCL).

An association between RPL and APA was first noticed in the latter third of the last century. The term antiphospholipid syndrome (APS) was introduced in 1986 (35) and formalized the association between RPL and APA as well as the association between APA and thrombotic events. The pathogenesis of pregnancy loss in women with APS has been ascribed to abnormal placental function, probably resulting from maldevelopment of the uteroplacental circulation. Extensive infarction, necrosis, and thrombosis have been identified in placentas from failed pregnancies in women with APA (36 ,37 ,38 ,39). A spiral arterial vasculopathy in decidual vessels also has been linked to APA-related fetal loss (40). It must be said, however, that the histologic abnormalities seen in APS cases are nonspecific.

Antiphospholipid Antibody Related Pregnancy Loss

The first investigators assumed that the hypercoagulability of APS was in some way having a negative impact on uteroplacental circulation, and numerous mechanisms have been subsequently considered. It is likely that vascular injury and/or endothelial cell activation (“second hit”) immediately precede the occurrence of thrombosis in patients with APS. The role of a second hit or cell activation step in APA-associated pregnancy loss or morbidity is uncertain. One proposed mechanism begins with activation or apoptosis of platelets and endothelial cells during which negatively charged phosphatidylserine migrates from the inner to the normally electrically neutral outer cell membrane. In the placenta, the migration of phosphatidylserine may occur during trophoblast syncytium formation. Circulating $ß_2$-glyoprotein I ($ß_2$GPI) then binds to phosphatidylserine. Antiphospholipid antibodies bind to the $ß_2$GPI dimer (41), activating complement and initiating a signaling cascade that induces cell surface tissue factor expression and adhesion molecules, causing platelets to aggregate and initiate thrombosis (42). An alternative, thrombotic hypothesis holds that APA competes in the placenta for phosphatidylserine with the natural anticoagulant placental anticoagulant protein I (annexin V) (43 ,44), possibly interrupting a shield that is thought to protect the fetus from maternal prothrombotic mechanisms (45 ,46). Others suggest that APA may operate through the signaling cascade. They inhibit production of placental prolactin, insulin growth factor $ß_1$, and the signal transducer and activator of transcription 5 (Stat5) (47), and they adversely affect formation of a trophoblast syncytium, placental apoptosis, and trophoblast invasion, all processes required for normal establishment of placental function.

In vitro, pathogenic APA induce adhesion molecule and tissue factor expression in endothelial cells and expression of GPIIb/IIIa on platelets (48) resulting in enhanced adherence of leukocytes to endothelium (49). In experimental animal models, APA cause fetal resorption (50 ,51) and the size and duration of trauma-induced venous and arterial thrombi (52 ,53). Inhibiting complement activation by a variety of mechanisms prevents experimental APA-induced fetal death (51); C5 knock-out mice carry pregnancies normally despite APA (54).

Pregnancy Loss Specific to Antiphospholipid Antibodies

Antiphospholipid antibodies are not frequently associated with sporadic pregnancy loss (55). Early pregnancy losses are more commonly due to chromosomal and other etiologies. The original description of APS included only women with fetal death, rather than earlier pregnancy loss. Subsequent series reported that positive tests for LA or IgG or IgM aCL are found in up to 20% of women with RPL (56 ,57 ,58 ,59 ,60 ,61); the majority of prospective treatment trials (62 ,63 ,64 ,65 ,66 ,67) have been composed mainly of healthy women with recurrent pre-embryonic and embryonic losses. The median rates of fetal death, preeclampsia, and preterm birth in these trials were relatively low, 4.5% (range, 0% to 15%), 10.5% (range, 0% to 15%), and 10.5% (range, 5% to 40%), respectively.

It should be noted that some investigators believe that women with APA identified in the setting of recurrent pre-embryonic and embryonic loss, without history of other clinical manifestations of APS, represent a different population from those identified because of thromboembolic disease, SLE, or adverse second or third trimester obstetric outcomes. Women with LA or medium-to-high positive IgG aCL have been shown to have losses more specific to the fetal period (68 ,69). In one study of 366 women with two or more consecutive pregnancy losses, investigators found that women with moderate-to-high levels of APA had significantly different pregnancy loss histories compared to women with low or absent levels (68). Although the overall rates of prior loss were similar in both groups (84%), 50% of the prior losses in women with moderate-to-high levels of APA were fetal deaths, compared to less than 15% in women without low or absent APA. In other prospective, large case series that included women with SLE, prior thrombosis, and other medical conditions, women with APS experienced high rates of preterm birth secondary to gestational hypertension-preeclampsia and uteroplacental insufficiency as manifested by fetal growth restriction, oligohydramnios, and nonreassuring fetal surveillance (70 ,71 ,72).

The etiology of APA related adverse pre-embryonic and embryonic outcomes (presenting as RPL) and later APA-related fetal complications are thought to be the same by some experts (73). The implication is that APA-mediated inflammation operates along the continuum of gestation to cause either pre-embryonic and embryonic or fetal damage. Other investigators question this theory, suggesting that women with recurrent pre-embryonic and embryonic losses and APA represent a largely different patient population than those who present with fetal death and other late pregnancy complications (74 ,75). The International Congress on Antiphospholipid Antibodies included both pre-embryonic-embryonic losses and the fetal-neonatal complications in their 1999 criteria, dividing them into three categories:

- One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation
- One or more premature births of a morphologically normal neonate at or before the 34th week of gestation
- Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation

Clinicians and investigators were strongly encouraged to stratify patients according to these clinical and laboratory criteria.

Treatment of Antiphospholipid Syndrome during Pregnancy

Treatment strategies for women with APA in pregnancy have been designed to suppress the immune system (prednisone and intravenous immunoglobulin [IVIG]), prevent thrombosis (heparin and aspirin), and improve placental blood flow by decreasing the thromboxane-to-prostacyclin ratio (aspirin). In addition to decreasing the risk of thrombosis, the ideal treatment would also improve maternal and fetal-neonatal outcome by preventing pregnancy loss, preeclampsia, placental insufficiency, and preterm birth. High-dose prednisone (at least 40 mg per day) in combination with low-dose aspirin (80 mg per day) was initially used to treat APS in pregnancy, resulting in successful pregnancies in 60% to 70% of cases (37 ,38 ,76). However, heparin became the treatment of choice after publication of a small, randomized trial found that maternally administered heparin was as effective as prednisone in reducing the risk of pregnancy loss (62). In most case series and trials, daily low-dose aspirin is included in the treatment regimen (62 ,63 ,64 ,65 ,66 ,77 ,78). In a recent meta-analysis of treatment trials (78), the live birth rate was improved by 54%. Other pregnancy complications associated with APS occur in spite of appropriate treatment (71 ,79). In a recent observational study of 107 pregnancies complicated by APS, preeclampsia occurred in 20%, preterm birth in 24%, and growth restriction in 15% of treated women (79).

The safe and effective dose of heparin for pregnant women with APS is debated, but should probably depend on individual patient history (74). Most authorities recommend full, adjusted-dose heparin for women with a history of a thrombotic event (80 ,81). Table 54-1 presents suggested regimens. Patients in most published series also received low-dose aspirin, although the benefit of adding aspirin is unknown. The goal of adjusted dose anticoagulation therapy with unfractionated heparin is to maintain an activated partial thromboplastin time (aPTT) 1.5–2.5 times the

normal value. Antifactor Xa levels are followed in patients positive for LA and should fall between 0.4 to 0.7 U/mL. Low molecular weight heparin (LMWH) has been also been used safely in women with APS during pregnancy (82 ,83). Full anticoagulation with enoxaparin is usually achieved by administering 1 mg/kg twice daily, in two equal doses 12 hours apart. However, because of pregnancy induced alterations in the pharmakinetics of LMWH, intermittent monitoring of antifactor Xa levels are recommended to ensure adequate dosing. The target antifactor Xa level for full anticoagulation using LMWH is 0.5 to 1.1 U/mL. In most cases, heparin should not be used in combination with high-dose prednisone because of an increased risk of osteopenic fractures and lack of improvement in fetal outcome with combination therapy (71).

Table 54-1: Subcutaneous Heparin Regimens Used in the Treatment of Antiphospholipid Syndrome during Pregnancy

Prophylactic Regimens	
Indications	Recommended in women with no history of thrombotic events. Diagnosis of antiphospholipid syndrome based on recurrent pre-embryonic and embryonic loss or prior fetal death or early delivery because of severe preeclampsia or severe placental insufficiency
Unfractionated Heparin	7,500–10,000 U every 12 hours in the first trimester, 10,000 U every 12 hours in the second and third trimesters
Low Molecular Weight Heparin	(1) Enoxaparin 40 mg once daily or dalteparin 5,000 U once daily, OR (2) Enoxaparin 30 mg every 12 hours or dalteparin 5,000 U every 12 hours
Adjusted-Dose Anticoagulation Regimens	
Indications	Recommended in women with antiphospholipid syndrome with a history of thrombotic event(s).
Unfractionated Heparin	>7,500 U every 8–12 hours adjusted to maintain the mid-interval heparin levels* in the therapeutic range
Low Molecular Weight Heparin	(1) Enoxaparin 1 mg/kg every 12 hours or dalteparin 200 U/kg every 12 hours (2) Intermediate dose (e.g., enoxaparin 40 mg once daily or dalteparin 5,000 U once daily until 16 weeks' gestation and every 12 hours from 16 weeks' gestation onwards

*Heparin levels = antifactor Xa levels. Women without a lupus anticoagulant in whom the activated partial thromboplastin time is normal can be followed using the activated partial thromboplastin time.

Heparin is also considered the treatment of choice during pregnancy for women with APS and no history of a thrombotic event. Treatment is usually initiated in the early first trimester after ultrasonographic demonstration of a live embryo. There is no evidence to support the initiation of heparin prior to conception. The dose of heparin required for safe and effective treatment is debated and both low-dose prophylaxis and adjusted-dose anticoagulation regimens have been reported (78). Live rates have exceeded 70% using either strategy (62 ,64). Women with a history of fetal death alone may be at higher risk for thromboembolism during pregnancy (84) and should probably receive higher doses of heparin prophylaxis. It is our practice to treat such women with generous thromboprophylaxis (e.g., 15,000 to 20,000 units of standard heparin or 60 mg of enoxaparin in divided doses daily) (74).

Warfarin is a known teratogen and should be discontinued either prior to conception or by the fifth week of gestation (menstrual). Even so, some experts recommend the judicious use of warfarin anticoagulation in pregnancy for women with particularly egregious thrombotic histories, such those with recurrent thrombotic events or cerebral thrombotic events and those who have had a recurrent thrombosis while on heparin (74). Likewise, clopidogrel and newer antithrombotic agents are not cleared for use in pregnancy and should be considered only patients unable to use heparin in consultation with a maternal-fetal medicine specialist.

Pregnancy losses continue to occur in 20% to 30% of cases even when heparin prophylaxis is given (71 ,78 ,85). Several alternative therapies have been tried in so-called refractory cases. Glucocorticoids, often in high doses, have sometimes been added to regimens of heparin and low-dose aspirin. Although there are anecdotal reports of success, this practice has never been studied in appropriately designed trials and the combination of glucocorticoids and heparin may increase the risk of preeclampsia and osteoporotic fracture (62). IVIG is also sometimes been given during pregnancy to women with APS who have continued to have poor obstetric outcomes despite treatment with heparin (86). However, two randomized, controlled trials found no benefit to this expensive therapy compared to heparin and low-dose aspirin (87 ,88). Hydroxychloroquine has been shown to diminish the thrombogenic properties of APA in a murine thrombosis model (89). Past concerns about ocular damage or defects with in utero exposure have been put to rest by recent reports of hydroxychloroquine use in pregnant women with lupus (90). Nevertheless, there are few case reports and no controlled trials of APS patients being treated during pregnancy with hydroxychloroquine.

Healthy women with recurrent embryonic and pre-embyronic loss and low titers of aPL probably do not require treatment (91). The controlled trial of Pattison et al. included a majority of such women and found no difference in live birth rates using either low-dose aspirin or placebo (66).

Alloimmune Theories of Recurrent Pregnancy Loss

Perhaps no subject in the area of immunologic reproductive failure has generated more controversy than the idea that many cases are a result of a maternal alloimmune response to her fetus, semiallogenic, because of maternally and paternally inherited gene products and tissue-specific antigens. Several potential allogeneic factors have been suggested and extensively investigated. Early reports proposed that human leukocyte antigens (HLA) compatibility of couples, the absence of maternal leukocytotoxic antibodies, or the absence of maternal blocking antibodies were related to RPL. Defects in molecular immunosuppressive factors (cytokines and growth factors) at the local decidual/trophoblast level were initially implicated (92 ,93). Elevated levels of maternal systemic NK cells have also been associated with RPL (94 ,95 ,96). Recent evidence suggests that pregnancy survival depends on inhibition of local inflammatory mediators (97 ,98 ,99 ,100).

Though no clear alloimmune mechanism for RPL has to date been identified, several immunologic treatments are given in some centers to women with RPL. Most commonly this includes transfusion of paternal leukocytes (lymphocytes) prior to conception and/or passive immunization with IVIG during pregnancy. Paternal leukocyte immunization treatment is based on the salutary effect that third party leukocytes have on allograft rejection in transplant patients. There is also some evidence that it results in a decreased number of NK cells in RPL patients (101). The use of IVIG is based on the possibility that it may cause down regulation of systemic NK cells (101 ,102) and abrogation of their activity at the implantation site resulting in a lower likelihood of miscarriage (95 ,103). Both treatments have been extensively studied in randomized controlled trials, most of which found no benefit to either treatment (104 ,105 ,106 ,107 ,108). Only two of seven trials of leukocyte immunization have found a beneficial effect on live births in women with a history of RPL (109 ,110). Both were heavily criticized because of an unusually low live birth rate in women who received placebo. One trial of IVIG, which included women with only two prior losses, reported an improvement in live births in women with RPL (111). Several others, which limited inclusion to women with three or more prior losses, found no statistically significant difference in live birth rates in women who received IVIG compared to those who were given placebo (112 ,113 ,114 ,115 ,116). Although there continues to be considerable debate regarding the efficacy of both leukocyte immunization and IVIG for the treatment of RPL, their use should currently be considered experimental and limited to research protocols.

Infertility

Background

Infertility is traditionally defined as 1 year of unprotected coitus without conception. Approximately 10% to 15% of reproductive age couples are affected (117). Causal factors are traditionally broken down into several categories including tubal and pelvic pathology, male factor, and ovulatory dysfunction. Infertility remains unexplained in 10% to 20% of affected couples who undergo evaluation (118).

Advancing maternal age probably contributes to unexplained infertility. Based on studies in a stable population of Hutterite men and women not using contraception, Tietze found that 33% of women were infertile at age 40, and 87% were infertile at age 45 (119). This may play a role in the observed rise in the rate of infertility in the United States where a steady increase in births among women aged 35 to 44 has been observed over the last several years (120 ,121).

Treatment of Infertility

Assisted reproductive technologies (ART) describe several treatments given to infertile couples attempting to conceive. Ovulation induction (OI) or stimulation begins with administration of gonadotropin-releasing hormone (GnRH) analogues to bring about desensitization of the pituitary gonadotropes to endogenous GnRH. Human menopausal gonadotropin is given to stimulate ovarian follicle maturation, followed by human chorionic gonadotropin (hcG), which is given to induce ovulation. The luteal phase is maintained by low doses of hCG and/or intramuscular injections of progesterone. The most promising oocytes, usually five, are retrieved using transvaginal ultrasound guidance. Ovulation induction is not without risks. Estrogen production must be monitored carefully as overproduction can lead to hyperstimulation syndrome, characterized by pain, markedly enlarged ovaries, capillary leak syndrome, fluid retention, and cytokine release syndrome. Hypertension and renal failure may occur in the most severe cases.

In vitro fertilization-embryo transfer (IVF-ET) refers to a number of techniques in which sperm and oocytes are manipulated to achieve fertilization, with the intent to place a growing zygote within the uterine cavity to establish a pregnancy. Table 54-2 describes other less common ART.

Immunologic Mechanisms of Female Infertility

Whether or not autoimmunity is responsible for primary infertility or an increased risk of failed ART is a matter of great debate. Antisperm antibodies, killer T cells, and a variety of more narrowly specified lymphocyte subsets, antileukocyte antibodies, antiphospholipid antibodies, and other immunologic aberrations have all been suggested as the cause of primary infertility and failure of IVF-ET. Aberrations in the immune system could theoretically lead

to premature ovarian failure (POF) and subsequent infertility. Because the ovary is not an immunologically privileged site, the immune system is free to attack its stromal, epithelial, and germ cell components. However, evaluations of an immune mechanism relating to infertility are severely hampered by the lack of adequately validated antiovarian antibody assays. Attempts to diagnose female immune infertility have relied on assays for nonspecific autoantibodies and other markers of immune system activation or dysregulation. In the end, autoimmunity probably plays only minor role in POF (~20%). Very rare autoimmune polyglandular syndromes, also characterized by idiopathic Addison disease, are found in about 3% of women with POF.

Table 54-2: Assisted Reproductive Technologies (ART)

Technology	Description
In vitro fertilization (IVF)	Laboratory culture of aspirated oocytes and spermatozoa followed by transcervical embryo transfer (ET)
Gamete intrafallopian transfer (GIFT)	Direct placement of aspirated oocytes and spermatozoa into fallopian tubes
Controlled ovarian hyperstimulation (COH)	Ovulation induction with monitoring in normal ovulatory women; intent is to induce multiple ovarian follicles
Intrauterine insemination (IUI) intracervical insemination (ICI) intratubal insemination (ITI)	Separation of spermatozoa from seminal fluid with suspension in buffer or culture media and insemination into the uterus, cervix, or fallopian tube
Zygote intrafallopian transfer (ZIFT)	Laboratory culture of aspirated oocytes with spermatozoa followed by direct placement of fertilized zygotes or embryos into fallopian tubes
Oocyte donation (OD)	Laboratory culture of aspirated oocytes from a donor woman followed by sperm/oocytes culture and transfer
Intracytoplasmic spermatozoa injection (ICSI)	Micromanipulation technique in which a single sperm is injected into an oocyte. It is used in cases of abnormal spermatozoal function or very low sperm counts

It has been hypothesized that the same immunologic mechanisms responsible for some cases of RPL could also affect earlier, unrecognized pregnancies as well, leading to unexplained infertility. Antibodies directed toward gametes or other critical components could theoretically inhibit fertilization, impair early embryo development, or hinder implantation or postimplantation/placental development. However, no disease-specific autoantibodies that adversely affect fertility have been convincingly identified.

SLE and Infertility

Fertility in patients with SLE (SLE) is thought to be equivalent to that of the general population (122). Likewise, disease activity does not appear to affect fertility (123 ,124). Some immunosuppressive treatments appear to have an adverse effect on fertility. Cyclophosphamide pulse therapy has been associated with POF in women undergoing treatment for lupus nephritis (125 ,126 ,127). Ranging from 12% to 62%, the incidence appears to be related to route of delivery, dosage and patient age at the time of therapy (128 ,129 ,130 ,131). Long-term nonsteroidal anti-inflammatory drugs (NSAIDs) have also been shown to interfere with ovulation (132 ,133). Successful pregnancy has been reported after withdrawal of NSAID therapy (134).

The increased serum estrogen concentrations that result from ovarian stimulation in preparation for ART have been associated with increased SLE disease activity (135 ,136), as well as with the onset of SLE in women who were previously healthy (137 ,138). In one retrospective series of ART in rheumatic disease pregnancies (139), 6/19 women suffered complications, regardless of whether or not ART was successful. Three patients experienced worsening of the primary rheumatic disease and three others suffered complications of the procedure itself.

The pregnancies that result from ART are in and of themselves complicated, in large part because many are multiple gestation pregnancies.

ART in autoimmune disease patients are not trivial. Infertile women with any type of rheumatic disease should be informed of risks prior to undertaking any form of ART. If competently done in carefully selected patients, ART do not appear to add substantial risk, nor are major disease specific complications apparent. However, multiple gestation pregnancies risk additional harm to the mother. No ART procedure should be performed in women with active or unstable disease.

Antiphospholipid Syndrome and Infertility

Antiphospholipid antibodies have been studied extensively in women with otherwise unexplained infertility. Proposed mechanisms by which these antibodies might affect fertility or IVF success include abnormal implantation, placentation, and embryonic vascular compromise. Laboratories across the globe disagree whether APAs (as well as other immunologic anomalies) contribute to infertility (140). Even so, it is not uncommon for reproductive failure clinics to perform so-called APA panels on women with

unexplained infertility and those contemplating IVF (141 ,142). In addition to LA and aCL, large APA panels typically include several other APA types, including antiphosphatidylserine, antiphosphatidyl choline, antiphosphatidylglycerol, antiphosphatidylethanolamine, and antiphos-phatidyl inositol. Based on the results of retrospective studies showing an increased prevalence of aCL in women with unexplained infertility (143 ,144 ,145), immunomodulating treatments and anticoagulation have been given to women who test positive for one or more types of antibodies in the APA panels. However, a meta-analysis of data from seven studies and more than 2,000 subjects undergoing IVF-ET found no statistically significant associations between the presence of APA and the clinical outcomes of IVF-ET, including clinical pregnancies and live births (146).

Some centers offer immunosuppressive and anticoagulation treatment to all APA-positive women undergoing IVF-ET (147 ,148). However, an association between APA status and infertility in well-designed prospective trials has not been confirmed (149 ,150 ,151). In a randomized, double-blinded, controlled trial, Stem et al. reported no difference in implantation rates between women attempting IVF-ET whether they were treated with aspirin plus heparin (8.9%) or placebo (9%) (149). In the most recent randomized double-blinded, placebo-controlled trial of heparin and aspirin for women undergoing IVF-ET with a history of prior IVF-ET failure, Stern et al. (150) reported no differences in pregnancy or implantation rates in 300 embryo transfers in 143 women, regardless of whether or not they received heparin and aspirin or placebo. Although other investigators have reported improved outcomes with heparin treatment in APA-positive women undergoing IVF-ET, none of their trials were randomized and only a few were controlled (Table 54-3).

Table 54-3: Empiric Treatment for Presumed Antibody-mediated Infertility

Trial	APA positive subjects treated	Treatment	Treatment Criteria	Outcome
Birkenfield et al., 1994 (153)	15	Aspirin/prednisone IVF	≥1 of 4 antibodies positive Prior IVF-ET failure	7/15 (46.6%) pregnancies, no differences from prior untreated cycles for # of ova or embryos
Sher et al., 1994 (147)	169	Heparin/aspirin IVF	≥1 of 18 APA positive organic pelvic pathology	82/169 (49%) clinical pregnancies
Schenk et al., 1996 (154)	35	Heparin/aspirin IVF	≥2 of 12 APA assays positive; unselected IVF-ET candidates	10/35 (51.4%) clinical pregnancies in seropositive/treated vs. 12/40 (30%) clinical pregnancies in seronegative/untreated [NS]. Implantation rates 28/140 (20%) in seropositive/treated vs. 9.7% in seronegative/untreated (p = 0.014)
Kutteh et al., 1997 (151)	19	Heparin/aspirin IVF	≥1 of 3 assays for ACL isotypes positive, no history of RPL	10/19 (52.6%) clinical pregnancies seropositive/treated 8/19 (42.1%) clinical pregnancies seropositive
Sher et al., 1998 (152)	52	Heparin/aspirin IVF	≥4 IVF failures	42% APA positive and 19% APA negative delivered (p = 0.02)
Geva et al., 2000 (155)	52	Aspirin/prednisone IVF	≥1 of 4 autoantibody or rheumatoid factor positive and ≥1 IVF-ET failure	17/52 (32.7%) clinical pregnancy rate, uncontrolled
Stern et al., 2003 (150)	143	Heparin/aspirin IVF	≥1 APA, ANA, and ≥10 prior IVF-ET failure	Implantation rates 20/296 (6.8%) for treated cycles and 22/259 (8.5%) for placebo cycles

Based on the available evidence, there is little on which to base the performance of APA panel testing in couples with otherwise unexplained infertility. There is even less justification to prescribe potentially dangerous immunomodulating

and anticoagulation treatment regimens to infertile women who do not meet the criteria for bona fide APS. Indeed, a pregnancy-related death associated with heparin and aspirin treatment for infertility was reported by the Centers for Disease Control (CDC) in 1996.

Subclinical Autoimmunity and Reproductive Failure

A role for autoimmunity in otherwise unexplained, primary infertility remains far from certain (156). Not withstanding, so-called reproductive immunology clinics offer a vast array of therapies said to improve the likelihood of IVF-ET success. Couples desperate to have children are drawn to these centers where they are subjected to a staggering number of assays for autoantibodies (157), the results of which are used to prescribe an equally impressive number of expensive and sometimes dangerous immunomodulating treatments. In truth, no adequately controlled trials of these therapies have been conducted in couples attempting ART. The use of desensitization, immunosuppression, anticoagulation, intravenous immunoglobulin, anti-TNF medications and other forms of immunomodulation is justified by only by reports of successful implantation in small case series and anecdotal reports.

Interventions of the past underline the need for caution in the use of unproven therapies during IVF-ET and in early pregnancy. One needs only to point to the tragedy of diethylstilboestrol (DES) in the last century. Based on the findings of one uncontrolled trial (158), DES was routinely prescribed to pregnant women thought to be at risk for miscarriage. Reports of an increased risk of cancer in laboratory animals (159) and the findings of a placebo-controlled trial showing no preventive effect on miscarriage and other pregnancy complications did little to dissuade physicians and patients from using DES (160). It was not until 1971 that a red flag was raised after Herbst et al. published the first case-control study showing that maternal use of DES could result in cancer and reproductive abnormalities in their female offspring 20 years after exposure (161).

Corticosteroid therapy is known to reduce the percentage of peripheral blood NK cells (162) and has been reported to improve pregnancy rates in women undergoing IVF-ET (153 ,155 ,163). Other investigators of have found no beneficial effect of corticosteroid therapy on implantation or pregnancy rates in women undergoing IVF-ET (164 ,165 ,166). A meta-analysis of treatments in APA positive women found no beneficial effect but reported a higher risk of pregnancy complications compared to women receiving placebo (78). Although necessary to control disease activity in women with unstable autoimmune disease during pregnancy, the use of corticosteroids for healthy women undergoing IVF-ET seems unnecessarily dangerous.

There is little to no evidence to support the use of other immunomodulation treatments in healthy women undergoing IVF-ET.

After a review of the available evidence, expert committees have found no evidence that autoimmunity is a cause of primary infertility (167 ,168). Moreover, unbiased authorities recommend that that the use immunomodulation therapies be restricted to research protocols under carefully controlled conditions.

Summary

- Immunotolerance during pregnancy is a poorly understood local phenomenon at the maternal-fetal interface.
- Most pregnancy loss is a sporadic, isolated event in the reproductive life of women with other successful pregnancies.
- Recurrent pregnancy loss is estimated to occur in 0.5% to 1% of couples.
- The etiology of recurrent pregnancy loss is found in 50% of couples undergoing evaluation.
- Most pregnancy loss occurs during the pre-embryonic-embryonic period (<10 weeks of gestation).
- Recurrent pregnancy loss does not appear to be more common among women with systemic lupus erythematosus.
- Antiphospholipid antibodies, particularly the lupus anticoagulant and IgG anticardiolipin antibodies, remain the only scientifically validated cause of recurrent pregnancy loss.
- Patients with antiphospholipid antibodies identified because of recurrent early pregnancy loss probably represent a different population than those identified because of fetal death or thrombosis.
- Heparin (usually with low-dose aspirin) is the treatment of choice for antiphospholipid syndrome during pregnancy.
- No clear mechanism for alloimmune recurrent pregnancy loss has been identified.
- There is no evidence to support the use of any immunomodulating treatments in women with so-called alloimmune recurrent pregnancy loss.
- Infertility is defined as 1 year of unprotected coitus without conception.
- Ten percent to 15% of couples attempting pregnancy are infertile.
- Assisted reproductive technologies (ART) describe several treatment regimens given to infertile couples attempting to conceive.
- Fertility in patients with systemic lupus erythematosus appears to be equivalent to that of the general population.
- Increased serum estrogen levels during ovulation induction may result in lupus flare.
- ART should not be performed in women with active or unstable systemic lupus erythematosus.
- Antiphospholipid antibodies are probably not associated with infertility or failure of IVF-ET.
- There is no evidence to support the use of immunomodulating treatments in healthy women undergoing IVF-ET.

Chapter 55

Lupus Nephritis: Pathology and Pathogenesis

Vivette D. D'Agati

Gerald B. Appel

Introduction

Lupus nephritis (LN) contributes significantly to the morbidity and mortality of SLE patients (1 ,2 ,3). This is in part because of the renal disease itself, and in part because of the side effects of therapies directed to the renal manifestations. Recent studies have clarified the major histologic patterns of renal involvement as well as differences in their clinical presentations and outcomes. The use of the World Health Organization (WHO) classification of LN, supplemented by activity and chronicity indices, has become the "gold standard" to gauge prognosis and determine appropriate therapy. A revised classification system for lupus nephritis, the ISN/RPS "WHO Classification Revisited" published in 2004, has replaced older classifications (4 ,5). With appropriate validation and increasing acceptance, this classification should provide a more reproducible system for investigators from different centers to standardize pathologic interpretation and to determine optimal therapy and study outcomes.

Histopathologic Classifications of Lupus Nephritis (LN)

LN is extremely pleomorphic. All four renal compartments, the glomeruli, tubules, interstitium, and blood vessels, may be affected. Adjacent glomeruli from a single biopsy may show variable involvement, as may the biopsies from patients with similar clinical manifestations. Over time glomerular lesions may transform from one pattern to another. Through the years, investigators have sought to define and quantify the many morphologic lesions of lupus nephritis in a comprehensive, systematic fashion. The earliest classifications of renal involvement in SLE patients divided glomerular changes only into mild forms (lupus glomerulitis), severe proliferative forms (active lupus glomerulonephritis) and membranous glomerulopathy (6 ,7).

Three major classification systems have been proposed over the last three decades. The original WHO classification was formulated in 1974 and recognized five major classes of lupus nephritis (Table 55-1) (8 ,9). In 1982, a modified WHO classification was promulgated by the International Study of Kidney Disease in Children (ISKDC), with further revisions in 1995 (10 ,11) (Table 55-2). It defines six major classes of lupus nephritis and a large number of subclasses with emphasis on distribution, activity, and chronicity of the lesions. Although it is much more detailed and precise than the original WHO classification, it has not been as widely accepted because of its greater complexity with excessive reliance on subclasses. Moreover, its treatment of mixed or overlapping classes of lupus nephritis has been controversial. A third classification proposed in 2004 by a consensus conference organized jointly by the International Society of Nephrology (ISN) and the Renal Pathology Society (RPS) retains the simplicity of the original WHO classification, while incorporating some of the refinements introduced by the modified WHO classification (4 ,5) (Table 55-3). The ISN/RPS classification has the advantage of standardizing pathologic criteria and defining more precisely the distinctions between the classes.

All three classifications are based entirely on evaluation of glomerular alterations. Although tubular, interstitial, and vascular lesions are common in lupus nephritis and may contribute significantly to overall disease severity, activity, and chronicity, they are not factored into these classifications. Accurate classification requires careful assessment of the glomerular alterations by light microscopy, followed by integration of the immunofluorescence and electron microscopic findings. The first step is to determine whether there is glomerular hypercellularity in the mesangial, endocapillary, or extracapillary zones. The distribution of hypercellularity (focal: <50% of glomeruli; diffuse: ≥50% of glomeruli affected) is assessed. Attention is given to the presence of infiltrating leukocytes, necrotizing lesions, and glomerular basement membrane thickening. These light microscopic findings are then interpreted in the context of the distribution of the glomerular immune deposits in mesangial, subendothelial, and subepithelial locations as detected by light microscopy, immunofluorescence and electron microscopy (Table 55-4). Immunofluorescence and electron microscopy are sensitive techniques for the detection of immune deposits. Since some lesions are focal, a proper classification depends on the adequacy of the glomerular sampling by the three modalities.

Table 55-1: Original WHO Classification of Lupus Nephritis (1974)

Class I	Normal glomeruli (by LM, IF, EM)
Class II	Purely mesangial disease a. Normocellular mesangium by LM but mesangial deposits by IF and/or EM b. Mesangial hypercellularity with mesangial deposits by IF and/or EM
Class III	Focal segmental proliferative glomerulonephritis (<50%)
Class IV	Diffuse proliferative glomerulonephritis (≥50%)
Class V	Membranous glomerulonephritis

Several recent studies have evaluated the reproducibility and validity of the new ISN/RPS classification versus the older WHO classification of lupus nephritis. A Japanese study reviewed the renal biopsies of 60 LN patients with a mean follow-up of 187 months (12). When compared with the modified WHO classification, the ISN/RPS classification gave higher consensus on pathologic interpretation (98% vs. 83%) and proved valuable in predicting prognosis. Likewise, a recent analysis of 420 Chinese patients found the ISN/RPS classification to be more reproducible than the modified WHO classification (96% vs. 87%) (13). Additionally, recent studies have already tested the validity of the subdivision of ISN class IV into diffuse segmental and diffuse global subtypes (14 ,15).

Table 55-2: Modified WHO Classification of Lupus Nephritis (1982)

Class I	a. Normal glomeruli (by LM, IF, EM) b. Normal glomeruli by LM but deposits seen by IF and/or EM
Class II	Purely mesangial alterations (Mesangiopathy) a. Mesangial widening and/or mild hypercellularity (+) b. Moderate hypercellularity (++)
Class III	Focal segmental glomerulonephritis (associated with mild or moderate mesangial alterations) a. With active necrotizing lesions b. With active and sclerosing lesions c. With sclerosing lesions
Class IV	Diffuse glomerulonephritis (severe mesangial, endocapillary or mesangiocapillary proliferation, and/or extensive subendothelial deposits). Mesangial deposits are present invariably and subepithelial deposits often, and may be numerous. a. Without segmental lesions b. With active necrotizing lesions c. With active and sclerosing lesions d. With sclerosing lesions
Class V	Membranous glomerulonephritis a. Pure membranous glomerulonephritis b. Associated with lesions of category II (a or b) c. *Associated with lesions of category III (a, b, or c) d. *Associated with lesions of category IV (a,b,c, or d)
Class VI	Advanced sclerosing glomerulonephritis

*Deleted from the 1995 Modified WHO Classification

Pathologic Features of Lupus Nephritis According to the ISN/RPS Classification

Class I (Minimal Mesangial Lupus Nephritis)

Class I denotes normal glomeruli by light microscopy with mesangial immune deposits detected by immunofluorescence and/or electron microscopy. The original WHO class I, defined as an entirely normal renal biopsy, was rarely if ever encountered because such patients typically have no clinical renal abnormalities and are not subjected to renal biopsy. Therefore, this “normal” category was eliminated from the ISN/RPS classification. By light microscopy the glomeruli are normocellular (Fig. 55-1). By immunofluorescence, immune deposits are limited to the mesangium (Fig. 55-2). The mesangial deposits tend to be small and vary from segmental to global in distribution. By electron microscopy corresponding electron dense deposits are present in the mesangium, without involvement of the peripheral glomerular capillary walls.

Class II (Mesangial Proliferative Lupus Nephritis)

Class II is defined as pure mesangial hypercellularity of any degree and/or mesangial matrix expansion by LM with mesangial immune deposits. Mesangial hypercellularity is defined as more than or equal to 3 mesangial cells in mesangial areas away from the vascular pole, assessed in 3 micron thick histologic sections. The mesangial proliferation is usually mild to moderate and does not compromise the glomerular capillary lumens (Fig. 55-3). By immunofluorescence, there are granular mesangial immune deposits. The pattern by immunofluorescence outlines the axial framework of the glomerulus, corresponding to the mesangial stalk (Fig. 55-4). By electron microscopy there are electron dense deposits within the mesangial matrix (Fig. 55-5). Strictly speaking, pure class II lupus nephritis should have no detectable subendothelial or subepithelial deposits. However, in practice, some cases of purely mesangial proliferative lupus nephritis will manifest rare small subendothelial electron dense deposits, particularly extending out from the adjacent mesangium. Cases of lupus nephritis with severe, but purely mesangial hypercellularity, without obliteration of the capillary lumina, may pose difficulties in classification. If the immune deposits are limited to the mesangium by immunofluorescence and electron microscopy, even cases of severe diffuse mesangial

proliferation should be classified as class II. If significant subendothelial deposits are present by immunofluorescence or by electron microscopy, or if they are visible by light microscopy, the case should be classified as focal proliferative (class III) or diffuse proliferative (class IV) depending on their distribution.

Table 55-3: ISN/RPS Classification of Lupus Nephritis (LN) (2004)

Class I	Minimal mesangial LN Normal glomeruli by LM, but mesangial immune deposits by IF
Class II	Mesangial proliferative LN Purely mesangial hypercellularity of any degree or mesangial matrix expansion by LM, with mesangial immune deposits. There may be a few isolated subepithelial or subendothelial deposits visible by IF or EM, but not by LM.
Class III	Focal LN* Active or inactive focal, segmental and/or global endo- and/or extracapillary GN involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations. III (A): Purely active lesions: focal proliferative LN III (A/C): Active and chronic lesions: focal proliferative and sclerosing LN III (C): Chronic inactive with glomerular scars: focal sclerosing LN
Class IV	Diffuse LN* Active or inactive diffuse, segmental and/or global endo- and/or extracapillary GN involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) when >50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) when >50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. IV-S (A) or IV-G (A): Purely active lesions: diffuse segmental or global proliferative LN IV-S (A/C) or IV-G (A/C): Active and chronic lesions: diffuse segmental or global proliferative and sclerosing LN IV-S (C) or IV-G (C): inactive with glomerular scars: diffuse segmental or global sclerosing LN
Class V	Membranous LN† Global or segmental subepithelial immune deposits or their morphologic sequelae by LM and by IF or EM, with or without mesangial alterations
Class VI	Advanced sclerosing LN ≥90% of glomeruli globally sclerosed without residual activity

Definitions of Pathologic Terms

Diffuse: a lesion involving most (≥50%) glomeruli.

Focal: a lesion involving <50% of glomeruli.

Global: a lesion involving more than half of the glomerular tuft.

Segmental: a lesion involving less than half of the glomerular tuft.

Mesangial hypercellularity: ≥3 mesangial cells per mesangial region in a 3 μ-thick section.

Endocapillary proliferation: endocapillary hypercellularity due to increased number of mesangial cells, endothelial cells and infiltrating monocytes, and causing narrowing of the glomerular capillary lumina.

Extracapillary proliferation or cellular crescent: extracapillary cell proliferation of more than two cell layers occupying one fourth or more of the glomerular capsular circumference.

Karyorrhexis: presence of apoptotic, pyknotic and fragmented nuclei.

Necrosis: a lesion characterized by fragmentation of nuclei or disruption of the basement membrane, often associated with the presence of fibrin-rich material.

Hyaline thrombi: intracapillary eosinophilic material of a homogeneous consistency which by immunofluorescence has been shown to consist of immune deposits.

Proportion of involved glomeruli indicates the percentage of total glomeruli affected by lupus nephritis, but excluding ischemic glomeruli with inadequate perfusion due to vascular pathology separate from LGN.

Combination of class III and class V requires membranous involvement of at least 50% of the glomerular capillary surface area of at least 50% of glomeruli by LM or IF.

Combination of class IV and class V requires membranous involvement of at least 50% of the glomerular capillary surface area of at least 50% of glomeruli by LM or IF.

In the report, active lesions have to be specified; the percentage of glomeruli with capillary wall disruption (necrosis) and crescents should be included in the diagnostic line.

*Indicate the proportion of glomeruli with active and with sclerotic lesions

Indicate the proportion of glomeruli with fibrinoid necrosis and with cellular crescents

Indicate and grade (mild, moderate, severe) tubular atrophy, interstitial inflammation and fibrosis, severity of arteriosclerosis or other vascular lesions.

†May occur in combination with III or IV in which case both will be diagnosed; may show advanced sclerosis

Table 55-4: Integration of LM, IF, and EM Findings by WHO Class

	Light Microscopy		Immunofluorescence		Electron Microscopy		
CLASS	MES	PCW	MES	PCW	MES	SENDO	SEPI
I	0	0	+	0	+	0	0
II	+	0	+	0	+	0	0
III	+	+	++	+	++	+	+/-
IV	++	++	++	++	++	++	+/-
V	+	++	+	++	+	+/-	++

EM, electron microscopic location of deposits; IF, immunofluorescence positivity; LM, light microscopic abnormalities; MES, mesangial; PCW, peripheral capillary wall; SENDO, subendothelial; SEP, subepithelial.

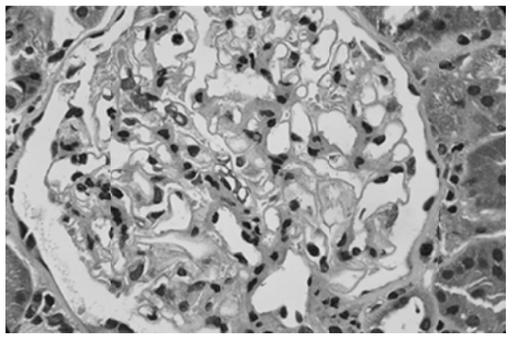

Figure 55-1. (See color plate.) Lupus Nephritis Class I. The glomerular tuft is normocellular with patent capillaries and glomerular basement membranes of normal thickness (Hematoxylin and eosin, × 400).

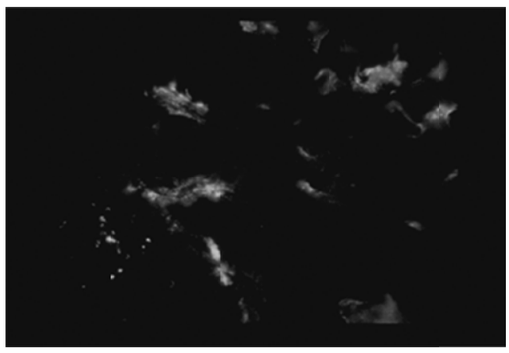

Figure 55-2. (See color plate.) Lupus Nephritis Class I. Immunofluorescence reveals delicate mesangial deposits of IgG. No deposits are identified involving the peripheral capillary walls. × 500).

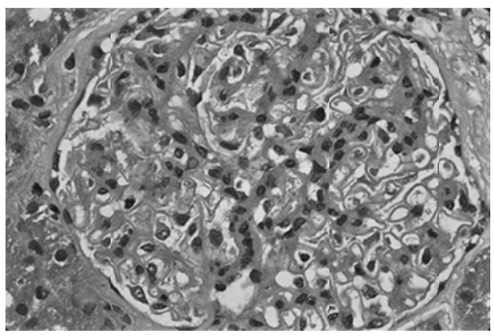

Figure 55-3. (See color plate.) Lupus Nephritis Class II. There is mild global mesangial hypercellularity. (H&E, × 400).

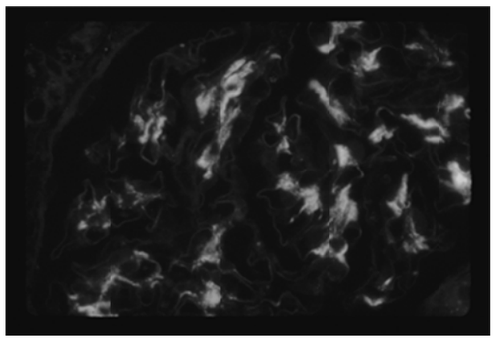

Figure 55-4. (See color plate.) Lupus Nephritis Class II. Immunofluorescence reveals global deposits of IgG outlining the mesangial stalk, with sparing of the peripheral capillary loops. (× 400).

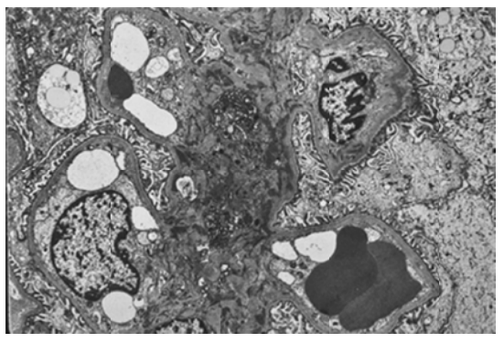

Figure 55-5. (See color plate.) Lupus Nephritis Class II. Electron microscopy shows electron dense deposits within the mesangial matrix, between adjacent capillaries. No deposits are detected involving the peripheral capillary walls (× 2,000).

Class III (Focal Lupus Nephritis) and Class IV (Diffuse Lupus Nephritis)

Most investigators consider class III and class IV lupus nephritis to be qualitatively similar glomerular lesions that differ only in severity and distribution. Therefore, these two related classes will be described together. Class III lupus nephritis is defined as focal segmental and/or global endocapillary and/or extracapillary glomerulonephritis affecting less than 50% of the total glomeruli sampled (Fig. 55-6). Class IV is defined as diffuse segmental and/or global endocapillary and/or extracapillary glomerulonephritis affecting more than or equal to 50% of glomeruli (Fig. 55-7). Both class III and class IV manifest subendothelial immune deposits (relatively focal in class III and diffuse in class IV), with or without mesangial alterations. The ISN/RPS Classification subdivides lupus nephritis class IV into those cases with diffuse segmental versus diffuse global proliferation (Table 55-3). The designation IV-S is used if more than 50% of affected glomeruli have segmental lesions (Fig. 55-8); the designation IV-G is used if more than 50% of affected glomeruli have global lesions. This subdivision was proposed to facilitate future studies addressing possible differences in outcome and pathogenesis between these subgroups.

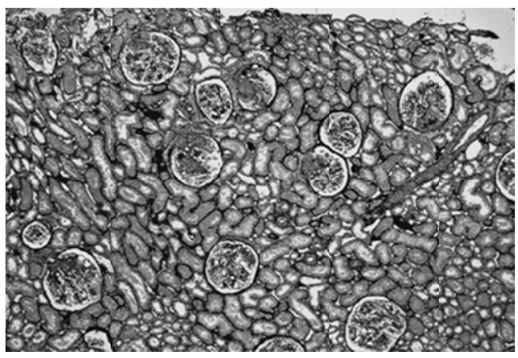

Figure 55-6. (See color plate.) Lupus Nephritis Class III. On low power examination, there is focal and segmental proliferation of the glomeruli. Overall, endocapillary or extracapillary proliferation affected <50% of the total glomeruli in this biopsy, qualifying as class III. (Jones methenamine silver, × 4).

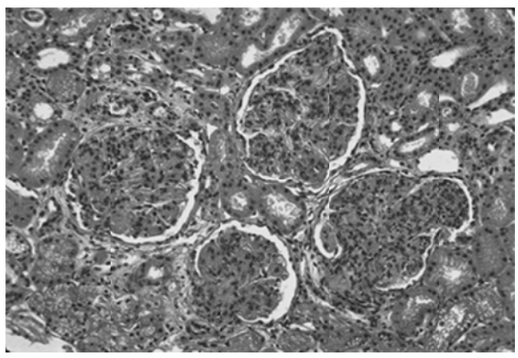

Figure 55-7. (See color plate.) Lupus Nephritis Class IV-G. A pattern of diffuse and global endocapillary proliferation is present. All four glomeruli illustrated show similar degree of glomerular involvement. (H&E, × 80).

Both class III and class IV may have active (proliferative) and/or inactive (sclerosing) lesions. In determining the percentage of total glomeruli affected by glomerulonephritis, both the proliferative and sclerosing lesions must be taken into account. Although most active glomerular lesions are endocapillary proliferative in nature,

both class III and class IV factor in glomerular lesions that are membranoproliferative, extracapillary proliferative, or consist of wire-loop deposits without associated proliferation. For these reasons, the ISN classification prefers the broader terms “focal lupus nephritis” and “diffuse lupus nephritis” over the more restrictive terms “focal proliferative lupus nephritis” and “diffuse proliferative lupus nephritis” used in the original WHO classification.

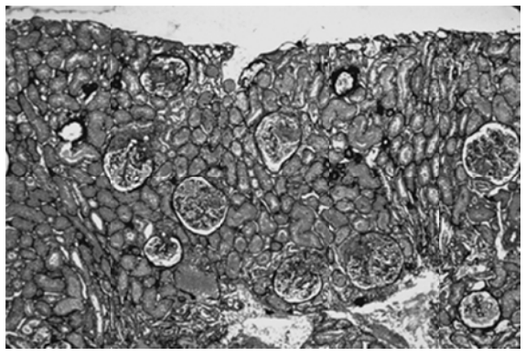

Figure 55-8. (See color plate.) Lupus Nephritis Class IV-S. Low power examination of the biopsy shows a pattern of diffuse glomerular proliferation involving >50% of glomeruli with a predominantly segmental distribution, involving a portion of each glomerular tuft (Jones methenamine silver, × 4).

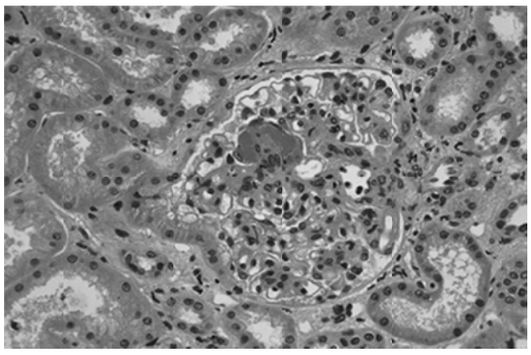

Figure 55-9. (See color plate.) Lupus Nephritis Class III. There is segmental glomerular necrosis with deposition of eosinophilic fibrinoid material, leukocyte infiltration and pyknosis (H&E, × 200).

The endocapillary proliferative lesions in class III tend to be relatively segmental (involving only a portion of the glomerular tuft), although some glomeruli may be affected globally (Fig. 55-9). In class IV, the endocapillary proliferation is typically more diffuse and global (Fig. 55-10). However, some examples of class IV have a diffuse and segmental distribution (designated IV-S in the ISN/RPS classification). The glomerular lesions in class III and IV are qualitatively similar. Common light microscopic features include wire-loop deposits, hyaline thrombi, leukocyte infiltration, necrosis, hematoxylin bodies, cellular crescents, and glomerular scarring, each of which is described below.

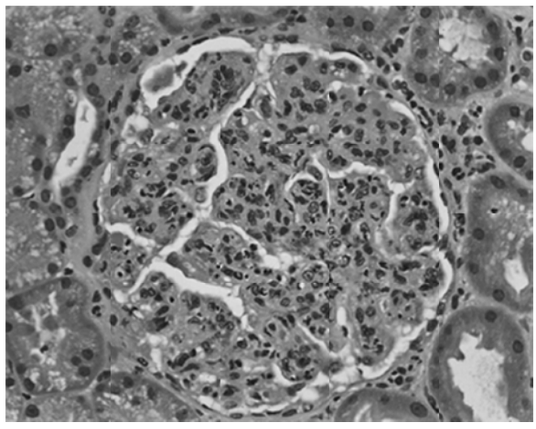

Figure 55-10. (See color plate.) Lupus Nephritis Class IV. A representative glomerulus displays global endocapillary proliferation including many infiltrating neutrophils, causing occlusion of the capillary lumina. (H&E, × 320)

In class III and class IV lupus nephritis, subendothelial immune deposits may be large enough to detect by light microscopy, forming “wire-loop” thickenings of the glomerular capillary walls (Fig. 55-11). Special stains reveal the deposits to be entirely or largely subendothelial, with preservation of an outer peripheral layer of glomerular basement membrane. In some cases, the subendothelial deposits are incorporated into the glomerular capillary wall by a subendothelial layer of neomembrane, producing a double contour. This may be accompanied by mesangial interposition giving a membranoproliferative appearance. Some cases of class III or class IV manifest large intracapillary deposits forming “hyaline thrombi” (Fig. 55-11). This term is actually a misnomer because these do not represent true fibrin thrombi but massive intracapillary immune deposits with the same composition by immunofluorescence as the neighboring subendothelial immune deposits.

In most cases of class III and class IV lupus nephritis, the endocapillary hypercellularity results from proliferation of glomerular endothelial and mesangial cells, as well as by leukocyte infiltration, including neutrophils, monocytes, and lymphocytes. However, several morphologic variants of class IV lack the typical picture of florid endocapillary proliferation with leukocyte infiltration. The first is the membranoproliferative variant. In this form, the endocapillary proliferation has a distinctly membranoproliferative aspect, with extensive mesangial interposition and duplication of glomerular basement membranes resembling membranoproliferative glomerulonephritis type 1. Other histologic variations including diffuse wire-loop deposits without glomerular hypercellularity or diffuse wire-loop deposits accompanied by mesangial proliferation. In each of these histologic variants, the sine qua non of active class IV is the presence of diffuse

subendothelial deposits, albeit with variable patterns of glomerular proliferation.

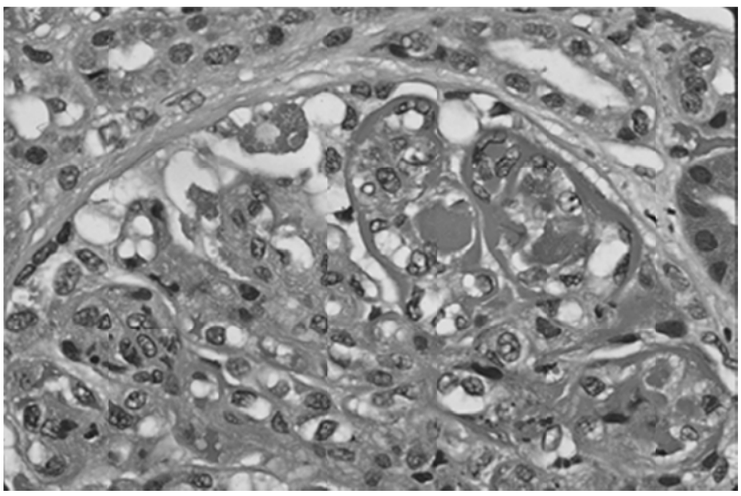

Figure 55-11. (See color plate.) Lupus Nephritis Class IV. A wire-loop thickening of the glomerular capillary wall is caused by a large subendothelial deposit. An adjacent glomerular capillary is occluded by an intraluminal immune deposit of similar composition, forming a "hyaline thrombus." (H&E, × 600).

Glomerular necrosis is a feature of active class III and class IV lupus nephritis and consists of foci of smudgy fibrinoid degeneration of the glomerular tuft. Necrosis may be accompanied by deposition of intracapillary fibrin, glomerular basement membrane rupture, and apoptosis of infiltrating neutrophils producing pyknotic or karyorrhectic nuclear debris ("nuclear dust"). Necrotizing lesions are typically segmental in distribution, but more than one glomerular lobule may be affected, particularly in diffuse proliferative lupus nephritis.

Hematoxylin bodies are the only truly pathognomonic lesion of lupus nephritis. However, they are extremely uncommon, affecting less than 2% of biopsy specimens of lupus nephritis (16). They consist of smudgy lilac-staining structures that may be smaller or larger than normal nuclei (17) (Fig. 55-12). They may be isolated or clustered and usually occur in glomeruli with very active proliferative and necrotizing lesions. Hematoxylin bodies are the tissue equivalent of the LE body and consist of naked nuclei whose chromatin has been altered following cell death with extrusion of the nucleus and binding to ambient circulating ANA.

Cellular crescents are a feature of active lupus nephritis that may be encountered frequently in both class III and class IV lupus nephritis (Fig. 55-13). They are common overlying necrotizing lesions. Glomerular scarring is a feature of chronic glomerular injury in class III and class IV lupus nephritis. In class III, the glomerular scarring is often initially focal and segmental. Associated fibrous crescents may form synechiae to the sclerotic segments. In chronic class IV lupus nephritis, the glomerular scarring is typically more global and diffuse.

By immunofluorescence in class III and IV lupus nephritis, there are subendothelial immune deposits that generally follow the distribution of the endocapillary proliferation. Thus subendothelial deposits tend to be relatively focal and segmental in class III (Fig. 55-14) and more diffuse and global in class IV lupus nephritis (Fig. 55-15). These subendothelial deposits are typically superimposed on generalized mesangial immune deposits. Hyaline thrombi form occlusive intracapillary globular deposits. Scattered subepithelial deposits are not uncommon in class III or IV and usually have a more finely granular quality. However, according to the ISN/RPS classification, the presence of regular subepithelial deposits involving over 50% of the glomerular capillary surface area of at least 50% of glomeruli exceeds what is acceptable in class III or IV alone and would warrant an additional diagnosis of membranous lupus nephritis class V. By electron microscopy, class III and IV lupus nephritis typically display subendothelial electron dense deposits that tend to be focal and segmental in class III and more diffuse and global in class IV, superimposed on a substratum of mesangial deposits (Fig. 55-16). The extent and distribution of deposits seen by electron microscopy

usually parallels that seen by immunofluorescence. Rare cases of class III of IV lupus nephritis have relatively sparse subendothelial deposits relative to the extent and severity of the active necrotizing lesions. Such cases resemble examples of “pauciimmune” focal segmental necrotizing glomerulonephritis (18), and some may be associated with antineutrophil cytoplasmic antibodies (ANCA) (19).

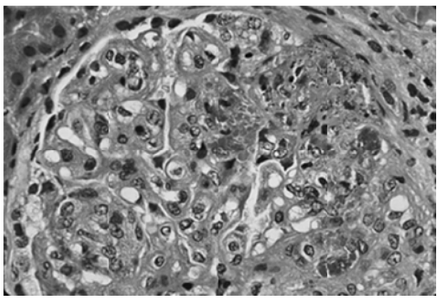

Figure 55-12. (See color plate.) Lupus Nephritis Class IV. Hematoxylin bodies appear as lilac-colored rounded bodies within a glomerulus with active proliferation. These structures consist of nuclei that have been extruded from damaged cells and have undergone clumping of their chromatin following interaction with ANA. (H&E, × 600).

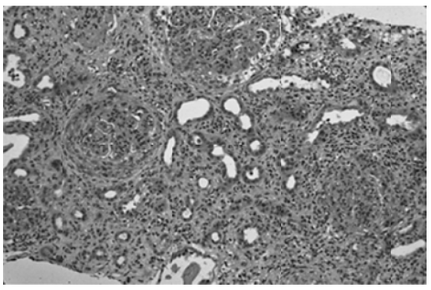

Figure 55-13. (See color plate.) Lupus Nephritis Class IV. A severe example shows glomerular crescents (extracapillary proliferation), as well as endocapillary proliferation. Severe interstitial inflammation and edema accompany the glomerular disease. (H&E, × 80).

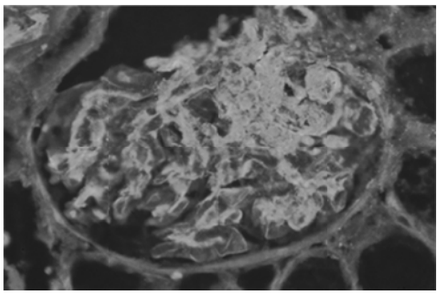

Figure 55-14. (See color plate.) Lupus Nephritis Class III. By immunofluorescence, there are segmental subendothelial deposits involving one segment of the glomerulus. Smaller mesangial deposits are noted in the adjacent segments (IgG, × 400).

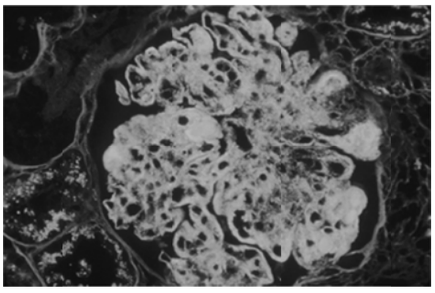

Figure 55-15. (See color plate.) Lupus Nephritis Class IV. By immunofluorescence, there are globally distributed subendothelial and mesangial immune deposits of IgG. Some glomerular capillaries are actually occluded by immune deposits, corresponding to “hyaline thrombi” (× 400)

Class V (Membranous Lupus Nephritis)

Class V designates membranous lupus nephritis, as defined by subepithelial immune deposits or their morphologic sequelae. The membranous alterations may be present alone or on a background of mesangial hypercellularity and mesangial immune deposits. There may be few small subendothelial immune deposits identified by immunofluorescence and/or electron microscopy, but not by light microscopy.

In the modified WHO classification, membranous lupus nephritis was subdivided into four subclasses, designated Va through Vd. It is important to be familiar with these categories because older outcome studies frequently employed these designations (20). Class Va denotes pure membranous lupus nephritis without associated mesangial deposits or mesangial proliferation. Class Vb included the typical peripheral capillary wall features of membranous glomerulopathy together with mesangial alterations, either mesangial deposits alone or with mesangial hypercellularity. The modified WHO classification also recognized class Vc (combined classes Va and III) in which there are typical features of focal and segmental endocapillary proliferative glomerulonephritis superimposed on the membranous pattern, and class Vd (combined classes Va and IV), in which there is superimposed diffuse endocapillary proliferative and membranous lupus nephritis. A major disadvantage of this system was to place undue emphasis on the membranous component rather than on the more serious proliferative component. According to the ISN classification, the designation mixed class III and class V replaces the Vc lesion, and the designation of mixed class IV and class V replaces the Vd lesion. In this schema, the additional designation of class V in the setting of class III or IV requires membranous involvement of at least 50% of glomerular capillary surface area of at least 50% of glomeruli by LM and/or IF. This approach is amply supported by clinical-pathologic studies demonstrating that class Vd has an extremely poor prognosis, even worse than pure diffuse proliferative class IV (21).

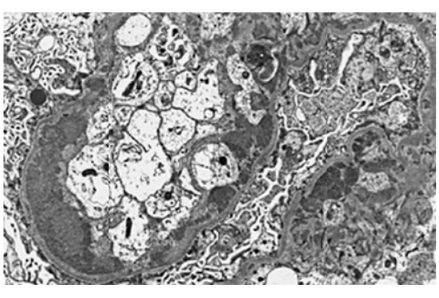

Figure 55-16. Lupus Nephritis Class IV. Electron microscopy shows a representative glomerular capillary with a large subendothelial electron dense deposit located between the endothelium and the overlying glomerular basement membrane. Smaller electron dense deposits are present in the adjacent mesangium at bottom (× 3,000).

By light microscopy, the peripheral glomerular capillary wall alterations display a spectrum and evolution similar to those of idiopathic membranous glomerulopathy. In early stages, the glomerular capillary walls may appear normal in thickness and texture by light microscopy, but subepithelial deposits are detected by immunofluorescence and electron microscopy. At this stage, the glomerular capillaries often have a rigid, ectatic appearance with visceral epithelial cell swelling. Well-established membranous lesions are typically characterized by uniform and diffuse thickening of the glomerular capillary walls (Fig. 55-17) with well-developed spikes of the GBM that are best demonstrated with

the silver stain (Fig. 55-18). As the lesions evolve, the deposits may become largely resorbed and overlaid by neomembrane formation producing a vacuolated glomerular basement membrane profile.

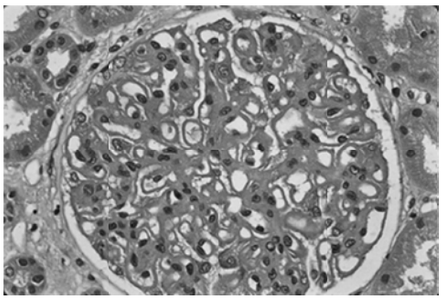

Figure 55-17. (See color plate.) Lupus Nephritis Class V. Membranous lupus nephritis displays global thickening of the glomerular capillary walls, which display a rigid aspect. Several mesangial areas also appear mildly hypercellular. (H&E, × 500).

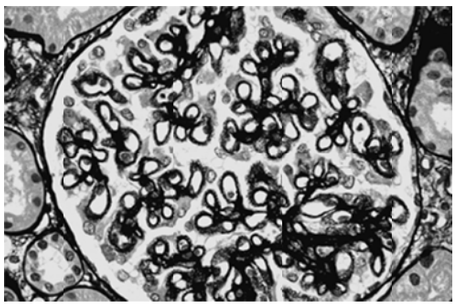

Figure 55-18. (See color plate.) Lupus Nephritis Class V. The Jones methenamine silver stain demonstrates that the thickening of glomerular capillary walls is due to basement membrane spikes. Spikes project at right angles from the glomerular basement membrane, like the bristles on a comb (× 500).

Patients with lupus nephritis class V are at risk for the development of renal vein thrombosis. Examination of the renal biopsy may provide clues to the occurrence of superimposed renal vein thrombosis. Suspicious findings include erythrocyte congestion and focal fibrin thrombosis of the glomerular capillaries as well as diffuse interstitial edema. In chronic renal vein thrombosis, there may be diffuse tubular atrophy and interstitial fibrosis out of proportion to the degree of glomerular sclerosis.

By immunofluorescence a diagnosis of class V is based on the presence of global or segmental continuous granular subepithelial immune deposits (Fig. 55-19). A background of mesangial immune deposits is commonly observed. By electron microscopy electron dense subepithelial deposits range from small to large, but involve the majority of capillaries. As the disease progresses, the same ultrastructural stages seen in idiopathic membranous glomerulopathy may evolve. Glomerular basement membrane spikes often separate the subepithelial deposits (Fig. 55-20). In more chronic cases, the deposits become overlaid by neomembrane and later become resorbed and relatively electron lucent. There is extensive foot process effacement in the distribution of the subepithelial deposits. Mesangial electron dense deposits are commonly observed. Sparse small subendothelial electron dense deposits also may be found, but are not accompanied by endocapillary proliferation.

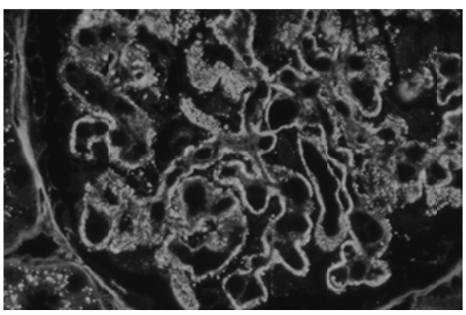

Figure 55-19. (See color plate.) Lupus Nephritis Class V. By immunofluorescence, there are finely granular deposits of IgG outlining the glomerular capillary walls in a subepithelial distribution (× 600).

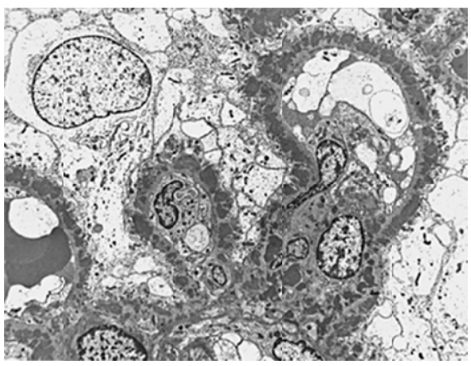

Figure 55-20. Lupus Nephritis Class V. Electron microscopy shows several glomerular capillaries with thickening of their walls owing to abundant subepithelial electron dense deposits. The deposits are located between the glomerular basement membrane and the visceral epithelial cells. Glomerular basement membrane spikes separate the deposits. Several electron dense deposits are also identified in the adjacent mesangial area (× 2,000).

Class VI (Advanced Sclerosing Lupus Nephritis)

Class VI is defined by global glomerular sclerosis affecting more than 90% of glomeruli without residual activity. Most such cases likely represent advanced class IV disease. However, patients with class V or repeated flares of class III also may progress to end-stage and manifest this pattern late in their course. By light microscopy there is extensive global glomerular sclerosis involving over 90% of glomeruli, without significant ongoing activity. Some glomeruli may be segmentally sclerotic. Glomeruli with less advanced sclerosis may display residual hypercellularity or thickenings of the glomerular basement membranes. Vestiges of old crescents may be discernible with the PAS stain as subcapsular fibrous proliferations with disruptions of Bowman's capsule. Severe tubular atrophy, interstitial fibrosis, inflammation, and arteriosclerosis usually accompany the glomerular sclerosis. In some cases, the process is so end-stage that a diagnosis of chronic lupus nephritis is difficult on morphologic grounds. By immunofluorescence there are usually some residual immune deposits in the few nonsclerotic glomeruli, as well as in the obsolescent glomeruli. Granular deposits may also be detected in the tubulointerstitial compartment or vessel walls. Despite the advanced

glomerular scarring, small electron dense granular deposits may still be detectable in the sclerosing tuft, as well as in the tubulointerstitial and vascular compartments.

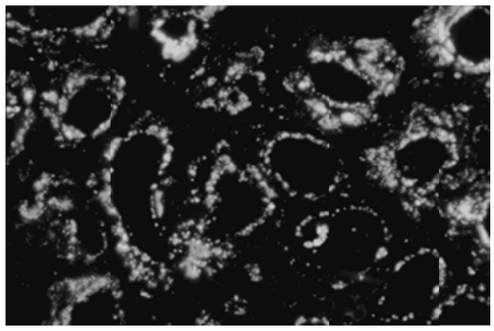

Figure 55-21. (See color plate.) Lupus Nephritis Class IV. Immunofluorescence reveals numerous granular deposits of C1q within the tubular basement membranes (× 100).

Immunofluorescence (General Features)

LN is one of the few renal diseases in which immune deposits can be found in all renal compartments, the glomeruli, tubules, interstitium, and blood vessels (Figs. 55-21 and 55-22) (8 ,22 ,23 ,24). More than one class of immunoglobulin is usually found. IgG is almost universally present, with codeposits of IgM and IgA in most specimens. IgG is usually dominant in intensity. Both C3 and C1q are commonly identified, and staining for C1q may be particularly intense (25). When all three immunoglobulin classes and both complement components are found, the designation “full house” staining is often used. Staining for fibrin-fibrinogen is common in the distribution of crescents and segmental necrotizing lesions. A frequently observed phenomenon in renal biopsies of lupus patients is the “tissue ANA” (26). This refers to nuclear staining of renal parenchymal cells in frozen sections stained with fluoresceinated antisera to human IgG. It results from the binding of patient's own ANA to nuclei that have been exposed in the course of cryostat sectioning. Tissue ANA may be found in all classes of LN and does not correlate with the activity of the LN.

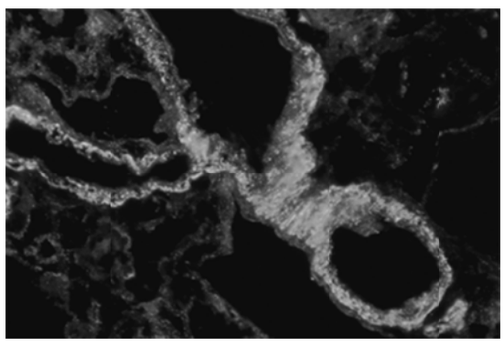

Figure 55-22. (See color plate.) Lupus Nephritis Class IV. A medium-sized artery contains finely granular deposits of IgG outlining its media (× 100).

Electron Microscopy (General Features)

The distribution of immune deposits seen by immunofluorescence corresponds to that observed by electron microscopy (8 ,22 ,23 ,24 ,27 ,28). Mesangial electron dense deposits are typically observed in all classes of lupus nephritis. Thus they may be considered the common substratum upon which the higher classes are built. Class III and class IV lupus nephritis display subendothelial as well as mesangial deposits. The distribution of the subendothelial deposits is more focal and segmental in class III and more diffuse and global in class IV, corresponding to the general distribution of the endocapillary proliferative lesions. An exception is the occasional case of class III or IV, in which there is a paucity of peripheral capillary wall deposits despite active necrotizing lesions, resembling the pattern in “pauci-immune” focal crescentic glomerulonephritis (18). Although scattered subepithelial deposits may also be detected in class III and class IV, regular subepithelial deposits are a distinguishing feature of class V.

In most cases, the texture of the glomerular electron dense deposits is granular. However, in a small percentage of cases, the deposits may exhibit an organized substructure known as “fingerprinting”(29). This corresponds to the presence of curvilinear microtubular or fibrillar structures composed of bands ranging from 10 to 15 nm in diameter. Fingerprint substructure may be more common in lupus patients with circulating cryoglobulins (30).

A common ultrastructural finding in lupus nephritis is “tubuloreticular inclusions” (TRI), 24-nm interanastamosing tubular structures located in the dilated cisternae of endoplasmic reticulum of renal endothelial cells (Fig. 55-23) (31 ,32 ,33 ,34).

These “interferon footprints” are readily identified in all classes of lupus nephritis, irrespective of disease activity.

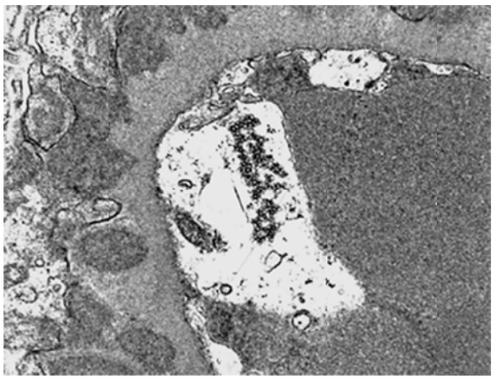

Figure 55-23. Lupus Nephritis Class V. A tubuloreticular inclusion (“interferon footprint”) is seen within the cytoplasm of a glomerular endothelial cell. It consists of an interanastamosing tubular structure located within cisternae of endoplasmic reticulum. Subepithelial electron dense deposits thicken the adjacent glomerular capillary wall, consistent with membranous features (× 15,000).

Pathogenesis of Lupus Nephritis

Although numerous immunologic abnormalities occur in SLE, it is unclear which factors relate directly to the pathogenesis of LN. SLE is a disease in which immune dysregulation leads to loss of self-tolerance and autoimmune responses. SLE has been associated with a decreased number of cytotoxic and suppressor T cells, increased helper ($CD4^+$) T cells, dysfunctional T-cell signaling, abnormal Th1 and Th2 cytokine production, polyclonal activation of B cells and defective B-cell tolerance (35 ,36 ,37 ,38). Activation and clonal expansion of $CD4^+$ T cells promote the activation of autoreactive B cells, leading to their proliferation and differentiation into cells that produce an excess of antibodies against a host of nuclear antigens, including DNA, Sm, RNA, Ro, and La (39). Immune complexes form, not only in kidney, but also at the dermal-epidermal junction, in the choroid plexus, pericardium, lung, and pleura.

Glomerular involvement in SLE has often been considered a human prototype of classic chronic immune complex induced glomerulonephritis as defined in experimental models. Three major mechanisms of immune deposition in the kidney have been identified: (1) binding of autoantibodies to nonglomerular autoantigens that have been planted in the glomerulus; (2) binding of autoantibodies to intrinsic glomerular antigens; (3) deposition of preformed circulating immune complexes. These mechanisms are not mutually exclusive and each may contribute in varying degrees to the pathogenesis of LN in a particular individual.

The size, charge, and avidity of the immune complexes, autoantibody specificity and cross-reactivity with glomerular constituents, and clearance of immune deposits through FcR interactions all influence localization within the glomerulus. Anti-dsDNA antibodies predominate in kidney eluates from patients with LN (40 ,41 ,42). Antibodies with specificity for nucleosomes, Sm, RNP, histone, SSA, SSB, and C1q have also been eluted from the kidney (40 ,41 ,42). Nucleosomes consisting of DNA bound to histone have affinity for anionic components of the glomerular basement membrane such as heparan sulfate (43 ,44). Nucleosomes liberated from apoptotic cells may bind to negatively charged cell surfaces or matrix components of the glomerulus in the course of filtration. Once planted in the glomerular filter through charge interactions, nucleosomal antigen may interact with circulating autoantibody, leading to the formation of ICs in situ (45).

There is also evidence that anti-DNA antibodies exhibit a broad range of cross-reactivities to normal glomerular constituents such as surface antigens on endothelial or mesangial cells (45 ,46 ,47), heparan sulfate proteoglycan (48), phospholipids (48 ,49 ,50), laminin (42 ,52 ,53), type IV collagen (52 ,54), podocyte antigens (52 ,54), and cytoskeletal proteins such as vimentin and α-actinin-4 (55 ,56 ,57). Such autoantibody cross-reactivities could promote in situ immune complex formation to glomerular structural proteins.

Passive deposition of preformed circulating immune complexes represents another possible mechanism of immune injury in LN (58). Drawing from models of chronic serum sickness, mesangial deposition is favored by relatively small amounts of intermediate-sized, high avidity complexes (59). When present in larger quantities, these may spill out into the subendothelial areas. Subepithelial deposits may be favored by smaller, low-avidity ICs formed in relative antigen excess (60). Such deposits may dissociate and reform in situ, allowing electrostatic interactions with the glomerular capillary wall's polyanionic constituents. The clearing ability of the mesangium and local hemodynamic factors also may play a role (61 ,62). In all these models, glomerular immune deposits may be amplified in situ by the binding of anti-C1q antibodies (63 ,64).

Once immune complexes are deposited, the complement cascade is activated leading to complement mediated damage, activation of procoagulant factors, monocyte and neutrophil infiltration, release of proteolytic enzymes, and elaboration of various cytokines regulating glomerular cellular proliferation and matrix synthesis (65). Renal influx of FcR-bearing cells as effector cells in lupus nephritis is critically important to the initiation of nephritis (66). Important chemoattractants implicated in murine or human LN include colony-stimulating factor, VCAM-1, ICAM-1, MCP-1, RANTES, and osteopontin (67 ,68 ,69 ,70 ,71 ,72). A number of inflammatory and fibrogenic cytokines are upregulated in active nephritis, including IL-1, IL-2, IL-6, TNF-α, IFN-γ, endothelin-1 and TGF-β (73 ,74 ,75 ,76 ,77 ,78 ,79). The dysregulated cytokine milieu promotes mesangial proliferation, crescent formation and progressive glomerulosclerosis. Glomerular and vascular damage may be potentiated by hypertension and coagulation abnormalities. The presence of antiphospholipid antibodies directed against a phospholipid-β_2-glycoprotein complex may promote endothelial and platelet dysfunction. These include procoagulant and antifibrinolytic effects through reduced production of prostacyclin, reduced prothrombinase activity, inhibition of protein C and S, and enhanced platelet aggregation (80 ,81).

Activity and Chronicity Indices

Most investigators have found it useful to supplement the WHO classification of LN with a semiquantitative grading of features of activity (potentially reversible lesions) and chronicity (irreversible lesions) (82 ,83). The NIH system of activity and chronicity indices is widely used. (Table 55-5). The activity index is calculated form the renal biopsy by grading each of six histologic features (including endocapillary proliferation, glomerular leukocyte infiltration, wire loop deposits, fibrinoid necrosis and karyorrhexis, cellular crescents and interstitial inflammation) on a scale of 0 to 3+.

Crescents and fibrinoid necrosis, the most severe lesions, are assigned double weight. The sum of the individual components yields a total histologic activity index score of from 0 to 24. Likewise, a chronicity index of 0 to 12 is derived from the sum of four features, each graded on a scale of 0 to 3+, including glomerulosclerosis, fibrous crescents, tubular atrophy and interstitial fibrosis. Early investigations found that either a high activity index (>12) or an elevated chronicity index (>4) predicted a reduced renal survival (82). However, subsequent studies not restricted to class IV disease but including all WHO classes failed to find a correlation between either the activity or chronicity index and long-term prognosis (84 ,85). More recent NIH studies on Class IV diffuse proliferative lupus nephritis patients have shown that the combination of an elevated activity index (>7) and chronicity index (>3) added prognostic information about long-term outcome (86). One clear benefit of these indices is to monitor changes in activity and chronicity over time in sequential biopsies from individual patients. This provides useful information about the efficacy of therapy and the relative degree of progressive histologic damage (87).

Table 55-5: Activity and Chronicity Indices

Index of Activity (0–24)	
Endocapillary hypercellularity	(0–3+)
Leukocyte infiltration	(0–3+)
Subendothelial hyaline deposits	(0–3+)
Fibrinoid necrosis/karyorrhexis	(0–3+) × 2
Cellular crescents	(0–3+) × 2
Interstitial inflammation	(0–3+)
Index of Chronicity (0–12)	
Glomerular sclerosis	(0–3+)
Fibrous crescents	(0–3+)
Tubular atrophy	(0–3+)
Interstitial fibrosis	(0–3+)

Tubulointerstitial Lesions

Tubulointerstitial disease commonly accompanies the glomerular lesions of LN (88 ,89 ,90). Whereas tubulointerstitial involvement may occur rarely as an isolated histologic finding in lupus biopsies, it is far more common for severe acute tubulointerstitial disease to accompany active proliferative lupus glomerulonephritis. Active lesions typically consist of interstitial inflammatory infiltrates including T lymphocytes (both CD4 and CD8 positive cells), monocytes, and plasma cells accompanied by interstitial edema (91 ,92). Immune deposits of immunoglobulins and/or complement components may be present in the tubular basement membranes, interstitial capillary walls or interstitial collagen (Fig. 55-21). Some studies have correlated the quantity of tubulointerstitial immune deposits with serologic activity (89 ,90). The degree of interstitial inflammation has also been correlated with a reduction in glomerular filtration rate and an elevated serum creatinine (90). In the more chronic stages of LN, interstitial fibrosis and/or tubular atrophy develop. Recently quantitative morphometry has been applied to the biopsies of patients with lupus nephritis (93). Using special stain picro-Sirius red and digitized light microscopic images, the cortex of renal biopsies from 48 patients with lupus nephritis was evaluated for the area occupied by nuclei, intratubular space, fibrillary collagen, and collagen matrix. Higher nuclear index correlated with parameters of clinical disease activity; higher collagen matrix index predicted relapse and progression to end stage renal disease; higher fibrillary collagen index and increased intratubular space correlated with an elevated serum creatinine (93).

Vascular Lesions

Vascular disease is common in lupus nephritis and may assume several morphologically distinct forms (94 ,95 ,96). Although vascular lesions contribute to disease severity and may influence prognosis, they are not factored into the WHO classification or the activity and chronicity indices.

Uncomplicated vascular immune deposits are a frequent and highly specific feature of lupus nephritis. They are most common in class III and IV lupus nephritis, but may be found in class II and V as well. They affect predominantly small arteries and arterioles, and to a lesser extent veins. By immunofluorescence and electron microscopy, granular immune deposits are detectable in the extracellular matrix of the media or the intimal basement membrane (Fig. 55-22). Usually these vascular deposits produce no obvious light microscopic changes. Rarely, thickening of the vascular basement membranes may be identified, but without significant compromise of the lumen. These lesions do not influence clinical course or prognosis.

Lupus vasculopathy is a term that refers to a noninflammatory necrotizing vascular lesion that primarily affects arterioles, most frequently in severe class IV lupus nephritis. The vascular wall is obscured by smudgy eosinophilic fibrinoid material that typically expands the intima and may occlude the lumen (97). There is frequent necrosis of medial myocytes and endothelial cells, but without inflammation of the vessel wall (Fig. 55-24). Thus, this lesion represents a vasculopathy rather than a true inflammatory vasculitis. By immunofluorescence, both immunoglobulins and fibrin-related antigens are detectable in the intima and media, indicating injury from combined immune deposition and intravascular coagulation. This lesion carries a poor prognosis with frequent associated hypertension and a rapid course to renal failure (95).

Thrombotic microangiopathy may affect small arteries, arterioles, and glomerular capillaries. It occurs in several distinct clinical settings including lupus anticoagulant syndrome, hemolytic uremic syndrome, thrombotic

thrombocytopenic purpura, and overlap with systemic sclerosis in some patients with mixed connective tissue disease (95 ,98 ,99 ,100 ,101 ,102). The renal thrombotic lesions may be limited to the kidney or may occur as part of a systemic thrombotic microangiopathy. Some patients with these lesions have documented anticardiolipin/antiphospholipid antibodies or manifest HUS-TTP like syndrome because of autoantibody to the Von willebrand factor cleaving protease (103). Thrombotic microangiopathy may supervene on any class of lupus nephritis. It should be suspected whenever there is intravascular coagulation that cannot be explained by the activity of the glomerular disease. Light microscopic features include fibrin thrombosis of glomerular capillaries and vessels, mesangiolysis, and arterial mucoid intimal edema with entrapment of fragmented erythrocytes (Fig. 55-25). Unlike lupus vasculopathy, these lesions contain predominantly fibrin-related antigens by immunofluorescence, without associated immune deposits.

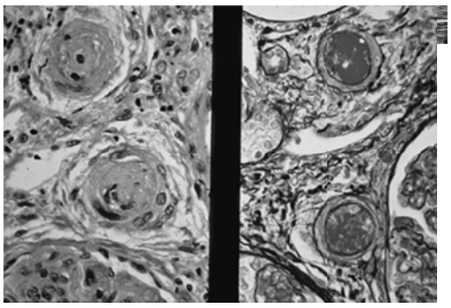

Figure 55-24. (See color plate.) Lupus vasculopathy. The left panel (H&E) shows luminal occlusion by fibrinoid eosinophilic material with smudgy necrosis of the arteriolar wall. The right panel (Lendrum stain for fibrin) shows that the intravascular eosinophilic material consists in part of fibrin (× 500).

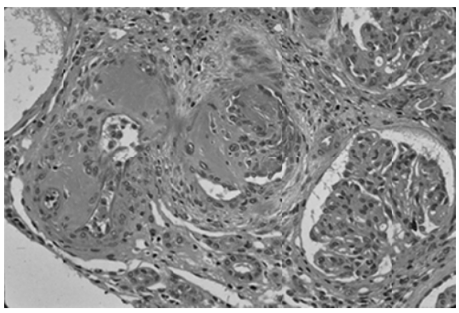

Figure 55-25. (See color plate.) Lupus anticoagulant syndrome with thrombotic microangiopathy. Several small arteries are severely narrowed by organizing thrombi. Fresh fibrin is deposited on a more chronic recanalized lesion, indicating acute and chronic thrombotic microangiopathy. The adjacent glomerulus displays ischemic retraction of the tuft and there is surrounding interstitial fibrosis. (H&E, × 80).

True necrotizing vasculitis is rarely identified in lupus nephritis (94 ,95). It may be renal-limited or associated with systemic vasculitis. It resembles microscopic polyangiitis with fibrinoid necrosis and inflammatory infiltration of the vessel wall. In most cases, no vascular immune deposits are detectable by immunofluorescence or electron microscopy. This lesion may occur in any class of lupus nephritis, regardless of the activity of the glomerular disease.

Silent Lupus Nephritis

“Silent lupus nephritis” defined as histologic renal involvement without clinically evident renal disease has been reported in a number of series of lupus patients (104 ,105 ,106 ,107). Some investigators require normal serology, inactive urinary sediment, absence of proteinuria, and a normal creatinine concentration to qualify as true “silent” disease, whereas others only require normal renal parameters. Although well described, both forms of “silent” LN appear to be rare (8 ,108). The majority of such patients will eventually manifest clinical renal findings at some time during the course of their nephritis.

Clinicopathologic Correlations and Outcomes According to Class

Patients with ISN/RPS class I, minimal mesangial lupus, have no evidence of clinical renal disease. Likewise, patients with class II, mesangial proliferative lupus nephritis, usually have no, or at most mild evidence of clinical renal disease (2 ,3 ,8 ,22 ,84 ,109). Although these patients may have an elevated anti-DNA antibody titer or low serum complement, urinary sediment is inactive, hypertension is infrequent, and the serum creatinine and GFR are usually normal. Proteinuria is rarely above a gram daily in patients with mesangial lesions. Class I and class II patients generally have an excellent prognosis unless they transform to another pattern.

An exception to this presentation is the concurrence of SLE and minimal change disease, known as lupus “podocytopathy” (110 ,111 ,112). These SLE patients present with sudden onset of the nephrotic syndrome and have renal biopsy findings of LN class I or II with extensive foot process effacement, correlating with the heavy albuminuria. The severe foot process effacement cannot be explained by the low immune complex load, which is limited to the mesangium, thereby supporting the presence of a primary podocyte injury. In individual patients, it is uncertain whether such cases represent a podocytopathy secondary to the altered cytokine milieu of SLE or a chance superimposition of two unrelated diseases. The nephrotic syndrome responds rapidly to steroid therapy akin to minimal change nephrotic syndrome.

ISN/RPS class III is often associated with markers of active serologic disease. However, the degree of serologic

activity does not necessarily correlate with the severity or extent of the histologic damage (109 ,113 ,114 ,115). Patients commonly have hypertension, proteinuria, and an active urinary sediment containing dysmorphic erythrocytes and erythrocyte casts. From one fourth to one third of patients present with the nephrotic syndrome, and as many as one fourth have an elevated serum creatinine at the time of renal biopsy. Some patients with class III disease have less extensive glomerular involvement and are more likely to be normotensive and have preserved renal function. Others may have more chronic scarred lesions with associated hypertension and reduced renal function, but without active urinary sediment. The course of patients with class III is extremely varied. Some with mild proliferation involving a small percentage of the glomeruli will respond well to therapy, with fewer than 5% progressing to renal failure over 5 years of follow-up (84 ,115 ,116 ,117 ,118). Others with more extensive glomerular involvement or with necrotizing features and crescent formation have a prognosis similar to class IV(A), active diffuse lupus nephritis.

Patients with class IV LN typically have the most active and severe clinical features. For this reason, most treatment studies of LN have included predominantly class IV patients. These patients have active serologic markers with have high anti-DNA antibody titers and low serum complement levels. Their urinary sediment is very active, containing erythrocytes and multiple urinary casts, hypertension is common, and proteinuria is universal with up to one half presenting with nephrotic range proteinuria at the time of renal biopsy (8 ,22 ,84 ,119 ,120). Although the serum creatinine may appear to be within the “normal” range, when measured, the glomerular filtration rate is usually reduced. Although the prognosis for patients with class IV diffuse proliferative disease has markedly improved in recent years, in most studies this group still has the worst renal survival. Survival is influenced greatly by such prognostic features as race, socioeconomic status, and renal features at presentation. A number of studies have confirmed a worse prognosis for patients with class IV compared to other classes.

A new and controversial feature of the ISN/RPS classification is the division of LN class IV into subcategories with diffuse segmental (IV-S) and diffuse global (IV-G) involvement. One study of 85 LN patients actually found a worse renal prognosis for “severe” focal proliferative class III patients (ISN/RPS class IV-S) than for patients with diffuse proliferative class IV lesions (ISN/RPS class IV-G) (121). This study emphasizes the different usages of the designation focal proliferative lupus nephritis among investigators using the older WHO classification and stresses the bad outcome for patients with segmental necrotizing lesions. A Japanese study of 60 lupus nephritis patients found that those patients with LN class IV-S had worse renal survival than those with IV-G (95-month survival vs. 214 months), although this did not reach statistical significance (12). By contrast, two studies from Boston and Paris have failed to find outcome differences between these subgroups (14 ,15). Further studies are needed to address the usefulness of this distinction.

ISN/RPS class V membranous LN differs importantly from the 1982 modified WHO class V. The older designation included patients with combined membranous and proliferative lesions under the rubric of class V. Hence a patient with focal proliferation and membranous features formerly was classified as WHO class Vc and one with diffuse proliferation and membranous features as WHO class Vd. These patients would now be designated ISN/RPS class V + III and ISN class V + IV, respectively. Patients with mixed membranous and proliferative patterns on biopsy have clinical features that reflect both components. Only those patients with pure membranous lupus nephritis or associated mild mesangial lesions are now included in ISN/RPS class V. Such patients typically present with proteinuria, and features of the nephrotic syndrome (20 ,84 ,109 ,122 ,123 ,124). However, up to 40% will have subnephrotic proteinuria, and up to 20% will have less than 1 gram of proteinuria daily at the time of renal biopsy. Patients with ISN/RPS class V typically have less serologic activity with normal serum complement levels and low anti-DNA antibody titers (84). Although some patients have active urinary sediment, hypertension, and renal dysfunction, these are far less common than in patients with proliferative lesions. Some ISN/RPS class V patients develop heavy proteinuria or what appears to be idiopathic nephrotic syndrome before the appearance of other clinical and laboratory manifestations of SLE (84). Patients with lupus membranous nephropathy are predisposed to thrombotic complications such as renal vein thrombosis and pulmonary emboli akin to patients with idiopathic membranous glomerulopathy (125).

Renal survival rates in class V patients depend upon whether patients have pure membranous lesions or superimposed (class III or IV) proliferative lesions (84 ,123 ,126). One U.S. study found the ten year survival rate was 72% for patients with pure membranous lesions but only 20% to 48% for those with superimposed proliferative lesions (126). In an analysis of 60 pure membranous lesions, we found a 75% 10-year renal survival with risk factors for renal progression by univariate analysis including Black race, elevated serum creatinine, higher degrees of proteinuria, hypertension, and transformation to another WHO pattern (unpublished observations). By multivariate analysis, only race (Black) was a significant predictor of progressive renal failure. Other U.S. studies in membranous SLE have had 10-year renal survival rates as high as 85% (117 ,124). In retrospective Italian studies largely composed of Caucasians, 10-year renal survival for class V was 93% (123). Outcomes were worse in those with superimposed proliferative lesions (WHO classes V + III or V + IV). Thus, the variability of prognosis in older studies of membranous LN can be explained in part by differences in racial composition of the study group, in biopsy findings and in therapy.

Advanced sclerosing lupus nephritis, ISN/RPS class VI, usually represents “burnt out” proliferative class III or IV

lupus nephritis. It may result from a single severe episode of resistant or overwhelming active disease, but more commonly is the result of years of lupus flares alternating with periods of inactivity. Nonimmunologic progression of renal disease with hyperfiltration of remaining glomeruli clearly contributes to this form of LN. Despite the lack of active or proliferative lesions on biopsy, and the lack of serologic activity, many class VI patients will have persistent microhematuria and some proteinuria. Hypertension and decreased glomerular filtration rate are common.

Other Histologic Prognostic Factors

Aside from histologic class, several other histologic parameters have been found to have prognostic value in patients with LN. These include: the degree of activity and chronicity on renal biopsy, the severity of tubulointerstitial involvement, the presence of crescents, and/or the presence of severe interstitial fibrosis. Additionally, particular histologic features on initial biopsy and their persistence on repeat renal biopsy have been shown to have prognostic value.

Utilizing biopsy features of reversible (active) or irreversible (chronic) damage, trials at the NIH documented that in patients with severe proliferative LN class IV, those with a higher activity index or chronicity index were more likely to progress to renal failure (82 ,83 ,86 ,116 ,127 ,128 ,129). In different patient populations, however, neither the reproducibility of these indices nor their prognostic value could be confirmed (84 ,85 ,130). Despite disagreement concerning the prognostic import of individual components of histologic damage, most studies agree that extensive glomerulosclerosis and interstitial fibrosis confer a worse long-term prognosis (131 ,132 ,133). In a large NIH study, patients with a combination of high activity (activity index >7) and high chronicity on biopsy (chronicity index >3) had worse outcomes (86). Similarly, those with the combination of cellular crescents and interstitial fibrosis on biopsy fared worse (86). In an independent study of 89 class IV patients, although no individual histologic variable predicted outcome, combined activity and chronicity on the biopsy did predict a poor outcome (134). In many studies, “flares” of renal disease have predicted a poor renal outcome (133 ,135). An Italian study of 91 patients with diffuse proliferative lupus nephritis found over 50% of patients to experience a renal flare over time, which correlated with higher activity index on biopsy (135).

Detailed histologic and clinicopathologic studies by a group of investigators assigned an important prognostic role to repeat renal biopsies performed 6 months after initiation of maximal therapy for LN (88 ,89 ,131 ,136). Certain histologic features found on repeat biopsy predicted 5-year progression to renal failure, including ongoing inflammation with cellular crescents, macrophages in the tubular lumens, and persistent subendothelial and mesangial deposits. The findings of both crescents and interstitial fibrosis on the repeat biopsy negatively impacted prognosis. By contrast, reversal of interstitial fibrosis and the presence of glomerular segmental scarring together with reduction of interstitial inflammation and immune deposition were favorable prognostic findings (136). Thus, not all chronic histologic changes are necessarily cumulative or immutable, and their stabilization or reversal despite repeated flares of disease activity may be critical to prevent ESRD.

Conclusions

The prognostic significance of the different patterns of renal involvement in lupus nephritis has been recognized since the seminal observations of Pollak and Pirani (7). The 2004 ISN/RPS classification was designed to standardize pathologic terminology, better define the threshold for diagnosis of each class and improve reproducibility between centers. Further validation of this classification in the coming years should confirm its benefits and facilitate multicenter studies exploring differences in optimal treatment and pathogenesis.

Chapter 56
Clinical and Laboratory Features of Lupus Nephritis

Mary Anne Dooley

Introduction

Renal involvement in systemic lupus erythematosus (SLE) remains the strongest predictor of overall patient morbidity and mortality. Although survival in lupus has improved with more than 90% 10-year survival in many cohorts, the survival in patients with nephritis lags behind at 83% over 10 years (1). The proportion of patients receiving dialysis in the United States as a result of lupus nephritis is rising (2). Renal involvement remains more frequent and severe among children, ethnic groups such as African Americans, and male patients (3). Although mortality rates from SLE have been relatively stable among Caucasians since the 1970s, they have increased among African-American patients, particularly ages 45 to 64, during this time span (1).

Chronic glomerulonephritis was first described in SLE in 1922 (4). Baehr et al. (5) observed wire-loop lesions at autopsy in 13 of 23 patients with lupus in 1935. In the late 1950s, Dixon, Holman, Mellors, Kunkel, Muller-Eberhard, among others (6 ,7 ,8), noted that positive LE-cell preps often were found in patients who had immune deposits in renal tissue. Introduction of the LE-cell prep in 1948 (9) allowed investigators to evaluate the prevalence of SLE in patients with idiopathic nephritis (10 ,11). Prior to the development of corticosteroid therapy and nitrogen mustard in the late 1940s and hemodialysis in the 1960s, onset of lupus nephritis was associated with a significant risk of death within 2 years.

This chapter discusses the epidemiology, incidence, clinical features, and natural course, and it reviews the general management concepts of renal lupus. Chapter 50 covers the immunopathogenesis, pathology, and clinicopathologic correlates of lupus nephritis. Detailed discussions of specific treatment modalities for renal disease are covered separately. The reader is referred to Chapter 56 , Systemic Corticosteroid Therapy in Systemic Lupus Erythematosus (corticosteroids and pulse steroids); Chapter 57 , Immunosuppressive Drug Therapy (cyclophosphamide, nitrogen mustard, azathioprine, chlorambucil, mycophenolate mofetil, cyclosporin and methotrexate); Chapter 58 , Nonpharmacologic Therapeutic Methods (apheresis, total lymphoid irradiation, hemodialysis, and transplantation); and Chapter 59 , Occasional, Innovative, and Experimental Therapies (γ globulin, 2-CDA).

Definition, Epidemiology, and Prevalence

Active lupus nephritis can be defined clinically and histopathologically. Clinical evaluation for lupus nephritis includes dipstick and microscopic urinalysis, urinary protein and creatinine excretion, serum creatinine determinations, and serologic studies (anti-dsDNA antibody titers and serum complement components C3 and C4). Additionally, serum albumin and cholesterol can be used to define the renal disease as nephrotic.

The urinary sediment is useful to characterize disease activity as the presence of glomerular hematuria, leukocyturia, or casts are typical only during periods of disease activity. Interestingly, in one large series of 520 cases of SLE, red cell casts were only present in 39 cases or 7.5% (12). In descending order, the most common abnormal sediment findings are leukocyturia, hematuria, and granular casts. As mentioned, a rising anti-DNA titer and hypocomplementemia, especially with low C3, is a strong indicator or predictor of active lupus renal disease. Hypoalbuminemia and hypercholesterolemia accompanied by significant proteinuria are components of the nephrotic syndrome, which may accompany active lupus renal disease. Although much diagnostic import is placed on glomerular findings, there is increasing recognition of tubulointerstitial injury in lupus nephritis. Urowitz's group have described proliferative lupus nephritis presenting with sterile pyuria alone (13). Typically, the severity of interstitial inflammation parallels the degree of renal impairment. Tubular damage, fibrosis, and atrophy are linearly associated with long-term renal function and can be associated with hyperuricemia and renal tubular acidosis.

Lupus renal disease is also defined immunohistopathologically. Tissue obtained by renal biopsy should be evaluated by light microscopy, immunofluorescence, and electron microscopy. There is a correlation between the pathologic class of lupus nephritis and clinical features (14 ,15 ,16). Despite this association, there are patients with so-called silent lupus nephritis who have normal urinalyses, absence of proteinuria, and normal serum creatinine, but who, on renal biopsy, have anywhere from mesangial to proliferative nephritis (17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26). Fortunately, progressive loss of renal

function typically does not occur without changes in urinary sediment and protein excretion. Lupus glomerulonephritis is now defined by the ISN classification developed by nephropathologists in conjunction with rheumatologists and nephrologists (27). This classification, discussed in Chapter 50 , must be compared with the pre-existing WHO classification system and the NIH-developed activity and chronicity indices as prognosis and therapeutic guidelines have been based on the prior system. Few studies have validated the relationship of the ISN scoring system with clinical outcomes to date (28).

The prevalence of renal disease in eight large cohort studies consisting of 2,649 SLE patients varied from 31% to 65% (12 ,29 ,30 ,31 ,32 ,33 ,34 ,35). A recent study reported a 10% annual incidence of nephritis in 384 lupus patients followed at the Johns Hopkins Medical Center between 1992 and 1994 (36). Most patients with SLE diagnosed prior to the 1982 revised American College of Rheumatology (ACR) criteria for SLE were found to have histologic evidence of lupus nephritis on renal biopsy, even in the absence of urine sediment abnormalities, elevated protein measurements, abnormal serum creatinine, and depressed C3 complement levels, and anti–double-stranded DNA (anti-dsDNA) determinations (17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26). This has been termed silent lupus nephropathy and is typically nonprogressive. Although these instances generally represent minimal disease histologically, diffuse, proliferative lesions occasionally have been found.

In a series of patients from the Wallace/Dubois practice studied from 1950 to 1991, the following criteria for lupus nephritis were found to have a greater than 95% sensitivity (12 ,37 ,38). One of the following must be present: (1) a renal biopsy showing WHO class IIb mesangial, focal proliferative, diffuse proliferative, or membranous glomerulonephritis; (2) a 30% decrease in creatinine clearance over a 1-year period in a patient with active lupus; and (3) urine protein greater than 1 g in 24 hours. Alternatively, at least three of the following in a 12-month period allow us to make a diagnosis of nephritis in an SLE patient: (1) a serum albumin level greater than 3 g/dL; (2) sustained 2 to 4+ proteinuria; (3) oval fat bodies or granular, hyaline, or red cell casts in the urine; and (4) persistent hematuria of greater than five red cell casts per high-power field in the urine. For each of these criteria, an alternative cause must be excluded. These criteria differ from the less extensive criteria of the ACR (Chapter 2 , Definition, Classification, Activity, and Damage Indices). In the 1987 ACR criteria, renal disorders of SLE are defined as persistent proteinuria (>0.5 g/day or >-3+), or cellular casts of any kind. With these or similar criteria, the prevalence of renal involvement varied from 29% to 65% among the eight series described in Table 56-1 . Tertiary referral centers tended to have higher percentages of patients with renal disease, as did studies that were published before 1965 (when antinuclear antibodies [ANA] became widely available and identified more mild cases of SLE). The true prevalence probably is approximately 40% (39). Nephritis is present in most children (see Chapter 43 , Systemic Lupus Erythematosus in Childhood and Adolescence). Although once thought rare in the elderly (40 ,41), subsequent studies have shown that race confounded the relationship with age (42). When race is controlled, older-onset lupus patients do not have “milder” features and the outcome of lupus may be worse a result of the increased prevalence of comorbidities (43 ,44).

Table 56-1: Findings in Patients with Systemic Lupus Erythematosus and Nephritis (*n* = 128) Compared with Those without Nephritis (*n* = 336)[a]

More Frequent	Less Frequent
Family history of SLE	Other CNS sx
Anemia	Seizures
High sedimentation rate	Thrombocytopenia
High serum cholesterol	Fibromyalgia
High serum triglycerides	
Positive ANA	
High anti-dsDNA	
Low C3 complement	
Low C4 complement	

[a] $P < .01$.
ANA, antinuclear antibody; dsDNA, double-stranded DNA; SLE, systemic lupus erythematosus

Several serologic and genetic risk factors are also associated with an increased risk of developing SLE nephritis. Patients with nephritis are more likely to have a family history of SLE, anemia, high anti-dsDNA antibody titers, and hypocomplementemia (37). The presence of anti-Sm autoantibodies is associated with more severe expressions of SLE, including lupus nephritis, and some studies suggest that anti-dsDNA and antihistone autoantibodies are associated with an increased risk of proliferative lupus nephritis (45).

The incidence and prevalence of SLE nephritis differs among patients of different racial/ethnic backgrounds. Despite much investigative attention, racial differences in lupus expression remain poorly understood. African Americans have a threefold increased incidence of SLE, develop the disorder at younger ages, and more frequently express anti-Sm and RNP autoantibodies (46 ,47 ,48 ,49 ,50 ,51). These patients develop nephritis more frequently than Caucasians and have onset of nephritis earlier in the course of their SLE. In an inception cohort of lupus patients in the southeastern United States, 31% of African-American patients versus 13% of Caucasian patients met ACR renal criteria within 18 months of diagnosis (52). Hispanic and Asian patients also have greater frequency and severity of nephritis compared with Caucasians. Once they have nephritis, African Americans and Hispanics are more likely to progress to end-stage renal disease (ESRD) than Caucasians (53 ,54 ,55 ,56 ,57 ,58 ,59 ,60). These findings have also been reported in studies based outside the United States (61 ,62). Despite the greater frequency of nephritis in Asians, generally good outcomes of cytotoxic therapy have been observed (63 ,64 ,65 ,66 ,67).

Important comorbidities such as diabetes, hypertension, patient compliance with medical regimens, socioeconomic, and psychosocial variables may also influence renal outcomes. In several studies, however, the worse outcome for African-American patients with lupus nephritis was independent of health care access, compliance with medications, and socioeconomic status (60 ,68). Others have shown a strong impact of poverty on renal outcomes (69 ,70). In some series, these patients may have more frequent or uncontrolled hypertension, hypocomplementemia, higher chronicity indices including interstitial fibrosis, and poorer compliance with therapy (56 ,57 ,58 ,59). However, other series have shown poorer response to cyclophosphamide despite similar presence and control of hypertension and activity or chronicity indices or a combination of these measures on biopsy (60 ,71). Lupus nephritis is only one of many kidney diseases in which African-American patients suffer more frequent adverse consequences. Ethnicity may also be associated with a nonlupus-related predisposition toward kidney failure following renal injury. African-American patients with hypertension, diabetes mellitus, HIV nephropathy, or focal segmental sclerosis develop renal failure significantly more often than Caucasian patients

The mean age at disease onset in patients with nephritis is younger than in those with SLE without nephritis (12 ,71 ,72). Most patients develop nephritis early in their disease (68 ,52 ,72); although, as some investigators have noted, the onset of renal disease can occur at any point in the patients disease course (36). The oldest patient with SLE and new-onset nephritis was 80 (B Hahn, pers. comm.). Smaller-scale surveys and the population-based Carolina Lupus study suggest that males have a relatively increased incidence or activity of renal disease (52 ,73 ,74).

Inheritance of the DR2 and B8 gene is associated with an increased risk of developing nephritis in some populations, and this risk is amplified if certain DQ beta genes also are present (see Chapter 6 , The Genetics of Human Lupus). Inheritance of the DR4 gene reduces the risk for lupus nephritis (75). Several studies have shown that allelic variants of the IgG Fcγ receptor RIIA and RIIIA, associated with poor binding and phagocytosis of IgG1 and IgG2 increase risk for lupus nephritis in several different ethnic populations (76). Such individuals may clear immune complexes less efficiently than persons who inherit other alleles for these receptors. However, the association has not been found in all populations, and a recent meta-analyses including data on over 3,000 patients with lupus, noted the population-attributable fractions of SLE cases because of the FcγRIIa-R131 allele were 13%, 40%, and 24% in subjects of European, African, and Asian descent, but was not a risk for lupus nephritis. Other researchers have noted familial antinuclear factors not associated with disease (77) and polymorphisms other pathways, such as the angiotensin-converting enzyme gene that may be associated with lupus (78). More recently, an interferon signature has been reported in patients with SLE, though not yet prospectively associated with disease activity or manifestations (79 ,80).

Clinical and Laboratory Presentation

Wallace et al. noted lupus patients with nephritis also expressed increased frequency of other severe lupus manifestations (12). Table 56-1 summarizes these findings. Piette's French group reported 180 of 436 patients with SLE nephritis. Renal patients had more malar rashes, psychosis, myocarditis, pericarditis, lymphadenopathy, hypertension, anti-DNA, and low C3 (81). Some investigators have proposed that rheumatoid-like arthritis is associated with a lower incidence of renal disease, especially if rheumatoid factor is present and the HLA-DR4 haplotype is present (82 ,83), although not all (12). Walker et al. (84) noted that arthritis and arthralgia were the most common symptoms in a group of 45 patients with lupus nephritis who were followed in New Zealand. Usually, elevated Westergren sedimentation rates, low C3 complement, elevated anti-dsDNA levels, and low serum albumin levels are associated with more active nephritis. Gallium scans demonstrate increased renal uptake with active disease (85 ,86) and roughly correlate with a biopsy activity index). Doppler ultrasounds are of value to exclude thrombosis, and elevated resistive indices, thinner cortex, and increased echogenicity correlate with greater chronicity index on biopsy (87 ,88).

Klippel (89) described five clinical types of lupus nephritis: occult, chronic active nephritis, rapidly progressive nephritis, nephrotic syndrome, and progressive renal insufficiency in patients with repeatedly normal urinalyses. Glomerulosclerosis, hypertension, diabetes, and occasionally, drugs (especially nonsteroidal anti-inflammatory drugs) probably cause renal insufficiency in most of the latter group. Patients in this group, along with those with occult disease and chronic active nephritis, often are asymptomatic. These clinical subtypes reflect the extraordinary clinical diversity of expression of nephritis in lupus. Mesangial lupus nephritis is often accompanied by normal diagnostic findings or a mild degree of proteinuria, but typically the absence of hypertension or abnormal urinary sediment. Focal and diffuse proliferative lupus glomerulonephritis are often associated with the worst prognosis for renal survival and can be accompanied by nephrotic syndrome, significant hypertension, and abnormal urine sediment. Membranous lupus nephritis often presents with moderate- to high-grade proteinuria, without hematuria or casts and often the absence of hypertension. The majority of patients have a good prognosis and relative preservation of renal function. However, in up to one third of patients, often those with persistent nephrotic range proteinuria, membranous lupus nephropathy can lead to decreased renal function and end stage renal disease (ESRD) (90).

Presentation with acute deterioration in renal function was observed in 36 (18.4%) of 196 SLE hospital admissions in the group followed by Yeung et al. (91 ,92). Infection and active central nervous system disease were frequent precipitating events, and recovery of renal function with aggressive management was reported in 76%. Others have confirmed these findings, even in patients requiring dialysis at presentation (49).

Nephrotic syndrome (defined as a serum albumin <2.8 g/dL with >3.5 g of urine protein per 24 hours) was observed in 13% to 26% of all patients with SLE in the eight well-detailed series shown in Table 56-1 . In contrast to mildly nephrotic subjects who may only have ankle edema on examination, frankly nephrotic states are associated with ascites, presacral edema, as well as pleural and pericardial effusions. Serositis as a result of lupus may be distinguished from uremia, because inflammatory effusions will have exudative rather than transudative features. Physical examinations often are deceptively normal except for hypertension in patients with isolated lupus nephritis. Indeed, as these patients are often young, blood pressure measurements may well be under 140/90 mm Hg, although hypertensive for the age of the patient. Patients with SLE have an increased incidence of renal tubular dysfunction, which is clinically characterized by a proximal or distal renal tubular acidosis (93). This is particularly evident in patients with Sjögren syndrome. (See Chapters 39 and 50 for a discussion of renal physiology abnormalities in SLE.).

Serologic features

Antinuclear Antibodies (ANA)

ANA are a sensitive screening test as more than 95% of lupus patients will be positive when the test is performed using a substrate containing human nuclei, such as HEP-2 cells. In 3% to 6% of cases, however, renal disease manifestations constitute the initial presentation of SLE (94 ,95 ,96 ,97). Cairns et al. (96) reported 11 ANA-negative patients whose onset of SLE began with clinical glomerulonephritis as the initial manifestation. All became ANA positive over a 6-year period. A similar group of 17 patients was described by Adu et al. (97), and three children by Gianuti et al. (98). ACR criteria may not be fulfilled at first even if the ANA is positive (95).

Complement

Complement is a protein whose levels are reduced with inflammation. Various tests of complement are available in the clinical laboratory that are relevant to lupus nephritis: C3, C4, total hemolytic complement, antibodies to C1q and C3d:C4d ratios. (Chapters 13 , Complement and Systemic Lupus Erythematosus, and 48 , Clinical Application of Serologic Abnormalities in Systemic Lupus Erythematosus, review the biology and clinical importance of complement). Low complement levels are associated with greater renal-disease activity (99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115). Falls in complement often predict disease exacerbation (100 ,101 ,102 ,103 ,104 ,107 ,108 ,109). The studies cited here suggest that the most specific test is C3, followed by total hemolytic complement and then C4. C3 correlates with activity indices on biopsy (112), and long-term normalization of complement is associated with a better prognosis (113). Conversely, low complement levels also may denote congenital or acquired deficiencies of various components, and a few patients have persistently low complement levels with no clinical evidence of disease activity. Gladman et al. (116) found 14 such patients in a group of 180 with SLE. Followed for a mean of 4.25 years, they had no symptoms and were on no medications, and none developed any evidence of lupus activity.

Anti-DSDNA

Anti-dsDNA is elevated in most patients with active nephritis, although its precipitous decline can presage a flare (100 ,102 ,103 ,104 ,107 ,113 ,117 ,118 ,119 ,120 ,121 ,122 ,123). Test methods include the enzyme immunoassays or the Farr assay to quantitate its presence. The *Crithidia luciliae* test also is available. Anti-DNA is found in 50% to 75% of patients with active nephritis; its levels often are normal in patients with pure membranous disease. Chapter 21 , Antibodies to DNA, and Chapter 48 , Clinical Application of Serologic Abnormalities in Systemic Lupus Erythematosus, review the biology and clinical importance of anti-DNA, which is not as reliable as C3 complement in assessing renal disease activity (101 ,124) and it may be elevated if extrarenal lupus activity is evident.

Other clinical correlates that might be useful in following renal disease activity have been sought. These include cryoglobulins (125 ,126), autoantibodies to poly(ADP)ribose (127), circulating immune complexes (103 ,128 ,129 ,130), IL-2-receptor levels (131), ANA patterns (132), antiendothelial-cell antibody levels (133), plasma thrombomodulin (134), antiheparin sulphate reactivity (135), decreased interleukin-1 receptor antagonist (136), antiribosomal P (137), and measurement of the activation and degradation components of complement (see Chapter 13 , Complement and Systemic Lupus Erythematosus). No one test (except for a dramatic change in serum creatinine or perhaps C3 complement) prompts the practitioner to action unless it is consistently abnormal, supported by other confirmatory laboratory tests and the clinical picture.

Measurements of Renal Function

The principal tests to evaluate renal function are blood urea nitrogen (BUN), serum creatinine, and creatinine clearance. The utility of the BUN is limited by its alteration with hydration status, bleeding, hepatic and dietary conditions. In clinical practice, the most convenient serial measurement of renal function is the serum creatinine. Serum creatinine level can vary with body weight, muscle mass, and state of hydration, and it tends to overestimate renal function by as much as 20% as it does not account for proximal tubular creatinine secretion (138 ,139). Creatinine is hypersecreted by injured tubules in patients with glomerulopathy. One study suggests that giving cimetidine (400 mg) tablets four times a day for 2 days blocks tubular secretion of creatinine and provides a more reliable measure of GFR (140). Because creatinine is calculated on a logarithmic scale, a rise from 1 to 2 mg/dL represents a 50% change, whereas a rise from 6 to 7 mg/dL reflects only a 3% change. Because determining a true, reliable renal function is vital in SLE clinical research, GFR measurements have

become the gold standard. Calculated by the standard formula (U cr V)/P, GFRs that are derived by inulin clearance, iothalamate clearance, and Tc99-DTPA clearance have proven to be reliable, but expensive and inconvenient (140 ,141). Hughes' group recently suggested that chromium-51 labeled EDTA-GFR may be a better predictor of nephritis than GFR indices alone (142). Reductions of GFR out of proportion to renal plasma flow indicate a low filtration fraction and greater disease severity (143).

Twenty-Four-Hour Urine Proteins

Twenty-four-hour urine proteins are valuable to follow only if they are elevated (100 ,137 ,143). Levels below 200 mg per 24 hours are normal; values of up to 1,000 mg can be seen in healthy subjects after vigorous exercise. When more than 3,500 mg per 24 hours are recorded, the patient usually has nephrotic syndrome, and ankle edema is present. Anasarca can be observed in patients who have more than 7,000 mg per 24 hours. In general, 24-hour urine proteins do not correlate well with disease activity, although this is not always the case (100). Decreases in 24-hour urine protein values usually reflect clinical improvement unless because of declining glomerular filtration. In this circumstance, dropping levels are a sign of renal failure.

Urinary Proteins and Sediment

Ropes (144) was the first rheumatologist to attach importance to following urinary sediment and protein level. She noted that 15 of 68 patients (22%) who had proteinuria and were not given corticosteroids had spontaneous disappearance of the proteinuria up to 14 years later. Table 56-2 summarizes Dubois' findings in 520 patients who were seen between 1950 and 1963 and who had multiple urine evaluations (145). Hematuria probably results from the escape of red cells through a gap in the glomerular basement membrane (146). Other reports in patients with nephritis have found microscopic hematuria in 33% to 78% (12 ,30 ,99 ,100 ,147 ,148), fat bodies in 33% to 48% (30 ,37), cellular casts in 34% to 40% (100 ,149), and greater than 1 g of urinary protein per 24 hours in 26% to 87%. Given the difficulty for most patients and settings in acquiring a valid 24 hour urine collection, reports have suggested that a random spot urine collection protein-to-creatinine ratio (corrected for a BSA of 1.75 m^2 BSA) has an excellent correlation with and may be more reliable than a 24-hour urine collection (150). Although the urinalysis may be normal despite abnormal findings on a renal biopsy, nearly all patients with clinically important renal disease have microscopic urine findings. The appearance of five or more leukocytes or red cells in a clean midstream urine specimen without infection, renal stones or other causes, especially with at least a trace of albumin, suggests active nephritis (151 ,152 ,153). Many patients may erroneously be considered to have urinary tract infections, and frequently have been given multiple courses of antibiotics. Confusing the picture, lupus patients may commonly experience increased frequency of urinary symptoms, or hematuria with menses and these circumstances must be excluded before assuming nephritis. As lupus damage advances, increased proteinuria and hyaline and fine granular casts, followed by coarse granular casts, red-cell casts, and white-cell casts are found. If nephrotic syndrome is present, urinary protein may be as high as 30 g per 24 hours, with good renal function. With further progression of renal disease, the numbers of all types of casts increase, waxy casts, broad renal failure casts appear, and a telescoped sediment becomes evident. Herbert et al. (154) found that a relapse of lupus nephritis can be predicted best by cellular casts followed by hematuria and white cells in the urine; these were more reliable than a drop in C3 complement.

Table 56-2: Abnormal Urinary Findings in 520 Cases of SLE

	Cases (n)	%
Albuminuria	240	46.1
WBCs in urine (more than 6/HPF in clean specimen)	185	35.5
Hematuria	170	32.6
Granular casts	164	31.5
Hyaline casts	148	28.4
RBC casts	39	7.5
Fatty casts	32	6.1
Oval fat bodies	23	4.4
Double refractile bodies	10	1.9
Waxy casts	9	1.7
Mixed fatty casts	6	1.2

HPF, High-powered field; RBC, red blood cell; WBC, white blood cell.

Analysis of Urine Protein Components

Albumin

Urine protein can be separated into albumin and gamma globulin fractions. Measurements of urinary albumin excretion by radioimmunoassay can pick up larger amounts than normally would be detected. Though not generally clinically useful, diminution in albumin excretion correlates with clinical response to treatment (155 ,156 ,157). Microalbuminuria is associated with mesangial disease (157), does not predict the development of nephritis (158), whereas polymeric albumin is associated with more serious disease (159).

γ Globulins

Urinary protein electrophoresis demonstrates increased γ-globulin levels during active disease; levels decrease with therapeutic response (160 ,161). No specific patterns are observed in SLE. Quantitative urine-protein analysis with can detect glomerular versus nonglomerular proteinuria (162).

Several groups have shown associations between levels of free immunoglobulin light chains and lupus nephritis activity (163 ,164 ,165 ,166 ,167 ,168 ,169).

Other Urinary Findings

Dubois observed bacterial cystitis or pyelonephritis in 22.5% of his 520 patients (145). Fries and Holman (30) reported dysuria in 14 of their 193 patients. Ropes reported urinary tract infections in 47% of her 150 patients (144). Meryhew et al. (170) studied urinary ANAs. Positive tests were found using both mouse kidney cells and Hep-2 cell substrates. IgG ANA was most frequently seen; one half had more than one immunoglobulin class detected. Anti-Sm, antiribonucleoprotein (anti-RNP), anti-Ro/SSA, and anti-dsDNA also were detected. The presence of anti-dsDNA and ANA correlated with increased clinical severity. ANA might appear in the urine as a result of decreased tubular reabsorption, antigen deposition, or genitourinary tract inflammation, but it probably is representative of glomerular leakage.

Nephrotic syndrome is associated with false-positive urine pregnancy tests (171). Numerous reports note urinary substances are increased with active lupus nephritis and are good markers of clinical activity including ferritin (172), anti-RNA polymerase I antibodies (173), neopterin (174 ,175), acid mucopolysaccharides (176), histuria (177), fibrin degradation products (178 ,179), several gastrointestinal enzymes (180), IL-6 (181 ,182), anti-DNA (183), soluble interleukin-2 receptors (184 ,185), urinary C4 (186), monocyte chemotactic and activating factor (187), retinal-binding protein (188), tumor necrosis factor-α and adhesion molecules (189), and low molecular weight C3 fragments (190), MCP-1, and CR1 (191 ,192).

Chapter 55 , Lupus Nephritis: Pathology, Pathogenesis, Clinical Correlations, and Prognosis discuss urinary prostaglandins, renal-tubular acidosis, aldosterone, the syndrome of inappropriate antidiuretic hormone, and renin activity measurements.

Clinicopathologic Laboratory Correlates

The six major parameters that are used to follow lupus nephritis disease activity are: (1) serum creatinine, (2) assessment of 24-hour protein excretion, (3) creatinine clearance, (4) C3 complement, (5) urine sediment, and (6) anti-dsDNA. Each of these tests tells the clinician different things; therapeutic decisions are based on considering the results for all of these values. Clinical trials also use other outcome criteria that are less important in a community practice. These include rigorous definitions for remissions, flares, relapses, exacerbations, and lupus activity scores (reviewed in reference (193)). Serum creatinine is an insensitive measure of the level of renal function; as the proximal tubule actively reabsorbs creatinine until the mechanism is saturated, a patient may have lost 50% of creatinine clearance with an increase in serum creatinine that remains within the normal range. Normalization of the creatinine level is associated with a favorable prognosis (98 ,141). A creatinine clearance of less than 10 mL/hr, or a serum creatinine of over 7 mg/dL, with uremic symptoms usually is an indication for dialysis. As mentioned earlier, hydration status, obstruction, severe infection, acute tubular necrosis, contrast-induced nephropathy and certain medications (especially nonsteroidal anti-inflammatory agents) can temporarily raise serum creatinine levels. Petri's group associated elevated serum creatinine with ages younger than 20 or older than 40, disease duration, and proteinuria, but not socioeconomic status, race, autoantibodies, or complement levels (56).

Renal Vein Thrombosis

Thrombosis of the renal veins complicating lupus nephritis was first reported in 1968 (194) and has been described in numerous cases since. It should be strongly considered in patients with nephrotic syndrome and/or antiphospholipid antibodies who present with flank pain and fever, thrombophlebitis, or pulmonary emboli (195 ,196 ,197 ,198). Bradley et al. (199) found renal-vein thrombosis in 11 of 280 patients with membranous glomerulonephritis or lupus glomerulonephritis. All 11 (three of whom had SLE) also had nephrotic syndrome, and 10 had pulmonary emboli. Six of 625 Taiwanese SLE patients developed renal-vein thrombosis; all were nephrotic (200). Renal-vein thrombosis needs to be differentiated from renal arteriolar thrombi seen on biopsy not correlated with antiphospholipid antibodies, but with a thrombotic microangiopathic picture (200 ,201). The clinical scenarios of accelerated or malignant hypertension or superimposed thrombotic thrombocytopenic purpura may also produce these findings. Renal-vein thrombosis was found in 27% of 11 patients with nephrotic syndrome, 62% of 13 with a history of thrombophlebitis, and none of 20 controls with SLE. Mintz's group concluded that a hypercoagulable state is a greater risk factor than the presence of nephrotic syndrome for renal vein thrombosis (197). Although the antiphospholipid antibodies predispose one to renal-vein thrombosis, their presence is not mandatory (202 ,203). Renal-vein thrombosis also has been reported in patients with SLE who have received renal allografts (204). If reasonable clinical suspicions exist (e.g., flank pain, hematuria, oliguria, peripheral edema), a magnetic resonance angiogram or renal ultrasound with Doppler blood flow assessment should be performed. Renal-vein thrombosis must be treated promptly with anticoagulants. Renal failure and pulmonary emboli are its most serious complications. Purified Malayan pit-viper venom (ancrod) may be useful as a defibrinator (205), but it generally is not available. Thrombolytic therapies have been successfully used for renal vein thrombosis in patients without SLE (206 ,207 ,208 ,209 ,210).

Antiphospholipid Antibodies, Renal Thrombotic Microangiopathy, and Lupus Nephritis

See Chapter 55 , Lupus Nephritis: Pathology, Pathogenesis, Clinical Correlations, and Prognosis, and Chapter 65 ,

Clinical and Management Aspects of the Antiphospholipid Antibody Syndrome.

Management of Lupus Nephritis

Therapeutic decisions for individual patients with lupus nephritis should be based on consideration of their clinical presentation, laboratory features, and histologic findings on biopsy. The principal goals of therapy are, first, to improve or prevent progressive loss of renal function. Prevention of ESRD is important because of the morbidity and mortality associated with its treatment. Mortality rates among lupus patients on dialysis do not differ from the overall dialysis population (10% per year), but the lupus patients are significantly younger, more frequently female and have fewer comorbidities such as diabetes. Second, because ESRD may be managed by dialysis or transplantation, treatment must do the overall patients as little harm as possible. Table 56-3 lists the toxicities of various therapies.

The general concepts and specific therapies outlined here have evolved over a nearly 40-year period with increasing rapidity recently as new data become available. The outcome of lupus nephritis has improved in some populations to a 10-year survival rate of over 80% with the guidance of the NIH recommendations for intravenous cyclophosphamide. The guidelines are by no means absolute, however, and many highly qualified rheumatologists and nephrologists treat lupus nephritis differently.

Table 56-3: Toxicities of Aggressive Regimens Used to Treat Proliferative Nephritis that May Occur >5% of the Time

I.	Prolonged high-dose oral prednisone therapy (1 mg/kg/day equivalent >6 weeks)
	Accelerated development of cataracts, glaucoma, hypertension, osteoporosis
	Diabetes mellitus
	Avascular necrosis of bone
	Diffuse ecchymoses
	Weight gain and marked cushingoid appearance
	Diplopia
	Emotional lability, mood changes
	Dyspepsia, ulcer risk
	Increased infection risk
	Menstrual irregularities
II.	Cyclophosphamide (more common in oral doses)
	Alopecia
	Amenorrhea, infertility
	Hemorrhagic cystitis
	Risk of malignancy
	Severe nausea and vomiting
	Increased risk of infection
	Teratogenicity
	Anemia, leukopenia, thrombocytopenia
III.	Azathioprine
	Nausea and vomiting
	Abnormal liver function tests
	Increased risk of infection

Intravenous Cyclophosphamide

Intravenous cyclophosphamide is given once a month for 6 consecutive months, starting at a dose of 0.5 to 0.75 g/m^2 body surface area (BSA) and increasing by 0.25 g/m^2 BSA on successive treatments (not to exceed 1g/m^2 BSA), provided that the 2-week leukocyte count remains above 3,000 cell/mm^3. As per the traditional NIH protocol, after the first 6 months, pulse cyclophosphamide is given every 3 months for a total of 24 months. Patients with significant renal impairment need a reduction in the dose of parenteral cyclophosphamide. The role for intermittent intravenous cyclophosphamide therapy was established by prospective, controlled clinical trials performed at the NIH (211 ,212 ,213 ,214). These trials demonstrated greater long-term renal survival with the use of cyclophosphamide as compared to corticosteroids alone. Academic community reports have also noted efficacy (215). Continuing quarterly pulse cyclophosphamide for at least 1 year after renal remission decreases the frequency of nephritic relapses and the risk of renal function deterioration (216 ,217 ,218).

Pulse Methylprednisolone

Pulse methylprednisolone as a single agent is not superior to cyclophosphamide-containing regimens (214). Typically at our institution, treatment for class IV or severe class III lupus nephritis is initiated with pulse methylprednisolone (7 mg/kg/day for 3 days) followed by intermittent intravenous cyclophosphamide and oral prednisone. Prednisone is started at a dose of 1 mg/kg/day (not exceeding 60 mg daily for adults) for the first month, followed by a gradual taper over the following 3 to 4 months. In two controlled trials for the treatment of proliferative lupus nephritis the combination of cyclophosphamide and pulse methylprednisolone monthly afforded a more rapid response and greater probability of renal remission, though at the cost of greater toxicity (212 ,214).

Azathioprine

The role of azathioprine in the treatment of proliferative lupus nephritis is less well established than that of cyclophosphamide. Early studies suggested improved outcomes with the use of azathioprine in combination with corticosteroids over corticosteroids alone, whereas in the NIH randomized, controlled trial azathioprine was no more effective than prednisone alone in reducing renal failure (211). However, azathioprine has fewer side effects than cyclophosphamide and may be considered for patients with focal proliferative (WHO class III) nephritis without markers associated with greater risk of ESRD (such as histologic findings

of necrosis, cellular crescents, or significant chronicity). In recent years, azathioprine has also been proposed as an effective maintenance regimen for patients with lupus nephritis following 6 months therapy with intravenous cyclophosphamide (219 ,220 ,221 ,222). Recently, measurement of azathioprine metabolites has become clinically available, allowing titration of the dose for individual patients to maximize therapeutic response and minimize the risk of toxicity (223). An ongoing study is evaluating the efficacy of this approach (J. Buyon, personal communication). In addition, patients lacking 6MMPT can be spared exposure to the drug (224).

Mycophenolate Mofetil

More recently, clinicians are choosing to shorten intravenous cyclophosphamide exposure to 6 months followed by a maintenance regimen of a purine synthesis inhibitor such as azathioprine or mycophenolate mofetil (MMF). Recently, Contreras et al. have shown improved overall and renal 5 year survival in patients receiving MMF or azathioprine following induction with 6 to 7 doses of IVC (219). In Europe, physicians have often employed shorter exposure to cyclophosphamide and use of maintenance with alternative immunosuppressants, or avoidance of IVC entirely. Euro-Lupus Nephritis Trial (ELNT) compared a modified NIH induction regimen (six monthly pulses followed by two quarterly pulses) to low dose (six biweekly pulses of 500 mg) IVC, followed in both treatment arms by maintenance with oral AZA at 1 mg/kg/day (225). Remission occurred in 71% of the low dose and 54% of the high dose group; the rate of long-term flares did not differ. Over a median follow up of 73 months, the probability of end-stage renal disease, doubling of serum creatinine, or death were not significantly different between patients in the low- versus high-dose IVC groups. Repeat renal biopsy in 20 of these patients after a mean of 27 months did not differ between treatment groups (226). On the whole, ELNT patients had less renal impairment at study entry compared with the NIH studies. Several reports and case series have noted efficacy of MMF in patients with resistant or relapsing lupus nephritis (227 ,228 ,229 ,230 ,231 ,232 ,233). Chan et al. noted comparable efficacy of MMF to oral Cytoxan therapy for severe nephritis (234). More recently, Ginzler et al. noted promising results in the use of MMF compared to IVC as induction therapy in a high risk population of U.S. patients with lupus nephritis (235). Ong et al. also noted the superiority of MMF to IVC as induction for severe lupus nephritis (236). Despite these encouraging results, it is currently premature to advocate the use of MMF as a first-line drug in the treatment of class IV lupus nephritis as data on duration of therapy required and long-term outcomes are still lacking.

Alternative Therapies

Cyclosporin has been shown to be effective in reducing clinical and histologic activity in proliferative lupus nephritis. Autoantibody formation and hypocomplementemia do not uniformly improve and the frequent occurrence of hypertension and nephrotoxicity limit the utility of this therapy (237 ,238). Case reports and series of efficacy of intravenous γ globulin in refractory severe lupus including nephritis have been noted (239 ,240). However, reports have also noted severe exacerbation of lupus with development of vasculitis have been described as toxicities following intravenous immunoglobulin (IVIG). Nephrotoxicity can be a serious rare complication of IVIG therapy because of osmotic nephrosis when sucrose is used in the preparation. Pre-existing renal disease, volume depletion, and older age are risk factors for such toxicity. Additionally, hyperviscosity complicated by neurologic events may occur. Previous variable results of IVIG treatment in SLE could be related to variable enrichment of different lots of IVIG in suppressive antipathogenic Id antibodies.

A controlled clinical trial showed no additional benefit of plasmapheresis for lupus nephritis compared with corticosteroids and short-course oral cyclophosphamide therapy alone (241). Plasmapheresis may however have a role in the treatment of patients with overwhelming disease in whom standard therapy is failing. The incidence of thrombotic thrombocytopenic purpura is increased in SLE. In the GDCN nephropathology database TTP occurs in 10% of patients with severe class IV lupus nephritis. In this disorder, plasmapheresis is lifesaving.

Renal Transplantation in Patients with SLE

Studies addressing the outcome of renal transplantation in patients with SLE compared to that of non-SLE patients have led to conflicting results (242 ,243 ,244 ,245 ,246). A case control study of 97 renal transplant recipients with SLE, matched for age, gender, race, type of allograft, number of previous transplants, and year of transplantation, revealed relative risk of graft loss of 2 when SLE was the cause of ESRD (242). Conversely, recent data from the United States Renal Data System compared the outcomes of 772 adults with ESRD from lupus nephritis and 32,644 adults with ESRD because of other causes who received a transplant between 1987 and 1994. After adjusting for potential confounding factors, the risk of graft failure or patient mortality was not increased in patients with SLE after first cadaveric and first living-related renal transplant (243). The reported rates of recurrent SLE disease post transplantation are also widely variable; however recurrent lupus nephritis appears to account for graft loss in <4% of grafts. The presence of antiphospholipid antibodies may be associated with an elevated risk of thrombotic complications and graft loss raising the question as to whether patients with a history of antiphospholipid syndrome should receive anticoagulant therapy in the immediate posttransplant period.

Clinical Guidelines for Evaluation and Treatment of Lupus Nephritis

- All patients who present with lupus nephritis should have a renal biopsy providing no contraindications exist (severe thrombocytopenia, refusal of blood

products, uncorrectable coagulopathy) and a physician who is expert in biopsy is available. Because therapy often differs greatly for different histopathologic classes, tissue evaluation is essential. In addition to classifying the lesion, activity and chronicity indices should be described with attention to high risk features such as crescent formation, karyorrhexis, or necrosis. A repeat renal biopsy may be required in patients with a changing clinical course in whom additional, more aggressive therapy is being considered.

- Evaluating renal activity should include: urine sediment appearance, serum creatinine, blood pressure, serum albumin, C3 complement determination, anti-DNA, proteinuria (often estimated by protein to creatinine ratio), and creatinine clearance. These may be monitored as the clinical situation dictates. Daily measurement of serum creatinine may be useful in rapidly progressive disease; other parameters require 1 to 2 weeks to change.
- Patients with antiphospholipid antibodies and nephritis have a poorer renal outcome, more histologic thrombotic microangiopathy, and increased complications with dialysis and transplantation. At a minimum, low-dose aspirin should be given; individuals with a history of a thrombotic event should be on lifelong warfarin or an equivalent thromboprophylactic regimen. This may complicate renal biopsy as anticoagulation is typically suspended for a time following biopsy to decrease the risk of bleeding at the biopsy site.
- Hypertension must be aggressively treated. With lupus nephritis the goal should be age-appropriate blood pressure (especially important in young patients). The target blood pressure for patients with a history of glomerulonephritis should be less than or equal to 120/80 mm Hg as for patients with other glomerulonephritides. The entire spectrum of antihypertensive agents have been used in patients with lupus, but there is ongoing interest in the benefit of angiotensin-converting enzyme (ACE) inhibitors, especially in patients with persistent proteinuria. ACE inhibitors may have renal protective properties, over and above their antihypertensive effects (247). The use of ACE blockers alone or in combination with ACE inhibitors is also commonly employed. Dietary restriction of salt is recommended in all patients with hypertension accompanying active lupus nephritis. Loop diuretics are used to diminish edema and control hypertension as needed, with appropriate electrolyte monitoring. Diuretics are often essential to control blood pressure while on high dose steroids with associated sodium retention. With nephrosis and hypoalbuminemia, torsemide may be more effective than furosemide. However, whenever possible, thiazide diuretics should be employed as they avoid the increased calciuria produced by loop diuretics, decreasing the risk of osteoporosis.
- Hypercholesterolemia must be controlled both to reduce the risk of premature atherosclerosis and to prevent decreased renal function. Fat intake should be restricted if hyperlipidemia is present or the patient is nephrotic. The new American Heart Association (AHA) guidelines of serum cholesterol below 180, rather than 200 should be the target for therapy, given the increase in cardiovascular disease with SLE. Although there are yet no prospective controlled studies published demonstrating improved outcome in lupus patients, such studies are underway in an inception cohort followed in the Systemic Lupus International Cooperating Clinics (248). Clinically, it is recommended that patients follow a low cholesterol, low-fat diet and when hyperlipidemia is persistent receive lipid lowering agents such as the HMG Co-A reductase inhibitors. Many clinicians, recognizing the increased risk of atherosclerosis in lupus patients, will advise patients to take an aspirin daily and folic supplementation of 1 to 5 mg daily. Plaquenil has also been associated with fewer cardiovascular events, particularly in patients who have APL.

  Additionally, patients with renal insufficiency may be placed on a low-protein diet to reduce the adverse effects of protein on renal hemodynamics and hyperfiltration. Supplementation with vitamin D 1,25 or erythropoietin may be required as patients develop chronic renal insufficiency as despite the best of efforts some patients will develop ESRD.

- Compulsive attention must be paid to the early detection and aggressive treatment of infections as they account for about 20% of deaths among patients with SLE.
- Whenever corticosteroids are used, measures must be taken to minimize the development of osteoporosis (following ACR guidelines to prevent steroid induced OP (249)). These include calcium and vitamin D supplementation, weightbearing exercise as tolerated and potential therapy with pharmacologic agents including calcitonin if renally impaired, bisphosphonates (unless contraindicated by azotemia or gastrointestinal toxicity) or recombinant PTH. (See Chapter 60 , Adjunctive Measures and Issues: Allergies, Antibiotics, Vaccines, Osteoporosis, and Disability).
- The following parameters are essential to monitor toxicity associated with corticosteroids, diuretics, and cytotoxic agents: blood pressure, complete blood count, platelet count, potassium, glucose, cholesterol, liver function tests, weight, muscle strength, gonadal function, and bone density. These are closely monitored as the clinical situation requires.
- Patients are instructed to avoid therapeutic doses of salicylates and nonsteroidal antiinflammatory agents, because they may impair renal function, exacerbate edema and hypertension, and increase risk of gastrointestinal toxicity (particularly in combination with corticosteroids and immunosuppressive agents). If absolutely necessary during the course of treatment for nephritis, they should be given for short periods at low doses with careful supervision. The cardiovascular risks with NSAIDs is presently unknown.
- Pregnancy should be discouraged in patients with active nephritis as the risks for maternal and fetal

morbidity and mortality, including renal failure, are increased. Pregnancy while requiring dialysis is high risk to both mother and fetus, has a low success rate and requires near daily treatments. Contraception, fertility, and pregnancy are important issues in this predominately female patient population. Advice on the choice of contraceptive method should be given, keeping in mind additive thrombotic risk factors, including the presence of antiphospholipid antibodies (aPL), hypertension, and nephrotic syndrome. Clinical trials of estrogen containing oral contraceptives in APL negative premenopausal women with SLE have recently been published, showing no increase in lupus flares (249 ,250). In postmenopausal women, an increase of 10% in risk of mild to moderate but not severe flares was noted with hormone replacement therapy (251). In small pilot studies of women with SLE, the use of the GnRH agonist leuprolide acetate appeared to prevent cyclophosphamide-induced ovarian failure (252 ,253 ,254). However, as this agent is an agonist, in the first few days levels of estrogen may be increased, raising the risks of ovarian hyperstimulation syndrome, multiple birth if pregnancy occurs and possible blood clots. These risks must be reviewed carefully with the patient and referring physicians: In young women with multiple risks or with a history of clotting, consideration of subcutaneous heparin until estrogen production is suppressed is wise. Of course, bone density must be assessed and maintained (254).

- Antimalarials may be given or continued for active skin disease or to reduce risks of antiphospholipid antibody syndrome, but will not impact nephritis.

Treatment of lupus nephritis requires an understanding of the immunopathogenesis, risk stratification by renal biopsy classification, appropriateness of renal biopsy, and finally, familiarity with the specific therapeutic modalities. Seasoned clinicians, familiar with the experience with hemo and peritoneal dialysis as well as renal transplantation in lupus patients, recognize the need to abandon immunosuppressive therapy once advanced glomerulosclerosis has developed. It is useful to discuss the various therapeutic agents for lupus nephritis in the context of the specific class of lupus renal disease. The following therapies are advised for specific biopsy patterns (Fig. 56-1):

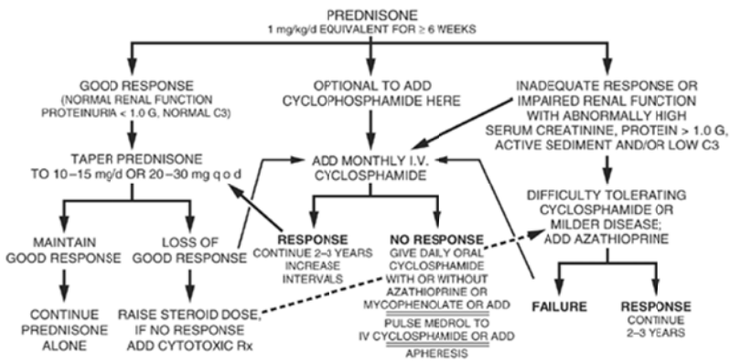

Figure 56-1. Algorithm for the treatment of proliferative (class III or IV) nephritis.

- ISN Class I (WHO class II): Many mesangial lesions do not need specific therapy. In patients with WHO class II patterns and over 1 g of proteinuria, high anti-dsDNA, and low C3 complement, we usually administer prednisone and hydroxychloroquine in accordance with the degree of extrarenal clinical activity.
- ISN III or IV (WHO class III and IV): These are treated similarly and have similar prognoses, especially when high risk features such as crescents or necrosis are present. (Fig. 56-1). Because the risk of end-stage renal disease in 10 years may exceed 50% especially in a majority African-American population, aggressive management is advised. We recommend the following:
  - Administration of 1 mg/kg/day of prednisone equivalent for at least 4 weeks, depending on clinical response. The race and age of the patient will impact steroid therapy. Children and young adults into the early 20s may be more steroid sensitive and require higher doses of prednisone than older patients. For issues in the treatment of lupus nephritis in children, see Chapter 41 , Systemic Lupus Erythematosus in Childhood and Adolescence. Pediatric rheumatologists not uncommonly employ high dose prednisone as 2 mg/kg/day. Cytotoxic drugs often take months to become effective, and glucocorticoids stabilize the patient in the interim. Prednisone is tapered over 3 to 4 months. Doses are decreased to a

maintenance of less than 15 mg of prednisone equivalent daily as needed for extrarenal activity.

- Prednisone treatment by itself can suppress evidence of proliferative disease, especially renal sediment abnormalities, but this course of action is associated with more renal scarring, and steroid related complications (211 ,212). Depending on the individual clinical situation, cytotoxic drugs should be added at the onset of therapy. Published studies suggest that the timely addition of cytotoxic drugs is associated with an increased probability of avoiding end-stage renal disease, as well as being steroid-sparing (255). Such benefit may require administration of cytotoxics for 2 years or longer in many patients.
- Intravenous cyclophosphamide administration is given monthly for 6 months as per the NIH regimen. We currently do not administer this therapy consecutively for more than 6 months. 2-Mercaptoethane sulfonate sodium (Mesna, Bristol-Myers Squibb Oncology/Immunology) can be given with infusions to minimize bladder toxicity, and ondansetron (Zofran, Glaxo Welcome Oncology/HIV) or granisetron (Kytril, SmithKline Beecham) minimize nausea. Based on the Contreras study (219), we follow induction with cyclophosphamide with up to 5 years of MMF or azathioprine. A current clinical trial is evaluating MMF versus cyclophosphamide therapy for 6 months' induction followed by a comparison of MMF versus azathioprine for maintenance therapy.
- Patients refractory to cyclophosphamide therapy. After 6 months of cyclophosphamide therapy, somewhere 10% and 40% of patients, especially minority patients (African American and Hispanic) and those with continued nephritic urinary sediment, will be refractory to prednisone plus intravenous cyclophosphamide (49). The following strategies may be considered:
  - Monthly pulse doses of methylprednisolone may be added to the intravenous cyclophosphamide for patients with severe renal damage, but should not be substituted for it (215).
  - Change to oral immunosuppressive with azathioprine, MMF, cyclosporin, cyclophosphamide, or combinations of these drugs.
  - Raising daily corticosteroid doses after induction is discouraged for renal indications as the higher dose may improve sediment abnormalities but does not improve long-term renal outcome.
  - Consideration of experimental therapies including B cell depletion with rituximab (anti-CD20), intravenous gamma globulin, addition of CTLA4-Ig to cyclophosphamide therapy or bone marrow transplantation.
- Acute flares with renal deterioration can be managed with pulse methylprednisolone and consideration of a new immunosuppressive regimen. Apheresis may be useful if the patient has cryoglobulinemia, hyperviscosity, catastrophic antiphospholipid antibody syndrome or thrombotic thrombocytopenic purpura.
- Special circumstances may warrant adjustments or changes in the above regimen. These include:
  - Corticosteroids: uncontrollable diabetes or hypertension, multiple sites of painful avascular necrosis, severe osteoporosis, steroid psychosis, life-threatening infection, severe myopathy.
  - Cyclophosphamide: refractory hemorrhagic cystitis despite Mesna therapy, severe nausea and/or vomiting, refusal to accept the possibility of infertility, prior radiation therapy, history of malignancy, cytopenia as a result of marrow suppression (cytopenias as a result of peripheral destruction are not contraindications).

  Azathioprine or mycophenolate mofetil usually is the second-line agent of choice. Infrequently, cyclosporine, chlorambucil, 2-CDA or nitrogen mustard (256) may be advised.

- Class V: Patients may be treated with 1 mg/kg/day of prednisone equivalent for 6 to 12 weeks, followed by its discontinuation if there is no response or tapering to a maintenance of 10 mg prednisone equivalent a day for 1 to 2 years if there is a response. Others may employ the Ponticuli protocol of alternate day prednisone. Cytotoxic drugs generally are not used unless patients have severe nephrosis (>10 g proteinuria daily) or developing renal insufficiency is present. Pure membranous lesions are uncommon, composing 15% to 30% of all biopsies. Recently, evidence has been presented suggesting that cyclosporine is effective in managing membranous nephritis, though this is controversial.
- Patients with a long-standing creatinine level over 3 mg/dL and/or a high chronicity index.
  - Aggressive management usually is not advised unless a high activity index also is present or extrarenal disease warranting cytotoxic therapy is evident. It is better to plan for dialysis and/or transplantation. Chronic renal insufficiency evaluation should include measurements of erythropoietin, vitamin D 1,25, calcium, PTH, and phosphorus levels.
  - Patients may be maintained on 5 to 10 mg of prednisone equivalent daily if needed to control extrarenal lupus, bearing in mind the increased risk of infection if the patient requires a peritoneal or hemodialysis catheter rather than a shunt or graft for dialysis access.
- Class VI. Patients who should not be treated include those with significant renal scarring or other evidence of irreversible disease. There is little benefit in aggressively managing patients with a stable creatinine level above 5 mg/dL; it frequently produces more harm than good. The reader is referred to Chapter 62 , Nonpharmacologic Therapeutic Methods, for a discussion of the management of patients with lupus and end-stage renal disease (specifically, dialysis and transplantation).

When Should a Renal Biopsy Be Performed?

An important issue in the evaluation and treatment of lupus renal disease is the necessity and timing of a renal biopsy. The strongest argument for a renal biopsy is the likelihood that the histopathologic findings will influence initiation, selection or discontinuation of therapeutic agents. Dubois noted two primary reasons to obtain a renal biopsy: confirmation of diagnosis in equivocal cases and determination, in advanced cases, whether further treatment was indicated. Diffuse scarring with little or no inflammation would prompt conservative management alone (256). Fries et al. (257) reviewed 177 renal biopsies, concluding that the information provided prognostic but added little clinical information. It was not cost-effective and had some inherent risks. Other reports appearing between 1978 and 1985 questioned the interobserver reliability between pathologic scoring, failed to correlate a clinical nephritis index with histologic patterns, and showed that the World Health Organization (WHO) histologic classification did not predict results of therapy at rebiopsy 12 months later (258 ,259 ,260 ,261 ,262 ,263 ,264).

Several advances have increased the frequency and safety of renal biopsies. The development of activity and chronicity indices by the NIH allowed comparison of lesions for outcome and for changes in response to treatment (265). High chronicity scores clearly are associated with a poor outcome and lack of response to immunosuppression. High activity indices, especially with more than 30% crescents, also are associated with poor outcomes but often are reversible with aggressive treatment (Table 56-4). However, some have questioned their value or reproducibility in a community setting (266 ,267). Availability of an improved renal biopsy needle, and real-time ultrasound guidance decreases the risk of significant bleeding. Evidence that tubulointerstitial disease, diagnosed only at biopsy, is of prognostic importance (268). Clinically, mesangial disease can present identically to proliferative disease. Because the therapies are different and only biopsy can distinguish the two, biopsy is desirable. Mesangial disease does not require cytotoxic therapy (146 ,153). Pure membranous disease has a different treatment and outcome than proliferative disease and can only be diagnosed by biopsy (269 ,270). Mixed membranous and proliferative nephritis may have a worse outcome than proliferative disease alone (271).Three well-designed studies document that biopsy patterns have prognostic importance and help to predict outcomes (264 ,272 ,273).

Table 56-4: Renal Pathology Scoring System[a]

Activity Index	Chronicity Index
Glomerular abnormalities	
1. Cellular proliferation	1. Glomerular sclerosis
2. Fibrinoid necrosis, karyorrhexis	2. Fibrous crescents
3. Cellular crescents	
4. Hyaline thrombi, wire loops	
5. Leukocyte infiltration	
Tubulointerstitial abnormalities	
1. Mononuclear cell infiltration	1. Interstitial fibrosis
	2. Tubular atrophy

[a]Fibrinoid necrosis and cellular crescents are weighted by a factor of 2. The maximum score of the activity index is 24; that of the chronicity index is 12. *Source:* From Austin et al. (69); with permission.

Despite these general correlations, there is substantial overlap in the clinical presentation of patients with the various histopathologic findings and it is very difficult to ascertain the type or severity of renal disease based on clinical grounds alone. For this reason, a renal biopsy is very useful—if not essential—in the management of patients with suspected lupus nephritis. It provides an invaluable guide to therapy by clarifying the clinicopathologic syndrome, and assessing the relative degrees of active inflammation and chronic scarring. It may also identify unsuspected causes for an acute worsening in renal function such as the development of a thrombotic microangiopathy, or a drug-induced tubulointerstitial nephritis.

Thrombotic microangiopathy is increased in frequency in SLE sometimes associated with antiphospholipid antibodies or with an overlap syndrome such as systemic sclerosis. Another difficulty in managing patients with lupus nephritis lies in the fact that the pathologic lesion may change from one form of glomerular injury to another. As reviewed in Chapter 55 , up to 30% of patients undergoing second biopsies transform to different patterns; Chapter 55 reviews the various patterns and their clinicopathologic significance.

Course of Lupus Nephritis

Over the last five decades, a tremendous change has evolved in the approach to lupus nephritis, and this has greatly altered its outcome (2).

Studies From 1950 to 1989

In the early 1950s, low-dose corticosteroids were used, with 5-year survival rates of close to zero (274). By the late 1950s and early 1960s, prolonged high-dose corticosteroids were employed (with a few centers using nitrogen mustard), and the overall 5-year survival rose to 25% (275). The mid to late 1960s were characterized by the availability of hemodialysis, moderate-dose steroid usage, and widespread use of high doses of azathioprine and oral cyclophosphamide. The overall 5-year survival then was 40% to 70%. By the early 1970s, physicians temporized their use of cytotoxic drugs and took advantage of newer antibiotics and antihypertensive agents, resulting in 60 to 80% 5-year survivals. (In the Dubois/Wallace series (20), 10-year survivals for middle-class patients diagnosed in the decades beginning in 1950 were 65% and then 60% [1960], 76% [1970], and 92% [1980]). The WHO classification system helped to stratify renal disease into pathologic subsets that

helped tailor therapy. The 1980s saw the introduction of intermittent, parenteral cyclophosphamide combined with corticosteroids. Activity and chronicity indices were described, and interventions with pulse-dose corticosteroids and apheresis became more common. In 1989, Esdaile et al. (276) were able to document 85% and 73% 5- and 10-year survivals, respectively, among 87 patients followed for a mean of 8.4 years. Unfortunately, in the United States, this improvement in mortality has not been experienced uniformly. Although the survival rates in Caucasians have improved, mortality rates continue to rise in African-American patients (1).

Recent and Cumulative Insights

Along the way, new insights were derived that allowed investigators to determine prognostic subsets and assess the impact of various therapies. Associated with a poorer outcome were nephrotic syndrome, nephritis with class IV lesions, high chronicity, hypertension, interstitial disease, smoking, infections, thrombocytopenia, and childhood onset of nephritis (20 ,27 ,62 ,70 ,207 ,208 ,209 ,277). The NIH group correlated corticosteroid therapy with progressive renal scarring and a worse prognosis than in those given corticosteroids plus cytotoxic treatments (211). Blacks, race, younger age at onset, low complements, anemia, and crescents on biopsy were similarly associated with a poor prognosis (21 ,49). Efforts also were made to correlate prognosis with biopsy pattern. Mcclusky (211) in 1975 and Pollak and Kant (212) in 1981 summarized several studies and found the 5-year survival rate of patients with minimal lesions to be 80% to 90%, with mesangial lesions to be 68%, mild proliferative lesions to be 40% to 80%, severe proliferative lesions to be 25% to 40%, and membranous lesions with proliferative changes to be 60% to 80%. The worst prognostic subset of lupus nephritis is nephrotic syndrome, in which one half were dead within 10 years (20 ,213). The most common causes of death were and continue to be complications of renal disease and sepsis (22). Papers in the last few years for the first time have mentioned discontinuing therapy after successful treatment (214 ,215), and more emphasis is being placed on decreasing the risk of evolving end-stage renal disease. In clinical research, emphasis is focusing on genetic susceptibility to severe nephritis and potential biomarkers of disease activity and response (278 ,279 ,280). Despite all these advances, however, certain subsets of patients with focal or diffuse proliferative lesions and scarring glomerular and tubulointerstitial regions still have a 50% chance of evolving into end-stage renal disease within 5 years, and aggressive management appears to be warranted (49 ,216 ,217 ,218 ,219). Of 150 patients who were seen by one of us, 10%, 19%, and 30% developed end-stage disease at 5, 10, and 15 years, respectively (27). Piette's French group followed 180 lupus nephritis patients at a single center. In 1999, their 5-, 10-, and 15-year renal survivals were 95%, 89% and 76%, respectively (2). Mok et al. followed 183 nephritis patients in Hong Kong. In 1999, their 5, 10, and 15 year renal survivals were 94%, 92%, and 75% (64). Remissions after initial therapy for nephritis correlate with an improved renal and patient survival (224).

Summary and Future Directions

In summary, lupus nephritis has evolved from a frequently terminal process to one in which a fairly normal quality of life and good outcome are possible. First, the treating physician must accurately stage the disease with laboratory and tissue evaluations. Next, therapy is fashioned for the specific disease subsets that are involved. Third, both side effects and the complications of treatment must be managed, along with frequent assessments and modifications of therapy depending on the patient's response. At present, many centers are reassessing the traditional 2-year NIH regimen of cyclophosphamide for severe lupus nephritis, reducing exposure to this toxic therapy and employing long-term maintenance with azathioprine or MMF. There are currently more than eight clinical trials of agents for treatment of lupus, including the introduction of biologic therapies (Discussed in Chapter 66 , Experimental Therapies in Systemic Lupus Erythematosus). These include monoclonal antibodies directed against anti-CD40 ligand, BLYS, BAFF, complement component C5, B cell depletion with anti-CD20 chimeric antibody, and T cell tolerogen CTLA4-Ig and anti-DNAase (reviewed in Table 56-1). None have so far been sufficiently evaluated to warrant their use outside of controlled clinical trials.

It is critical for expert clinicians to interpret this rapidly changing field to best advise individual physicians and patients on the optimal individual therapeutic regimen.

Section VI
The Management of Lupus

Chapter 57
Principles of Therapy and Local Measures

Daniel J Wallace

Formulation Overview

One of the most difficult and misunderstood aspects of lupus is its management. Before therapy is initiated, the practitioner must determine the type of lupus and, on this basis, formulate a treatment program. Because the prognosis of each clinical subset differs widely, it is essential that the patient database be completed before an educational session is initiated. Have all blood tests, radiographic measures, biopsies, and scans providing information that can affect treatment been performed? Once these prerequisites have been met, the physician should be able to answer the following questions:

- Does the patient meet the American College of Rheumatology (ACR) criteria for systemic lupus erythematosus (SLE)?
  - If not, does the patient meet biopsy criteria for discoid lupus or subacute cutaneous lupus? If not, is the physician satisfied that the patient has SLE, in spite of lacking four criteria? (This distinction is a matter of clinical judgment.)
  - If not, does the patient have an undifferentiated connective-tissue disease (UCTD)? Some patients with clear-cut inflammatory arthritis, a positive antinuclear antibody (ANA), and constitutional symptoms are treated similarly to lupus patients (see Chapter 49). About 14% with UCTD evolve to classical SLE.
  - If so, are related disorders such as mixed connective-tissue disease (MCTD), scleroderma, and dermatopolymyositis excluded?
- If the patient has SLE, is life-threatening organ involvement present? If not, does the patient have mild SLE?
- Which subset best describes the disease? Does a particular aspect of the patient's disease require specific considerations, intervention, or counseling (e.g., antiphospholipid syndrome, Ro (SSA) positivity, seizures, inappropriate behavior, concurrent fibromyalgia)?

Some patients have been labeled as having SLE, when in fact they do not. The implications of telling a patient that he or she has lupus are tremendous. The emotional and psychologic effects of receiving this diagnosis open up new worlds of powerful and expensive medications, influence career planning and family life, alter one's productivity and lifestyle, and in the United States, makes it difficult to obtain health, life, or disability insurance. If a patient is not certain of the diagnosis, they should not lock themselves in (1).

The Educational Session

All newly diagnosed patients, as well as those who are new to the treating physician, deserve an educational session that includes concerned family members and loved ones. The session is supervised by the physician and may involve other health professionals or use audiovisual aids. Several studies have demonstrated that socioeconomic differences account for the widely divergent outcomes in those with SLE (2 ,3) (see Chapter 69). It is critical that the patient establish a relationship and a rapport with the physician, speak a common language, keep appointments, take medication as prescribed, have transportation to the medical office, and have access to medical assistance or advice 24 hours a day. Educational and informational literature relating to various aspects of the disease, including therapy, are available from organizations such as the Arthritis Foundation and the Lupus Foundation of America (see Appendix 2 for additional resource information).

The treatment of lupus erythematosus is divided into three categories: (1) physical and psychologic measures, (2) drug therapy, and (3) surgery. The latter is employed occasionally, and the first is infrequently discussed. Table 57-1 summarizes the issues that should be discussed with the patient and family during the educational session.

General Therapeutic Considerations

Rest, Sleep, and the Treatment of Fatigue

Fatigue is present in at least one half and up to 87% of all patients with SLE, and it can be their most disabling symptom (4 ,5). Potentially reversible causes of fatigue should be ruled out first. These include anemia, fever, infection, hypothyroidism, hormonal deficiencies, hyperglycemia, and complications from medication. In SLE, fatigue may be related to cytokine dysfunction as well as to inflammation.

The administration of certain cytokines is known to induce fatigue (6), and hypoimmune fatigue syndromes could reflect decreases of the stress response (7) (see Chapters 17 and 38).

Table 57-1: Issues to Be Covered in the Educational Session

1. What is lupus, and what are its causes?
2. Many types of lupus exist. You have (cutaneous, mild, organ-threatening) lupus erythematosus, which has a (fair, good, excellent) prognosis with treatment.
3. Physical measures include the use of heat, exercise, and diet. Physical, occupational, or vocational therapy may be helpful. Discuss general preventive strategies that relate to osteoporosis, avoiding infections, and immunizations.
4. Psychologic measures include dealing with fatigue, emotional stress (in appropriate cases), physical trauma, family and job problems, and pain. Genetic counseling and a discussion of lupus and pregnancy may be needed.
5. Medication includes salicylates, nonsteroidal antiinflammatory drugs, antimalarials, corticosteroids, cytotoxic drugs, and innovative therapies. Adjunctive measures such as vitamins, birth control, and the prevention of antiphospholipid antibody complications may be helpful.
6. Resource information includes patient education materials, counseling availability, self-help, websites, exercise groups, and useful telephone numbers.

Reduced muscle aerobic capacity may play a role (8). The concept of pacing is paramount in managing fatigue. Total bed rest can worsen fatigue as well as promote osteoporosis, muscle disuse, atrophy, and contractures. Overexertion and fatigue denial also are counterproductive. Patients should pace themselves. An hour or two of morning activity should be followed by a midmorning break. A couple of hours of late-morning activity could be followed by a restful lunch break. Periods of activity followed by periods of rest usually permit most patients with lupus to attain an improved level of functioning and productivity.

The quality of sleep in SLE is impaired compared with healthy controls. This is most likely because of depressed mood, fibromyalgia, steroid therapy, and lack of exercise (9 ,10).

Treatment of fatigue requires consideration of the source and contributory factors. Iron deficiency anemia is common because of dietary deficiency, heavy menstrual periods, and/or blood loss resulting from the use of salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs). If the fatigue is caused by parenchymal pulmonary disease, oxygen may be helpful; if it is secondary to inflammation, anti-inflammatory drugs are used. In addition to corticosteroids, quinacrine and hydroxychloroquine (Plaquenil, Sanofi) are cortical stimulants and may decrease fatigue in patients without organ-threatening involvement (11 ,12). Dehydroepiandrosterone (DHEA), modafinil (Provigil, Cephalon) and selective serotonin reuptake inhibitors (e.g., fluoxetine [Prozac, Dista)] can be useful. Many patients with SLE who have minimal disease activity and normal blood work (other than a positive ANA) complain of profound fatigue. Depression, fibromyalgia, and emotional stress must be excluded as causes. Three surveys have suggested that fibromyalgia or depression are the most common causes of fatigue in SLE (13 ,14 ,15). Secondary fibromyalgia with a concomitant sleep disorder is not uncommon (16). Some physicians empirically prescribe low doses of thyroid, vitamin B12 injections, or amphetamines for the nonspecific fatigue of SLE; however, the routine use of these agents should be discouraged. Occasionally, I have found methylphenidate hydrochloride (Ritalin, Novartis) to be useful in severe cases. In contrast, the use of agents that promote restorative sleep should be considered.

Exercise, Physical Therapy, and Rehabilitation

A major cause of fatigue in SLE is from deconditioning. Aerobic capacity is 62% of the average expected in healthy, age-matched females (10). Inflamed peripheral muscles in SLE may result in decreased aerobic exercise capacity (8 ,17). Exercise regimens improved physical functioning and fatigue (18 ,19 ,20 ,21). The patient with SLE should remain physically active and avoid excessive bed rest. Exercises that strengthen muscles and improve endurance while avoiding undue stress to inflamed joints are desirable. Activities such as swimming, walking, low-impact aerobics, and bicycling should be encouraged. Recreational activities involving fine-motor movements and placing stress on certain ligamentous and other supporting structures (e.g., bowling, rowing, weight lifting, golf, tennis, jogging) should be considered on an individual basis. Exercises involving sustained isometric contractions increase muscle strength more than isotonic exercises do (e.g., stretching, Pilates). Physical measures, such as the use of local moist heat or cold, decrease joint pain and inflammation. Many patients benefit from a whirlpool bath (Jacuzzi), hot tub, or therapy pool, or from merely soaking in a tub of hot water.

Physical therapists instruct patients in strengthening and toning exercises, improved body mechanics, and gait training. No specific measures or treatment approaches are unique for patients with lupus. Joint deformities develop in approximately 10% of patients; physical and occupational therapies to minimize deformities are desirable in this group. Splints are useful for most patients with carpal-tunnel syndrome related to SLE. Corrective-tendon surgery and joint replacement are helpful in advanced cases.

Occupational therapists instruct patients in the principles of energy conservation and joint protection. They evaluate activities of daily living and advise on the use of devices or aids, such as wrist splints, comb handles, and raised toilet seats, when needed.

Vocational rehabilitation may be important in retraining a patient with SLE who can no longer work in the sun

(e.g., farmer, construction worker, fishermen) or perform tasks requiring fine hand-motor function (e.g., computer ergonomics).

Tobacco Smoke and Alcohol

Smoking impairs oxygenation, raises blood pressure, and worsens Raynaud among other adverse actions. Two studies have associated smoking with the formation of autoantibodies, including ANA (22 ,23). A study of 56 patients with SLE failed to show an immunosuppressive effect of tobacco, which has been held to improve ulcerative colitis (24). Three reports (25 ,26 ,27) correlated tobacco use with worse cutaneous-lupus or disease activity than among nonsmokers. Additional comparisons have confirmed that chronic, cutaneous lupus is more common in lupus than in nonsmokers (28), as is SLE (29 ,30). Two epidemiologic surveys (31 ,32) associated smoking with a 2.3 and 6.69 odds ratio for developing SLE. Because tobacco smoke contains potentially lipogenic hydrazines (see Chapter 3 , Environmental Aspects of Lupus), abstinence and avoiding second-hand smoke are important. The efficacy of antimalarials may be decreased in smokers, perhaps as a result of the effect of tobacco upon the cytochrome P450 enzyme system that metabolizes chloroquines (33 ,34).

Although alcohol can worsen reflux esophagitis common in SLE and is not advised in patients taking methotrexate, two studies have concluded that moderate alcohol use was inversely correlated with the presence of SLE (29 ,30 ,31), and two showed no influence on its development (27 ,32). A meta-analysis of 7 case-controlled and 2 cohort studies found an overall 1.5 odds ratio for developing SLE (35).

Weather and Seasons

Changes in barometric pressure can aggravate stiffness and aching in patients with inflammatory arthritis (36). In other words, whether a climate is hot or cold or wet or dry per se does not influence joint symptoms; barometric alterations do (e.g., hot to cold or wet to dry). Patients with lupus should expect some increased stiffness and aching in these circumstances and not to feel that they have done anything wrong.

Does increased summer sunlight or seasonal changes affect SLE? In Norway and Finland, there are fewer flares in January and more sun sensitive rashes during the summer (37 ,38). Sixty-six French lupus patients had significantly more organ-threatening flares during the summer (39). Israeli patients had more phototoxicity in summer months (40), but more joint pains, weakness, fatigue, and Raynaud during the winter (41).

Pain Management

Patients with lupus have an increased prevalence of pain management problems (42 ,43). Patients with inflammatory arthritis respond poorly to analgesics with no anti-inflammatory effects. The use of propoxyphene, codeine, or pentazocine in SLE should be limited to postoperative management and other situations. These drugs can induce dependence, have short-lived effects, and do not address the underlying problem. Anti-inflammatory drugs (e.g., salicylates, NSAIDs, corticosteroids), therefore, are more effective in treating pain symptoms in SLE. Some patients with chronic pain problems who are unresponsive to simple measures should be referred to pain-management centers, which use measures such as acupuncture, transcutaneous electrical nerve stimulation units, biofeedback, psychologic counseling, and physical therapy to alleviate pain and eliminate narcotic dependence. Other causes of pain in patients with SLE include avascular necrosis, headache, steroid-induced hyperesthesia, and fibromyalgia.

Role of Stress and Trauma

Many studies have shown that certain forms of emotional stress, including depression and bereavement, as well as physical trauma can affect the immune system for example, causing decreased lymphocyte mitogenic responsiveness, lymphocyte cytotoxicity, increased natural killer-cell activity, skin homograft rejection, graft-versus-host response, and delayed hypersensitivity (44 ,45 ,46). Stress, unfortunately, is difficult to quantitate for evaluation of its clinical effects. Could the impairment in T-cell immune functions be responsible for a clinical flare of lupus that is mediated by B-cell hyperreactivity? Acute stress in SLE may correlate with increased urine neopterin levels, IL-4 levels, decreased natural killer-cell response, and increased numbers of β_2 adrenoreceptors on mononuclear cells with or without a clinical disease flare (47 ,48 ,49).

Have these immune abnormalities been reproduced in patients with lupus? Can the neuroendocrine axis influence immune responses? Chapters 17 and 18 review the results of basic science, animal studies, and psycho-neuro-hormonal-immune links in this area.

Can Stress Induce Lupus?

In 1955, McLeary et al. (50) related the onset of disease to significant crises in interpersonal relationships in 13 of 14 patients with SLE. In 1967, Otto and Mackay (51) compared 20 patients with SLE to 20 controls. The SLE-hospitalized group experienced significantly more stress than other hospitalized, seriously ill controls before the onset of disease. All patients thought that stress provoked their illness. In another study, 18 of 36 patients with SLE (50%) who were interviewed believed that psychologic factors triggered disease onset, and an additional 25 thought that it was possible (52).

Can Stress Exacerbate Pre-Existing SLE?

Ropes observed 45 serious disease flares in her 160-patient cohort over a 40-year period. Of the 45 patients, 41 believed that emotional stress precipitated their flare (53).

Hinrichsen et al. (54) exposed 14 women with SLE, 14 healthy controls, and 12 sarcoidosis patients to acoustic stress. Significant increases in polymorphonuclear leukocyte and lymphocyte counts as well as significant elevations of circulating B and $CD8^+$ T lymphocytes, with a relative reduction in $CD4^+$ T lymphocytes, were noted in the healthy controls but not in the patients with SLE or sarcoidosis. The difference in effects was not steroid related. A follow-up study by this group (55) suggested that patients with SLE have significantly reduced cell mobilization to psychologic stress compared with that of controls.

Recently, Dobkin et al. reviewed various ascertainment methods for evaluating psychosocial distress and were able to correlate it with increased disease activity among 44 lupus patients (56). Recent studies have correlated clinical flares with increased psychological stress and improvements with a stress reduction program (57 ,58). One study suggested that sexual abuse (a form of chronic stress) raises ANA titers (59), and another correlated daily stress rather than stressful life events with lupus activity (60). Patients with lupus vary widely in their responses to stress (61). Nevertheless, stress reduction is a helpful measure in the overall management of SLE.

Can Physical Trauma Cause or Exacerbate Lupus?

No evidence has shown that physical trauma is related to the causation or exacerbation of SLE. Many patients' conditions, however, appeared to worsen after major vehicular accidents. Discoid lupus erythematosus (DLE) can develop as a result of physical trauma; King-Smith (62) first observed this in 1926. In 1956, Kern and Schiff (63) reported on five well-documented cases and sent a questionnaire to 400 dermatologists. Of these, 54 reported having treated 78 patients. The most common causes of DLE were blows from various objects, lacerations, and scars. In 1963, Lodin (64) confirmed these findings and noted that 10 of 458 Swedish patients (2.2%) with DLE had a documented preceding trauma. These observations were reinforced by Eskreis et al. (65) in 1988 and de Boer et al. in 1997 (66). On the other hand, profound stress or trauma may improve lupus. Ten patients of mine with diffuse, proliferative nephritis living near the epicenter of the 1994 Los Angeles earthquake showed improvements in their sedimentation rates, anti-DNA levels, and 24-hour urine proteins 30 to 45 days after the quake occurred (67), but this was not confirmed in a study from Taiwan after a 1999 earthquake (68). One report of catastrophic antiphospholipid syndrome provoked by trauma has appeared (69).

In summary, several authors have implicated stress as a factor that can induce or exacerbate SLE. However, a definitive study using large numbers of patients and controls with a similar chronic illness is needed before the association can be considered established. Until then, stress reduction is both prudent and important.

Is There a Lupus Diet?

Patients with SLE should eat three well-balanced, nutritious meals daily. Animal studies suggesting that fish-oil intake might be beneficial in the treatment of autoimmune diseases have led to several human clinical trials based on the findings that eicosapentaenoic acid and docosahexaenoic acid inhibit platelet aggregation, leukotriene B4 production by polymorphs, and 5-lipoxygenase products in polymorphs and monocytes (70 ,71 ,72). Although a small-scale, open-label study suggested immunologic benefits (73) and another an improved sense of well-being (74), in contrast to rheumatoid arthritis, three of four double-blind, placebo-controlled studies of SLE failed to show any anti-inflammatory actions or other clinical benefits, except for a slight lowering in plasma triglyceride and an elevation of high-density lipoprotein levels (75 ,76 ,77 ,78 ,79). Fish-oil derivatives may prevent miscarriages associated with antiphospholipid antibodies (80). Flaxseed does not benefit lupus nephritis (81). Substituting dietary polyunsaturated fatty acids with saturated fats (which may not be such a good idea according to this chapter's author) was suggested in one uncontrolled study (82). A diet high in fatty meats may be associated with more severe disease (83). The reader is referred to an excellent critical review of the subject (84).

The ingestion of alfalfa sprouts can induce lupus in primates and might exacerbate human SLE; thus, alfalfa sprouts should be avoided (85 ,86 ,87 ,88 ,89 ,90). The offending agent is probably an amino acid, L-canavanine, which has been shown to alter both T- and B-cell responses (85).

Milk may decrease the risk of developing SLE (31). Two controlled studies have found patients with SLE to have increased food allergies (91 ,92), but the clinical significance of this observation is uncertain (see Chapter 67 , Adjunctive Measures and Issues: Allergies, Antibiotics, Vaccines, Osteoporosis, and Disability).

Patients taking large doses of corticosteroids and those who are hypertensive should restrict their salt intake. Some patients with nephritis need to be salt, potassium, and protein restricted. Potassium supplementation may be needed for some patients on diuretics, and patients with anemia often benefit from foods with a high iron content (e.g., red meat). Steroids can increase lipid levels and induce a chemical diabetes, and a low-fat or diabetic diet should be implemented if this occurs (93).

In summary, patients with lupus should have a healthy, well-balanced diet. Avoidance of alfalfa sprouts and eating two fish meals a week may be prudent. More restricted diets are mandated among those taking corticosteroids and patients with renal impairment.

Do Vitamins Play a Role in Managing Lupus?

Almost all of my patients have asked about the efficacy of vitamins in SLE. No controlled studies have been published demonstrating any clear-cut benefits from their use. Low homocysteine levels are more common in

SLE, are associated with increased atheroembolic complications, and are treated with the administration of folic acid (see Chapter 44). Vitamin B12 and folic acid can be used to treat specific types of anemias, and vitamin E may improve wound healing. Vitamin B6 (pyridoxine) is a diuretic and has been used in carpal-tunnel syndrome as an adjunctive agent. In a controlled study, the administration of Vitamins C and E to lupus patients was associated with decreased lipid peroxidation after 3 months, but did not affect endothelial cell function (94). Vitamin C may decrease lupus activity (95).

In 4 studies, lupus patients had low serum 25-hydroxyvitamin D3 levels (96 ,97 ,98 ,99). This is associated with renal impairment and hydroxychloroquine use (which inhibits the conversion of 25 (OH)- to 1,25 (OH) vitamin D. Vitamin D, with calcium supplementation, may retard the osteoporosis that is induced by corticosteroids. Other than these nonspecific measures, the judicious use of vitamins by patients with lupus is probably harmless and often has a placebo effect as long as intake is not excessive.

The older literature is replete with references to the successful use of many systemic drugs. Vitamin B12 and pantothenic acid have been reported in controlled studies to be of benefit (100 ,101 ,102). Authorities such as Sulzberger (103) have recommended the use of vitamin B12, liver extract, and bismuth (104 ,105 ,106) for the treatment of discoid LE. Ayres and Mihan (107 ,108) reviewed ten papers that evaluated the use of the antioxidant vitamin E for discoid lesions. Nine were published prior to 1955, and a recent report suggested no benefits (109).

How Important Is Patient Compliance and Treatment Adherence?

Part of the patient educational session with a new lupus patient must be a discussion relating to compliance. In the Lupus in Minority populations: Nature Vs Nurture (LUMINA) Texas- and Alabama-based cohort, nearly half of the patients were noncompliant. They tended to be young, unmarried, African American, and ill (110 ,111). Adherence to treatment regimens tends to be problematic. One third of 195 Canadian lupus patients did not participate in mandated annual eye examinations to monitor antimalarial therapies (112). Compliance problems among 112 lupus patients in Detroit were related to depression, medication concerns, physical symptoms, short-term memory problems, and the need to child or elder care (113). Failure to comply with physician recommendations was shown to be the cause of renal failure in 5 of the 17 patients at the University of Toronto between 1995 and 1998 (114). In Great Britain, the rate of compliance was treatment specific among 50 females with SLE, ranging from 41% for using sun protection, 83% for hydroxychloroquine, to 94% for steroids and 100% for azathioprine therapy (115). Ninety-five patients at the University of Cincinnati had a similar outcome when one examined pharmacy refill records (116). Adherence to treatment plans in a critical component in managing SLE.

Sun Avoidance and Phototoxicity

UV light consists of three bands, two of which are important in SLE. UVA light (i.e., 320 to 400 nm) is responsible for drug-induced photosensitivity (i.e., photoallergic reactions) and delayed tanning, and it is constant during the day. It takes approximately 1 hour of UVA exposure to induce sunburn. UVB light (i.e., 290 to 320 nm) is more significant in SLE. It is more pronounced during midday (10 am to 3 pm) and causes sunburn readily (i.e., phototoxic reactions).

Hundreds of prescription drugs can cause photoallergic and/or phototoxic reactions. The most common are phenothiazines, tetracyclines, nalidixic acid, sulfa-containing agents, piroxicam, methotrexate, amiodarone, psoralens, phenytoin, and carprofen (117). Photosensitizing chemicals are found in certain perfumes, mercury-vapor lamps, xenon-arc lamps, tungsten iodide light sources, discotheques, color television sets, halogen lamps (118), and photocopier machines (119).

Although 93% of lupus patients have abnormal phototest results (120), clinical and self-reported sun sensitivity is reported less often. One study of 125 patients with SLE noted that 73 are sun-sensitive (121). In 42 of patients, sun exposure exacerbated systemic symptoms, and in 35, it had a significant effect on lifestyle. The mechanism by which this occurs is probably related to the action of ultraviolet (UV) light on epidermal DNA, which enhances its antigenicity, allowing anti-Ro to be exposed to the cell surface, which promotes an inflammatory response, and skin production of cytokines, prostaglandins, and oxygen free radicals (see Chapters 29 ,30 ,31).

The presence of anti-Ro/SSA antibody is associated with photosensitivity in more than 90% of white patients with SLE (122). Fluorescent lights are a source of UVA and UVB, but only rarely might their avoidance be beneficial (123). Clear jacket and bulk covers that control UV emanation without reducing visibility are available and, for all practical purposes, eliminate any risks (124 ,125).

Which Sunscreen Should Be Used in Lupus?

Although the UV end of the spectrum is the most damaging to lupus skin lesions, heat and infrared exposure also can cause exacerbations. The flares produced by infrared exposure are characterized by a marked increase in erythema of short duration. These are frequently experienced by patients with SLE who work near a hot stove, oven, or furnace for any length of time. One characteristic of DLE and SLE is that skin burns and scalds can produce localized lesions of DLE at the site of trauma (i.e., the Koebner phenomenon) even in apparently normal skin (62 ,63 ,64). Sunscreens are UV light-absorbing chemical agents in a cream, oil, lotion, alcohol, or gel vehicle. These chemicals can block UVA, UVB, or both. They include aminobenzoic-acid esters (UVB), cinnamates (UVB), salicylates (UVB), benzophenones (UVA, UVB), avobenzone (UVA), anthralites (UVA, UVB), and butylmethoxydibenzomethanes (UVA, UVB).

Physical sun blocks containing titanium dioxide and zinc oxide scatter light. A sun protection factor (SPF) value is the ratio of the time that is required to produce erythema through a UVB sunscreen product to the time that is required to produce the same degree of erythema without it. The SPF ranges from 2 (i.e., minimal protection) to 50 (i.e., highest protection). We advise outpatients to use agents with a high SPF (i.e., at least 15). A sunscreen with SPF of 15 will block 93% of UVB, whereas one with SPF 50 will block only 5% more. The Food and Drug Administration (FDA) permits sunscreen manufacturers to claim broad-spectrum protection if their products block at least part of UVA-2 light in addition to UVB. Table 57-2 lists some of the best agents. Although few of these have been tested in lupus patients, the reader is referred to the only critical, brand-name comparison study published (126).

Unfortunately, because of irritation, contact dermatitis, and occasional photosensitivity, patient compliance is poor, and it may be necessary to try several compounds before an acceptable block is found. Particularly, the alcohol base in p-aminobenzoic acid (PABA) and PABA esters may sting and dry the skin. Wind, heat, humidity, and altitude can decrease an agent's protective effect.

Table 57-2: Useful Sunscreens Currently Available for Lupus Patients

Broad-spectrum UVA/UVB sunscreens containing parsol 1789
Cetaphil Daily Moisturizer SPF 15
Coppertone Shade Spray Mist SPF 30
Coppertone Shade Sunblock Lotion SPF 30/45
La Roche-Posay Anthelios ‘L’ Cream SPF 60
Ombrelle Sunscreen Lotion/Spray SPF 15/30
Presun Ultra Lotion/Gel SPF 15/30
Solbar AVO SPF 32
Sunscreens for very sensitive skin (generally contain titanium dioxide or zinc oxide)
Clinique City Block SPF 15/25
DuraScreen SPF 30
Elta Block SPF 30/32
Estee Lauder Sunblock SPF 15/30
MD Forte Total Daily Protector SPF 15
Neutrogena Sensitive Skin Sunblocker SPF 17
Presun Sensitive Block SPF 28
Vanicream SPF 15/35
Sunscreen for lips or eyelids
Chapstick Ultra SPF 15/30
Coppertone Lipkote SPF 15
Coppertone Shade Sunblock Stick SPF 30
La Roche-Posay Antherpos Ceralip SPF 50
Neutrogena Lip Moisturizer SPF 15
Neutrogena Sunblock Stick SPF 25
Presun Lip Protector SPF 15
Moisturizer/sunscreen combinations
Cetaphil Daily Facial Moisturizer SPF 15
Elta Block SPF 30/32
Eucerin Daily Lotion SPF 15/25
Keri Skin Renewal SPF 15
Lubriderm Daily UV Lotion with Sunscreen SPF 15
Neutrogena Healthy Skin SPF 15
Neutrogena Moisture SPF 15
Oil of Olay Daily UV Protectant SPF 15
Purpose Dual Moisturizer Lotion/Cream SPF 15
Waterproof/sweat-resistant sunscreens
Coppertone Shade Spray Mist SPF 30
Coppertone Sport Spray/Stick SPF 15/30
Elta Block Super Waterproof SPF 30
La Roche-Posay Anthelios ‘S’ Cream SPF 30
Neutrogena Sunblock Spray/Stick SPF 20/25
Presun Ultra Spray SPF 27
Solbar Cream SPF 50
Oil-free sunscreens
Clinique Oil Free Sunblock SPF 15
Coppertone Shade Oil-Free Gel SPF 30
Neutrogena Oil Free Sunblock Lotion SPF 30
Neutrogena Sunblock Spray SPF 20
Ombrelle Sunscreen Spray SPF 15

Recommendation of sunscreens currently available commercially in the United States. (This list was adapted from a list published on the RxDerm-L Internet chat group in 1997. It has been updated by the authors for this review). It should be noted that this list was generated as a result of the “expert opinion” of a number of practicing dermatologists across the United States. Unfortunately, there are virtually no current published data resulting from systematic comparisons of the efficacy of various commercial products in the categories indicated in this table. Please note that LE patients are recommended to use a product containing an SPF of 30 or greater whenever possible.

Sunscreens should be applied over active and healed lesions and to areas that may burn, including the cheeks, nose, lips, and arms approximately 30 minutes before sun exposure. They can be applied over the scalp hair before going outdoors, and cosmetics may be applied over sunscreens. Two forms of UV light exposure often are overlooked. Skin lesions frequently are more intense on the left cheek and the lateral aspect of the left arm because of UVA exposure while driving a car. If the lesions are primarily distributed in these areas, the physician should inquire whether such exposure might be responsible and advise the patient on avoiding it (127). Merely keeping the window closed or tinting the window may filter the sunlight sufficiently. Automotive glass blocks UVB effectively but not UVA. Another unnoticed source of exposure is UV light that is reflected off the surface of sand, water, cement, or snow, and UV radiation is greater at higher altitudes. For example, the intensity at 5,000 feet is 20% higher than that at sea level. Patients should be cautioned about these sources of danger. A cloudy day only decreases UV exposure by 20% to 40%.

Sunscreens block vitamin D activation in the skin, and oral supplementation may be required. An occasional patient develops eye sensitivity to UV light that is not responsive to wearing ordinary sunglasses. Special coated lenses to protect

the eyes are available (128). In patients with lupus erythematosus and a definite UV sensitivity, walking a few blocks without any protection usually is permitted. If further exposure is necessary, general measures such as wearing a broad-brimmed hat (4-inch or greater is advised) and long sleeves, as well as using an umbrella can be used; these decrease UV exposure by 30% to 50%. When a remission occurs, either spontaneously or induced, greater freedom of sun exposure is permitted. Frequently, otherwise asymptomatic patients have a persistent butterfly erythema that is aggravated by sun exposure, and use of antimalarials and local sunscreens usually controls this if it is severe enough to warrant therapy. Numerous web sites offer information related to specialized sun protective clothing, local daily UV indices and guides for sun protection. They can be referenced via Dr. Richard Sontheimer or the Lupus Foundation of America.

Avoidance of UV exposure has been so overemphasized that many patients are irrational about going out during the day. Unless definite evidence of exacerbations that are provoked by such exposure is noted, normal activities need not be restricted or curtailed. Although it is advisable to caution the patient that sun exposure may cause increased local erythema or development of new skin lesions, the physician should avoid causing a sunlight phobia. The average patient, even one who is photosensitive, usually can walk a few blocks at midday without protection and experience no ill effects. The question of how limited light exposure should be must be determined on an individual basis. The physician must use judgment so that the patient's way of life is interrupted as little as possible. Because sun exposure is greatest midday, outdoor activities should be undertaken in the morning or later in the afternoon.

Antimalarial therapy increases the patient's tolerance to sun exposure even in those who were extremely sensitive to UV light before taking them (129 ,130 ,131 ,132). The degree of limitation must be reevaluated frequently, because the tendency to sunlight-induced exacerbation of skin lesions can subside, particularly with disease remission (either spontaneous or drug-induced). Even NSAIDs can be photoprotective (133).

Local Therapy for Cutaneous Lupus Erythematosus

Local treatment is used for isolated lesions of DLE or for refractory skin lesions in patients with DLE or SLE. The most effective, safe, and least scarring type of local therapy is the use of various steroid preparations. These can be fluorinated or nonfluorinated, and they may be of low, intermediate, or high potency (Table 57-3). Most nonfluorinated steroids include hydrocortisone cream or ointment and now are available as over-the-counter (OTC) preparations in strengths of less than 1%. These agents are less expensive but less potent than the fluorinated preparations, which produce more stinging, dermal atrophy, depigmentation, striae, telangiectasia, acne, folliculitis, and Candida superinfection (134). Fluorinated steroids cannot be applied to the face for more than 2 weeks at a time without expecting cutaneous side effects. Studies show that betamethasone dipropionate 0.05% (Diprolene, Schering) and clobetasol propionate 0.05% (Temovate, Glaxo Wellcome) creams or ointments are the most effective dermatologic agents for short-term treatment of discoid lesions, especially in conjunction with antimalarials (135).

These preparations should be used three or four times daily for optimal effectiveness and only applied directly over the lesions. Patients should be warned not to use them on normal skin, because they induce atrophy. Improvement usually is noted within a few days. Unfortunately, recurrences frequently appear within a few days to weeks after the cessation of treatment, but small lesions can be controlled adequately and indefinitely by the intermittent use of this method. Old, indurated, and chronically scaling lesions respond poorly to this form of treatment alone and require occlusive therapy (discussed later), intracutaneous injection, and/or antimalarials. Patients usually start on an intermediate-strength steroid cream or ointment and move up to high-potency agents for resistant lesions. Ointments generally are used for dry skin and creams for oily skin, but the ointment form is more effective than a cream, gel, or lotion. Fluorocarbon-propelled sprays are the least effective. Thin skin is more permeable to topical steroids as well.

The introduction of Actiderm (ConvaTec) patches allows for the improved absorption of high-potency steroids with less irritation. This should complement the use of translucent plastic, steroid-impregnated tape (Cordran Tape, Oclassen), and occlusive dressings such as plastic wrap, which increase percutaneous absorption by a factor of 100 and have been documented to be effective for those with severe DLE (136 ,137 ,138 ,139 ,140). Airtight occlusion of the skin causes obstruction of the sweat ducts, however, which may exacerbate pruritus and foster bacterial overgrowth on the skin surface. Jansen et al. (141) reported that topical fluocinolone acetonide cream 0.025% (Synalar, Medicis), when applied by massaging into the lesions four or five times daily or by using an occlusive dressing daily, was effective in 43 of 59 patients with DLE. It was necessary to supplement local therapy with antimalarials or corticosteroids in 11 patients. Of these 59 patients, five failed to respond, and 23 who had required antimalarials were able to discontinue them with the consistent use of local medication. All 24 patients who responded well to topical therapy and were followed through two summers did well, except for three who relapsed and required retreatment.

In another study (142), daily application of triamcinolone acetonide 0.5% in a flexible collodion base to recalcitrant DLE lesions was effective in six of seven patients compared with the use of nonmedicated collodion as a control. It may be especially helpful in the external ear, where occlusive dressings are impractical.

Intralesional therapy often is helpful when topical applications fail. Several studies have shown the value of intradermal injections of steroids. Callen, as well as other

investigators, have documented the superiority of this method to the use of topical or oral steroids in resistant lesions (140 ,143 ,144 ,145). Triamcinolone suspensions have been the most widely used; these include triamcinolone diacetate 1.25% or 2.5% suspension (Aristocort Diacetate Parenteral), triamcinolone acetonide 10 mg/mL (Kenalog Parenteral, Westwood-Squibb), and 1% or 2.5% aqueous suspension (Meticortelone Acetate Suspension).

Table 57-3: Topical Corticosteroids Ranked by Potency (65)*

Group	Generic Name	Brand Name
I. Superpotent	Clobetasol propionate cream, ointment, gel, or emollient, 0.05%	Temovate
	Betamethasone dipropionate cream or ointment, 0.05%	Diprolene
	Diflorasone diacetate ointment, 0.05%	Psorcon
	Halobetasol propionate cream of ointment, 0.05%	Ultravate
II. Potent		
	Amcinonide ointment, 0.1%	Cyclocort
	Betamethasone dipropionate cream, 0.05%	Diprolene
	Betamethasone dipropionate ointment, 0.05%	Diprosone
	Desoximetasone cream or ointment, 0.25% and gel, 0.05%	Topicort
	Diflorasone diacetate ointment, 0.05%	Maxiflor
	Fluocinonide cream, gel, or ointment, 0.05%	Lidex
	Halcinonide cream, 0.1%	Halog
	Mometasone furoate ointment, 0.1%	Elocon
III. Midpotent		
	Amcinonide cream or lotion, 0.1%	Cyclocort
	Betamethasone dipropionate cream, 0.05%	Diprosone
	Betamethasone valerate ointment, 0.1%	Valisone
	Diflorasone diacetate cream, 0.05%	Maxiflor
	Fluocinonide cream, 0.05%	Lidex-E
	Fluticasone propionate ointment, 0.005%	Cutivate
	Halcinonide ointment, 0.1%	Halog
	Triamcinolone acetonide ointment, 0.1%	Aristocort A
IV. Midpotent		
	Fluocinolone acetonide ointment, 0.025%	Synalar
	Flurandrenolide ointment, 0.05%	Cordran
	Hydrocortisone valerate ointment, 0.2%	Westcort
	Mometasone furoate cream, 0.1%	Elocon
	Triamcinolone acetonide cream, 0.1%	Kenalog
V. Midpotent		
	Betamethasone dipropionate lotion, 0.05%	Diprosone
	Betamethasone valerate cream, 0.1%	Valisone
	Fluocinolone acetonide cream, 0.025%	Synalar
	Flurandrenolide cream, 0.05%	Cordran
	Fluticasone propionate cream, 0.05%	Cutivate
	Hydrocortisone butyrate cream, 0.1%	Locoid
	Hydrocortisone valerate cream, 0.2%	Westcort
	Triamcinolone acetonide lotion, 0.1%	Kenalog
VI. Mild		
	Alclometasone dipropionate cream or ointment, 0.05%	Alcovate
	Betamethasone valerate lotion, 0.05%	Valisone
	Desonide cream, 0.05%	DesOwen
	Flumethasone pivalate cream, 0.03%	Locorten
	Fluocinolone acetonide cream or solution, 0.01%	Synalar
	Triamcinolone acetonide cream, 0.1%	Aristocort A
VII. Mild		
	Topicals with hydrocortisone, dexamethasone, flumethasone, prednisolone, and methylprednisolone	

*Group I compounds are arranged by potency.

Occasionally, acute swelling may occur at the site of injection, but this usually subsides within 24 hours. A local depression also may appear because of tissue reabsorption; this may be noted in five of patients (145) and usually disappears within several months. It is probably a pseudoatrophy resulting from true tissue destruction. James (145) reported nine patients with DLE who were treated in this manner: five had an excellent response, and the benefit was satisfactory in two. Rowell (146) treated 28 patients with multiple intralesional injections of triamcinolone at 3-week intervals. In 13 patients, the injected lesions cleared, and 13 other patients improved. Only two patients did not respond. Smith (147) also described favorable results in 13 patients with DLE. Biopsy studies before and after therapy showed a diminution of follicular plugging and hyperkeratosis in all patients, accompanied by some thinning of the epidermis. Vascular dilatation and cellular infiltration disappeared, and skin atrophy was not observed.

Topical Calcineurins for Cutaneous Lupus

The availability of 0.1% tacrolimus (Protopic) and pimecrolimus (Elidel) for eczema and allergic dermatitis has led to their anecdotal use for cutaneous lupus. In contrast to fluorinated steroids, these agents have the advantage of being applied facially without fear of inducing cutaneous atrophy. Six reports involving 20 patients report a collective 50% response rate among refractory patients (148 ,149 ,150 ,151 ,152 ,153) (see Chapter 66).

Skin Transplantation, Intralesional Antimalarials and Innovative Therapies

The transplantation of normal skin to sites of excised quiescent lesions has been successful in a small number of patients (154 ,155 ,156). Transplantation of 4-mm, hair-bearing punch grafts into active plaques of patients with DLE, however, showed recipient dominance, with a decrease in hair survival and the appearance of discoid lesions in the implanted skin (157).

Intralesional administration of quinacrine and chloroquine was used in the 1950s with good results (129 ,158 ,159), but it was abandoned because of the high incidence of hemorrhagic bullae, local discomfort, erythema, bleeding, and crusting of blood. A form of topical chloroquine clearly protects one from UVB (129). Caustic acids, intralesional gold, topical 5-fluorouracil, nitrogen mustard, BCNU, cryotherapy, imiquimod, apheresis, and topical retinoids and vitamin D analogs and solid carbon dioxide also have been used (160–167, see Chapter 66).

The reader is referred to an excellent review of the subject of topical therapies for cutaneous lupus (168).

Can Lupus Patients Undergo Topical Cosmetic Procedures?

There is no published, evidence-based material on the subject. Andrew Franks, a dermatolupologist at the New York University School of Medicine, published his anecdotal experience in the Lupus Foundation of America newsletter (Lupus News, Fall 2004, p 34–35). Lasers, collagen, hyaluronic acid gels, Botox, thermage, microdermabrasion, and sclerotherapy have been used for butterfly rashes, blemishes, telangiectasias, scars, skin tightening, blemishes and spider veins for both lupus and nonlupus-related purposes. If appropriate precautions are taken (e.g., waiting until steroids are stopped or are at their lowest possible dose, skin testing the patient with collagen first), these procedures can improve one's quality of life and appearance.

Topical Therapy for Systemic Lupus Erythematosus

Triamcinolone acetonide in an emollient dental paste (Kenalog in Orabase, Westwood-Squibb), used two or three times daily and at bedtime, is useful for sensitive lupus mucous membrane lesions. A buttermilk or hydrogen peroxide swish or gargle also is effective as an adjunctive agent. Over the long term, systemic antimalarials are more efficacious for lupus mucous membrane involvement.

Joint aches can be managed with topical nonsteroidal gels such as ketoprofen (20%) with or without muscle relaxants (e.g., 1% cyclobenzaprine) if fibromyalgia is also present. These preparations are available from compounding pharmacists.

Chapter 58

Nonsteroidals and Salicylates for Systemic Lupus Erythematosus

Arash A. Horizon

Michael H. Weisman

Nearly 80% of patients with systemic lupus erythematosus (SLE) are treated with nonsteroidal anti-inflammatory drugs (NSAIDs) for fever, arthritis, serositis, and headaches. This chapter reviews the literature on nonselective and selective inhibitors of cyclooxygenases, with an emphasis on the efficacy and safety profile reported in SLE patients. All NSAIDs, regardless of their cyclooxygenase selectivity, induce renal side effects including sodium retention and reduction in glomerular filtration rate. Additionally, lupus nephritis is a risk factor for NSAID-induced acute renal failure. Hepatic toxic effects to NSAIDs are increased in SLE patients as well as cutaneous and allergic reactions. Finally, aseptic meningitis has been reported more frequently in SLE patients with NSAID use. Nevertheless, and in spite of these caveats, NSAIDs can safely be prescribed to most lupus patients, provided they are evaluated and closely monitored on a regular basis.

Beginning with phenylbutazone in 1953, indomethacin in 1965, and ibuprofen in 1974, enormous quantities of NSAIDs have been tested, manufactured, and sold worldwide. They are among the most commonly prescribed drugs in the world, with estimates as high as $2 billion spent annually in the United States (1). Despite the fact that the Food and Drug Administration (FDA) has not approved a commercial preparation of NSAIDs in the management of SLE, these agents have been used widely for the treatment of SLE-associated fever, arthritis, pleuritis, and pericarditis. Although the number of well-controlled evidenced-based actual studies in SLE patients is low, this review will discuss the role of NSAIDs in the management of lupus patients, and evaluate some of the major side effects associated with their use.

Prostaglandin Synthesis and Metabolism

The cellular membrane bilayer provides the substrate for the synthesis of prostaglandins and thromboxanes. Arachidonic acid is initially produced in response to chemical or mechanical stimuli by the actions of the enzyme phospholipase A. Arachidonic acid is subsequently metabolized either by cyclooxygenase A to form an unstable endoperoxide called PGH2 or by 5-lipooxygenase to produce leukotrienes. PGH2, in turn, degrades to form prostaglandins PGI2, PGE2, PGD2, toxic oxygen radicals, and thromboxane A2. Prostaglandins induce a variety of inflammatory effects such as swelling, erythema, changes in vascular permeability, and neutrophil chemotaxis (2 ,3 ,4). Additionally, prostaglandins have a myriad of effects on multiple organ systems, including the renal, gastrointestinal (GI), and musculoskeletal systems.

NSAIDs inhibit the rate limiting step in the production of prostaglandins by binding to cyclooxygenase A. It is now recognized that there are three distinct proteins that process cyclooxygenase activity, known as COX-1, COX-2, and COX-3. COX-1 is ubiquitous throughout the body in renal collecting tubules, platelets, endothelial cells, smooth muscle, and gastric mucosa, whereas the COX-2 gene is expressed in a limited number of cells such as neurons, synoviocytes, and smooth muscle cells (5). COX-3, which is inhibited by high-dose acetaminophen, is constitutively expressed in brain and heart tissue and thought to be responsible for febrile reactions (6).

Both COX-1 and COX-2 enzymes use arachidonic acid to produce prostaglandins, which in turn, are modified to generate bioactive lipids. Since 1998, four COX-2 selective inhibitors have been introduced to the U.S. market. Rofecoxib, valdecoxib, and celecoxib have all been shown to be as effective as naproxen for pain control in rheumatoid arthritis and osteoarthritis patients. They are highly selective for COX-2 enzymes even at doses significantly higher than the manufacturers' recommended dosage. Initially designed to minimize GI toxicity, they were regarded as safer agents compared to many nonselective COX inhibitors. Nevertheless, they have been observed to cause serious gastroduodenal injury in large clinical trials at a rate greater than placebo but less than nonselective COX inhibitors (7 ,8 ,9). Most recently, there has been extensive debate regarding the safety profile of COX-2 inhibitors, including the increased cardiovascular risk associated with their use (10).

Clinical Efficacy in SLE

Nonsteroidals were first used in the treatment of SLE patients in 1953 by Langhof, who reported that phenylbutazone improved “subacute” lupus in four patients (11).

This was followed by observations from Harvey et al. in 1954; 7 of 19 patients experienced significant improvement with treatment doses of aspirin. Additionally, four patients experienced a lower febrile response without great clinical improvement (12). In 1956, Dubois noted a “remission” in 39% of his patients with the combined use of aspirin and bed rest (13). In 1966, he suggested treatment doses as high as 300 mg of phenylbutazone may improve the symptoms of SLE (14). Additionally in 1975, Dubois found that in seventeen patients given an average of 2,400 mg of ibuprofen, a 69% significant clinical improvement occurred (15).

Table 58-1: Summary Points Relating to the Use of NSAIDs in Systemic Lupus

1. No NSAIDs are currently approved by the FDA for use in SLE.
2. Over 70% of patients with SLE use an NSAID on a regular basis, mostly for fever, adenopathy, headache, myalgias, arthralgias/arthritis, and/or serositis.
3. Only one controlled trial has ever been conducted on the use of NSAIDs in SLE. In that study aspirin was superior to ibuprofen; a prospective celecoxib trial is in progress.
4. Lupus patients have more complications from NSAIDs than healthy persons without SLE; transaminitis, sun sensitized or sun-induced rashes, fluid retention, hypertension, gastrointestinal ulcerations and aseptic meningitis are probably more common in this population. It is not completely understood if disease activity, disease related risk factors (renal disease, for example) or concomitant medications play a supporting role in these events.
5. NSAIDs can safely be prescribed to most lupus patients provided they are closely monitored on a regular basis.
6. NSAIDs, especially COX-2 inhibitors, should be used with caution in women of childbearing age if pregnancy is a possibility.
7. The risks and benefits must be heavily weighed and discussed with the use of NSAIDs, especially of COX-2 inhibitors, in lupus patients. More long-term data are needed to fully appreciate the potential adverse cardiovascular and cerebrovascular events associated with their usage.

COX-2, cyclooxygenase-2; FDA, Food and Drug Administration; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

The National Institutes of Health (NIH) conducted the first double-blinded, controlled study of NSAIDs for SLE. Nineteen patients with fever, arthritis, and serositis were randomized to receive 3,600 mg of aspirin or 2,400 mg of ibuprofen for 10 days. Seventeen patients completed the trial; seven of the nine on aspirin and two of eight on ibuprofen had dramatic improvement in swollen joints and joint pain. Two patients randomized to ibuprofen had decreases in creatinine clearance and an elevation in liver enzymes; these findings reversed upon drug cessation (16).

In 1989, the rheumatology division at Cedars-Sinai Medical Center found 77% of 925 lupus patients had been treated with NSAIDs, and 41% with salicylates. Though no direct evidence supported NSAIDs efficacy in SLE, its usage appeared to improve fever, headaches, arthralgias, and serositis associated with the disease (17). A similar finding was reported by Ramsay-Goldman et al. at the University of Pittsburgh, where 73% of the patients with SLE were taking NSAIDs (18). Moreover, in 1989, steroid sparing properties were reported in 30 Hungarian patients taking piroxicam for 3 months (19). In 1993, Espinoza et al. treated six patients who had refractory nephritic syndrome with indomethacin. A reduction in proteinuria and persistent modest improvements in serum albumin were noted in four of the six patients (20).

Several studies have led to aspirin use for the treatment of antiphospholipid syndrome. Patients with antiphospholipid syndrome are at increased risk for arterial and venous thrombosis, in addition to recurrent fetal loss. Gattenby et al. reported a decrease in fetal loss from 88% to 55% in SLE patients with positive antiphospholipid antibodies following treatment with low dose aspirin. Additionally, several other studies have shown similar findings in this population with low dose aspirin use. ASA is thought to stimulate interleukin-3 production, which in turn promotes placental and fetal development. Moreover, low-dose ASA blocks the production of thromboxane A2, thereby decreasing potential vasoconstriction and platelet aggregation. Most recently, Lander et al. showed in 50 SLE patients that the selective COX-2 inhibitor, celecoxib, was both safe and effective in a community-based SLE population with a predominance of musculoskeletal complaints and less severe organ involvement (21).

The number of randomized controlled clinical trials monitoring SLE patients with NSAIDs use, especially comparing those with renal involvement and those without, is extremely limited. Therefore, current clinical use of NSAIDs in SLE is based primarily on case reports and series as well as documented efficacy displayed in nonlupus patients with other rheumatic diseases, such as rheumatoid arthritis or osteoarthritis (Table 58-1).

Adverse Side Effects of NSAIDs in SLE

Although NSAIDs are often the first line of therapy in patients with SLE, there are risks associated with its use. Many variables, including comorbid conditions, multiple medication usage, baseline renal function, and age may all contribute to its potential toxicity.

Renal

The most common and worrisome side effect is acute renal insufficiency, typically occurring in patients with additional risk factors such as advanced age, intravascular volume contraction, or pre-existing renal insufficiency (22).

Currently it is felt that NSAIDs induce renal side effects by inhibiting prostaglandin synthesis which plays a key role in vasodilatory regulation (23). Prostaglandins affect vasodilatory effects on a cellular level with subsequent compensatory adjustments in renal perfusion. Documented in animal models with lupus nephritis, they are also thought to play a role in the inhibition of T lymphocyte induction and tissue damage (4). In 1977, Kimberly and Plotz noted a 58% reduction in creatinine clearance as well as a 163% increase in serum creatinine in 13 of 23 lupus patients after minimum of 7 days of aspirin therapy. These reversible changes were more prominent in patients with low complement levels and active nephritis (24). Additionally, there have been several studies detailing reductions in glomerular filtration rate (GFR) with NSAID use. Borg et al. noted a 15% reduction in GFR with normal renal blood flow in 13 lupus patients without significant renal disease. Two other controlled studies in lupus patients revealed a 16% reduction in GFR with ibuprofen or indomethacin consumption. Patients with active lupus glomerulonephritis were found to have larger changes in renal function compared to lupus patients without renal disease (25 ,26 ,27). Moreover, there have been reports of acute tubular necrosis in lupus patients with the use of ibuprofen, naproxen, and fenoprofen (28 ,29 ,30). A case-control study revealed a twofold increase in chronic renal disease with daily NSAID use. After risk factor adjustments, men older than 65 appear to be at an increased risk (31). In a Malaysian prospective study of 259 patients with a minimum total of 1-kg analgesic intake, renal papillary necrosis was noted in 29 patients by computed tomography (CT), ultrasound, or intravenous urography (32). Thus, careful review of the above collected data stresses the need for a risk/benefit decision in each individual case before the use of NSAIDS in considered in lupus patients with underlying or active renal disease.

Finally, there are no long-term observational studies evaluating the effects of NSAIDs in lupus patients. Renal papillary necrosis and chronic renal failure have been associated with prolonged NSAIDs intake in normal human subjects; however, the actual risks for these complications have not been established (7).

Gastrointestinal

Currently there are no published studies evaluating GI side effects associated with nonsteroidals in lupus patients. In the general population, it has been noted that dyspepsia develops in approximately 10 to 20% of patients taking nonsteroidals on a regular basis. Endoscopic evidence showing gastric mucosal damage secondary to aspirin use was first shown 60 years ago. Numerous studies have substantiated such damage, as well as both the direct toxicity on GI mucosa and indirect damage secondary to prostaglandin blockade (33).

Many therapies have been studied to prevent GI mucosal injury. The FDA has approved the use of misoprostol four times daily to prevent NSAID-induced ulcers. Although beneficial in certain cases, misoprostol use has been associated with diarrhea, bloating, and increased risk of spontaneous abortion (34). H2 blockade has been shown to prevent duodenal ulcers in two randomized studies but was not as effective for gastric ulcer prevention (35 ,36). Proton pump inhibitors are effective in preventing mucosal injury (37).

A lower incidence of ulceration has been associated with nonacetylated salicylates as they seem to inhibit prostaglandins to a lesser degree. Second-generation NSAIDs with an affinity for COX-2, such as etodolac and nabumetone have a lower GI risk as well (38).

COX-2 inhibitors have shown promise in the prevention of GI toxicity (4 ,5 ,39). However, the long-term GI safety of COX-2 inhibitors in SLE has yet to be determined. Reports have suggested the COX-2 enzyme may be associated with gastroduodenal ulcer healing. Not only has COX-2 been located at the rim of gastroduodenal ulcers in human models, but is also associated with the healing of gastric mucosal damage in mice (40 ,41). The mechanism of COX-2 inhibition prevention remains unclear. Theories suggest a possible interaction with other causal agents of gastrointestinal ulcers; more trials are needed to substantiate such positions.

Hepatic

To date, there are no reported cases documenting clear chronic hepatitic sequelae secondary to the use of NSAIDs in lupus patients. However, there have been several studies addressing the possible risks associated with salicylate usage. Mild elevations of serum transaminases without associated elevations of bilirubin or alkaline phosphatase have been noted in patients with lupus and juvenile rheumatoid arthritis (42). A dosage of 2 g/day is the current threshold that may carry a significant risk. Aspirin, secondary to a direct toxic effect associated with the orthoacetyl moiety, appears to be the most frequent offending agent (43). In 1975, Fries and Holman reported transaminase elevations in 48 of their 192 lupus patients taking aspirin. This was followed in 1978 by a report from Travers and Hughes, who reported similar elevations in seven of their 74 lupus patients using aspirin at recommended doses. Interestingly, four of these seven patients replaced aspirin with diflunisal for approximately 2 months; no corresponding transaminase elevations were noted.

Central Nervous System

NSAID-induced aseptic meningitis is a rare event, but reports indicate that it occurs more often in SLE. Forty-three reported cases have been noted in the literature thus far. Of those, many presented with a clinical scenario similar to

infectious meningitis. A headache, stiff neck, and fever were often the major complaints. It appears that a rechallenge with the same NSAID will cause the event to take place again; this is based on the author's anecdotal experience as fortunately such situations are even more rare. CSF analysis revealed an elevated white blood cell (WBC) count, elevated protein, and normal glucose level. No bacteria were isolated (44 ,45 ,46 ,47 ,48). Of these patients in the literature, 18 cases were associated with SLE. Ibuprofen was by far associated with the highest percentage of cases, followed by tolmetin, sulindac, naproxen, and diclofenac (29 ,49 ,50 ,51 ,52). The mechanism and etiology of such association is not well understood. Hypersensitivity reaction, a lack of suppressor cells in SLE patients leading to an exaggerated response, and a cell-mediated cross-reactivity with ibuprofen have all been postulated (32).

Dermatologic

When compared to the general public, SLE patients have higher rates of allergic reactions to all drugs, especially antibiotics and, to a lesser extent, NSAIDs (53 ,54). Most NSAIDs usage reactions are mostly associated with cutaneous reactions manifestations. Angioedema, urticaria, erythema multiforme, exanthema, and Stevens-Johnson syndrome have all been linked to NSAID use in SLE patients. Naproxen, aspirin, diflunisal, and sulindac have a 5% incidence of rash (55 ,56). A specific photosensitivity rash presenting within 3 days as a vesiculobullous eruption has been reported with piroxicam (57).

Sulfonamide-containing medications continue to present a problem for some SLE patients. In 1992, Petri and Allbritton (58) published a case-control study of 221 patients with SLE. Thirty-one percent of the SLE patients exposed to sulfonamides developed allergic reactions, such as rash, angioedema, bronchospasm, and fever, whereas only 12% in the control group experienced similar complications. Moreover, six patients had documented lupus flares in the sulfonamide group. A retrospective study published in 1993 compared drug hypersensitivity reactions in 340 lupus patients and 306 controls; 56% of the former group developed complications and only 14% in the latter group. Of these, sulfonamide antibiotics were the leading causative agents, followed by penicillin, cephalosporins, and NSAIDS (59). Once again, several lupus flares were noted in the SLE patients.

Celecoxib, a COX-2 inhibitor, is a derivative of bezenesulfonamide. This raises a concern as COX-2 therapy is often used first line in patients who may or may not even have lupus or before the disease is diagnosed. Structural differences among sulfonamide antibiotics and celecoxib exist. Notably, the lack of an arylamine group located at the N4 position is perhaps the most critical. Without this moiety, the incidence of cross-reactivity with resulting clinical adverse reactions is rarely seen (60 ,61). In a retrospective analysis of fifty SLE patients who were followed for 8 months while openly being treated with celecoxib for musculoskeletal pain, there were no differences in the incidence of allergic reactions in patients with a self-reported history of sulfa allergy compared to those without such complaints (11).

Potential Increased Cardiovascular Risk

Great debate has recently taken place regarding cardiovascular risks associated with NSAID usage. The largest risks appear to be associated with COX-2 selective inhibitors. In the mid-1990s, selective COX-2 inhibition was thought to favor thrombosis by mostly inhibiting the COX-2-derived vascular prostacyclin without affecting the COX-1 mediated generation of thromboxane A2 (62). The Vioxx Gastrointestinal Outcomes Research (VIGOR) trial suggested a fivefold increase in the risk of myocardial infarction with the use of rofecoxib versus naproxen (63 ,64). The lack of a placebo group, in addition to the possible antithrombotic effects of naproxen made the study difficult to interpret (65 ,66). Recently, results of three randomized, placebo-controlled case studies have suggested elevated cardiovascular risks associated with COX-2 inhibitors (67). The APC (Adenoma Prevention with Celecoxib) trial included patients with a history of colorectal cancer; these patients were randomized to celecoxib or placebo. A 2.3% cardiovascular endpoint of death secondary to cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, or nonfatal heart failure was achieved in patients taking 400 mg of celecoxib per day. A 3.4% cardiovascular endpoint was noted in patients receiving 800 mg of celecoxib per day. This is in contrast to the 1% composite cardiovascular endpoint noted in the placebo group (68). In early December 2004, the NIH subsequently suspended the trial because of its increased cardiovascular events. The APPROVe (Adenomatous Polyp Prevention on VIOXX) trial randomized patients with a history of colorectal adenomas to 18 months of rofecoxib or placebo. An increased risk of thrombotic complications (1.5 events/100 patient-years vs. 0.78 events/ 100 patient-years) was noted in the rofecoxib arm (69). Lastly, in a study of post-CABG patients, subjects were randomized to valdecoxib/parecoxib or placebo. This study also noted an increase in cardiovascular events associated with COX-2 inhibitor use (2.0 % vs. 0.5% for the placebo group.) In summation, recently published large scale studies have strongly suggested increased cardiovascular risks with COX-2 inhibitor use and emphasize the need for additional data collection and careful risk assessment when these agents are employed.

Drug Interactions

Adverse reactions may come from medication alone or in combination with other therapy. SLE patients often take multiple medications with the increased opportunity for potential interactions. NSAIDs have been shown to diminish the antihypertensive effects of thiazide and loop diuretics (70). Additionally, NSAID usage may increase prothrombin

time if taken with warfarin. Documented cases of bone marrow aplasia and renal failure have been published when methotrexate is used with aspirin, naproxen, or indomethacin (45 ,71).

One additional potential concern is the interference of aspirin, in anti-inflammatory doses, with systemic and renal clearance of methotrexate. This in turn, may lead to higher methotrexate levels and potential toxicity (72).

Pregnancy

Indomethacin (Indocin) is the most studied NSAID that is commonly used during pregnancy. Although generally considered safe until the third trimester, indomethacin has been associated with oligohydramnios, premature closure of the fetal ductus arteriosus with subsequent persistent pulmonary hypertension of the newborn, fetal nephrotoxicity, and periventricular hemorrhage (73). Other NSAIDs, such as ibuprofen, have been studied less often during pregnancy. However, an analysis of 50 pregnant patients who overdosed on ibuprofen revealed no evidence of fetal abnormalities (74).

Most recently, several population based cohort studies have shown an increased risk of miscarriages associated with exposure to NSAIDs (75 ,76). The highest risk of miscarriage was associated with NSAIDs use around the time of conception, which may be related to altered prostaglandin interactions during normal implantation. This risk may be further increased with the use of COX-2 inhibitors, as inducible prostaglandins are thought to be necessary for proper implantation. However, there is very limited information on the indications for NSAIDs use in these observational studies. The finding that filling a prescription for an NSAID was associated with an increased risk for miscarriage may simply reflect a higher proportion of women with rheumatic diseases in the exposed group. In a large randomized controlled trial, low-dose aspirin was not associated with an increased risk for miscarriage (77). Whether this association is caused directly by NSAIDs or by the indication for prescribing the drug is still not understood. It may be prudent for physicians caring for these patients and women who are planning to be pregnant to be aware of potential miscarriage risks and avoid using NSAIDs, especially COX-2 inhibitors, around the time of conception.

Monitoring Therapy

Most lupus patients take NSAIDs on a regular basis, even though they are at an increased risk for experiencing complications from the drug. In our practice, lupus patients on NSAIDs are seen at least quarterly, at which time a history is obtained, physical examination performed that screens for hypertension and edema, and blood tests are obtained, which include a complete blood count, hepatic and renal screen.

Conclusion

Current literature review reveals that NSAIDs can be used with caution in the management of non-organ threatening SLE inflammation such as arthralgia, myalgia, headache, serositis, fever, and synovitis. However, lupus patients, specifically those with active nephritis, are at increased risk for developing renal toxicity associated with NSAIDs and should have close regular monitoring in order to avoid toxicity.

Additionally, great controversy has recently surrounded the safety of COX-2 inhibitors. Several studies have linked their usage to increased cardiovascular and cerebrovascular events. In September 2004, Merck voluntarily withdrew rofecoxib from the market and valdecoxib in March 2005, because of their increased risk of myocardial infarction and stroke. The NIH soon followed by suspending the APC clinical trial because of the increased cardiovascular events associated with the use of celecoxib. Three days later, the NIH halted the ADAPT (Alzheimer's Disease Anti-inflammatory Prevention Trial), because this study revealed an increased risk of cardiovascular events in patients receiving naproxen, but not in those given celecoxib. Thus, it is alarmingly clear the benefits and risks must be heavily weighed and compared before employing the use of COX-2 inhibitors. Moreover, recent data suggests this risk/benefit ratio must be strongly considered in all NSAID use.

Chapter 59
Antimalarial Therapies

Daniel J. Wallace

Antimalarials are effective nonsteroid drugs for some patients with systemic lupus. Unlike other disease-modifying therapeutic agents that are used to treat systemic lupus erythematosus (SLE), antimalarials do not suppress the bone marrow or increase the risk for opportunistic infections.

Historical Perspective

Antimalarials were first used therapeutically in 1630 as an antipyretic (1). They were first employed in the treatment of cutaneous lupus in 1894, when Payne (2) tried quinine. In 1928, Marstenstein (3) reported good results in 22 of 28 patients with discoid and subacute systemic lupus who were treated with pamaquine (Plasmachin), which is similar to quinine in that both are substituted 8-aminoquinolines. In 1938, Davidson and Birt (4) reported excellent results in 19 of 29 patients who were treated with quinine bisulfate. In 1941, Prokoptochouk (5 ,6) successfully treated 35 patients with discoid lupus erythematosus (LE) by giving daily doses of 300 mg of quinacrine (Atabrine, mepacrine), a compound first synthesized by the Germans during the 1920s but possibly first discovered by Paul Ehrlich a decade earlier (7). During World War II, quinine supplies were cut off by the Japanese, and the U.S. Surgeon General declared Atabrine to be the official drug to treat malaria (8 ,9). Between 1943 and 1946, 3 million Americans took the drug daily (10). Anecdotal evidence of its efficacy in treating some skin disorders among British soldiers prompted Page (11) to study the drug for use in the treatment of discoid lupus. Unaware of Prokoptochouk's work, in 1951, Page reported its benefits in an uncontrolled study of 18 patients with lupus and two with rheumatoid arthritis (RA), and the report received wide attention. These findings were soon confirmed at the Mayo Clinic by O'Leary et al. (12).

Subsequently, it was shown that other antimalarials also are effective. Chloroquine was patented in 1934 and hydroxychloroquine synthesized by the mid-1940s and shown to be less toxic than quinacrine. In 1953, Goldman et al. (13) reported that chloroquine was helpful in 21 patients, including 3 with subacute disseminated disease, and in 1954, Pillsbury and Jacobson (14) noted that 15 of 16 patients with SLE taking chloroquine improved. Synthesized by Surrey and Hammer in 1946, hydroxychloroquine (Plaquenil) was released in 1955 after it was found to be effective in SLE and RA, with fewer adverse reactions than chloroquine (15 ,16 ,17 ,18). Amodiaquin (Camoquin) also was efficacious in SLE, but it was taken off the market in the United States in the early 1970s because of its propensity to induce agranulocytosis (19 ,20 ,21). It is still available in other countries. Finally, an extremely potent antimalarial, Triquin (which contained chloroquine, hydroxychloroquine, and quinacrine) took advantage of the synergy between quinacrine and the chloroquines. It was released in 1959 after a report claimed that 44 of 45 patients with lupus, mostly antimalarial-resistant, at Boston City Hospital had dramatic responses (22). The preparation sold well until it was withdrawn in 1972 as part of a campaign against the use of combination drugs. Sanofi-Winthrop discontinued the production of Atabrine in 1992, but it is still available from 2,500 compounding pharmacists in the United States who can obtain quinacrine hydrochloride powder from chemical suppliers (23).

Pharmacology of the Antimalarials

Chloroquine

Chloroquine (7-chloro-4-{4-diethylamino-1-methylbutylamino}) (Fig. 59-1). Water soluble and almost completely absorbed by the gastrointestinal (GI) tract, it achieves a peak concentration in 8 hours and is only 10% is fecally excreted. Renal excretion (50%) is increased by acidification and decreased by alkalinization. The drug is bound by plasma proteins and largely deposited into tissues. High concentrations can be found in the liver, spleen, kidney, lung, and all blood elements (2 ,24 ,25 ,26), as well as in pigmented tissues. This can be 6,000 to 20,000 times the plasma level (15). Doses of 250 mg a day lead to plasma concentrations of 100 to 500 ng/mL after 2 months (27). Chloroquine is broken down into three N-dealkylated metabolites that are of toxologic and pharmacologic importance, including desethylchloroquine and bisdesethylchloroquine. Chloroquine and desethylchloroquine competitively inhibit CYP2DI/6-mediated reactions in vivo and in vitro. The R (-) chloroquine enantiomer may be more potent, has a longer half-life, and higher unbound plasma concentrations (28 ,29 ,30). The drug readily crosses the placenta and is excreted in small amounts in breast milk. A child receives less than 1% of the maternal dose (31 ,32).

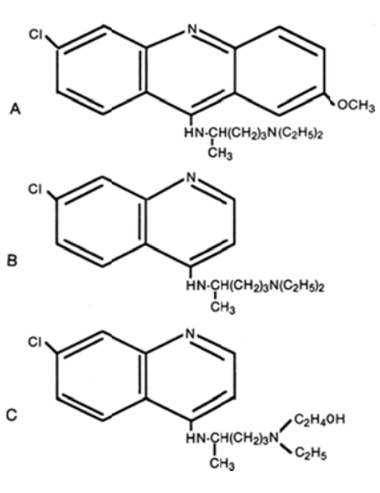

Figure 59-1. Structural formulas of commonly used antimalarial drugs. **A.** Quinacrine. **B.** Chloroquine. **C.** Hydroxychloroquine. (From

Wallace DJ. Antimalarial agents and lupus. *Rheum Dis Clin North Am* 1994;20:243–263, with permission.

)

Chloroquine is slowly excreted with elimination half-lives of 20 to 60 days, but detectable amounts in the urine, red cells, and plasma for as long as 5 years after discontinuation (33). The half-life is governed by dose-dependent kinetics, increasing from 3 hours after a single 250-mg dose to 13 days after 1,000 mg. Chloroquine decreases creatinine clearance by a mean of 10 in 55% of its users, probably by increasing plasma aldosterone levels (34 ,35). Drug interactions have been reported with ampicillin and methotrexate (chloroquine decreases its bioavailability), but not with aspirin (36 ,37 ,38). It has in vitro synergy with cyclosporine and antagonism with d-penicillamine (39).

Hydroxychloroquine

Hydroxychloroquine sulfate (2-[[4-[(7-chloro-4-quinolinyl) amino]pentyl]ethylamin]ethanol sulfate; Plaquenil is a 4-aminoquinoline that differs from chloroquine by a hydroxyl group at the end of a side chain (Fig. 59-1). The two agents have similar pharmacokinetics. The 200-mg tablets contain 155 mg of hydroxychloroquine base, consisting of equal amounts of (-)-(R) and (+)-(S) enantiomers. The (+)-(S) form has greater bioavailability (40) but a shorter half-life (41). Hydroxychloroquine is broken down into three metabolites: desethylchloroquine, desethylhydroxychloroquine (to the greatest degree), and bidesethylchloroquine by CYP2D6, -2C8, -3A4, and -3A5 human p450 enzymes (42 ,43). Hydroxychloroquine is 75% to 100% absorbed in the GI tract, with 50% in 2 to 10 hours and 50% bound by serum proteins (44 ,45 ,46). Some is conjugated with glucuronide and excreted in the bile, but 30% to 60% is biotransformed in the liver. Excretion occurs in two stages: a rapid one, with a half-life of 3 days; and a slower one, with an overall half-life of 40 days. Forty-five percent is excreted by the kidney, 3% by the skin, and 20% fecally. It takes 6 months to reach a 96% steady state. Much of the drug is deposited into tissues, with the highest concentrations in the adrenal and pituitary glands. Other areas with high concentrations include melanin-containing tissues, liver, spleen, and leukocytes. It has been disputed whether inflammatory disease activity or toxicity correlates with drug blood concentrations (42 ,47). Hydroxychloroquine is approximately two thirds as effective as chloroquine and half as toxic (48).

The drug may slightly alter kidney function; 15 of 118 patients with RA had a mean 10% decrease in creatinine clearance (34). The dosage must be reduced in patients with renal failure. Dialysis does not help overdosage, because the agent is extensively sequestered (46).

Hydroxychloroquine can interact with digoxin and reduce its levels (a quinidine-like effect) (49). It increases the potency of adding methotrexate in combination (50). One five-center survey has suggested that hydroxychloroquine administration may decrease the frequency of liver enzyme abnormalities seen in patients with RA who are on methotrexate or salicylate therapy (51), and this has been confirmed by another report (52).

Quinacrine

Quinacrine (6-chloro-9-[-methyl-4-diethylamine]butylamine- 2-methoxyacridine; Atabrine, mepacrine, Atebrine, chinacrin, Erion, Acriquine, Acrichine, Palacrin, Metoquine, Italchin) differs from chloroquine only in having an acridine nucleus (i.e., an extra benzene ring) instead of a quinoline (Fig. 59-1). The drug is rapidly absorbed after oral administration. Plasma levels rise in 2 to 4 hours, reaching a peak in 8 to 12 hours (53). Plasma concentration increases rapidly during the first week, and 94% equilibrium is attained by the fourth week. The drug is distributed widely in tissue but is slowly liberated, with the highest concentrations in the liver and spleen and the lowest concentrations in the brain and heart. The liver concentration may be 20,000 times that in plasma. Skin deposits often are clearly visible. Quinacrine crosses the placenta and reaches the fetus. Spinal fluid levels are 1% to 5% of plasma levels. Eighty percent to 90% of the drug is bound to plasma proteins in therapeutic doses, and it has a half-life of 5 to 14 days. It is slowly excreted from the body; less than 11% is eliminated in the urine daily (54).

Figure 59-2. Blue-black pretibial pigmentation from prolongued antimalarial administration.

Quinacrine also can be administered intralesionally (55 ,56), for discoid lesions, intramuscularly, intravenously, rectally, transcervically, or delivered through a chest tube for malignant pleural effusions (54 ,57 ,58).

Figure 59-3. Nail-bed pigmentation resulting from antimalarial therapy.

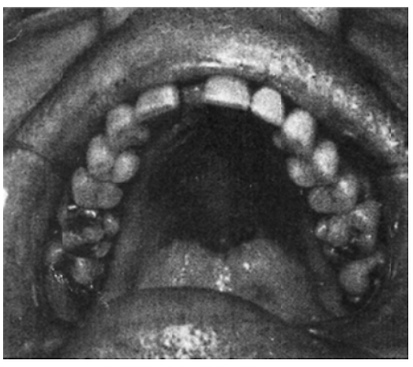

Figure 59-4. Blue-black pigmentation on the hard palate caused by antimalarial therapy.

Mechanisms of Action

Light Filtration

One of the major aggravating factors in patients with SLE is ultraviolet (UV) light exposure. More UV radiation is absorbed (Table 59-1) when skin concentrations of antimalarials are higher (45 ,46 ,47). Antimalarials deposited in the skin absorb UV light in a concentration-dependent manner (59 ,60 ,61). Hydroxychloroquine, but not methotrexate, methylprednisolone, or saline, blocked cutaneous reactions induced by UV light (62). Topical chloroquine protects against UVA- or UVB-induced erythema (63). Sontheimer's group (64) has shown that chloroquine modulates UV activation of the c-jun proto-oncogene, which protects against UV damage. Ironically, the chloroquines and quinacrine can also induce a photosensitivity reaction (65 ,66 ,67). An anti-inflammatory effect or downregulating action on keratinocytic function also might be important (68). Quinacrine can impede photodynamic actions, inhibit laser-induced photosensitivity, and increase UV light tolerance (11), perhaps by scavenging water radicals (69 ,70 ,71).

Table 59-1: Important Mechanisms of Action of Antimalarial Drugs

Immunologic actions
Blocks antigen processing by raising intracytoplasmic pH, which depletes cells of their receptor sites with consequent decrease in cytokine production (especially IL-1, IL-6, and TNF-α)
Inhibit natural killer activity, mitogenic stimulation
Impedes formation and helps dissolve immune complexes
Inhibits toll receptor activation
Antiinflammatory effects
Inhibits phospholipase A_2 and C
Prostaglandin antagonization
Stabilizes lysosomal membranes
Decreases fibronectin release by macrophages
Blocks superoxide release at multiple sites
UV light absorption
Hormonal actions
Decreased estrogen production
Hypoglycemic, impairs insulin release
Antiproliferative activities
Blocks graft versus host disease
Intercalates with DNA
DNA, RNA polymerase inhibition
Decreased tumor size and chemotherapy resistance
Inhibits platelet aggregation and adhesion
Antimicrobial effects, decrease antibiotic resistance
Anticholinesterase and sympatholytic actions
Quinidinelike cardiac actions, reduction of infarct size
Lowers cholesterol and LDL levels by 15% to 20%

TNF, tumor necrosis factor; IL, interleukin; LDL, low-density lipoprotein.

Immunologic Effects

The principal mechanism of action of hydroxychloroquine and chloroquine relates to their elevation of intracytoplasmic pH. Because antigen processing is an acidic, pH-dependent component, the chloroquines turn off this process by decreasing the number of autoantigenic peptides presenting on the cell surface (15 ,72 ,73). The tendency of chloroquine and hydroxychloroquine to target macrophage-mediated cytokines such as interleukin-1 (IL-1), IL-2, and tumor necrosis factor-α (TNF-α) to a greater extent than T-helper cell–mediated cytokines, such as IL-2, IL-4, and IL-5 suggests that its sites of action are preferential (74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83). Hydroxychloroquine can inhibit calcium signals in T cells (84). Chloroquine also inhibits interferon-γ production by CD4- and CD8-positive synovial T cell clones in patients with RA (85), suppresses natural killer cell activity (86 ,87), and suppresses IL-6 immune activity in a variety of mitogenic stimulation studies (86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95). Both chloroquines can enhance IL-10 activity (96), block tumor necrosis factor expression (97), and inhibit monocyte chemoattractant production (98).

Raising the pH of cytoplasm has a profound effect on the lysosomal membranes, which are stabilized (90 ,99 ,100 ,101 ,102 ,103 ,104). Chloroquine is concentrated in the nuclear and lysosomal fractions of white blood cells (100 ,105). Chloroquine becomes trapped in lysosomes and alters their pH, which results in an increase in lysosome number and volume. Inclusion bodies (i.e., myelin bodies) containing plasma membrane phospholipid accumulate, because of the reversible inhibition of membrane recycling; this remarkable action leads to decreased phagocytosis, chemotaxis, and cell functioning. More specifically, it substantially depletes the cell of its surface receptors (trapping approximately 50% of them), which alters the cell's responsiveness to mitogenic stimuli (45 ,69 ,101 ,102 ,106). Quinacrine probably has similar actions (69 ,107 ,108 ,109).

Chloroquine has opposing actions, in that it inhibits the formation of antigen-antibody complexes in vitro and enhances the association of such complexes in a dose-dependent fashion (110) or can split them (111). Chloroquine has been used to dissociate antigen-antibody complexes as part of a laboratory technique that is used in typing red blood cells with a positive direct antiglobulin test (112 ,113). Also, it strips human leukocyte antigens (HLAs) from lymphocyte and platelet membranes (114 ,115 ,116). Clinically, it has been shown to decrease circulating immune complex levels in patients with RA (117).

Chloroquine blocks the DNA–anti-DNA reaction by binding not to the anti-DNA antibody but to the DNA (118). Competition for binding sites on DNA among chloroquine, sodium ions, and anti-DNA antibodies occurs only under nonphysiologic conditions (119). Work from Dubois' and Kunkel's laboratories documented that the binding of quinacrine to nucleoproteins can block the LE cell factor (120 ,121 ,122).

Antiinflammatory Effects

Chloroquine is a strong prostaglandin antagonist (especially against phospholipase A2) and a weak agonist (123 ,124 ,125 ,126). The antagonist effect clearly is demonstrable at concentrations

that are reached in human plasma when the drug is used therapeutically (126). Chloroquine reduces prostaglandin synthesis through the inhibition of phospholipases A2 and C and blocks mitogen activated protein kinase signalling (124 ,127 ,128 ,129 ,130). Antiphospholipase A2 blockade decreases the actions of bradykinin in synovial fibroblasts, suppresses its algesic effects, and decreases histamine release from basophils (131 ,132 ,133 ,134 ,135). In vitro hexosamine depletion of intact articular cartilage by E prostaglandins is accomplished through the DNA-dependent RNA synthesis of cathepsin-like proteases (136). This can be inhibited by chloroquine through the inhibition of DNA primer.

Chloroquine and hydroxychloroquine also exhibit anti-inflammatory actions by decreasing IL-1–induced cartilage degeneration, perhaps through inhibiting elastase (137 ,138 ,139), fibronectin release by macrophages (140), and reactions that are dependent on sulfhydryl-disulfide interaction (141). Chloroquine inhibits angiogenesis in vitro, which results in anti-inflammatory effects (142 ,143).

Quinacrine also is a potent inhibitor of phospholipase A2, which results in decreased leukotriene and prostaglandin release (125 ,127 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,150 ,151 ,152 ,153). It is a nonselective antilipolytic agent that decreases prostaglandin E2 production in a dose-dependent fashion. Thromboxanes B2 and A2 are specifically suppressed. Quinacrine also stabilizes cell membranes as a result of its Na-K-adenosine triphosphatase (ATPase) inhibitory effects (150), and it inhibits lysosomal enzymes that are involved in phospholipid catabolism. Strongly concentrated in leukocytes and lysosomes, quinacrine has a stabilizing effect (145). Phagocytosis, chemotaxis, RNA synthesis, and hexose monophosphate shunt burst activity are inhibited by the drug (69 ,70 ,154 ,155 ,156). Chloroquine and quinacrine also are antipyrogens (157 ,158 ,159).

Neuroprotective and Antiprion Effect

Quinacrine can decrease glial injury and reaction through its inhibition of phospholipase A2 (160). It also acts as a noncompetitive inhibitor of prion formed channels (161 ,162) and is a candidate to manage some prion-associated disorders.

Hormonal Effects

Chloroquine may reduce estrogen production (163) and have an adrenal-stimulating effect (164). In patients with RA, SLE and sarcoidosis, it decreases 1,25-hydroxyvitamin D levels (165 ,166 ,167). A major area of interest concerns its applications in diabetes as a result of the agent's hypoglycemic action. This occurs secondary to chloroquine-induced decreased degradation of insulin (168 ,169), inhibiting lysosomal proteolysis (170), decreased gluconeogenesis (171), and, possibly, decreasing insulin-induced loss of receptors (172). Although hydroxychloroquine lowers blood sugars in patients with SLE by a mean 5 mg/dL (173), occasional reports of clinically evident, chloroquine-associated hypoglycemia have been published (174 ,175 ,176).

Quinacrine accumulates in peptide hormone-producing cells (177 ,178), and it can block prolactin (179 ,180) and insulin release. Conflicting reports about its effects on 17-ketosteroids have been published (11 ,134).

Antioxidant Effects

In high doses, chloroquine can inhibit polymorphonuclear oxidative bursts (181). Chloroquine, hydroxychloroquine, and quinacrine block superoxide release by actions at multiple sites on the metabolic pathway (150 ,155 ,182 ,183 ,184 ,185 ,186), which may have a beneficial effect on bronchial asthma (187).

Antiproliferative and Graft versus Host Effects

Chloroquine interferes with protein synthesis in vivo and in vitro (188 ,189). It blocks DNA and RNA biosynthesis and produces rapid degradation of ribosomes and dissimilation of ribosomal RNA. By intercalation, chloroquine inhibits DNA and RNA polymerase reactions in vitro and DNA replication and RNA transcription in susceptible cells (190). Chloroquine does not alter the ability to repair damage from UV light–induced DNA excisions (191). It impedes DNA synthesis stimulated by platelet-derived growth factor (192). Interest has focused on its anticarcinogenic properties. Chloroquines can inhibit the replication of Moloney leukemia virus and tumor development in newborn mice (193), be toxic to melanoma cells (194), block breast tumor growth (195), and inhibit pancreatic adenocarcinoma cell growth (196). Further, it can potentiate hyperthermia therapies with or without radiation (197 ,198 ,199), block Z-DNA formation (200), and enhance chemotherapy cytotoxicity in multiple drug-resistant human leukemic cells (201). Both chloroquine and hydroxychloroquine decreased alloreactivity in three separate studies as part of preventing graft-versus-host disease among transplant patients (202 ,203 ,204).

Quinacrine also binds to DNA by intercalation between adjacent base pairs (205 ,206 ,207). Quinacrine blocks radiation-induced DNA strand breaks, activates innate immunity, and potentiates the antiproliferative effects of radiation (71 ,207 ,208 ,209 ,210 ,211 ,212 ,213). It reduces the incidence of cancer in rats given nitrosourea (214), decreases the number of somatic mutations induced in murine leukemia cells (215), enhances carmustine therapy in rat gliomas (216), decreases tumor size in mice (199 ,217), and reverses resistance to vincristine (218). Lymphocytes in vitro treated with quinacrine show increased chromosomal aberrations (219).

Antiplatelet and Antithrombotic Effects

Hydroxychloroquine and chloroquine that accumulate in blood platelets can inhibit platelet aggregation and adhesion in a dose-dependent fashion (220 ,221 ,222 ,223 ,224). A desludging effect was demonstrated in the retinal veins of 20 patients with RA (225), and additional studies suggested that hydroxychloroquine reduces the size of thrombi and does not prolong bleeding

time (222 ,226 ,227). Hydroxychloroquine reverses platelet activation induced by human IgG antiphospholipid antibodies (228), and reduces anti-β_2-glycoprotein-1 titers in mice (229). As a result, the drug has been used for thromboprophylaxis of postoperative pulmonary emboli in orthopedic patients (230). Quinacrine also can inhibit platelet aggregation, probably because of its antiphospholipase actions or its interaction with 38,58-cyclic guanosine monophosphate (cGMP) (231 ,232 ,233 ,234 ,235).

Antimicrobial Effects

Inhibition of DNA replication may be the mechanism of action for the antimicrobial effects of chloroquine. It does not impede the growth of viruses but does protect the cells against virus-induced cell damage (236). Chloroquine's discontinuation has been associated with flares of viral infections (237). Chloroquine and hydroxychloroquine inhibit replication of the human immunodeficiency virus in T cells and monocytes (238 ,239), which may account for the negative association between AIDS and SLE (240). Quinacrine has antiparasitic, antiprotozoan, antibacterial, antiviral, and antifungal actions (54 ,241). It can prevent resistance to various antibiotics and increase interferon production (242), and perhaps prevent pneumocystis infection (243).

Muscle and Nerve Effects

Chloroquine is a muscarinic receptor antagonist, which results in an atropine-like effect in humans (242 ,244). The agent also can block dopamine ß-hydroxylase (245). Quinacrine is a strong inhibitor of cholinesterase, because of its inhibition of cGMP (151 ,202 ,246 ,247). It can block ß-agonists, α-adrenergic actions, and norepinephrine (151 ,246 ,248 ,249 ,250). Quinacrine protects mice from lethal amounts of snake venom neurotoxins (251).

Cardiac Effects

Both chloroquine and quinacrine possess quinidine-like actions. Chloroquine increases heart rate, lowers blood pressure, and decreases premature ventricular contractions in humans (252 ,253 ,254). Patients taking chloroquine routinely show electrocardiographic flattening of T waves and a slight prolongation of the QT interval (255). Quinacrine's antiarrhythmic actions occur as a result of slowing inward current and decreasing the automaticity of Purkinje fibers; it can treat atrial fibrillation and prevent ventricular fibrillation (256 ,257). The antiphospholipase A2 actions of chloroquine and quinacrine resulted in studies demonstrating that both can decrease acute myocardial ischemic damage in dogs, rats, pigs, and cats (258 ,259 ,260 ,261 ,262 ,263 ,264 ,265 ,266 ,267 ,268).

Antihyperlipidemic Effects

Animal studies have shown that chloroquine decreases serum bile acid and cholesterol levels by 10% to 20% (269 ,270 ,271). Lysosomotropic agents reduce the proteolysis of many plasma membrane receptors, and chloroquine increases the number of low-density lipoprotein (LDL) receptors (272 ,273 ,274 ,275). Alternatively, inhibition of the hydrolysis of internalized cholesterol esters also may lead to increased LDL receptor levels (273 ,274) (discussed later).

Promotion of Apoptosis and Inhibition of Toll Receptor Activation

Hydroxychloroquine induces lysosome mediated apoptosis (276 ,277). Meig et al. (278) showed that hydroxychloroquine was able to induce apoptosis in lupus peripheral blood lymphocytes in a dose- and time-dependent manner, and Potvin et al. (279) were able to reproduce this with chloroquine in human endothelial cells. Krieg's group (280) suggested that this could be prevented in vitro when CpG dinucleotides activate NF-κB. Chloroquine is able to inhibit the production of proinflammatory cytokines induced by TLR9 (toll receptor 9) (280a).

Clinical Studies

Chloroquines: Antilupus Activity

As early as 1956, Ziff et al. (281) noted a favorable response in 11 of 12 patients with SLE who are given antimalarials and commented on the reduction of steroid requirements (Table 59-2). Dubois (282) claimed that 90% to 95% of patients had a favorable response. To evaluate the effectiveness of medication for the treatment of discoid LE, it is essential to know the incidence of spontaneous remissions. In Dubois' (283) studies, 10% of patients had a history of spontaneous improvement. In the series of Herrman et al. (284), 14% of patients healed spontaneously, compared with 85% or more who improved with antimalarials (285 ,286). Callen (287) treated 62 patients with discoid lupus at the University of Louisville over a 5-year period, and he reported on 34 who were given hydroxychloroquine. Of these, nine patients were said to have an excellent response, 15 were very good, 6 good, 3 fair, and 1 poor.

Rothfield et al. (288 ,289 ,290) studied the discontinuation of antimalarial therapy on SLE activity in 27 patients who had developed maculoretinopathy. Exacerbations during the 2 years before and 1 year after discontinuation were compared. On this basis, ten patients had more exacerbations during the year after antimalarials were stopped than during either of the 2 previous years while receiving these drugs. Of these, three had no increase in the number of exacerbations, and four had fewer exacerbations after the discontinuation of therapy. The required maintenance dose of prednisone was higher after the discontinuance of antimalarial treatment. The data suggested that chloroquine therapy is a factor in the suppression of disease in ten of 17 patients and is steroid-sparing. Hughes (291) found hydroxychloroquine to be particularly useful for anti-Ro/SSA–positive disease, confirmed its steroid-sparing properties, and advocated combined antimalarial therapy for resistant cases.

Table 59-2: Major Clinical Trials of Chloroquines in SLE

Source	Findings
Ziff et al. (281)	11 of 12 patients had favorable responses; steroid-sparing properties noted
Dubois (282,283)	90% with nonorgan-threatening disease improved with hydroxy chloroquine; over 300 patients treated
Rothfield et al. (288,289,290)	27 patients who stopped chloroquine, because of macular changes had more flares after 1 year than in either of the prior 2 years while taking it
Callen (287)	33 of 34 given hydroxychloroquine for cutaneous lupus responded (9, excellent; 15, very good; 6, good; 3, fair; 1 poor)
Esdaile et al. (293)	47 patients controlled with hydroxychloroquine were given continued therapy or placebo for 24 weeks; treated group had fewer disease flares and severe disease exacerbations
Williams et al. (295)	71 patients in controlled/placebo trial of articular complaints showed subjective joint pain assessment improvement with hydroxychloroquine
Meinao et al. (297)	24 patient, double-blind study in Brazil; chloroquine was steroid sparing and prevented disease flares
Molad et al. (301)	Slows the rate of SLICC/ACR Damage index among 151 patients
Harley & colleagues (300)	When given to those without but early lupus symptoms, delays onset of disease

The Canadian Hydroxychloroquine Study Group (292 ,293) studied 47 patients with SLE whose disease was controlled with hydroxychloroquine and randomized them to either continued hydroxychloroquine or placebo for 24 weeks. The hydroxychloroquine group had significantly fewer disease flares and a lower risk of severe disease exacerbation. A 3-year follow-up study by the group confirmed this. Hydroxychloroquine was felt to have a favorable impact on the morbidity and mortality of the Johns Hopkins Lupus Cohort (294).

Nine centers from the Cooperative Systemic Studies of the Rheumatic Diseases studied hydroxychloroquine versus placebo among 71 patients with mild SLE in a 48-week trial. Patient assessment of joint pain significantly improved, and only two patients withdrew because of adverse effects (295). Similarly, Littlejohn's group in Australia noted only 8% of patients with lupus who were given hydroxychloroquine discontinued the drug at 12 months, and only 24% at 24 months (296). A double-blind study of chloroquine in 44 steroid-dependent patients with SLE found it to be steroid-sparing and to prevent disease flares (297). Petri and Yadia (298) negatively associated hydroxychloroquine use with the development of proteinuria. Ruzicka et al. (299) compared acitretin, a retinoid with hydroxychloroquine in 58 patients with cutaneous lupus. Although the drugs were only given for 8 weeks, 50% in both groups cleared; however, the retinoid group had many more side effects. Hydroxychloroquine may delay the onset of SLE and decrease the rate of increase of the SLICC/ACR damage index (300 ,301 ,302).

Antilupus Actions: Quinacrine with or without Chloroquines

The results of the last quinacrine-alone clinical trial were published in 1961, but between 1940 and 1961, 20 reports on 771 patients were published (54) (Table 59-3). Remarkable for the similarity of their findings, 27% of patients had an excellent response, 46% improved, and 27% did not respond. Cutaneous and constitutional symptoms improved first, and the chloroquines were superior to quinacrine in treating synovitis.

Combinations of chloroquines with quinacrine have shown favorable results. Ten of 14 patients with chloroquine- or hydroxychloroquine-resistant cutaneous disease cleared their lesions when quinacrine was added in one survey (303), and 13 of 15 cleared their lesions in another (304). Toubi et al. (305) confirmed this in 13 patients by lowering Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) scores (306).

Adjunctive Useful Actions of Antimalarials in Patients with Lupus

Antithrombotic Effects

The actions of chloroquines on platelets were reviewed earlier. In 1985, I reported that the antiplatelet effects of hydroxychloroquine were associated with a statistically significant decrease in thromboembolic disease among 92 patients evaluated (307). A follow-up survey suggested that this trend was applicable to patients with anticardiolipin antibody (308 ,309). Petri et al.'s (310 ,311) 393-member lupus cohort has confirmed this in a prospective study, and McCarty and Hellman (312) noted it among 121 patients at the University of Indiana, as did the 384 member LUMINA cohort (313).

Antihyperlipidemic Effects

As discussed earlier, antimalarials have an antihyperlipidemic action. In 1990, our group showed that hydroxychloroquine induced a 15% to 20% decrease in serum

cholesterol, triglyceride, and LDL levels in 150 patients (314) (Table 59-4). These actions might decrease the hyperlipidemic and atherogenic effects of corticosteroids and suggest a greater adjunctive role for hydroxychloroquine. Hodis et al. (315) confirmed these findings, as did Petri et al.'s (316) longitudinal regression analysis among her 264 patient cohort and the results of other investigators (317 ,318 ,319 ,320 ,321 ,322 ,323 ,324), including in children (325). Quinacrine also lowered lipid levels in a double-blind, placebo-controlled trial of 16 patients with diabetes (326). See also Chapter 19 .

Additional Actions: Sjogren, Nodulosis, and Bone Density

Fox (327) found that hydroxychloroquine decreased antibody levels in patients with Sjögren syndrome, most of whom reported less dryness after 1 to 3 years of therapy. Other studies tend to support this (328 ,329). It may also inhibit glandular cholinesterase (330). Reports also have suggested that hydroxychloroquine or chloroquine ameliorate methotrexate-induced rheumatoid nodulosis or liver function abnormalities (51 ,52 ,331) and has analgesic actions (332). Hydroxychloroquine significantly improved autoimmune urticaria in 18 patients (333), and protects against low bone mineral density in SLE patients (334).

In conclusion, in spite of only a small number of well designed controlled studies, it seems to be generally agreed that antimalarials are effective for cutaneous manifestations, polyarthralgia, pleuritis, and low-grade pericardial inflammation associated with SLE. Additionally, some of the associated malaise and lethargy are ameliorated. Antimalarials are of no effect in seriously ill patients with central nervous system involvement, hematologic changes, or renal disease. They help in withdrawing steroid therapy once remission has been induced by steroids and other agents (290 ,335) and may be useful in diminishing the atheroembolic complications of SLE.

Dosage

The dosing schedule used in the treatment of discoid LE varies with extent of the skin lesions and the patient's tolerance of the drugs. Theoretically, it is advisable to begin with a larger initial dosage so that equilibrium can be reached sooner. From a practical standpoint, however, the treatment of discoid LE is not urgent. Although an initial loading dose is advisable for the moderately ill patient with SLE, larger starting doses produce a high incidence of side effects, such as nausea, vomiting, and diarrhea, and therefore discourage the patient from further trials with the drug (336). In our experience, some patients who note cutaneous or gastrointestinal side effects with generic hydroxychloroquine do not have the same problems with brand name Plaquenil (337 ,338).

Hydroxychloroquine usually should be initiated in a dosage of 400 mg daily (given once daily or in 200-mg divided doses). This should approximate 5 to 6.5 mg/kg/day ideal body weight (339). Responses usually begin in 2 to 3 months, but the drug does not reach its peak efficacy for 6 to 12 months. In more urgent situations, 600 mg daily may be given for 1 to 2 months. This is associated with a greater incidence of GI complications and retinotoxicity if used for more than a few months (340 ,341).

Smoking may decrease the effectiveness of hydroxychloroquine in cutaneous lupus (342 ,343 ,344).

Chloroquine usually is given in a dosage of 250 to 500 mg daily; this should approximate 4 mg/kg/day. Chloroquine works within 1 to 2 months but is associated with a 10% incidence of retinotoxicity, compared with less than 3% for hydroxychloroquine (345). Hence, the eyes should be checked at 3-month intervals for patients on chloroquine and at yearly or recommended intervals for those on hydroxychloroquine. Plasma levels do not correlate with efficacy (346). After a response is achieved in 1 to 3 months, maintenance chloroquine dosing should not succeed 250 mg a day.

If additional therapy is required, quinacrine can be added. It has an established synergy with the chloroquines (22 ,54 ,60 ,303 ,304 ,305 ,347). Usually, 100 mg are given daily (although up to 200 mg daily can be administered), but as little as 25 mg may be effective. Occasionally, therapy can be initiated with quinacrine as opposed to the chloroquines when ophthalmologic considerations contraindicate the latter's use. Also, quinacrine is a much greater cerebral cortical stimulant than the chloroquines and is used for patients in whom fatigue is overwhelming (348). Quinacrine is not retinotoxic. Its onset of action is 3 to 6 weeks.

In my experience, at least 95% of patients with skin lesions of discoid LE and SLE show moderate to significant benefit from treatment with antimalarials (349). The most common cause of failure is the physician's impatience in giving the drugs adequate time to work. After 1 to 2 years of therapy, antimalarials can be tapered. Hydroxychloroquine is decreased to 200 mg daily for 3 to 6 months, then reduced by eliminating days of the week (e.g., the next decrement from 200 mg daily would be 5 days a week for 3 months, then 3 days a week). One or two tablets per week may be all that is required to suppress skin lesions, and this helps to minimize toxicity. Chloroquine can be reduced to 1 to 2 tablets a week. The reader is referred to Bernstein (345) for a more detailed discussion of the issues reviewed in this section.

Pregnancy

See Chapter 51 .

Adverse Reactions

Table 59-5 lists the adverse reactions to antimalarials, which are discussed here.

Generalized and Gastrointestinal Reactions and Overdosage

Considering their remittive potential, antimalarial therapies generally are well tolerated when compared with other disease-modifying drugs. In one study, more than 90% of patients who were prescribed hydroxychloroquine for lupus were still taking the drug a year later (296). Approximately 10% of those receiving hydroxychloroquine and 20% receiving chloroquine complain of anorexia, abdominal distention and cramps, heartburn, nausea, vomiting, diarrhea, and/or weight loss. These symptoms are transient, decrease, or disappear with lower dosing or

changing to brand name Plaquenil, and they do not cause long-term sequelae. In Esdaile's group's (336) cohort, 20 of 156 (13%) patients followed for up to 15 years stopped antimalarials due to side effects, half of which were gastrointestinal. Quinacrine may create these symptoms in up to 30% of patients, and diarrhea may be particularly pronounced. It can be alleviated with lower doses or by taking a bismuth suspension (e.g., Pepto-Bismol) with quinacrine. The chloroquines are associated with musculoskeletal, flulike symptoms of aching and fatigue in 5% to 10% of patients, but symptoms resolve within 1 to 2 weeks even if therapy is continued.

Table 59-5: Non-Ocular Toxic Effects of Chloroquine and Hydroxychloroquine

1. Seen in 1%–20% given chloroquine and 1%–10% given hyroxychloroquine
   a. Skin—pruritus, urticaria, morbilliform rash, maculopapular rash, increased skin pigmentation
   b. Gastrointestinal—nausea, vomiting
   c. Nervous system—insomnia, nervousness
2. Seen in <5% given chloroquine and <1% given hydroxychloroquine
   a. Nervous system—neuropathy, hearing change, tinnitus, nervousness, confusion, psychosis, vestibular change, seizure
   b. Skin—dryness, desquamative rash, porphyria, hair loss, hair bleaching
   c. Blood—leukopenia, anemia
   d. Gastrointestinal—anorexia, abdominal distension, heartburn, diarrhea, weight loss, liver function abnormalities

Antimalarials rarely are hepatotoxic (54 ,329). One report of hepatic failure possibly associated with hydroxychloroquine has appeared (350).

As little as 1 g of chloroquine can be fatal to a child, and 3 g can be fatal to an adult. The pills taste bitter, which tends to discourage abuse. Overdoses are managed with mechanical ventilation, epinephrine, activated charcoal, and diazepam (351 ,352 ,353 ,354). Patients have survived up to 22G of hydroxychloroquine as part of an overdose (355 ,356).

Neuromuscular and Cardiac Effects

In 1948, Nelson and Fitzhugh (357) first reported that the chronic administration of chloroquine to rats induces necrosis of cardiac and voluntary muscle. The term chloroquine neuromyopathy has evolved over the years; it is clinically evident in fewer than 1% of those taking chloroquine and has been the subject of fewer than 20 case reports with hydroxychloroquine (358 ,359 ,360 ,361 ,362 ,363 ,364 ,365 ,366 ,367 ,368 ,369 ,370 ,371 ,372 ,373 ,374 ,375). Nord et al. recently reviewed the literature (376). Biopsy findings demonstrate a vacuolar myopathy, myeloid and curvilinear bodies. Patients complain of muscle weakness, numbness, and tingling, and they sometimes have myasthenic symptoms. Active inflammatory myositis, hypokalemia, and steroid myopathy must be considered in the differential diagnosis. A myasthenia gravis–like picture with ptosis occasionally appears, which is reversible with drug discontinuation (377 ,378). The patient may present with an acute polyneuropathy. Peripheral nerves may demonstrate segmental demyelination and cytoplasmic inclusions in Schwann cells (and in perineural and endothelial cells to a lesser extent). Histopathologic investigation of the muscles reveals a vacuolar myopathy, acid phosphatase–positive vacuoles in type I fibers, and lysosomal hyperreactivity with large secondary lysosomes. Electron microscopy reveals electron-dense curvilinear bodies and concentric and parallel lamellae within the muscle (379). Both skeletal and cardiac muscle can be involved. Muscle enzyme levels only occasionally are elevated. Electromyography reveals fibrillations, positive sharp waves, complex, repetitive discharges, and sometimes a myotonia pattern. Dramatic recovery is associated with discontinuation of the drug. Plasma chloroquine levels do not correlate with the clinical or pathologic picture (380). Muscle enzyme levels only occasionally are elevated. This syndrome does not occur with quinacrine.

Rarely, acute urinary retention, heart block, or a congestive cardiomyopathy has been associated with chloroquine, but not with hydroxychloroquine (381 ,382 ,383 ,384 ,385 ,386 ,387).

Cutaneous and Pigmentary Changes

Antimalarials can induce skin dryness, pruritus, pustulosis, porphyria, erythema annulare, urticaria, changes in pigment, rashes, psoriatic flares, and exfoliating lesions (388 ,389). Approximately 3% of patients have to discontinue the drug secondary to adverse cutaneous reactions (378). Psoriatic flares result from the ability of hydroxychloroquine to interfere with epidermal transglumatase activity, which stimulates epidermal proliferation (390). Quinacrine is associated with a lichen planus or eczema-like eruption that, if ignored, can be the first sign in a chain of events that ultimately leads to aplastic anemia. Any rash resulting from quinacrine requires its immediate cessation (54).

Pigment changes occur in 10% to 25% of those who are receiving long-term chloroquine therapy and in a smaller percentage of those taking hydroxychloroquine (391 ,392 ,393 ,394). These adverse effects rarely, if ever, require discontinuing treatment. Gum pigmentation is common (395), and grayness at the roots of scalp hair, eyelashes, eyebrows, and beard may be observed, along with gray streaks in the hair. A blue-black discoloration occasionally is noted on the skin (Fig. 59-2). Chloroquine binds with melanin in vivo and in vitro by the electrostatic attraction of positively charged drug molecules to negative groups of the melanin polymer; this probably is supplemented by van der Waals forces or charge transfer complexes. These changes are reversible when chloroquine therapy is stopped. Nail beds can be affected and appear to be diffusely pigmented (Fig. 59-3) or to display transverse bands.

Chloroquines frequently can cause light sensitivity (396 ,397) or, rarely, porphyria (398) in patients with SLE.

Quinacrine also binds to melanin. Membrane-bound intracellular quinacrine granules combined with large amounts of iron and sulfur produce asymptomatic black-and-blue marks, especially on the shins and hard palate (Fig. 59-4) (399 ,400). Quinacrine also can induce a yellow stain that, like the pigment, is dose related and resolves with cessation of therapy or lowering of the dose. The stain may be evident in up to 30% of patients; it sometimes looks like a suntan and may enhance the patient's appearance (54). All of these changes also are reversible.

Central Nervous System

Quinacrine and, to a lesser extent, the chloroquines, are cortical stimulants. Engel et al.'s (348) classic study documented electroencephalographic patterns that were compatible with pronounced psychic stimulation in a group of healthy volunteers given 200 to 1,200 mg of quinacrine daily for 10 days. Symptoms of fatigue and mental clouding may be ameliorated. On the other hand, excessive dosing can result in psychosis, seizures, and hyperexcitability (54 ,282 ,348 ,401 ,402 ,403 ,404). A 0.4% incidence of reversible, toxic psychosis was reported among 7,604 U.S. soldiers who were given 100 mg of quinacrine daily in World War II and in 28 patients among 30,000 who were treated for malaria (0.1%) (405 ,406). Central nervous system (CNS) complications of chloroquine, such as mania or insomnia, have infrequently been noted in SLE (407 ,408).

Hematologic Toxicity

Hydroxychloroquine has been associated with only one case of agranulocytosis, in a patient who was given 1,200 mg daily (409), which is three to six times the current recommended dose. Chloroquine, but not hydroxychloroquine, has been implicated in some reports with glucose-6-phosphatase deficiency hemolysis (410) and with agranulocytosis (411). Toxic granulation has been observed in the leukocytes of patients receiving long-term chloroquine, which represents large, membrane-bound myelin bodies in mature neutrophils and lymphocyte (412 ,413).

The prevalence of aplastic anemia among U.S. soldiers in the Pacific during World War II increased from 0.66 to 2.84 per 100,000 after quinacrine's introduction (414). This represented 58 patients, 48 of whom received quinacrine. Of these, 16 were associated with overdoses, and two received other marrow-suppressant drugs concurrently. Wallace's review analyzes these cases, reviews the literature, and suggests ways to prevent this from occurring (54 ,415 ,416).

Miscellaneous Effects

Antimalarials may inhibit gastric motility based on their parasympatholytic effects (417), and they may induce hypokalemia (418), and its quinine-like actions are responsible for sensineural hearing loss (419).

Ocular Toxicity

Corneal, Ciliary Body, and Lens Changes

Corneal deposits of chloroquine are observed in 18% to 95% of patients, appear within several weeks, and are symptomatic in 50% of patients (342 ,420 ,421 ,422 ,423 ,424 ,425). Keratopathy is limited to the corneal epithelium; the pattern can vary from punctate opacities to whirling lines. Visual acuity is not reduced, but patients may complain of halos around light sources and of photophobia. No residual damage occurs, and corneal deposits disappear with drug discontinuation and usually are not a reason to stop therapy. Corneal sensation may be decreased by 50% (426). Because recommended chloroquine doses have decreased over the last 30 years, corneal problems now occur less frequently (427). Two studies were unable to find any corneal changes among 164 patients who were given hydroxychloroquine for 3 to 7 years (428 ,429). Easterbrook (430 ,431) reported a 5% to 10% incidence of corneal infiltrates with hydroxychloroquine, but none were symptomatic. A decreased dosage is advised for these patients. Hydroxychloroquine crystals may be seen in the tear film by slit-lamp examination (420). In doses three to six times greater than those currently recommended, quinacrine can induce corneal edema rarely (432 ,433).

Alterations in accommodation and induction of cataracts rarely occur with long-term chloroquine therapy and have not been reported with hydroxychloroquine or quinacrine (424). Patients who discontinue hydroxychloroquine have resolution of keratopathy and the drug can be restarted upon its disappearance without recurrence.

Retinopathy

Since the first report appeared in 1957 (434), approximately 300 cases of chloroquine and hydroxychloroquine retinopathy have been reviewed in the literature. Retinopathy is an often-misunderstood problem that needlessly deters patients from initiating antimalarial therapy. Patients taking chloroquine have an approximate 10% risk for developing retinopathy using appropriate doses, which is usually but not always reversible (345). In 2003 and 2004, Mavrikakis et al. conducted a prospective study and literature review and concluded that “no documented case exists of hydroxychloroquine induced retinopathy in patients who were taking the drug in recommended doses for less than 6 years and had normal renal function” (435 ,436). It was noted in 2003 that 19 cases of confirmed hydroxychloroquine retinopathy had been reported in the literature since 1957. All had abnormal renal function, had taken the drug for more than 6 years, or were dosed using their actual body weight as opposed to their ideal body weight (339 ,340).

Clinical Presentation and Pathophysiology

SLE can induce retinal vascular lesions secondary to disease activity that are unrelated to any form of therapy, and macular degeneration is a common feature of the normal aging process. Thus, it is not always easy to implicate antimalarials as the cause of retinal dysfunction. The chloroquines usually take years to induce pathology, and early retinopathy is asymptomatic. Patients with lupus who are aware of the retinotoxicity of antimalarials often complain of visual symptoms weeks after starting therapy; this can be attributed to corticosteroid or nonsteroidal anti-inflammatory drug (NSAID) treatment, or to psychopathology.

The most common presenting symptoms are difficulty in reading, photophobia, blurred distance version, visual-field defects, and light flashes. Premaculopathy consists of fine pigmentary stippling of that area. Eventually, it becomes surrounded by a zone of depigmentation encircled by an area of pigment, giving a bull's-eye appearance (Fig. 59-5). Rods and cones (which compose the macula) are particularly sensitive to the chloroquines. With more extensive retinal damage, the arterioles show generalized attenuation and segmental constriction with disk pallor. In the periphery

of the fundus, a prominent choroidal pattern and fine granularity of the retina are seen. Many years later, gross pigment changes of hereditary retinal depigmentation may occur, and color vision and the foveolar reflex are lost (424 ,425 ,437 ,438 ,439 ,440).

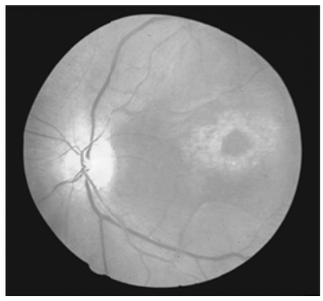

Figure 59-5. Bull's-eye macular pigmentation secondary to hydroxychloroquine (1,200 mg/dL for 15 months in a 90-lb woman).

Several theories account for chloroquine retinopathy. Retinal pigmented epithelial cells perform as macrophages and digest the discarded outer segments of photoreceptor cells as they are physiologically shed. Lysosomal accumulation (discussed earlier) results in an intracellular buildup of lamellar myelin bodies, which leads to scotoma (441 ,442). Alternatively, melanin deposits in the retina produce pigmentation of the rods and cones and of the pigmented cells in the outer nuclear and outer plexiform layers, with resulting pathology (443 ,444). Platelet-activating factor or chloroquine's effect on inhibiting protein synthesis may play a role (445 ,446). Cases of retinopathy have been reported, however, in the absence of pigment deposition (447). Chloroquine, but not hydroxychloroquine, breaks down the blood–retina barrier, as documented by vitreous fluorophotometry (447 ,448).

Important Clinical Studies in Lupus Erythematosus

The incidence of retinopathy has decreased over the last 30 years, because currently recommended doses of both chloroquine and hydroxychloroquine are approximately 50% of the formerly recommended doses. In 1992, Bernstein (449) reviewed all published cases of hydroxychloroquine retinopathy and those reported by the Food and Drug Administration (FDA) between 1960 and 1990. Only 20 patients fulfilled validated criteria. In 15 of the patients, recommended dosing levels were exceeded, and the remaining five patients took the drug for longer than 10 years.

The reader is referred to previous editions of this textbook for a review of 37 studies that review the prevalence and characteristics of retinal toxicity of the chloroquines since 1957 in thousands of patients which are listed here (437 ,438 ,439 ,440 ,441 ,442 ,443 ,444 ,445 ,446 ,447 ,448 ,449 ,450 ,451 ,452 ,453 ,454 ,455 ,456 ,457 ,458 ,459 ,460 ,461 ,462 ,463 ,464 ,465 ,466 ,467 ,468 ,469 ,470 ,471 ,472 ,473 ,474 ,475 ,476). They come to strikingly similar conclusions that are summarized in this section.

Only one case of questionable retinotoxicity has been reported with quinacrine (477). Zuehlke et al. (478) noted no eye toxicity from quinacrine in 26 patients followed at the University of Iowa over a 30-year period and reviewed the literature. None of the 200 patients treated with quinacrine by Dubois or those that I have treated have evolved retinopathic changes (54).

Once the lesion appears, no specific therapy other than cessation of the antimalarial is required. Although antimalarial excretion can be increased by acidification with ammonium chloride, ascorbic acid, or British antilewisite, nothing indicates that the ocular lesion is improved (437). The best and only treatment is discontinuation of the drug if even equivocal changes of retinopathy occur. Mackenzie and Szilagyi (479) suggested that sunglasses may prevent the retinal lesion. They showed that high-dose chloroquine concentrates in melanin in pigment epithelium, blocking the normal light-absorbing action of melanin, and thereby removing its protective mechanism. This has been supported by laboratory studies in rats (480), but it is premature to advocate the use of sunglasses in all patients who are taking antimalarials.

Retinal Testing and Clinical Correlates

Ophthalmologists have many techniques that purport to evaluate retinal and macular integrity and function, but most agree to disagree about the optimal sequence of testing. Helpful reviews of these methods for antimalarial monitoring have been published (424 ,481).

If color vision is abnormal, testing is inexpensive and reliable; some investigators believe it is the most sensitive method (482). The time it takes to recover macular function after illumination of the retina is known as the macular dazzle test. Although it is thought to be prolonged in patients with early antimalarial maculopathy (483), Easterbrook (484) found that it is abnormal in almost all patients who are on antimalarials and does not distinguish those with retinopathy from those without. Fluorescein angiography shows striking macular uptake. Its sensitivity and specificity ratings are disappointing (424), however, and it was less reliable than color vision testing in a controlled, comparative study (482).

Visual field testing, especially if augmented by Amsler grids, is a simple and inexpensive screen for paracentral scotomas (484). Amsler grids can be self-administered and are easily reproducible in cooperative patients, but not always reliable (485 ,486). Electo-oculography (EOG) reflects the metabolic integrity of the retinal pigment epithelium but correlates poorly with macular changes that are induced by chloroquines (487). Electroretinography (ERG) is another technically complex procedure that detects late changes, but it is difficult to interpret in early disease. It can show paracentral loss, foveal loss, peripheral loss, and generalized loss (488 ,489 ,490 ,491). Whether or not it can detect preclinical changes is controversial. Additionally, many nonspecific abnormal readings are noted in normal patients. Dark adaptation testing probably is of little value. One controlled study found contrast sensitivity testing to be superior to pattern visual-evoked potentials and EOG (492). In a fascinating report, a British survey found that rheumatologists could identify 52 of 65 minor retinal changes in patients on chloroquine and concluded that expensive, frequent eye examinations generally are unnecessary (493). Table 59-6 provides a summary of, and our group's recommendations for, eye toxicity in antimalarials.

When Is Retinal Testing Cost Effective?

Rynes et al. (494) estimated that $20 million is spent on retinal testing in the United States for patients taking hydroxychloroquine each year. Two groups have suggested that $126,000 to $200,000 is spent on biannual exams or $74,000 on annual exams to pick up each case of retinopathy (472 ,495).

Table 59-6: Eye Toxicity from Antimalarial Medications

Cornea	Symptoms of photophobia and halos around light sources, decrease in sensation
	Usually mild and can come and go; rarely requires drug to be stopped
	These changes are always reversible with drug cessation; no permanent damage reported
	Chloroquine: noted in 50%
	Hydroxychloroquine: found in 5%–10%
	Quinacrine: reported in 5%
Retina	Melanin deposits or lamellar myelin bodies in retinal pigmented epithelial macrophages
	Clinically presents as scotomas; especially targets rods and cones
	Must be differentiated from macular degeneration associated with aging
	Chloroquine: found in 10% after 10 years of continuous use; can be irreversible
	Hydroxychloroquine: found in <3% after 10 years of continuous use; always reversible if doses of <6.5 mg/kg/day used with lean body weight and patient not in kidney failure
	Quinacrine: not reported

Published Guidelines for Retinal Testing

The Physician's Desk Reference (PDR) recommends quarterly eye examinations for both chloroquine and hydroxychloroquine (496). The American Academy of Ophthalmology (AAO) assembled a task force to develop more realistic screening recommendations that would be in accordance with both modern knowledge and the economic realities of practice (497 ,498). Noting that there are extremely infrequent reports of toxicity in individuals taking more than 6.5 mg/kg/day of hydroxychloroquine or 3 mg/kg/day of chloroquine for less than 5 years, they advised dividing patients into low- and high-risk groups. The latter consists of those taking the drugs for more than 5 years, those older than 60 years of age, or individuals with a high body fat level, renal or hepatic disease. All patients should have a baseline ophthalmologic exam and visual field testing. Low-risk patients do not need to be re-evaluated for 5 years. Patients at higher risk should be evaluated annually. A Canadian Concensus Conference recommended similar testing for all patients on hydroxychloroquine at 12- to 18-month intervals (499). A United States consensus conference recommended annual eye examinations in low-risk individuals on hydroxychloroquine therapy who have been on the drug for less than 10 years in doses of 6.5 mg/kg/day or less (500).

Thus, the PDR guidelines, which were written in the 1950s and have not been revised since, do not reflect the experience of several million patients who have taken the drug, and this writer feels comfortable with more recent recommendations.

Summary

- Three antimalarials that are commercially available in the United States have documented efficacy in the treatment of lupus erythematosus: chloroquine, hydroxychloroquine, and quinacrine.
- These agents are recommended for patients with non–organ-threatening lupus who require more than sunscreens, steroid salves, or NSAIDs.
- Chloroquines are most effective for treatment of the following features of LE (in decreasing order): cutaneous lesions, arthritis-arthralgias, fatigue, and serositis. Chloroquine is more powerful than hydroxychloroquine. Quinacrine is most effective for the following (in decreasing order): cutaneous lesions, fatigue, arthritis-arthralgias, and serositis.
- Chloroquine and quinacrine are effective in 1 to 2 months; hydroxychloroquine often requires a 3- to 6-month wait. Chloroquines and quinacrine are synergistic and can be combined.
- Antimalarials work by turning off antigen processing by raising intracytoplasmic pH. They also work by blocking damaging UV light, suppressing immune reactivity, promoting apoptosis, inhibiting antibody formation, and blocking prostaglandin and leukotriene synthesis by the inhibition of phospholipase A2. They also inhibit platelet aggregation and adhesion, decrease membrane receptor sites because of lysosomal membrane accumulation, and are antimicrobial and antiproliferative.
- Steroid-sparing actions also have been documented.
- Higher dosing can cause a faster response but also greater toxicity.
- Generalized gastrointestinal and musculoskeletal complaints are reversible and usually minor. The only serious complication of the chloroquines is retinotoxicity, which is observed in 10% of patients on chloroquine and in less than 3% of those on hydroxychloroquine. This can be minimized by frequent eye examinations and the use of hydroxychloroquine. Irreversible retinal changes have never been reported in a patient with lupus who was taking hydroxychloroquine in recommended doses for up to 6 years with normal renal function and undergoing eye checks every 6 months (501). Quinacrine is not retinotoxic, but blood counts need to be monitored because it can cause aplastic anemia (rarely).

Chapter 60

Systemic Glucocorticoid Therapy in Systemic Lupus Erythematosus

Kyriakos A. Kirou

Dimitrios T. Boumpas

Phillip Hench was the first to introduce glucocorticoids (GC) into clinical medicine when he successfully treated a patient with rheumatoid arthritis (RA) in 1949 (1). The long record of GC in the management of rheumatic diseases testifies to their clinical usefulness. However, GC benefits occur at a high cost of serious side effects. Therapeutic strategies aiming to decrease exposure to GC are, therefore, imperative. The treating physician, optimally a rheumatologist with experience in the management of SLE (2), should carefully evaluate the patient and attempt to distinguish inflammation because of disease flare from infection, thrombosis, and drug (including GC) adverse effects. Combination therapies of GC with other immunosuppressive or anti-inflammatory agents can help achieve disease control with less exposure to GC. Hopefully, future research on both SLE pathogenesis and mechanisms of GC action will add safer and more effective therapies to our armamentarium against SLE.

In this chapter we will briefly review the basic pharmacology of endogenous and synthetic glucocorticoids, the mechanisms of their action at the molecular level, and their anti-inflammatory and immunosuppressive effects. Next, the pharmacokinetics and drug interactions of GC will be discussed, and the authors' opinions regarding their use in SLE will be presented. Lastly, adverse effects of GC with relevance to SLE will be analyzed, and the glucocorticoid withdrawal syndrome will be briefly reviewed.

Endogenous and Synthetic Glucocorticoids

Steroidogenesis in the adrenal cortex produces endogenous glucocorticoids, mineralocorticoids (MC), and adrenal androgens (3 ,4). Cortisol (hydrocortisone) is the main human endogenous GC and is secreted primarily in response to adrenocorticotropic hormone (ACTH). Secretion follows a circadian rhythm that achieves maximum plasma concentration at 8 A.M (16 μg/dL) (3 ,4 ,5). However, in the context of stressful stimuli and hypothalamic-pituitary-adrenal (HPA) axis stimulation, these levels can increase to more than 60 μg/dL losing their diurnal variation (5 ,6). The ability of an organism to maintain appropriate GC levels before and during stress is quintessential for its survival (7 ,8).

Synthetic GC, more potent and with less mineralocorticoid effects than cortisol, have been developed. Figure 60-1 shows the biochemical structure of cortisol and synthetic GC; Table 60-1 compares their pharmacological properties. Regulatory mechanisms of synthetic GC with regard to binding to the corticosteroid-binding globulin (CBG), tissue specific metabolism, affinity for GC receptors (GR), and interaction with transcription factors may substantially differ from those of native GC (4 ,9 ,10).

The great need for improved synthetic GC with less adverse effects and intact anti-inflammatory/immunosuppressive action has led to the development of newer synthetic GC, by modifying their pharmacokinetic or pharmacodynamic properties. With regard to the first, GC with high topical activity, but low systemic bioavailability because of rapid first-pass liver inactivation such as budesonide, have been designed. Thus, by design, this agent is suitable only when topical anti-inflammatory action is desired such as in asthma (given by inhalation), and in active Crohn's disease (orally) (11 ,12). Of more interest to rheumatology is the development of liposomal glucocorticoids by encapsulating GC in polyethylene glycol (PEG)-coated liposomes. Since liposomes are preferentially phagocytosed by activated macrophages and PEGylation limits their removal by the mononuclear phagocyte system in liver and spleen, these GC are able to remain in the circulation for prolonged periods of time and target inflamed tissues efficiently. A single dose of liposomal GC strongly inhibited inflammation in collagen type II arthritis for 10 days with evidence of localization in the synovial lining of only the affected joints (13). With regard to pharmacodynamics, substantial progress has been made in the development of synthetic GC that dissociate their potent activator protein-1 (AP1) and nuclear factor κB (NF-κB) transrepression activities (anti-inflammatory) from their weak transactivation ones (see below) that are likely responsible for GC adverse effects (14 ,15 ,16). Another category are the nitric oxide (NO) glucocorticoids that take advantage of the synergistic (to the GC) anti-inflammatory effect of NO, as well as the fact that these agents induce tyrosine nitration of the GC receptor (GR), which further enhances their anti-inflammatory effects (17).

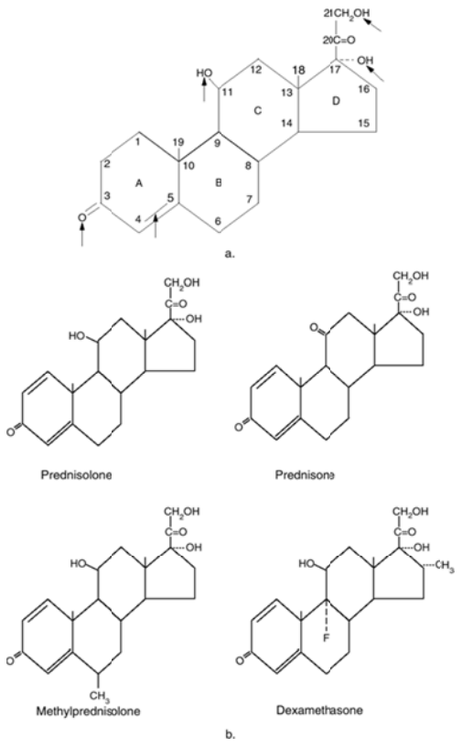

Figure 60-1. A. Structure of cortisol (hydrocortisone). All Δ4 double bond, 3-keto group, and 11ß-OH group are essential for glucocorticoid function and the first two are also required for mineralocorticoid activity. The hydroxyl group at C21 is required for mineralocorticoid activity and is present on all natural and synthetic GC. The 17α-hydroxyl group, present on cortisol and synthetic GC (but not on corticosterone), enhances GC potency. **B.** Structure of selected common synthetic GC. The addition of a Δ1 double bond on cortisol (as in all shown GC) selectively increases glucocorticoid activity and delays GC metabolism. The methyl group at position 6α (methylprednisolone) increases GC, over MC, activity even further. Notably, fluorination at the 9α position (fludrocortisone; not shown) greatly enhances GC and MC activity (the latter much more than the former). However, when modified with a Δ1 double bond and a methyl group substitution at C16α, fludrocortisone loses all MC activity and becomes dexamethasone.

Molecular Mechanisms of Glucocorticoid Action (see Table 60-2)

Glucocorticoid effects are mainly mediated via specific GC receptors (GR). These are conspicuous cytoplasmic proteins and operate as hormone-activated transcriptional regulators (reviewed in (18 ,19 ,20)). Hydrocortisone and some other GC are also capable of binding mineralocorticoid receptors (MR) with higher affinity than they bind GR and mediating aldosterone-like effects (Table 60-1). GR specificity, at the relatively low baseline body cortisol levels, is maintained because of the action of 11-β-hydroxysteroid dehydrogenase2 (11-β-HSD2), a steroid metabolizing enzyme expressed at MC-sensitive tissues (i.e., the kidney). 11-β-HSD2 metabolizes hydrocortisone to its inactive 11-keto derivative (cortisone) (3 ,4 ,7).

Table 60-1: Relative Biologic Potency and Pharmacokinetics of Selected Glucocorticoids (GC)

GC	Genomic Anti-Inflammatory	Mineralocorticoid Activity	Half-Life (Minutes)	Biologic Half-Life (Hours)
Cortisol	20	1	60	8–12
Cortisone	25	0.8	60	8–12
Prednisone	5	0.8	180	12–36
Prednisolone	5	0.8	180	12–36
Methylprednisolone	4	0.5	180	12–36
Triamcinolone	4	0	180	12–36
Dexamethasone	0.75	0	220	36–72

Table 60-2: Mechanisms and Examples of Anti-Inflammatory and Immunosuppressive Actions of GC

A.	Transrepression through protein-protein cross-talk: activated glucocorticoid receptor (GR) monomers interact and inhibit proinflammatory transcription factors. Mainly NF-κB is affected, but also AP1, NFAT, and so on with end result the transcriptional inhibition of:  1. Cytokines: IL1-β, IL2, IL4, IL5, IL6, IL12, TNF, GMCSF, etc. 2. Chemokines: IL8, MCP-1, MIP1-α, eotaxin, etc. 3. Proinflammatory enzymes: iNOS, COX2, collagenase. 4. Adhesion molecules: ICAM1, E-selectin, etc.
B.	Transactivation of anti-inflammatory genes through binding of activated GR dimers to glucocorticoid responsive elements (GRE) on the corresponding gene promoter or enhancer regions.  Annexin-1 (Anx1 or lipocortin-1; a phospholipase A2 inhibitor), IκB (inhibitor of NFκB), IL1 receptor antagonist (IL1Ra; inhibitor of IL1-β), MAPK phosphatase-1 (MKP1), secretory leucocyte inhibitory protein (SLPI), neutral endopeptidase, IL10, etc.
C.	Post-transcriptional effects through inhibition of p38 MAPK. Probably mediated through induction of MKP1 and inhibition of p38 MAPK (see B) Decreased mRNA stability of cytokines, COX-2, iNOS.
D.	Rapid nongenomic effects through cytoplasmic GRE. Activation of enthothelial NOS (eNOS) and generation of NO through GR-mediated activation of phosphatidylinositol 3-kinase (PI-3K) and protein kinase Akt. Rapid phosphorylation of Anx1 and blockade of activation of cytoplasmic PLA2 by growth factor receptors.
E.	Rapid nongenomic effects through membrane GR.
F.	Rapid nonspecific effects through physicochemical interaction with cell membranes. These are thought to occur at pulse IV doses of GC. Disruption of calcium and sodium cycling with low intracellular calcium levels, as well as mitochondrial proton leak, probably contribute to rapid GC-mediated immunosuppression.

Anx1, annexin-1 (or lipocortin-1); AP1, activator protein-1; COX-2, cycloxygenase-2;GMCSF, granulocyte-macrophage colony-stimulating factor; ICAM1=intercellular cell adhesion molecule-1, IκB=inhibitor κB; IL, interleukin; iNOS, inducible nitric oxide synthase; MAPK, Mitogen-activated protein kinase; MCP-1, monocyte chemoattractant protein-1; MIP1α, macrophage inflammatory protein-1a, NFAT, nuclear factor of activated T cells; NF-κB, nuclear factor κB; NO, nitric oxide; PLA2, phospholipase A2; TNF, tumor necrosis factor.

Glucocorticoid receptors, when inactive, are bound to several receptor associated proteins (RAP) including the heat shock proteins HSP90 (of critical role in GR ligation and activation) and HSP70, immunophilins (IP), and the Src kinase of the mitogen activated protein kinase (MAPK) signaling pathway (18 ,19 ,20). Upon GC binding, GR dissociate from these proteins and translocate to the nucleus. There they mediate their effects mainly via two mechanisms (see Table 60-2):

- They form homodimers and bind to glucocorticoid responsive elements (GRE) on gene promoters and enhancers with positive (i.e., annexin-1 [Anx1] (21), and IκB (22 ,23)) and negative gene transcription effects (i.e., osteocalcin; (24 ,25)). Notably, such GRE-mediated (transactivation) effects have also been implicated in neoglycogenesis, by means of inducing the transcription of phosphoenolpyruvate carboxykinase (PEPCK), and glucose-6-phosphatase, and therefore, in diabetogenesis. Moreover, transactivation of phosphatases can indirectly lead to decreased mRNA stability of cytokines and inducible enzymes (26 ,27 ,28 ,29) (Table 60-2).
- Alternatively, activated GR monomers are able to transrepress the function of other transcriptional factors like NF-κB (15 ,30), AP1 (31 ,32 ,33), and signal transducers and activators of transcription (STATs) (34) through direct protein-protein "cross-talk."

The recent development of transgenic mice that express a homodimerization deficient GR (GRdim/dim) has helped address the hypothesis that anti-inflammatory effects of GC are primarily mediated by transrepression, whereas adverse effects by transactivation (35). In these mice GR cannot form dimers and thus cannot have GRE-mediated effects. However, the same GR in their monomeric form can transrepress NF-κB and AP1. Indeed topical dexamethasone (DEX) inhibited PMA-induced skin inflammation and endogenous GC terminated LPS-induced systemic inflammation in these mice as well as it did in wild type mice. Additionally, inflammatory cytokines were strongly inhibited in macrophages and T cells from these mice in vitro and NFκB was inhibited without a parallel IκB induction. A more recent study described the use of ZK 216348, a nonsteroidal selective GR agonist (SEGRA) with dissociated activity for transrepression (potent) and transactivation (weak) in a mouse model of skin inflammation (16). The compound showed comparable anti-inflammatory activity to prednisolone, but markedly less increases in blood glucose levels and somewhat less skin atrophy. However, ACTH suppression was similar with the two agents.

Besides having GR-mediated transcriptional genomic effects that depend on new protein synthesis and therefore have a delayed onset (at least 30 minutes), GC may have more rapid (seconds or minutes) nongenomic effects (36 ,37 ,38 ,39) (Table 60-2). These GC effects usually occur at relatively large pharmacologic or pulse GC doses and can be either cell surface receptor-mediated and therefore specific, or initiated by physicochemical interactions (mainly with pulse GC) with cellular membranes and nonspecific (36 ,37). Membranous GR-mediated effects have been described in amphibian brains (40), and these receptors have been recently identified on human peripheral blood mononuclear cells (PBMC) by an ultrasensitive flow cytometry immunofluorescence technique (41). On the other hand, inhibition of cation cycling and respiration in concanavalin A-stimulated rat thymocytes constitute nonspecific GC effects (36 ,37). Interestingly, DEX and methylprednisolone (MP) are 5 and 3.3 times, respectively, more potent than prednisolone as far as these high-dose nonspecific nongenomic effects are concerned (42 ,43).

Anti-Inflammatory and Immunosuppressive Effects

The biologic effects of GC are multiple, affect all tissues, and are essential for body homeostasis during normal or stress conditions. Although, in clinical medicine, GC are used to suppress inflammation and pathologic immune responses, a growing number of studies "paradoxically" attributes immune enhancing effects to these agents (7 ,9 ,10 ,42 ,44 ,45 ,46). It seems that endogenous GC have an important overall regulatory role in modulating immune responses that develop to such stressors as infections. For example, GC on one hand act permissively to help immune responses develop adequately and in a timely fashion in order to fight the invading organisms and on the other, act suppressively to restrain a potentially deleterious "overshoot" of those same responses (7). Parameters that determine the direction of GC immune effects include primarily the serum levels and timing of GC exposure relative to the initiation of stress. Higher (pharmacologic) levels such as those occurring after the initiation of stress are in general immunosuppressive, whereas lower physiologic levels of GC present before stress initiation may enhance immune responses. Notably, acute stresses (or short exposure to GC) enhance immune responses, whereas chronic exposure to stress or GC has the opposite effect (44). Endogenous GC (cortisol) appear to mediate both types of effects. DEX, however, a synthetic GC, mediates predominantly immunosuppressive effects, a phenomenon that may be explained by DEX's inefficient binding to CBG, its longer half life, its higher affinity for GR and absence of MC effects (Table 60-1) (9 ,10 ,44). The immune-enhancing GC effects may be mediated through MR. Augmentation of T-cell proliferation to antigenic stimuli (46), of lymphocyte trafficking to skin and regional lymph nodes (during a DTH response) (44), of cytokine production (including macrophage migration inhibitory factor or MIF) (45 ,47), as well as synergy with different cytokines (such as with IL6 in the induction of acute phase responses) and upregulation of cytokine receptors (7 ,9 ,10) and CD40L (48) are some of these effects.

The anti-inflammatory effects of GC (Tables 60-2 and 60-3) are complex, mediated via their GR and correlate with dose and duration of GC treatment. At the level of blood vessels, GC inhibit vasodilatation and vascular permeability, limiting therefore erythema, plasma exudation, and swelling.

The inhibitory GC effects on the upregulation of the inducible nitric oxide synthase (iNOS), and therefore NO synthesis, by TNF, IL1-ß, and IFN-γ (49) may contribute to this effect. Neutrophils are affected primarily in their ability to migrate to inflammatory sites. This effect is probably due to inhibition by GC of chemokine synthesis (i.e., IL8) (50) and adhesion molecule expression (ICAM1, E-selectin) (51) and induction of annexin I (Anx1 or lipocortin-1) (52 ,53). In patients with RA, inhibition of neutrophil ingress into inflamed joints was seen as early as 90 minutes after pulse GC therapy (54), and was associated with rapid modulation of adhesion molecules and inflammatory mediators in the joints (54 ,55). Inhibition of synthesis and secretion of inflammatory mediators by the different cells involved in the inflammatory reaction (such as monocytes-macrophages, fibroblasts, and endothelial cells) is central in the action of GC. Eicosanoid generation is inhibited by GC through induction of transcription and/or rapid phosphorylation of Anx1, which is a potent inhibitor of phospholipase A2 activity (21 ,38 ,56), and inhibition of IL1-ß (or LPS)-mediated cyclooxygenase-2 (COX-2) induction (57). Additionally, destructive tissue enzymes such as collagenase are downregulated by GC (32 ,33). Inhibition of cytokine generation constitutes another important anti-inflammatory effect. Specifically, synthesis (and sometimes action) of IL1ß, IL2, IL3, IL4, IL5, IL6, IL8, IL12, TNF, GMCSF, IFN-γ, RANTES, and MCP1, etc. is blocked (15 ,27 ,30 ,50 ,58 ,59). On the other hand, synthesis of IL10 and TGF-ß cytokines considered to have anti-inflammatory properties, is either not affected or induced (60 ,61 ,62). The differential effects of various GC therapeutic regimens on cytokine production have been elegantly shown in human arteritis-severe combined immune deficiency (SCID) mice chimeras by Brack et al. (61). SCID mice engrafted with human temporal arteries were studied with regard to the effects of in vivo intraperitoneal GC therapy on inflammation of the temporal arteries. Doses of 0.04 and 0.4 mg DEX/kg for 7 days induced IκB transcription, inhibited nuclear NF-κB protein expression, and decreased transcription of the NF-κB-regulated genes iNOS, IL1ß, IL2, and IL6. Inhibition of IFN-γ (AP1-dependent) could only be achieved by high doses of DEX (4 mg/kg for 7 days) or chronic therapy (0.4 mg/kg for 28 days), whereas TGF-ß transcription was not inhibited by any DEX regimen. Interestingly, in a follow-up study, aspirin was much more potent than GC in inhibiting AP1 and IFN-γ (63).

Table 60-3: Important Anti-Inflammatory and Immunosuppressive Effects of Glucocorticoids

A. Anti-Inflammatory Effects
   1. Inhibition of blood vessel dilatation and permeability (i.e., because of downregulation of NO synthesis).
   2. Inhibition of neutrophil and monocyte migration to periphery (probably via inhibition of chemokine synthesis and adhesion molecule expression in leukocytes and endothelial cells).
   3. Inhibition of synthesis of inflammatory mediators such as eicosanoids by downregulating phospholipase A2 (via Anx1 induction) and COX-2.
   4. Downregulation of destructive enzymes (i.e., collagenase).
   5. Alteration of cytokine balance in favor of anti-inflammatory cytokines (i.e., IL10, TGF-ß) whereas proinflammatory cytokines (i.e., TNF, IL1-ß, GMC-SF) are suppressed.

B. Immunosuppressive effects*
   1. Lymphopenia** (T cells affected more than B cells and CD4 T cells more than CD8 T cells). Probably because of lymphocyte redistribution (mainly to bone marrow and spleen) and perhaps apoptosis.
   2. Inhibition of signal transduction events critical for T-cell activation (i.e., early tyrosine phosphorylation, CaM-kinase II activation, calcineurin-dependent transactivating pathways).
   3. Inhibition of IL2 synthesis and signaling.
   4. Downregulation of cell surface molecules (i.e., LFA1, CD2) important for full T-cell activation and function.
   5. Inhibition of antigen-presenting cell function (by blocking cell surface expression of MHC class II and CD80 molecules). Depletion of plasmacytoid dendritic cells and production of interferon-alpha.
   6. Deviation of immune responses towards a Th2-type cytokine formation (by preferentially inhibiting synthesis of IL12 over that of IL4 and IL10).
   7. Induction of T-cell apoptosis (of questionable contribution to GC-mediated immunosuppression).

CaM-kinase II, Ca^{2+}/calmodulin–dependent protein kinase II.

*Immunosuppression concerns primarily the cellular and less so the humoral immunity and is more evident with intermediate to high doses of glucocorticoids.

**When lymphopenia is associated with lymphocyte migration towards the regional nodes of inflammation, it represents immune enhancement rather than immunosuppression (see text for discussion).

Although GC induce peripheral neutrophilia, by reducing neutrophil migration to tissues, the peripheral numbers of eosinophils, basophils, monocytes, and lymphocytes decrease upon even a brief exposure to GC (18 ,19 ,20). Lymphopenia has been attributed to redirection of lymphocytes to bone marrow and spleen (64 ,65 ,66), but also to the

skin and regional lymph nodes of inflammation sites (44). T-cell numbers decrease more than B cells and CD4 T cells more than CD8 T cells (66). GC immunosuppression is mediated by inhibition of several stages of T-cell activation, including early tyrosine phosphorylation events (67), activation of $Ca2^{+}$/calmodulin-dependent protein kinase II (CaM-kinase II) (68), and calcineurin-dependent transactivating pathways (69 ,70). As already mentioned, GC inhibit IL2 synthesis, which is critical for T-cell proliferative responses (28 ,71), and additionally inhibits signaling of this cytokine (67 ,72). Downregulation of LFA-1, CD2, c-myc, and induction of cAMP (by inhibiting phosphodiesterase activity) further contribute to T cell dysfunction (73). Glucocorticoids also affect T-cell function indirectly by inhibiting the expression of MHC class II and CD80 molecules on antigen-presenting cells and by decreasing the number and IFN-α synthetic capacity of plasmacytoid dendritic cells (19 ,74). With regard to IFN-α, we and others have also noted a profound downregulation of IFN-α–inducible gene mRNA in PBMC from SLE patients after their treatment with PGC (75 ,76). Notably, B-cell function and immunoglobulin synthesis are relatively resistant to the immunosuppressive GC effects. Glucocorticoids have also important effects in shaping the developing immune responses as they favor deviation to Th2-type cytokine formation by preferentially inhibiting IL-12 synthesis and sparing IL-4 and IL-10 (62 ,77 ,78 ,79). This effect might suggest that these agents are more potent in the treatment of diseases characterized by Th1-type cytokine predominance, like RA. They also promote IgE synthesis in the presence of IL4 through induction of CD40 ligand (CD40L) (48).

The ability of GC to induce apoptosis of double-positive thymocytes (77) and activated mature T cells (80) correlates with low cellular levels of bcl-2 and appears to have important implications for maintenance of central and possibly peripheral tolerance as well (77). Interestingly, TCR-mediated activation-induced cell death (AICD) and GC-mediated apoptosis are mutually antagonistic, an effect that may be in part a result of downregulation of Fas ligand by GC (77 ,81). The degree to which GC-mediated apoptosis contributes to immunosuppression is not known, however. Seki et al. correlated clinical resistance to GC in SLE patients with decreased in vitro apoptosis of anti-CD3 activated PBMC (82). In another study, γ/δ T cells, that may be implicated in SLE pathogenesis, showed increased in vitro susceptibility to GC-mediated apoptosis (without requiring previous activation), and their in vivo downregulation by GC therapy correlated with disease control in SLE patients (83). Tables 60-2 and 60-3 summarize anti-inflammatory and immunosuppressive effects of GC.

Glucocorticoid Resistance

Pharmacokinetic causes of resistance to GC may include impaired oral bioavailability because of decreased GC absorption (i.e., by cholestyramine), or increased GC metabolism (i.e., by hyperthyroidism or drugs, such as barbiturates) (84). Additionally, decreased reactivation of cortisone to cortisol, because of reduced activity of 11-β-HSD1 in RA synovial cells, has been reported and the defect was hypothesized to be a result of the loss of sympathetic nerve fibers in the synovial tissue (85).

With regard to pharmacodynamic causes, resistance to endogenous GC can rarely occur in the generalized inherited glucocorticoid resistance (GIGR) syndrome characterized by GR abnormalities, high plasma cortisol levels, and the absence of Cushing syndrome symptoms (86 ,87 ,88). The opposite picture, increased primary GC sensitivity, has also been noted (86). Additionally, an acquired GR abnormality has been observed in a subset of AIDS patients that present with Addisonian symptoms and hypercortisolism (89). The acquired, tissue-specific GC resistance, which is clinically more important, has been studied best in steroid-resistant bronchial asthma, where the lack of GC benefit on airway inflammation contrasts with a high incidence of GC adverse effects from other organs (90). Cytokines, secreted in the context of such diseases as bronchial asthma, rheumatoid arthritis, SLE, and depression, are thought to play an important role in mediating tissue-specific GC resistance by inhibiting GR function. One way by which cytokines do that is perhaps the augmentation of the overall cellular activation level. For example, T cells costimulated by IL2 or CD28, in contrast to those only triggered through their antigen receptor, are resistant to GC-mediated inhibition of proliferation (91). This phenomenon was though to be a result of the potent induction of c-Fos (which together with c-jun form AP1) by the two costimuli. Notably, AP-1 has been reported by others to be mutually antagonistic with GR for transactivation effects (32 ,33). Additional proposed mechanisms of tissue-specific GC resistance include IL2-mediated induction of p-glycoprotein (P-gp) (92), inhibition of GR translocation, and induction of the beta isoform (GRß) of GR via alternative splicing of the GR pre-mRNA (90 ,93). GRß has been proposed as an important inhibitor of the functionally active GRα (94).

In SLE, increased catabolism of hydrocortisone by lymphocytes (95) and resistance to GC-mediated apoptosis of $CD8^{+}$ T cells have been proposed as mechanisms of GC resistance (82). More recently, high levels of P-gp (the product of the multidrug resistance-1 [MDR1] gene) were noted on lymphocytes of patients with active SLE who were resistant to high doses of prednisolone (96). Steroid-exclusion analysis revealed low intracellular DEX levels in lymphocytes form these patients. GC resistance was reversed after intensive immunosuppressive therapy, and in one case only by cyclosporine-A, which functions as a competitive inhibitor of P-gp.

Pharmacokinetics and Drug Interactions

Oral absorption of GC is excellent. Prednisone (PDN) is 80% to 90% absorbed when orally administered, whether on an empty or full stomach. Once systemically absorbed, a large fraction of GC (90% for hydrocortisone) binds to serum proteins and only their free fraction is biologically active (3 ,4). Of the two GC binding proteins, transcortin, or cortisol-binding protein (CBG), binds to GC with high affinity and low capacity, whereas albumin binds with low affinity and high capacity. Since hydrocortisone and prednisolone bind to both CBG and albumin their protein binding is concentration-dependent and varies from 90% at lower doses (i.e., with standard oral doses) to 60% at higher doses. In contrast, MP and DEX bind almost exclusively (99%) to the high-capacity albumin, and, therefore, have concentration-independent protein-bound fractions (. The difference in the plasma free concentrations of DEX and prednisolone at standard oral doses may explain the better CSF penetration and better efficacy of the former in the preventive therapy of meningeal leukemia (97). The 11-keto GC derivatives such as PDN and cortisone are inactive unless reduced by 11-ß-HSD1 in the liver to their 11-OH analogs prednisolone and hydrocortisone (Fig. 60-1) (3 ,4). Inactivation of GC occurs predominantly in the liver and involves the sequential reduction of the Δ4 double bond (the rate-limiting step in cortisol metabolism), and the 3-keto group (Fig. 60-1). Glucuronidation and sulfation follow, which confer water solubility and allow for urine excretion. Additionally, 6ß-hydroxylation by the cytochrome P450 microsomal enzyme, CYP3A4, also enhances water solubility and urinary excretion of GC. Serum half-lives of different GC differ and vary from 60 to 300 minutes. However, biologic half-lives of GC are dependent on their tissue levels and are much longer than their serum half-lives (Table 60-1).

Since, in liver failure, decreased conversion of PDN to its active form (prednisolone) is overcompensated by reduced clearance of unbound prednisolone (resulting in higher prednisolone concentrations after oral PDN administration), there is no reason to substitute PDN with another inherently active GC agent in these patients. Additionally, low serum albumin does not seem to decrease the unbound concentration of prednisolone, and therefore, (mild) dose adjustments of GC should be based only on the lower clearance of these agents in liver failure and not on the albumin levels per se (reviewed in (98)).

In addition to the above mentioned inhibition of enteric GC absorption by cholestyramine, other important drug interactions also exist. Drugs that induce hepatic microsomal enzymes (especially CYP3A4), such as phenobarbital, phenytoin, rifampin, and carbamazepine, increase GC elimination. In contrast, ketokonazole, erythromycin, ethynylestradiol, and norethindrone inhibit CYP3A4 and can increase GC activity. Mifepristone (RU 486), an antiprogestin drug marketed as an abortifacient outside the United States, has potent antiglucocorticoid properties (at the level of GR) as well (99). Conversely, GC can also reduce the serum level of salicylates (100) and CYP3A4 substrates. Additionally, pulse GC have been recently shown to significantly increase INR, 2 to 6 days after their administration, in patients on oral anticoagulation therapy (101).

Pharmacodynamic interactions include the GC sparing effect of theophylline, and long-acting ß-receptor agonists in asthma (102). More relevant to lupus, Kammal et al. recently used phytohemagglutinin-treated T cells from SLE patients to study the interactions of prednisolone and other commonly used immunosuppressive agents (103). They noted additive effects of dehydroepiandrosterone (DHEA), synergy with tamoxifen, and slight antagonism with mycophenolic acid. Other studies have shown synergy with cyclosporine-A and sirolimus (104). Again, aspirin at anti-inflammatory doses, but not indomethacin, can complement the anti-NF-κB GC activity with anti-AP1 activity in a mouse model of temporal arteritis (63).

General Principles of Glucocorticoid Therapy

Uncontrolled disease activity in SLE can be both debilitating and life-threatening and thus demands rapid and effective intervention. The value of therapy with high doses of GC (i.e., more than 0.6–1 mg PDN/kg/day) in dramatically improving SLE survival has been established (already by data from the predialysis era) in patients with diffuse proliferative glomerulonephritis (DPGN) (105 ,106). Subsequent studies focused on evaluating different strategies of GC use in order to maintain high effectiveness and yet reduce the risk of the increasingly apparent grave adverse effects. Although parenteral corticotrophin (ACTH) has been used clinically as a substitute to GC (i.e., acute gout), there are no obvious advantages of such practice and no studies in SLE. With regard to dosage, ample evidence exists that high GC doses (especially when time intervals between doses are small) for prolonged periods of time are invariably toxic. In fact, Sergent et al. have shown increased infection-related mortality in patients with severe neuropsychiatric SLE (NPSLE) when treated with PDN doses of more than 100 mg/day, for 37 days on average (range, 8–68 days) (107). On the other hand, low-dose GC (LDGC) therapy (dose equivalent to ≤7.5 mg/day of PDN) appears to be better tolerated but not risk-free, since complications such as growth suppression, osteoporosis, and cataract formation can still occur. Therefore, the ultimate goal of therapy should always be complete cessation of GC, if possible.

Alternate day GC therapy (ADGC) also has a better safety profile compared to that of daily GC regimens. The incidence of skeletal growth inhibition, HPA-axis suppression, hypertension (HTN), Cushing syndrome, hypokalemia, overcatabolism, myopathy, and infection have been noted to be reduced (108). However, ADGC effectiveness is less and, excluding perhaps membranous nephritis with nephrotic syndrome, its use should be restricted to GC-tapering or maintenance regimens.

Definitions of GC therapy with regard to dosage. In addition to ADGC, we have previously classified the various dose GC regimens in: (1) Pulse GC (PGC: 15–30 mg MP/kg/day or 1 g MP/m^2 body surface area IV × 1–3 days); (2) very high-dose GC (VHDGC: >1–2 mg PDN/kg/day); (3) high-dose GC (HDGC: 0.6–1 mg PDN/kg/day); (4) medium-dose GC (MDGC: 0.125–0.5 mg PDN/kg/d); and e) low dose GC (LDGC: <0.125 mg PDN/kg/d), based on

GC usage in SLE trials or clinical practice (109). Particularly, HDGC were separated from VHDGC, based on two facts. First, HDGC therapy, for up to 6 to 8 weeks, has been considered as one of the standard regimens for the treatment of lupus nephritis (110), perhaps the most important and best studied SLE manifestation, and second the fact that for very severe disease manifestations, larger doses (VHDGC) are usually required. Additionally, the latter regimen is probably more toxic, especially if followed for more than a few weeks (107) without appropriate dose tapering. Since then, the First European Workshop on Glucocorticoid Therapy has proposed a similar terminology for GC doses (43), taking also into account the percent saturation of GR at different doses: 42%, 63%, and almost 100% at oral doses of 7.5, 15, and more than 100 mg (respectively) of PDN. It was also noted that nongenomic effects become increasingly important with VHDGC and PGC. These definitions have been adopted here (Table 60-4).

Table 60-4: Usual Regimens of Systemic Glucocorticoid Therapy in SLE*

GC Regimen	Representative Indications	Common Adverse Effects (AE)
Pulse GC (PGC): ≥250 mg PDNeq/d × 1–5 days. Typically 0.5–1 g MP/d IV × 1–3 d, monthly as indicated. Usually with oral GC (30–60 mg PDNeq/d).	Life or organ-threatening complications (i.e., RPGN, myelopathy, severe acute confusional state, alveolar hemorrhage, vasculitis, optic neuritis)** HDGC-refractory Disease DPGN or severe FPGN	Same as with HDGC (see below), but overall incidence of AE may be lower, partly because they allow more rapid taper of oral GC doses. Special considerations because of large dose and route of administration: fluid overload, hypertension, neuropsychiatric symptoms. Rarely: cardiac arrhythmias-sudden death, myalgias/arthralgias, seizures, intractable hiccups, GC-anaphylaxis
Very High Dose GC (VHDGC): >100 mg PDNeq/d, IV/PO (Start with divided doses)	Life or organ-threatening complications (as for PGC)**	Same but more severe than with HDGC Psychosis Risk of severe-fatal infection may be particularly high (avoid use for more than 1–2 weeks)
High Dose GC (HDGC): >30 mg and >100 mg PDNeq/d, IV/PO	DPGN or severe FPGN (for less than 6–8 weeks)† Thrombocytopenia/hemolytic anemia Acute lupus pneumonitis; “Lupus crisis”‡	Same AE for both HDGC and MDGC but incidence and severity are at lower levels with the latter.
Moderate Dose GC (MDGC): >7.5 mg and ≤30 mg PDNeq/d, IV or PO	Moderate SLE flares (i.e., myositis, severe pleurisy, ophthalmoplegia [except optic neuritis], thrombocytopenia) With PGC, or CY/AZA for severe disease	HPA-axis suppression, Cushing syndrome, hypertension, hypokalemia, hyperglycemia, hyperlipidemia, atherosclerosis, OP, ON, risk of infection, skeletal growth retardation, glaucoma, cataracts, skin fragility, acne, insomnia, steroid psychosis, mood swings, etc.
Low Dose GC (LDGC): ≤7.5 mg PDNeq/d, PO	Arthritis, mild constitutional symptoms (unresponsive to analgesics/NSAID/AM). Generalized LN Maintenance therapy	Least toxic daily regimen. Cataracts, GC-withdrawal symptoms (upon tapering to or below LDGC), skeletal growth retardation can occur. Probably minimal OP, ON, HPA-axis suppression.
Alternate Day GC (ADGC)	Membranous nephritis with nephrotic syndrome (120 mg PDNeq) During tapering GC dose. Maintenance therapy (i.e., 15 mg PDNeq for GN)	Decreased adverse effects (i.e., HPA-axis suppression, skeletal growth retardation, infection, Cushing syndrome) compared to daily regimens OP can occur.

AZA, azathioprine; CY, cyclophosphamide, LN, lymphadenopathy; MP, methylprednisolone; ON, osteonecrosis, OP, osteoporosis; PDNeq, prednisone equivalent; RPGN, rapidly progressive glomerulonephritis: FPGN, Focal proliferative glomerulonephritis; AM, Antimalarial.

*All PDNeq doses assume a 60 Kg patient; adjustments should be done for different weights.
**Cyclophosphamide therapy, usually I.V. (IVCY), is often needed as well.
†In combination with IVCY.
‡Lupus crisis refers to the acutely and severely ill patient with high fever, extreme prostration, and other symptoms of active SLE (i.e., pleurisy, arthritis, vasculitic rash), who requires large doses of GC for disease control. Infection has of course been excluded as the cause of the symptoms.

The most effective approach to initiating HDGC or VHDGC for severe SLE disease, and especially when constitutional symptoms (i.e., high fever and prostration) are present, is to administer it in 2 to 4 doses per day (19).

A notable exception is the management of severe focal or diffuse proliferative glomerulonephritis (FPGN or DPGN) where once-a-day regimens are adequate (110). Should the condition prove GC-unresponsive, use of pulse GC and/or additional immunosuppressive agents is necessary. Most disease complications will respond in less than 1 to 2 weeks. However, markers of lupus nephritis (especially proteinuria) may take more than 2 to 6 weeks to improve.

Within 1 to 2 weeks from initiation of therapy, whether a satisfactory response has occurred or a cytotoxic agent has been added to the regimen for refractory disease, tapering of GC therapy should be initiated (19). The first step is to consolidate the GC regimen into a once-a-day morning dose. The daily dose can then be decreased by 5 mg (or 5%–10%) per week until a dose of 0.25 to 0.5 mg/kg/day is reached, and more slowly thereafter, aiming for either a complete withdrawal or, if that is not possible, for LDGC. It may be preferable to follow an ADGC tapering regimen during which the second day's dose is usually first gradually decreased to zero, before further dose decreases are made. Caution should be applied during tapering, as too fast or too slow dose decrements can lead to disease flare/withdrawal symptoms and increased GC toxicity respectively. In the event of a flare during the tapering, the dose is increased to the immediate previous effective level for a few weeks, before the next, perhaps slower, tapering attempt. Less severe SLE manifestations are managed with LDGC or MDGC accordingly (19 ,110). Table 60-4 provides an overview of the suggested GC use in SLE. Finally, some studies have argued for the use of prophylactic GC in SLE patients with serologic flare as defined by increases in anti-dsDNA titers or decreases in complement levels (111 ,112). In those studies clinical relapses were prevented without increased cumulative GC doses.

The importance of other immunosuppressive agents (such as cyclophosphamide, azathioprine, etc.) in helping control the disease while allowing safe tapering of GC (steroid-sparing activity) cannot be overemphasized. DPGN is the best studied SLE complication and randomized controlled clinical studies have documented the superiority of IV cyclophosphamide (IVCY)-containing regimens over those with GC (113 ,114 ,115 ,116) or IVCY alone (117). Moreover, with combinations therapies a more effective GC tapering scheme can be achieved. Additionally, many observational studies, case series, and case reports favor the use of cyclophosphamide (mainly IV) in other life/organ-threatening SLE complications that may be refractory to GC alone (at appropriately high doses or pulse therapy) (118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129). Severe NPSLE of nonthrombotic etiology (especially acute confusional state, myelopathy, optic neuritis) (118 ,119 ,120 ,121 ,122 ,123 ,124), pulmonary hemorrhage (126), interstitial pneumonitis (127), acute cardiomyopathy (128), and severe vasculitis of other systems such as the GI (129) are such examples. In such grave cases, patients might benefit from simultaneous administration of GC and other immunosuppressives (mainly IVCY) from the outset of the disease. For less severe disease manifestations such as arthritis, serositis and mild constitutional symptoms, agents such as hydroxychloroquine, NSAIDs, analgesics, and local GC (i.e., intraarticular) should be given priority, and systemic GC used only if necessary and at the lowest effective dose. Dehydroepiandrosterone (DHEA; or prasterone), an adrenal androgen with immunomodulatory properties whose serum levels are low in SLE and further decrease with GC therapy, was recently shown to have a steroid sparing effect in a double-blind, randomized, placebo control trial (130). However, the effect was seen only in a subgroup analysis of active at baseline SLE patients (SLEDAI of >2) who received the high dose of DHEA (200 mg daily).

The above approach to GC use in SLE is based on the assumption that alternative noninflammatory or nonautoimmune diagnoses have been carefully excluded, before a patient is committed to prolonged immunosuppressive therapy. Infections hold the first priority and they can closely mimic many lupus complications, including acute confusional states, aseptic meningitis, lupus nephritis, lupus pneumonitis, arthritis, and GI vasculitis. Presentations of SLE patients with acute abdomen (AA) are a particularly challenging problem in management. For example, Medina et al. reported that although vasculitis correlated with overall SLE disease activity (53% of 36 patients with active vs. none of 15 with inactive lupus patients), common surgical diagnoses and primary abscesses (in immunosuppressed patients) were more common (131). Interestingly three cases in the active group had abdominal thrombosis and high anticardiolipin titers. Only one patient with hepatic artery thrombosis survived after thrombectomy and 100 mg/day PDN therapy. In the same study, a delay in surgery for more than 48 hours (excluding the cases that had a complete response to HDGC) was associated with much higher mortality, especially in the active group. Once infection was ruled out, however, vasculitis responded to PGC with or without IVCY (131).

Generally, arterial or venous thrombosis without concomitant SLE activity (i.e., CVA secondary to the antiphospholipid syndrome) require anticoagulation alone and increases of GC dosage should be avoided (19 ,110). If TTP is diagnosed, plasma exchanges may be useful (110). Late complications of SLE (132), such as advanced atherosclerosis-CAD, scarring nephritis (with high chronicity and low activity indices on kidney biopsy) osteonecrosis, shrinking lung syndrome and chronic dementia should discourage heroic interventions (107 ,110). Seizures or acute confusional states may not be secondary to SLE and in fact may result from hypertension or metabolic/electrolyte abnormalities, whereas psychosis might result from GC therapy itself (107). The probability of these alternative diagnoses substantially increases when SLE activity in other systems is low. In such cases of isolated seizures or psychosis, conservative management (that may include anticonvulsant and psychotropic agents) along with careful monitoring is all that is usually required (107).

When managing certain SLE complications with GC, it is often prudent to aim for “reasonable” but not complete resolution of disease activity, since often the latter translates

into higher and more toxic GC dosages. For example, asymptomatic hemolytic anemia or ITP with a hematocrit and number of platelets of more than 30% and 20,000 to 50,000 (and no other coagulopathy) respectively do not, per se, warrant increases of GC therapy (110). In more severe cases that invoke long-term HDGC therapy for adequate control, splenectomy and or cytotoxic medicines should be considered (110).

Pulse Glucocorticoid Therapy

Pulse glucocorticoid (PGC) therapy, traditionally 1 g (or 1 g/m^2 of body surface area) of MP IV per day for 3 days that may be repeated at monthly intervals, was first used in SLE to treat DPGN (110 ,113 ,116 ,133 ,134). PGC are also effective for pneumonitis (110), serositis (135), vasculitis (136 ,137), and thrombocytopenia (110 ,138). Many published series showed a role of PGC in moderate-severe NPSLE (110 ,119 ,120 ,122 ,123 ,124 ,138), although a recent randomized controlled trial that compared PGC with IVCY clearly demonstrated the superiority of the second (139). It is generally felt that for very severe DPGN (or rapidly progressive glomerulonephritis; RPGN) PGC work faster than standard oral HDGC and probably permit both use of MDGC (0.5 mg/kg/day) at therapy initiation and a faster taper of GC dose (116). However, two randomized controlled trials showed that PGC therapy (monthly for 6 months or for at least 1 year, respectively) was not as effective as an IVCY-containing regimen (monthly for 6 months and then quarterly) for proliferative lupus nephritis (113 ,116). The second study and especially another more recent NIH trial (117) that included 5 years of protocol therapy with IVCY, PGC, or both and an extended median follow-up of 124 months, have both suggested that the combination can lead to a better renal outcome than therapy with either agent alone. It appears that concurrent use of both agents offers a therapeutic advantage for severe SLE in general (120 ,126 ,140), possibly because of a synergistic effect between the two agents. PGC appear to have additional nongenomic immediate effects (36) that may allow for a faster and more effective action than conventional HDGC. On the other hand IVCY has better long-term effects on the scarring consequences of inflammation (141) and a very potent ability to suppress humoral immunity (140). Advocates of PGC therapy argue that this therapy may have less adverse effects than oral GC alone, partly because it allows a more rapid tapering of the latter. A small case control study of the authors suggested that use of PGC was not associated with more osteoporosis/osteopenia than use of oral GC alone despite significantly larger cumulative (pulse and oral) GC doses in the first group (142). A more recent 12-month randomized prospective controlled study of RA patients also reported that PGC did not cause bone loss, in contrast to oral GC that did (143). The cosmetogenic and diabetogenic effects of PGC may be less severe as well (133). However, complications, such as glucocorticoid-induced osteonecrosis (GION) (116 ,144), major infections (116 ,133), and mood disorders/psychosis (145) can still occur. Seizures (146), myalgias/arthralgias, and dangerous cardiac arrhythmias attributed to potassium deficits (147 ,148), and anaphylaxis (116) have been rarely reported, as well, with this therapy.

Badsha et al. have recently published the results of a small retrospective study of 55 very active SLE that examined the safety and effectiveness of two PGC regimens for 6 months after therapy (149 ,150). Patients who received 500 mg of MP IV daily X3 days (low dose) had less serious infections (in 7 out of 26 patients) and the same therapeutic response as those who received the high dose (1 g MP IV daily × 3 days; infections in 17/29 patients). Most infections were a result of Gram-negative bacteria and occurred within 1 month of PGC. Hypoalbuminemia, was a risk factor and the authors recommended “low” over “high” PGC, especially for those patients with low serum albumin.

Although MP appears to be the most frequently used GC agent for PGC therapy, megadoses of DEX have also been very effective for the same indications, including severe NPSLE (151). Becuase there are no head to head studies comparing pulse DEX and pulse MP, it is not clear whether there is an advantage to either therapy at equivalent doses. With regard to NPSLE management, both agents appear to be comparable in their capacity to penetrate CSF, based on their protein binding characteristics (see pharmacokinetics section). In cases of severe brain edema, where agents with low MC activities might be preferable, although both MP and DEX are suitable, the latter might offer a slight advantage (Table 60-1).

Use of Depot Glucocorticoid Agents

Depot preparations of GC are designed to have long-lasting effects (3–4 weeks) after a single intra-articular (IA) or IM injection. Examples include MP acetate and triamcinolone hexacetonide. Intramuscular injections are used for their potent systemic effects and IA injections for their local action in the affected joint. However, even in the latter case, some systemic absorption and GC toxicity can occur (152). Use of IM depot GC can be considered for the treatment of acute minor flares of the disease. Interestingly, Dasgupta et al., in a controlled trial for polymyalgia rheumatica, used regular 3-weekly IM depot MP acetate injections in comparison with standard oral GC therapy. Adverse effects, especially fractures and weight gain, were less with the depot GC therapy, probably a result of lower cumulative GC dose in that arm of the study (153). A brief (<2 weeks) suppression of the HPA has been reported, even after one IA dose (154).

Glucocorticoid Use During Pregnancy and Lactation

Use of GC therapy during pregnancy is indicated primarily to treat active SLE in the mother and probably for incomplete heart block of neonatal lupus in the fetus. Because only fluorinated GC (i.e., DEX, betamethasone) are able to

enter the fetal circulation in significant amounts, as they are only partially metabolized by the placental 11-β-HSD2 (155), nonfluorinated GC (usually PDN) are used for the first and fluorinated GC for the latter indication. Saleeb et al. (156), in a retrospective study, have found that fluorinated GC given to mothers with anti-Ro or anti-La antibodies at the time of echocardiographic detection of fetal CHB, were able to at least prevent progression of second-degree blocks and reverse hydropic fetal changes. However, and of some concern, oligohydramnios were seen more frequently in the treatment than in the placebo group.

When treating the mother for active SLE, the lowest effective GC dose should be employed. Although development of cleft palate has been reported in animal studies with use of GC (155 ,157), this fact probably carries no clinical significance and should not restrict use of GC when otherwise indicated (155). Other GC adverse effects on pregnancy outcomes include a high incidence of preterm deliveries, which are mainly a result of premature ruptured membranes (158 ,159 ,160 ,161) and possibly fetal growth restriction (155). Gestational hypertension or diabetes mellitus (158 ,160 ,161) are not uncommon. Additionally, osteoporosis (155 ,162) and, probably less commonly, maternal cataracts (160), or GION can also occur (155). With regard to osteoporosis, the combination of GC and heparin may be particularly toxic to the bones and vertebral fractures have been reported (162). Mothers treated with GC during pregnancy may need stress GC doses in the peripartum period, especially when there is prolonged labor/delivery or a C-section is required (155). Careful monitoring of the neonates born to these mothers for development of adrenal insufficiency is also recommended (155). In order to avoid disease flares that can lead to both disease and treatment complications, patients that are already on hydroxychloroquine should probably be kept on this (relatively safe) therapy during pregnancy (163 ,164 ,165). Additional immunosuppressive medications that may be safe during pregnancy, such as azathioprine, cyclosporin A, and IVIG, should be considered for moderate-severe SLE disease activity (155) and might help decrease GC doses.

Because of their unfavorable adverse effect profile, GC have lost ground to the combination of heparin and aspirin in treating the pregnancy loss of the antiphospholipid syndrome (APLS) (158 ,159 ,161). Additionally, Laskin et al. found the combination of PDN and aspirin of no benefit to the treatment of women with autoantibodies (including antiphospholipid antibodies) and recurrent fetal loss (160). However, GC may still have a place in the management of women with APLS secondary to SLE to treat thrombocytopenia or a concomitant SLE flare (161).

The use of PDN at doses below 20 to 30 mg/day in breastfeeding mothers is probably safe as less than 10% of the active drug enters breast milk (155). It is prudent to wait 4 hours after GC intake before breastfeeding, especially when higher doses are necessary (155).

Use of Glucocorticoids During Stress

Because of the high risk of HPA-axis suppression (see below), patients on chronic GC therapy should be given supplemental GC during the stress of surgery or moderate-severe illness. Traditional recommendations called for 100 mg of a water-soluble form of hydrocortisone (i.e., sodium succinate) IV every 8 hours, tapered as the patient recovers. However, more recent data have shown that individuals with intact adrenal function rarely generate more than 150 to 200 mg of cortisol even during major surgery (5 ,166). Based on this information, more recent recommendations argue that 25 mg of hydrocortisone (or its equivalent) should be given daily for 1 to 3 days during minor stress, whereas for moderate and severe stress 50 to 75 mg and 100 to 150 mg daily for 1 to 3 days should be given respectively (5 ,167). Another argument in favor of this approach may be that unnecessarily high GC doses that might interfere with wound healing and increase the risk of infection are avoided (5 ,167). Glucocorticoid agents with less mineralocorticoid activity than hydrocortisone would be preferable when dealing with fluid-overload states (i.e., in a lupus nephritis patient).

Adverse Effects of Glucocorticoids

Both clinicians and patients should be fully aware that adverse effects (AE) of GC therapy are not uncommon and can in fact be very serious. Although brief courses of high dose GC therapy (i.e., for bronchial asthma) are probably well tolerated and AE (i.e., Cushing syndrome, glucose intolerance, HPA-axis suppression), if they occur, are rapidly reversible (84), more prolonged therapy, as it is usually the case with SLE patients, invariably leads to complications. Of note, some AE (i.e., skeletal growth inhibition, HPA-axis suppression, GION, cataracts) occur even with LDGC, others usually require larger doses of GC before they occur (i.e., infection, psychosis, myopathy, hyperlipidemia). Because susceptibility to GC AE may vary from person to person, according to individual pharmacokinetic differences, Sarna et al., in order to minimize AE, have suggested the use of specific GC exposure indices (instead of the absolute or cumulative GC doses) in guiding GC dosing of children with transplants (168). Comorbid conditions and risk factors that may predispose to more severe GC AE (i.e., hyperlipidemia, hypertension, hyperglycemia-DM, hypokalemia, osteoporosis, personal or family history of cataract or glaucoma, prior exposure to tuberculosis) should be identified prior to institution of GC therapy. Patients and their families should be educated to recognize and promptly report symptoms of such complications as infection (i.e., fever), diabetes, psychosis, and osteonecrosis (joint pain). In parallel, careful clinical and laboratory monitoring for the development of osteoporosis, DM, hyperlipidemia, hypertension, glaucoma, and so on, should not be neglected (2). Interventions known to prevent or

ameliorate GC AE (summarized in Table 60-5) should be undertaken (2). This is particularly true for GIOP, infection susceptibility, myopathy, and atherosclerosis (see below). Reversal of some AE (i.e., HPA-axis suppression, Cushing syndrome, and psychosis) can be achieved with cessation of GC therapy, or at least modification into the safer ADGC or LDGC regimens. Unfortunately some AE, like cataract formation, GION, osteoporotic fractures, growth retardation in children, and atherosclerotic vascular events, are irreversible (169).

Table 60-5: Suggested Monitoring and Preventive-Therapeutic Interventions for Selected GC Adverse Effects (AE)*

AE	Monitoring for	Intervention
HPA-axis suppression	Symptoms of adrenal insufficiency during significant stress (illness, or surgery)	Choose low-risk GC regimens (LDGC, ADGC) when possible. Medical alert bracelet. Stress-doses of GC perioperatively or during severe illness.
Osteoporosis	BMD at baseline and q12 months thereafter if bisphosphonates are not given. (for high risk patients more aggressive monitoring is probably necessary)	Smoking/ETOH cessation; exercise; low salt diet; calcium (1,500 mg/d) and vitamin D (400-800 IU/d). Bisphosphonates** for patients initiating GC therapy with ≥5 mg PDNeq/d for ≥3 months, or patients on long-term GC ≥5 mg PDNeq/d and low BMD (T-score <-1) Gonadal hormone replacement in hypogonadic patients on long-term GC therapy.† Calcitonin if bisphosphonates cannot be used.
Osteonecrosis	Unexplained joint/bone pain. (Perform MRI to detect early GION if plain radiography not revealing).	Avoidance of weight bearing and joint-salvage surgery (core decompression, osteotomy, non vascularized or vascularized bone grafting) may arrest progression to bone collapse.
Cardio-vascular‡ Lipidemia Hypertension Hyperglycemia Obesity	Baseline fasting serum lipid profile (TC, HDL-C, LDL-C, TG) and then yearly TC. Symptoms of polyuria, polydipsia; after baseline serum glucose, urinary glucose tests q3–6 months; baseline serum potassium. BP at baseline and every visit. Edema, shortness of breath	Diet (to control one or all of hyperlipidemia, hyperglycemia, and hypertension, accordingly) Aerobic exercise Antimalarial therapy (cholesterol-lowering and anticoagulant properties) Lipid-lowering and/or antihypertensive agents, if previous measures not adequate. Folate, and vitamins B6, B12, for elevated homocysteine levels
Infection	Fever; PPD skin testing (+anergy panel); severe lymphopenia.§ Maintain high index of suspicion for OIs	Vaccinations for influenza, pneumococcus, tetanus. Antituberculosis therapy, if PPD+, or evidence for TB exposure. PCP prophylaxis¶ avoid contact with children vaccinated with OPV¶
Muscle	Proximal muscle weakness	Muscle strengthening exercises
Psychiatric	Symptoms of depression, psychosis	Antipsychotics as an adjunct therapy to GC dose lowering or cessation
Eye	Visual changes,	Decrease/cessation of GC dose (for glaucoma).
PUD	Other PUD risk factors (NSAIDs, co-morbidities)	Gastroprotection (H_2-blockers, proton-pump inhibitors, misoprostol)

BMD, bone mineral density; TC, total cholesterol; HDL-C, high-density lipoprotein cholesterol; TG, triglycerides; BP, blood pressure; PPD, purified protein derivative; TB, tuberculosis; OI, opportunistic infection; PCP, pneumocystis carinii pneumonia; OPV, oral polio virus; PUD, peptic ulcer disease.

*Generally, if GC cessation is not feasible, tapering to LDGC or modification to an ADGC regimen, is the safest intervention for most GC adverse effects.
**Caution in premenopausal women.
†Caution with estrogen in the presence of prothrombotic risk factors, atherosclerosis, or active lupus.
‡APLA, homocysteine, and SLE activity are GC-unrelated but significant cardiovascular risk factors in SLE patients.
§Usually when lymphocytes <350/mm3, but PCP can occur with higher numbers.
¶For severely immunosuppressed SLE patients (i.e., on combination therapy with moderate-high GC and other immunosuppressive agents and/or significant lymphopenia).

Iatrogenic Cushing syndrome (with the typical centripetal body fat redistribution), a characteristic feature of GC excess can occur in a period of less than 1 month during HDGC therapy (4). It differs from the native Cushing syndrome in that there is less androgen excess (androgens are suppressed by GC excess) and less hypertension (4). On the other hand, the prevalence of GION, posterior subcapsular cataracts, glaucoma, pseudotumor cerebri, pancreatitis are more commonly seen.

Recent studies have shown that damage in SLE, as measured by the Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) Damage Index, is clearly associated with GC use (170 ,171). One of these studies described an inception cohort of 73, mostly Caucasian patients, and noted that although disease-activity related damage occurred early, GC-associated damage accumulated over time to constitute most of the damage at 15 years. (170). This was especially true for musculoskeletal damage (55% of patients at 15 years) mainly because of osteonecrosis and deforming arthritis, and ocular damage (32%) as a result of cataracts.

Chronic Suppression of the Hypothalamic-Pituitary-Adrenal Axis

Suppression of the HPA-axis after chronic exposure to moderate-high doses of GC begins from suppression of corticotropin-releasing hormone (CRH) and ACTH and eventually leads to atrophy of adrenal zones fasciculate and reticularis, the principal cortisol-producing structures (secondary adrenal failure). Exposure to GC for periods of less than 2 to 3 weeks or for longer periods to low dose GC (<10 mg/day of PDN, as long as is not taken as a single bedtime dose) are considered safe and do not lead to clinically significant adrenal insufficiency (4 ,84). On the other hand, patients exposed to any doses of more than 20 mg/day for more than 3 weeks should be considered as having HPA-axis suppression (4 ,84). These patients need proper GC supplementation during surgical procedures or illnesses. Recovery from suppression varies depending on the intensity of GC exposure but usually lasts from 6 to 9 months and is gradual. CRH secretion recovers first, followed by ACTH, and lastly by cortisol secretion. Additionally, adrenal responsiveness to stress normalizes much later than the baseline adrenal cortisol secretion. Patients should be informed about the potential dangers of this important problem, advised not to abruptly discontinue their GC unless authorized by their physician, and wear medical alert bracelets (4 ,84). GC withdrawal should start by tapering GC dose to physiologic levels (20 mg of hydrocortisone or 5 mg of PDN in a single morning dose). Serum AM cortisol levels are measured and only when they are more than 10 μg/dL can maintenance dose be discontinued. However, these patients may still have abnormal cortisol responses to stress and coverage should be given when necessary. Next, an acute ACTH test is performed. If 30- or 60-minute cortisol serum levels, after subcutaneous injection of 250 mg of cosyntropin (synthetic ACTH1–24), are more than 20 μg/mL, adrenal insufficiency is unlikely and stress GC supplementation is no more necessary. However, exceptions can occur and if there is any clinical suspicion of adrenal insufficiency (i.e., hypotension after surgery), GC coverage should be given (4 ,84).

Bone Toxicity

Glucocorticoid-induced osteoporosis (GIOP) and osteonecrosis (GION) are frequent adverse effects of GC and contribute substantially to the morbidity associated with these agents. Recent advances in bone biology have shown that osteoblasts and osteoclasts are both derived from bone marrow precursors and that osteoblastogenesis is a prerequisite for osteoclastogenesis (172). The link is provided by osteoprotegerin ligand (OPGL, or ODF, or TRANCE or RANK ligand), a member of the TNF family of proteins, which is expressed on committed preosteoblastic cells and mediates osteoclast differentiation and activation (172 ,173). The main histologic findings in GIOP are decreased bone formation rate, decreased wall thickness of trabeculae, a strong indication of decreased osteoblastic work output and in situ death of portions of bone (172). Weinstein et al., by studying a mouse model of GIOP, found that there was an early (7 days after exposure to GC) increase in osteoclast perimeter and bone resorption (174), an effect that might have been because of OPGL induction by GC (175). On the other hand chronic GC exposure (27 days) led to decreases in bone turnover and bone formation, probably explained by inhibited osteoclastogenesis and osteoblastogenesis respectively. Osteoblast function was further compromised as these cells underwent increased GC-induced apoptosis (174). Additionally, the augmented osteocyte apoptosis observed was proposed by the authors as a potential mechanism for GC-induced osteonecrosis as osteocytes are critical in sensing microdamage and regulate bone remodeling accordingly (172). Dysregulation of calcium balance (decreased intestinal absorption and increased urinary excretion), gonadal hormone repression, myopathy, and in SLE downmodulation of DHEA are other proposed mechanisms of GIOP (176 ,177 ,178 ,179).

Glucocorticoid-induced osteoporosis predominantly affects cancelous bone and the axial skeleton. During the first 3 to 6 months of GC therapy there is a rapid bone loss (up to 12%) which slows down thereafter to 2% to 5% annually (172). SLE patients may have additional risk factors for osteoporosis such as use of sunscreens (inadequate vitamin D formation) inability to exercise due to musculoskeletal inflammation or fatigue, hormonal changes (including premature ovarian failure due to cyclophosphamide therapy), kidney damage, or medications known to induce osteoporosis (heparin, anticonvulsants, cyclosporin) (177). Additionally, the disease itself could theoretically cause bone loss given the recent evidence that activated T cells express functionally active OPGL (180).

Careful evaluation of SLE patients before and after initiation of GC therapy should be performed to identify other potentially modifiable OP risk factors and guide further management. Specifically, baseline and every 6 to 12 months thereafter, evaluation of BMD is essential to assess bone loss. Markers of bone formation and bone resorption might offer additional help in assessing the effectiveness of current OP-preventive measures. Serum levels of 25-hydroxyvitamin D, luteinizing hormone (LH; for females) and gonadal hormones can be measured if indicated to help identify potential targets of intervention. General measures for OP prevention including a well-balanced, low salt diet, avoidance of alcohol and smoking and weight-bearing muscle-strengthening exercises should be encouraged. A short-acting GC at the lowest effective dose should be preferentially used, although doses as low as 6 mg PDN per day, on average, may lead to spinal bone loss (181). Unfortunately, alternate-day therapy does not seem to protect from GIOP (177). As a first step to GIOP prevention, calcium and vitamin D intake should be optimized and 1,500 mg/day (by diet or supplements) and 400 to 800 IU/day should be taken respectively. Use of pharmacologic doses of vitamin D are discouraged except in the case of documented vitamin D deficiency (182). Active vitamin D metabolites, like calcitriol, have been shown to preserve bone during GC therapy (183) but the relatively high risk for hypercalcemia/hypercalciuria and its potential association with soft tissue calcifications in SLE patients with lupus nephritis (184) make their use less desirable. Thiazide diuretics (with potassium supplementation) might be useful in the case of hypercalciuria (177). Hormone replacement therapy (HRT) should be considered in all postmenopausal women, and documented hypogonadism in men and premenopausal women, if there are no contraindications (176 ,185 ,186). In SLE patients, there is concern that estrogen therapy might induce flares of the disease. In fact the Safety of Estrogens in Lupus Erythematosus-National Assessment (SELENA) trial has shown only a small risk for mild/moderate lupus flares in postmenopausal (without prothrombotic risk factors) patients that received HRT compared to placebo-treated women (187). Nevertheless, because of the recent negative data regarding the cardiovascular effects of HRT, this therapy has lost ground in the treatment of OP (188). The best evidence regarding effective prevention and treatment of GIOP exist for bisphosphonates, especially during initiation of GC therapy when bone loss is worse (189 ,190 ,191). Although there is some concern with prolonged use of these agents in young individuals (because of their long-term retention in bones) (176), this should not discourage physicians from using them when clearly indicated in young SLE patients (i.e., those on HDGC at high risk for, or already with, OP). However, bisphosphonates should not be used in pregnancy or moderate-severe renal failure and their discontinuation considered when GC doses have been substantially tapered with stabilization of BMD. Calcitonin has been recommended for GIOP, but it does not seem as effective (176 ,182 ,192). If the above measures fail, bone anabolic agents such as low doses of slow release sodium fluoride could be cautiously used (178). Other promising therapies for GIOP have, in the meantime, emerged. Specifically, daily subcutaneous injections of human parathyroid hormone 1–34 (hPTH [1–34]) in postmenopausal women, that also received HRT and calcium supplementation, reversed GIOP in the lumbar spine, whereas control therapy with HRT and calcium alone did not (193).

The pathogenesis of GION remains largely unknown. Proposed mechanisms include blood vessel occlusion by either external compression (fat accumulation in the bone marrow), or intravascular flow obstruction by thrombosis or fat embolism (194 ,195). Apoptotic death of osteocytes, which are considered as mechanosensors and initiators of repair in bone, has been recently proposed as a mechanism of femoral head collapse in the context of GC therapy (172). Pathologically, GION is characterized by empty lacunae in trabeculae, bone marrow necrosis, and later by repair processes such as vascular granulation tissue and appositional (on the dead bone) new bone formation (194). Although pure medullary infarcts are asymptomatic, corticocancellous osteonecrosis can lead to pain and joint destruction depending on the extent and location of lesions (194 ,195). Symptoms usually take a few months to a few years to develop after GC exposure (194 ,196 ,197). Typical sites of involvement include the subchondral regions of convex bone ends such as the proximal and distal femur, and the proximal humerus. With regard to time of onset, it has been suggested that the process of ON occurs within 1 to 2 months of exposure leading to early asymptomatic MRI lesions at 40 to 100 days after HDGC (58 mg PDNeq/day on avaerage) (198). In that study, 44% patient developed such lesions in hips and knees and the lack of progression to symptoms after 12 months was attributed to the brief followup time. The incidence of clinically occult ON was only 12% in another study perhaps because of lower mean GC doses and also no progression was seen after 1 year of follow-up (199). Notably, even short-term PGC doses (200), adrenal insufficiency replacement doses (201), and intraarticular injections (202) have been implicated in GION. Predicting which patients will develop GION is very difficult. In SLE patients, besides the magnitude of GC exposure (203 ,204 ,205 ,206 ,207), development of Cushing syndrome has been implicated in many studies (204 ,205 ,206), but there is no agreement with regard to the role of antiphospholipid antibodies (204 ,205 ,208). Patients should be informed about this potentially very serious GC complication that often occurs when SLE disease activity is under control; educated how to recognize GION symptoms (i.e., groin pain upon weight-bearing); and instructed to avoid high-impact activities (194 ,195 ,207). When hip GION is at an early stage, relief of weight bearing is recommended (179 ,180 ,191). For this purpose, Simkin and Gardner have suggested the use of crutches with a four-point walking

pattern to avoid excessive load on the opposite (at risk) hip (180). Operative management of precollapse lesions include core decompression, osteotomy, and nonvascularized and vascularized bone grafts (194 ,195 ,207). Advanced disease (stages III–IV by plain radiography according to the Ficat staging system) often requires total joint replacement therapy (194 ,195 ,207). Interference with potential key mechanisms of GION such as fat accumulation (i.e., by statins), intraosseous hypertension (i.e., vasodilators), coagulation (i.e., stanozolol) or osteocyte apoptosis (i.e., PTH) may offer additional hope in managing this disease in the near future (172 ,207 ,209).

Effects on Intermediary Metabolism: Abnormalities in the Metabolism of Glucose, Lipids, and Protein

Glucocorticoids induce insulin synthesis, but oppose its effects on glucose metabolism predisposing to or aggravating (if already present) diabetes mellitus (DM). These effects of GC are mediated mainly through decreased peripheral utilization of glucose and induction of gluconeogenesis in the liver. The latter is in part a result of the increased substrate availability for gluconeogenesis as a result of the GC enhancing effects on lipolysis and protein catabolism (3 ,4). The hyperglycemic effects of GC may be of particular importance in SLE, a disease with an increased prevalence of DM (210 ,211 ,212) and perhaps an increased frequency of the prediabetic insulin resistance syndrome (213).

Dyslipoproteinemias with elevated serum levels of triglycerides (TG), very low-density lipoprotein cholesterol (VLDL-C), and decreased levels of HDL-C and apoprotein A-I can occur in active SLE even before GC treatment (214 ,215). Nephrosis, when present, is an additional aggravating factor for hyperlipidemia. GC have an important impact on lipid metabolism themselves as they act permissively to enhance the lipolytic effect of catecholamines and growth hormone (GH) and induce a centripetal body fat redistribution (4). GC can also induce cholesteryl ester synthesis by macrophages, in vitro, an effect that could be blocked by progesterone (216). Ettinger et al. have shown that administration of 0.35 mg PDN/kg/day for 14 days in healthy men increased their levels of VLDL-C, HDL-C, and triglycerides (TG) (217). In SLE, increases of TC, VLDL-C, LDL-C (215 ,218), and TG (215 ,219) have been noted and only PDN doses of more than 10 mg/day had significant hyperlipidemic effects (212 ,219). Moreover, Petri et al. have found that an increase in the PDN dose by 10 mg daily was associated with a 7.5 mg/dL increase in cholesterol levels (220). Interestingly, antimalarial therapy can counteract this GC effect and decrease cholesterol (220 ,221).

Despite inducing weight gain as a result of their appetite enhancing effects (220), GC favor protein breakdown and lead to steroid myopathy and poor wound healing (see below).

Cardiovascular Effects

Hypertension because of GC occurs at high doses. This is partly a result of the permissive effects of GC on the action of vasoactive substances (angiotensin II [ATII], catecholamines) on the vessel wall and myocardium that result in increased systemic vascular resistance (SVR), and increased cardiac contractility (3 ,4). Inhibition of PGE2 and kallikrein synthesis by GC also contributes to their adverse effects on blood pressure (BP). When 11-β-HSD2 functions normally, GC mineralocorticoid effects on BP are unlikely, except perhaps in very high doses of cortisol. In the Hopkins Lupus Cohort increases of PDN doses by 10 mg were associated with BP increases by 1.1 mm Hg (220).

Urowitz et al., in 1976, reported the occurrence of accelerated atherosclerosis in young premenopausal females with SLE (222). The prevalence of clinical atherosclerosis manifesting with angina, myocardial infarction, or peripheral vascular disease has been estimated to be 7% to 10% (211 ,212 ,223 ,224). Subclinical atherosclerosis is even higher (according to some studies (225 ,226). Disease activity of SLE itself is considered at least in part responsible for hyperlipidemia (214 ,215), and atherosclerosis (226) a process that is now considered inflammatory with evidence of immune activation (227). Experimental evidence that immune complexes (in association with high-cholesterol diet) can induce atherogenesis in rabbits (228) and that lupus sera are capable of accelerating cholesterol uptake by human aortic smooth muscle cells (229) may offer additional support to a pathogenetic association of SLE and atherosclerosis. Along these lines, Rahman et al., in a comparison study of patients with accelerated atherosclerosis with and without SLE, found one less traditional risk factor in patients with SLE, which led the authors to suggest that SLE itself be considered a cardiovascular risk factor, similarly to DM (230). Importantly, duration of GC therapy was found to be an independent risk factor for development of CAD in SLE (211 ,212 ,231), along with older age at diagnosis of SLE, hypercholesterolemia (210 ,211 ,212), and other cardiovascular risk factors including hypertension, obesity (212 ,226), elevated homocysteine (231) and even antiphospholipid antibodies (214 ,217 ,231) and CRP (226). Notably, some more recent studies failed to demonstrate a role for GC in development of subclinical atherosclerosis (232 ,233). Nevertheless, the potential of GC to aggravate SLE-atherosclerosis, based at least on their adverse effects on serum lipids and BP, cannot be overemphasized and every attempt should be made to keep their doses at levels below the equivalent of 10 mg of PDN daily. Moreover, activity of the disease should be adequately controlled, and other cardiovascular risk factors (including homocysteine levels) identified and properly addressed. If dietary measures and antimalarial therapy are not enough to control hyperlipidemia, lipid-lowering agents should be added to the therapeutic regimen.

Neuropsychiatric Adverse Effects

CNS GC effects are relatively common. Mood changes are probably the commonest occurring in half the patients (4). Depression more commonly, or euphoria can occur. Additionally, cognitive dysfunction and decreased duration of REM sleep can be seen (4). A recent cohort study reported a 5% incidence of psychiatric events after a mean of 3 weeks of initiation of GC therapy (234). Three of 92 SLE patients developed psychosis and another three mania. All episodes resolved with reduction of GC dose from 40 mg to 18 mg of PDN daily. Hypoalbuminemia was an independent risk factor for psychiatric events (234). When manic behavior, psychosis, or seizures supervene during therapy, they require differentiation from primary NPSLE (107 ,145 ,235). The distinction can be difficult but the temporal relationship to increases in GC dose, along with lack of focal neurologic signs or CSF abnormalities suggest the correct diagnosis. Discontinuation or reduction of GC therapy along with phenothiazine suffices to reverse GC-induced psychosis (235). Benign intracranial hypertension (pseudotumor cerebri) occurs only rarely.

Infection

Glucocorticoids predispose to infection and at the same time may mask clinical clues of infection as a result of their immunosuppressive and anti-inflammatory effects. On the other hand, reduction of inflammation is probably responsible for the improved outcomes observed when *Pneumocystis carinii* pneumonia and *Haemophilus influenza* meningitis are treated with adjunctive high-dose GC therapy (236 ,237). The incidence of infection after GC therapy was examined in a metaanalysis by Stuck et al., and was found to be 12.7% (1.6-fold that of the control population). In the same study, patients treated with less than 10 mg of PDN daily, or a cumulative dose of less than 700 mg were spared from a higher risk to infection (238). Besides increasing the incidence of bacterial infections, GC can reactivate latent tuberculosis (TB) or histoplasmosis and predispose to an accelerated form of herpetic keratitis that culminates in blindness (4). Active SLE, by itself, increases the risk of bacterial (239 ,240 ,241), and, more rarely, opportunistic infections (242), probably as a result of several immune system perturbations (reviewed in (243)). Therapy with GC further augments the susceptibility of SLE patients to infection (169 ,239 ,241 ,242 ,244). Interestingly, in one study treatment with GC and cyclophosphamide improved survival but at the same time was associated with sepsis as a cause of death (244). Sepsis has been frequently cited as the first cause of death in SLE patients being responsible for 19% to 54% of all deaths (169 ,222 ,239 ,241 ,243 ,244).

With regard to opportunistic infections, GC at relatively high doses (more than 40 mg of PDN daily) can increase the risk of PCP, especially when combined with other immunosuppressive agents and/or coexistent peripheral lymphopenia (242 ,245 ,246). Prophylaxis for PCP should be considered in such patients. Since use of trimethoprim-sulfamethoxazole may be of concern in SLE, alternative prophylaxis regimens should be tried (i.e., dapsone 100 mg/day) (247). Additionally, purified protein derivative (PPD) testing will help identify patients exposed to TB who will be candidates for antituberculosis prophylaxis. Notably, for patients on GC doses equivalent to more than or equal to 15 mg/day of PDN for 1 month or more, a PPD skin reaction more than or equal to 5 mm of induration is considered positive and warrants preventive therapy (248). Immunizations with *H. influenza* type B, tetanus toxoid, and pneumococcal vaccines were recently found safe and able to induce protective antibody titers in SLE patients (249). However, a trend towards lower protective antibody titers was noted for patients on immunosuppressive agents, perhaps suggesting that immunizations should best be done before initiation of such therapy. Vaccinations for influenza, *Pneumococcus,* (killed vaccines), and tetanus (component protein or peptide vaccine) are therefore highly recommended for SLE patients. In contrast, vaccinations with live attenuated viruses such as oral polio, varicella, and MMR should be avoided in immunosuppressed patients as they may lead to disease (247). Notably even contact with children vaccinated with OPV (but not MMR) is risky (247).

Steroid Myopathy

Glucocorticoids have permissive actions necessary for normal function of skeletal muscle. However, exposure to fluorinated GC or large daily doses (>30 mg of PDN) (250) of nonfluorinated GC administered for more than a few weeks (and in one study of cancer patients, within 15 days) (251) can cause a proximal myopathy characterized primarily by atrophy of type IIB muscle fibers (84 ,250 ,251 ,252 ,253). Usually the pelvic girdle muscles (252) are more severely affected and sometimes respiratory muscle weakness can occur (253). Although muscle enzymes are usually normal, urine creatine (252) and serum LDH (in SLE) might be elevated (253). Exercise (both resistance and endurance) is effective in attenuating GC-induced muscle atrophy (254).

The rare syndrome of acute myopathy of intensive care can occur in critically ill patients treated with high dose IV GC and neuromuscular junction-blocking agents (255). These patients develop a severe quadriplegia characterized by impaired muscle membrane excitability and a necrotizing myopathy with loss of thick filaments on muscle histopathology (255 ,256 ,257).

Skeletal Growth Retardation

Children treated with GC, especially during their prepubertal years, display delayed skeletal maturation and growth (258 ,259 ,260). Even regimens considered to be relatively safe, such as LDGC, ADGC, and inhaled or intranasal therapy have been implicated in growth retardation (260 ,261 ,262), which, of interest, has been observed in one

study without concomitant HPA-axis suppression (as assessed by AM serum cortisol levels and standard cosyntropin testing) (262). Among children treated with ADGC for cystic fibrosis, persistent growth impairment was observed only in boys (but not girls) after cessation of therapy (260). Mechanisms of GC AE on skeletal growth may include inhibition of chondrocyte IGF-I production, GH- and IGF-I-receptor expression, GH secretion, collagen type I synthesis, and upregulation of collagenase-3 expression (263 ,264). GC-treated children respond to GH therapy with increased growth velocity but responsiveness is not optimal and correlates negatively with GC dose (259 ,263).

Other AE

Effects of GC on protein catabolism, fibroblast function, and collagen metabolism are probably responsible for suppression of wound healing processes and skin atrophy-purpura. Notably, chronic steroid therapy in SLE patients has been associated with tendon ruptures (265).

Posterior subcapsular cataract formation is not uncommon with systemic, topical or inhaled GC use and children may be more susceptible to this complication. Open-angle glaucoma may occur rapidly with topical ocular administration, but may take years before it occurs with systemic GC therapy. Glaucoma, in contrast to cataracts, often resolves with GC discontinuation. Regular ophthalmologic follow-up for both potential AE is required (266).

There is probably no association between GC use and development of peptic ulcer disease (PUD) or its complications (267). However concomitant use of NSAIDs confers a higher risk of PUD (268) and the same is probably true when other comorbid conditions (i.e., CHF, renal failure, old age) are present (169).

Hypersensitivity reactions and severe anaphylaxis to GC can rarely occur. Intravenous, intraarticular, soft tissue, and intradermal injections have been usually implicated, but association with topical and oral GC use has also been reported (269 ,270 ,271). Asthmatics with atopy may be more susceptible to this complication (269). It has been suggested that injectable epinephrine and diphenhydramine be readily available in rheumatology offices, in case anaphylaxis to GC injections occurs (271).

Glucocorticoid Withdrawal Syndrome

Symptoms upon withdrawal of GC can be a result of either SLE reactivation or because of adrenal insufficiency. The latter usually occur with attempts to taper GC below physiologic levels (i.e., 5–7.5 mg of PDN) and consist of anorexia, nausea, weight loss, arthralgias, myalgias, lethargy, weakness and mild orthostatic hypotension-tachycardia. These can rarely occur even with normal adrenal function, as defined by normal morning cortisol levels and a normal ACTH stimulation test, and in that case may be due to GC resistance from prolonged LDGC use (4 ,84).

Future Directions

After half a century of continuous GC use in clinical practice, important advances have been made regarding both mechanisms of GC action and the rational usage of these agents for the benefit of our patients. However, much more research and progress is still needed in this field. First, developing new and safer GC agents is of utmost importance. In this direction some progress has already been made with the emergence of the “dissociated” GC and their encouraging results in animal models of inflammation. Hopefully, their dissociation of anti-inflammatory transrepression effects from transactivation effects that underlie at least some of GC adverse effects will hold also in human clinical trials. Second, understanding the pathogenesis of GC-induced adverse effects will help develop more effective interventions for their prevention or treatment. Along these lines, for example, the osteocyte antiapoptotic activity of PTH might explain its promising effects in GIOP (and perhaps GION). Blocking OPGL might be another approach to the management of GIOP. Finally, successful research into the mechanisms for GC resistance might help predict effective GC doses before therapy initiation and at the same time allow for design of new therapeutic interventions that will aim to decrease GC resistance. Use of inhibitors of proinflammatory transcription factors such as AP-1 and/or NFκB that are mutually antagonistic with GR might be one such approach. The design of these therapies for SLE patients should also, however, take into account parallel advances in our understanding of the pathogenesis of this disease.

Chapter 61

Immunosuppressive Drug Therapy

W. Joseph McCune

Wendy Marder

Mona Riskalla

Immunosuppressive agents are widely used in the treatment of serious manifestations of systemic lupus erythematosus (SLE) to minimize irreversible injury characterized by fibrosis and organ dysfunction and to reduce toxicity from corticosteroids. Recent research efforts have focused on minimizing cyclophosphamide use, including evaluation of sequential therapies utilizing intravenous bolus or daily oral cyclophosphamide for induction of remission, followed by azathioprine or mycophenolate mofetil for maintenance of remission, and de novo therapy of severe lupus with mycophenolate mofetil rather than cyclophosphamide. In the near future, addition of new biologic agents to conventional immunosuppressives will have the potential to further reduce our reliance on alkylating agents.

Most studies of immunosuppressive agents in lupus have been performed in patients with nephritis. The availability of histology and relatively accurate tests of renal function allow a fairly accurate estimation of the response to therapy; however, the duration of such trials, usually 1 to 5 years, has been much less than the anticipated survival of most patients with lupus. Especially in patients who do not have fulminate disease, long-term trials are required, unless sensitive markers for treatment failure are employed (e.g., doubling of serum creatinine instead of progression to renal failure), prolonged treatment of patients randomized to suboptimal regimens may not be practical.

A meta-analysis that included 440 patients with lupus nephritis in 19 clinical trials concluded that the use of immunosuppressive drugs (azathioprine and/or cyclophosphamide) in addition to prednisone and the use of prednisone alone significantly reduced the risks of end-stage renal disease (ESRD) or death by 12.9% and 13.2%, respectively (1). These findings were consistent with those of Felson and Anderson (2), who in 1984, combined eight clinical trials employing prednisone alone versus prednisone plus azathioprine and/or cyclophosphamide for the treatment of lupus nephritis. They concluded that progression to both renal failure and death was delayed by immunosuppression, particularly in patients with diffuse proliferative nephritis, although statistical significance was lost when the azathioprine- or cyclophosphamide-treated groups were analyzed separately. A more recent meta-analysis from 2004 examined randomized controlled trials of therapeutic options for diffuse proliferative lupus nephritis and found 25 papers meeting criteria (3). This analysis concluded that cyclophosphamide plus corticosteroids remains the first choice for preservation of renal function, but that every effort should be made to limit the exposure to cyclophosphamide to the extent possible because of associated gonadal toxicity. There was no evidence from the analysis that azathioprine therapy had an effect on renal outcomes, and there was at that time insufficient evidence to draw conclusions about therapy with mycophenolate mofetil.

This chapter focuses on widely used immunosuppressive agents, emphasizing controlled trials, most of which have enrolled patients with lupus nephritis, and reviews the use of the alkylating agents, azathioprine, cyclosporine, methotrexate, and mycophenolate mofetil (MMF) and their roles in induction as well as sequential therapies following treatment with cyclophosphamide.

Alkylating Agents

Of the more than a dozen alkylating agents that are currently in use, cyclophosphamide (CYC), chlorambucil and nitrogen mustard (HN3) have been applied sufficiently in the treatment of SLE to warrant discussion. Although there are inherent similarities in mechanisms of action, the clinical effects, both therapeutic and toxic, of the individual alkylating agents differ from each other and may vary depending on the dose, route of administration, duration of administration, and cumulative dose of these agents. Larger cumulative doses of alkylating agents are associated with escalating risk of toxicity, particularly gonadal failure, and secondary malignancies. Because alkylators are the most effective agents studied in long-term trials for management of lupus nephritis, familiarity with strategies to minimize toxicity is important in order to use these drugs with maximal benefit.

The earliest use of alkylating agents, reported by Osborne et al. (4) in 1947, was topical application of nitrogen mustard in cutaneous lupus, followed in 1949 by the description by Chasis of the efficacy of nitrogen mustard in glomerulonephritis (5). Despite its toxicity and difficulty of administration, nitrogen mustard has proven to be a potent and rapidly acting immunosuppressive agent that is clearly effective both in lupus nephritis and rheumatoid arthritis (RA). However, CYC has effectively replaced nitrogen mustard in routine clinical practice. Chlorambucil, despite its efficacy and lack of bladder toxicity, is unacceptably toxic to the bone marrow and oncogenic in our opinion; its use is

reserved for the rare patients with CYC-induced bladder toxicity who still require an alkylating agent.

Cyclophosphamide

Cyclophosphamide is a mechlorethamine derivative that is inactive as administered. It is metabolized by mitochondrial cytochrome P-450 enzymes in the liver to a variety of active metabolites, an increasing number of which have been shown to have both therapeutic and toxic actions. It has been proposed that various genetic polymorphisms of the P-450 enzymes are associated with both the toxicity of CYC, as well as the clinical response to the drug in patients with lupus nephritis (6). In a retrospective study, 62 patients with proliferative lupus nephritis treated with CYC were genotyped for common variant alleles of the P-450 enzyme. Homozygosity or heterozygosity for a particular variant allele (CYP2C19*2) predicted not only lower rates of ovarian toxicity, but a worse clinical response, including higher risk of ESRD and doubling of serum creatinine, suggesting that efficacy and toxicity were both related to the effective dose given.

Active metabolites of CYC include 4-hydroxycyclophosphamide, phosphoramide mustard, and acrolein, all of which have differing rates of synthesis, half-lives, immunologic effects, and toxicities. Serum levels of these metabolites are not routinely measured; hence, dose adjustment in patients with renal or hepatic failure is largely empiric. Dosage should be reduced approximately 30% in patients with a creatinine clearance of less than 30 mL/minute. Furthermore, CYC is incompletely cleared by dialysis, and therefore, the dose should be lowered for these patients as well. The effect of hepatic insufficiency on CYC toxicity is incompletely understood, in part because the liver is responsible for both the production of active metabolites and their degradation. CYC is metabolized not only in the liver, but also in lymphocytes and transitional epithelial cells in the bladder, which may result in local toxicity and/or immunosuppression. CYC may have toxic and/or therapeutic effects in cells that are not actively dividing as well as in dividing cells.

CYC is well absorbed orally, and the oral and intravenous doses are equivalent. Large boluses of CYC can be given orally, achieving comparable serum levels versus IV administration. Approximately 20% is excreted by the kidney, and 80% is processed by the liver.

The immunologic effects of CYC have been described (7 ,8). Direct effects of CYC on DNA result in cell death. These effects may occur at any stage during the cell cycle. Direct immunomodulatory effects also may occur and may be responsible for the relatively rapid onset of therapeutic efficacy of CYC (i.e., within 2 to 4 days) that is seen in some patients at a time when attrition of immunocompetent cells, because of the inhibition of cell division, would not be expected. Putative mechanisms of action include alteration of macrophage function, increased production of prostaglandin E2, alteration of gene transcription, and direct functional effects on lymphocytes (7 ,8). IVC induces suppression of T cell activation by a combination of monoclonal antibodies to the CD2 antigen (9 ,10); however, modulation of T cell function has not been convincingly shown to play an important role in the treatment of lupus.

Cyclophosphamide produces dose-related lymphopenia, which is probably therapeutically important. However, a direct relationship between the degree of lymphopenia and therapeutic efficacy of CYC has not been established. Therapeutic doses of CYC produce dose-dependent reduction of both $CD4^+$ and $CD8^+$ T cells (9 ,10 ,11). IVC reduces the population of $CD4^+$ and $CD8^+$ lymphocytes and B cells, with a more marked reduction of $CD4^+$ lymphocytes and B cells during monthly therapy. Following cessation of monthly therapy, B cell populations rapidly return to baseline (9), but $CD4^+$ populations remain relatively suppressed during less intensive IVC therapy, resulting in prolonged reduction of the $CD4^+/CD8^+$ ratio (11). Persistent reduction of the percentage of $CD19^+$ lymphocytes and of the $CD4^+/CD8^+$ ratio 6 months after completion of 6 months of therapy has been reported (12). Other studies have suggested specific reduction of B cell function (13). Reduction of autoantibody production has been demonstrated in patients with SLE who are treated with both oral and IVC and in patients with rheumatoid arthritis who are treated with oral CYC (9 ,14). Despite reduction of pathogenic autoantibody production, reduction of overall levels of immunoglobulin (Ig) classes IgG, IgA, and IgM, and IgG subclasses has not been observed in our patient population. This suggests that specific suppression of autoantibody production is a function of CYC when used in therapeutic doses and may underlie its beneficial action in SLE.

Low doses of CYC in both animals and humans can heighten immune responses. This has been noted in both antibody-mediated and cell-mediated immunity, and it has been theorized that low doses of CYC could enhance antitumor immunity in humans (15). Low doses of CYC accelerate the production of diabetes in the nonobese diabetic (NOD) mouse (16). The mechanism of action of CYC in these situations is unclear, but it may represent functional alterations as well as depletion of lymphocyte subsets. These observations suggest that tapering the dose of CYC may produce unexpected effects. As a practical matter, however, there are no clinical data to support the hypothesis that during tapering of immunosuppressive drugs, particularly CYC, immunosuppression is supplanted by immunostimulation.

Daily oral CYC is usually initiated at 1 to 2 mg/kg/day. Dosing is adjusted downward in the presence of renal failure, edema, obesity, or inadequate bone marrow reserve. The use of a standard maximum dosage of 2mg/kg/day, with dose reduction in the presence of leukopenia (WBC <3,500) or neutropenia (WBC <1,000), is a common practice. Another treatment strategy that has been employed is gradually increasing the dose of CYC with the goal of producing mild leukopenia. Although these approaches have not been directly compared in a single trial, it is likely that avoidance of leukopenia, coupled with prophylaxis against *P. carinii,* may significantly reduce morbidity and mortality from infection during CYC therapy. Monitoring for toxicity

includes complete blood counts weekly initially and advanced to monthly when stable, urinalyses to detect hemorrhagic cystitis, and annual urine cytology.

Monthly bolus CYC (IVC) usually begins with a dose of 500 to 750 mg/square meter body surface area administered intravenously over 1 hour in normal saline. For each subsequent monthly treatment, the dose may be increased 10% to 25% with a goal of achieving a nadir of the white blood count to 2,000 to 3,000 cells/mm^3. Dose reduction should occur if the nadir of the CBC is less than 2,000 WBC/mm^3 or 1,000 granulocytes/mm^3. Many physicians limit the maximum CYC dose to 1 g/square meter, with dose adjustment downward in renal failure. To avoid bladder toxicity, it is important to instruct patients to drink several liters of water during the 24 hours prior to CYC treatment. They are then hydrated vigorously with half-normal saline during the infusion, followed by oral or IV hydration to maintain urine output more than 100 mL/hour continued for 24 hours. Additionally, sodium 2-mercaptoethane sulfonate (mesna) totaling 80% of the CYC dose is administered in divided doses over 12 hours. Patients unable to completely empty their bladder, such as those with neurogenic bladders, may require catheter drainage or irrigation during treatment. In our institution, two patients with decreased urine output who received IVC without bladder irrigation developed severe posttreatment hemorrhagic cystitis. Antiemetics, such as granisetron or ondansetron, are also routinely administered; initial administration of dexamethasone 5 to 20 mg, diphenhydramine 25 to 50 mg and/or lorazepam 1 mg may also be used. Potential toxicities of cyclophosphamide are described below.

Hemorrhagic Cystitis and Carcinomas of the Bladder

Acrolein is a CYC metabolite, which is directly toxic to the bladder. Exposure to acrolein in the bladder has been associated with hemorrhagic cystitis, a premalignant lesion identified in 50% of patients receiving CYC who eventually develop transitional cell carcinoma of the urinary tract, particularly the bladder. The risk of hemorrhagic cystitis (as well as bladder fibrosis) is increased with daily oral administration of CYC (reported in 5% to 34% patients) (17 ,18 ,19 ,20). Monthly urinalyses are therefore advised during treatment. The finding of hematuria warrants CYC discontinuation pending urologic evaluation. Hemorrhagic cystitis may present either with microscopic or gross hematuria, which may be life-threatening, mandating immediate discontinuation of CYC (18). If hemorrhagic cystitis occurs, therapy with CYC should not be reintroduced even after symptoms resolve. Furthermore, these patients should have annual evaluation by a urologist, including cystoscopy and urine cytologic examination (14). The risk of bladder carcinoma associated with CYC therapy is dose dependent and is markedly increased after a total dose of 30 g (19 ,20). In a study of RA patients, 9 of 119 CYC-treated patients developed bladder carcinomas after 20 years, of whom seven had received more than 80 g of CYC (21).

In comparison to oral administration, monthly IVC is rarely complicated by bladder injury if proper hydration and bladder emptying occur. However, it has been reported in patients who did not receive IV hydration and in cancer chemotherapy patients receiving high doses. IVC is not safe after bladder complications of daily CYC, however. As mentioned above, the use of mesna has been advocated to reduce the concentration of acrolein and perhaps other toxic metabolites in the bladder. Vigorous hydration and mesna used together may provide the best protection, although there is no established standard of care.

Other Malignancies

Development of malignancies following CYC administration is well described in patients with rheumatic diseases, particularly rheumatoid arthritis (RA) and Wegener granulomatosis (17). Nonurinary tract neoplastic complications of CYC include skin cancers and hematologic malignancies, as well as cervical atypia, which can be seen even in patients who have received cumulative doses of CYC less than 20 g. In those patients who have received 80 to 120 g cumulative CYC doses, myelodysplastic syndromes are observed, characterized by monozomy-5 and/or monozomy-7 (7 ,22). Long-term follow-up studies by Baltus et al. (23) and Baker et al. (18) of RA patients treated with oral CYC have established an approximately 10% additional incidence of malignancy compared with age-matched controls after a total dose of 30 g. Doses of less than 10 g are almost certainly safer; doses of 100 g or more are even more likely to produce malignancy. The overall incidence of hematologic malignancies in patients receiving more than 30 g of CYC may approach 5%. Radis et al. (21) reported a 20-year follow-up of the original study by Baker et al. and showed continued occurrence of CYC-induced malignancies, including bladder cancer throughout the 20-year follow-up period. At the completion of this study, only 40% of the original patient population that was treated with CYC remained cancer-free.

Although there is little data, there is no reason to believe that comparable doses of other alkylating agents, such as chlorambucil or nitrogen mustard are safer than CYC. An increased incidence of cutaneous malignancies, including melanomas, squamous cell carcinomas, and aggressive basal cell carcinomas, has been observed (24). Additionally, there is an increased risk of cervical dysplasia and carcinomas of the cervix and vulva. This risk is also a problem for transplant patients receiving various immunosuppressive drugs (24 ,25). IVC therapy of patients with lupus has not been associated with a statistically significant increase in the incidence of fully developed cancers, probably because of the lower cumulative doses and the use of IV hydration to protect the urinary tract. This information may be deceptive because of the relative shorter lengths of follow-up obtained thus far.

Hematologic Toxicity

Compared with other alkylating agents such as nitrogen mustard, the acute effects of CYC are relatively benign. Stem cells appear to be quite resistant to CYC. After pulse therapy, the nadir of the lymphocyte count occurs on approximately day 7 to 10, and that of the granulocyte count on approximately day 10 to 149. There usually is a prompt recovery from granulocytopenia after 21 to 28 days. In some patients, the recovery period may be prolonged, necessitating longer dose intervals. Prior use of alkylating agents may be associated with delayed recovery. Immunologically mediated cytopenias often improve after treatment with appropriate doses of IVC, whereas they are more likely to worsen after azathioprine administration. Daily oral CYC can result in the progressive development of macrocytosis and cytopenias. After prolonged administration, with cumulative doses in the range of 60 to 120 g, the risk of hematologic malignancies, particularly myelodysplastic syndromes, is increased. Thrombocytopenia, which rarely occurs as a result of treatment except after prolonged therapy, may signify the onset of a myelodysplastic syndrome.

Gastrointestinal Toxicity

Intravenous CYC can be associated with short term nausea and gastrointestinal dysmotility during treatment. Occasio-nally, significant hepatic toxicity may occur with the doses used for autoimmune diseases. With oral CYC treatment, both anorexia and nausea may occur, particularly with high doses.

Pulmonary Toxicity

Pulmonary toxicity is an infrequent complication during therapy with CYC. The most frequently encountered pulmonary involvement of CYC therapy is acute interstitial pneumonitis. Pulmonary injury due to alkylating should be suspected in patients treated with CYC during the past 6 months prior to presentation who have bilateral reticular or nodular diffuse opacities on chest radiograph, or peripheral ground-glass opacities in the upper lung fields on chest CT. Additionally, a late-onset pneumonitis associated with fibrosis may present insidiously after months to years of CYC therapy, even with relatively low doses (26). These late conditions are minimally responsive to corticosteroids, irreversible, and usually result in terminal respiratory failure or lung transplantation.

Gonadal Toxicity and Teratogenicity

CYC is toxic to the granulosa cell and, as a consequence, reduces serum estradiol levels and progesterone production, inhibits the maturation of oocytes, and reduces the number of ovarian follicles, ultimately resulting in ovarian failure. Studies in patients with breast cancer receiving CYC show that in women in their 40s, 30s, or 20s, the respective cumulative doses of CYC required to produce ovarian failure were 5, 9, or 20 g (7). Amenorrhea or premature ovarian failure is less likely to occur in patients who receive short-term (approximately 6 months) monthly IVC.

Several approaches to preserve fertility in women undergoing treatment with CYC have been proposed. These include preservation of oocytes, embryos, or ovarian tissue (a topic recently reviewed in the New England Journal of Medicine) (27), and the use of gonadotropin hormone-releasing analogs (depot-GnRH-a) to suppress the metabolism of the ovaries during cytotoxic therapy with CYC (28 ,29 ,30). We recently reported the results of an open trial of depot-leuprolide acetate (a synthetic GnRH-a) administration for ovarian protection during monthly IVC therapy (31). In this study, premature ovarian failure occurred in only 1 of 20 (5%) GnRH-a treated patients versus 6 of 20 (30%) of controls matched for age and cumulative CYC dose (p <0.05, McNemar test). Furthermore, time-to-event analysis demonstrated improved cumulative ovarian protection over time in the GnRH-a treated group (p = 0.04) (31). These data, in addition to other data from nonrandomized trials in the field of chemotherapy and reproductive preservation, suggest that this GnRH-a protocol for ovarian protection in women receiving CYC is both safe and effective. Should it prove to be effective in further trials, ovarian protection with leuprolide has the potential advantages of being noninvasive in severely ill patients, less expensive, well tolerated, and the additional advantage of not only preserving fertility but also avoiding premature menopause with its attendant consequences.

Patients who are receiving CYC may also develop transient amenorrhea resulting from their illness (i.e., hypothalamic amenorrhea) or true ovarian failure as described above. The risk of osteoporosis is increased by amenorrhea regardless of its cause.

Azoospermia frequently occurs in men following treatment with CYC, and therefore sperm banking should be considered prior to therapy (32). It has also been reported that testosterone supplementation offers protection of testicular function in men during CYC therapy, as evidenced by one report in which recovery of normal sperm counts was higher among men with azoospermia treated with testosterone vs. no testosterone during CYC therapy (33).

CYC is a potent teratogen that can cause severe birth defects after administration of as little as 200 mg during early pregnancy (34 ,35 ,36 ,37 ,38). Reported abnormalities included absent thumbs, absence of the great toes or all toes, palatal abnormalities, and a single coronary artery. Because fertility is preserved in most lupus patients, highly effective contraceptive techniques (e.g., oral contraceptives or injected progestins in appropriately selected patients) should be strongly considered. Use of CYC in life-threatening lupus during late pregnancy is controversial, but may be appropriate in special circumstances because fetal loss is extremely likely when severe maternal flares are uncontrolled. Major CYC-induced toxicities are felt to occur during the first half of pregnancy (39 ,40).

Infections

The risk of bacterial infections and herpes zoster is increased with CYC therapy (17 ,41 ,42), as is the risk of *P. carinii* pneumonia (PCP) (42). This risk is further increased when more than 20 mg/day of prednisone or bolus corticosteroids are administered concomitantly. In CYC-treated patients with lupus, increased risk of infection has been associated with higher daily doses of prednisone and depression of the $CD4^+/CD8^+$ ratio in circulating lymphocytes (43). Prophylaxis against PCP, now routine in the treatment of Wegener, has lagged in lupus treatment, perhaps because of reluctance to administer trimethoprim-sulfamethoxazole (TMP-SMX) to lupus patients. We have used TMP-SMX three times weekly in lupus patients known to tolerate this drug, and otherwise have used dapsone (100 mg/day) in patients without glucose-6-phosphate dehydrogenase deficiency or sulfa allergy. Hypogammaglobulinemia should be considered in patients who develop infections (44). Granulocyte colony-stimulating factor (GCSF) can also help decrease the morbidity and mortality associated with drug-induced leukopenia during CYC therapy.

Table 61-1: Controlled Trials of Cyclophosphamide and/or Azathioprine in the Treatment of Lupus Nephritis

Study	Patients (*n*)	Results
Fries et al. (52)	14	P > CTX alone
Garancis and Piering (53)	22	P + CTX > P + AZA
Donadio et al. (54,55,56)	26	More recurrences with P; P vs. P + CTX = survival, and on dialysis
Ginzler et al. (117)	14	P + AZA = P + CTX
Balow et al. (47)	111	P + IVC > P + AZA + CTX > P + AZA > P
Boumpas et al. (58)	65	IVC for 30 months >IVCX for 6 months >MP
Sesso et al. (60)	29	IVC or MP both unsuccessful
Gourley et al. (59)	80	IVC > MP; trend for IVC + MP > IVC

AZA, azathioprine; POC, oral cyclophosphamide; IVC, intravenous, intermittent cyclophosphamide; MP, bolus methylprednisolone; P, prednisone.

Finally, the syndrome of inappropriate antidiuretic hormone (SIADH) can also occur following IVC administration.

Clinical Trials Employing Cyclophosphamide for Lupus Nephritis

The literature regarding the use of CYC in SLE, particularly lupus nephritis and central nervous system (CNS) lupus, continues to increase at an exponential rate precluding a detailed review of all studies here. Tables 61-1 and 61-3 summarize results of controlled trials. Table 61-4 summarizes results of controlled trials of sequential therapy using CYC for induction of remission. In this discussion, trials of monthly bolus CYC will be emphasized, but many modified regimens have been proposed, such as weekly or biweekly bolus CYC given intravenously and boluses of CYC given orally (45 ,46). These regimens have been reported to be safe and effective in small series. More complicated regimens, including bolus CYC synchronized with plasmapheresis, high-dose CYC, and sequential regimens using CYC followed by azathioprine or mycophenolate mofetil will be discussed below.

A 20-year clinical trial comparing most of the regimens that have been widely used to treat lupus nephritis was performed at the National Institutes of Health (NIH) including patients with mostly proliferative nephritis, all of whom were treated with daily oral glucocorticosteroids at the initiation of immunosuppressive therapy (47 ,48 ,49 ,50). Patients were given (a) no additional therapy, (b) oral azathioprine, (c) oral azathioprine plus oral CYC, (d) oral CYC, or (e) IVC. The duration of administration of these agents differed, ranging from approximately 2 to 4 years. The IVC treated patients had a variable number of monthly pulses (often three) before being assigned to once-every-3-months CYC therapy (Fig. 61-1). There were several key findings:

- Differences in outcome were not apparent until more than 5 years had elapsed. Until that time, prednisone-treated patients had the same rate of renal failure and death as immunosuppressed patients. This may relate in part to the relatively mild degree of renal compromise in some patients at entry and the use of renal failure or death as endpoints. After 10 years, however, there were marked differences in renal survival, favoring any regimen that included CYC over the administration of prednisone alone.
- There was a trend for patients treated with either prednisone alone or with oral CYC to have higher death rates than patients who were treated with IVC or azathioprine plus CYC. This probably reflects the toxicity of oral CYC and ineffectiveness and toxicity of prednisone alone.
- The combination regimen of oral azathioprine plus CYC appeared to work as well as IVC in terms of progression to renal failure or death.
- Retrospective analysis suggested that the presence of chronic change on initial biopsy was a poor prognostic factor, predicting a poor outcome unless immunosuppressives were used.

Table 61-2: Parameters 40 Days after Nitrogen Mustard Administration

	Incidence		Disappeared at 40 Days		
Parameter	*n*	**%**	*n*	**%**	**Mean Duration of Response (mo)**
Hematuria	45/56	80	14/45	31	46
Hyaline casts	28/58	48	11/28	39	33
Granular casts	32/56	57	11/32	34	63
Oval fat bodies	19/56	34	2/19	11	—

	Decreased			
Parameter	*n*	**%**	**Criteria for Decrease**	**Mean Decrease**
Serum creatinine level	13/33	39	≥0.1 mg/dL	0.63 mg/dL
Serum cholesterol level	19/27	70	≥1 mg/dL	99 mg/dL
24-hour urine protein level	31/38	82	100 mg	3,595 mg
Prednisone dosage	26/43	60	≥1 mg	19 mg
Weight	39/57	68	≥0.1 kg	2 kg

From Wallace DJ, Podell TE, Weiner JM, et al. Lupus nephritis. Experience with 230 patients in a private practice from 1950 to 1980. *Am J Med* 1982;72(2):209–220, with permission.

Table 61-3: Controlled Trials Including Bolus Methylprednisolone, Cyclosporin, or IV Immunoglobulin in SLE

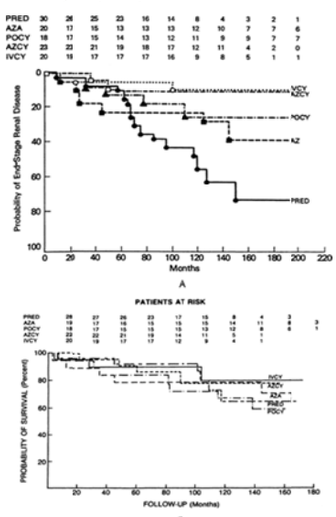
Author	Therapeutic Arms	Result
Boumpas (58) 1992	IVC short-term	Long-term IVC > short-term
	IVC long-term	Bolus MP < either IVC
	Bolus MP	
Sesso (60) 1994	IVC	Equivalent outcome
	Bolus MP	38% renal failure/15 months
Gourley (59) 1996	IVC	IVC > Bolus MP
	Bolus MP	Trend for IVC + Bolus MP > IVC
	IVC + Bolus MP	
Fu (57) 1998	CS without P	Similar renal outcome
	POC + P	38% renal failure/15 months
Boletus (61) 1999	IVC	Equivalent short-term results
	IVIG	

CS, cyclosporine; IVC, intravenous cyclophosphamide; IVIG, IV immunoglobulin; MP, methylprednisolone; POC, oral cyclophosphamide; P, prednisone.

Table 61-4: Controlled Trials Using Sequential Therapy with Azathioprine or Mycophenolate Mofetil Following Induction with Cyclophosphamide in the Treatment of Lupus Nephritis

Study	Patients (n)	Results
Chan et al.	42	MMF > AZA + CYC
Houssiau et al.	90	Low dose IVC + AZA = high dose IVC + AZA
Contreres et al.	59	MMF/AZA > = and less toxic than quarterly IVC + MP
Yee et al.	32	IVC + MP followed by AZA = and less toxic than POC + MP followed by AZA

AZA, azathioprine; IVC, intravenous, intermittent cyclophosphamide; MP; methylprednisolone; POC, oral cyclophosphamide.



- In the subset of patients who underwent serial biopsies, progression of chronic change occurred initially in all patients. Immunosuppressive-treated patients appeared to stabilize after an initial period of scarring; prednisone-treated patients had further scarring.

Oral Cyclophosphamide

Most studies of CYC have compared CYC and prednisone versus prednisone alone. An interesting study by Fries et al. (51) in 1973, however, compared oral CYC alone versus prednisone alone for a mean of 9 weeks in 14 patients with lupus, 10 of whom had nephritis. CYC failed to control either minor or major manifestations, despite development of leukopenia, and significant additional toxicity in many patients. Patients who were changed to prednisone from CYC did better. These results suggest that CYC and prednisone may act synergistically.

In a randomized trial, Garancis and Piering (52) treated 22 patients with biopsy-proven membranoproliferative glomerulonephritis using low-dose prednisone (approximately 10 mg/day) and 2 mg/kg/day of either CYC or azathioprine. After 6 to 36 months, the CYC-treated patients had better renal function and fewer deaths (0 vs. 4).

In another randomized trial, Donadio (53 ,54 ,55) assigned 50 patients with diffuse proliferative glomerulonephritis to treatment either with 6 months of oral CYC plus prednisone or with prednisone alone, retreating patients who subsequently flared with 6 additional months of oral CYC. The CYC-treated group had fewer flares of renal disease after 2 years and was felt to have a more favorable clinical course. CYC appeared to have a steroid-sparing effect. Patients with advanced renal insufficiency (i.e., creatinine clearance <30 mL/min) appeared not to benefit from this regimen. After 4 years, however, there was no difference in progression to death or renal failure between the two groups.

Fu et al. (56) compared daily oral CYC with cyclosporine in children with nephritis and found no difference in efficacy. The details of this somewhat atypical protocol are reviewed below (see Cyclosporine).

Recently there has been renewed interest in use of daily oral cyclophosphamide in lupus nephritis for remission induction followed with azathioprine (AZA) (57 ,58). Chan et al. studied 42 patients with moderately active diffuse proliferative glomerulonephritis who were randomized to daily CYC for 6 months followed by AZA for 6 months with high-dose MMF for 6 months followed by low-dose MMF for 6 months. At long-term follow-up, the results of this study reveal that in the MMF group, 81% experienced a complete remission, and 14% experienced partial remission. In the group randomized to CYC and AZA, 76% experienced a complete remission and 14% experienced a partial remission. In a second study, long-term outcomes in a cohort of lupus patients with diffuse proliferative nephritis who received sequential therapy with oral CYC and prednisolone for induction followed by AZA for maintenance therapy were studied (58). Sixty-six patients were included, of whom 82.4% achieved complete remission, and 39.1 of whom

relapsed during the follow-up period of 91.7 +/-36.7 months. There was no end-stage renal failure or death among study patients, although three (4.4%) patients had doubling of baseline creatinine.

Bolus Cyclophosphamide in Lupus Nephritis

Monthly bolus cyclophosphamide (IVC), first described as a treatment for lupus in 1984 by Sessoms and Kovarsky (59), is now the best studied immunosuppressive regimen for severe lupus. Early experience indicated that 6 months was too short a duration of treatment for patients with lupus nephritis, approximately 50% of whom experienced flares after discontinuation.

These observations were confirmed by Boumpas et al. (60), who compared three regimens in a relatively sick group of patients with lupus nephritis: seven monthly pulses of prednisone, seven monthly pulses of IVC, or seven monthly pulses of IVC followed by maintenance pulses of IVC every 3 months. All groups received oral prednisone. End points, including doubling of serum creatinine, were relatively sensitive, and differences between the treatment groups were evident after a few years. In this study, seven monthly pulses of IVC followed by an every-3-month maintenance regimen resulted in fewer flares and fewer doublings of serum creatinine compared with seven monthly pulses of CYC without maintenance pulses every 3 months or seven monthly pulses of methylprednisolone (Fig. 61-2). The longer IVC regimen resulted in more toxicity, however, particularly ovarian failure. Additionally, bolus methylprednisolone was not as effective as long-term CYC.

A related study compared bolus IVC versus bolus methylprednisolone versus both regimens as treatment for lupus nephritis (61). As in the previously described study, CYC was clearly superior to bolus methylprednisolone. Interestingly, although statistical significance was not achieved, there was a strong suggestion that addition of bolus methylprednisolone to bolus CYC increased the efficacy of the latter. Patients who received methylprednisolone pulses had more osteonecrosis than those who did not. During an extended follow-up with a median of 11 years (62), an intention-to-treat survival analysis of the patients in the above protocol revealed the likelihood of treatment failure to be significantly lower in the groups who received CYC (*P* = 0.04) and combination therapy (*P* = 0.002) than in group who received methylprednisolone alone. Furthermore, not only were there no more adverse events in the group treated with combination therapy versus the group treated with CYC alone, but the proportion of patients who had doubling of serum creatinine concentration was significantly lower in the combination group than in the CYC group. This study is noteworthy because it confirms the utility and relative lack of additional risk with combination pulse CYC and methylprednisolone therapy for lupus nephritis over methylprednisolone or CYC alone.

An opposite conclusion was reached by Sesso et al. (63). They compared short-term IVC versus bolus methylprednisolone in 29 patients with severe lupus nephritis. Patients received eight pulses (roughly comparable with the short-term arm on the previously described study by Boumpas et al. (60) in terms of total dose) over a 13-month period without maintenance IVC. This study found no difference in outcome. Survival without renal failure was a disappointing 62% over a mean 15 months of follow-up; 5 of 29 patients (17%) died. The high rate of initial treatment failures in the cyclophosphamide group and shorter-term follow-up could explain the lack of differences in outcome compared with those of other studies.

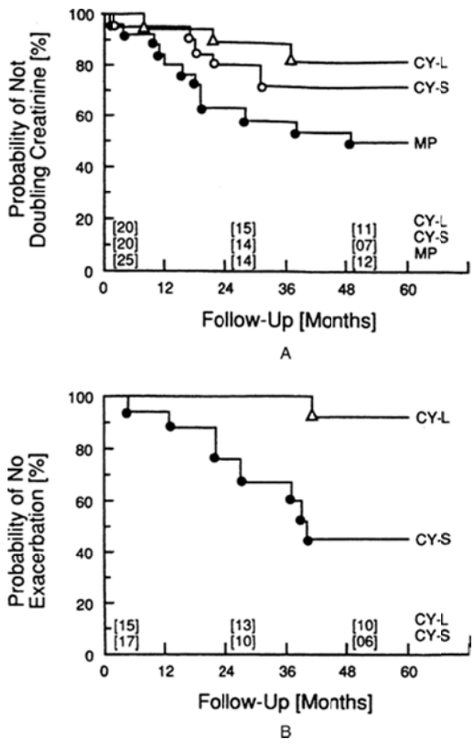


Figure 61-2. Treatment of severe lupus nephritis. **A,** Probability of not doubling serum creatinine levels in 65 patients with severe active lupus nephritis randomly assigned to receive: IV methylprednisolone (MP), 1.0 g/m^2 monthly for 6 months; IV cyclophosphamide (CY-S), 0.5 to 1.0 g/m^2 monthly for 6 months; or IV cyclophosphamide (CY-L), 0.5 to 1.0 g/m^2 monthly for 6 months, followed by quarterly infusions for 24 months (Gehan test comparing CY-L with MP, p = 0.037). **B,** Probability of no exacerbation of lupus activity on completion of monthly pulses in groups randomly assigned to receive CY-L and CY-S (Gehan test, p = 0.006). Numbers of patients that remain at risk at various times are shown along the abscissa. (From Boumpas DT, Austin HA, Vaughn EM, et al. Controlled trial of pulse methylprednisolone versus two regimens of pulse cyclophosphamide in severe lupus nephritis. *Lancet* 1992;340:741–745, with permission.)

Boletis et al. (64) compared IVC with ten immunoglobulin infusions and found equivalent results over an 18-month period. Proteinuria actually increased slightly in the IVC group.

The possibility that brief administration of CYC might be effective in inducing remission was suggested by the

Euro-Lupus Nephritis Trial (65). In this study, 90 patients with proliferative glomerulonephritis were randomized to either “high dose” CYC (6 monthly and 2 quarterly pulses increased according to their WBC nadir) or “low dose” CYC (6 doses of 500 mg CYC every 2 weeks). Maintenance therapy was with azathioprine. Renal remission was achieved in 71% of low dose versus 54% of high dose patients, and renal flares were observed in 27% of low dose and 29% of the high dose group.

Sequential Therapy for Lupus Nephritis

Studies in both lupus and other systemic inflammatory diseases, particularly Wegener granulomatosis, have begun to focus on minimizing exposure to CYC by substituting less toxic immunosuppressive therapies after disease control with IVC has been achieved. In a 2004 study by Contreras et al., 59 patients with lupus nephritis WHO class III (14), IV (46) or Vb1 were treated with NIH IVC protocol for

7 doses (66). Patients were randomized to maintenance dosing for 1 to 3 years following initial therapy consisting of either quarterly IVC, MMF, or azathioprine (AZA). During maintenance therapy, there were four deaths in the CYC group and one death in the MMF group, and the incidence of chronic renal failure was three in the CYC group, one in the MMF group, and one in the AZA group. The 72-month event-free survival (defined as no death or progression to hemodialysis) was higher in groups treated with MMF ($p < .05$) and AZA ($p < 01$) versus CYC. The relapse-free survival was also higher in MMF versus CYC ($p < .02$) groups (see Fig. 61-3).

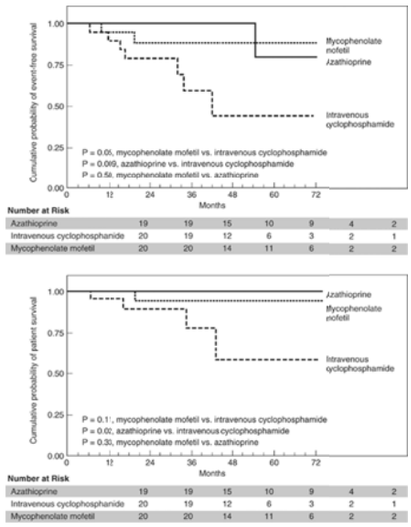

Figure 61-3. Mycophenolate for lupus nephritis.

Several clinical trials have employed daily oral CYC followed by AZA (57 ,58). For example, Chan et al. studied 42 patients with somewhat active diffuse proliferative glomerulonephritis who were randomized to daily CYC for 6 months followed by AZA for versus high-dose MMF for 12 months followed by low-dose MMF at 6 months. At long-term follow-up, the results of this study reveal that in the MMF group, 81% experienced a complete remission and 14% experienced partial remission. In the group randomized to CYC and AZA, 76% experienced a complete remission, and 14% experienced a partial remission. The study design does not afford comparison of this regimen with IVC, but oral CYC did appear to be more toxic than MMF.

As noted above, The EURO Lupus study compared “high dose” versus “low dose” CYC in lupus patients with proliferative nephritis who were then switched to maintenance therapy with AZA65.

Another study that employed sequential therapy, “The EULAR randomized controlled trial of pulse cyclophosphamide and methylprednisolone versus continuous cyclophosphamide and prednisolone followed by azathioprine and prednisolone in lupus nephritis” (67), suggested that there were no significant differences between these regimens; however, enrollment was difficult and only 32 patients were treated. The authors encountered cytopenias in the 2 mg/kg oral CYC group and concluded that, “the initial dose of 2 mg/kg oral cyclophosphamide was felt by the investigators to be too toxic to persist with. The intermittent intravenous pulse regimen appears to be better tolerated than oral continuous treatment, with less severe adverse effects.”

These studies provide examples of regimens utilizing sequential therapy, but because the regimens used for induction differed and the treatments were not compared with traditional treatment with monthly followed by quarterly CYC, it is not possible to compare these maintenance regimens with each other or with quarterly IVC.

For a summary of these studies involving sequential therapy for lupus nephritis, please refer to Table 61-4 .

Intravenous Cyclophosphamide in Nonrenal Lupus

In general, severe nonrenal manifestations of lupus that result from immune complex disease respond more rapidly and completely to IVC plus corticosteroids than to corticosteroids alone. The required treatment duration and size of individual IVC boluses varies with different disease manifestations. For example, severe transverse myelitis may respond to a shorter course of treatment than severe nephritis, and immune-mediated thrombocytopenia may respond to lower than usual doses. During treatment of severe lupus with IVC, improvement of minor manifestations, including constitutional symptoms, fevers, arthralgias, rash, pleurisy, and serologic abnormalities, and reduced prednisone requirements usually occur within 3 months.

Neuropsychiatric Lupus

No clear guidelines exist regarding therapy for neuropsychiatric lupus (NPSLE) with various modalities, including corticosteroids, CYC, and/or anticoagulation. Distinction between various primary pathogenic mechanisms, such as immune complex–mediated vasculitis, antibody-mediated cerebral injury, microangiopathy, thrombosis, or secondary causes such as atherosclerosis or infection, is notoriously difficult, and is further complicated by the multifactorial etiology of many events. In many cases, skilled physicians must make a “seat-of-the-pants” decision regarding the use of immunosuppression, anticoagulation, or both based on clinical, serologic, or magnetic resonance imaging evidence, unless there is biopsy evidence of tissue inflammation or cerebrospinal fluid pleocytosis. In many series, treatment decisions have been made (apparently appropriately) on the basis of clinical judgment rather than on specific inclusion criteria.

In our hands, active, steroid-refractory cerebral lupus that is adjudged to be secondary to immunologically mediated injury has responded well to IVC with or without bolus methylprednisolone in most cases. Anticoagulation has been used simultaneously when it has been impossible to distinguish thrombotic from inflammatory disease or to rule out the possibility that vascular inflammation is contributing to the development of thrombosis. Neither the presence of antiphospholipid antibodies nor involvement of one or more large vessels rules out use of immunosuppression as opposed to anticoagulation. Boumpas et al. (68) treated nine patients with monthly IVC, three of whom had transverse myelitis and five of whom had focal neurologic findings, seizures, or both. The duration of symptoms ranged from 3 to 45 days. All nine patients had findings suggesting an inflammatory process, including anti-DNA antibodies, and five had cerebrospinal fluid pleocytosis. Five of these patients concomitantly had antiphospholipid antibodies. All patients recovered either partially or completely. These observations suggest that in selected patients who have antiphospholipid antibodies that may not be the major cause of their events, IVC administration is associated with clinical improvement.

Other series of IVC in NPSLE report favorable results. Neuwelt et al. (69) retrospectively reviewed 31 patients with neuropsychiatric lupus who were treated with IVC and who had failed a variety of prior therapies, including corticosteroids, Coumadin, chlorambucil, and azathioprine.

Indications included organic brain syndrome in 55% of patients, strokes in 35%, peripheral mononeuropathies in 32%, seizures in 29%, and transverse myelitis in 16%. Patients with anticardiolipin antibodies were treated with warfarin. Treatment regimens varied from low to high doses of IV cyclophosphamide, and plasmapheresis was added to some patients when they appeared not to improve after IVC. Overall, 61% of patients were reported to improve, of whom 26% were not initially improved after 9 months of therapy and appeared to respond to addition of plasmapheresis. The failure rate for patients with organic brain syndrome was 83%, compared with 37% for other indications. Malaviya et al. (70) treated 14 patients with a variety of focal and diffuse neurologic deficits. All patients except the two with seizures stabilized or improved.

Numerous studies have demonstrated improvement of transverse myelitis with IVC, with or without bolus corticosteroids (71 ,72). Because of the catastrophic nature of transverse myelitis and the importance of prompt therapeutic intervention, it may be appropriate to have a very low threshold for prompt institution of IVC when this syndrome appears suddenly, with or without concomitant high-dose (e.g., 1 g/m^2) methylprednisolone. In our institution, prompt use of bolus CYC for transverse myelitis has been associated with preservation of the ability to ambulate in most patients, although many have continued to have neurogenic bladders.

Ten patients with bilateral corticosteroid-refractory optic neuritis and severe visual compromise were treated with bolus IVC for 6 months (73). Ten of 20 eyes recovered completely, six partially, and four did not.

Baca (74) treated seven children with NPSLE (including seizures, focal neurologic deficits, transverse myelitis, and organic brain syndromes) with monthly bolus CYC combined with three initial boluses of 30 mg/kg methylprednisolone. Three patients had anticardiolipin antibodies but were not anticoagulated. Six patients recovered completely and one had a minor residual deficit.

Other Disease Manifestations

Numerous corticosteroid-refractory manifestations of lupus have been reported to benefit from pulse CYC in case reports and uncontrolled series, including systemic vasculitis, gastrointestinal vasculitis and pneumatosis intestinalis (75). Hematologic conditions reported to respond include aplastic anemia (76 ,77), acquired factor VIII deficiency (78), and acquired von Willebrand disease (79), as well as lupus-induced cytopenias, particularly thrombocytopenia. Thrombocytopenia in active lupus possibly may respond to lower pulses of CYC than are necessary to control other disease manifestations. Roach and Hutchinson (80) successfully treated steroid-refractory thrombocytopenia on two occasions in one patient with only 400 mg of IVC. Boumpas et al. (81) found overall improvement of thrombocytopenia in patients who were treated according to the NIH protocol. Although IVC should not, in our opinion, be substituted for plasmapheresis and plasma exchange in thrombotic thrombocytopenic purpura (TTP) in patients with lupus, it has been added to plasma exchange for this indication (82 ,83). Bolus CYC alone may be ineffective for lupus-related TTP; two of our patients developed TTP during monthly bolus CYC therapy for nephritis, and, despite prompt addition of plasma exchange, one patient died and the other progressed to renal failure.

Several studies suggest that lupus-related interstitial lung disease and bronchiolitis obliterans may respond to monthly CYC (84 ,85). Fukada et al. (86) also noted a response of pulmonary hemorrhage to IVC. In our experience, IVC is associated with control of pulmonary hemorrhage in patients with lupus who appear to be steroid refractory in the majority of cases. Although cases of idiopathic inflammatory myositis have not uniformly responded well to IVC in the published literature, three patients with SLE were reported by Kono et al. (87) to have remission of refractory polymyositis with the addition of IVC.

In summary, these nonrenal manifestations of lupus appear to respond to IVC in most cases when steroid therapy had apparently failed. These results do not establish the superiority of IV over oral CYC for these indications, however.

Bolus Cyclophosphamide in Children

IVC has been used successfully in children of all ages, including infants (88). Studies by Lehman and Onel (89) of treatment with IVC for 36 months have shown good disease control and arrest of progression of the chronicity index. This group has also added intravenous methotrexate to IVC in refractory patients with benefit (90). It is our opinion that daily oral CYC is clearly less desirable in children with lupus, as it is in adults, because of its toxicity, and that it should not be used as first-line therapy instead of bolus CYC.

Combination therapy for severe lupus with synchronized plasmapheresis and CYC has been proposed by Euler et al. (91 ,92). The rationale for this mode of therapy is that the depletion of circulating autoantibodies may stimulate increased activity of lymphocytes and plasma cells that are responsible for immunoglobulin formation, resulting in increased susceptibility to CYC. Two regimens have been proposed, one of which involves performing a single plasmapheresis before each of a series of monthly pulses of CYC. A controlled trial did not show significant benefit from adding plasmapheresis to IVC. The second, more intensive protocol includes daily plasmapheresis on three successive days of 60 mL/kg, followed on days 4, 5, and 6 by three pulses of 12 mg/kg of IVC. Patients are then treated over a 6-month period with escalating doses of oral CYC and 1 mg/kg/ day of prednisone that gradually is tapered. This treatment regimen is highly toxic even when GCSF is employed to treat leukopenia, and deaths have resulted. However, in a patient population with mixed indications for therapy including pneumonitis, nephritis, retinal vasculitis, and pericarditis, there was marked overall reduction of disease activity in

12 of 14 treated patients, and at final assessment, eight patients were reported to be clinically well for a mean follow-up time of 6 years. Seven patients developed amenorrhea. This highly complex protocol appears to achieve satisfactory results in most patients when in expert hands, but it has been extremely toxic (92 ,93 ,94 ,95). It may represent an intermediate intensity of treatment between conventional and high-dose cyclophosphamide regimens.

Aggressive Cyclophosphamide-Containing Regimens

High-dose CYC regimens sufficient to arrest production of hematopoietic cells are being tried in lupus. Because stem cells are resistant to CYC, the marrow recovers after a period requiring support with cells and colony stimulating factors. Brodsky et al. (96) reported treating patients with severe SLE with 200 mg/kg CYC with complete responses in half the patients. There were no deaths. Another study by Petri et al. examined the effect of high dose CYC in a group of 14 lupus patients ages 21 to 45 who had failed prior immunosuppressive therapy (5 of 14 had prior CYC) (97). In this population, 9 of 14 had active renal disease, of whom 5 had diffuse proliferative glomerulonephritis and 4 had membranous disease. The serum creatinine levels ranged from 0.4 to 2.0, and SLEDAI scores reflected a range of lupus activity: 5 patients had scores of 0 to 4, 5 patients had scores of 5 to 8, and 4 patients had scores of 10 to 16. Treatment in this protocol was with CYC 50 mg/kg × 4 days, followed by granulocyte colony stimulating factor six days after the last dose of CYC. Results of the trial revealed that a complete renal response was achieved in 5 patients, a partial response in 7 and no response in 2, one of whom had renal failure. SLEDAI score significantly improved (pretreatment average score was 6.8, posttreatment average score 2.7), and prednisone doses were also significantly decreased in the posttreatment group (20 mg to 5 mg). This open trial suggests that this regimen is efficacious but does not allow comparison with alternate regimens such as monthly bolus CYC plus methylprednisolone or MMF.

Autologous stem cell transplantation utilizing high-dose CYC with or without additional immunosuppressives is being evaluated in a number of rheumatic diseases. One study reported enrollment of nine patients in a protocol (98), of whom one died during induction and seven ultimately underwent transplantation. Fluid overload occurred in all patients; three required dialysis or hemofiltration and two were intubated. All patients responded clinically and were able to discontinue immunosuppressive medications. The dramatic disease suppression reported appears to exceed that of high-dose cyclophosphamide regimens. However, the short-term toxicity appears to be greater. Across the world the mortality of stem cell transplantation for rheumatic diseases exceeds 10%. This figure may improve with modifications of treatment regimens and criteria for patient selection.

Summary of Cyclophosphamide Therapy for Lupus

- There is no evidence that IVC is more effective than oral CYC in patients with lupus in the long run, but it is unquestionably less toxic.
- Prednisone has been employed with oral or IVC in all studies showing efficacy. Daily oral CYC without prednisone was not effective in a single controlled study.
- Addition of bolus methylprednisolone to monthly bolus CYC for lupus nephritis has the potential to improve efficacy with only modest increased risk of toxicity.
- The cumulative dose of CYC predicts the risk of gonadal injury and risk of secondary malignancies. Meticulous surveillance for malignant and premalignant conditions (especially those resulting from human papilloma virus [HPV]) is indicated in CYC-treated patients.
- Failure of active lupus to respond to IVC does not imply that the disease manifestation is inherently untreatable. If the deterioration is clearly a result of active lupus nephritis, addition of bolus methylprednisolone, which has proven to be beneficial in a controlled trial, addition of another immunosuppressive to IVC, high-dose CYC or stem cell transplantation, may be appropriate. In the near future, use of biologic agents in this situation is likely to become the norm.
- Approximately 80% of patients with nephritis respond to IVC treatment after 6 monthly pulses, of whom at least 20% will flare if the frequency of IVC is reduced to every 3 months and continued for an additional 2 years. If no immunosuppression is given after the first 6 months, the flare rate approaches 50%. Alternatively, maintenance therapy with AZA or MMF may provide equivalent or superior protection against flares with reduced toxicity. In the event of a partial but unsatisfactory response, continued monthly treatment after initial 6 months may be successful. Sequential therapy should be considered in all patients receiving CYC as induction therapy for lupus nephritis after 6 months.
- Proteinuria and features of nephrotic syndrome usually improve substantially during the first 6 to 12 months. Patients who are not in complete remission after 6 months (e.g., proteinuria reduced but not yet <1 g) may have continued reduction of proteinuria during less intensive therapy. Patients who fail to achieve remission after 6 months have a worse prognosis and presumably require more aggressive therapy than patients who have achieved remission.
- Patients with renal insufficiency average an approximately 30% improvement in creatinine clearance during the first 6 months, but tend to backslide toward baseline values after 1 to 2 years. It is interesting to speculate that this may result from continued glomerular scarring in the apparent absence of inflammation, as described by Chaghac in total lymphoid irradiation-treated lupus nephritis patients (99). However, it is possible that inflammation recurs as immunosuppression is reduced or that other processes

such as occult hypertension and hyperfiltration may be important factors.

- The indications for IVC therapy for neurologic disease are poorly characterized. The possibility that an antiphospholipid antibody syndrome exists is not in itself a contraindication to the treatment of apparent inflammatory disease. In catastrophic neurologic disease in which the etiology is unclear, combined anticoagulation and immunosuppression should be considered.

Nitrogen Mustard

Nitrogen mustard (mechlorethamine) is a highly potent alkylating agent with prolonged immunosuppressive and immunomodulatory effects. Although it is infrequently used at the present time, a detailed review is in order because it appears to be quite efficacious in severe lupus and may have different properties than IV cyclophosphamide. For instance, studies in patients with rheumatoid arthritis show that nitrogen mustard, when administered intravenously, is effective in suppressing disease activity, whereas IV cyclophosphamide given monthly probably is not.

Nitrogen mustard is administered in its active form and has potent caustic, immunosuppressive, and carcinogenic effects on exposed tissue. These properties are responsible for the high incidence of thrombophlebitis and local irritation at IV infusion sites, as well as for the risk of severe tissue necrosis if the drug is extravasated. These effects also occur during topical application and are responsible for the reports of successful therapy for both cutaneous lupus and other cutaneous diseases, such as mycosis fungoides. Topical application of nitrogen mustard is associated with the induction of primary or secondary malignancies at the application site.

Nitrogen mustard is considered to be a more potent stimulant of nausea and vomiting than cyclophosphamide. Reviews that deal with this side effect generally were written before the introduction of highly effective antiemetic agents or antiemetic combinations, such as the combination of ondansetron, lorazepam, diphenhydramine, and dexamethasone. Judicious use of these agents when coupled with vigorous hydration, both immediately after drug administration to reduce local tissue damage effects and during the period of time that nausea and vomiting may occur, could considerably reduce the immediate toxicity of this drug.

The bone marrow effects of nitrogen mustard differ from those of cyclophosphamide. Hematologic toxicity of nitrogen mustard following the administration of a single course of this drug has been reported to be relatively modest by Dubois (100), who treated patients only after a bone marrow examination to rule out bone marrow hypocellularity. In this setting, the nadir of the leukocyte count is said rarely to fall below 2,500 cells/mL, although the period of leukopenia is far longer than that associated with cyclophosphamide, on the order of 6 weeks. This appears to result in part from the increased toxicity of nitrogen mustard to stem cells. Although reports of secondary hematologic malignancies in nitrogen mustard–treated patients with lupus are rare, patients who were treated with nitrogen mustard for hematologic diseases have an increased incidence of secondary hematologic malignancies, including myelodysplastic syndromes. The rarity of such reports in patients with connective tissue disease may relate in part to the lower cumulative doses that usually are administered in this population, which may relate in turn to the cumbersome nature of this therapy.

Nitrogen mustard is given as a course of approximately 0.3 to 0.4 mg/kg (15 to 20 mg), either as a single IV dose administered in a large amount of fluid over 1 hour and followed by vigorous hydration, or as two divided doses given 12 hours apart. In some patients, courses have been repeated as often as every 6 weeks.

Clinical responses to nitrogen mustard have been observed as rapidly as within several days, and they are more protracted than those to IV cyclophosphamide. During a period when the prognosis of lupus nephritis was poor, outcomes were in general better than those obtained with prednisone alone, although they were worse than those obtained today with improved supportive care and adjunctive agents (Table 61-2). It therefore is difficult to evaluate nitrogen mustard in the context of modern therapeutic adjuncts.

In 1954, Dubois (100) reported the treatment of 33 patients with 20 mg of IV nitrogen mustard. He initially treated most patients with steroids or antimalarials, only adding nitrogen mustard after 2 months of unsuccessful therapy with prednisone. Twenty-six of the 33 patients had renal disease. Interestingly, none of the patients who did not have nephritis benefited from treatment; 13 of 16 nephrotic and 7 of 10 nonnephrotic patients with renal disease improved. In many cases, Dubois observed diuresis within a few days in patients with nephrotic syndrome. Long-term survival was greater in those patients with nephritis who responded to the treatment. Wallace et al. (101) reviewed the therapy of nephritis in the same practice, including 44 patients receiving 74 courses of nitrogen mustard. After 40 days, improvement of multiple parameters, including urinary sediment, serum cholesterol, steroid dosage, serum creatinine, and urine protein excretion was noted (Table 61-2). The response rate again was noted to be higher in patients with nephrotic syndrome. Favorable responses to one or two courses were said to have lasted for years in some patients.

In 1973, Dillard et al. (102) described the treatment of 17 patients with diffuse proliferative glomerulonephritis using nitrogen mustard. Five patients died of renal failure, four within 6 weeks. The remaining 12 patients improved, seven of whom had no exacerbation of renal disease after a mean follow-up of 33 months. All were reported to have normal renal function and protein excretion at follow-up. Nitrogen mustard was felt to be steroid sparing and to be associated with reduction of the level of activity in serial renal biopsies, although the severity (i.e., chronicity) score was not reduced by therapy. Results were said to be unsatisfactory in patients with high levels of both disease activity and scarring.

Wallace and Metzger (103) reported that administration of one or two courses of nitrogen mustard, 0.4 mg/kg,

resulted in improvement of disease activity in two patients with severe nephritis and nephrotic syndrome who failed to respond to monthly IVC, one of whom had failed 32 prior courses of IVC. Topical application of nitrogen mustard has been advocated in severe cutaneous lupus; however, this can result in local induction of malignancy (104).

Summary of Nitrogen Mustard Therapy for Lupus

The role of nitrogen mustard in the management of severe lupus is unclear at present. In patients with nephritis, it appears to offer the potential to dramatically reduce severe disease activity for several months after a single intervention, perhaps in patients who have failed cyclophosphamide or pulse steroid therapy.

Chlorambucil

Chlorambucil is an alkylating agent that differs from nitrogen mustard because it does not produce local irritative effects, and from cyclophosphamide because it is not metabolized to acrolein and does not cause hemorrhagic cystitis. In patients with lupus, it is administered orally in daily doses of from 2 to 12 mg. It has been used as an IV bolus in patients with multiple sclerosis (105) or sarcoidosis (106). Chlorambucil is toxic to dividing cells (107), but it also may have immunomodulatory effects. In idiopathic membranous nephritis, reduction of the number of T cells and reduction of the $CD4^+/CD8^+$ ratio resulted from alternating monthly oral prednisone and oral chlorambucil (108). Monthly pulse chlorambucil in multiple sclerosis was reported to disproportionately reduce circulating B cells (105). The dose, rate of administration, and underlying disease probably alter the observed effects of chlorambucil on immune function, as is the case with cyclophosphamide.

Side effects of chlorambucil that may differ from cyclophosphamide include both marrow suppression and malignancy. Recovery of stem cells is less rapid than after cyclophosphamide administration. Published series suggest that substantial difficulty is encountered during treatment resulting from suppression, which may be irreversible, of individual circulating cell lines (red cells, leukocytes, and platelets) (109).

Chlorambucil is a potent oncogen. Its oncogenicity relative to cyclophosphamide is controversial; however, it is in our opinion more dangerous than IVC. Somatic and germ cell mutations (107 ,109), leukemias, myelodysplastic syndromes, and cutaneous malignancies are increased. Of 144 patients with polycythemia vera who were treated with chlorambucil, 11% developed leukemia after 5.4 years, representing a 13.5-fold increase over patients treated with phlebotomy alone (110). Patapanian et al. (111) identified significant excess malignancy compared with controls in 39 patients with rheumatoid arthritis after 5 years; three hematologic and eight cutaneous malignancies were identified.

Studies of this potentially useful agent are too limited to permit comparison with other immunosuppressive drugs. However, it almost certainly is effective against lupus when combined with prednisone.

In 1973, Snaith et al. (112) reported improvement of steroid-resistant nephritis in five of five patients and of active lupus in a sixth using chlorambucil, 2 to 5 mg/day. Amenorrhea developed in four patients. In 1974, Epstein and Grausz (113) reported improved survival in 16 of 31 patients with lupus and diffuse proliferative nephritis who received chlorambucil in addition to prednisone, but they also reported serious toxicity, including marrow aplasia in five patients, leading to one death. Egypt, Sabbour and Osman (114), in a retrospective study of a group of patients with very high mortality (58% over 5 years), found prednisone plus chlorambucil to be associated with better survival than prednisone alone or prednisone plus oral cyclophosphamide. Survival and reduction of proteinuria were markedly better in chlorambucil-treated patients than in other groups; however, the chlorambucil-treated patients were treated much more recently than other groups

Summary of Chlorambucil Therapy for Lupus

There has been little recent work with chlorambucil in lupus; however, it has been extensively studied in idiopathic membranous and proliferative nephritis and nephrotic syndrome. Regimens containing chlorambucil generally have been felt to be effective, and in one study they were found to be superior to monthly pulse cyclophosphamide (115 ,116).

Azathioprine

Azathioprine (AZA) has been in use for more than 50 years for organ transplantation and to treat autoimmune diseases. Although less potent and slower in onset of efficacy than CYC as treatment for acute severe autoimmune disease, AZA is being recognized both as a steroid sparing agent and as a “maintenance” drug to be used after initial control of severe systemic autoimmune diseases with CYC.

AZA is inactive as administered and is metabolized intracellularly to the purine antagonists 6-mercaptopurine (6MP) and 6-thioinosinic acid. The immunologic effects of AZA and 6MP differ despite the fact that 6MP is the major active metabolite of AZA, suggesting that additional metabolites of AZA may also be active. AZA reduces the numbers of T cells, B cells, and natural killer cells, thereby inhibiting both cellular and humoral immunity, suppressing autoantibody formation and inhibiting prostaglandin synthesis.

In contrast to cyclophosphamide, AZA has not been extensively studied in the past decade as an initial therapeutic agent in lupus nephritis. Recent studies have emphasized the potential role of AZA as a maintenance drug after induction of remission in lupus nephritis. No one has yet demonstrated that MMF, which is viewed by many rheumatologists

as the most promising conventional immunosuppressive drug for lupus nephritis, is superior to AZA for maintenance of remissions.

The caveats that apply to older studies of nephritis (i.e., potentially confounding effects on renal survival of differences in management of hypertension, use of angiotensin-converting enzyme [ACE] inhibitors or other measures to prevent progression of renal disease) apply to the evidence regarding AZA as a first-line agent (Table 61-1). The following controlled studies of azathioprine have yielded disparate results, suggesting that azathioprine is effective in some, but not all, patients.

In the large NIH trial, low-dose azathioprine added to low-dose cyclophosphamide plus prednisone was as effective as IV cyclophosphamide (administered every 3 months) plus prednisone, with comparable mortality and toxicity (49 ,50 ,117). Compared with oral cyclophosphamide, renal survival was the same, but there was a trend that failed to reach statistical significance for the combination regimen to be associated with lower mortality. Thus, azathioprine appears to have a cyclophosphamide-sparing effect when used in combination with that drug. Overall outcomes in the NIH study of azathioprine alone plus prednisone (without cyclophosphamide treatment with azathioprine) were intermediate between prednisone and cyclophosphamide-containing regimens and failed to achieve significance, although they were better than prednisone alone. In our opinion, the slow onset of action of AZA may be partially responsible for its failure as initial therapy for active nephritis, and the studies below do not necessarily suggest that it will not be effective as an agent either in early relatively mild nephritis or as a maintenance agent after initial control of severe nephritis has been achieved.

Donadio et al. (118) randomized 16 patients to azathioprine plus prednisone versus prednisone alone. After 6 months, there was improvement in histologic measures of disease activity (i.e., karyorrhexis, proliferation, fibrinoid deposition, hyaline thrombi, necrosis) in both groups, but there was no difference in outcome after 6 months or after 2 to 3 years (119). Hahn et al. (120) randomized severely ill patients with lupus to prednisone with or without azathioprine over a 2-year period and found no differences in outcome. However, patients with nephritis entered into the azathioprine group were more likely to have severe renal disease with diffuse proliferative glomerulonephritis on biopsy, possibly resulting in underestimation of the efficacy of this drug.

In a study that illustrates the difficulty of distinguishing the toxicity of one drug regimen from the efficacy of alternate therapy, Cade et al. (121) used four different regimens to treat 50 patients with lupus, including prednisone alone, prednisone plus azathioprine, azathioprine alone, and azathioprine plus heparin. Unfortunately, 13 of 15 prednisone-treated patients died, with a mean survival of 19 months, after receiving 60 to 100 mg of prednisone daily for 6 months. In the azathioprine plus prednisone group (which received lower doses of prednisone), 9 of 13 patients survived, with a mean survival of 38 months. Compared with the very high-dose prednisone group, azathioprine alone or in combination with either prednisone or heparin produced superior results. In a double-blind, crossover trial, Ginzler et al. (122) compared azathioprine plus prednisone with prednisone alone and found no benefit.

Recent studies suggest that azathioprine may be most useful either in early stages of nephritis to prevent development of more severe lesions or as maintenance therapy after IVC (as noted earlier). Esdaile (123) conducted an elegant study in the 1980s at Yale of patients who received immunosuppression for lupus nephritis. Almost all immunosuppressed patients were treated with azathioprine. When patients who received early biopsies and treatment were compared with those who had delayed biopsies and treatment, there was strikingly increased preservation of renal function and reduced mortality in the early treatment group. These patients, who were less sick than those reported in earlier trials described above, appeared to be more responsive to treatment with azathioprine, suggesting that there may be a role for immunosuppressives that are safer than IVC when new-onset, relatively mild nephritis is diagnosed. In our experience, however, some AZA-treated patients develop progressive renal disease that responds dramatically to the discontinuance of azathioprine and institution of IVC.

Azathioprine has been used for a variety of nonrenal indications in active SLE. During a controlled trial in patients with active nonrenal lupus, Sztejnbok et al. (124) added AZA 2.5 mg/kg/day to prednisone in half the patients. Azathioprine was reported to be unhelpful in controlling acute disease but to be steroid sparing and reduce mortality. A study randomizing patients with well-controlled lupus to continuation or withdrawal of azathioprine has demonstrated more exacerbations in patients who discontinued the drug (125).

Azathioprine has been reported to be effective in severe cutaneous lupus in several series (126 ,127 ,128 ,129) and to have a steroid-sparing effect. It has been reported to be useful in treating chronic active hepatitis complicating lupus, as well as nonvirally mediated chronic active hepatitis in non-lupus patients. The relatively slow onset of action as well as the lack of dramatic responses of disease activity to this drug mandate consummate clinical judgment on the part of the treating physician when decisions are made regarding whether use of this agent has been effective.

Two recent studies that have highlighted the potential role of AZA as a maintenance agent are reviewed in the section on combined therapies.

Summary of Azathioprine Therapy for Lupus

Azathioprine appears to be less effective than either cyclophosphamide or nitrogen mustard in arresting active, very rapidly progressive nephritis, but it may be effective in both early nephritis and as a maintenance drug after IVC. It appears to be both corticosteroid and cyclophosphamide

sparing. Although slow in onset of action, AZA is a very useful agent in mild to moderately severe SLE. Recent important studies utilizing AZA to maintain remission after induction of remission with IVC in patients with lupus nephritis are described in the section on “Sequential Therapy for Lupus Nephritis .”

Cyclosporine

Cyclosporine (CS) has complex immunologic effects, predominantly inhibition of T cell gene activation, transcription of cytokine genes, and lymphokine release. Additionally, it inhibits the recruitment of antigen-presenting cells and antigen presentation. It is unclear which, if any, of these effects is relevant to the pathogenesis of SLE, except perhaps high-level control of T cell activation of antibody production (130). CS is administered orally or intravenously, with marked variation in bioavailability after oral dosage. Absorption requires formation of an emulsion with bile and can be altered by a variety of gastrointestinal conditions, including diarrhea, malabsorption, and delayed gastric emptying. The drug is highly lipophilic, and levels may be increased in patients with hypocholesterolemia. It is eliminated by cytochrome P-450 with formation of multiple metabolites and excreted in the bile. CS levels are influenced by numerous medications, including rifampin, phenytoin, phenylbutazone, and phenobarbital, which decrease concentrations; and calcium channel blockers, progesterone and macrolide antibodies, and ketoconazole, which increase concentrations. As a consequence, monitoring CS levels is recommended at currently employed doses.

A major adverse effect is nephrotoxicity. Reduction of glomerular filtration may be underestimated because of compensatory hyperfiltration and the increasing contribution of tubular secretion of creatinine to the measured creatinine clearance as renal function declines (131). This side effect appears to be dose related, but it is not completely absent even in studies using doses as low as 2 mg/kg. In a population of 192 adults and children, including 152 with diabetes, who were treated with CS for a mean of 13 months before biopsy, 41 had biopsies that were consistent with CS-induced nephropathy (132). There is an association of nephropathy with maximal dose, mean dose, and cumulative dose before biopsy, but not with blood levels. Deray et al. (133) evaluated 16 patients with autoimmune uveitis who were treated with CS, 5 mg/kg/day initially. CS was adjusted according to the serum creatinine. There was a progressive decline of creatinine clearance throughout the study from the baseline of 120 mL/minute to 75 mL/minute at 24 months. The glomerular filtration rate (GFR) decreased from 116.8 to 75.3 mL per minute. There was a significant increase in total cholesterol levels. Altman et al. (134) treated patients with rheumatoid arthritis sequentially with the following regimens: first with a nonsteroidal anti-inflammatory drug (NSAID), then with CS, 5 mg/kg, then with both. At the end of the study, there was a significant increase in blood urea nitrogen and creatinine levels in 9 of 11 patients, and an additive effect of the two drugs was postulated. This side effect, in our opinion, is the major potential limiting factor in its use in SLE.

Compared with alkylating agents, bone marrow suppression is uncommon. Lymphoproliferative syndromes frequently are observed in CS-treated patients with organ transplants, but they are rare in patients with autoimmune disorders. CS appears to have little, if any, ovarian toxicity and has been employed in a limited number of pregnancies without obvious birth defects. Hypertension has been observed in 50% to 80% of transplant recipients. CS impairs the excretion of potassium, uric acid, and magnesium, and it is a notorious cause of refractory gout. It can cause hypomagnesemia and has been implicated in CNS toxicity, including headache, tremors, and occasionally, focal neurologic defect. Hirsutism, gingival hyperplasia, and gastrointestinal disturbances may occur.

Application of CS in SLE has been the subject of only a few controlled trials. Balletta et al. (135) randomized ten patients with lupus nephritis to either CS, 3 mg/kg/day, plus prednisone or to prednisone alone. After 12 months, there was no significant change in creatinine or creatinine clearance, but there was a reduction in proteinuria in the CS-treated group. In the CS-treated group, the proteinuria declined from 2.7 to 0.3 g per 24 hours, whereas in the prednisone-alone group, proteinuria increased from 2.1 to 2.6 g per 24 hours.

In an open randomized trial, Fu et al. (56) treated 40 children with World Health Organization (WHO) class III or IV lupus nephritis with either CS (2.5 to 5 mg/kg) alone (without corticosteroids) or prednisolone 2 mg/kg plus cyclophosphamide 2 mg/kg orally (P + C) for 1 year. At entry, all children had growth retardation following more than 1 year of corticosteroids. Subjects received an intense regimen of corticosteroids just prior to randomization until lupus activity diminished. There was comparable control of disease activity and resolution of proteinuria. Hemolytic complement (CH_{50}) and C3 levels were actually lower at the end of treatment, however. The authors concluded that CS controlled clinical but not serologic activity. The alternate regimen, although quite toxic, was probably effective, suggesting that CS as monotherapy also had some activity in order to achieve comparable results.

A number of open trials have suggested efficacy, using 2.5 to 10 mg/kg CS. Favre et al. (136) treated 26 lupus nephritis patients with CS 5 mg/kg/day, adjusted to achieve through levels of 250 to 350 mg/mL, plus prednisone, reporting a reduction of disease activity and proteinuria compared with baseline after 2 years. They reported an overall reduction of disease activity, stable serum creatinine levels, and slightly improved GFR, with striking reduction of proteinuria. By their estimation, activity was reduced on biopsy, and chronicity was slightly improved. In 1986, Feutren et al. (137) added CS, 5 to 10 mg/kg/day for 9 to 18 months, to prednisone in nine patients with systemic disease, and they reported apparent benefit in six patients and reduction of mean prednisone dose from 0.8 to 0.3 mg/kg/dy without changes in DNA antibody titers or complement C4 levels. Proteinuria declined

from 1.6 to 0.9 per 24 hours. In another trial, Isenberg et al. (138 ,139) treated five patients with a relatively large dose, 10 mg/kg/day, of CS, but these patients failed to respond, except for improvement of arthralgias in two. There were complications, including angioedema associated with the decline of Cl esterase inhibitor levels (139), in three patients, increased serum creatinine in three, and a sensation of being unwell in all patients. The study was terminated as a result.

Radhakrishnan et al. (140) treated ten lupus patients with membranous nephropathy, complicated in three cases by mesangial lesions, with CS, 4 to 6 mg/kg/day. Serial biopsies revealed an increase in the chronicity index and an increase in the stage of the membranous nephropathy, which is somewhat analogous to the chronicity index that is applied in proliferative disease. Several patients had reduction of proteinuria.

Tokuda et al. (141) treated 11 women with lupus with initial CS doses of 3 mg/kg/day. Hypertension occurred in 40%, and modest clinical improvement was observed.

Hussein et al. (142) treated five women with lupus nephritis, two of whom were pregnant, using CS plus low-dose prednisone. They noted stable renal function in all but one patient and hypertension in three.

In an open trial, Caccavo et al. (143) treated 27 lupus patients who had an unsatisfactory response to either corticosteroids alone or corticosteroids plus an immunosuppressive for 24 months with an initial dose of CS 2.5 to 5 mg/kg. Disease activity, minor manifestations, cytopenias, and neurologic disease improved. Proteinuria was reduced, and the mean serum creatinine increased from 0.89 to 0.96 mg/dL (p = NS).

Dostal et al. (144) treated 11 patients with nephritis with CS, 5 mg/kg/day. After 1 year there was improvement of proteinuria, slight reduction of mean serum creatinine levels, and reduction of the mean Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) from 26 to 4. Hypertension occurred in seven patients. At repeat biopsy, inflammation improved, and “chronic” changes were increased in five patients and reduced in three.

Tam et al. (145) administered CS 5 mg/kg/day to 17 patients with class IV nephritis, of whom 12 completed 24 months of treatment. (Three of the remaining patients had azathioprine added.) Reduction of proteinuria was gradual, with only partial resolution at 1 year and further improvement in the subset of patients who reached year 5. Biopsy findings were of interest: no patient had evidence by repeat biopsy of persistence of inflammation at 1 year. There was no increase in chronicity (mean chronicity index 5.1 at baseline vs. 5.7 at 1 year).

Morton and Powell (146) reviewed treatment of mostly nonrenal lupus in 43 patients with CS (mean 4.1 mg/kg/day). Hypertension occurred in 14 patients, and a rise of creatinine more than 30% in nine. The drug was stopped in 39 of 47 treatment courses because of toxicity or lack of efficacy. Hallegua et al. have suggested that CS is helpful in membranous nephritis (147).

Cyclosporine has been reported to be well tolerated in pregnancy (142), useful when added to cyclophosphamide for nephritis (148), and has been combined with immunoadsorption in pregnancy (149).

Summary of Cyclosporine Therapy for Lupus

Although the mechanism by which cyclosporine may alter the course of lupus is uncertain, it is likely that it favorably affects some manifestations of lupus, such as proteinuria, over the relatively short period of 1 to 2 years, and may reduce overall disease activity. The outcome of studies in membranous nephropathy will be of great interest. In both controlled and open trials, glomerular filtration has not improved, as would be expected in bolus cyclophosphamide-treated nephritis patients, and some patients have developed hypertension and reduced GFR. Stabilization of GFR might reflect amelioration of nephritis combined with mild toxicity from the drug. Experience with other immunosuppressives (e.g., prednisone, daily cyclophosphamide) emphasizes the importance of long-term follow-up in determining risk versus benefit. CS still does not have the track record of successful long-term use in lupus shared by cyclophosphamide and azathioprine, and is better suited to empiric use when irreversible injury is not imminent.

Methotrexate

Methotrexate (MTX) is a folate antagonist, which when administered at the doses used in rheumatic diseases has less obvious immunosuppressive effects than alkylating agents or azathioprine. In fact, it may act by other means. There is no convincing association of changes in lymphocyte subsets, surface markers, lymphocyte function, or autoantibody levels with therapeutic effects on rheumatic diseases. It appears to have multiple anti-inflammatory effects including increased adenosine levels at sites of inflammation, inhibition of leukotriene B2 formation, interleukin-1 (IL-1) effects, fibroblast proliferation, and preferential cyclooxygenase-2 inhibition (150 ,151). Other putative mechanisms of action include inhibition of neutrophil function, interference with the action of IL-1, suppression of lipoxygenase formation, and inhibition of the intracellular enzyme 5-aminoimidazole-4-carboxamide ribonucleotide transformylase (152). It is unclear which mechanisms of action are important in lupus treatment.

Side effects of MTX, particularly hepatotoxicity and cytopenias, are well known. Selected aspects will be reviewed. MTX toxicity is increased in patients with depressed renal function, and increases in patients maintained on a stable dose of MTX who sustain a decline in renal function (e.g., from active nephritis) (151 ,153). Side effects occur less frequently in rheumatoid arthritis patients given 1 mg/day of folate, and drug efficacy (against rheumatoid arthritis) appears unaltered. MTX increases homocysteine levels and cardiovascular risk in lupus patients, an effect that is also reduced by simultaneous administration of folate (142 ,143 ,144 ,145 ,146 ,148 ,149 ,150 ,151 ,153 ,154 ,155).

Pulmonary toxicity, which has been reported in 2% to 7% of patients with rheumatoid arthritis, is characterized by cough, bilateral or unilateral pulmonary infiltrates, and dyspnea (156 ,157 ,158 ,159 ,160). There is a nonspecific interstitial inflammatory cell infiltrate and an increased number of T cells on bronchoalveolar lavage (158). Reported mortality is 17%, with a 50% recurrence rate on rechallenge and up to 50% mortality associated with recurrences. Pneumocystis prophylaxis for patients receiving MTX plus moderate- to high-dose corticosteroids should reduce the number of episodes of PCP pneumonitis requiring distinction from MTX pneumonitis. MTX is teratogenic and an abortifacient (161 ,162). Rheumatologists have been shown to inadequately identify and address the need for contraception in women taking MTX (163). MTX-induced malignancies appear to be rare. A reversible lymphoproliferative disease can occur, and has been reported to evolve into Hodgkin disease (164).

Other forms of MTX toxicity, including acute hepatic injury, hepatic fibrosis, stomatitis, and, in high doses, central nervous system toxicity, have been reviewed elsewhere (152).

Methotrexate has gained considerable popularity in the treatment of systemic rheumatic diseases, including rheumatoid and psoriatic arthritis, Wegener granulomatosis (157 ,165), and Takayasu disease (166). In Wegener, the efficacy of MTX appears to be less than that of daily oral CYC (as also is the case for IVC).

In SLE, there is a paucity of data. Two early studies, the treatment of seven patients with 7.5 mg/week for 6 weeks by Dubois (167), and administration of either daily oral MTX, 2.5 mg, or 50 mg of IV MTX weekly by Miescher and Riethmuller (168), produced equivocal results. Rothenberg et al. (169) treated 10 patients with MTX, 7.5 to 10.0 mg weekly, of whom 7 patients improved. Improvement was noted in myositis, rash, pleurisy, arthritis, and proteinuria, but leukopenia was observed in three patients. Wilke et al. (170) treated 17 patients with lupus using a mean MTX dose of 1 g over 8 months. They reported benefit in 57% of patients and toxicity in 70%, with an increase of toxicity associated with use of diuretics or NSAIDs. They noted elevation of liver function tests and gastrointestinal side effects, but not cytopenia. In an open trial in pediatric patients, Abud-Mendoza et al. (171) treated 10 patients with MTX, 5 to 10 mg weekly, in addition to their previous regimens, which in four cases included both prednisone and cyclophosphamide. Of the 10 patients, 2 had a poor outcome, and 5 had excellent responses with discontinuation of cyclophosphamide and other drugs. Wilson et al. (172) treated 12 SLE patients who lacked renal or CNS disease with MTX and noted apparent clinical improvement without change in antibodies to DNA or complement. Corticosteroid dose was reduced in six patients. Hashimoto et al. (173) treated two patients with myositis, fever, and pancytopenia complicating lupus, and they noticed a fall in the number of CD20 positive cells. Walz et al. (174) found MTX to be well tolerated and effective in a review of five patients.

Rahman et al. (175), in a retrospective controlled study, concluded that there was a 60% reduction of the joint count in MTX-treated lupus patients with antimalarial-resistant synovitis versus 12% in the control group. In this study, MTX was not steroid sparing. In a retrospective study, Kipen et al. (176) also concluded that MTX had not been steroid sparing. Gansauge et al. (177), in an open trial of MTX 15 mg/week administered to 22 patients, noted overall improvement.

In a double-blind, randomized, placebo-controlled trial, Carneiro and Sato (178) treated 41 patients with MTX, 15 to 20 mg/week versus placebo. After 6 months, compared with the placebo group, MTX-treated patients had significantly more resolution of arthritis, rash, and hypocomplementemia (the most frequent clinical features at entry), and more improvement of the SLEDAI score. Mean prednisone doses at follow-up were increased in the placebo group and significantly decreased in the MTX group.

Summary of Methotrexate Therapy for Lupus

Methotrexate is relatively safe and well tolerated and helps some lupus patients, particularly those with synovitis. Monitoring of renal function is essential to ensure safety.

Mycophenolate Mofetil

MMF has established itself as a successful immunosuppressive medication in multiple applications. In recent years, MMF has been used in SLE with increasing success and has been the focus of much study. MMF has a unique mode of action that may be particularly applicable to control of SLE. MMF is the morpholinoethyl ester of mycophenolic acid (MPA). MPA was originally isolated from *Penicillium* species in 1896. In the 1960s, MPA was found to have antifungal and anticancer activities. In the 1970s, MPA was studied as a treatment for psoriasis. Although it was effective, poor and erratic absorption along with a high incidence of gastrointestinal toxicity limited further study (179).

MPA is a potent, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), a necessary enzyme in the de novo pathway of purine synthesis. The de novo synthesis pathway is uniquely essential (180) in activated lymphocytes, whereas most other cells use the salvage pathway of purine synthesis. Not only do lymphocytes primarily depend on the de novo synthesis pathway, but activated lymphocytes predominately use the second isoform of IMPDH against which MPA is most specific (181 ,182). Activities of MPA include inhibition of both T- and B-lymphocyte proliferation in vitro in response to mitogenic stimulation (183) and inhibition of antibody formation in humans to horse antilymphocyte globulin (180) and tetanus toxoid (184). Suppression of IgG anti–antithymocyte γ-globulin (ATGAM) antibody production by MMF is greater than that of azathioprine (AZA) (180). MPA also interferes with the production and/or function of adhesion molecules necessary for the migration of lymphocytes to areas of inflammation (185). MMF has also been shown to suppress the induction of the inducible form of nitric

oxide synthetase (iNOS) (186). Studies of various animal models of atherosclerosis and arterial injury demonstrate protective effects of MMF with decreased vessel wall thickening and cellular proliferation (187 ,188 ,189).

MMF is rapidly hydrolyzed to MPA and is 94% bioavailable by the oral route. The drug is reversibly converted in the liver to an inactive glucuronide—mycophenolic acid glucuronide (MPAG)—and excreted into the gastrointestinal tract. Much of MPAG is deglucuronidated by intestinal flora and undergoes enterohepatic recirculation. It is eventually excreted primarily through the kidney (179). Serum drug levels are increased in patients with renal insufficiency. In renal transplant studies, doses of 2.0 g/day or 3.0 g/day were studied with little gain in efficacy but increased toxicity at the 3.0 g/day dose (190 ,191 ,192). A review of patients at our institution suggests that, in practice, rheumatologists are using dosage ranges between 0.75 and 2.5 g/day for the treatment of SLE, and about 50% of patients cannot tolerate 2 g/day (193).

MMF has proven to be a potent antirejection agent in experimental animal models (183 ,194). MMF appears to be effective in experimental autoimmune disease including Heymann nephritis and experimental autoimmune uveitis (195 ,196). Studies in the Medical Research Laboratory lymphoproliferative (MRL/lpr) and New Zealand black (NZB) × New Zealand white (NZW) F1 mouse models of SLE have shown suppression of development of lupus glomerulonephritis, a decrease in glomerular immunoglobulin deposits in MMF-treated mice, and improved survival (197 ,198 ,199).

MMF currently has Food and Drug Administration (FDA) approval for prevention of acute allograft rejection in kidney transplantation and for use in cardiac transplantation. MMF has been widely accepted as a more potent agent than AZA in pediatric and adult transplantation. Three large, multicenter, randomized controlled studies of human cadaveric renal transplants have compared MMF with either AZA or placebo. Findings among the studies showed statistically significant decreases in acute rejection and steroid use, suggesting MMF is superior to AZA or placebo (190 ,191 ,192). Studies of lung, liver, and heart transplant elicited similar results (179). A successful trial of renal transplant utilizing MMF without prednisone was reported (200).

Successful treatments reported in adults with autoimmune diseases include a randomized trial suggesting superiority to or against AZA in Crohn disease (201). MMF has been explored in the treatment of uveitis, rheumatoid arthritis, Takayasu arteritis, psoriasis, pemphigoid, and pyoderma gangrenosum (202 ,203 ,204 ,205 ,206 ,207 ,208).

The role of MMF in the treatment of SLE is expanding. MMF for SLE has been investigated in both uncontrolled and controlled studies for both renal and nonrenal disease. MMF may be valuable as induction therapy of lupus nephritis (LN), potentially replacing CYC as initial treatment for severe LN and may also prove to be useful in the treatment of LN that is not CYC responsive. In addition it is likely that MMF (and/or AZA) will become much more widely used for maintenance of remission following induction therapy with CYC—“sequential therapy.” The uncontrolled studies in SLE have overall shown improvement in LN and other lupus symptoms. Several short-term controlled trials in LN have generally shown MMF to be similar to or even superior to standard treatment.

In 1999, Dooley et al. (209) evaluated 12 patients with relapsing or resistant LN, most of whom had prior IVC therapy, and followed them for a mean of 12.9 months. They found significant improvements in proteinuria and improvement or stabilization of serum creatinine in all patients. Gaubitz et al. (210) studied ten patients with SLE whose systemic and renal manifestations of disease were inadequately controlled on corticosteroids and AZA or CYC. All patients had improvement in clinical disease activity measured by the Systemic Lupus Activity Measure (SLAM) with scores decreasing from mean 15.5 ± 5.5 to 8.0 ± 3.3 after 6 months of therapy. The mean corticosteroid dose decreased significantly over 6 months. Pashinian et al. (211) reported on eight severe SLE patients who had failed one or two immunosuppressive agents. After 6 months, four of six patients had improvement in SLEDAI scores, and all patients with nephritis had decreased proteinuria (211). Petri (96) studied 22 SLE patients requiring immunosuppressive therapy who were treated with MMF. Although eight failed and required cyclophosphamide, most showed sustained improvement in overall disease activity, prednisone, C4, and anti–double-stranded DNA (dsDNA). The 10 patients with nephrotic-range proteinuria showed a mild but not significant improvement in proteinuria while on MMF.

Since these early studies, a number of investigators have published their results of uncontrolled studies using MMF in LN refractory to other treatments. Most of these studies, focused on proliferative LN, have a recurring theme of overall but not universal improvement in renal function and SLE serologic markers of disease activity.

In a retrospective review, Kingdon (212) evaluated thirteen SLE subjects who had a long history of difficult-to-treat LN of various types (two with membranous LN and 11 with proliferative LN, four of whom also had membranous nephropathy). Generally, improvements were seen in serologic disease activity markers in nine patients, corticosteroids were reduced in 8 of 10 patients, and the mean proteinuria decreased. Karim et al. (213) evaluated a very similar group of 21 subjects and found significant improvements in SLEDAI score and reduction in corticosteroid dose, but little change in serologic markers of lupus activity. These positive responses are extending to those difficult SLE patients with membranous LN. Recently, Karim et al. (214) published a retrospective study of 10 subjects with predominantly membranous LN. After a mean of 18.8 months of treatment, 24-hour urinary protein excretion decreased from a median of 2.26 g to 0.66 g. Kapitsinou (215) described treatment of 18 LN patients, including 6 patients with membranous nephritis with 2 g/day MMF. All but 5 had prior CYC treatment. Except in the membranous nephritis patients, the results were described as favorable with 10 of 18 complete and 4 of 18 partial remissions after a mean follow-up period of 15 months. The

membranous (MLN) patients had nonstatistically significant resolution of proteinuria (from a mean of 1.9 +/- 1.4 g/24 hour to 1.0 +/- 1.0 g/24 hour), and the mean creatinine clearance was not improved. This observation in a small number of patients highlights the necessity of separately analyzing the outcome of lupus patients with MLN; it is possible that the expectation of reduction of proteinuria to less than 0.5 g/24 hour may be too stringent and fail to identify patients who benefit from treatment.

The controlled trials using MMF for, primarily, LN have been well designed and have added substantially to the body of literature on this medication. In the first well known randomized trial comparing treatment of class IV nephritis with MMF plus prednisone (P) for 1 year versus daily oral CYC plus P for 6 months followed by AZA plus P for 6 months, responses were favorable and equivalent in both groups, with reduction of proteinuria and stabilization of serum creatinine levels (57). Neither regimen resulted in improvement of creatinine levels, which has been seen in some series. In a separate report, Chan (216) followed up these subjects for a median of 63 months. The subjects in the MMF group received on average 28.3 months of treatment with MMF. In this long-term follow-up, neither group showed a significant change in serum creatinine over time. In another study of induction therapy with MMF compared to IVC, Hu et al. concluded that MMF was superior to IVC after 6 months of therapy based not only on clinical response but also on serial biopsies (217). In an important multicenter controlled trial in the study of MMF for LN, Ginzler et al. randomized 71 subjects to 3.0 g/day of MMF and 69 subjects to monthly IVC by the NIH protocol for induction therapy of LN. Complete and partial remissions were more frequent and toxicity was lower in the MMF group at 24 weeks (218). Although MMF may have a promising role as induction therapy, most recent interest has been directed toward its use as sequential therapy after induction with IVC (see earlier sections on sequential therapy) (66).

Overall, MMF has had lower toxicity than alkylating agents. In controlled trials for the prevention of renal transplant rejection, diarrhea was increased in patients receiving MMF, with an incidence of up to 36%, compared to 21% for patients receiving AZA and 14% for patients receiving placebo. Few patients (up to 2%) developed severe neutropenia (absolute neutrophil count <0.5 × 103/L). The incidence of malignancies among the patients enrolled who were followed for 1 year was similar to the incidence reported in the literature for renal allograft recipients. There was a slight increase in the incidence of lymphoproliferative disease in the MMF treatment groups compared to the placebo and AZA groups. In three controlled studies for prevention of rejection, similar rates of fatal infections or sepsis (<2%) occurred in patients while receiving MMF or control therapy in combination with other immunosuppressive agents (43 ,219).

The following data are from a compilation of six studies involving MMF and SLE in which adverse events were reported. Out of 81 patients, 21 (26%) had gastrointestinal symptoms—nausea, vomiting, and/or diarrhea. Four patients (5%) had recurrence of herpes stomatitis. Two patients each had vertigo and prurigo. One patient had severe leukopenia, severe anemia, pancreatitis, and a flare of existing vaginal candidosis. Pneumonia and asymptomatic leukopenia each occurred in two patients (209 ,210 ,211 ,220 ,221). In the study published from our group (193) to evaluate the overall tolerability of MMF in patients with SLE, we identified 54 SLE patients followed for a mean of 12.4 person-months on MMF. Twenty-one of 54 patients (38.9%) had a total of 28 gastrointestinal adverse events. Twenty-four of 54 (44.4%) patients had a total of 37 infections, only one of which required hospitalization. Leukopenia occurred 3 times but never required dose adjustment. Adverse events occurred at a similar rate at all MMF doses. Pisoni et al. (222) published a similar report in which they evaluated 93 SLE patients retrospectively. Forty-three percent of patients (37 subjects) developed an adverse event, of which gastrointestinal intolerance was found in 25 subjects and infections in 20. Only 14 patients (16%) discontinued the drug, though, because of adverse events. Ginzler et al. reviewed the tolerability and toxicity in their randomized trial of MMF versus IVC (218). Most adverse events were GI or infection related. Seventeen patients in the IVC group had upper GI distress, 6 of which required hospitalization. Nineteen MMF patients had mild or moderate GI symptoms. Hematologic toxicity was unusual and seemed to be similar in both groups with the exception of lymphopenia, which developed in 28 patients on IVC versus 18 on MMF. The authors reported a trend toward decreased serious infections in patients on MMF.

Summary of Mycophenolate Mofetil Therapy for Lupus

- Several relatively short term studies suggest that MMF is less toxic and may be at least as effective for LN as IVC used as initial therapy for severe nephritis. MMF has not been compared to the combination of monthly IVC + monthly bolus methylprednisolone, which is probably our most effective “conventional” therapy.
- Sequential therapy utilizing IVC followed by MMF is, in our opinion, highly likely to be as effective as monthly IVC followed by q 3-month IVC and is less toxic.
- Although MMF has a better track record than AZA as an initial agent to treat active lupus nephritis and is in our opinion likely to be shown to be faster acting, its superiority and/or better safety profile compared with AZA as a maintenance agent has not been established. It is possible that AZA will work equally well in this setting.
- There are no guidelines for using MMF when there is severe renal insufficiency. In this setting, IVC may be more easily and effectively administered.
- Overcoming the problems of high variability of MMF levels in individual patients and difficulty measuring levels in individual patients may improve results in future trials.

- There is emerging evidence that MMF may prevent atherosclerosis, at least in transplant patients. An “antiatherosclerotic” effect would make MMF highly desirable as a treatment for lupus.

Leflunomide

Leflunomide is a relatively new inhibitor of de novo pyrimidine synthesis. It has been used extensively for the treatment of rheumatoid arthritis (RA), and has been shown to be as effective as methotrexate and sulfasalazine (223 ,224). Leflunomide is a cytotoxotic isoxazole derivative and is structurally unrelated to other immunomodulatory drugs (225). Leflunomide is rapidly converted to its active metabolite, A77–1726, a malononitrilamide, which is a known inhibitor of the mitochondrial enzyme dihydroorotate dehydrogenase (DHODH), a key enzyme in the de novo synthesis pathway of the pyrimidine ribonucleotide uridine monophosphate (rUMP) synthesis which prevents activated lymphocytes from moving from the G1 to the S phase (226 ,227). A77–1726 has other known anti-inflammatory roles as an inhibitor of cyclo-oxygenase (COX)-2 activity and an inhibitor of leukocyte adhesion. Furthermore, leflunomide may also have antiviral activity and has been proposed as therapy for CMV in renal transplant patients (228).

Studies with leflunomide for treatment of lupus and other systemic autoimmune diseases are underway. One study of leflunomide in 11 patients with mild to moderate SLE revealed improvements in ECLAM score in 8 patients and reduction in corticosteroid dosing in 4, but did not reach statistical significance (229). In a retrospective study of eighteen patients, 15 of whom met ACR criteria for SLE and had moderate disease activity, leflunomide was administered for 2 to 3 months (230). There was a significant decrease in SLEDAI score and ESR from baseline among the 14 patients finishing the study, with no serious adverse events reported. However, four patients stopped leflunomide because of GI complications, a rash, and an unrelated hospitalization. Another study of SLE patients with refractory arthritic symptoms revealed that 6 of 20 patients achieved a complete response to leflunomide at a dose of 40 mg/day within 1 month, suggesting that leflunomide may have a role particularly in joint-based symptoms of lupus not responsive to treatment with methotrexate or hydroxychloroquine (231).

In addition to observational studies, there are several controlled trials of leflunomide in SLE. One double-blinded placebo controlled study randomized twelve lupus patients with mild to moderate disease activity, who were taking less than 0.5 mg/kg/day of prednisolone, to receive either leflunomide or placebo for 24 weeks (232). The primary outcome was a change in the SLEDAI, and secondary outcomes included changes in proteinuria, complement levels, anti-dsDNA and prednisolone dosage. The results of the study reveal that there was significant reduction in the SLEDAI in both the leflunomide and placebo groups, but the reduction in the leflunomide group was significantly greater compared with the placebo group (11.0 +/- 6.0 in the leflunomide group and 4.5 +/- 2.4 in the placebo group, $P = 0.026$). The secondary endpoints were similar in both groups.

A second controlled trial was a prospective multicenter study evaluating safety and efficacy of leflunomide in the treatment of 51 patients with proliferative lupus nephritis (233). Patients enrolled in this study had biopsy-confirmed proliferative lupus nephritis and were divided into three treatment groups. Those patients with recent onset nephritis who had never received treatment with immunosuppressive drugs received either leflunomide or IV cyclophosphamide. A third group consisted of patients with recurrent nephritis who had received immunosuppressive therapy within 3 months; they received leflunomide. As reported in the English language abstract, the results of the study after 6 months revealed no difference in the response or remission rates of patients initially treated with either leflunomide or cyclophosphamide. Furthermore, renal parameters such as proteinuria, serum albumin and creatinine, as well as SLEDAI improved similarly in both groups. Among the 14 patients enrolled with relapsed nephritis, the total response rate was 60% and complete remission rate was 6.7% following treatment with leflunomide. Four patients withdrew from the study due to adverse events, including herpes zoster and severe lung infection.

Leflunomide is orally administered at a dose of 10 to 20 mg/day. Although early studies with leflunomide employed a loading dose of 100 mg daily for three days, the practice has been largely abandoned to reduce toxicity. The drug has a relatively long half-life (15 days) and is well absorbed, undergoing extensive enterohepatic recirculation. Prior to treatment, complete blood counts and liver function tests should be obtained and monitored at monthly intervals for the first 6 months and at least every 2 months thereafter.

Several potential side effects of treatment associated with leflunomide, including diarrhea, nausea, and alopecia, have been noted to decrease in frequency with continued treatment (234) and if a loading dose is not used (235). Severe hepatotoxicity has also been reported, although its actual incidence remains controversial. Unacceptably high rates of transaminase elevation, cirrhosis and liver failure were reported in initial studies and postmarketing data regarding leflunomide (236). However, a subsequent FDA review of this data found that that most patients with hepatic involvement were concomitantly taking other potentially hepatotoxic drugs such as methotrexate, or had confounding comorbidities such as viral hepatitis or alcohol abuse. A review of 3,325 leflunomide-treated patients found that abnormalities in liver function testing were cited as reasons for drug discontinuation in 5% of patients (237). Furthermore, the review identified no deaths attributable to leflunomide.

An important aspect to consider when using leflunomide in lupus patients, many of whom are young women, is that it is a potent teratogen rated category X for pregnancy by the FDA, and therefore absolutely contraindicated in women who are at risk for becoming pregnant. Leflunomide can persist after administration for up to 2 years (161), and should therefore be used with reluctance in any woman of

childbearing age. To assure safety following discontinuation of leflunomide, patients must be instructed to avoid pregnancy until undetectable plasma levels (<0.02 µg/mL) are demonstrated. If need be, the drug can be removed from the body by administration of cholestyramine (161).

Conclusion

Refinement of the use of immunosuppressive agents and the introduction of both sequential therapies and ovarian protection regimens to reduce the toxicity of CYC therapy is taking place in the context of the introduction of new and potentially highly potent biologic agents, such as rituximab, anti-BLyS antibodies, and CTLA4-Ig. These biologic agents may prove to be effective either as monotherapy or in combination with traditional immunosuppressive agents (or each other). Use of these drug combinations has the potential to markedly reduce reliance on alkylating agents and/or corticosteroids, presumably dramatically decreasing the toxicities associated with conventional agents.

Chapter 62

Nonpharmacologic and Complementary Therapeutic Modalities

Daniel J Wallace

In addition to medication, physical measures, and psychologic support, the treatment of systemic lupus erythematosus may necessitate the use of other nonpharmacologic modalities. These include dialysis and transplantation for end-stage renal disease, lasers for cutaneous lesions, apheresis for life-threatening complications of the disease, and lymphocyte depletion for selected patients with refractory disease. Because most lupus patients use some form of alternative or complementary remedies, this topic is also reviewed herein.

Dialysis and End Stage Renal Disease

Patients with end-stage renal disease (ESRD) from chronic SLE represent 1.5% to 2.0% of all dialysis patients in the United States (1 ,2). Three thousand to 4,000 patients with lupus are dialyzed annually; 10% succumb each year (2). As patients with SLE are surviving longer, the incidence of ESRD is increasing. Between 1982 and 1995, it increased from 1.16 to 3.08 cases per million person years (3).

Patients with SLE who develop renal failure have improved mental well being but worse physical functioning and general health compared to lupus patients not in renal failure (4).

Uremia

Uremia was the major cause of death in patients with SLE until the 1960s, when dialysis became available. Only a small percentage of dialysis patients have SLE. Between 1977 and 1985, 5,726 persons in Australia and New Zealand were placed on dialysis; only 63 (1.1%) had SLE (5). Despite therapeutic advances, 26 of 128 patients with nephritis who were followed by Wallace between 1980 and 1989 evolved ESRD that required dialysis (6 ,7); all but three of the 26 had nephrotic syndrome. Between 1972 and 1993, 104 of 566 patients diagnosed with SLE in Okinawa, Japan, evolved ESRD (8). The reader is referred to Cheigh and Stenzel's excellent literature review (9).

Uremia and dialysis both are associated with a decrease in the systemic activity of SLE in many, but not all, patients (10 ,11). Mojcik and Klippel summarized the results in 179 patients in seven studies, and concluded that clinical, serologic, and steroid requirements decreased (12). Szeto noted that most disease flares occur during the first year of dialysis (13), and a high level of disease activity during this time also was found by Bruce et al. (14). Ziff and Helderman (15) have speculated that the toxic effects of uremia on the immune system are responsible for its ameliorative effects on extrarenal disease. It also is possible that the disease has run its course in some individuals and subsided but, by that time, the chronic renal damage is irreversible.

Reversibility

Some patients who develop renal failure from lupus nephritis can discontinue dialysis. This was true in 41% of the 41 patients of Kimberly et al.; 11 were dialyzed for less than 2 months (16). On the other hand, 37% died. Five were transplanted successfully. Coplon et al. (17) reported on their experience with 28 dialysis patients followed between 1969 and 1980. Of these, 8 were dialyzed for a mean of 4.3 months before discontinuation, 6 deaths occurred in the patients with the highest steroid requirement, 7 were transplanted, and only 3 had extrarenal disease. The first few months on dialysis appear to be critical. A high mortality rate is observed, but many of those who survive can either discontinue dialysis or become candidates for transplantation (18). Acute tubular necrosis superimposed on lupus nephritis can induce transient renal failure (19).

Prognosis

Survival on dialysis is good. Ziff and Helderman's 30 patients had a 67% 5-year survival rate (15), Jarrett et al.'s had 59% (20), and Cheigh et al.'s had 65% in the late 1970s (21). These figures compare favorably with those of non-SLE dialysis patients. Some reports have documented a better survival rate: 71% in Australia and New Zealand at 5 years (5), and 89% in 55% Dutch patients at 5 years (22). Males had a poorer renal survival than females (23), and African American women fare poorly with 58% of 19 dead at 5 years (24). In these studies, nonrenal SLE activity was minimal. Most deaths were related to infection or vascular-access problems.

At the University of California, only three of 12 patients on dialysis for lupus nephritis needed corticosteroids after

31 months' mean observation (25). In 1990, Cheigh et al. (26) presented a follow-up of 59 patients with ESRD who were seen at New York Hospital between 1970 and 1987. Of these, 86% were female, and mean age was 27.4 years at ESRD onset. They were followed for a mean of 6.5 years. SLE disease activity at years 1, 5, and 10 was 55%, 6.5%, and 0%, respectively. The 5- and 10-year survival rates were 81.1% and 74.6%, respectively. Erythropoietin decreases the morbidity of patients with SLE on dialysis (27). In Taiwan, a 2003 report demonstrated 73% and 38% 10-year survival rates among 26 patients with ESRD (28). Hospitalizations for cardiovascular and cerebrovascular morbidity as well as leading to mortality does not differ between lupus and nonlupus patients with ESRD (29).

Ginzler et al.'s multicenter trial of 1,103 patients with SLE (30) showed that dialysis has little impact in evaluating causes of death in SLE, although dialysis patients have a much higher rate of infection (10 ,31). Socioeconomic considerations also are important. In the largely indigent group at Los Angeles Harbor-University of California at Los Angeles (UCLA) Medical Center, six of nine dialysis patients died at 1 to 28 months, and five of these six had disease flares (32). The quality of life of patients on dialysis has been reviewed. They tended to have good mental well being but reduced physical function and general health (33).

Hemodialysis versus Peritoneal Dialysis

The success of hemodialysis in ameliorating disease activity may result from its ability to remove circulating pathogenic immune complexes, complement, and other factors (34). Hemodialysis also has anti-inflammatory effects, decreases T-helper lymphocyte levels, and diminishes mitogenic responsiveness (35 ,36). Three cases of a patient developing SLE while on hemodialysis have appeared (37 ,38 ,39), and although rare, successful pregnancies while on hemodialysis are noted occasionally (40). Nephrogenic fibrosing dermopathy is a rare complication of hemodialysis in SLE patients (41).

In contrast, peritoneal dialysis does not cause these changes. Several studies have documented more reactivation of SLE, higher anti–double-stranded DNA (anti-dsDNA) levels, more thrombocytopenia, and higher steroid requirements with peritoneal dialysis (13 ,19 ,35 ,36). In one center, four of six patients who were started on peritoneal dialysis had to be switched to hemodialysis (42), although this has not been found by others (43). Nossent et al. (22 ,44) noted among 55 patients that peritoneal dialysis was associated with poorer survival, more serositis, cytopenias, and serologic activity. Switching to it from hemodialysis could reactivate lupus. In a gender matched, controlled study comparing nondiabetic lupus patients on peritoneal dialysis with those who did not have SLE, the lupus patients had a higher infection rate (45). SLEDAI scores are higher in peritoneal dialysis than hemodialysis lupus patients (46).

It is my experience that barring extenuating or unusual circumstances, hemodialysis is preferable to peritoneal dialysis.

Transplantation

Patients with lupus account for 3% of all renal transplantations in the United States (47). Perhaps a result of medical comorbidities, lupus patients are less likely than others to be transplanted with ESRD (48). Nevertheless, 772 of 32,644 patients who received a kidney transplant in the United States between 1987 and 1994 had lupus nephritis (49). By 1996, the overall graft survival for all diseases at one year had improved to 93.9% from living donors and 87.7% from cadaveric grafts, compared to 88.8% and 75.7%, respectively, in 1988 (50).

Graft and Patient Survival in Adults

By 1975, patients with SLE in the United States were being transplanted, and 150 were transplanted between 1975 and 1980 (51 ,52). These studies concluded that allografts from a living, related donor have a much better survival rate. Two-year graft survivals averaged 50%. In Australia and New Zealand, 19 transplants performed between 1977 and 1985 were associated with 95% and 83% survival rates at 1 and 5 years, respectively, and with 75% and 70% 1- and 5-year graft survival, respectively (5). In 1987, Roth et al. (53) reported a 93% patient survival and an 84% graft survival at 6 years among 15 patients who were transplanted at their institution. Of 2,510 renal transplants performed at the University of Minnesota between 1969 and 1987, 33 (1%) were for SLE (54), as were 20 of 616 (3%) at Albert Einstein College of Medicine (55). Of Cheigh et al.'s 59 patients with lupus and ESRD (discussed earlier), 18 were transplanted over a 17-year period (26). Massry's group at Los Angeles County/University of Southern California Medical Center transplanted 64 indigent (60% Hispanic or black) patients with SLE between 1979 and 1992 (56); 80 received cadaveric transplants. Five-year graft and patient survivals were 61 and 86, respectively. Currently, 5-year graft survivals average 70% to 80% (22 ,26 ,54 ,55 ,57 ,58 ,59 ,60 ,61 ,62 ,63). Criswell's group has undertaken three large-scale reviews of transplantation in the cyclosporin era and compared their results with 97 patients to others in a literature review (64 ,65 ,66). Graft survival compared to nonlupus controls was 82 (vs. 88%) at 1 year but only 19 (vs. 35%) at 10 years. Allograft failure risk was doubled and associated with HLA mismatches, smoking, and delayed allograft functioning (67). An excellent, current review has appeared (68).

Outcomes in Children

254 children between the ages of 1 and 21 with lupus nephritis were transplanted in the United States between 1987 and 1997 (69). Cadaveric allografts did not do as well, and these children had an increased mortality rate. Bartosh et al. retrospectively analyzed 100 renal transplants among 94 lupus patients enrolled in the North American Pediatric Renal Transplant Cooperative Study. The 3-year

graft and patient survival was 69 and 89%, respectively (70). Indigent pediatric populations do not do as well. Among 17 children with SLE who were transplanted in Brooklyn (71), 80% and 45% 1- and 4-year graft survivals, respectively, were reported. The availability of cyclosporine has resulted in a decreased use of azathioprine to prevent rejection. One study comparing these drugs in SLE transplants (19 received azathioprine and 17 cyclosporine) documented the statistically significant superiority of cyclosporine in graft survival (72), whereas another came to opposite conclusions (73).

Antiphospholipid Antibodies

Patients with antiphospholipid antibodies are clearly at an increased risk for thromboembolic events, which can have an adverse effect on graft survival (74 ,75 ,76 ,77), the course of dialysis (78) and vascular access viability (79). Stone et al. identified 25 patients with antiphospholipid antibodies who were transplanted at University of California, San Francisco. Fifteen had thromboembolic events, and ten died (80). Antiplatelet drugs should be employed, and the addition of warfarin may be necessary.

Serologic Features and Disease Recurrence

Patients undergoing transplantation may have persistent elevations of antinuclear antibody and anti-DNA antibody titers as well as reduced complement levels. These serologic abnormalities are of little importance and do not affect the outcome of the graft (10 ,51 ,53). These abnormalities were present in four of seven patients who were transplanted by our group between 1980 and 1989. Despite this, disease recurrence in the transplanted kidney is rare. Various centers have noted nephritis in 0 of 12 patients (81), 0 of seven (10), 1 of 17 (71), 2 of 15 (53), 1 of 28 (22), 1 of 14 (62), and 1 of 18 patients (51), for a total of 6 in 111 patients (8). However, Goral et al. have suggested that up to half of transplanted lupus nephritis patients biopsied have some evidence for recurrent disease activity, even though it is usually mild (mesangial or membranous) and rarely threatens the graft. Isolated case reports of disease recurrence suggest that a disproportionate number of these patients had undergone peritoneal dialysis or had active disease at the time of transplantation (82 ,83 ,84 ,85 ,86). Criswell's group noted 9 of 97 cyclosporin treated patients had recurrent lupus nephritis by biopsy (64). Only three had abnormal serologies and one was symptomatic. Their literature review suggested that using serologic parameters or serum-complement levels to evaluate for recurrence was inaccurate (66). Little specific information of the impact of tacrolimus and sirolimus on transplant outcomes have been published.

Despite this, most of the allografts were still functioning well (87). Extrarenal lupus activity usually is quiescent after renal transplantation (88). One case of de novo SLE in a renal transplant patient has appeared (89).

Pregnancy

According to the National Transplantation Pregnancy Registry, 60 pregnancies were reported among 38 lupus patients (90). 77% were successful, though many were complicated by pre-eclampsia and hypertension.

In conclusion, to achieve the optimal transplant environment, patients should be in remission, be on hemodialysis or no dialysis, and receive an allograft from a living, related donor. Cyclosporine, tacrolimus, or sirolimus with mycophenolate mofetil (MMF) and low-dose prednisone now constitutes the immunosuppressive regimen of choice, but this regimen has not been specifically studied in lupus.

Dialysis and Transplantation in SLE: Summary

- Up to 10% of SLE patients evolve ESRD. Their 5-year survival with optimal care is 80% to 90%.
- Hemodialysis has theoretical advantages over peritoneal dialysis, is associated with fewer infections, and perhaps less lupus activity.
- The majority of lupus patients have their disease activity improve when uremic.
- Graft survival for SLE patients in the United States at 1 year is less than the 93.9% national average, and usually is in the 80% to 90% range.
- Transplantation is most successful if lupus is not active at the time of surgery.
- Patients with a history of antiphospholipid antibody-related events have a poor outcome.

Laser Therapy

Carbon-dioxide lasers have been used to treat discoid lupus lesions and telangiectasias. These lesions can be vaporized, but cellular alterations in nonvaporized cells that are several hundred microns away may be responsible for decreased disease activity (91 ,92). Argon lasers also have been used (93), for atrophic facial scars, and telangiectasias although flares have been reported with its use (94 ,95 ,96).

Lymphocyte Depletion

Basic Principles

Evidence that the lympholytic actions of alkylating agents, corticosteroids, and radiation were responsible for ameliorating certain disease states has led to investigations of the role of thoracic-duct drainage, total-lymphoid irradiation, and lymphapheresis in rheumatic diseases. Lymphoid tissue occupies up to 3% of the total body weight; this includes 1% lymphocytes, or 10^{12} lymphocytes per 70 kg. Lymphocytes are widely distributed and consist of both long- and short-lived populations. T cells compose roughly 90% of the lymphocytes in the thoracic duct lymph, 65% in peripheral blood, 75% in the mesentery, and 25% in the spleen; most of

these are long-lived. Therefore, thoracic duct drainage and localized radiation remove lymphocyte populations in a different manner than those removed by lymphapheresis (97).

Thoracic Duct Drainage

Pioneered by researchers at UCLA in the early 1970s, cannulation of the thoracic duct followed by removal of billions of lymphocytes clearly improved disease activity in patients with SLE (98). The procedure is not practical for clinical use, however, because it is technically difficult, expensive, frequently complicated by infection, and only can be done once.

Lymphapheresis

Online lymphocyte depletion has not been studied adequately as a treatment modality for SLE. No commercially available membranes selectively remove lymphocytes without other leukocytes, so only cell separation by centrifugation methods have been used. Because most patients with SLE are lymphopenic, and this is aggravated by the concomitant use of corticosteroids or cytotoxic drugs, it often is difficult to remove the lymphocyte fraction on cell separators. Our studies in patients with rheumatoid arthritis have shown that a 5×10^9 lymphapheresis performed three times a week for 6 weeks can induce a significant lymphopenia that persists for 4 to 6 months (99). Unlike plasma removal, 15% of the body's total blood volume must be extracorporeal to perform a lymphocyte cut on centrifugation devices, and this requires a near-normal cardiovascular and pulmonary status. Additionally, blood transfusions may be required. Despite these drawbacks, however, Spiva and Cecere (100) reported that a combination of lymphapheresis and plasmapheresis was clinically beneficial in 16 of 19 patients with SLE on concurrent immunosuppression, and that helper-to-suppressor T-cell ratios were decreased.

Total Lymphoid Irradiation

Between 1980 and 1997, a total of 17 patients with lupus nephritis and nephrotic syndrome refractory to conventional drug therapy received 2,000 rad of total lymphoid irradiation over a 4- to 6-week period at Stanford University (101 ,102 ,103 ,104 ,105 ,106). Clinical responses were seen within 3 months and sometimes persisted for years. At follow-up ranging from 12 to 79 months, seven patients were off corticosteroids and without nephrosis; however, one patient died, one ultimately required chronic dialysis, and four developed neutropenia, one developed thrombocytopenia, three developed bacterial sepsis, and four developed herpes zoster. T-helper populations (i.e., $CD4^+$ cells) decreased, and selective B-cell deficits documented by diminished pokeweed mitogen-induced immunoglobulin secretion were observed. Both total and serum immunoglobulin-specific IgE levels were not altered. The survival rate at 7.5 years was identical to that of a historical control group treated with steroids and immunosuppressives, with an equal prevalence of serious complications. Genovese et al. published a long-term follow up on these patients in 2002 (107). Six of 21 had died, and four developed cancer. 57% were dialyzed, and 33% had developed opportunistic infections.

Trentham et al. (108) at Harvard also used total lymphoid irradiation (for rheumatoid arthritis), but they no longer advocate its use. These authors agree that although short-term benefits are apparent, the high probability of disease recurrence after several months to years limits the physician's options in giving alkylating agents to patients who have already been irradiated (109). Further, a high infection rate is observed, and newer therapeutic strategies (e.g., parenteral cyclophosphamide) probably are superior to total lymphoid irradiation. An Israeli group noted unsatisfactory results in two patients who underwent total lymphoid irradiation (110).

Total lymphoid irradiation has no place in the management of SLE.

Photopheresis

In extracorporeal photochemotherapy, commonly known as photopheresis, leukocytes obtained at apheresis are treated with ultraviolet A (UVA) irradiation after the patient has received a photoactivatable drug, p-methoxypsoralen (111). Leukocytes reinfused into the patient can function but have diminished responses. Although only 5% of one's total circulating lymphocytes are treated, photopheresis clearly is beneficial for cutaneous T-cell lymphomas. Knobler et al. (112 ,113) observed modest improvements in eight patients with SLE in an uncontrolled study and Richard et al. found little benefit (114).

Summary

No online lymphocyte depletion method has been shown to be safe and effective in managing lupus.

Plasmapheresis

Basic Principles

Apheresis refers to the removal of a blood component (e.g., red-blood cells, lymphocytes, leukocytes, platelets, plasma) by centrifugation or a membrane cell separator, with return of the other components to the patient. Removing 1 L of plasma decreases plasma proteins by 1 g/dL, but because of compartmental equilibration and protein synthesis, 2.5 L of plasma must be exchanged weekly to decrease protein levels. In the intravascular space, 50% of the total IgG and 67% of the total IgM are found. Nine exchanges of 40 mL/kg over 3 weeks leave only 5% native plasma. The removal rate of plasma proteins and components depends on charge, solubility, avidity to other plasma proteins, configuration, synthesis, and uptake rates. In immunologic disorders, the recovery of immunoglobulin levels can be slowed by the concurrent use of immunosuppressive agents. If none are used, then antibody rebound, or the tendency of certain antibody levels to rise rapidly above their prepheresis baseline after initially decreasing, is observed; this often correlates with a disease flare (91). Plasma usually is replaced with a combination of albumin, salt, and water. Certain complications of lupus (e.g.

thrombotic thrombocytopenic purpura) necessitate the use of fresh-frozen plasma replacement, because a plasma factor is deficient. When performed by personnel at experienced blood banks or dialysis facilities, plasmapheresis usually is safe; serious complications (e.g., hypotension, arrhythmia, infection) occur less than 3% of the time in this group of sick patients (115). The reader is referred to my detailed reviews of the subject (116 ,117 ,118).

Rationale In Systemic Lupus Erythematosus

Plasmapheresis can remove circulating immune complexes and immune reactants (e.g., free antibody, complement components), alter the equilibrium between free and bound complexes, and restore reticuloendothelial phagocytic function (119). Three different centers have documented reversal of the reticuloendothelial system blockade by plasmapheresis (120 ,121 ,122). Plasmapheresis may improve suppressor-cell functioning (123), promote a Th1 shift (124), reduce IL-10 levels (125), reduce GM-CSF secreting peripheral blood mononuclear cells (126) and selectively remove IgG anti-DNA (127). Steven et al. (128) demonstrated improved bacterial killing by monocytes after plasmapheresis, and in patients with mild disease, Tsokos et al. (129) found no change in proliferative responses to mitogens or lymphocyte subpopulation percentages. In 17 steroid- and immunosuppressive-resistant patients with lupus nephritis, however, Wallace et al. (130) reported normal B- and T-cell counts but diminished mitogenic responsiveness and CD4 levels (compared with preplasmapheresis values) after 15 exchanges.

Clinical Studies in Systemic Lupus Erythematosus

The use of plasmapheresis was reported first by Jones et al. in 1976 (131). Follow-up observations brought the conclusion that patients who are the most seriously ill and have the highest levels of circulating immune complexes respond best (132 ,133 ,134 ,135). Patients who are treated concomitantly with plasmapheresis, prednisone, and cyclophosphamide do better than those who are treated with prednisone and azathioprine (136), and those who are on prednisone alone may become worse (137). The procedure is well tolerated in children and pregnant women with SLE (138 ,139). Over 1,000 case reports of apheresis improving specific aspects of SLE and antiphospholipid syndrome have been published. Only controlled studies or large series are cited in this section.

Lupus Nephritis

The most impressive results were reported in patients with lupus nephritis who had active disease and minimal scarring. Of 31 Finnish patients in this subset, 24 responded to treatment (140). Kincaid-Smith's group (141) rebiopsied eight patients with acute crescentic proliferative lupus nephritis several weeks after they received prednisone and cyclophosphamide and underwent plasmapheresis, and they found dramatic improvements in seven. A literature review in 1986 noted that 69% of 42 cases of diffuse proliferative nephritis improved after plasma exchange (142). These and other promising reports (143 ,144 ,145) led to two controlled trials. Lewis' group randomized 86 patients with new-onset proliferative nephritis to oral cyclophosphamide and prednisone, with or without plasmapheresis (146 ,147 ,148 ,149). Both groups improved, and no differences in the outcome were noted. Numerous methodologic flaws minimize the value of this study, however (150). Wallace et al. (130 ,150) restricted their study to 27 patients with nephrotic syndrome who were resistant to a minimum 3-month trial of steroids and cytotoxic drugs. Of these, ten were randomized to continue their therapy, and plasmapheresis was added to 17. After 2 years, seven had a good outcome (i.e., normal serum-creatinine level and resolution of nephrotic syndrome), and seven had a poor outcome (i.e., dialysis or death). All seven who had a good outcome underwent plasmapheresis (p = 0.026). Of the seven responders, five had undergone apheresis. The poor responders could not be predicted in advance by any of 30 variables used (130 ,150).

Antiphospholipid Syndrome and Congenital Heart Block

Interest has focused on the removal of anticardiolipin antibody and the lupus anticoagulant by plasmapheresis during pregnancy or in patients who have experienced recurrent thromboembolic episodes (151). Results have been mixed (152 ,153 ,154 ,155 ,156 ,157 ,158 ,159). Plasmapheresis is safe during pregnancy (160) and can be used weekly for the temporary removal of anticardiolipin (161 ,162 ,163 ,164). It is especially helpful if large amounts of the IgM isotype are present (165). The apheretic removal of anti-Ro/SSA in mothers whose fetuses show signs of congenital heart block has been reported but no conclusions can be made from published studies (166 ,167 ,168 ,169).

CNS, TTP, Cryoglobulinemia, Hyperviscosity, and Pulmonary Hemorrhage

Six French patients with central nervous system lupus had favorable responses (170), and this was confirmed by Neuwelt et al. in a larger study (171). The usefulness of plasmapheresis in cryoglobulinemia, thrombotic thrombocytopenic purpura, and hyperviscosity syndrome is well established (117 ,172 ,173), and these complications occasionally occur in patients with SLE. Several reports have suggested that plasmapheresis is useful for pulmonary hemorrhage (174 ,175 ,176).

Pulse Synchronization Therapy

Euler's group in Germany has devised an innovative approach for the treatment of seriously ill patients with SLE (177). It involves deliberately inducing antibody rebound with plasmapheresis, followed by high-dose intravenous cyclophosphamide to eliminate the increased numbers of malignant clones. Their pulse synchronization

technique has resulted in some spectacular successes with long-term, treatment-free remissions (146 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184). The net result was that pulse/synchronization does not work using conventional cyclophosphamide doses for lupus nephritis (185) or for the disease in general (186 ,187). Using higher-dose cyclophosphamide can be more effective, though much riskier.

Membrane Technologies

New membrane technologies have enabled selective plasmapheresis to be performed. Membranes that remove cryoproteins (188), anti–single-stranded DNA (189 ,190), IgG containing circulating immune complexes (191), and anti-dsDNA by immune adsorption (192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200) have been developed. Unfortunately, membranes activate complement and may present additional risks of hemolysis. In my experience, any theoretic cost saving obtained by avoiding albumin replacement is countered by the frequent clogging of expensive membranes, which necessitates termination of the procedure or use of a second membrane. Also, many patients with SLE do not have anti-DNA, and it is only one of many putative autoantibodies that may accelerate the disease process. Flares with treatment also have been reported (201). Further, selective membranes remove fewer plasma proteins than conventional plasmapheresis; this usually is not the practitioner's intent. Some promising approaches, such as a C1q column immunoadsorption have definite clinical effects (202). Adacolumn adsorbs granulocytes and monocytes and in pilot study of 15 patients appears to be well tolerated and not associated with an increased infection rate (203 ,204).

Summary

At this time, plasmapheresis should be used only for patients with renal disease who are resistant to corticosteroid and cytotoxic drug therapy, specific disease subsets in which its efficacy is established (e.g., those with hyperviscosity syndrome, cryoglobulinemia, or thrombotic thrombocytopenic purpura), and in those with acute, life-threatening complications of SLE, in each instance in combination with corticosteroids and cytotoxic therapy (Table 62-1).

Table 62-1: Indications for Apheresis in Systemic Lupus Erythematosus

I. Absolute—benefits are clear-cut and often life-saving
   1. Thrombotic thrombocytopenic purpura
   2. Cryoglobulinemia
   3. Hyperviscosity syndrome

II. Relative—acceptable to use when clinically indicated
   1. Severe organ-threatening disease that is underresponsive to steroid and cytotoxic drug therapy.

III. Investigational
   1. Antiphospholipid antibody removal in pregnancy
   2. Anti-Ro/SSA antibody removal in pregnancy

IV. Contraindicated
   1. Mild lupus or nonorgan-threatening lupus

Ultraviolet UVA-1 Radiation

McGrath et al. (205 ,206 ,207 ,208 ,209) have reported modestly beneficial effects of the longer wavelengths of UVA-1 radiation (340 to 400 nm) in open-label, double-blind, placebo-controlled, and long-term follow-up studies. Disease activity indices, cutaneous lesions, and anti-dsDNA levels improved. No side effects were reported. In a small double-blind placebo controlled study of 12 patients, Polderman et al. showed modest improvements in SLAM and SLEDAI scores with minimal toxicity (210 ,211). UVA1 photons may promote DNA repair, cell mediated immunity, apoptosis, and reduce B-cell function leading to anti-inflammatory effects (212 ,213).

In summary, cold UVA-1 light may be marginally beneficial in selected cases of SLE.

Complementary and Alternative Medicine

Up to 40% of Americans use CAM to treat chronic conditions, spending $27 billion a year (214). Moore et al. followed 707 lupus patients from Canada, the United States, and the United Kingdom. In 2000, they reported that one half used CAM (215). The users were younger and better educated, exhibited poorer levels of self-related health status and satisfaction with medical care, but did not have worse disease than nonusers. CAM was defined as including relaxation techniques, massage, herbal medicine, lifestyle diets, self-help groups, imagery, folk remedies, spiritual healing, chiropractic, megavitamin therapy, homeopathy, energy healing, commercial weight loss, biofeedback, acupuncture, and hypnosis. Ernst's review also included autogenic training, Alexander technique, aromatherapy, colonic irrigation, Feldenkrais, magnet therapy, meditation, osteopathy, reflexology, Tai Chi, and vitamins (216). Leong et al. interviewed 192 Chinese lupus patients in Singapore and found that 38% used CAM to manage the disease, whereas 28.6% employed it for cultural or other health reasons (217). In Mexico, patients who used alternative therapies had more disease severity and/or complications (218). Physicians managing lupus should ask their patients whether they are using CAM approaches, since certain may have a negative impact on the disease or interfere with other medications. For example, certain Chinese and Peruvian herbs and echinacea also contain chemicals that are harmful in SLE, and many herbal preparations contain sulfa (219 ,220 ,221).

The use of CAM approaches is discussed in other sections of this monograph. This includes diet and vitamins (Chapter 57), biofeedback or cognitive behavioral therapy for Raynaud and cognitive dysfunction (Chapters 38 and 57),

physical measures (Chapter 57). In this writer's opinion, any approach that promotes spiritual healing, relaxation, or improves blood flow (e.g., biofeedback) or uses the mind-body connection (e.g., CAM approaches that influence the sympathetic nervous system) are usually beneficial in SLE. Unfortunately, there is almost no evidence-based literature on the subject. Areas not covered elsewhere are summarized below (222). Other drugs and modalities that have been tried include tuberculin (223); Chinese herbs, especially T Wilfordii Hook F (224 ,225 ,226 ,227 ,228 ,229 ,230 ,231 ,232); arsenic (233); heliotherapy (234); hemotherapy (235); auricula acupuncture (236); hyperbaric oxygen (237), sarei-to (238), acupuncture (239), pulsed magnetic fields (240), and Pycnogenol phytotherapy (241). Witchcraft has even been used successfully (242). Tables 62-2 and 62-3 summarize CAM approaches that have been utilized in autoimmune disease patients.

Table 62-2: Complementary and Alternative Treatments Used by Lupus Patients

1. Manipulative, physical, and manual therapies

a. Acupuncture
b. Alexandra technique
c. Chiropractic
d. Osteopathy
e. Pilates
f. Reflexology
g. Tai chi
h. Yoga

Comment: Any technique that strengthens muscles and promotes aerobic conditioning is acceptable. Some also diminish pain. Fibromyalgia can be aggravated by some of these techniques, and caution and modifications are advised if synovitis is present (see Chapter 57).

2. Methods that promote relaxation, cognitive improvement, and greater disease understanding

a. Aromatherapy
b. Autogenic training
c. Biofeedback
d. Cognitive behavioral therapy
e. Guided imagery
f. Feldenkrais therapy
g. Hypnotherapy
h. Meditation
i. Self help groups
j. Spiritual healing

Comment: Any activity that works with the mind-body connection, decreases anxiety, or promotes restful sleep is usually acceptable (see Chapters 38 and 57).

3. Detoxification regimens

a. Colonic irrigation
b. Magnet therapy
c. Chelation therapies

Comment: Unproven for any aspect of lupus. Colonic irrigation is dangerous in patients who had thin bowel lining from corticosteroids; chelation therapies can be dangerous.

4. Herbal, dietary, and nutraceutical approaches

a. Homeopathy
b. Herbal anti-inflammatory regimens
c. Lifestyle diets
d. Elemental or hypoallergenic diets
e. Elimination or fasting diets
f. Folk remedies
g. Megavitamin and or vitamin regimens
h. Commercial weight loss programs
i. Dietary fatty acid regimens

Comment: Diets and vitamins are discussed in Chapter 57; specific supplements are listed in Table 62-3. Supplements are not FDA-regulated and their bioavailability varies as well as packaging and preservatives. A well-balanced diet is important.

5. Ayurvedic system (Indian healing system that combines aspects of the above approaches)

Table 62-3: Herb Chart (for Antiarthritics, Skin Treatments, and Gastrointestinal Treatments)

Herb	Claimed Uses	Active Ingredients	Potential Side Effects
Alfalfa	Antiarthritic	Nonprotein amino acid (L canavanine) and some saponins	In large quantities, could produce pancytopenia (decreased white blood cell count, anemia); could reactivate systematic lupus erythematosus
Arnica	Analgesic, anti-inflammatory (external application)	Sesquiterpenoid lactones (helenalin, dihydrohelenalin)	May cause contact dermatitis; cannot be taken internally; causes toxic effects on the heart and increases blood pressure
Black cohosh	Antirheumatic, sore throat, uterine difficulties	Substances that bind to estrogen receptors of rat uteri; also acetin, which causes some peripheral vasodilation	Information on toxicity is lacking; could cause uterine bleeding
Burdock	Treatment of skin conditions	Polyacetaline compounds that have bacteriostatic and fungicidal properties	Side effects may result from addition with belladonna
Calamus	Digestive aid, antispasmotic for dyspepsia	Unknown	Use only Type 1(North American) calamus, which is free of carcinogenic iso a sarone (may promote cancers)
Calendula (marigold)	Facilitate healing of wounds lacerations)	Unknown	Unknown
Capsicum	Counterirritant used to treat chronic pain (herpes zoster, facial neuralgia, or surgical trauma)	Capsaicin (proven analgesic in osteoarthritis, used externally)	Use caution in application; avoid getting into eyes or other mucous membranes; remove from hands with vinegar
Catnip	Digestive, sleep aid	*Cis-trans*-nepetalactone (attractive only to cats)	Unknown; does not mimic marijuana when smoked
Chamomilles, yarrow	Aids digestion, anti-inflammatory, antispasmotic, anti-infective	Complex mixture of flavonoids, coumarins, d-bisabolol motricin and bisabololoxides A + B	Infrequent contact dermatitis and hypersensitivity reactions in susceptible people
Chickweed	Treatment of skin disorders, stomach and bowel problems	Vitamin C, various plant esters, acids, and alcohols	Unknown
Comfrey	General healing agent, stomach ulcer treatment	Atlantoin, tannin, and mucilage, some vitamin B_{12}.	Hepatotoxicity (liver); can lead to liver failure, especially when the root is eaten; also causes atropine poisoning due to mislabeling
Cranberry	Treatment of bladder infections	Antiadhesion factors (fructose and unknown polymeric compounds) prevent adhesion of bacteria to lining of bladder	Increased calories if used in large doses (12–32 ounces per day) as a treatment rather than as a preventative (3 ounces per day)
Dandelion	Digestive, laxative, diuretic	Taraxacin (digestive), vitamin A	Free of toxicity except for contact dermatitis in people allergic to it
Devil's claw	Antirheumatic	Har pagoside	None
DongQuai	Antispasmotic	Coumarin derivatives	Large amounts may cause photosensitivity and lead to dermatitis, possible bleeding
Echinacea	Wound healing (external), immune stimulant (internal)	Polysaccharides, cichoric acid, and components of the alkamide fraction	None reported, but allergies are possible; be sure product is pure and not adulterated with prairie dock (can cause nausea, vomiting); may flare lupus

Evening primrose	Treatment of atopic eczema, breast tenderness, arthritis	*Cis*-gamma-linoleic acid (GLA) (some suggestive data)	No data; borage seed oil (20% as GLA) may be a substitute and does have toxic side effects (liver toxicity, carcinogen)
Fennel	Calms stomach, promotes burping	*Trans*-anethole, fenchone, estragole, camphene, L-pinene	Do not use the volatile oil—causes skin reactions, vomiting, seizures, and respiratory problems, no side effects with use of seeds
Fenugreek	Calms stomach, demulcent	Unknown	None
Garlic	GI ailments, reduces blood pressure, prevents clots	Allin (sulphur-containing amino acid derivative), ajoene	Large doses are needed (uncooked, up to 4 grams of fresh garlic a day), which may result in GI upsets; can "thin" the blood (anticoagulant)
Gentian	Appetite stimulant	Glycosides and alkalids; increases bile secretion	May not be well tolerated by expectant mothers or people with high blood pressure (possibly increasing pressure)
Gingko biloba	Helps dementia	Antioxidant	Well tolerated
Ginseng	Adaptogen, cure-all, anti-stress agent	Triterpenoid saponins	Be sure the product is pure; some insomnia, diarrhea, and skin eruptions have been reported; possible immune stimulant (antagonizes other medications)
Goldenseal	Digestive aid, treatment of genitourinary disorders	Alkaloids (hydrastine and berberine)	In *huge* doses, may cause uterine cramps
Honey	Sore throat, antiseptic, anti-infective, antiarthritic, sedative	Fructose, glucose, sucrose, tannin	Do not give to children under 1 year of age; may cause botulism in infants
Lovage	Diurectic, promotes burping	Lactone derivatives (ph thalides)	Some photosensitivity with volatile oil of lovage
L-Tryptophan	Sleep aid, antidepressant	Essential amino acid that increases chemical serotonin, leading to some sleepiness	Be sure product is pure; contaminants may cause a serious blood disorder and a scleroderma-like illness
Mistletoe	Stimulates smooth muscle (American), antispasmotic and calmative (European)	Phoratoxia and viscotoxin (depending on the plant species)	Berries are highly toxic, and the leaves may also cause cell death; in animals lowers blood pressure, weakens, constricts blood vessels
Nettle	Antirheumatic, antiasthmatic, diuretic, against BPH	Histamine, acetylcholine, 5-hydroxytryptamine	Skin irritation from the active ingredients
New Zealand green-lipped mussel	Antiarthritic	Amino acids, mucopolysaccharides	No toxicity or side effects except in those allergic to seafood
Passion flowers	Calmative, sedative	Unknown or disputed	None
Peppermint	Calms stomach, promotes burping, antispasmotic	Free menthol and esters of menthol	Do not give to infants and young children, who may choke from the menthol
Pokeroot	Rheumatism, cure-all	Saponin mixture (phytolaccatoxin), mitogen, pokeweed mitogen (PWM)	Vomiting, blood cell abnormalities, hypotension, decreased respiration, gastritis
Rosemary	Antirheumatic, digestive, stimulant	Camphor, borneol, cineole, diosmin (a flavonoid pigment)	Large quantities of the volatile oil taken internally cause stomach, intestinal, and kidney irritation

Rue	Antispasmotic, calmative	Quinoline alkaloids, coumarin derivatives	Skin blisters and photosensitivity following contact; gastric upsets when taken internally; may be an effective antispasmotic but is too toxic to be used
St. John's wort (Hypericum)	Antidepressant, anti-inflammatory, wound healing	10% tanin, xanthones, and flavonoids that act as monoamine oxidase inhibitors (antidepressants)	Photosensitivity dematitis in those who take the herb for extended periods; Prozac-like; increases serotonin
Sairei-to	Antiarthritic	12 herbs in combination	Diarrhea, abdominal pain, rash
Sassafras	Antispasmotic, antirheumatic	Safrole	Active ingredient is carcinogenic in rats and mice
Senna	Cathartic	Dianthrone glycosides (sennosides A + B)	Diarrhea, gastric, and intestinal irritation with large and/or habitual doses
Tea tree oil	Antiseptic (external application only)	Terpene hydrocarbons, oxygenated terpenes-4-01)	No side effects except skin irritation in sensitive individuals
Valerian (garden heliotrope)	Tranquilizer, calmative	Unknown	None noted
Yucca	Antiarthritic	Saporins	None noted

Chapter 63

Fibromyalgia in SLE and the Use of Complementary and Alternative Medicine

R. Swamy Venuturupalli

Introduction

Fibromyalgia (FM) is a common painful musculoskeletal condition associated with widespread tenderness or other somatic conditions, which has been described for centuries in the literature. Between 10% and 12% of the general population has chronic widespread pain. Women are affected more than men, and the prevalence of widespread pain increases with age (1). The mandatory symptom of this syndrome is widespread pain not explained by an inflammatory or degenerative musculoskeletal disorder. There are no “objective markers” of disease. The presence of many tender points in soft tissue locations validates the diagnosis. To this day, there remains significant controversy within the field of rheumatology about the existence of this syndrome and its true definition (2). A small but distinguished minority of academicians including rheumatologists have expressed the view that FM is a nondisease or a “medically unexplained syndrome.” This controversy highlights the concept that FM is not a single disease, but a group of disorders that is classified under the functional somatic syndromes. The disease fibromyalgia represents a group of heterogeneous individuals suffering from chronic pain (3 ,4).

Given the heterogeneity of patients with this condition, it has been difficult to study fibromyalgia. Various diagnostic criteria for FM were proposed and field tested. The 1990 American College of Rheumatology classification criteria (5) for FM have been adopted by most investigators in the past 10 years. In that study, 293 consecutive patients with FM were compared with 265 control patients who had regional chronic musculoskeletal pain or a systemic rheumatic disease. Training sessions were used to increase interrater reliability, and independent blinded assessors recorded the history and performed the physical examination. The symptom of widespread pain and the finding of mild or greater tenderness in at least 11 of 18 specified tender points on digital palpation provided a sensitivity of 88% and specificity of 81% in distinguishing FM from other causes of chronic musculoskeletal pain. Thus, the definition of fibromyalgia for classification purposes requires the presence of widespread chronic pain along with 11 of 18 tender points on digital palpation. However, the American College of Rheumatology (ACR) study committee found no difference in patients with FM who had a concurrent medical condition. Therefore, in regard to classification criteria, no distinction is made as to comorbid illness or possible associated trauma (5).

Distinguishing Fibromyalgia from SLE:

Fibromyalgia is much more common than SLE. Using current classification criteria, the estimated prevalence of FM in the general community is 2% for both sexes, 3.4% for women, and 0.5% for men. The prevalence increases with age, reaching greater than 7% in women aged 60 to 79 years. Fibromyalgia is the second most common diagnosis in rheumatology clinics (2). The prevalence of SLE in white women in the United States is approximately 10 to 50 per 100,000. It is 4 to 5 times more prevalent in African American women. Thus, fibromyalgia is 20 times more common than SLE, though a ratio of 65:1 or 75:1 is plausible (6).

Secondly, the prevalence of a positive ANA is much higher than the prevalence of connective tissue diseases. Hence, there is a high prevalence of positive ANA's in FM. In a study of 485 healthy volunteers, 20% of women and 7% of men and 31% of women over 40 were ANA positive (7). Slater et al. studied 1010 consecutive patients in a tertiary care center who underwent ANA testing by performing chart reviews. They found that 15% of all patients and 40% of patients over 65 years had a positive ANA. Overall, the sensitivity of the ANA test for SLE was high, but the positive predictive value was low for SLE or other rheumatic diseases (8). Given that the specificity of the ANA is low, it is not a reliable tool to differentiate inflammatory from noninflammatory conditions.

In light of the unreliability of ANA testing, the history and physical examination are extremely important in differentiating between inflammatory conditions and other conditions that mimic symptoms of autoimmune disease. Differentiating lupus from fibromyalgia can pose some problems to clinicians because patients often complain of the

same symptoms such as fatigue, arthralgias, sun sensitivity, neuropathies, memory deficits, morning stiffness, and chest wall pain. As an example, through a careful history, it is important to rule out seborrhea and rosacea when investigating a malar rash. Similarly, clinicians should inquire about the duration of sun exposure and factor in the altitude, latitude, and the skin pigmentation of an individual when inquiring about photosensitivity (6). When performing a physical examination, the clinician should look for evidence that supports the diagnosis of lupus or for evidence that the symptoms have another explanation. For example, the malar rash typically spares nasolabial folds, which are involved in rosacea and seborrhea, oral ulcers in lupus are more common on the hard palate, and acrocyanosis is commonly seen in lupus, particularly when the examination room is cool.

Lastly, clinicians should have a high index of suspicion for fibromyalgia, and feel comfortable making the diagnosis of fibromyalgia based on history and physical examination alone. Completely normal blood tests are consistent with a diagnosis of FM. Clinicians should also be attuned to the fact that fibromyalgia symptoms are reported in patients with increased stress, depression, anxiety, lack of sleep, lack of exercise and traumatic life experiences.

Prevalence of Fibromyalgia in SLE

Different studies have estimated that the prevalence of fibromyalgia in SLE is between 5% and 60%. Pistiner et al., reporting on 570 patients with SLE in the 1980s, reported the incidence of fibrositis to be 22% (9). Middleton et al. reported that 22% of patients in their cohort met ACR criteria for fibromyalgia and another 23% had clinical FMS without meeting the ACR criteria (10). Similarly, Moreland et al. (11) reported that 25% of SLE patients in their cohort had fibromyalgia using the Yunus criteria (12).

Other groups have reported a lower incidence of fibromyalgia in SLE; notably, a study by Friedman et al. (13) studied the prevalence of fibromyalgia prospectively and longitudinally in a group of 266 SLE patients. The prevalence of FM was then calculated, as was the prevalence of FM-like manifestations (widespread pain with at least 6, but fewer than 11 of 18 tender points). Fibromyalgia was seen only in 5% of patients, and fibromyalgia like illness was noted in another 13% of patients. If the patients with fibromyalgia like illness were included in the analysis, the prevalence of FM is approximately the same as prior studies.

Internationally, there is a variable prevalence of fibromyalgia. A Spanish study (14) reported that only 10% of Spanish patients with SLE had FM. It was suggested that the low prevalence of could be the result of geographical, psychological, sociocultural, and therapeutic factors. Handa et al. (15) reported that only 8.2% of patients in their cohort of Indian SLE patients were found to have fibromyalgia. Age, sex, marital status, educational level, disease duration, disease activity, and the organ involvement in patients with SLE and FM were comparable to those in patients not having fibromyalgia. They hypothesized that fibromyalgia appears to be distinctly uncommon in Indian patients with lupus and posited that a strong social support network, racial variation, and the lack of disability benefits in India could explain the differences between their results and other reports. However, even though family support is strong is Turkey, the prevalence of FM in Turkish patients with SLE is about 25% and is comparable with North American populations (16).

Only one study has shown a 61% prevalence of FM in SLE (17). The author hypothesized that other studies may have underestimated the prevalence of FM because the patients may have been treated with pain medications and nonsteroidal anti-inflammatory drugs (NSAIDs), which in turn would have increased their pain threshold and altered the tender point examination.

Overall, these studies point that the prevalence of FM is around 20% in patients with SLE, unless the prevalence of FM in the general population being studied is different from the prevalence of FM in the United States.

Etiology of Fibromyalgia in SLE

The etiology of fibromyalgia is not completely understood. Current thinking suggests that fibromyalgia is caused by a combination of factors such as central sensitization, dysfunction of the autonomous nervous system, and inappropriate secretion of neurotransmitters, cytokines, and hormones. The symptoms are exacerbated by stress, lack of sleep, and psychological dysfunction. A brief summary of some of the current theories on the etiopathogenesis of fibromyalgia is presented below.

Central Nervous System Disturbances

Patients with fibromyalgia have a generalized hypervigilance to both pain and auditory stimuli, with alteration in nociception. The heightened pain response at tender points is now considered to be a manifestation of altered central nervous system (CNS) processing of nociceptive stimuli (2). In one study, FM patients who were given electrocutaneous stimuli had a secondary hyperalgesia in the upper extremities (18). In other studies, elevated levels of substance P and abnormal antinociceptive peptides were demonstrated in the CSF of patients with FM (19 ,20). Further evidence for a central role can be inferred from brain imaging studies in women with FM, which demonstrate low regional blood flow to the caudate nucleus and the thalamus; areas previously determined to be involved in pain perception (21).

Sleep and Endocrine Abnormalities

Slow-wave–sleep abnormalities are fairly prominent in fibromyalgia. The most frequent finding has been alpha intrusion in non–rapid-eye-movement (NREM) sleep. Research has also found alterations of various neurohormones in FM. There is also an exaggerated corticotropin response to corticotropin-releasing hormone and variable disturbances of

sympathetic nervous system activity in FM. Low levels of somatomedin C, which reflects growth-hormone release, also have been noted in patients with FM. Evidence of sympathetic-parasympathetic imbalance, specifically related to neurally mediated hypotension, has been found in FM and CFS. Cervical spine pain, benign joint hypermobility, and steroid withdrawal also have been identified by some authors as contributing to the pathogenesis of FM (2).

The exact etiology of the development of fibromyalgia in SLE is not understood. In patients with SLE, there is hyperactivity of the immune system, which leads to immune complex formation and deposition in tissues. These immune changes can theoretically lead to pain either directly, because of inflammation, or indirectly, by causing tissue damage. However, several studies have shown that pain and fatigue, which are features of fibromyalgia in SLE patients do not correlate with disease activity measures (22 ,23). Thus, severity of SLE tissue damage is not linked to the development of fibromyalgia and indeed the presence of fibromyalgia in SLE patients does not correlate with SLE disease activity measures (24).

One possible theory for the etiology of fibromyalgia is the presence of severe fatigue in lupus patients, which in turn may lead to inactivity, which is a predisposing factor for the development of fibromyalgia. In one study, although the presence of fatigue did not affect disease activity of SLE, fatigue correlated strongly with depression, FM, and lower health status in SLE patients. This may represent poor coping abilities in these patients (22).

Various authors have hypothesized that steroid therapy is an import trigger for the development of diffuse pain (25). Handa et al. reported that corticosteroid withdrawal or dose reduction was the probable precipitating factor in nearly one third of their patients, who had concomitant FM and SLE (15). Smythe et al. reported that in a group of 54 patients, 26 of whom had received corticosteroid therapy for at least 3 years, there was a predisposition to develop tenderness of the shins in the patients who received steroids (26). This finding was recently duplicated by Buskilla et al. in patients with inflammatory bowel disease who were receiving corticosteroids (27).

Clinical Implications of FM in SLE Patients

The recognition of FM as a major contributor to the symptoms of concurrent rheumatic conditions, such as rheumatoid arthritis and SLE, has changed the approach to the treatment of these conditions and provided renewed interest in the psychosocial aspects of the common rheumatic disorders (10 ,24). The prevalence of fibromyalgia in SLE has several important clinical consequences.

Though the presence of FM in SLE patients does not seem to directly influence disease activity scores, it affects the ability of a clinician to correctly determine disease activity. Moreland et al. reported that there were no significant differences in disease expression between SLE patients with or without concomitant FM. However, they reported that patient and physician disease activity ratings did not correlate with SLAM scores in SLE patients with FM. This implies that concomitant FM affects the clinical ability to predict activity of disease (11). In another study, it was found that SLE patients with FM, suffered significantly more headaches, morning stiffness, diffuse alopecia, muscle pain, arthralgias, and renal involvement but the presence of FM did not correlate with lupus activity. Although the authors of this small, uncontrolled study noted that FM can interfere with assessment of lupus activity, they maintained that FM itself did not affect SLE activity (28). These findings were recently confirmed in a prospective study of FM in SLE, where clinical measures of disease activity, disease damage, specific organ dysfunction, sociodemographic factors and serologic features were not correlated with FM in their early SLE cohort (13).

There is good evidence that the presence of FM appears to affect the quality of life in a negative manner for lupus patients. Health-related quality of life is impaired in patients who have SLE and those that have FM. Patients with FM in fact have higher levels of impairment compared with SLE patients in several domains (29). In a cross-sectional study of 119 patients with SLE, SLE outcome measures such as disease activity or damage did not correlate with quality of life, but quality of life measured with the SF-36 reflected the presence of FM (24). Another study reported that SLE patients were dissatisfied with their quality of life, and this dissatisfaction was more prominent in those SLE patients who had FM (30).

Moreover, the presence of FM can decrease the productivity of patients who have SLE. Middleton et al. reported that SLE patients with FMS were more likely to be unemployed and receiving disability benefits but did not differ in terms of disease activity measures (10). Friedman et al. reported that SLE patients with FM, had poorer self-reported physical functioning (13).

Conclusions

Fibromyalgia is highly prevalent in patients with SLE. The exact etiology of fibromyalgia in SLE is not known. The clinical examination is the most important way to distinguish fibromyalgia from SLE. The presence of fibromyalgia in SLE patients does not adversely affect their outcomes, but seems to portend a worse quality of life for these patients. Thus, the recognition and treatment of fibromyalgia in SLE patients can have a high impact on their functional status and sense of well being and should be part of the assessment of lupus patients.

The Use of Alternative Therapies in Lupus with Fibromyalgia

Introduction

Complementary and alternative medicine, as defined by the National Center for Complementary and Alternative Medicine (NCCAM), is a group of diverse medical and health care systems, practices, and products that are not

presently considered to be part of conventional medicine. While some scientific evidence exists regarding some CAM therapies, for most there are key questions that are yet to be answered through well-designed scientific studies—whether these therapies are safe and whether they work for the diseases or medical conditions for which they are used (31). Table 63-1 gives a classification of CAM therapies.

Table 63-1: Classification of CAM Therapies

Type	Description	Examples	Comments
Alternative Medical Systems	Alternative medical systems are built upon complete systems of theory and practice.	Homeopathy, ayurvedic medicine and traditional Chinese medicine.	No human clinical trials of these medical systems as a whole exist.
Mind-Body Interventions	Mind-body medicine uses a variety of techniques designed to enhance the mind's capacity to affect bodily function and symptoms	Meditation, prayer, mental healing, and therapies that use creative outlets such as art, music, or dance	No human clinical trials
Biologically Based Therapies	Biologically based therapies in CAM use substances found in nature, such as herbs, foods, and vitamins	Dietary supplements, herbal products and nutraceuticals	Some human trails, summarized in the text
Manipulative and Body-Based Methods	CAM are based on manipulation and/or movement of one or moreparts of the body	Chiropractic, massage therapy or osteopathic manipulations	No human clinical trials
Energy Therapies	Energy therapies involve the use of energy fields. They are of two types: biofield therapies, and biomagnetic based therapies	Qi gong, Reiki, and therapeutic touch	No human clinical trials

Prevalence of CAM Usage in SLE

Twenty-five percent of the general population of the UK, and 15% of Canadians use the services of a complementary medicine provider and about 35% of Americans use some form of complementary therapy (32 ,33 ,34). In rheumatology practices, the use may be even higher, with about two thirds of rheumatology clinic patients reporting CAM use (35), especially for certain conditions such as fibromyalgia and osteoarthritis. A follow-up study of the same patients did not show any difference in outcomes between patients who used CAM and those who did not (36).

CAM usage is very prevalent in SLE patients. Seventy of 107 consecutive SLE patients (65%) attending one of two rheumatology clinics in a Mexican city used alternative medical therapies (37). A large study of 707 patients with SLE from Canada, UK, and the United States, showed that 49.8% of SLE patients used alternative therapies with similar usage rates in all three countries. This study may have underestimated the actual use of CAM therapies, because they assessed CAM use over the last 6 months, rather than a “year prior use” definition used by other studies and it has previously been reported that patients who use CAM may not want to disclose their use of CAM because of fear that their physicians may not approve its use (38).

Generally, users of CAM therapies are younger and better educated than nonusers (38 ,39). SLE patients who use CAM exhibit poorer levels of self-rated health status and satisfaction with health care, though objectively they do not have worse disease. SLE patients who use CAM do not have higher objective disease measurement scores nor do they incur higher indirect costs (such as loss of productivity), thus suggesting that they are not sicker. However, interestingly, they incur larger costs for conventional care, thus suggesting that the use of CAM in lupus patients may be a marker for care-seeking behavior associated with higher consumption of conventional medical resources (38).

Utility of an Evidence-Based Approach to CAM

There is considerable public demand that alternative medical therapies be covered by existing public and private health insurance plans. However, critics of this movement suggest that the costs of nonconventional therapy will substantially increase the costs of caring for lupus patients, and the

integration of unproven therapies will not make the delivery of care more cost-effective. The lay public believes that herbal medicines are safe because they are natural as compared to allopathic medicines, which are manufactured. Although most physicians remain skeptical of nontraditional therapies, patients appear to be satisfied with the complementary approach to their own care (36). Because CAM therapies can have potential side effects and may interact with conventional medications, it is important to obtain a history of use of CAM from patients. In order to engage their patients about CAM usage in a constructive manner, it is imperative that physicians educate themselves about those therapies, for which sound evidence exists and those therapies that may be harmful. Thus, nonconventional therapies should be subjected to rigorous scientific study and the outcomes of diseases treated with complementary therapies measured, so that those therapies with evidence of effectiveness may be integrated with conventional therapies for SLE.

In the next section, the available scientific evidence for the use of nonconventional therapies for SLE is discussed. English language literature from 1966 to 2005 was searched using the PubMed database. Key words included SLE, complementary and alternative therapies, all the common forms of CAM used by lupus patients (see Table 63-2), and the common and scientific names of herbs used for the treatment of SLE. Only those therapies for which human clinical trials have been published have been reviewed below.

Table 63-2: Complementary and Alternative Therapies Used by SLE Patients.

Therapy	Comments
Relaxation techniques	No evidence for efficacy
Massage therapy	No evidence for efficacy
Herbal medicine	Some evidence for efficacy (see text)
Lifestyle diets	No evidence for efficacy
Self-help groups	No evidence for efficacy
Imagery	No evidence for efficacy
Folk remedies	No evidence for efficacy
Spiritual healing	No evidence for efficacy
Chiropractic	No evidence for efficacy
Megavitamin therapy	Some evidence for efficacy (see text)
Homeopathy	No evidence for efficacy
Energy healing	No evidence for efficacy
Acupuncture	Weak evidence for efficacy
Hypnosis	No evidence for efficacy
Copper bracelets/magnets	Weak evidence for pulsed magnetic fields

Adapted from Moore AD, Petri MA, Manzi S, et al. The use of alternative medical therapies in patients with systemic lupus erythematosus. Trination Study Group. *Arthritis Rheum* 2000;43(6):1410–1418.

Dietary Factors in SLE

Although dietary factors are not strictly under the purview of CAM and have been discussed in another chapter (Chapter 57 , Principles of Therapy and Local Measures), alternative practitioners recommend specific diets to patients and hence a brief summary of the main dietary studies in lupus is listed below.

Caloric and protein restriction may have a beneficial role in lupus. Severe caloric restriction in lupus rats is associated with delayed onset of glomerulonephritis (40). The exact etiology of how this works is not known, but animal studies show that caloric restriction is associated with lower levels of proinflammatory cytokines, decreased circulating immune complexes and decreased production of prostaglandin E2 (41). Restricted protein intake is also associated with higher survival in lupus rats. Similarly, diets low in the amino acids phenylalanine (found in beef and dairy products), casein, and tryptophan have been shown to be beneficial in lupus mice. Other animal studies indicate harmful effects of diets rich in saturated fats and omega-6 fatty acids, and L-canaverine (found in alfalfa) in lupus mice. Zinc deficient diets given to MRL/1 mice resulted in improved survival (41).

Nutritional Supplements

Several nutritional factors have been studied in lupus patients including omega 3 fatty acids, vitamin E, vitamin A and selenium. The rationale for their use and the clinical data is presented below.

Rationale for Use

Omega-3 fatty acids inhibit the production of eicosanoids (proinflammatory compounds), whereas omega-6 fatty acids such as arachidonic acid are metabolized into proinflammatory eicosanoids. Omega-3 fatty acids can displace arachidonic acid from cell membranes and compete with arachidonic acid for cyclooxygenase and lipoxygenase enzymes, themselves being poor substrates for cyclooxygenase, the rate limiting step in the synthesis of production of PGE2, a proinflammatory eicosanoids. Omega-3 fatty acids also decrease T-cell activity and cytokine concentration, which has the effect of decreasing the process of peroxidation (the final common pathway in inflammatory tissue damage) and thus free radical damage to tissues. Vitamin E, selenium, and other antioxidants may work further downstream in this process to prevent oxidative tissue damage (41).

Clinical Studies of Supplements

Fish oil supplements retard the development of lupus in mice, and prolong their survival. Fish oil may work through several mechanisms, including its high content of omega-3

fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). Although the majority of animal studies show that omega-3 fatty acids ameliorate the severity of autoimmune disease, only modest anti-inflammatory effects have been reported in humans with lupus. In one study, 8 out of 17 SLE patients given 3.7 g of EPA/DHA and 2 of 17 controls improved at 3 months (42). In an uncontrolled study of 12 patients given 6 to 18 g of fish oil, (1.8 to 5.4 g of EPA/DHA), no significant improvement in immune complexes, anti-DNA titer, or prostacyclin was noted (43). In a double-blind cross-over study of fish oil therapy, 26 patients with lupus nephritis were followed for 2 years. The fish oil dietary supplementation had no significant effect on proteinuria, isotope glomerular filtration rate, disease activity index, or steroid consumption. However, it did have a significant effect on lipid levels (44). Pending further studies, fish oil has no proven benefit in human lupus.

Vitamin E use for lupus has been reported since the 1940s, and a review of the literature shows that large doses of vitamin E may be beneficial in some cases. Several studies reporting positive effects of Vitamin E in SLE and other reporting negative results have been published (41). Thus, it is unclear whether the use of vitamin E is effective for SLE. A recent meta-analysis of trials of high dose vitamin E for cardiovascular protection reported higher rates of death in patients taking high dose vitamin E, suggesting that prescribing high dose vitamin E (greater than 400 IU/day) may be unwise at this time (45).

Vitamin A has been reported to be beneficial in SLE. Three patients with skin flares were given 50 mg of beta-carotene three times daily, and experienced clearing of all lesions within 1 week of treatment (46). Other researchers reported benefits of high-dose vitamin A therapy in lupus patients, in a number of immune function parameters (47). However, patients should be advised to avoid ingesting high doses of vitamin A from animal sources, which are fat-soluble and can cause significant toxicity.

Selenium supplementation, when administered along with tocopherol succinate, to lupus mice increases their survival, probably through its effect on increasing glutathione peroxidase activity. However, excess selenium ingestion can lead to toxicity with symptoms of diarrhea, vomiting, hair loss, skin lesions and nervous system dysfunction (41).

Herbal Medications

Flaxseed oil, composed of 70% omega-3 fatty acids, has been shown to have a direct effect on the antibody profile of SLE patients. In a small uncontrolled study, nine patients were enrolled, eight of whom completed the study. After the baseline studies, patients were given 15, 30, and 45 g of flaxseed/day sequentially at 4-week intervals, followed by a 5-week washout period. The 30 g flaxseed/day dosage was well tolerated and conferred the most benefit without side effects in terms of renal function as well as inflammatory and atherogenic mechanisms important in the pathogenesis of lupus nephritis. There were no outcome data reported in this study (48). Patients should be cautioned about the possibility of allergic reactions with flaxseed.

Evening primrose oil, which has a high concentration of linolenic acid (GLA), has been reported to increase survival time in autoimmune mice. No human studies of evening primrose oil in lupus patients have been reported.

Tripterygium wilfordii hook F (TwHF) is a plant that has been used in China for over 2,000 years. TwHF has been found to inhibit IL-2, interferon-1, and prostaglandin E2 (49). During the past three decades, thousands of patients with a variety of autoimmune diseases have been treated successfully with TwHF. However, it should be emphasized that although efficacy has been claimed, few of these claims have been substantiated in randomized controlled trials. TwHF preparations have been used in the treatment of SLE, in 5 open trials in a total of 249 patients. In these trials, treatment with TwHF improved clinical manifestations of SLE, including fatigue, arthralgia, fever, skin rash, lymphadenopathy, hepatomegaly, and laboratory abnormalities, such as proteinuria, thrombocytopenia, antinuclear antibodies, and renal function. In two studies, TwHF treatment reduced prednisone requirements in SLE patients. The results suggest that TwHF might be an alternative or additional drug for those SLE patients in whom steroid therapy is insufficiently effective or contraindicated (50).

The most common side effects of TwHF are diarrhea, nausea, vomiting, hair loss, dryness of mouth, headaches, leukopenia, thrombocytopenia, rash, skin pigmentation, angular stomatitis, oral ulcers, gastritis, abdominal pain, weight gain, weight loss, diastolic hypertension, and vaginal spotting (51). Serious side effects have been reported with the use of TwHF, including infertility, and suppression of lymphocyte proliferation. A young man reportedly died from cardiac toxicity, and teratogenicity has also been reported (50). The possibility that serious side effects may be underreported in clinical trials coupled with the lack of any large randomized controlled trials, places a large question mark on the utility of this medication in management of lupus.

Other Preparations

Other drugs and modalities that have been tried but are only of historical interest include tuberculin, (52) arsenic (53), heliotherapy (54), and hemotherapy (55). Auricula acupuncture (56), hyperbaric oxygen (57), and sarei-to (58) have been reported in case series. Acupuncture is used widely by SLE patients, but a review of published studies showed that the studies lacked sufficient quality (59). Pulsed magnetic fields (60), and pycnogenol phytotherapy (61) have been reported to be useful in lupus as has witchcraft (62).

Conclusions

CAM usage is very prevalent in SLE. There are very few human clinical trials for the commonly used CAM methods in SLE. There is no strong evidence that any of the CAM

therapies have any disease modifying effects. However, there is some suggestion that a few of these therapies may be helpful as adjunct treatments. Generally, any technique that strengthens muscles and promotes aerobic conditioning is acceptable. Some of these also diminish pain, whereas fibromyalgia can be aggravated by some of these techniques, and caution and modifications are advised if synovitis is present. Any activity that works with the mind-body connection, decreases anxiety or promotes restful sleep is usually acceptable. Some therapies such as colonic irrigation can be dangerous in patients who have a thin bowel lining from corticosteroids, and others such as chelation therapies which use intravenous infusions of chemicals can be dangerous.

Given that patients are attracted to CAM, it is important for physicians to maintain an open mind, and have an honest discussion with their patients about the evidence while directing them toward more healthy lifestyles in general, and away from potentially harmful or expensive therapies for which no evidence exists.

Chapter 64
Hormones and Gender-Related Issues

Joan T. Merrill

Jill P. Buyon

Summary and Precis

The underlying causes of SLE are without a doubt multifactorial, evolving from several alternative triggering events that impair the orderly balance of immune responses in susceptible hosts (1). Hormones are critical to the homeostasis equilibrium of immunity, and hormonal factors might play a significant role in the development of lupus-like disease. During young adulthood (childbearing years), the ratio of women with lupus to men may be as high as 9:1, but this female preponderance is not so striking in children and the elderly (2). Some interesting reports have suggested that a variant of SLE can be seen in men with Klinefelter syndrome (3 ,4) and that men with SLE have unique androgenic profiles (5). Other studies have suggested that estrone metabolites in both men and women seem to favor 16-hydroxylated metabolites (6 ,7), that women with SLE oxidize testosterone to androstenedione at a greater rate than males, and that lupus, like many other chronic diseases, can result in low levels of the weak androgen, dehydroepiandrosterone (DHEA) and its inactive sulfated form, DHEA-S, which is thought to provide a reservoir for sex steroids in healthy individuals (8 ,9 ,10 ,11 ,12). However, despite characteristic hormonal abnormalities, it should be stressed that SLE is not strongly associated with infertility or any other identifiable gender-linked disparities in either men or women.

Until recently, the use of hormonal therapies for lupus patients was in broad disfavor, which seemed logical based on the observations cited above, and a significant experimental literature in murine models (13). Additionally, there were published reports of patients suffering disease flares while receiving exogenous hormones, one of which was a retrospective study in patients with pre-existing renal disease (15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24).

However, hormonal imbalance need not dictate that all exogenous hormone combinations would be necessarily toxic. The perceived advantages to hormonal use in some clinical situations (effective birth control, osteoporosis prevention, ovulation induction, and preservation of fertility in patients receiving cyclophosphamide), suggested a need to determine if such therapies could be used safely or at least within a rational therapeutic window. The potential impact of this possibility should not be underestimated. The rate of elective abortion in SLE patients approaches 23% in some reports (25 ,26 ,27). Although the cardiac and neuropsychologic effects of estrogen replacement have become controversial, osteoporosis is a major cause of damage in SLE patients (Fig. 64-1) and up to 20% of patients may have vertebral fractures when carefully studied (28). Premenopausal patients are not optimal candidates for bisphosphonate therapy, particular in the setting of inadequate birth control. Finally, there may be subsets of SLE patients who could derive a therapeutic benefit from hormone supplementation. This hypothesis arises from the intriguing clinical observation is that SLE patients have a tendency to experience disease exacerbations around the time of menses, when estrogen levels drop, as opposed to being elevated. Two reports have even suggested that, despite the experience that hormones may trigger flares in some individuals, oral contraceptive pills (OCPs) can in fact control cyclical or other disease activity in certain SLE patients (29 ,30).

Finally, some theoretical benefits may derive from supplementation with DHEA, which exerts androgenic effects on its own, but is predominantly metabolized to female hormones in women. To date, pivotal trials of this agent have failed to meet their primary endpoints, despite data suggestive of potential therapeutic responses in some patients. The current review will summarize clinical experience with female hormone supplementation and weak androgen therapy in SLE, and discuss the immunologic basis for their use. Other endocrine disorders associated with SLE will be briefly reviewed, although the literature is less extensive in these areas.

Female Hormone Supplementation for Birth Control or Postmenopausal Replacement

Hormonal contraception is the most effective form of birth control and is the preferred method of the majority of Caucasian and African-American women between 15 to 44 years (31). In 1988, approximately 10.7 million women in the United States were taking oral contraceptives (32). This form of contraception has the added advantage that it may protect against ovarian and endometrial cancers (33).

Combination OCP contain both synthetic estrogen and progesterone preventing ovulation for the most part by inhibiting gonadotropin secretion, progesterone-suppressing luteinizing hormone, and estrogen suppressing follicle-stimulating hormone. Additionally, estrogen stabilizes

endometrium to prevent bleeding, and progesterone increases cervical mucus viscosity, decreases tubal peristalsis, and inhibits the endometrium from supporting a pregnancy. Each of the progestational effects is enhanced by the estrogen supplement contained in the combined pill (33).

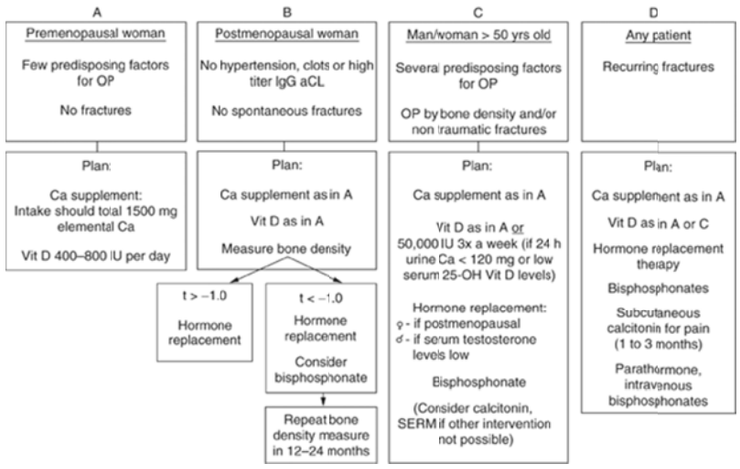

Figure 64-1. Algorithm for prevention and treatment of osteoporosis in patients with systemic lupus erythematosus.

Progesterone-only pills are potential alternatives to classic combination oral contraceptives in patients with SLE, and two studies found no instigation of flares with these treatments (14 ,34). The arguments for progesterone-only in SLE are clear. In the NZB/NZW experimental murine lupus model, progesterone prolonged survival in castrated males, was less deleterious in castrated females than estrogen, but was associated with high levels of autoantibodies in both genders (13).

Additionally, progesterone may be less thrombogenic than estrogen (35), a significant consideration for lupus patients who are already at increased risk for thrombosis and accelerated atherosclerosis. Unfortunately progesterone-only pills may be less effective as contraceptives than the combination pill (31) and are associated with more ectopic pregnancies than combination contraceptives. Thirdly, progestins may inhibit beneficial effects of estrogen on adverse lipid profiles (36 ,37), which are often seen in lupus patients. Unpredictable breakthrough bleeding is also seen with progesterone treatment, and this has been reported to occur in lupus patients (Table 64-1) (34 ,38 ,39).

Potential Benefits and Risks of Hormone Therapy for Women with SLE

Estrogen elicits both direct (40) and indirect effects on bone metabolism. Positive changes in calcium homeostasis are achieved by enhancing synthesis of 1,25 (OH)2D and absorption of calcium in the intestines (41). Additionally, the bone-resorbing cytokines interleukin-1 and interleukin-6 are inhibited by estrogens (42 ,43). The net effect is not only

to prevent bone loss but also to increase bone mass in individuals with osteopenia (44 ,45 ,46 ,47 ,48). Most of the increase in bone mass occurs during the first 12 months of therapy (47 ,48) consistent with a model that the primary mechanism is inhibition of bone resorption, allowing the ongoing complementary process of bone formation to reinstitute the bone mass over a prolonged period (49).

Table 64-1: Comparative Plasma Levels of 17 ß-Estradiol (pg/mL)

Menstrual cycle	
Peak (day 12–14, late follicular)	200–500
Nadir (day 1, early follicular)	40–100
Pregnancy	
Peak (38–40 wk)	16,000–30,000
Ovulation induction	1,000
Menopause	5–20
Estrogen replacement	
Premarin 0.625 mg	40–100
Transdermal (after 6 months of use)	40–100

Many endogenous and exogenous factors contribute to the development of osteoporosis, including genetics, caffeine, alcohol, smoking, body stature, physical activity levels, renal disorder, thyroid disease, and treatment with glucocorticoids (50). Glucocorticoid use contributes significantly to risk of osteoporosis in women with SLE. Ramsey-Goldman et al. surveyed the frequency of fractures and associated risk factors in 702 women with lupus who had been followed for 5,951 person-years (51) and found that fractures occurred in 12.3% of the patients, an almost fivefold increase compared with a background population. Older age at diagnosis and longer duration of steroid use were important variables. Two recent studies addressed bone mineral density (BMD) in premenopausal women with SLE. Sinigaglia et al. reported osteoporosis in 22.6% of 84 premenopausal patients, and both disease duration and glucocorticoids were associated risks (52). Gilboe et al. observed similar results in a study of 75 SLE (combined pre- and postmenopausal) patients and concluded that premenopausal patients taking glucocorticoids were at particularly high risk (53). Not surprisingly, observational studies suggest that women who receive OCP may have higher adjusted BMD than women who do not (54). The American College of Rheumatology (ACR) Task Force on Osteoporosis Guidelines has in fact recommended OCP to prevent glucocorticoid-induced osteoporosis in premeno-pausal women with oligo- or amenorrhea (55).

Despite recent controversies, to be discussed below, a significant literature supports the hypothesis that estrogen supplementation, in as yet to be determined formulations, given to appropriate patients, may provide significant protection against the development of atherosclerosis. Prior to menopause, the incidence of atherosclerosis-related events is eight times less common for women than for men (56). Following menopause and its associated decrease in ovarian hormone production, the rate of cardiovascular disease accelerates rapidly, so that by age 65 the risk in women is equal to that of men.

Estrogens exert several biological properties that should be cardio-protective, including favorable effects on the lipid profile, stabilizing effects on vascular endothelium, and improved fibrinolysis (57 ,58 ,59). Estrogens increase HDL-cholesterol and decrease LDL and lipoprotein (a) (60). Estradiol decreases circulating P-selectin, which connects leukocytes to endothelial cells and activated platelets (61) and reduces the vascular response in an in vitro model of immune injury, the rabbit cardiac allograft, which may mimic the pathogenesis of SLE accelerated atherosclerosis (62). Levels of plasminogen-activator inhibitor type 1 (PAI-1) (fibrinolysis inhibitor) has been linked to risk of cardiovascular disease (63 ,64 ,65 ,66). Exogenous estrogen can significantly reduce PAI-1 levels in postmenopausal women (67 ,68 ,69 ,70). Observational studies additionally suggest that estrogen levels correlate with decreased homocysteine, a risk factor for vascular occlusion (71). Finally, estrogens have an antioxidant effects, inhibiting important steps in atherosclerotic plaque development (60 ,72).

Most clinical data on the benefits and risks of hormone replacement is retrospective and uncontrolled. The only published controlled, prospective trial of HRT effects on cardiovascular outcomes, the Heart Estrogen-Progestin Replacement Study (HERS) had a negative result, showing no net benefit of estrogen plus progestin treatment over a 4-year period in women with previously established coronary artery disease (73). Additionally, hormone replacement was associated with an increased risk for coronary thrombotic events, limited to the first year of treatment, in this higher risk group of women (73). This does not prove, with finality, an absence of cardioprotective benefits for estrogen in general, but rather illustrates the complexities in the acute and chronic effects of estrogen and the contextual caution with which any further exploration of its use in lupus (or in any group of women who may have pre-existing heart disease) needs to be considered. The increased acute estrogen-induced thrombotic risk may outweigh its protective effects on atherosclerosis in women with established plaque, at least for the first years before longer term plaque-preventing effects can begin to have a major impact. It should be stressed that several clinical and animal studies in lower risk populations, have weighed in with positive cardioprotective outcomes, including the large Nurses Health Study (74 ,75 ,76 ,77 ,78 ,79). These considerations are of critical importance to patients with SLE given mounting evidence that accelerated development of atherosclerosis is a significant risk for morbidity and mortality in these patients (80 ,81 ,82 ,83 ,84 ,85 ,86 ,87). However, the subset of patients with antiphospholipid antibodies, with a substantial literature supporting a measurable risk of thrombosis, may be a group for whom hormonal supplementation is currently out of the question, supported by the observation of Asherson et al. describing 10 patients with aPL, all of whom developed vascular complications while taking oral contraception (88).

Several biologic properties of estrogens and aPL may contribute to similar pathways leading to thrombogenesis potential. It is generally accepted that platelets play a critical role in the dynamic regulation of arterial forms of thrombosis, whereas disturbances of the clotting cascade most frequently result in venous thrombosis. Patients taking estrogens or combined OCP may have increased platelet aggregation (89), but these effects are not clearly distinguishable from the associated factor of concomitant cigarette smoking (90). Estrogens can increase the concentration of coagulation factors VII, IX, X, XII, and prothrombin (reviewed in (91)). Most patients taking OCP have decreased partial thromboplastin times and prothrombin times, primarily as a result of increased levels of fibrinogen (35). Both estrogens and aPL can inhibit prostacyclin production by endothelial cells (92 ,93). Synthetic estrogens are more “procoagulant” than natural preparations, and oral

estrogen formulations influence coagulation to a greater degree than transdermal preparations, since the latter avoid the first-passage effect of oral estrogens (91). Importantly, the impact of estrogen on various clotting factors is dose dependent, with little if any effect at doses less than 50 µg of ethinyl estradiol (94). The U.S. Food and Drug Administration (FDA) issued a bulletin stating that the rate of DVT in women taking low-dose OCP containing 20 to 40 µg ethinyl estradiol was 4 per 10,000, which approximates that of women not taking OCP, 3 per 10,000 (95).

Experimental data suggest that “antiphospholipid” antibodies include specificities that recognize a number of coagulation-regulating proteins, the best characterized of which is $ß_2$GPI (96 ,97 ,98). which inhibits contact activation of the intrinsic coagulation pathway (99), platelet prothrombinase activity (100), and ADP-induced platelet aggregation (101). Since $ß_2$GPI has been shown to possess multiple inhibitory functions in coagulation pathways, its interaction with aPL may eventually lead to an explanation for the thrombotic diathesis observed in patients with these antibodies. Preliminary data support a decrease in the circulating levels of $ß_2$GPI in the second trimester of pregnancy (102), but the effect of exogenous hormones on these levels is unknown.

A known prothrombotic effect of OCPs is a decrease in the anticoagulant, protein S (103). In addition, inflammatory diseases such as SLE, may also contribute to an acquired protein S deficiency, whereby protein S may be excessively bound by a complement protein, C4BP, which is its major plasma inhibitor. In most acute phase responses, the relationship between free (active) and bound (inhibited) protein S is preserved (104), but this breaks down in dysregulated inflammatory states such as sepsis, disseminated intravascular coagulation (DIC), and flares of lupus (105 ,106 ,107 ,108). Autoantibodies to protein S are common in patients with lupus and the antiphospholipid syndrome, further suggesting relationships between hormonal regulatory pathways and effects of antiphospholipid-related autoantibodies on coagulation. It could be hoped that in the future, rational pharmacology might develop from the application of better knowledge about the pros and cons of hormonal agents on pathways destabilized by antiphospholipid-related antibodies.

The Use of Gonadotropin Agonists to Protect from Cyclophosphamide-Induced Infertility

Empiric use of leuprolide acetate, a gonadotropin-releasing hormone agonist, to protect against ovarian failure in lupus patients receiving cyclophosphamide had evolved through preliminary reports and anecdotal exchanges in some centers over a number of years. Therefore a recent published series involving 40 women with severe SLE receiving cyclophosphamide (half of whom were treated with a depot leuprolide acetate) was of interest (109). One out of 20 patients who received leuprolide developed premature ovarian failure versus 6 of 20 controls (30%), who had been matched by age and cumulative dose of cyclophosphamide. This was a statistically and clinically significant finding. Despite the theoretical issue of whether gonadotropin agonists could provoke SLE flare (110) and one case report of lupus nephritis after leuprolide treatment, (111) it is usually considered reasonable to consider this kind of therapy while patients are receiving aggressive immune suppression. On the other hand, the use of leuprolide is not without other risks. The association of this treatment with changes in coagulation parameters and/or thrombotic manifestations (112 ,113 ,114 ,115 ,116) should be carefully factored in to decision making for this high risk population. Extended use of leuprolide is also associated with bone mineral loss (117 ,118), although the latter is likely to be of minor concern in the context of the disease and treatments for which it would be considered here.

Do Hormones Exacerbate SLE Disease Activity?

What is the evidence that oral contraceptives might exacerbate lupus disease activity? The largest database evaluating this question examined oral contraceptive history and onset of SLE in 121,645 women (119). In this robustly powered study, the use of OCP was associated with a small risk (1.4) for the development of SLE, however the clinical significance of this in the context of a relatively rare disease remains uncertain. Some case reports have described lupus onset in the context of OCP use as well (15 ,16 ,17). However, in at least one retrospective series, lupus patients taking OCP did not experience increased flares as compared to a control group (38). A survey study on the use of OCP in patients with an established diagnosis of lupus found that there were no differences in the percentages of lupus vs. healthy control participants who had ever used oral contraceptives, but far less use after the diagnosis of lupus, despite the fact that overall these pills were reported to be well tolerated with a calculated flare rate of 0.45 per 100 patient months (23). Importantly, oral contraceptives have evolved over the years, so that previous doses of up to 50 µg ethinyl estradiol have been largely replaced with preparations containing 30 to 35 µg.

The SELENA study was a two-armed prospective study to evaluate the safety of oral contraceptives and estrogen replacement therapy in lupus patients. In the oral contraceptive arm (120), 183 premenopausal patients were randomized to placebo or triphasic 35 mg ethinylestradiol/0.5 to 1 mg norethindrone for twelve 28-day cycles. Severe flares were rare occurring in 7/91 (7.7%) of patients taking oral contraceptive versus 7/92 (7.6%) on placebo. Mild/moderate flares were also equivalent: 1.41 versus 1.40 flares/person-years (oral contraceptive vs placebo) and there was no significant difference in the 12-month combined flare rates (70% vs. 60%; $P = 0.42$). There was 1 DVT in the OC arm, and 1 ocular thrombosis and 1 superficial thrombophlebitis in the placebo arm. One death (placebo) occurred after trial cessation.

It was concluded that OC do not increase the rate of severe or mild/moderate flares in SLE, although patients with unstable SLE activity or at increased risk for thrombosis were excluded from this study.

Table 64-2: Guidelines for Use of Oral Contraceptives in Women with Systemic Lupus Erythematosus

1. Inactive or stable/moderate disease
2. No history of venous or arterial thrombosis
3. IgGaPL <40, IgMaPL <40, IgAaPL <50, no circulating lupus anticoagulant (unknown if presence of low-to-moderate titer of aPL in the absence of a previous thrombosis is contraindication)
4. Nonsmoker
5. Normotensive
6. For combined pill, use lowest dose of ethinyl estradiol (30–35 μg)
7. Patient without migraine headaches
8. Can add low-dose aspirin therapy to hormone regimen if there is concern about risk factors

In the hormone replacement arm of the SELENA study, 351 menopausal lupus patients were randomly assigned to either placebo or Premarin plus discontinuous progesterone for 12 months (121). Severe flares were infrequent in both groups and were not significantly increased in women taking hormone therapy. Women taking hormone replacement had more mild to moderate flares than those taking placebo (1.14 flares vs. 0.86 flares/person/year) although the clinical significance of this was not concerning. Four women taking the hormones and one woman taking placebo had thromboembolic (blood clotting) events. Women with high levels of anticardiolipin antibodies, lupus anticoagulant, or previous incidences of thrombosis were excluded from the study at the onset. On the basis of these data it was concluded that adding a short course of hormone therapy might be associated with a small risk for increasing the flare rate of lupus, but most of the flares recorded were mild to moderate, and in many or even most patients the contained risks observed in this study might be favorably weighed against the potential amelioration of peri-menopausal symptoms (Table 64-2).

Could Androgens Benefit Women with SLE?

Deficiency of the weak androgen dehydroepiandrosterone (DHEA), and its primary metabolite DHEA-sulfate have been reported in chronic medical conditions, including SLE (8 ,9 ,10 ,11 ,12), and DHEA might have impact on a number of immunologic functions relevant to SLE. Endogenous circulating DHEA levels vary widely by gender, age and ethnicity, and can be affected by changes in corticosteroid levels, alcohol intake, smoking, body mass index, medications, and thyroid function (122 ,123). With this level of complexity in DHEA metabolism it is not surprising that clinical confirmation of efficacy in SLE has been inconsistent and controversial, hampering drug development for this theoretically promising treatment.

The pharmacokinetics and metabolism of DHEA depends on the target organ. Aromatase and 17-β-hydroxylase activity are increased in breast and other adipose tissue, suggesting that obesity might increase the conversion of DHEA to estrogens (124). Selective expression of 17-β-hydroxylase genes in various organs suggests that the liver, ovary, endometrium, and testis are prominent sites for estrogen synthesis and that placenta, liver, testis, endometrium, prostate, adrenal and skin are regions where androgen synthesis takes place (125). The skin has a high expression of enzymes required to transform DHEA into dihydrotestosterone, whereas conversion of DHEA in the vagina would be mainly to estrogens (126 ,127). The net effects of DHEA supplementation could be estrogenic or androgenic, then, and either conducive or inhibitory to health or disease depending on the hormonal and metabolic background and the responsiveness of the target organ(s) to hormonal effects. This concept is critical to understand, since low levels of DHEA are associated with breast cancer risk in premenopausal patients, whereas high levels have been associated with breast cancer risk in postmenopausal patients. It stands to reason, then, that when considering DHEA for SLE, it might require individualized approach to optimize dosing and administration of this agent in specific patients.

Theoretical Background for DHEA Supplementation in Lupus

Estrogens have been observed to increase autoantibody production whereas androgens can have the opposite effect (128). In mouse models of lupus, low DHEA is associated with the Th2 dominant cytokine profiles characteristic of B cell autoimmunity (129). Exogenously administered DHEA induced a change in the cytokines to a Th1-characteristic profile (130 ,131). DHEA and corticosteroids sometimes have opposite effects on gene expression critical to immunity (132), and in the case of the immune system, a finely tuned system of checks and balances, these kinds of opposing actions might be therapeutic or harmful, depending on the degree of change, and the immunologic background.

Low DHEA levels in lupus patients have been reported in a number of studies (8 ,9 ,10 ,11 ,12), but it remains unclear to what degree this is pathogenic or simply reflective of chronic disease, given the many disorders, including normal aging in which DHEA levels are seen to drop. Low DHEA levels have been found at the onset of lupus, prior to corticosteroid treatment, although an inverse relationship to corticosteroid levels has also been described (9 ,10 ,11 ,12). This suggests that adrenal androgen deficiency might be intrinsic to SLE and might be worsened by corticosteroid treatment, despite the therapeutic

benefits that also occur with corticosteroids. In pregnant SLE patients, estradiol, progesterone, and DHEAS concentrations seem to be decreased as compared to healthy controls (133).

DHEAS delays the onset of lupus-like disease, prevents formation of antibodies to dsDNA, and prolongs survival in the NZB/W F1 female murine lupus model (134 ,135 ,136). It increases levels of the cytokine IL-2 in both murine models and human studies (10 ,11 ,137). An association between interferon gamma production and DHEAS levels has been reported in healthy individuals, but was found to be lacking in lupus patients (9), suggesting a peculiar defect in lupus T cells. Additionally, DHEA has been found to inhibit apoptosis of blood cells isolated from SLE patients, which, in general might be guessed to increase, not decrease risk for lupus-like disease (138).

Clinical Trials of DHEA in Lupus Patients

van Vollenhoven reported the treatment of ten female patients with mild to moderate SLE who were given 200 mg/day of DHEA orally (139). After 3 to 6 months of treatment, global disease activity (SLEDAI), physician's global assessment were improved, and corticosteroid requirements were lessened. In a subsequent double-blind, placebo-controlled, randomized trial in 28 female patients with mild to moderate SLE, 200 mg/day of DHEA was associated with improvement in the SLEDAI score, and improved patient's and physician's global assessments (140). Prednisone dose was also decreased in the DHEA-treated group. In another report, 50 female patients with mild to moderate SLE were treated with oral DHEA 50 to 200 mg/day. DHEA therapy increased serum levels of DHEA, DHEA sulfate, and testosterone and was associated with. decreased disease activity and lowered prednisone doses (141). In a multicenter randomized, double-blind, placebo-controlled trial conducted in Asia, 120 adult women with active SLE were treated with 200 mg/day DHEA or placebo for 24 weeks leading to significantly decreased flares in the DHEA-treated group, and improved patient's global assessment suggesting the possibility that this treatment could have an impact on the quality of life in these patients (142). However, global disease activity using the SLAM was not affected by treatment in this study.

In a double-blind, randomized trial 191 female SLE patients receiving moderate doses of prednisone (10–30 mg/day) were given either placebo, 100 mg or 200 mg of oral DHEA and subjected to a protocol steroid taper. Patients with sustained reduction of prednisone (< or = 7.5 mg/day) were considered responders, and this definition was met by 41% of the placebo-treated group, 44% of the 100-mg prasterone group, and 55% of the 200-mg group (*p* = ns). However, when only those patients who had active disease at baseline were evaluated, 29%, 38%, and 51%, respectively, were responders and there was a statistically significant difference between the 200 mg treatment group and the placebo group (143).

Only one trial has evaluated DHEA for severe lupus. This was a double-blind, placebo-controlled, randomized clinical study in 21 patients with nephritis, serositis or hematological abnormalities (144). Patients were treated with DHEA 200 mg/day versus placebo for 6 months, followed by a 6-month open label period, given in addition to corticosteroids and immune suppressive therapies as warranted. Improvement in the principal baseline manifestation was seen in 7 of 9 evaluable patients on DHEA versus 4 of 10 of the evaluable patients on placebo and the mean SLEDAI improvement was also greater in the DHEA-treated group. These differences were not statistically significant, although the DHEA group was found to have greater disease activity at baseline. Furthermore, this study was underpowered for the detection of what could potentially be clinically significant differences.

A significant positive relationship between DHEAS and bone mineral density has been reported in premenopausal women with SLE, as well as a negative relationship between DHEAS and glucocorticoid dose and iPTH (145). Significant differences in bone mineral density changes were found in treatment versus placebo groups for lupus patients treated with DHEA (144), and thus DHEA seemed to have a potential bone-protecting effect in lupus patients. This was not borne out in a recent study in which osteoporosis protection would have been the primary outcome.

The most common side effects of DHEA are linked to its androgenic effects and include acne, hirsutism, and the potential for unfavorable effects on lipid metabolism. As mentioned previously some studies have confirmed androgenic effects on lipids, in particular that DHEA lowers high-density lipoprotein (HDL) (146). Most of the expected side effects from DHEA were borne out and no new side effects of concern were reported in the lupus studies (140 ,141 ,142 ,143 ,144 ,145 ,146), suggesting an overall good safety profile. In considering the long-term use of this agent however (which might come under serious consideration for patients with lupus), the possible growth-stimulating effects on hormone-dependent malignancies particularly of the prostate or breast should be kept in mind as well as the theoretical potential for DHEA to exacerbate lupus in some clinical situations via its immunostimulating and antiglucocorticoid effects (147). This might be a relevant issue in patients with more severe lupus which may be more likely to involve a complex, mixed immune disorder or in patients who rely on glucocorticoids for clinical stability. Finally, it is possible that DHEA or its metabolites may have effects on intracellular signaling pathways that are as yet largely unexplored (10 ,11). For this reason side effects might still occur in susceptible patients that are currently unforeseen.

Inflammatory Mediators and Female Hormones

The regulation of the menstrual cycle and/or invasion and implantation of the uterine wall by an embryo, requires an ebb and flow of inflammatory mediators, which is unique

to the adult female environment. The need to protect a fetus from immune attack without initiating graft-versus-host disease also sets a high bar for balanced immune regulation and counter-regulation. This explains the fundamental requirement, in women, for vascular-based inflammatory responses by hormones. For example, progesterone is important in suppressing the inflammatory reaction that would be expected in response to the presence of a foreign body, such as an embryo. Populations of macrophages and neutrophils in the uterus are under the control of estrogen and progesterone, and progesterone can antagonize the ability of estrogen to recruit macrophages and neutrophils into the mouse uterus (148). Progesterone may also suppress interleukin-8 and cyclooxygenase-2 expression (149), suggesting that progesterone withdrawal at the time of menstruation might promote these inflammatory mediators in preparation for the increased tissue inflammation that accompanies the extrusion process.

Complex Effects of Sex Hormones on Inflammation

Estrogen replacement in postmenopausal women may increase C-reactive protein (150 ,151) while decreasing a number of other inflammatory mediators (152 ,153 ,154 ,155). In the context of a rapidly advancing literature, it may be that a complex network of endometrial cytokines are normally regulated by hormones produced during the ovulatory cycle (156). However, signal cascades are two-way streets, so, inflammatory mediators will also have impact on hormones. For example, lipopolysaccharide, a potent stimulator of monocytes, induces a lengthening of the follicular phase in monkeys associated with decreased estradiol concentrations and increased pituitary release of LH and FSH (157). Complex relationships between hormones and vasculature, inflammatory mediators and vasculature, and hormones and inflammatory mediators are intrinsic to reproduction and the preservation of the species, which sets the stage for the female preponderance of autoimmune diseases.

Sex Hormones, Immune Activation, and the Vascular System

Estrogen receptors are found on human monocytes, B cells, and T cells, indicating a direct role for estrogens in the regulation of immune cell activation (158). General B cell activities seem to be enhanced by estrogen whereas T cell reactivity may be suppressed (159). In rats, endotoxin-induced expression of adhesion molecules, associated with an influx of inflammatory cells, increases in pregnant rats as compared to hormonally cyclic animals (160). Estrogen and/or progesterone are now known to enhance numerous inflammatory events, but, importantly, the differences in their effects against different hormonal background is simply not known (161 ,162 ,163 ,164). On the other hand, estrogen has been found to decrease class II expression in vascular allografts, accompanied by decreased inflammatory cell infiltration (165). Low doses of 17-ß-estradiol have been found to inhibit interleukin-6 secretion by human endothelial cells (166).

Inflammation and inflammation-induced coagulation mechanisms are sometimes predictors of cardiovascular events (167 ,168 ,169 ,170 ,171 ,172 ,173). Because of this there may be indirect effects of sex steroids on the risk of vasculature thrombosis through immune-modulating effects. For example, estrogen can improve markers of fibrinolysis and vascular inflammation in arteries of postmenopausal women (152) as well as having other anti-inflammatory properties which may have beneficial impact on cardiovascular risk (174). Atherosclerotic plaque demonstrates features similar to inflammation. Inflammatory cytokines induce adhesion molecules in blood vessel walls, augmenting inflammatory cell adhesion and subsequent development of atherosclerosis. One study has observed a statistically significant increase in several of these adhesion molecules when men and untreated postmenopausal women with coronary artery disease were compared with postmenopausal women with coronary disease who were receiving estrogen replacement (175). This contradicts other findings, mentioned above, which suggest that estrogen can augment adhesion molecule activity (160 ,176). These issues may resolve around the multiple signaling pathways and dose-responsiveness of estrogen therapies. Estrogen, then, may either augment or help to limit the inflammatory response to injury by modulating the expression of endothelial adhesion molecules. And, as discussed in the first part of this chapter, it may take a sophisticated set of biomarkers in order to utilize estrogen for the benefit and minimize risks in postmenopausal women at risk for atherosclerosis.

Menstrual Irregularities, Sexual Dysfunction, and Pregnancy Complications

Although reproductive abnormalities may be a frequent feature of SLE, much of the available literature is in the form of abstracts, editorial letters, and/or case reviews. Some reports suggest the possibility that SLE patients can develop significant menstrual irregularities and/or endometriosis (177 ,178 ,179 ,180 ,181 ,182); however, this has not been systematically examined. Several interesting papers have correlated flares to menstrual cycles, and observed that patients seem to flare more often in the second half of the cycle or just before menses (183 ,184 ,185). Sexual dysfunction may occur in SLE secondary to direct or indirect effects of disease activity, disturbances of the hypothalamic-pituitary axis or toxic effects of immune suppressants (186). Antisperm antibodies have been recorded in both male and female patients (187 ,188), correlating to anti-DNA antibodies and disease activity. Autoantibodies are known to have the potential to interfere with fertilization, implantation, embryonic development and placental function (186). Antiphospholipid and other related autoantibodies are directly associated with embryonic or fetal losses and other pregnancy complications such as preeclampsia/

eclampsia and the HELLP syndrome (189). However, there is no evidence that fertility is impaired overall in either male or female lupus patients.

Table 64-3: Thyroid Function and Antibody Studies in Systemic Lupus Erythematosus

Parameter	Gordon and Isenberg (237)	Byron and Mowat (200)	Goh and Wang (236)	Miller et al. (239)	Ropes (238)	Boey et al. (240)

Hyperthyroid (%)	2.4	10.9	2.8	5.0	—	8.9
Hashimoto disease (%)	—	—	0.6	—	2.1	3.9
Thyroid antibodies (%)	—	—	—	20	—	32.2

Thyroid Disorders and Their Relationship to SLE

Overlap between thyroiditis and other autoimmune or rheumatic disorders is described in some studies (190 ,191 ,192 ,193 ,194); however, like other endocrine disorders in lupus, some of the most intriguing reports are in the form of abstracts or letters. Although there are few formal incidence studies, data from the British National Health Service suggests that thyroid disease may be more frequent in SLE than in the general population (195). In one autopsy study 2 of 74 patients with thyroiditis had SLE opposed to none in a matched control group (196). Symptoms and signs of thyroid disorders may overlap with those of SLE and Petri et al. have reported that 46% of patients with autoimmune thyroid disease have a positive ANA. Similarly, testing for TSH levels may uncover subclinical thyroid disease in patients with SLE (197 ,198 ,199). Studies of SLE patients suggest that hyperthyroidism can precede the diagnosis of SLE, which may indeed arise in the context of treatments for the former disorder (197 ,198 ,199 ,200). Associations between hypothyroidism, SLE, and red cell aplasia have been reported as well as combined overlap of SLE, thyroiditis and Sjogren syndrome (201 ,202 ,203). However, no common risk factors or integrated pathophysiologic insights have as yet emerged from these reports. An antimicrosomal antibody (anti-Mic-1) has been observed in patients with SLE and hyperthyroidism but not in patients with Hashimoto thyroiditis or rheumatoid arthritis (204 ,205), as well as some evidence that thyroid peroxidase antibodies in SLE may be different from those in primary Hashimoto disease (206). Anti-TSH antibodies have also been reported in association with SLE (207 ,208) supporting a model of autoimmunity as an overlapping spectrum of disorders (Table 64-3).

Other Endocrine Disorders

As above, some of the most pertinent reports on other endocrine disorders in lupus are preliminary or only available in abstract form. Positive ANA has been described in up to 41% of patients with type I diabetes (209) and mild features of SLE have been reported in up to 30% of patients with insulin receptor antibodies (210 ,211 ,212 ,213 ,214). Seven percent of patients in the Johns Hopkins SLE cohort have been reported as diabetic (215). Steroid-induced hyperglycemia is common in the SLE population and some evidence suggests an association of this complication with anti-insulin antibodies (216).

Cushing syndrome and adrenal insufficiency are of significant concern in the lupus population, given the frequent induction and/or tapering of steroids in these patients. Adrenal insufficiency has also been described in the context of cortical infarction (217 ,218 ,219 ,220 ,221 ,222), amyloid or adrenal hemorrhage (210 ,223 ,224 ,225 ,226). Not surprisingly, in two case reports, SLE disease activity improved with the onset of Cushing disease (227) and was observed to flare after a pituitary adenectomy in a patient with Cushing syndrome (228).

Hyperprolactinemia has been described in up to 20% of patients with SLE (229 ,230 ,231), associated with increased prolactin/cortisol rations, corticosteroid use, antiprolactin antibodies and/or CNS lupus manifestations. Some of those reports suggest that there may be some improvement with bromocriptine therapy. Correlations between prolactin and SLE disease activity have been found in some but not all studies (232 ,233 ,234 ,235). Interpretation of this literature is hampered by differences in assays and in the assessment of disease activity.

Chapter 65

Clinical and Management Aspects of the Antiphospholipid Antibody Syndrome

Michelle Petri

Antiphospholipid (aPL) antibody syndrome now is recognized to be a misnomer. The field is more accurately described as antibody-mediated thrombosis, because multiple antibodies directed against plasma proteins, with or without attached phospholipid, can lead to hypercoagulability. These antibodies likely act by way of multiple mechanisms. This chapter will review: (a) the aPL and anti-plasma protein antibodies of clinical importance; (b) laboratory assays that the clinician must interpret; (c) epidemiology; (d) clinical presentations; and (e) treatment.

Characteristics of Antiphospholipid Antibodies

The original triumvirate of aPL antibodies included the false-positive test for syphilis, the lupus anticoagulant (LA), and anticardiolipin (aCL) antibody. The false-positive test for syphilis has not been associated with thrombosis in all studies, but will be described here, for completeness. The list of "new" aPL and anti-plasma-protein antibodies continues to lengthen. Several of these, including anti-$ß_2$-glycoprotein I ($ß_2$GPI), and antiprothrombin, may have clinical utility, and will be discussed.

False-Positive Test for Syphilis

The biologic false-positive test for syphilis was the first aPL to be recognized (1). Patients with a false-positive test were found to be at risk (5% to 19%) for the development of lupus or another connective tissue disease (1 ,2), but they did not seem to be at increased risk for thrombosis or pregnancy loss. The Venereal Disease Research Laboratory (VDRL) titer correlates with aCL levels only in sera from syphilis, not in sera from autoimmune patients (3). Mixing cardiolipin with phosphatidylcholine and cholesterol, as is done in the VDRL antigen, improves the binding of syphilitic aPL antibodies, but it decreases the binding by autoimmune aPL antibodies (3 ,4). It now is understood that aCL antibodies in patients with syphilis are not dependent on $ß_2$GPI (5). Patients may have the LA or aCL antibody and not have the false-positive test for syphilis, and vice versa. However, we have found a correlation of the false-positive test for syphilis with multiple other aPL antibodies, including anti-$ß_2$GPI. Additionally, in the Hopkins Lupus Cohort, a false-positive test for syphilis is predictive of later thrombosis.

Lupus Anticoagulant

A circulating anticoagulant in three patients (two of whom had probable autoimmune disease) was reported in 1948 by Conley et al. (6), who recognized that it blocked the conversion of prothrombin to thrombin. Although patients with LA who had a hemorrhagic diathesis tended to have a second coagulation defect (7), the term "lupus anticoagulant" became accepted. The second irony of this term is that as many as one half of patients with LA do not have lupus (8 ,9).

LAs, which are IgG or IgM immunoglobulins, potentially could inhibit any of four procoagulant-phospholipid complexes or two anticoagulant phospholipid-dependent reactions; however, the in vitro effect appears to be inhibition of the prothrombinase reaction (10). LA assays do not actually measure a titer of antibody, but are functional tests. However, it is likely that a large amount of antiphospholipid antibody is necessary to measure as a LA. It has been recognized for some time that LAs were heterogeneous; no one assay is able to detect 100% of LAs. Two groups, one in which LA activity could be separated from aCL activity and one in which the LA and aCL activities were inseparable, have been found (11). In the first group, LA activity was dependent on human prothrombin (12). In the second group, LA was dependent on the plasma protein $ß_2$GPI (as is aCL antibody) (11).

The in vitro detection methods for LA may not be relevant to its in vivo action. LAs prolong clotting times in vitro, because they agglutinate phospholipids in the plasma, thereby preventing their participation as cofactors in coagulation steps. If a more physiologic surface, such as

endothelial cells, is used for assembly of the prothrombinase complex, agglutination of phospholipids does not occur. For example, Oosting et al. (13) found that only 4 of 22 IgG fractions (18%) with LA activity were able to inhibit prothrombinase activity on endothelial cells.

In addition to the identification of coagulation proteins that combine with negatively charged phospholipids to form the epitopes that are targets for aPL antibodies, the nature of the phospholipid that is involved in LA activity also has been studied. Both the physical nature and the phase behavior of the phospholipid are important. LA antibodies have a greater affinity for hexagonal phase than bilayer phospholipid (14 ,15).

If LAs can be subgrouped by the plasma-protein–phospholipid targets, it follows that thrombotic mechanisms in patients with different subgroups of LA might be different. Among the potential mechanisms that have been suggested are procoagulant activity of endothelial cells (mediated by thrombin generation, fibrinopeptide A generation, and/or platelet aggregation) (16 ,17), perturbation of the thromboxane-prostacyclin balance (18), and perturbation of the protein C, protein S, and thrombomodulin pathways (13 ,19). Most recently, complement activation has been found as a cause of pregnancy lose (20) and thrombosis (21) in APS murine models.

Anticardiolipin Antibody

Realizing that cardiolipin was the major antigenic component of the false-positive test for syphilis, Harris et al. (22), in the Graham Hughes laboratory, developed a radioimmunoassay for aCL antibody. Over time, an enzyme-linked immunosorbent assay (ELISA) replaced the radioimmunoassay and underwent several revisions to optimize diluents and buffers, create multiple standards for calibration curves, and shorten incubation times (4 ,23 ,24).

Cardiolipin, which is found in mitochondria, originally was thought unlikely to be the antigen against which the antibodies detected in solid-phase assays are directed in vivo. However, cardiolipin recently has been found to be a normal plasma component, with more than 94% found as part of VLDL, low-density lipoprotein (LDL), and high-density lipoprotein (HDL) fractions (25). Because aPL antibodies cross-react with other negatively charged phospholipids (e.g., phosphatidylserine), cardiolipin can serve as a representative antigen in the solid-phase system (26 ,27). Phosphatidylserine also may serve as the antigen (28).

The rationale for the measurement of aCL isotypes (i.e., IgG, IgM, and IgA) was the finding in several studies that IgG aCL was the major predictor of thrombosis and pregnancy loss (29 ,30 ,31), although other groups have reported similar clinical associations with IgM aCL as well (32 ,33). However, polyclonal assays for aCL also have shown predictive value for thrombosis, both in cross-sectional studies (34) and in prospective ones (35). Recent work has demonstrated that IgM aCL is associated with not only hemolytic anemia (36 ,37 ,38) but also with thrombosis (33). Although the classification criteria for APS do not include IgA aCL, recent work suggests that some patients with APS manifestations may have IgA as their only isotype (39). Additionally, in one series, IgA aCL was associated with vasculitis (40). The highest aPL titers were of the IgA isotype in one study (41). Anti-β_2GPI of IgA isotype has been associated with venous thrombosis, thrombocytopenia, valvular disease, livedo reticularis, and seizures (42). In contrast, one study found true IgA aPL antibody in only two systemic lupus erythematosus (SLE) patients, both of whom also were positive for the IgG isotype (43). Some groups have reported the highest titer, regardless of isotype, as being the most predictive of APS complications (44 ,45).

Higher-titer IgG aCL antibody has shown a stronger association with thrombosis and pregnancy loss (29 ,30 ,46). Lower titers of aCL (often with concurrent LA, but not necessarily) also occur in patients with classic manifestations of aPL antibody syndrome (34 ,45 ,47). Thus, although aCL antibody assays are able to quantify the antibody titer (as opposed to LA assays), it is not clear that the titer of aCL antibody is the only predictor of pathogenicity.

Anti-β_2GPI

In 1990, three groups simultaneously reported that a plasma protein, β_2GPI (also called apolipoprotein H), acted as a cofactor in the aCL antibody assays, improving the binding of aCL (47 ,48 ,49). This finding explained why investigators had previously noted that use of adult bovine serum (50) and fetal calf serum (51), both of which contain β_2GPI, improved the performance of the assay. β_2GPI has multiple roles in vivo, including the inhibition of ADP-induced platelet aggregation, activation of the intrinsic coagulation pathway, and activation of platelet prothrombinase activity (52 ,53 ,54). Although there was much initial discussion (55), it now is accepted that the true antigen against which most aCL antibodies are directed is a complex of negatively charged phospholipids with β_2GPI (56). Recently, some (57) but not all (58 ,59) groups have identified antibodies that they believe are directed against β_2GPI alone (60 ,61 ,62). An epitope in the fifth domain of β_2GPI is exposed when assays use polystyrene plates that previously were oxygenated by γ irradiation (63 ,64 ,65). Although levels of β_2GPI are determined by genetic factors, ethnicity, gender, and age (66 ,67), levels do not seem to influence the antibody response or risk of thrombosis (68).

The binding of autoimmune aCL antibodies is enhanced by the presence of β_2GPI, as opposed to aCL antibodies that are made in response to infections (49). Thus, it now is possible to differentiate aCL caused by infections (with little association with thrombosis (69)) from those caused by autoimmunity, which are associated with the aPL antibody syndrome (APS).

Even though β_2GPI is the target of aCL antibodies, aCL and anti-β_2GPI antibody results may be discrepant in

individual patients (70). Patients can be positive for anti-ß$_2$GPI, but negative for aCL, if they have antibodies that recognize human epitopes, or ß$_2$GPI epitopes that are hidden when cardiolipin is bound. Conversely, patients can be positive for aCL, but negative for anti-ß$_2$GPI, if their antibodies recognize cardiolipin alone, epitopes in cardiolipin bound to ß$_2$GPI, or bovine epitopes (71). In one study, 11% of SLE patients made antibodies to ß$_2$GPI alone (72).

Multiple studies have suggested that anti-ß$_2$GPI may be a more specific marker than aCL for thrombotic events (57 ,60 ,73 ,74 ,75 ,76 ,77). Because it is unusual for a patient with APS to be negative for both aCL and LA, anti-ß$_2$GPI is not yet part of the routine work-up for patients with hypercoagulability.

It is not as clear if anti-ß$_2$GPI is a more specific marker than aCL for pregnancy morbidity. An association with pregnancy-induced hypertension, preeclampsia (78 ,79), and pregnancy loss (80) has been reported. However, several studies have found no association with pregnancy loss (81 ,82 ,83 ,84).

Lupus Anticoagulant and Anticardiolipin Antibodies: Separate, but Related

With the development of assays for aCL antibodies, investigators initially wondered if these solid-phase immunoassays would detect the same antibodies as LA assays (85). Most studies found aCL antibody more frequently than LA in patients with lupus (34 ,86), even when sensitive assays for LA were used. The two antibodies are discordant in as many as 35% of patients (69 ,87). In our study, SLE patients followed prospectively over 5 years continue to show discordance for the two antibodies (Fig. 65-1). Proof that the two antibodies can be different ensued from separate isolation from patient plasmas using multiple techniques (12 ,88 ,89 ,90).

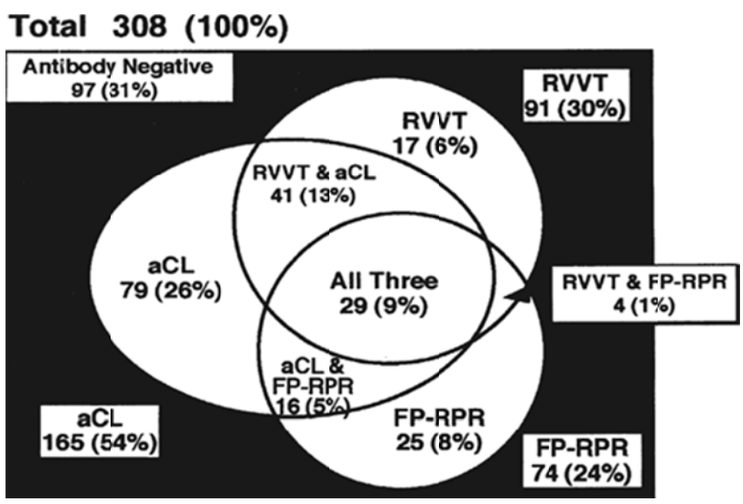

Figure 65-1. Venn diagram showing the percentage of patients in the Johns Hopkins Lupus Cohort who have had a positive acle antibody, LA (as determined by the modified RVVT assay, or a false-positive test for syphilis during proscpective followup). FP-RPR-false-positive rapid regain test.

Studies of monoclonal antibodies suggested that LAs preferentially bound hexagonal-phase phospholipids (15). The chain length and degree of saturation of the fatty-acid chains also are critical determinants. Levy et al. (91) found that aPL antibodies bound better to C18:1 phosphatidylglycerol than to C18:0 or C18:2, and that binding was greater to C18 than to C14:0 or C16:0 phosphatidylglycerol.

The demonstration that ß$_2$GPI (apolipoprotein H) is a requirement for autoimmune aCL antibody-binding in solid-phase assays (47 ,48) was the next step in understanding the different specificities of aCL and LA antibodies. Although many LA antibodies also were dependent on ß$_2$GPI (17 ,92), some were directed against other plasma cofactors, including prothrombin (12).

Antiprothrombin

Antiprothrombin antibodies represent a subset of LAs. They have been found in 33% of SLE patients in one study (93). Several retrospective studies have shown an association with thrombosis (94 ,95 ,96). The prospective ATBC study of deep-venous thrombosis (97) and myocardial infarction (98) has shown an association, as well. However, multiple other studies, including our own, have failed to find an association with thrombotic events (99). Antiprothrombin antibodies most closely associate with the profile of LA detected by the kaolin clotting time (KCT), which is less associated with thrombosis than LA detected by the dilute Russell viper venom time (RVVT) (100). In fact, antiprothrombin antibodies may cause hypoprothrominaemia and, therefore, bleeding (101).

Antiannexin

Annexin V is an anticoagulant in placental villi. Antiannexin V antibodies, by reducing annexin V at the maternal-fetal interface, may contribute to pregnancy losses in APS (102). Antiannexin V can have LA properties (103). The prevalence of antiannexin V in SLE patients ranges from 3.8% (104) to 19% (105). It has been found in association with both thrombosis and pregnancy loss (106). However, one study found no association with clinical manifestations of APS (107).

Antiphosphatidyl Serine

Antiphosphatidyl serine has been found in 32% of SLE patients in one series (108).

Antithromboplastin

Antithromboplastin has been found in 35% of SLE patients. It is associated with thrombosis, pregnancy loss, and thrombocytopenia (109).

Antioxidized Low-Density Lipoprotein

Oxidized LDL is one of the pivotal steps in the pathogenesis of atherosclerosis. Multiple studies have found an association of anti-oxidized LDL with atherosclerosis (110 ,111 ,112 ,113 ,114 ,115 ,116 ,117). In contrast, multiple groups have failed to find an association with atherosclerosis (118 ,119 ,120). In SLE, antioxidized LDL is associated with arterial, but not venous thrombosis (121 ,122). In prospective studies, antioxidized LDL has predicted myocardial infarction over 5 years in middle-aged men (112), myocardial infarction in men aged 50 years or older (123) and in middle-aged dyslipidemic men (110).

Laboratory Detection of Lupus Anticoagulant

Laboratory Definition

Laboratory criteria for LA almost certainly will continue to evolve as more knowledge about negatively charged phospholipid and plasma-protein neoantigens is obtained. The Scientific and Standardization Committee Subcommittee for the Standardization of LAs published criteria for the laboratory detection of LAs in 1995 (124). These criteria included the following:

- Prolongation of phospholipid-dependent clotting tests (e.g., KCT, dilute RVVT, tissue-thromboplastin inhibition test, plasma-recalcification clotting time, or sensitive partial thromboplastin time [PTT]).
- The clotting time of a mixture of test and normal plasma should be significantly longer than that of the normal mixed with various plasmas from patients without LA.
- There should be a relative correction of the defect by the addition of lysed, washed platelets or, preferably, phospholipid liposomes containing phosphatidylserine or hexagonal-phase phospholipids.
- It should be nonspecific for any individual clotting factor, rapidly lose apparent activity on dilution of test plasmas with saline (i.e., nonparallel lines in factor assays), usually fast acting, associated with positive aPL antibody ELISAs, and identified as an immunoglobulin whenever possible.

Some very practical summary recommendations also were made. The first was to use high-speed centrifugation (10 minutes at 5,000 g) and/or filtration to remove platelets. Platelet-poor plasma is essential to maximize the sensitivity of most assays, especially if frozen plasma is used (77). The second recommendation was to use a sensitive test to screen for LAs. The activated PTT (aPTT), for example, which is the most common screening test, often uses a thromboplastin reagent that is insensitive to LA. The third recommendation was to select an LA test that struck the right balance between sensitivity and specificity (125 ,126).

Triplett (127 ,128) has extracted what he considers to be minimal criteria for the laboratory diagnosis of LA: (a) an abnormality of an in vitro phospholipid-dependent coagulation test(s), (b) demonstration of an inhibitor (i.e., anticoagulant) as the cause of the abnormal screening test (i.e., mixing step), and (c) proof that the inhibitor is directed at phospholipid coagulation factors and not at specific coagulation factors. The use of two sensitive screening tests, such as a sensitive PTT and RVVT, may be preferable, because no one test is capable of detecting all LAs (129). The importance of using a battery of screening tests was demonstrated by McHugh et al. (130). Of 13 patients with LA, only four were abnormal on all three of the clotting assays that were employed (i.e., KCT, RVVT, and tissue-thromboplastin inhibition test). In addition, if a 1:1 patient to normal control plasma mixing study is not diagnostic, an additional mixing study with 4:1 patient to normal control plasma should be performed (128). Confirmatory tests that prove the inhibitor is directed at phospholipid include those that decrease the amount of phospholipid in the test system to accentuate the inhibitor effect (i.e., the RVVT), increase the amount of phospholipid to neutralize the LA (i.e., the platelet neutralization procedure [PNP]), or use specific hexagonal-phase phospholipids to neutralize LA (131).

Individual Assays

aPTT

The sensitivity of detection of LA using the aPTT is highly dependent on the choice of reagents (126 ,132 ,133), activator, and phospholipid to be used as a platelet substitute (134). Both the phosphatidylserine concentration (135) and the physical state of the phospholipid (i.e., hexagonal or not) (131) can affect the sensitivity of the test. Most hospital laboratories have used aPTT reagents that were insensitive to LA, but sensitive aPTT reagents now are available commercially (136). Comparative studies have demonstrated that Actin FSL (American Dade), Automated APTT (Organon Teknika Corp), and Thrombosil (Ortho Diagnostics) all are sensitive to LAs (129 ,134 ,137 ,138 ,139). A sensitive aPTT using a sensitive reagent is an excellent screening test (127). However, a sensitive aPTT may not be an appropriate screening test during pregnancy, because it is affected by rising factor VIII.

Modified (Dilute) Russell Viper Venom Time

The modified RVVT can be used as an initial, sensitive screening test for LA or as a confirmatory test (140). Its sensitivity has equaled or surpassed those of the KCT and tissue-thromboplastin inhibition tests in two studies (140 ,141), but it was not as sensitive as a sensitive aPTT in another (127). In comparison to other tests for LA, the RVVT is relatively resistant to deficiencies of clotting factors and to clotting factor antibodies. It is unaffected by antibodies to factors VIII, IX, and XI, and it remains normal in plasma that is deficient in factors VII, IX, and XI. However, factor V or X levels below 0.4 U/mL do prolong the RVVT (140). The source of phospholipid can affect the RVVT (142), as can the source of venom. These factors can lead to variability in the method of

performance and, therefore, the results of the RVVT (143). The RVVT method can be automated (144).

Kaolin Clotting Time

The KCT is an aPTT without added platelet substitute, with the kaolin acting as an activator and phospholipid surface (145). The KCT is affected by residual platelets and therefore requires a filtration step to remove platelets from the patient plasma (146). Originally, Exner et al. (147) performed multiple determinations of the KCT using different ratios of patient to normal plasma. A simplified KCT using just patient plasma has been developed, without important reduction in sensitivity or specificity (148). In some comparative studies, the KCT has not been as sensitive as a sensitive aPTT (127).

Platelet Neutralization Procedure

One approach to proving that an inhibitor is phospholipid dependent is to neutralize the inhibitor by increasing the amount of phospholipid in the assay (as in the platelet neutralization procedure [PNP]) or to accentuate the prolonged coagulation time by reducing the phospholipid (as in the tissue-thromboplastin inhibition time). The tissue-thromboplastin inhibition time is not widely used, however, because in most studies, it is both less sensitive and less specific than the PNP (133 ,137 ,141 ,149). The PNP can be combined with screening tests for LA by using freeze-thawed platelets with the sensitive aPTT or RVVT test to correct or shorten the abnormal clotting time (150).

The Anticoagulated Patient

No LA screening test is valid in the presence of heparin. In a patient who presents with a thrombotic event, plasma should be sent for LA testing before administration of heparin is begun. A more difficult problem is evaluation of the patient on warfarin. If the patient has moderate or high-titer aCL antibody, diagnosis of the APS is secure, and the LA test is not necessary for diagnosis. In some patients, however, solid-phase assays for aPL antibodies may be negative, and it may not be possible to stop anticoagulation to allow the LA testing to proceed. In this setting, mixing studies with normal plasma before LA testing (to correct deficiencies in vitamin K-dependent factors) or an LA test that already includes a mix with normal plasma (e.g., KCT or dilute aPTT) can be considered, although no consensus or criteria exist for the diagnosis of LA in this setting.

Standardization of Lupus Anticoagulant

Because of the heterogeneity of LA, it is unlikely that any one assay will be accepted as the preferred standard. Instead, a battery of the most sensitive tests (e.g., a sensitive aPTT and the RVVT) is the best approach to screening. The best assays will be those with predictive value (i.e., high relative risks) for future thrombosis or pregnancy loss.

Laboratory Detection of Anticardiolipin Antibody

The aCL antibody assay, which is the most widely used solid-phase aPL test, is a multistep procedure. In the first step, ELISA plates are coated with the negatively charged phospholipid, which usually is cardiolipin, although phosphatidylserine (28) and mixtures of phospholipid also are used (151). To prevent nonspecific antibody from binding to the plate, adult bovine serum, bovine serum albumin, or fetal calf serum are added and then washed from the plate. Diluted patient sera (the diluent should contain $ß_2$GPI, which is the cofactor for binding) then are incubated in the wells. After the incubation step, the wells are washed, and an enzyme-labeled antihuman antibody (e.g., anti-IgG, anti-IgM, anti-IgA, or polyclonal) is added. After washing, the enzyme substrate is added to develop the color reaction; the absorbance is then read.

The aCL antibody distribution is not Gaussian in most studies (34 ,152). Major differences have existed in the cutoff of negative from positive values in different laboratories. To facilitate calibration and comparative studies between laboratories, two international workshops have established and tested positive standards for the IgG and IgM isotypes, leading to the report of results in IgG isotype phospholipid (GPL) or IgM isotype phospholipid (MPL) units (23 ,24 ,153). However, use of calibrated standards may not solve the problem of standardization, because the slopes of each standard change with the buffer that is used and are different for each standard (154).

Epidemiology of Antiphospholipid Antibodies

Prevalence and Incidence of Antiphospholipid Antibodies in Normal Individuals

Published study designs primarily have been cross-sectional, with one ascertainment of aCL and/or LA status. Thus, the results represent the frequency or point prevalence of aPL, not a true prevalence (i.e., prevalence equals the incidence multiplied by the duration) or incidence. Despite the methodologic issues discussed earlier, published studies are, in large part, quite consistent regarding the frequency of aPL in normal individuals. Table 65-1 shows representative studies. The great majority of studies consisted of young women, whether pregnant or not. Most studies included aCL assays, but fewer included LA or anti-$ß_2$GPI.

Studies of prevalence (i.e., repeated measures of aCL or LA in normal individuals) are important. aPL antibody titers fluctuate in patients with lupus over time because of disease activity and treatment, meaning that an assay performed at

one point in time has less predictive value. If fluctuations occur within the normal population, this will influence the design of prospective studies on aPL antibodies in normal individuals.

Table 65-1: Frequency of Antiphospholipid Antibodies in Normal Controls

Source of Control Population	LA (%)	Anticardiolipin (%)	Anti-β_2 GPI (%)	References
Blood donors	0.0–3.6	0.0–9.4		(155,665,666,667,668)
Pregnant women	0.0–13.7	0.0–9.9	1.0–3.0	(32,35,78,148,156,157,158,159,160,161,162,163,164,165)
Healthy women		7.5		(45)
Osteoarthritis		14.0		(178)
Neurologic disorders		1.2		(296)

Frequency of Antiphospholipid Antibodies in the Elderly

Because both the frequency of antinuclear antibodies and antithyroid antibodies increases with age, it is not surprising that several studies have addressed the frequency of aPL antibodies in the elderly. As these studies employed different definitions of a positive aCL (i.e., any positive versus highly positive [>5 SD from the mean]), they are not directly comparable. However, it does appear that a positive aCL is more common in the elderly (Table 65-2). A recent study found aCL in the elderly with chronic diseases but not in the healthy elderly (155).

Frequency of Antiphospholipid Antibodies in Systemic Lupus Erythematosus

The frequency of LA (Table 65-3), aCL antibody (Table 65-4), and anti-β_2GPI (Table 65-5) in SLE has varied widely among studies. Some of this variation results from differing sensitivities of the assays, selection of patients, and bias introduced by retrospective study designs. Detection of aPL antibodies in any cross-sectional study also may be influenced by transient production of the antibody. For example, Hedfors et al. (156) reported a woman who only made aCL antibodies transiently during early pregnancy. My own group (34) and others (157 ,171) have reported patients whose aPL antibody titers or assays drop, or become negative, at the time of a thrombotic event.

Table 65-2: Anticardiolipin Frequency in the Elderly

Study	Patient (*n*)	Mean Age (y)	aPL Positive (%)
Chakravarty et al. 1990 (297)	100	75.6	0 (aCL >5 SD)
Fields et al. 1989 (669)	300	70.0	12 (aCL IgG and IgM)
Manoussakis et al. 1987 (665)	64	80.0	50 (aCL)
Juby et al. 1998 (155)			
Healthy	63		0
Chronic disease	301		13.3

Generally, the LA assays appear to be more easily suppressed by treatment for active lupus (158), but treatment also may suppress aCL levels (44 ,159). Active lupus may increase the titer of either aCL antibody or LA (159 ,160 ,161 ,162 ,163) Thus, it is not surprising that studies with multiple determinations of aPL antibodies will find a higher prevalence of antibody positivity (44 ,164) or that many patients fluctuate from their entry category of negative, low positive, or high positive (163).

Occurrence of Antiphospholipid Antibodies in Diseases Other Than Systemic Lupus

Erythematosus

APL antibodies commonly occur in infections, especially human immunodeficiency virus (HIV) (165 ,166 ,167), but in many other bacterial, protozoan, and viral illnesses as well. Most microbial aPL antibodies are IgM isotype and nonpathogenic. Most of the infection-related aPL antibodies are not dependent on β_2GPI (168) or associated with APS. In one study, however, aCL was associated with cerebral perfusion defects in HIV-positive patients (166). One patient with AIDS and aCL developed a splenic infarction (169). Another patient with AIDS and a stroke had aCL (167). In a large study of 74 HIV-infected men, however, the presence

of aCL (in 86%) or protein S deficiency (in 33%) was not associated with the development of thrombosis (165).

APL antibodies also occur in other autoimmune diseases, including connective tissue diseases such as rheumatoid arthritis (170 ,171), Sjögren syndrome (172), eosinophilic fasciitis (173), scleroderma (174 ,175 ,176), and related conditions such as hemolytic anemia (177) and idiopathic thrombocytopenic purpura (178 ,179 ,180 ,181). They also have been reported in small-vessel (182), medium-vessel (i.e., microscopic polyarteritis (183 ,184 ,185)), and large-vessel (i.e., giant-cell arteritis (186 ,187 ,188) and Takayasu arteritis (189 ,190 ,191)) vasculitides. APL antibodies have been found in 38% of patients with sarcoidosis (192). Several reports of aPL antibodies in Behcet disease also exist (193 ,194 ,195), but there has been no consistent association with thrombotic disorders.

APL antibodies can occur with multiple malignant conditions (196 ,197). Whether they might be responsible for Trousseau syndrome in these patients has not been adequately studied.

APL antibodies result from many of the drugs that are known to cause drug-induced lupus, including the major tranquilizers (198), procainamide, thiazides (177), and anti-TNF biologics. They have not been associated with thromboses in chlorpromazine-treated patients (199). However, aCL (both IgG and IgM) also can be found in drug-free, multiply affected families with schizophrenia (200).

*Studies are ordered by frequency of anticardiolipin positivity.

APL antibodies have been found in 68% of a series of 25 patients with sickle cell anemia, suggesting that structural alterations in the red-cell membrane may be associated with autoantibody production (201).

Children who are on hemodialysis had a high frequency of aCL in one study. Those children with aCL had more fistula thromboses (202). In a study of 39 adult hemodialysis patients, however, the LA and aCL were β_2GPI independent, suggesting that they would not be procoagulant (203). A large study of 84 patients with end-stage renal disease found no association between thrombosis and aCL or LA (204). No thromboses occurred in the nine patients with IgG aCL or IgM aCL in a study of 42 patients who were dialyzed using cuprophane membranes (205).

Effects of Gender and Ethnicity

APS has been reported in several patients with Klinefelter syndrome (206 ,207 ,208 ,209). The effect of ethnicity has only been adequately studied in African-American and Caucasian populations; the frequency of LA and high-titer aCL is significantly less common in African Americans than in Caucasians.

Genetic Factors

Familial

In descriptions of Sneddon syndrome, which is a syndrome that overlaps significantly with APS, studies have remarked on the frequent occurrence of more than one affected family member (210 ,211 ,212). Familial cases of LA and/or aCL antibody also have been reported (210 ,213 ,214 ,215 ,216). The increased frequency of lupus or other autoimmune disease (including idiopathic thrombocytopenic purpura and autoimmune thyroid disease) in the relatives of patients with SLE is well recognized. In one study of 37 pediatric patients with SLE and 107 first-degree relatives, the occurrence of aPL in relatives was not always related to aPL positivity in the probands, and none of the aPL-positive relatives had thrombosis (217). Whether family members of patients with APS are more likely to have APS and/or autoimmune disease, and whether this results from an autosomal-dominant autoimmune gene that is incompletely penetrant, or a second APS gene, currently is under study in multiple centers. Murine models suggest that APS is multigenic (218). The valine/leucine 247 polymorphism of β_2GPI is a genetic risk factor for anti-β_2GPI (219).

HLA

Multiple HLA-DR or DQ associations with aPL antibodies have been described. In a study of 13 patients with the primary form of APS, HLA-DR4 (p <0.01) and Drw53 (p <0.05) were increased, but no correction was made for multiple comparisons (220). In a study of 20 patients with SLE and LA, an association with HLA-DQw7 (DQB1*0301), linked to HLA-DR5 and DR4 haplotypes, was found (and was increased versus that in normal controls; p = 0.002) (221). In previous studies of HLA and aCL, Savi et al. (222) found an increase of HLA-DR7 in Italian patients, and McHugh and Maddison (223) found an increase in HLA-DR4 in British patients with SLE (223). Our group's results failed to find any association of DQB1*0301 with either aCL or LA in SLE (224), and no HLA association with aCL positivity was found in a study of 139 patients with SLE (225). In a recent study, the association of aCL with DRB4 and DRB1 was investigated, with the conclusion that at the DRB1*04 locus, the *0402 allele is most common (226).

Complement Genes

One group has suggested that patients with either partial C4A or C4B null allotypes are more likely to have aCL antibody (227 ,228 ,229). In contrast, patients in the Hopkins Lupus Cohort study who were homozygous for C4A deficiency had a lower frequency of aCL and LA than patients with SLE who did not have this deficiency (230). Additionally, the subgroup of patients with C4A deficiency who had a C4A deletion were less likely to have a positive polyclonal aCL antibody (p = 0.02) than those without the deletion.

Prospective Studies

Most studies of aPL antibodies have been cross-sectional, with retrospective review of patients' case histories. One requirement to determine a pathogenic role for aPL antibodies is to document their presence before the clinical event, whether it is fetal loss (231) or thrombosis (35). In the case of fetal loss, there is further documentation of pathogenic significance, in that multiple murine models of fetal loss associated with aPL antibodies exist (232 ,233 ,234 ,235).

Multiple prospective studies in the general population have shown the predictive value of aPL antibodies for a first episode of deep-venous thrombosis (236), stroke (237 ,238), or myocardial infarction (112 ,123 ,238) as well as recurrent venous thrombosis (239) or stroke (240). Finazzi et al. found that 34 of 360 patients with aPL had a thromboembolic event over 4 years (241).

APL are present for a mean of 3 years before SLE onset and 3.1 years before a thrombotic event (242). Only 8% of primary APS patients later develop SLE, with an additional 5% developing lupus-like disease (243).

Our prospective study, the Hopkins Lupus Cohort, has shown that both aCL and LA are predictive of later thrombosis (244). The risk of venous thrombosis is 50% after 20 years (245). Most thrombotic events after cohort entry were arterial, with stroke leading the list. An occasional SLE patient makes aPL antibodies for the first time after a thrombotic event. A second large study in SLE has shown that both LA and IgG aCL are associated with thrombosis (246). Several prospective studies in cancer suggest the importance of aPL antibodies in later thrombosis. In children with acute lymphoblastic leukemia treated with L-asparaginase, four of eight with aPL antibodies had thrombosis (247). In a series of lymphoma patients, the risk of thrombosis was 5.1%/year with aPL antibodies versus 0.75%/year without aPL antibodies (248).

Prognosis and Natural History

Several studies have suggested that recurrent thrombotic events will be in the same distribution as the initial event (249). In our experience, however, the distribution may cross over, from venous to arterial and arterial to venous. Many patients seem to peacefully coexist with their aPL antibodies until a “second hit” occurs. However, several studies have failed to show that genetic hypercoagulability—specifically Factor V Leiden—is an additional risk factor in patients with aPL antibodies who thrombosed (250 ,251).

Risk factors for thrombosis include the LA, high-titer aCL, and IgG isotype of aCL. However, there are no firm rules. IgM aCL, for example, also has been associated with venous thrombosis (252). Primary APS patients, on average, have higher avidity anti-$ß_2$GPI antibodies than SLE patients (253). A risk factor for recurrence of thrombosis includes persistence of aPL antibodies for 6 months after the thrombotic event.

Seven studies, four of APS with both arterial and venous events (254 ,255 ,256 ,257) and three of APS with venous events (239 ,258 ,259), have addressed the natural history of recurrent thrombotic events in patients who already are diagnosed with APS. In the four studies that included patients with both arterial and venous thrombotic events, the risk of recurrence was high if the patient did not remain on adequate anticoagulation (254 ,255 ,256 ,257). There was a 50% risk of recurrent deep-venous thrombosis within 2 years in one study (258).

The natural history and prognosis of patients with APS who present with stroke have been studied extensively. In a retrospective review, Levine et al. (260 ,261 ,262) found a high frequency of recurrent events. In the Antiphospholipid Antibody and Stroke Study, the odds ratios for recurrent stroke or for all events (i.e., recurrent stroke, myocardial infarction, or death) were significantly higher in stroke patients with aCL than in those without aCL (240 ,263).

In a study of 139 patients with SLE, IgM aCL (present either in the past or as a persistent finding) was the only aCL isotype to be negatively associated with survival (225). A history of thromboembolic events had a strong negative association with survival, but thromboembolic events were not among the common causes of death. Further, the negative association of IgM aCL with survival was not related to the clinical criteria of APS. A second survival study of 667 patients with SLE found that APS led to decreased survival because of some (i.e., thrombocytopenia, arterial

occlusions, and hemolytic anemias), but not all, APS manifestations (264). In a third study, LA was a predictor of mortality (because of vascular occlusions) in SLE (265). Further longitudinal cohort studies may clarify the predictive value of aPL antibodies for morbidity and mortality in SLE.

Classification Criteria for Antiphospholipid Antibody Syndrome

Classification criteria for APS were proposed at the International Conference in Sapporo, Japan (266) (Table 65-6). The Sapporo criteria, in their simplest form, require either a thrombotic manifestation (venous, arterial, or vasculopathy) or pregnancy morbidity, in the setting of mild- to moderate-titer aCL or LA.

These new classification criteria differ from previous criteria in three major ways. First, vasculopathy now is included as a thrombotic manifestation. This is an important clarification, because some patients with the catastrophic presentation of APS do not have a defined thrombosis in one named vessel, but present instead with vasculopathy, usually widespread. Second, the pregnancy criterion has been revised extensively. One late fetal loss, for example, now is sufficient for the diagnosis of APS. Much more controversial is the inclusion of severe preeclampsia or placental insufficiency as part of the pregnancy morbidity criterion, because not all studies have confirmed an association of aPL antibodies with these outcomes (267). Third, thrombocytopenia is no longer a "stand alone" clinical criterion for APS.

Table 65-6: Criteria for Classification of the Antiphospholipid Antibody Syndrome*

Clinical	Laboratory
Vascular thrombosis One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by imaging or Doppler studies or histopathology, with the exception of superficial venous thrombosis. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.	Anticardiolipin antibody of IgG and/or IgM isotype in blood, present in medium or high titer, on two or more occasions, at least 6 weeks apart, measured by a standard enzyme linked immunosorbent assay for $ß_2$-glycoprotein I-dependent anticardiolipin antibodies.
Pregnancy morbidity a. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th weeks of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or b. One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe pre-eclampsia or eclampsia, or severe placental insufficiency or c. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic, or hormonal abnormalities and paternal and maternal chromosomal causes excluded.	Lupus anticoagulant present in plasma on two or more occasions at least 6 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostatsis

Patients with the syndrome should have at least one clinical plus one laboratory finding during their disease. The aPL test must be positive on at least two occasions more than 3 months apart.

From Wilson WA, Gharavi AE, Koike T, et al. International consensus statement on preliminary classification criteria for definite antiphospholipid syndrome: report of an international workshop. *Arthritis Rheum* 1999;42:1309–1311.

Even the Sapporo classification criteria fail to address some important clinical manifestations of APS. Currently, there is no way to classify nonthrombotic neurologic manifestations, such as chorea and transverse myelitis, or to classify cardiac valvular vegetations.

The Sapporo classification criteria have shown good sensitivity, specificity, and positive and negative predictive value in a validation study (268). However, only 61% of SLE patients with secondary APS were classified correctly.

At the Sydney APS conference, revisions were made to the Sapporo classification criteria. In the laboratory criteria, anti-$ß_2$GPI IgG and IgM isotypes were added. Repeat positive assays are now required over a 3-month period, instead of the previous 6-week rule. Clinical criteria occurring greater than 5 years before the positive assays can no longer be classified as APS. Older patients must have other causes of thrombosis ruled out. Clear definitions of placental insufficiency are now given (269).

SLE is the disease overwhelmingly associated with secondary APS. Patients who have “lupus-like disease” may not fit either primary or secondary classification well (270). The distinction between primary (i.e., without associated connective tissue disease) (271 ,272 ,273) versus secondary (i.e., with associated connective tissue disease, usually SLE) forms of APS is controversial. Some authors have argued, and quite convincingly, that no distinction need be made (55 ,274), because neither the clinical features nor the aPL antibody specificities differ in the primary and the secondary forms. In one series representing three European referral centers, equal numbers of patients with primary and secondary APS were seen. The clinical features were similar, but cardiac valvular disease, hemolytic anemia, hypocomplementemia, and neutropenia were more common in those with secondary APS (275).

Some overlap of primary and secondary APS is inevitable, and this may result from a shared genetic predisposition (276 ,277). A few patients with primary APS may evolve into secondary APS over time (278 ,279 ,280). In a recent study, 8% developed SLE and 5% lupus-like disease (243). Progression to secondary APS may be more frequent in young women (281).

Differential Diagnosis of Hypercoagulability

Major causes of genetic hypercoagulability include Factor V Leiden, the prothrombin mutation, protein C, protein S, and antithrombin III deficiency. Elevated levels of homocysteine can predispose to arterial thrombosis and to atherosclerosis.

Major acquired causes of hypercoagulability include pregnancy and the postpartum period, oral contraceptives and estrogen replacement therapy, nephrotic syndrome, diabetes mellitus, hyperlipidemia, obesity, postoperative state, vasculitis, and malignancy (282).

A different approach to hypercoagulability is to consider acute versus chronic presentations (APS can present in both ways) of thrombotic angiopathies (283). Acute presentations include hemolytic uremic syndrome/thrombotic thrombocytopenia purpura, allograft rejection, drugs (cyclosporin, FK506, and OKT3), chemotherapeutic agents (mitomycin, cis-platin, and bleomycin), hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome (which can be associated with APS), malignant nephrosclerosis, systemic sclerosis, radiation nephritis, and HIV. Chronic presentations include healing hemolytic uremic syndrome, radiation nephropathy, transplantation nephropathy, dysfibrinogenemias, and polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS) syndrome.

Prevalence of Antiphospholipid Antibody Syndrome

Retrospective or cross-sectional studies allow only an estimate of the prevalence of APS in patients who have aPL antibodies. Patients with a clinical manifestation of APS, but who are negative for aPL at the time of the study may have had aPL at the time of the event. In an editorial, Hughes (284) quoted an APS frequency of 35% in SLE. McNeil et al. (285) concluded that the frequency of thrombosis was 42% in aPL-positive patients with SLE and 31% in all patients with aPL. The review of Love and Santora listed 30% (286). These figures, however, may reflect selection bias, will be affected by length of follow-up, and are not adjusted for age, gender, or ethnicity background.

Frequency of Antiphospholipid Antibody Syndrome in Venous Thrombosis (Non-SLE)

In a study of 100 patients with verified venous thrombosis, 24 had aCL antibody, and four had LA (287). In a second study, 15% had aPL antibodies (288). In a third study, 30% had aPL (289). A lesser prevalence of 6% also has been reported (290). In the large Spanish multicenter study on thrombophilia (EMET) consisting of 2,132 patients with venous thrombosis, only 4% had aPL antibodies (291). Given new knowledge of the importance of factor V Leiden mutation as a cause of resistance to activated protein C, new and comprehensive studies of the frequency of various genetic or acquired predispositions to deep venous thrombosis in the general population are needed. No association of aPL antibodies has been found in upper extremity deep venous thrombosis (292).

In patients with pulmonary emboli, 10% have had aPL antibodies (293). APL antibodies are most frequently found in chronic thromboembolism (64%) (294).

Frequency of Antiphospholipid Antibody Syndrome in Arterial Thrombosis (Non-SLE)

Stroke

The most common arterial thrombotic presentation of APS is stroke. The frequency of aPL in unselected patients with thrombotic stroke has ranged from 5% to 29% (295 ,296 ,297 ,298 ,299 ,300 ,301 ,302). Some studies (298 ,301 ,340 ,343), but not all (295 ,299), have found the frequency of aPL in stroke patients to be significantly higher than that in controls.

The frequency of aPL in younger stroke patients (<50 years of age) appears to be higher (303 ,304 ,305 ,306 ,307 ,308 ,309). In studies that included aCL antibody assays, the frequency of aPL has ranged from 18% to 46%. Two studies, which used only LA assays (304 ,305), reported much lower frequencies, (2% to 4%). It is possible that aCL antibody is more prevalent than LA in stroke patients, but the use of insensitive LA assays also may explain the low reported frequencies. The Stroke Prevention in Young Women study, a population based case-control study, found that either anticardiolipin or lupus anticoagulant positivity increased the odds of stroke to 1.87 (237).

Coronary Artery Disease

Myocardial infarction in aPL antibody-positive patients without atherosclerosis represents a “pure” thrombotic event (310 ,311 ,312). The role of aPL antibodies in coronary

artery disease (or atherosclerotic disease in general), however, remains highly controversial. Carotid intima media thickness was increased in connective tissue disease patients with aPL antibodies (versus controls) (313).

Certainly, there is a scientific basis for interest in this potential association (314 ,315). The importance of oxidized LDL in the induction of atherosclerosis and cross-reaction between aPL and oxidized LDL antibodies suggest a potential mechanism for the progression of atherosclerosis (316 ,317). Patients with aPL antibodies have decreased paraoxonase activity, leading to increased LDL oxidation (318). Using neural network models, anti-oxLDL, aCL, and anti-β_2GPI (in decreasing order) were associated with atherosclerosis (319).

In contrast, some studies have shown that aPL antibodies might be protective against atherosclerosis. In LDL receptor–deficient mice, the passive administration of aPL antibodies reduces atherosclerosis (320). In patients with SLE, those with aPL antibodies have lower amounts of plaque and coronary calcium (321).

Several studies have found an association of aCL with myocardial infarction (321 ,322 ,323 ,324), either with graft occlusion (323 ,325) or in coronary artery disease (326 ,327). In contrast, many large studies have failed to find either an association with coronary atherosclerotic disease or with a higher rate of subsequent adverse events (328 ,329 ,330 ,331 ,332 ,333 ,334). In a nested, case-control study of middle-aged dyslipidemic men participating in the Helsinki Heart Study (112), aCL was significantly higher in those who had suffered a myocardial infarction or cardiac death. In the highest quartile of aCL, the relative risk for myocardial infarction was 2.0 (95% confidence interval, 1.1 to 3.5), independent of confounding factors. An association of aCL with antibodies to oxidized LDL was also found in this study. Anticardiolipin was predictive of myocardial infarction in the Honolulu Heart Program (238).

Association of Lupus Anticoagulant versus Anticardiolipin Antibody with Risk of Antiphospholipid Antibody Syndrome

In eight studies that used different, but equally valid, LA assays, the LA test was a more specific associate of thrombosis in patients with lupus than was aCL (34 ,96 ,335 ,336 ,337 ,338 ,339 ,340 ,341). In patients with lupus and aCL, the simultaneous demonstration of LA also increases the specificity for APS manifestations (130). In a study that used the PTT (which my group has shown will fail to detect 50% of LAs), however, aCL was found to be a better predictor of fetal distress (231). Very few studies of fetal loss have taken into account that rising factor VIII levels during pregnancy will affect many of the commonly used assays for LA, including the aPTT. In this setting, the RVVT remains a valid assay (342).

A second, although related, question is if patients with both antibodies are at greater risk for APS. In two studies, patients with both antibodies had an increased risk of thrombosis over those with LA alone (337 ,343). Patients with both have been found to have more arterial thrombosis (344) and recurrent pregnancy losses (345). In contrast, Triplett et al. (69) did not find an increased risk of thrombosis with both autoantibodies.

In general, the greatest risk is associated with LA (versus aCL), higher titer aCL, IgG isotype of aCL, and persistence of either antibody for 6 months or longer (346 ,347).

Multifactorial Nature of Risk Factors for Thrombosis in Systemic Lupus Erythematosus

The fluctuating titers of aPL antibodies in patients with SLE, associated with disease activity or treatment, suggests that the thrombotic risk engendered by these antibodies might not be constant over time. Additionally, it is important to recognize that patients with lupus can have multiple other risk factors for thrombosis. Hasselaar et al. (16) found reduced concentrations of antithrombin III, plasminogen, free protein S, and protein C in some patients. Mayumi et al. (348) found raised concentrations of fibrinopeptide 20A, and thromboxane B2 in some patients with lupus and LA.

In our group's prospective study of patients with lupus, we have emphasized the role of factors other than aPL antibodies in predicting future thrombotic events. Serologic markers of disease activity (both a low serum C3 level and elevated antidouble-stranded DNA), hypertension, and hypercholesterolemia all are significantly associated with future thrombotic events (35 ,349).

Clinical Presentation

Dermatologic Manifestations

The important role of the dermatologist in recognizing APS has been emphasized by Alegre et al. (350). In their series, 41% of patients had a skin lesion as the first sign of disease. Multisystem thrombotic events developed in 40% of their patients with cutaneous manifestations of APS. Livedo reticularis, in particular, predicts multisystem thrombosis (351). Frances et al. found that livedo reticularis was significantly associated with cerebral or ocular ischemic arterial events, seizures, all arterial events, cardiac valve abnormalities, and systemic hypertension (352).

Livedo reticularis is the hallmark dermatologic manifestation of APS (271 ,351 ,352 ,353 ,354 ,355 ,356). Its association with thrombosis was recognized before APS was described, first by Champion and Rook (357) in a patient with angina, claudication, and cerebral thrombosis, and then by Sneddon (358), who described six patients with livedo reticularis and cerebral ischemia. The name Sneddon syndrome continues to be used to describe the clinical syndrome of livedo reticularis and transient ischemic attacks, strokes, or other cerebral ischemia (359). Livedo reticularis also occurs in infectious illnesses, including syphilis and tuberculosis; other immunologic diseases, including polyarteritis nodosa and cryoglobulinemia; and in cholesterol crystal embolization (360). In a mild form, it is a normal variant in young women (361). Patients with

lupus may have both cryoglobulins and aPL antibodies, thus further confusing the differential diagnosis (362).

The pathology of the livedo reticularis in Sneddon syndrome is an endarteritis obliterans without vasculitis (357 ,358 ,363). Some skin biopsy specimens have shown endothelial proliferation of deep dermal vessels, and some have been normal (364 ,365 ,366). Sneddon syndrome differs from APS in that the clinical presentation is one of livedo reticularis and predominantly cerebral arterial thromboses rather than recurrent pregnancy loss, venous thrombosis, and thrombocytopenia. In fact, there are patients with Sneddon syndrome who do not have aPL antibodies (360). However, many patients with Sneddon syndrome do have aPL antibodies, such as one patient (367) who had central retinal artery occlusion, cerebral ischemia, livedo reticularis, and aCL antibody.

The relationship between aPL antibodies and vasculitis remains controversial. Most skin biopsies of livedo reticularis or other cutaneous manifestations of APS show bland, noninflammatory pathology, but reports of vasculitis exist (368). In some cases, this may reflect the coexistence of two different disease processes in a patient with lupus; in other cases, there appears to be a causal link. In the study by Weinstein et al. (355), patients with livedo reticularis had histologically proven vasculitis at sites that were unrelated to the livedo reticularis. Livedoid vasculitis has been associated with central nervous system involvement in lupus (369). When vasculitis occurs in livedo reticularis, it can be associated with ulceration (370 ,371).

A second, but less common, cutaneous manifestation of APS is leg ulceration, often resembling pyoderma gangrenosum (271 ,350 ,372 ,373 ,374 ,375 ,376 ,377 ,378 ,379 ,380 ,381). There appears to be a spectrum of pathology, with vascular thrombosis, capillary proliferation, endarteritis obliterans, and lymphocytic infiltration all playing a role (382).

Distal cutaneous ischemia, presenting as erythematous and purplish macules on fingers or toes, is another cutaneous manifestation of APS (379). Severe cutaneous necrosis also is reported (350 ,383 ,384 ,385 ,386 ,387 ,388). Cutaneous necrosis may be multifactorial, as in one patient with both protein S deficiency and aPL antibodies (389). Cutaneous necrosis occurred in one patient treated with LMW heparin (390). Cutaneous necrosis can be the initial manifestation of APS (391).

Both superficial thrombophlebitis (350 ,356 ,392 ,393) and thrombosis of dermal vessels have been reported (350 ,379). In the series of Alegre et al. (350), 34% of patients with LA had thrombophlebitis, and in this retrospective series, it was the most common cutaneous manifestation.

Davies and Triplett (394) have described a patient with LA and aPL antibodies who developed the blue-toe syndrome when given corticosteroids for thrombocytopenia. Blue-toe syndrome is more classically associated with microembolism of fibrin-platelet debris or cholesterol crystals from proximal atherosclerotic lesions (395), or with warfarin, with destabilization of coagulation over ulcerated atherosclerotic plaques (395).

Subungual splinter hemorrhages also have been reported in patients with aPL antibodies by several groups (396 ,397 ,398 ,399). Nailfold capillary changes with hemorrhages and hemosiderin deposits can be seen (400).

Venous Thrombosis

Deep venous thrombosis remains the most classic site of thrombosis in patients with LA. In the review by Lechner and Pabinger-Fasching (139), deep venous thrombosis occurred in 64% of 25 patients with thrombosis and in 71.2% of 80 cases from the literature. This prevalence far exceeded that of arterial thrombosis: 25% of patients had cerebral thrombosis, and 16% had peripheral arterial thrombosis. Only four patients had both venous and arterial thrombosis. Venous thrombosis in other distributions certainly occurred, including the retinal and renal veins, but was less common. Superior mesenteric vein (401), renal vein (402 ,435), splenic vein (403), and hepatic venous thrombosis (404) also have been reported.

A special clinical concern in patients with aPL antibodies and venous thrombosis is the pattern of recurrent thrombosis (405). In the series of six patients reported by Asherson et al. (405), five of the six second events were deep venous thrombosis, but one was a myocardial infarction. All occurred 6 to 12 weeks after warfarin was stopped. Long delays between events are not unusual, however, such as the patient who started with a deep venous thrombosis of the leg at age 24, only to develop Budd-Chiari syndrome 6 years later (406).

Neurologic Syndromes

After deep venous thrombosis, cerebral events are the most commonly encountered thrombotic events in patients with APS. Levine and Welch (407) have reviewed the spectrum of neurologic disease in APS, which includes focal cerebral ischemia, ocular ischemia, transverse myelopathy, complicated migraines, chorea, seizures (usually secondary to cerebral ischemic events), apnea, multi-infarct dementia, ischemic encephalopathy, pseudotumor cerebri, and transient global amnesia. Recently it has been recognized that EEGs are frequently abnormal, with all APS patients having abnormalities and 71% of aPL-positive patients in one series (408).

Neurologic disease in patients with aPL antibodies who are selected from hospital clinics is not rare. Twenty-five of 80 patients with elevated aCL in one study had neurologic disease, with four patterns being found: (1) encephalopathy, (2) multiple cerebral infarctions, (3) migraine-like headaches, and (4) visual abnormalities, including amaurosis fugax and ischemic optic neuropathy (409). In a study of 48 patients with aPL antibodies and both cerebral and visual problems, the most common presentations were transient cerebral ischemia (12 patients) or cerebral infarction (23 patients) (410). Severe vascular headache also was seen in 16 patients, as was visual disturbance (11 patients), seizures (5 patients), vascular dementia (3 patients), transient global amnesia (3 patients), and cerebral venous thrombosis (2 patients).

Methodologic issues abound in cross-sectional studies. One issue is persistence of aPL antibodies. In a study of 120 patients with transient ischemic attack or stroke, 19 of 21 with aCL showed persistence, but only 9 of 20 with a LA demonstrated by dilute prothrombin time (411).

Transient Ischemic Attacks

Landi et al. (412) reported two young women with LA and transient ischemic attacks who had normal cerebral arteriograms. Levine et al. (410) also found that patients with transient neurologic dysfunction tended to have normal cerebral angiograms; however, two of their patients with transient ischemic attacks or recurrent amaurosis fugax had ipsilateral carotid artery stenosis of greater than 75%. Therefore, it is not clear from available reports whether cerebral angiograms should be done in all young patients with transient ischemic attacks and aPL antibodies. Although the typical patient is younger than would be expected for the presentation of atherosclerotic neurologic disease, many patients have had other risk factors, including hypertension, diabetes, and smoking (412 ,413).

Cerebral Infarction

APS and Sneddon syndrome overlap in important ways. In one study, patients with Sneddon syndrome who did not have aPL antibodies were more likely to have large livedo racemosa. Those with aPL antibodies were more likely to have seizures, mitral regurgitation, and thrombocytopenia (414).

Cerebral infarcts in APS can occur in any territory and have been found in both the anterior and posterior circulation. They generally involve the superficial cerebrum, although deep infarcts also are seen (410). In a series of 15 patients, 10 had anterior circulation infarcts, 5 had posterior circulation infarcts, and one had epilepsy (415). Magnetic resonance imaging (MRI) is consistently more sensitive than computed tomography in detecting infarcts in patients with APS (410). Some strokes in patients with aPL antibodies are embolic, with mitral valve vegetations (i.e., Libman-Sacks endocarditis) and intracardiac clot being two possible sources (416).

Strokes in APS often are multiple, recurrent, and can lead to a multi-infarct dementia, as reported by Asherson et al. (417) in 9 of their 35 patients with cerebrovascular disease (418 ,419 ,420). Encephalopathy also has been reported in patients with APS, and in some patients, it may occur before true infarction can be demonstrated on brain scan (421). Molad et al. (422) found that focal white matter brain lesions on MRI were more common in patients with systemic lupus and the LA. Cerebral venous thrombosis in two patients with LA has also been reported (423).

Cerebral atrophy has been noted in several studies and case reports of patients with APS. It is assumed that the mechanism is cerebral infarction (424 ,425). Cerebral hypoperfusion also has been reported in APS (426).

Multiple Sclerosis

The differentiation of neurologic APS from multiple sclerosis is not always possible. In one study, patients with multiple sclerosis had a higher severity score of white matter lesions, whereas patients with APS had higher scores in the putamen (427).

Transverse Myelopathy

Lupoid sclerosis is a syndrome in SLE in which neurologic events such as optic neuritis and transverse myelitis occur, resembling multiple sclerosis (428). All four patients with transverse myelitis in the series of 500 patients with SLE reported by Lavalle et al. (429) had aCL antibody. Four other patients with lupus, transverse myelitis, and aCL antibody have been reported (430 ,431 ,432 ,433), as has anterior spinal artery syndrome (434). In a British series of SLE patients, 73% with transverse myelitis had aPL antibodies (435). Not all series have found an association of aPL antibodies with myelitis, including a recent study (436).

Ocular Symptoms

In addition to amaurosis fugax, multiple other ocular syndromes have been reported in patients with aPL antibodies, including retinal artery occlusion (367), ischemic optic neuropathy (437), occlusive vascular retinopathy (438 ,439), and retinal vein occlusion (440 ,441). A recent case-control study suggested an association with aCL, but not LA, for retinal vasculopathy (442).

Migraine

Severe, recurrent migraine episodes sometimes are reported in patients with aPL antibodies who later go on to have a cerebral ischemic event (410 ,416). In one study, six of 16 patients with migrainous cerebral infarction had aPL antibodies (443 ,444). However, other studies have failed to confirm any association of aPL antibodies with migraine (445).

Apnea

One patient with lupus and two episodes of apnea as well as other evidence of brainstem dysfunction was found to have aCL antibody (446). She also had cerebrospinal fluid oligoclonal bands.

Chorea

Chorea, whether in patients with or without SLE, can be associated with aPL antibodies (447 ,448 ,449 ,450 ,451). In a review of 12 patients with chorea, six had lupus like disease and six had SLE (452). All of the patients in this series were women, but men and children also have been reported (453). In the Asherson et al. series (452), 8 of the 12 patients with chorea had features of APS, including thrombocytopenia, recurrent

pregnancy loss, and thrombosis, and most had aPL antibodies. Four patients with aPL antibodies developed cerebral infarcts, and three others had transient ischemic attacks. One patient developed dementia at the time that chorea appeared. Cardioembolic caudate infarction was the cause of chorea in one patient with LA (454).

In the largest case series of 50 patients with APS and chorea, other manifestations of APS were frequent, including 28% with stroke, 24% with venous thrombosis, 18% with pregnancy loss, 6% with peripheral arterial disease, 4% with myocardial infarction, and 44% with thrombocytopenia. Multiple treatment regimens were used, with the majority of patients responding to corticosteroids or haloperidol (455).

Cognitive Function

Experimental murine APS includes cognitive function abnormalities, such as hyperactivity, in its neurologic presentations (456).

Two major studies have suggested that persistence of aPL antibodies is associated with cognitive dysfunction in humans. In one study, persistent IgG aCL was associated with problems in speed of attention and concentration (457). In the second study, both persistent IgG aCL and IgA aCL were associated with cognitive dysfunction, in the areas of psychomotor speed and conceptual reasoning/executive ability, respectively (458).

Cardiac Manifestations

Cardiac manifestations of APS have been reviewed (459).

Angina and Myocardial Infarction

Both angina and myocardial infarction have been reported in association with aPL antibodies, although these appear to be less frequent than neurologic arterial events in APS (460). Coronary artery disease secondary to premature atherosclerosis is a well-recognized complication of corticosteroid therapy in patients with lupus (461 ,462), but myocardial infarction without sufficient risk factors (463) and without atherosclerosis on coronary arteriography (460) is the usual presentation in young patients with aPL antibodies. Often, thrombus is demonstrated as the cause of the ischemia (464 ,465).

Valvular Disease

Multiple groups have found an increased prevalence of valve vegetations and mitral regurgitation in patients with aPL antibodies (310 ,466 ,467 ,468 ,469 ,470 ,471 ,472). In patients with cerebral events and aPL antibodies, cardiac valvular vegetations are a potential source of emboli (416 ,466 ,473). APL antibodies were found in three of 15 patients with cyanotic congenital heart disease, and two of these three had thrombotic episodes and false-positive VDRL (474).

Intracardiac Thrombus

Intracardiac thrombus has been described in several patients with aPL antibodies (475 ,476 ,477 ,478 ,479).

Coronary Vasculopathy

A patient has been reported with coronary artery vasculopathy in the setting of aPL antibodies (480). Vasculopathy secondary to aPL antibodies is a well-recognized clinical presentation of APS (481 ,482 ,483).

Atherosclerosis

In a small series of patients, an association of atherosclerosis of the lower limbs with aPL antibodies was reported (484). Three of these patients also had myocardial infarction.

Pregnancy Manifestations

Pregnancy Loss

In a review of 110 women with multiple obstetric complications, 5% had aCL (485).

The most specific association of aPL antibodies is with late (midtrimester) pregnancy loss (486 ,487 ,488 ,489).

An association with early first-trimester losses has been much more difficult to confirm. In a case-control study of 93 women with first-trimester losses versus 190 controls, there was no association with aPL antibodies (490). However, in a prospective study of 325 pregnancies, aCL and antiphosphatidylserine (but not anti-β_2GPI) predicted pregnancy loss (83).

Pregnancy-Associated Thromboembolism

Both genetic causes of hypercoagulability and aPL antibodies are associated with pregnancy thromboembolism (491 ,492).

Preeclampsia

Some studies have found an association of aPL antibodies with severe preeclampsia (78 ,79 ,493 ,494 ,495 ,496 ,497 ,498) but others have failed to confirm this (499 ,500 ,501). HELLP syndrome has been reported in several case reports (502 ,503 ,504).

Intrauterine Growth Retardation

Most studies have not found an association of aPL antibodies with intrauterine growth retardation (493 ,500 ,505 ,506 ,507).

Infertility

Several studies have suggested an increase in aPL antibodies in infertility and in vitro fertilization (IVF) failures, but methodologic problems with study design hamper interpretation of these studies (508).

Pulmonary Manifestations

Pulmonary Emboli

Pulmonary emboli are a frequent complication of deep venous thrombosis in patients with APS (139). When thoracic imaging was done in 88 patients with APS, 10% had pulmonary emboli (509).

Pulmonary Hypertension

Pulmonary hypertension has been reported in several patients with aPL antibodies (510 ,511). In most, the mechanism has been pulmonary emboli (512 ,513), although in situ thrombosis remains a possibility (514 ,515).

Pulmonary Capillaritis with Hemorrhage

Pulmonary capillaritis is an unusual APS presentation usually manifested clinically by hemorrhage (516). Pulmonary hemorrhage is a recognized pulmonary manifestation of APS (517) and in one case was associated with microvascular pulmonary thrombosis, not capillaritis, which responded to methylprednisolone (518).

Pulmonary Alveolitis

There is one report of fibrosing alveolitis in an APS patient (519).

Pulmonary Vasculopathy

A noninflammatory vasculopathy can occur in the lungs with APS (520).

Pulmonary Artery Thrombosis

Pulmonary artery thrombosis has been reported (514 ,544), including a postpartum case (521 ,551).

Adult Respiratory-Distress Syndrome

Multiple cases of adult respiratory distress syndrome in patients with APS have been reported (522 ,523).

Renal Manifestations

Glomerular Thrombi and Renal Insufficiency

APS of the kidney is associated with hypertension, elevation of serum creatinine, and progression of histiologic lesions on repeat biopsy (524). Kant et al. (525) described two patients with lupus and LA who had thrombi in the glomerular capillaries and prominent vascular disease in the renal biopsy specimen. This work was extended in a second study of

23 biopsy specimens from 14 patients with LA (526). Thrombi were found in 14 of 18 specimens with LA, which was increased significantly over the rate in biopsy specimens without LA. In a series of 16 cases of primary APS, small-vessel occlusive lesions and focal cortical atrophy were found (527).

Renal biopsy findings in 12 women with LA, four of who had systemic lupus, showed a pattern of narrowing of the arteries because of recanalizing thrombi and cellular intimal proliferation (528). Renal function was impaired severely in four of these patients.

Hyalinosis of arterioles, fibrin thrombi of arterioles, and intimal proliferation in small- or medium-sized arteries was found on renal biopsy in four patients with APS (529). One patient with endothelial swelling of the glomerular capillary wall and intimal proliferation with focal luminal occlusion on renal biopsy had a deterioration in renal function when she was switched from coumarin to aspirin (530).

Accelerated Hypertension

Accelerated hypertension was reported in a 14-year-old girl with LA who had ischemic changes on renal biopsy (531). Asherson (532) has emphasized the importance of hypertension as a feature of the catastrophic aPL syndrome, which is a presentation of APS with multiorgan failure and prominent vasculopathy.

Renal Artery Thrombosis

Renal artery thrombosis leading to renovascular hypertension has been reported in a 13-year-old girl with aPL antibodies (533).

Nephrotic Syndrome

Pérez-VÄsquez et al. (534) have found a negative association between nephrotic syndrome and APS in patients with lupus. This may be partially explained by urinary loss of IgG (534). In dialysis patients, maintenance of graft access is more difficult in aPL-positive patients.

Renal Transplant

APS may contribute to early graft loss (535) and other renal transplant morbidity (536) in SLE.

Endocrine Manifestations

Adrenal Failure

Adrenal failure now has been reported in multiple patients with aPL antibodies (522 ,537 ,538). Multiple mechanisms may contribute, but hemorrhage or hemorrhagic infarction is the most common (539). Most of the adrenal hemorrhages reported so far have been spontaneous (453 ,540 ,541 ,542 ,543 ,544 ,545), but some have been in the setting of anticoagulation (544 ,546 ,547 ,548). Another typical presentation appears to be postoperative or exertion-related hemorrhage (392 ,544 ,549 ,550 ,551 ,552). Adrenal infarction after cessation of warfarin therapy also has been reported as a cause of adrenal failure (546).

Gastrointestinal Manifestations

Portal and Hepatic Vein Thrombosis

aPL antibodies are one of the major predisposing factors to both portal and hepatic vein thrombosis. In one study, 11% with portal vein thrombosis and 19% with hepatic vein thrombosis had an aPL antibody (553). In a second study of 23 patients with portal vein thrombosis, 17% had IgG aCL, 4% had IgM aCL, and one patient had a lupus anticoagulant (554). Hepatic vessel thrombosis was reported in two patients with APS after liver transplant (555).

Other Arterial Manifestations

Arterial thrombi in virtually every known territory have been reported in patients with aPL antibodies. Of particular note are aortic syndromes (556 ,557 ,558) and digital or extremity gangrene (559 ,560). Acute extremity arterial insufficiency has been reported secondary to emboli after pyelography (561).

Hematologic Manifestations

Thrombocytopenia

Thrombocytopenia is so well recognized as a manifestation of APS that it is was one of the former major criteria for the syndrome (29 ,562). Some LA antibodies bind and can induce a morphologic change in platelets (563 ,564). Similarly, aCL antibodies have been shown to bind to platelets (471). Thrombocytopenia in both patients with autoimmune disease (565) and patients with chronic immune thrombocytopenia purpura (566) is associated with aCL antibody. Patients with SLE and with primary aPL antibody syndrome make antibodies that react with a 50- to 70-kd internal platelet protein (567).

Some investigators (180), but not all (179), have found that the presence of aPL antibodies in patients with thrombocytopenia is associated with fetal loss, thrombosis, and bleeding. Thrombocytopenia was more common in APS patients who had arterial thrombosis in one study (568). Although 7 of 27 patients with immune thrombocytopenia purpura had aPL antibodies, this did not separate this subgroup in clinically meaningful ways (569).

Hemolytic Anemia

Both aCL (especially IgM) and LA are associated with the positive Coombs test and with hemolytic anemia (36 ,37 ,570 ,571 ,572).

Bone Marrow Necrosis

Rare cases of bone marrow necrosis have been reported secondary to APS (573 ,574).

Hemorrhage

Patients with the lupus anticoagulant directed against prothrombin, on rare occasions, may develop clinically important hypoprothrombinemia leading to hemorrhage. This complication appears to occur more often in children (101 ,575).

Vascular Access

Multiple thromboses of vascular access have been reported in patients with APS. In one study, this was associated with antibodies to bovine thrombin (used by surgeons) (576).

Musculoskeletal

An association of aPL antibodies with avascular necrosis of bone was not found in four large series of patients with SLE (159 ,577 ,578). In four other series, however, avascular necrosis was more frequent in patients with SLE and aPL antibodies (578 ,579 ,580 ,581). In one case report, the catastrophic form of APS presented as multiple sites of avascular necrosis (582). Avascular necrosis also was found in a single vertebral body in an APS patient (583). Asymptomatic avascular necrosis occurs in 2% of primary APS patients (584). Generally, patients with avascular necrosis have a multiplicity of thrombophilic and hypofibrinolytic abnormalities (585).

Neonatal Manifestations

Transplacental transfer of aPL antibodies can lead to APS manifestations in neonates. There is one report of umbilical cord thrombosis (586), several reports of stroke (587 ,588), seizures (589), multiple thromboses (590) and fatal aortic thrombosis (591).

Other consequences of placental insufficiency as a result of APS include growth restriction (486), although this has not been confirmed in all studies (591 ,592 ,593), and severe preeclampsia (494), also not confirmed in all studies (594).

Drug-Induced Lupus Anticoagulant

Several commonly used medications, including phenothiazines, procainamide, hydralazine, and anti-TNF biologics can induce not just lupus but also drug-induced aPL antibodies. Many of the drug-induced LAs are IgM rather than IgG and, for some time, were regarded as benign. However, drug-induced LAs rarely may be associated with the thrombotic events that characterize APS (69 ,595).

Treatment

Newly Diagnosed, Asymptomatic Patients with aPL Antibodies

Asymptomatic patients with aPL antibodies either may remain untreated (596) or be treated with low-dose aspirin. Reduction of other risk factors for thrombosis, including smoking cessation and avoidance of oral contraceptives, should be undertaken as well. There are no prospective studies proving that low dose aspirin will prevent future thrombosis, however. In fact, the Physician's Health Study did not find aspirin to be effective in preventing future deep venous thrombosis or pulmonary emboli in male physicians (236). Erkan et al. have shown, in a retrospective chart review of women with pregnancy-related APS, that low dose aspirin was associated with a reduction in later thrombosis (597). Aspirin does inhibit the activation of endothelial cells by aPL antibodies (598). In a decision analysis, aspirin was favored as the best prophylactic therapy, with an eleven month gain in survival in a typical patient (599). However, as many as 25% of the general population is resistant to aspirin.

In patients with SLE and aPL antibodies, our prospective cohort study has shown that the use of hydroxychloroquine

reduces the odds ratio for future thrombosis (244 ,600). The mechanism is likely multifactorial, because hydroxychloroquine lowers titers of aPL antibodies, controls disease activity (601) and may have a beneficial rheologic effect. In an animal model, hydroxychloroquine reduces thrombus size (21). Additionally, hydroxychloroquine reverses platelet activation induced by aPL antibodies (602). Quinacrine, another antimalarial drug, reduces anticardiolipin titers (603).

Management of Acute Arterial Thrombosis

Treatment of an acute arterial event in a patient with APS must balance aggressive therapy to recanulate the vessel with the risk of hemorrhagic complications or of further thrombosis resulting from instrumentation of the vessel. Thrombolytics (604) and angioplasty (605 ,606) have been used successfully in individual cases. Heparin remains the usual therapy in most cases, however. Heparin inhibits the binding of $ß_2$GPI to phospholipids and promotes plasmin-mediated inactivation of $ß_2$GPI (607). However, in a murine model of APS pregnancy loss, the therapeutic role of heparin is not anticoagulation, but anti-inflammatory, by inhibiting complement activation (608).

Management of Acute/Chronic Venous Thrombosis

Heparin or thrombolytics is the usual therapy for acute deep venous thrombosis or pulmonary embolus. Thromboendarter-ectomy has been performed successfully in chronic pulmonary thromboembolism (609).

Long-Term Management after a Thrombotic Event

The high frequency of recurrent thrombotic events in APS has been demonstrated conclusively (254 ,262). Case reports or small series have suggested the utility of warfarin as a long-term treatment (278 ,412 ,416 ,417 ,610 ,611), and three large studies have addressed this issue in detail. Rosove and Brewer (254) reported that intensive warfarin with an international normalized ratio (INR) of three or greater was the most effective antithrombotic treatment. Khamashta et al. (255) reached a similar conclusion. One potential explanation for why patients with APS might need a higher-than-usual intensity of anticoagulation is if the INR underestimates the anticoagulant effect of warfarin when the patient has LA (612). Derksen et al. (258), in a study that was limited to venous thrombosis in APS, found the probability of no recurrence to be 100% with oral anticoagulation versus 22% with no treatment. The price to be paid for the intensive anticoagulation, however, is the increased risk of bleeding. If low-dose aspirin is added to the regimen, this will further increase the bleeding risk.

These case series did not address several important clinical issues. First, the need for high-intensity warfarin was not demonstrated prospectively, or shown to be necessary for both arterial and venous thrombosis. Venous and arterial events were not separated in two of the case series (254 ,255). It often is assumed that recurrent thrombotic events occur in the same distribution, arterial or venous, and that APS can be divided into these two subgroups in terms of treatment. We have disagreed personally with this stance, because about 25% of our patients with recurrent thrombosis had initially venous thromboembolism and then “crossed over” with recurrent thrombosis on the arterial side of the circulation, or vice versa.

It is important to acknowledge that there are studies suggesting low-intensity warfarin may be sufficient to prevent recurrent venous thromboembolism (613 ,614 ,615), although these studies did not specifically address APS. Furthermore, there are studies (256 ,257 ,259) including a prospective one (239) showing that an INR below three, even below two, may be sufficient to prevent recurrent venous thromboembolism in aPL antibody syndrome.

Second, patients whose thromboembolic event occurred with an identified precipitant, especially pregnancy or oral contraceptive use, are not separately analyzed. If a known precipitant can be removed, does the patient still require long-term anticoagulation?

Third, the case series do not adequately address the addition of low-dose aspirin to warfarin. Is this helpful in those who present with arterial, rather than venous, thromboembolism?

Fourth, the potential beneficial role of hydroxychloroquine (which patients with secondary APS might be taking for SLE manifestations) on titers of aPL antibodies (244) and thrombosis prophylaxis has not been a focus of the major case series or clinical trials.

Fifth, the special management concerns in the profoundly thrombocytopenic patient are not emphasized. We have advised caution in patients with a platelet count below 50,000. The platelet count should be raised above 50,000 (using intravenous immunoglobulin, prednisone, danocrine, etc.) and then warfarin can be begun cautiously, aiming for the “lower end” of the therapeutic range.

Ultimately, case series cannot be the standard by which treatment is decided. A pivotal clinical trial of APS patients compared usual intensity warfarin with high intensity warfarin in patients with thrombosis due to primary or secondary APS. Efficacy was equal in both arms (616). Clinical trials comparing warfarin, low molecular weight heparin, aspirin, warfarin/aspirin, and aspirin/hydroxychloroquine still are required.

Management of Stroke

An analysis of aPL antibodies at the baseline visit of the WARSS trial (warfarin versus aspirin after a first stroke) was surprising for several reasons (617). First, the aPL positive patients did not have a worse prognosis. Second, there was no difference in outcome of recurrent stroke or vascular events in the two arms. This suggests that aspirin, 325 mg, might be an acceptable therapy for stroke with aPL antibodies (618). An important caveat is that patients with aPL in the WARSS trial did not meet either the Sapporo (persistence of

antibodies for 6 weeks) or Sydney (persistence for 3 months) classification criteria for APS.

Long-Term Anticoagulation

A decision analysis concluded that long-term anticoagulation was the optimum management in APS (619). There still is no consensus on the recommendation that patients with APS thrombosis receive long-term anticoagulation with warfarin (620). For example, in one study, 51% of patients with APS had no recurrence of thrombosis with no warfarin (621). The roles of low-dose corticosteroid therapy, immunosuppressive drugs, anti-platelet drugs other than aspirin, and intravenous immunoglobulin (622) in the long-term treatment of APS are unknown.

Patients with Thrombocytopenia and Antiphospholipid Antibody Syndrome

Thrombocytopenia does not protect patients with APS from either thrombosis or pregnancy loss. The patient with APS and both thrombosis and thrombocytopenia remains a special treatment challenge. In one report, heparin-induced thrombocytopenia developed in 56% of LA-positive patients who had pulmonary hypertension, further confusing the issue (293). Our group has recommended using prednisone, danocrine, intravenous immunoglobulin, or other therapies for thrombocytopenia to keep the platelet count above 50,000/mL if therapy with heparin or warfarin is contemplated. There is a report of low dose aspirin correcting thrombocytopenia, but this seems to be the exception (623). Careful introduction of warfarin (with less-intensive anticoagulation, such as an INR of 2 to 2.5) can then be considered. Splenectomy may be an option for patients with refractory life-threatening thrombocytopenia (624 ,625), but we have seen recurrences postsplenectomy.

Treatment of Cardiac Valvular Disease

Valvular vegetations occur most frequently on the mitral or aortic valve. They represent a major source of embolic transient ischemic attacks and strokes. Studies differ on the efficacy of treatment with anticoagulation alone. In a series of 13 patients, warfarin and antiplatelet therapy had no effect (626). Thus, corticosteroids may have a role in addition to anticoagulation (627).

Treatment for Transverse Myelitis and Chorea

Transverse myelitis and chorea may represent largely nonthrombotic manifestations of aPL antibodies. However, some patients have true cord or basal ganglia infarcts on MRI. Acute therapy usually is with intravenous methylprednisolone “pulse” therapy, 1,000 mg daily for 3 days, followed by high-dose corticosteroids with or without immunosuppressives (628). The need for immunosuppression has been emphasized in a recent series (435). The addition of anticoagulation must be made on a case-by-case basis, taking into account the presence of any thrombosis on MRI or history of thrombosis elsewhere.

Treatment for Pregnancy Loss

The preferred treatment for pregnancy loss has been heparin in prophylactic doses and aspirin (629 ,630), although a third clinical trial found aspirin to be equally beneficial (631). Low molecular weight heparin appears to be equivalent in benefit to unfractionated heparin (632).

Treatment for Catastrophic APS

Although rare, catastrophic APS has a high mortality (50%) in most series. Precipitating factors are found in 22%, including infections, drugs, surgery, and cessation of warfarin (273). We have also found oral contraceptives and pregnancy to be precipitants. Thrombocytopenia has been reported in 68% (273). Treatment includes heparin, to prevent additional thrombosis; corticosteroids to treat the “cytokine storm” and to prevent further production of aPL antibodies; and plasmapheresis or intravenous immunoglobulin to remove circulating aPL antibodies. Plasmapheresis appears to improve survival in case series (273), although it increases the risk of severe infections (633). Intravenous immunoglobulin may be able to substitute for plasmapheresis, which is a difficult procedure in an unstable patient. Treatment of catastrophic APS has been reviewed by Asherson (532).

Other Therapies

B Cell Tolerance

The ideal prophylactic treatment would be to prevent production of aPL antibodies, by the reintroduction of tolerance. The technology of B cell tolerance has reached fruition in LJP394, a B cell toleragen for anti-dsDNA. LJP394 has been shown to reduce anti-dsDNA in patients with SLE (634), but failed to prevent lupus nephritis flares in two clinical trials (635).

The great benefit of this approach in APS would be its ability to induce specific autoantibody tolerance, whereas sparing normal immune function. To induce tolerance, B cells are exposed to an antibody-binding epitope that leads to cross-linking of surface receptors. In the absence of T cell help, B cell anergy and apoptosis then occur.

Iverson and colleagues have identified a peptide epitope that binds anti-β_2GPI–dependent aCL antibodies and covalently linked it to an organic platform. Multivalent presentation of this peptide epitope on the organic platform reduced antibody production in an immunized mouse model (636). A bioconjugate B cell toleragen for domain I of β_2GPI led to a 89% to 96% reduction in anti-β_2GPI in an animal study (637).

High-Dose Cyclophosphamide, with or without Stem-Cell Rescue

A more radical attempt to induce tolerance is high dose cyclophosphamide with autologous stem cell rescue. One 19-year-old woman with SLE and secondary APS later developed refractory Evans syndrome and underwent stem cell transplantation. Her conditioning regimen consisted of cyclophosphamide, anti-T lymphocyte globulin, and prednisone, followed by transplantation with autologous $CD34^+$ stem cells and progenitor cells. Eight months after the procedure, her aPL antibody assays, both aCL and lupus anticoagulant, remained negative (638).

Our group has raised concerns about the durability of the response to high-dose cyclophosphamide with or without stem-cell rescue: when long-term follow-up is available, relapses are common (639 ,640). Although long-term clinical remissions occur (639), most patients continue to have aPL antibodies in our series. However, Gladstone et al. have reported on several SLE patients who become aPL negative after high-dose cyclophosphamide (641).

Intravenous Immunoglobulin

Commercial preparations of intravenous immunoglobulin (IVIG) have been found to contain both aPL and anti-DNA autoantibodies in addition to antiidiotypic antibodies, but the autoantibodies have not been found to be pathogenic (642). In fact, in murine models of APS, IVIG has been beneficial (643). This beneficial effect of IVIG is likely mediated through multiple mechanisms, including antiidiotypes, IL-3 secretion (644), and saturation of the IgG transport receptor (645).

IVIG remains of interest in APS for the following multiple reasons: it binds aPL antibodies, down-regulates their production, and can raise the platelet count in thrombocytopenic patients. About 30% of women with APS and pregnancy loss fail treatment with heparin and aspirin, and require consideration of alternative treatments, such as IVIG.

However, the successful use of IVIG has been in case reports and small series, leading to the potential of publication bias. It often is combined with heparin, aspirin, and even prednisone, making it more difficult to assess the added benefit of IVIG. Multiple regimens have been used daily, although the two most common are 400 mg/kg for 5 days monthly or 1 g/kg/day for 2 days monthly (646). In a pilot clinical trial, the addition of IVIG did not improve pregnancy outcome in APS (647 ,654). IVIG, because it is usually low risk, likely will continue to be used in the treatment of pregnant patients failing conventional therapy (648). However, IVIG has been associated with thrombotic events (649 ,650).

It is even more difficult to assess the role of IVIG in infertility. Multiple groups have shown an increase in aPL antibodies in women with unexplained infertility and in women with recurrent IVF failures, but negative series also exist (651). In a large case-control study, heparin and aspirin improved IVF results. The addition of IVIG in women who had failed two consecutive IVF attempts with heparin and aspirin improved the birth rate to 41% from 17%, if antiphosphatidylserine or antiphosphatidylethanolamine were present (652). These results require confirmation from other groups, however, before IVIG can be recommended routinely to women with IVF failure and aPL antibodies.

Anti-TNF

In a murine model of APS pregnancy loss, TNF-α is involved downstream of complement activation, and anti-TNF strategies are beneficial (653). However, anti-TNF biologics, used for rheumatoid arthritis, can induce aPL antibodies (654), possibly because of infections (655).

Statins

One statin, fluvostatin, has been shown to reduce aPL-induced thrombosis and endothelial cell activation in an animal model (656). It inhibits the up-regulation of tissue factor by aPL (657). Experience in humans is needed, however, because statins can cause drug-induced lupus.

Rituximab

Rituximab, a B cell depleting monoclonal antibody used in the treatment of non-Hodgkins lymphoma, has reduced or normalized aPL antibody titers in several case reports (658 ,659).

Future Therapies

The recognition that complement activation is a requirement for aPL-mediated thrombosis (21) and pregnancy loss (20) may lead to studies of biologics that block complement (660 ,661 ,662).

Peptide Therapies

In murine models of APS, several promising novel therapeutic approaches have been studied. Peptides that react specifically with anti-$ß_2$GPI monoclonal antibodies were identified and found to inhibit endothelial cell activation and expression of adhesion molecules. These peptides prevented experimental APS in BALB/c mice (663).

Oral Tolerance

A novel approach in murine APS is to induce oral tolerance to low-dose $ß_2$GPI. If $ß_2$GPI was given orally before priming the BALB/c mice with $ß_2$GPI, it completely prevented experimental APS. However, it had less effect if given 70 days postimmunization. The induction of suppression was $ß_2$GPI specific, but also mediated by TGF-ß (664).

Chapter 66
Additional Therapies Used in the Management of Lupus

Daniel J. Wallace

Previous chapters have discussed therapies for lupus erythematosus including general measures, local applications, nonsteroidal antiinflammatory drugs, antimalarials, corticosteroids, and traditional immunosuppressive agents. Occasionally, specific subsets of lupus require additional approaches, and some patients with refractory disease benefit from innovative management. This chapter reviews these approaches.

Medications

Antileprosy Drugs

Dapsone

Dapsone, or 4,4-diaminodiphenylsulphone, interferes with folate metabolism and inhibits para-aminobenzoic acid. It also blocks the alternate pathway of complement activation and neutrophil cytotoxicity (1), and it inhibits superoxide and hydroxyl generation in patients with rheumatoid arthritis (2 ,3). Its use is limited by its toxicity, which includes sulfhemoglobinemia and methemoglobinemia, a dose-related hemolytic anemia, a “dapsone hypersensitivity syndrome,” and aplastic anemia (4 ,5). In a case reported during 1978, it was said to benefit urticaria associated with systemic lupus erythematosus (SLE) (6). Small series (5 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16) have reported that dapsone can ameliorate vasculitis, bullae, urticaria, oral ulcerations, thrombocytopenia, lupus panniculitis, and subacute cutaneous lupus. Dapsone may be steroid-sparing, and it can be effective in chloroquine-resistant patients.

Dubois' group found dapsone to be helpful in three of seven patients, but three developed a significant anemia (17). Coburn and Shuster (18) reported that 9 of 11 patients with discoid LE improved on 100 mg daily. Lindskov and Reymann (19) gave dapsone to 33 patients with chronic-cutaneous LE—8 had excellent and 8 had fair results, but 17 (52%) had no response. Dapsone occasionally can make rashes worse (20 ,21), perhaps because of its sulfa component.

All patients treated with dapsone should have their baseline glucose-6-phosphate dehydrogenase levels determined; the drug should not be given to individuals with low levels. Complete blood counts should be performed every 2 weeks for the first 3 months and then every 2 months thereafter. Dapsone should be started at a dose of 25 mg twice daily and eventually raised to 100 mg daily. Dapsone also interacts with all oxidant drugs, such as phenacetin and macrodantin. Concurrent administration of 800 U of vitamin E daily may decrease the degree of dapsone-induced hemolysis (22). Delayed hypersensitivity reactions can occur (23).

I believe that dapsone has a place in the treatment of cutaneous (especially bullous and lupus profundus) and musculoskeletal lupus, especially when steroids are ineffective or contraindicated. Hematologic toxicity is high, however, and the drug should be used infrequently and cautiously.

Thalidomide

Thalidomide has become one of the newer options for refractory cutaneous lupus, which carries significant concerns and promise.

Mechanism of Action

Also known as -N-phythalimidoglutarimide, thalidomide is a highly teratogenic drug with antileprosy and antilupus effects. It has no influence on the complement system, but it can stabilize lysosomal membranes, reduce tumor necrosis factor-α (TNF-α) activity, antagonize prostaglandin, inhibit neutrophil chemotaxis and angiogenesis, and alter cellular and humeral immunity (23 ,24 ,25 ,26). Thalidomide inhibits ultraviolet B (UVB)-induced mouse keratinocyte apoptosis in both TNF-α–independent and independent pathways (27), as well as UVB-induced erythema (28).

Clinical Studies

Barba Rubio et al. (29 ,30) pioneered thalidomide's use in discoid LE in Mexico during the mid-1970s. Improvement begins within weeks on doses between 100 and 400 mg daily (31). Knop et al. (32) reported that in 46 patients with antimalarial-resistant discoid LE given 400 mg/day and followed for up to 2 years, 90% had complete or marked regression. Also, 71% relapsed on its discontinuation and improved

when it was restarted, and 25% developed a polyneuritis. The drug also can heal antimalarial-resistant lesions (33). Forty-four percent of 16 patients at Graham Hughes' London unit had complete cutaneous remissions with thalidomide; another 37% had a partial response. Twenty-seven percent developed a peripheral neuropathy (34 ,35). Twenty of 23 Brazilians with chloroquine-resistant chronic-cutaneous lupus had clearing of lesions with thalidomide; 52% experienced drowsiness and 22% abdominal distension (24). Twenty-nine patients had a 74% complete response at the Wake Forest (36), 66% of 27 patients in Leeds given 100 mg a day or less without neurotoxicity (37), and a Greek group also found similar efficacy without neurotoxicity with lower dosing (38).

Similar favorable responses and toxicity have been noted by others in smaller groups of patients (25 ,31 ,39 ,40 ,41 ,42), and in hypertrophic lupus (43) and lupus profundus (44). Lymphocyte counts tend to increase whereas inflammatory parameters and serologies are usually not altered with its use in lupus (45).

Adverse Reactions

Side effects of thalidomide include teratogenicity, fatigue, dizziness, weight gain, constipation, amenorrhea, dry mouth, and a polyneuropathy that is associated with chronic administration. It is sensory, axonal neuropathy, which does not always resolve with the drug's discontinuation (46 ,47). Other important side effects include amenorrhea and pustuloderma, and thrombosis (48 ,49). Higher doses (above 200 mg a day) are associated with a thrombotic risk (50 ,51 ,52). It is available in the United States from physicians who have registered with the New Jersey-based Celgene Corporation and comply with stringent requirements.

Conclusions

Thalidomide is a useful, second-line treatment for severe, cutaneous disease refractory to standard treatment. Caution should be exercised in using doses of more than 100 mg a day and it thalidomide should be conceived as a bridge therapy to clear the skin so that other modalities can ultimately be used chronically. Thalidomide should never be used in women who are pregnant or contemplating pregnancy.

Clofazimine

In 1976, Krivanek et al. (53) reported resolution of discoid LE in all of nine patients treated with 100 to 300 mg/day of clofazimine (Lamprene, Novartis) for 3 months, but a follow-up paper (54) found it to be effective only in early, acute-onset lesions. The drug has antileprosy, antibacterial, and antimalarial activity. It is sequestered in macrophages, stabilizes lysosomal enzymes, and stimulates the production of reactive oxidants (55). Two other favorable studies have appeared (56 ,57), but Dubois' group had no responses among eight patients treated (17). Long-term use of clofazimine in LE can result in cutaneous pigment deposits (58).

Other Novel Immune Suppressives

Chapter 61 reviews most immune-suppressive agents that at least occasionally are used to manage SLE. A few additional ones deserve mention here.

Antimetabolites

Cytarabine helped three patients with refractory cutaneous lupus (59). Fludarabine is a purine antimetabolite that helped one lupus patient (60), but was associated with a graft-versus-host reaction in another (61). Eleven patients were studied at the National Institutes of Health (NIH) but the study was terminated early because of a high rate of bone marrow suppression (62 ,63). The nucleoside analog, 2-chlordeoxyadenosine (2-CdA, cladribine) was given to 12 patients with proliferative nephritis as an infusion. Fifty percent had substantial improvement at the NIH (64), but disappointing results in two others (65).

Immunophylles: Tacrolimus, Pinecrolimus, Rapamycin

Immunophylles block IL-2 cell stimulated T cell proliferation. Chapters 57 and 61 discuss cyclosporin, topical tacrolimus, and pinecrolimus.

Seventeen Hong Kong patients followed by Mok et al. with diffuse proliferative lupus nephritis did as well as cyclophosphamide after 3 months in a preliminary report (66). Three of four patients who were resistant to cyclosporin or cyclophosphamide improved somewhat with tacrolimus (Prograf, FK-506) (67 ,68). It was well tolerated in six cases of pediatric lupus (69). Several of our renal transplant patients have tolerated rapamycin (sirolimus, Rapamune, Wyeth Ayerst), but no studies of its use in lupus have been published (70).

Mizoribine

Mizoribine is an oral immune suppressive similar to azathioprine, which is available in Japan. A nucleoside of the imidazole class, in several studies, doses of 5 to 10 mg/kg/day have been suggested to be effective for lupus nephritis, children, and as a steroid sparing vehicle, but no controlled trials have been published (71 ,72 ,73 ,74 ,75). It has also been studied in rheumatoid arthritis.

Gold

In the 1940s and 1950s, gold frequently was used to treat LE. It was thought to be beneficial but toxic (76 ,77 ,78 ,79). Reports of this period antedated criteria for defining SLE and rheumatoid arthritis as well as the introduction of lupus serologies. As a result, the *Physicians' Desk Reference* listed SLE as a contraindication for using gold sodium thiomalate.

In 1983, 16 patients with SLE but without renal involvement were given oral gold at the University of California, San Diego (80). They had fevers, fatigue, arthritis, serositis, vasculitis, rashes, and mouth ulcers. Gold was of modest benefit, with significant improvement noted only in physician assessment and steroid dose reduction. A British group treated 22 patients with biopsy-documented cutaneous lupus with oral gold for up to 1 year (81). Of these, 12 had dramatic clearing of lesions, and 5 others demonstrated definite improvement. In another report (82), 7 of 12 patients who received aurothioglucose injections had improved arthritis and decreased steroid requirements. Some still are concerned that gold can flare SLE (83), and further studies are needed to define its potential role.

Vitamin A, Beta Carotene, and Retinoids

Beta carotene, vitamin A, and retinoids are related compounds that may have antilupus actions because of their sun-blocking and antioxidant activities. Skin tests with vitamin A have revealed an increased hyperreactivity in patients with SLE and their relatives compared with controls (84), and its oral administration in SLE enhances natural killer-cell activity and mitogenic responsiveness (85).

Beta carotene has been used to treat polymorphous light eruption, erythrohepatic protoporphyria, and discoid LE. Of seven patients with cutaneous lupus, six improved in two reports (86 ,87), but Dubois and Patterson (88) found beneficial results in only 1 of 26 patients.

Retinoids inhibit collagenase, prostaglandin E2, and rheumatoid synovial proliferation; interfere with intracellular-binding proteins; and interact with kinases, such as cyclic AMP (89 ,90). Additionally, epidermal antibodies can be altered, and an effect on epidermal cell differentiation may be observed (91). Three retinoids have been evaluated in cutaneous lupus: (1) isotretinoin (13-cis-retinoic acid; Accutane, Roche Laboratories); (2) etretinate (Tegison, Roche Laboratories); and (3) the aromatic retinoid acitretin (Soriatane, Roche Laboratories). When given in doses of 40 mg twice daily, isotretinoin induced complete resolution of lesions in eight of ten patients, including several with refractory, subacute-cutaneous lupus (91). In another open trial, it was effective in 20 of 24 patients (31). Other case reports and a literature review have confirmed these findings (92 ,93 ,94 ,95 ,96).

I have had similar success, but unless the patient is kept on a maintenance dose of 10 to 40 mg daily, recurrences are common. Isotretinoin can cause arthralgias and skeletal hyperostoses (97). Etretinate also may ameliorate cutaneous lesions (98), but extraspinal tendon and ligamentous calcifications have resulted from therapy (99). The drug is no longer is available in the United States. An aromatic retinoid, acitretin (Soriatene), is still available in the United States. In one paper (100), seven favorable reports were reviewed, and 15 of 20 patients studied had complete clearing of all lesions. This included five of six patients with refractory, subacute-cutaneous lupus. A randomized, double-blind study found that 46 of patients treated with acitretin improved (101). The recommended dose is 20 to 50 mg a day. The teratogenicity of the retinoids is a major concern in treating females of childbearing age. Topical retinoids with sunscreens also may be useful (102).

In summary, retinoid derivatives are useful for subacute cutaneous lupus and may ameliorate antimalarial resistant cutaneous disease.

Miscellaneous Hormonal Interventions

Chapter 63 discusses the use of contraceptive and other menses-altering or menses-regulating hormones.

Danazol

Danazol (Danocrine, Sanofi) is an impeded androgen whose effects in SLE are unclear. It may decrease Fc receptor expression and platelet-associated IgG, can reverse protein S deficiency (103), and also may have a hormonal downregulating action. Danazol displaces steroids by binding to steroid-binding globulin, which frees the latter compound. Its most promising use so far is for the treatment of idiopathic thrombocytopenia, in which a 67% response rate and steroid-sparing effects are observed, and after an initial response, low doses can be administered as maintenance therapy (104 ,105).

Hematologic Manifestaions

Idiopathic thrombocytopenia caused by SLE responds well in some patients to between 400 and 800 mg/day of therapy (106 ,107 ,108 ,109 ,110). Cervera et al. (111) noted that all of 16 patients given danazol achieved a complete remission when it was started at 200 mg/day and increased stepwise up to 1,200 mg until benefit or toxicity was observed. Danazol in combination with corticosteroids or hydroxychloroquine resulted in a 64% response among 18 French ITP patients (112). Several reports also have documented its efficacy in cases of SLE with autoimmune hemolytic anemia (110 ,113 ,114 ,115 ,116). Danazol has been used in case reports of red cell aplasias and cytopenias (117 ,118).

Other Manifestations and Toxicities

Additionally, danazol has been reported to help patients with persistent, premenstrual LE flares (119). In combination with cyproterone acetate, 11 patients with SLE had fewer exacerbations, and persistent, disabling mouth ulcers disappeared in three (120). Danazol may be effective in discoid LE (121); of 21 patients given danazol in a controlled trial with corticosteroids, all had fewer flares, lower steroid requirements, and higher hemoglobin levels, platelet counts, and C4 complement levels than 20 patients taking steroids alone. Of the 21 patients in the danazol group, however, eight withdrew because of hepatotoxicity, gastric symptoms, or asthenia (122).

Occasionally, danazol can worsen SLE (123), and it has been associated with the development of hepatocellular carcinoma in one patient (124) and with hyperglucagonemia in another (125).

Danazol is useful for ITP and possibly hemolytic anemis in SLE has no role in the management of life-threatening, nonhematologic manifestations of lupus.

Testosterones

In 1948, Lamb gave androgens to five patients with lupus, but without significant improvement (126). In 1950, Dubois et al. and Fromer (127 ,128) treated several female patients with massive doses of testosterone, both orally and intramuscularly, using as much as 500 to 1,000 mg/day for as long as 5 weeks without benefit.

After a 30-year hiatus, interest in androgen therapy resurfaced. Lahita and Kunkel (129) treated four men and four women with 19-nortestosterone (Nandrolene) for 2 months to 2 years. The condition of the men grew worse, but some women improved. Minimal masculinization was noted, sedimentation rates and anti-DNA levels decreased slightly, and hemoglobin and white counts both improved. Swaak et al. (130) found that modest improvements were outweighed by hirsutism and voice alterations among 36 patients in a placebo-controlled trial, and Hazelton et al. (131) observed no clinical change in ten patients treated with the drug. A Soviet androgen preparation, Sustanon-250, has been purported to decrease disease activity (132 ,133 ,134). Our group studied a testosterone patch being developed by Proctor and Gamble to 60 women as part of a double-blind, placebo controlled trial with SLE. No change in disease activity or sexual dysfunction was noted (135).

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a steroid precursor of androgens, and to a lesser extent estrogens. Produced in the adrenal gland, its levels decline with age. DHEA increases IL-2, soluble-adhesion molecules, and interferon (IFN) while downregulating interleukin-4 (IL-4), IL-5 and IL-6 (136 ,137 ,138). It increases growth-hormone levels, may improve bone density, fatigue, libido, and cognitive dysfunction (139 ,140). Although available over the counter as a “dietary supplement,” a quality control review of 16 preparations showed that 0% to 150% of what was claimed on the label was actually in the product (141).

Early studies at Stanford University showed that in doses of 100 to 200 mg a day, favorable effects were reported in mild-to-moderate lupus in an open-label study (142), double-blind trial (143), and at long-term follow-up (144 ,145). In patients with severe SLE, bone density improved but disease activity changes were not statistically significant (146). Several pivotal trials were ultimately performed. A double-blind, randomized, placebo-controlled trial of 191 female lupus patients suggested that it was steroid sparing in individuals with a SLEDAI score greater than 2 (147). In another trial, 381 patients given 200 mg daily or placebo noted significant improvements in myalgias, oral stomatitis, and serum C3 complement (148). In a Tawanese study, 120 women randomized to DHEA versus placebo showed decreased flare rates and improved patient global assessment. IL-10 synthesis was suppressed (149 ,150). The drug was well tolerated with mild acne and hirsutism being common but rarely requiring drug discontinuation. Suggestions that the drug might improve bone mineralization in steroid dependent lupus patients led to a controlled trial that failed to reach its primary endpoint (151 ,152 ,153). The FDA did not approve DHEA for lupus as it objected to a post hoc analysis by the pharmaceutical company, and noted that the drug did not improve sedimentation rate, SLEDAI scores, or anti-DNA. Concomitant fibromyalgia was not assessed. In my practice, I use compounded DHEA in patients with fatigue and cognitive impairment as an adjunct in some individuals in doses of 50 to 100 mg a day.

Tamoxifen, Bromocriptine, and Growth Hormone

A double-blind, cross-over trial treating 11 patients with SLE using tamoxifen, an antiestrogen, demonstrated no benefits from the drug (154). Prolactin appears to have proinflammatory effects, and interest has centered on the use of prolactin suppression with bromocriptine in SLE (see Chapter 64). In one report, recombinant growth hormone reactivated a previously quiescent nephritis (155).

Gamma Globulin and Intravenous Immune Globulin

Intravenous immune globulin (IVIG) delays the clearance of antibody-coated autologous red blood cells, competitively inhibits reticuloendothelial Fc receptor blockade, has anti-idiotypic antibody activity, modulates the release and function of proinflammatory cytokines and adhesion molecule expression, and decreases pokeweed mitogen-induced B cell differentiation (156 ,157 ,158 ,159 ,160). Hypogammaglobulinemia with recurrent infections is a rare event in SLE (see Chapters 45 and 46), and use of intramuscular gamma globulin to prevent infection in lupus is not uncommon, even though no controlled studies have documented its efficacy (161 ,162 ,163).

Intravenous gamma globulin first was used in a case of lupus nephritis in 1982 (164), and its use has increased since then (165). It may be acutely helpful for autoimmune thrombocytopenia secondary to SLE (166 ,167 ,168 ,169) and for the neonatal thrombocytopenia that is seen in children of mothers with SLE (170). Gamma globulin is thought to be useful for serious disease exacerbations (171 ,172 ,173), such as in central nervous system (CNS) lupus (174 ,175), pericarditis (176), cardiac dysfunction (177), acquired factor VIII deficiency (178 ,179), pancytopenia (180 ,181), refractory cutaneous lupus (182 ,183 ,184), myelofibrosis (185), nephritis (186 ,187 ,188 ,189 ,190), polyneuritis (191), hypoprothrombinemia with the lupus anticoagulant (192), pulmonary hemorrhage (193), and for preventing recurrent fetal loss in patients with the antiphospholipid syndrome (194–200, see Chapter 54). In a controlled study, low molecular weight heparin was superior to IVIg (200). Seventeen of 20 Israeli

lupus patients with a variety of clinical manifestations responded to therapy (201). In patients with mild disease, little response to gamma globulin has been noted (202).

The use of gamma globulin for the treatment of lupus nephritis is controversial (203). The drug is expensive and potentially dangerous. The reader should appreciate that it often is ineffective (204) or temporarily effective (205). It can flare disease activity (206), induce acute renal failure (207 ,208), myocardial infarction (209), aseptic meningitis (210), and vasculitic rashes (211) among other symptoms. Low or absent IgA (seen in 5% with SLE) is a relative contraindication to its administration.

Summary

IVIG is a first-line therapy for idiopathic thrombocytopenic purpura, IgG subclass deficiency, and chronic inflammatory demyelinating polyneuropathy associated with SLE. It may be useful in other serious manifestions of SLE as a second line therapeutic approach in refractory cases.

Levamisole

The T cell immunostimulant drug levamisole, now widely used to manage colon cancer, first was noted to be effective for SLE in 1975, in a case report of an ANA-negative patient (212). This was followed by uncontrolled studies with conflicting results (213 ,214 ,215 ,216 ,217 ,218 ,219 ,220 ,221). The only controlled trial of levamisole was performed by Hadidi et al. (222). In their study, 26 patients with SLE who had been inadequately controlled by up to 30 mg/day of prednisone were given either 150 mg of levamisole or a placebo weekly for 6 months. Most patients had to have their steroid doses increased, and no improvements were observed.

Antilymphocyte and Antithymocyte Globulin

Because antilymphocyte globulin is immunosuppressive, it has been tried experimentally in a number of patients with SLE and is part of some ongoing stem cell protocols. Treatment usually has been combined with steroids and other agents. Fever as well as local and hematologic reactions have been frequent. Results generally are equivocal (223 ,224 ,225). In the largest and only controlled study (226), nine patients given antilymphocyte globulin, azathioprine, and prednisone did no better than those in a prednisone-only treated group. Pancytopenia was reversed in one patient given anti-thymocyte globulin (227).

Antibiotics

Chloramphenicol and its analogues inhibit antibody production by interfering with nucleic acid synthesis or (228). An analogue of chloramphenicol, thiamphenicol, was given to six patients with lupus nephritis (229). Following a 16-day course of 2 g daily, four patients had increased complement and decreased anti-DNA levels, lower antinuclear antibody titers, and disappearance of glomerular-bound gamma globulin. Sustained remissions function lasted for 9 months to 3 years following a single course of therapy. In 1979, Richmond (230) gave thiamphenicol to 13 patients with lupus nephritis for 2 weeks (231) and then reviewed the drug's record of inhibiting cell-mediated immune reactions and prolonging rat renal allograft survival. Symptomatic improvement was noted in only two patients, but six had serologic improvement.

Penicillin (232 ,233), sulfonamides (234 ,235 ,236), tetracycline (237), and streptomycin (238 ,239) also have been purported to help in SLE. The usefulness of these approaches is doubtful, however, and no controlled studies are available.

Interferon and Other Antiviral Agents

Interferon (IFN)-α induces the formation of anti-DNA and antinuclear antibodies (240). Numerous reports document the induction of SLE in patients who receive the drug for a variety of reasons (241 ,242 ,243 ,244 ,245 ,246 ,247 ,248 ,249 ,250), as well as IFN-ß-1a (251). IFN-γ administered for presumed rheumatoid arthritis induced multisystemic SLE in two patients (252 ,253), and 13 cases of its induction after therapy for hepatitis C have been reviewed (254). Schapira reviewed 24 cases of interferon-induced Raynaud (255). Surprisingly, IFN-α (especially intralesional) has been effective in managing patients with refractory discoid and subacute cutaneous lupus (256 ,257 ,258 ,259).

In one case report (260), isoprinosine given to a patient with lupus for a viral infection produced improvement in disease activity.

Thymosin and Thymectomy

Because the thymus gland is an important lymphoid organ in which lymphocytes differentiate, proliferate, and mature, experimental thymectomy has been undertaken to treat SLE, but with uniformly negative results (261 ,262 ,263 ,264 ,265 ,266). The administration of thymosin, or thymic hormone, represents the opposite approach. It increases T-lymphocyte counts, improves lymphocyte responsiveness, and decreases null-cell counts in vitro (267 ,268 ,269 ,270). Thymulin inhibits cytokine response in SLE (271). Factor V thymosin was given to four patients with SLE, and improvement was claimed in three, with no adverse reactions observed (272). Unfortunately, improvement was not defined or described, nor was the degree of disease activity in these patients stated. Thymus factor X was thought to be useful in a poorly documented report (273).

Vasodilators as Disease Modifying Agents

Prostaglandin E1 (PGE1) is a vasodilator that can suppress the effector systems of inflammation and both enhance and diminish cellular and immune responses (274). Several case reports have associated PGE1 infusion with improved renal function in lupus nephritis and decreased levels of

circulating immune complexes (275 ,276 ,277), as well as improving cerebral function and blood flow (278 ,279 ,280). Pentoxyfylline inhibits TNF-α gene transcription and may improve refractory nephrotic syndrome in high doses (800–1,600 mg) (279). Renal function also improved in a double-blind, crossover study of ten patients given a thromboxane inhibitor (281) as well as an open-label one (282 ,283), and the angiotensin-converting enzyme (ACE) inhibitor captopril (284) may be capable of reducing proteinuria. Chapters 35 and 36 discuss the use of vasodilators for pulmonary hypertension, severe Raynaud, and digital gangrene.

Rheumatoid Arthritis Biologics: TNF-α Blockers and Anakinra

Although TNF-α blockers have shown promise in animal models of SLE, their use in SLE has been complicated by the development of antinuclear antibody, anti-dsDNA and anticardioloipin antibody in 10% to 40% of lupus patients, especially those receiving chimeric preparations such as infliximab. This is infrequently clinically relevant, but numerous cases of drug-induced lupus have been reported with these agents (285 ,286 ,287 ,288 ,289). On the other hand, many patients with rheumatoid-like arthritis with SLE who do not have autoantibodies other than antinuclear antibody have had anecdotal good responses to TNF-α blockers. Recently, Smolen's group has shown that 6 lupus patients demonstrated clinical improvement with infliximab in patients with both renal and musculoskeletal disease (290) (see Chapter 44). The author believes that if the patient has a prominent inflammatory arthritis with a negative anti-dsDNA, TNF blockers can be carefully employed in selected patients with SLE.

Anakinra was well tolerated in 3 SLE patients with modest effects (291).

Drugs to Avoid: D-penicillamine, Minocycline, Sulfasalazine

d-Penicillamine, minocycline, and sulfasalazine clearly are effective for rheumatoid arthritis, and d-penicillamine may have antiscleroderma actions. These drugs have been given to patients with SLE who were thought to have rheumatoid arthritis or scleroderma. Because sulfa drugs and tetracyclines may exacerbate lupus (and can be photosensitizing) and d-penicillamine can induce lupus, extreme caution is advised if SLE is suspected (292 ,293 ,294) (see Chapter 44). The issue with sulfasalazine is more problematic because three reports among 15 patients have suggested that the drug is modestly effective for chronic-cutaneous (but not systemic) lupus (295 ,296 ,297). Several reports of drug induced lupus have appeared (298 ,299 ,300 ,301). It has been suggested that responders who are less prone to light-sensitive reactions tend to be rapid acetylators (295). I advise against using this drug in view of numerous reports of its exacerbating or inducing SLE (301) (see Chapter 44).

Should Radiation Therapy Be Avoided?

Although total lymphoid irradiation has been used to manage SLE (see Chapter 58), anecdotal reports of disease flares in patients undergoing radiation therapy for cancers are widespread. A review of the literature reveals cases of preexisting cutaneous lupus flared by radiation therapy (302 ,303 ,304) and one of widespread pelvic necrosis (305). On the other hand, a definitive 1993 matched-controlled, prospective evaluation of 61 patients with collagen vascular disorders failed to find an increased incidence of reactions compared with the autoimmune group (306). A smaller survey of six lupus patients supports this (307). Benk et al. reported that radiation therapy is often inappropriately denied to lupus patients, who uniformly tolerated treatments well at the University of Toronto (308).

Scleroderma patients seem to tolerate radiation therapy poorly with accelerated cutaneous and systemic fibrosis (309 ,310 ,311), and radiation issues with rheumatoid arthritis and other autoimmune diseases have been reviewed.

In summary, unless a patient has lupus with a scleroderma crossover, radiation therapy is very infrequently associated with any complications. I advise my patients who need radiation therapy to undergo it and have not had any problems.

Miscellaneous Agents

The use of novel immune suppressives such as lobenzarit, 15-deoxyspergualin, and the 5-lipoxygenase inhibitor zileuton (312 ,313 ,314) appear to be safe and have shown antilupus effects in small, open-labeled human trials. Heparin has been purported to help lupus psychosis (315).

The Russian literature contains numerous reports of the beneficial effects of methylxanthines, splenin, lysozyme, and prospidin (316 ,317 ,318 ,319). Other drugs and modalities that have been tried include tuberculin (320); arsenic (321); heliotherapy (322); paraaminobenzoic acid (323 ,324); colchicine (325); aminoglutethimide (326); hemotherapy (327); transfer factor (328); auriculo acupuncture (329); phenytoin (330); hyperbaric oxygen (331), topical DNCB (332), the complement inhibitor nafamostat mesylate (333); and sodium diethyldithiocarbamate (334). Routine splenectomy has been advised in patients without significant hematologic complications (335).

Chapter 62 discusses complementary, herbal, and vitamin therapies.

Chapter 67

Adjunctive Measures and Issues: Allergies, Antibiotics, Vaccines and Disability

Daniel J Wallace

Some of the most common queries that lupologists are asked to deal with relate to adjunctive issues. They do not concern treating lupus per se; rather, they relate to handling circumstances that have the potential to impact the disease. This chapter explores the following commonly encountered problems: (1) Do patients with lupus have more allergies than others, and in any case, should they receive allergy shots? (2) Should patients with lupus receive antibiotic prophylaxis before special procedures, and are there any antibiotics that warrant extra caution? (3) What about immunizations in general? (4) When and how are lupus patients disabled?

Do Patients with Lupus Have More Allergies (ATOPY) Than Healthy Individuals?

In 1976, Goldman et al. (1) first documented that patients with lupus had a significantly increased incidence of allergic rhinitis and drug allergy, although IgE levels were not different from those in healthy subjects. In 1985, a Spanish group (2) used Goldman et al.'s methodology and confirmed their data among 63 patients with systemic lupus erythematosus (SLE) compared to 51 autoimmune individuals, and 133 healthy volunteers. Of patients with SLE, 73% had evidence for urticaria, rhinitis, pharyngitis, conjunctivitis, asthma, or allergy to foods, drugs, and insect stings, compared with 37% of others. Sequeira et al. (3) found that 132 patients with SLE had significantly greater drug allergies, skin allergies, and insect allergies than 66 individuals with non-SLE disorders. Interestingly, their family members also had more allergies than the control group. Fifty-six percent of 44 Israeli patients with lupus had self-reported allergies (4). A series of papers in the last 10 years is at complete variance with these earlier conclusions. Sekigawa et al. concluded that 52 lupus patients had less allergies than 52 matched controls (5 ,6), confirming an abstract that atopic disorders are decreased in SLE (7), and a study among 101 lupus patients that pollen allergies are no different than in 130 healthy volunteers (8). Also life-threatening angioedema is extremely rare in SLE (9).

Elkayam et al. associated SLE flares in atopic patients with higher IgE levels (10), and 36 children of 26 Japanese mothers with SLE had higher IgE levels (11). However, a case-controlled study of 49 lupus patients in England found no increased risk of IgE mediated/associated allergic disorders (12). Two additional reports have confirmed elevated IgE levels in SLE patients (13 ,14), and two other studies suggest that this may reflect IgE-ANA and increased autoantibody formation (15 ,16).

Why Might Patients with Lupus Have More Allergies?

The issue of causation has been addressed on several levels. Diumenjo et al. (2) hypothesized three mechanisms: (1) a higher level of hypersensitivity to exogenous antigens, (2) anaphylactoid products of complement activation, or (3) cytotropic autoantibodies. Gruber et al. (17) found IgM-anti-IgE (in 27%) and IgG-anti-IgE (in 34%) antibodies among 67 patients with SLE. Significant correlations were observed with articular involvement, with lymphadenopathy, and anti-DNA antibodies as compared to those without the antibodies. IgE levels are increased in SLE, correlate with disease activity and not necessarily allergy (1 ,18 ,19). Urticaria and hives may or may not represent allergic responses to exogenous antigens. Sekigawa et al. has hypothesized that higher IgE levels noted in male SLE patients may reflect stronger hyperresponsiveness because of DNA hypomethylation that is not related to the influence of sex hormones (13 ,20).

Should Allergic Patients with Systemic Lupus Erythematosus Receive Allergy Shots (Immunotherapy)?

Immunotherapy (i.e., desensitization protocols) was introduced early in this century to help allergy sufferers, and it became clear that giving immunotherapy to otherwise healthy individuals carried a risk of nonspecific formation of

autoantibodies. In a study at Louisiana State University, 40% of patients with allergic rhinitis (one half of whom were receiving immunotherapy) had a positive antinuclear antibody (ANA), compared with 11% who had miscellaneous medical diseases and 10% of healthy controls. This observation did not extend to rheumatoid factor, anticytoplasmic antibodies, or anti-DNA (21). Among asthmatics, 7 of 50 (four of whom were receiving immunotherapy) had an ANA of 1:40 or greater, compared with none of 35 patients with miscellaneous medical diseases (22). Phanuphak and Kohler (23) related the onset of polyarteritis nodosa with immunotherapy in six patients. On this basis of studies such as these, as well as of personal anecdotal experiences that autoimmune patients flared their disease after receiving allergy shots, the World Health Organization (WHO) Working Group of the International Union of Immunological Sciences formally recommended in 1989 that patients with autoimmune disease not receive immunotherapy (24 ,25). Tanac et al, studied 63 asthmatic children. Of those who underwent immunotherapy, 17.5% developed autoantibodies, but none were symptomatic (26). Table 67.1 summarizes these considerations.

Table 67-1: Lupus, Allergies, and Allergic Reactions

1. There is probably no increased prevalence of atopy and allergies in lupus patients.
2. Lupus patients have higher IgE and IgE associated autoantibodies, but this is not clinically relevant.
3. Lupus patients are more sensitive to sulfa based antibiotics, which can flare the disease, and this is rarely cross-reactive with sulfa-based nonantibiotic preparations.
4. Allergy immunotherapy needs to be individualized; it can lead to disease flares and increased autoantibody formation in a minority with SLE.

In our own practice, about one half of our lupus-allergy patients have at least a mild flare of symptoms after having allergy shots, and we prefer alternative therapies to desensitization protocols.

Lupus and Antibiotic Allergies

In 1992, Petri and Albritton (27) published an exhaustive case-control study of 221 patients with SLE, their 186 best friends, and 178 relatives from the Johns Hopkins Lupus Cohort. As expected, sulfa antibiotic lupus flares (in 21%) and reactions (defined as rash, hives, fever, asthma, nausea, or lupus flare, and noted in 31%) were the most pronounced. Significantly increased reactions also were found among those given penicillin/cephalosporins, tetracyclines, and erythromycins. A letter to the editor responding to Petri and Albritton's survey confirmed these findings (28). Of 250 drug reactions reported in one center among patients with SLE, 30 were to sulfonamides, 25 to penicillin, 20 to cephalosporin, 19 to tetracyclines, and 18 to erythromycin. This represented 57% of 340 patients with lupus, compared with 14% of their 303 chronic arthritis clinic patients. Forty-seven reactions were to nonsteroidal anti-inflammatory agents (NSAIDs). Another survey reported an odds ratio of 2.6 for medication allergies and 1.8 for hives in a case-control study of 195 patients with SLE (29). Pope et al. queried 249 patients, 145 of whom had SLE. Over half with lupus were sulfa allergic (p = 0.003) (30). This was confirmed by Cooper et al. among 265 recently diagnosed patients in the Carolinas who had an adjusted odds ratio of sulfa allergy at 2.8 (31).

Are There Any Antibiotics that Lupus Patients Should Avoid?

Because patients with SLE tend to develop more infections than healthy people, the choice of optimal antibiotics is a frequently encountered problem. Sulfonamides (and, to a lesser extent, tetracyclines) are noted for their sun-sensitizing properties, which can flare rashes, occasionally induce fevers, and exacerbate the disease in general (27 ,28 ,29 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40). Sulfa antibiotics are only rarely cross-reactive with sulfonamide nonantibiotics (nonarylamine sulfonamides). Thus patients who need diuretics, diabetic oral agents or nonsteroidals that contain sulfa rarely encounter a problem (41).

Minocycline can induce a lupuslike reaction, autoimmune hepatitis and a positive p-ANCA directed against myeloperoxidase (42 ,43 ,44 ,45). Among 27,688 acne patients aged 15 to 29, individuals taking minocycline had a 8.5-fold increased risk for developing a lupus reaction (46). Hess recently reviewed some of the speculative mechanisms by which this could occur (47). The above-mentioned antibiotics commonly are prescribed for young women by their dermatologists (for acne) and gynecologists (for urinary-tract infection), who frequently are unaware that treating a patient with lupus warrants special antibiotic considerations. The previous section details the studies that document this (27 ,28 ,29).

On a practical level, we tend to divide antibiotic reactions into those that cause skin rashes or urticaria alone (penicillins/cephalosporins, erythromycins) and those that produce disease flares as well. Sulfa-based antibiotics are well-known provocateurs of disease activity and should be used with extreme caution; preferably, they should be avoided. Although uncommon, ciprofloxacin and its relatives can induce a vasculitic reaction (48), arthralgias (49), and flares of SLE (50).

Should Lupus Patients Receive Antibiotic Prophylaxis?

Although bacterial endocarditis is rare, an established consensus recommends that antibiotic prophylaxis be given to high-risk patients before dental and certain surgical procedures (51). Miller et al. found that 18.5% of 361 lupus outpatients had a heart murmur, but only 13 (3%) had a

significant valvular abnormality warranting antibiotic prophylaxis (52). However, patients with SLE, especially those with antiphospholipid antibodies, are at an increased risk for developing cardiac vegetations. These vegetations usually are asymptomatic, and they are noted on two-dimensional echocardiograms approximately 30% of the time (53) (see Chapter 32). Because as many as 40% of patients with lupus have at least one antiphospholipid antibody, and because mitral valve prolapse is more prevalent in patients with SLE we recommend that all of our immune-suppressed patients with lupus receive antibiotic prophylaxis before dental procedures (54). The drug of choice is amoxicillin, although erythromycin, penicillins, and cephalosporins are acceptable alternatives in ampicillin-sensitive patients.

Should Patients with Lupus Be Immunized?

The issue of immunization is both controversial and misunderstood. This section attempts to clarify the misunderstandings and to summarize the salient points, including the following:

- Infrequent reports have claimed that immunizations induce systemic lupus (55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63). Older et al. and Shoenfeld et al.'s 1999 and 2000 literature reviews report 24 cases of SLE following vaccination: 10 after hepatitis B, 3 typhoid/paratyphoid, 8 “combinations”, 2 anthrax, and 1 tetanus (64 ,65).
- Patients with SLE tolerate most immunizations well, and adverse reactions are uncommon (66). Disease flares, however, may be slightly more frequent than the incidence of spontaneous flares (67).
- Immunizations are less effective in patients with SLE who are on high doses of corticosteroids. In one survey, protective levels of antibody after immunization were achieved in 90% receiving tetanus toxoid, 88% with *Haemophilus influenza* type B, and slightly more than half receiving pneumococcus (68). Antibody responses depend on the concentration of antigen, HLA type, and concurrent medication. Patients with lupus might make more anti-DNA and other autoantibodies after repeated immunizations (69).
- Immunizations with killed vaccine (e.g., pneumococcus, influenza, tetanus) generally are regarded as safe, but the safety of live vaccines (e.g., polio, mumps, Flu Mist, yellow fever, measles, rubella) has not been established in patients with SLE who are on high doses of steroids or cytotoxics. When somebody living with a severely immune-compromised patient with lupus receives a live vaccine, the patient should avoid secretory contact with them for 2 weeks.
- The putative mechanisms by which vaccine associated lupus can arise include: rabbits or mice immunized with protein or oligopeptides that are lupus autoantigens can develop clinical lupus, killed microbial components of the vaccine can produce an adjuvant reaction, and molecular mimicry (reviewed in (70)).

What About Specific Immunizations?

In 1980, Jarrett et al. (71) reported on their experience administering pneumococcal vaccine to patients with SLE. Mean antibody levels at both 1 and 12 months following vaccination were significantly lower than those in control patients in this and other groups (72 ,73 ,74). However, in follow-up studies (75 ,76), the persistence of pneumococcal antibodies in immunized patients was found to be protective for a mean of 3 years. In a double-blind, controlled study, Klippel et al. (77) obtained similar results. Concurrent immunosuppression did not affect response (78).

In similar studies of *influenza vaccination* in patients with SLE, Williams et al. (79) noted no disease flares but decreased antibody titers compared with a control group in a double-blind trial. Three other studies have reported similar findings (80 ,81) whereas two others found no increased rate or disease flares or decreased effectiveness (82 ,83) Herron et al. (84) observed that antibody responses are especially decreased in steroid-treated patients; of 20 immunized patients, one experienced a serious flare after injection. Influenza vaccines rarely induce a systemic vasculitis (85). Mitchell et al. (86) attempted to study the kinetics of specific anti-influenzal antibody production by cultured lymphocytes following immunization, but in vitro responses (which have been reported to be decreased) (87 ,88) did not correlate with in vivo changes. Louie et al. reported that four of 11 immunized patients did not develop significant levels of antibodies and one developed new-onset proliferative nephritis (89). Abu-Shakra reported the short-lived formation of IgG or IgM cardiolipin antibodies in 9 of 24 lupus patients after influenza vaccination (90).

Abe and Homma (91) administered *tetanus toxoid* to 200 subjects with SLE and a similar number of controls. No difference in antibody titer existed between these groups following both primary and secondary immunizations, but a subgroup had lower antibody responses. In one study, the time of appearance of the antibodies and serum titers were normal in patients with SLE (92), but others found lower responses (93) and documented a restricted IgG1 response (94). Nies et al. (95) studied antitetanus toxoid antibody synthesis after booster immunization in SLE and a control group. The patients with SLE had decreased prebooster antibody levels, and one third had a blunted antibody response. It was shown that the blunted response results from poor B-cell responsiveness and is not related to T helper or suppressor function. In an ominous follow-up report (69), this group found increased anti-DNA production in vitro following keyhole limpet hemocyanin immunization. This was especially true after secondary immunization and might represent a risk from the repeated immunization of patients with SLE, although there is no evidence that the anti-DNA contains pathogenic subsets.

Severe exacerbations of SLE have been reported after *hepatitis B vaccines* (62 ,96 ,97), and the vaccine has been thought to induce lupus (59 ,60 ,61 ,63 ,98 ,99). Fifteen lupus patients had a lower antibody index compared with

14 normal controls, and in one unit, all SLE pediatric dialysis patients failed to seroconvert after hepatitis B vaccination (100 ,101). Self-reported associations are higher. Forty-two patients responded to a query in a Lupus Foundation of America newsletter claiming the onset of lupus within weeks of hepatitis B vaccine (99).

Additional reports have examined responses to other microbes. Antibody responses after immunization with flagellin derived from *Salmonella* Adelaide, Proteus 0X-2, and *Rickettsia rickettsi* were normal (92 ,102), decreased with antistreptolysin O, *Escherichia coli,* and *Shigella* sp. (102 ,104), and both increased and decreased with *Brucella* sp. (103 ,105).

In summary, we recommend that patients with SLE should receive all necessary immunizations. Children of patients with SLE who are immunocompromised and receive live-virus vaccines should avoid secretory contact with their parent for approximately 1 to 2 weeks, or a rheumatologist should be consulted. They also should be consulted before giving routine, but not necessary, immunizations (e.g., influenza) to patients on steroids or to those with active disease. In 1996, the British Society of Rheumatology Clinical Affairs Committee issued guidelines stating that (a) patients on 40 mg of prednisolone a day should have vaccinations postponed until at least 3 months after immune-suppressive treatment has been stopped, or doses lowered to 20 mg a day, and (b) though hepatitis B vaccination is usually safe, further study of its role in autoimmunity was recommended (106).

The Economic Impact of SLE and Disability Issues

Health resource utilization in SLE has only recently been addressed. A three-country study suggested that the mean cumulative costs per patient over a 4-year period in Canada, the United States, and the United Kingdom were $13,509, $22,724, and $15,537, respectively. Thus, increased expenditures in the United States did not assure superior health outcomes (107). The same group noted that direct costs were one third and indirect two thirds of the total (108). Most of the indirect costs related to disability.

Being able to work has a significant impact on our economy and productivity, and most lupus patients who wish to work are employed. Lupus patients often find employment difficult due to fatigue, inflammation, swollen joints, medications, cognitive dysfunction, cardiopulmonary compromise, seizures precluding having a driver's license, or difficulty coping with the disease. Cutaneous lupus limits outdoor employment; Raynaud mandates a warmer workplace. Lupus patients often function best in a flexible environment where they do not have to “clock in or out” and their job is more task or project oriented. They should be able to pace themselves with several rest periods during the day.

Many lupus patients find it difficult to obtain disability insurance. Historically, Social Security disability with Medicare benefits has been reserved for patients with active, organ-threatening disease even though many of them are working without any obvious impairment.

A small number of studies have addressed the employability of lupus patients. Out out of Petri's 916 patients in the Hopkins cohort, 197 were receiving disability payments (109). They tended to have increased Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) damage scores. Two early surveys suggested that disability correlated with disease activity, marriage or family responsibilities, and musculoskeletal complaints (110 ,111). The advent of the Stanford Health Assessment Questionnaire (HAQ), clinical activity, and damage indices resulted in three recent disability surveys with differing results. In Saskatchewan, Canada, only 14% of 160 SLE patients were receiving disability payments, which did not correlate with HAQ scores and suggested only mild functional impairment (112). HAQ scores do not measure psychological impact or deal with concurrent fibromyalgia. Partridge et al.'s university-based group from five centers noted that 40% of 159 newly diagnosed SLE patients had quit work within 3.4 years (113). The predictors of early work disability were not having greater than a high-school education, receiving Medicaid, being without health insurance, having a job requiring physical strength, an income below poverty level, or greater disease activity at diagnosis. Half were African American. Murphy et al. similarly noted that 52% of 46 patients at the University of Pennsylvania (most were African American) had applied for disability as a result of fatigue, musculoskeletal, or neuropsychiatric symptoms (114). The musculoskeletal objective findings were minimal. In our experience, most community-based SLE patients with a high-school diploma are employed. If fibromyalgia is excluded, most disability is found among those with serious organ-threatening disease, neuropsychiatric impairments, and avascular necrosis (115).

Chapter 68

Issues in Drug Development in SLE: Clinical Trial Design, Outcome Measures, and Biomarkers

Vibeke Strand

Introduction

No new treatments for SLE have been approved in over 40 years. The heterogeneous population combined with the multisystemic and variable disease course has made it extremely difficult to develop and gain regulatory approval for new treatments. The difficulty defining outcome measures that function well in randomized controlled trials (RCTs) has slowed clinical testing of new therapies, while the absence of a regulatory precedent, against which new treatments may be compared, has made it difficult to draw meaningful conclusions from existing data.

This chapter will review how to assess outcome in RCTs in SLE, lessons learned and future directions. The U.S. Food and Drug Administration (FDA) has recently released the *Guidance for Industry Systemic Lupus Erythematosus—Developing Drugs for Treatment* to help develop a roadmap for development of promising new therapies. Its recommendations are discussed, as well as the use of biomarkers as early endpoints to assess efficacy in RCTs, and to prospectively identify a patient population with active disease who may best respond to a new therapeutic intervention. Although there are no newly approved therapies at this time, there are many efforts underway to facilitate their development.

Domains to Assess in SLE RCTS: OMERACT Recommendations

The international consensus effort in rheumatology: “outcome measures in rheumatology clinical trials” (OMERACT) recommended in 1998 that five domains be assessed in all SLE trials: disease activity, damage, health related quality of life (HRQOL), adverse events, and economic impact (1 ,2). No recommendations have been made regarding how the domains should be measured in RCTs, and SLE specific instruments have largely been developed based on data from longitudinal observational studies and may not perform as well in clinical trials (Table 68-1).

Measures of Disease Activity

Disease Activity Indices

Six disease activity indices (DAIs) have been developed; Chapter 47 discusses these. They are the: British Isles lupus assessment group index (BILAG), systemic lupus erythematosus disease activity index (SLEDAI) and safety of estrogen in lupus erythematosus national assessment trial version of SLEDAI (SELENA-SLEDAI), systemic lupus activity measure (SLAM), European consensus lupus activity measurement index (ECLAM), lupus activity index (LAI) and SLE index score (SIS). The SLEDAI/SELENA-SLEDAI/SLEDAI 2000, SLAM/SLAM-R, BILAG, ECLAM, and LAI have all been shown to be sensitive to change and validated against each other (1 ,3 ,4 ,5 ,6). Ideally, DAIs facilitate comparisons across patients with differing organ system involvement.

Although validated against each other, the DAIs do not function interchangeably, because of differences in their methodologic development, items included and weighting of disease manifestations (7). Although there is good evidence for validity, discrimination, and feasibility in cohort studies, few DAIs have been used or validated in RCTs, and no agreement exists as to which indices perform best (8 ,9). SLEDAI preferentially weights involvement in the CNS and renal organ systems, whereas SLAM scores fatigue and other patient-reported symptoms. An early version of the SLEDAI was first used in a placebo-controlled withdrawal trial supporting the efficacy of hydroxychloroquine in SLE (10). Both SLEDAI and SLAM have been updated: SELENA-SLEDAI/SLEDAI 2K, and SLAM-R, in part because of difficulties with their use in clinical trials (11 ,12). The most detailed of the instruments is the BILAG, which assesses each involved organ system in detail, resulting in a score that recommends when treatment should be instituted or changed. It has also been regularly updated (13 ,14).

Because SLE can have a relapsing, remitting course, DAIs identify disease activity, which may or may not imply severity, outcome, or damage (1 ,15). Although SLEDAI scores at initial presentation have been shown to correlate with

mortality, organ damage and development of coronary artery disease, these outcomes may not occur within the limited time frames pragmatically assessed in RCTs (16 ,17). Physician assessments may not correlate with patient assessments of disease activity or severity—renal involvement is frequently asymptomatic until it is severe or long-standing, or active cerebritis may interfere with a patient's understanding and reporting of disease manifestations (18). Thus, DAIs may not accurately reflect outcome in relatively short-term RCTs, and should be supported by secondary measures.

Table 68-1: OMERACT Domains and Measurement Tools

Domain	Measurement Tool
1. Disease activity	Disease activity indices: SLEDAI/SELENA-SLEDAI/SLEDAI 2K, SLAM/SLAM-R, BILAG, ECLAM, LAI and SIS Renal flares SLE flares
2. Damage	SLICC/ACR damage index (SDI) End-stage renal disease (ESRD) Renal biopsy
3. Health-related quality of life (HRQOL)	SF-36 SLE specific measures under development
4. Adverse events	Organ damage Hospitalization Death
5. Cost or economic impact	Direct and indirect costs Health utilities; EQ 5D, HUI, SF-6D

Additionally, without sufficient training, even scoring within the same index can vary dramatically. Currently, it is recommended to use a computer program to generate scores for all five DAIs from a single-entry form, although pragmatically it has not been possible to collect all components of each index within a single program (13 ,19). Efforts to develop standardized reporting will allow researchers to utilize their index of choice and facilitate clinical research efforts and exchange of information within the scientific and medical community.

Renal Flares

Measures including renal flare (either proteinuric or nephritic based on changes in urinary protein and sediment) and/or treatment failure, e.g., lack of improvement in renal function, have been successfully utilized as endpoint measures in the NIH series and recent trials with abetimus sodium (20 ,21 ,22). These outcomes have been shown to be valid in RCTs, especially if confirmed by a separate data adjudication committee (23 ,24).

Although results from the NIH trials have informed clinical practice for several decades, application and confirmation of the clinical significance of similar definitions to current, multicenter RCTs are problematic. Site-specific spun urine sediments cannot be accurately verified at a central lab after shipment, nor is it pragmatically possible to confirm reported findings using a local lab. Changes in 24-hour urine protein levels per se are not useful, unless considered in the context of accurate creatinine clearance (CCr) determinations, which may be influenced by administration of/or changes in ACE inhibitors, NSAIDs, or COX-2 selective inhibitors. Although iothalamate glomerular filtration rates (GFR) most accurately reflect changes in renal function, they are expensive, performed differently across sites and remain unavailable at many other sites, further challenging their practical utilization in multicenter RCTs. Recent publications, reflecting experience in RCTs and observational cohorts, demonstrate that urinary protein/creatinine ratios predict clinically meaningful changes and when to perform 24-hour CCr and protein determinations—indicating they are a pragmatic and appropriate substitute, given the frequency of inaccurate sample collections (25).

Another concern with using renal flare as the sole measure of disease activity is that rarely do renal manifestations represent isolated organ system involvement. In one series, when isolated hematuria (>5 RBC/hpf) was observed, 81% of SLE patients had nonrenal disease manifestations, 48% other renal abnormalities, 53% decreased complement levels, or increased anti-dsDNA Abs. In patients with isolated pyuria (<5 WBC/hpf without infection), 82% had nonrenal manifestations, 58% other renal abnormalities, and 57% either decreased complement or increased anti-dsDNA Abs (26). It is therefore important to assess all organ systems in a RCT in SLE, as patients may not develop the same pattern of involvement with each disease exacerbation. An added complexity is that patients with active disease may have improvement in one organ system yet develop new or worsening manifestations of SLE in another system. Thus, defining improvement in disease activity can be very complex.

SLE Flares

The Fortin definition of “Major SLE Flare”—initiation or increase in immunosuppressive or high dose corticosteroid therapy, hospitalization, or death because of SLE—is easily applied and may not require adjudication when utilized in an RCT (27 ,28). Recent trials have prospectively defined “mild/moderate” and “severe” SLE flares, by increases in SELENA SLEDAI greater than or equal to 3 or SLEDAI-2K greater than or equal to 4 (11 ,29 ,30 ,31 ,32 ,33). The BILAG DAI identifies disease flares as “A” for major flare and “B” for moderate flare, and improvement from an A to a C or D in these absolute states may function well as an endpoint in a clinical trial, provided it is linked with disease activity indices and patient reported outcomes reflecting overall “no deterioration,” e.g., stabilization or improvement (34).

Other definitions for disease flares—renal, major SLE, or other—have evolved over time. All may function equally well in a RCT, but must be defined a priori. Accepted, standardized definitions for disease and organ-specific SLE flares would help to compare results across trials in differing protocol populations.

Measures of Damage

SLICC/ACR Damage Index

The SLICC/ACR damage index (SDI) measures organ system damage that has been present for at least 6 months, because of the disease or its treatment (35 ,36 ,37). It is designed to identify irreversible damage, and should not be assessed more frequently than every 6 months. It has successfully demonstrated that early damage is associated with high dose corticosteroid use and is a predictor of mortality (38 ,39). Nonetheless, experiences in several recent RCTs with the SDI indicate that deterioration, as well as improvement, may be identified with both placebo and active treatments—whether a result of difficulties in interpretation and training, patient heterogeneity, or inter-intra observer variability. The SDI should be used as a component of outcome where improvement in disease activity must also be considered in the context of no worsening in any organ system. It may be particularly useful as a means of stratifying patients at trial entry because increased damage is prognostic of a worse outcome.

Other Measures of Damage

End-stage renal disease (ESRD) is a valid measurement of damage, but usually occurs too infrequently to be practical as an endpoint in RCTs of 6 to 18 months duration. Importantly, progression to ESRD is variable: in a variety of RCTs, it was identified in 6% to 29% of patients over 3 to as long as 20 (mean 8.36) years of observation (40 ,41 ,42 ,43 ,44 ,45 ,46). Importantly, less than 10% of patients studied developed ESRD within 3 to 5 years, the maximal length of time it is pragmatically feasible to observe patients following enrollment in a clinical trial. Useful predictors of progression to ESRD include: lack of response of proteinuria to initial treatment, high serum Cr and/or high disease activity or chronicity by renal biopsy, racial differences, male gender, age, severe infection, hypertension and duration of disease at baseline (40 ,43 ,47 ,48 ,49). Doubling of serum Cr has been found to be highly correlated with development of ESRD (50). A more pragmatic definition for use in RCTs may be an approximately 50% increase from baseline in serum Cr (51).

In a cohort study of 87 patients with SLE nephritis, the delay between diagnosis of renal disease and renal biopsy was a significant predictor at the time of first biopsy for subsequent renal insufficiency and death (52). Biopsy definitions of activity and chronicity help to define the need to add or change therapy, but have neither been utilized nor are accepted as regulatory endpoints in RCTs (53 ,54). In part, this may be a result of the potential morbidity of the procedure and its limitations, including sampling errors; as well as the difficulty mandating clinical practice within a clinical trial setting.

Measures of Health Related Quality of Life (HRQOL)

Valid, objective measures of HRQOL are clinically useful, as patient and physician perceptions of disease activity and global health may differ (55 ,56). HRQOL has been found to be lower and uniquely affected in patients with SLE compared with normal age- and gender-matched controls, as well as patients with other chronic diseases. Furthermore, decrements in HRQOL correlate with increased disease activity and organ system damage (57 ,58 ,59).

Assessment of HRQOL is difficult to capture on a large scale, as mean changes across treatment groups in RCTs may not be statistically significant, yet clinically meaningful to individual patients. Furthermore, mean or median improvements in a treatment group that are statistically significant compared with placebo may not necessarily be clinically meaningful or readily understood. An individualized patient reported measure of improvement, stabilization, or deterioration in HRQOL can be a valuable addition to disease assessment and management.

Measures of physical function, including the Health Assessment Questionnaire (HAQ), modified HAQ (MHAQ), Arthritis Impact Measurement Scale (AIMS), and Krupp Fatigue Severity Scale (KFSS) measure physical function and/or fatigue, but do not assess HRQOL across multiple domains in SLE (1). The generic Medical Outcomes Survey Short Form-36 (SF-36) has best reflected the impact of SLE in observational cohort studies (60 ,61 ,62 ,63 ,64). It accounts for fatigue and physical function, including discretionary activities such as walking a mile or shopping. Thumboo et al. showed SF-36 to have high internal consistency, with acceptable test-retest reliability, except role-physical, with mean differences in repetitive test scores of less than 2 points in five of eight domains. SF-36 scores weakly correlated with BILAG scores and SDI (damage) scores, suggesting divergent construct validity of the SF-36—meaning it offered an independent assessment of the impact of SLE (65).

The SF-36 has been widely tested, translated in many languages and culturally back translated and extensively validated in a variety of chronic diseases including rheumatoid arthritis, osteoarthritis, psoriatic arthritis and systemic sclerosis (66 ,67). As country specific normative values are available, this allows comparison of HRQOL in SLE with other chronic diseases within a given society. It has been recommended to assess HRQOL in patients with SLE since 1995 (68). Improvements in SF-36 scores correlate with decreases in disease activity and damage (69). Decrements in SF-36 scores reflect ESRD and immunosuppressive use (70). Together with a patient global assessment of disease activity by Visual Analog Scale (VAS), the SF-36 performs well as a patient reported measure of HRQOL in SLE, where both physical and mental domains are frequently affected by active disease.

Adverse Events

Adverse events are reported in a standardized manner in RCTs and may include organ damage, hospitalization, or death—attributable to treatment and/or the disease. Demonstration of clinical utility of a therapy necessarily requires assessment of its risk/benefit profile. Requiring that a patient must not have developed a severe or irreversible

adverse event before assessing clinical response may facilitate such an evaluation (71).

Economic Costs

The direct cost of resources utilized because of disease, therapy, or adverse event needs to be evaluated in any new treatment of SLE. There are also defined indirect costs: time lost from work, work in the home, childcare costs, loss in productivity, and so on that affect the patient (59). Treatment and medical costs, as well as personal and productivity losses, need to be accounted for in a systematic manner. Recently, a study of 485 patients in Canada, the United States, and the United Kingdom found mean cumulative costs per patient over 4 years were $15,845, $20,244, and $17,647 in the three respective countries. Canadian and British patients utilized 20% and 13% less resources than U.S. patients, but experienced similar health outcomes (72). Merely spending more money treating SLE does not guarantee superior health outcome. Furthermore, indirect costs are at least as large as, if not larger than, the direct costs of SLE (73). Reducing the economic impact of SLE requires treatments that reduce inability to work both within and outside the home, as well as the direct costs of the disease and its treatment.

Lessons Learned: It Is Difficult to Assess Outcome in SLE RCTS Disease Activity Indices

In a recent RCT, SLAM and SLEDAI did not similarly identify patients with active disease nor demonstrate similar improvements or deterioration in the same patients (71). SLAM scores range from 0–86 (SLAM-R 0–8 1), active disease is defined by a score more than 7 (4). SELENA/SLEDAI scores range from 0 to 105, rarely do patients have scores more than 20; scores approximately 2 have been shown to reflect inactive disease (74). Changes in SELENA/SLEDAI/SLEDAI 2K scores have been used to define “flare”: flare = an increase more than or equal to 3 or more than or equal to 4, “improvement” = a reduction more than 3, “persistently active disease” = a change of +/- 3, and “remission” = a score of 0 (11 ,29 ,30 ,31 ,32 ,33).

The adjusted mean SLEDAI (AMS) was developed as a way to summarize disease activity over time (16 ,17). It is equivalent to the area under the curve of SLEDAI-2K over time divided by time interval and is able to capture the multiple facets of a patient's profile over any time period. Used with a time-dependent covariate survival regression, change in AMS and length of time from visit to visit is accounted for, versus fixed variables, such as gender or SLEDAI-2K at presentation. AMS can reflect disease activity over time as an important predictor of major outcomes in patients with SLE, but has never been utilized in an RCT (16 ,17). As with all AUC analyses, it is difficult to interpret whether small statistically significant changes are clinically meaningful or that an overall positive result despite a fluctuating course of improvements and deteriorations is a desired outcome.

Only one disease activity score, BILAG, specifically developed to identify the need to institute, increase, maintain or discontinue current treatment based on clinical signs and symptoms—may perform best of the DAIs to “protocolize” management of patients in a clinical trial—that change of therapy would only be allowed when indicated by BILAG. If used in this way to manage patients on a per-visit basis, its use as a primary outcome measure in a clinical trial may be confounded. To date, there is no experience with using it as a primary outcome measure in a regulatory sanctioned RCT, nor as an “area under the curve” analysis of disease activity.

Definitions of “Flare”

Over time a body of evidence has developed that shows the number of major and/or minor SLE flares over 12 months can be predicted in selected populations, which can be used as a meaningful measure of clinical benefit. Decreased number of flares with active treatment implies prevention—the amount of time required to demonstrate this as clinically meaningful remains unclear.

In the anti-CD40L mAb RCT reported by Kalunian et al., the SLE flare index identified flares over 12 months in 65% of patients receiving placebo; 10% of these were considered severe (75). In a series of 250 patients, Gordon and Isenberg identified 26% with BILAG “B” and 10% with “A,” or major SLE flares, over a 12-month period (33). Not dissimilarly, in the SELENA RCTs, in 351 and 183 randomized patients: 51% to 64% and 89% to 76% flared; in 5% to 8% and 8% to 9% these were severe (30 ,32). As demonstrated in both abetimus sodium protocols, a predefined definition of “renal flare” was shown to be reproducible, adjudicated, and confirmed by a separate “renal events committee” (23). In patients with elevated anti dsDNA antibodies, and a prior history of SLE nephritis, renal flares were reported in 3% and 4% receiving active therapy, and 21% and 20% placebo (76). In comparison, analyses applying the Fortin, or “generic” definition of major SLE flare identified flare rates of 24% with active therapy in both studies, compared with 42% and 31% with placebo (24). The lower rate of major SLE flares in the placebo group in the second study may be attributed to a variety of causes, including differing patient populations and background immunosuppressive use, but the identical renal and/or major SLE flare rates with active therapy in both protocols are striking. In both the SELENA and abetimus sodium RCTs, it was shown that patients with a history of renal disease or stable active disease have higher rates of major disease flares.

Definitions of Renal Damage

A positive response to treatment of SLE nephritis may be defined by stabilized or improved renal function. Several clinical measures of response and/or remission have been

used in RCTs and are summarized by Schiffenbauer et al. (21 ,22). Positive responses have included: approximately 50% decline in hematuria with less than 5 RBC/hpf, nonnephrotic proteinuria less than 1 g/day or nephritic proteinuria less than 3 g/d with an approximately 50% decrease, and no cellular casts (Table 68-2 and 68-3).

In a RCT comparing mycophenolate mofetil (MMF) with azathioprine (AZA) in patients with diffuse proliferative lupus nephritis by Chan et al., definitions of complete and partial remission functioned well, with long-term responses in 90% of each group in a follow up publication (77 ,78). Only 4 patients, all randomized to receive CTX-AZA, developed ESRD or death. Contreras et al. compared MMF with AZA or CTX for maintained remission following induction therapy with CTX or AZA and found significant differences between treatment groups (51). In the open label comparison of MMF with CTX for induction therapy, Ginzler et al. employed the following definitions: Complete remission on initial regimen: +/- 10% of normal Cr, inactive urinary sediment and proteinuria less than 500 mg/24 hour; partial remission: less than or equal to 50% improvement of baseline values, without 10% worsening in any parameter; and treatment failure in patients failing to show greater than or equal to 30% improvement in greater than or equal to 1 renal parameter at 12 weeks who were offered cross-over to the alternate therapy (79). Although specific definitions of response and deterioration in renal function varied, all successfully identified clinically meaningful lack of improvement or worsening, which occurred in a small number of patients over protocol observation periods of 12 to 18 months.

Table 68-2: Severe SLE Flares≫ over 12 Months: Data from Longitudinal Observational Studies [LOS] and Randomized Controlled Trials [RCTs]

Study	Flare Definition	[n]	Flare Rates
IDEC 131[75] anti CD40L RCT	SLE Flare Index	n = 94	65% any flare 10% severe flare
Isenberg [34] Gordon: LOS	BILAG	n = 250	62% “A or B” flare 10.4% severe, “A” flare
LJP RCTs [23,76]	“Fortin definition”[28]	n = 250	35% major flare
Buyon [32]	SELENA SLEDAI	n = 351	51–64% any flare
HRT RCT			4.9–8.1% severe flare
Petri [30]	SELENA SLEDAI	n = 183	69–76% any flare
OC RCT			8.4–8.7% severe flare
Sanchez [31]	Δ in SLEDAI	n = 162	84–95% any flare
Guerrero			3.0–9.0% severe flare
RANGE:	“Any flare” mild, mod or severe: “severe flare”: Relative risk for “severe flare”: stable active disease: “Major or severe flare” in patients w/ history of renal disease:	49–95% over 12 months 3–10% over 12 months 2.87–3.50 [p <0.05] history of renal disease: 2.2 [p = NS] [30,32] 31–42%, mean 35% over 12 months [23,76]	

Other Definitions of Damage: Bone Mineral Density

Patients with SLE receiving glucocorticoids show bone mineral density (BMD) loss over time because of disease activity as well as corticosteroid treatment. In a RCT in SLE patients with mild to moderate disease receiving glucocorticoids, prasterone (dehydroepiandrosterone [DHEA]) treatment significantly increased BMD at both lumbar spine and total hip (80). Bone mineral density can also be used as a measure of damage due to SLE and/or its treatment.

What Have We Learned from HRQOL Assessments?

Use of SF-36 physical and mental component (PCS and MCS) summary scores can lead to a falsely negative result when real changes in HRQOL have occurred. The summary scores minimize changes, especially in SLE where decrements and improvements in multiple domains, mental as well as physical, may frequently occur simultaneously. In an observational study of patients with depression, use of the PCS was insensitive to change whereas scoring each domain reflected improvements with treatment (81). Examining changes across all eight domains, rather than the summary PCS and MCS scores, may better reflect treatment associated improvements.

Table 68-3: Examples and Definitions of Endpoints in Some Renal Trials

Renal flare
Illei et al.: an episode of increased activity of SLE nephritis; classified as either proteinuric (defined as an increase in protein uria >2 g/day with a stable serum creatinine level and inactive urinary sediment, no cellular casts and <10 red blood cells (RBCs)/high powered field (hpf)) or nephritic (defined as mild or severe; mild: defined as reappearance of cellular casts or >10 RBCs/hpf with an increase in proteinuria <2 g/day and with a stable serum creatinine level; severe: defined as reappearance of cellular casts or >10 RBCs/hpf with an increase in serum creatinine 30% over the level at the time of complete response regardless of the level of proteinuria).
Alarcon-Segovia et al.: that it be attributed to SLE by the treating physician and/or medical monitor and one or more of the following three criteria were met:
A. a reproducible increase from baseline in 24 hour urine protein;
B. a reproducible increase from baseline in serum creatinine of >20% or at least 0.3 mg/dL, whichever was greater, accompanied by proteinuria (>1,000 mg/24 hours), hematuria (>4 RBC/hpf) and/or red cell casts; or
C. new reproducible hematuria (>11–20 RBC/hpf) or a reproducible increase in hematuria by two grades compared to baseline associated with >25% dysmorphic red blood cells of glomerular origin, exclusive of menses, accompanied by either an 800-mg increase in 24-hour protein or new appearance of RBC casts.
Treatment Failure
Houssiau et al.: defined as one of the following three features:
D. For patients with baseline serum creatinine levels >1.3 mg/dL and <2.6 mg/dL: absence of a primary response

1. serum creatinine levels >1.3 at 6 months;
2. for patients with baseline serum creatinine >2.6 mg/dL: serum creatinine levels that did not improve by 50% at 6 months;
3. for patients with nephritic syndrome but without renal impairment at baseline; persistence of nephritic syndrome at 6 months.

E. Glucocorticoid resistant flare. Doubling of serum creatinine over the lowest value reached at any time during follow up and confirmed on two consecutive visits 1 month apart
Complete Renal Remission
Chan et al.: proteinuria <0.3 g/24 hours, with normal urinary sediment, normal serum albumin and serum creatinine and creatinine clearance values within 15% of baseline values.

Reported HRQOL, by SF-36, improves significantly in patients with sustained reductions in anti-dsDNA Abs, whether receiving active treatment or placebo (82). Furthermore, active treatment-related improvement is maintained, even in those who develop renal or major SLE flares (83). In these trials, patient global assessments of disease activity paralleled reported SF-36 scores, showing improvement when HRQOL was maintained or improved. Interestingly, patient perceptions of improvement and deterioration were not symmetrical (82).

The minimum clinically important difference (MCID) or degree of improvement in patient reported outcomes perceptible to them, on an individual basis, is considered to represent clinically meaningful change. Improvements of 33% to 36% over baseline (or 18% >placebo) are thought to be clinically important (84 ,85). In rheumatoid arthritis, and osteoarthritis, improvements of 5 to 10 points in individual domain scores of SF-36 and 2.5 to 5 points in PCS and MCS summary scores can be considered to represent MCID (86 ,87 ,88 ,89 ,90). Although these definitions are relevant only on an individual basis, when median changes within a treatment group exceed MCID, the majority of patients are reporting clinically meaningful changes. Another analysis that has been helpful in RA has been comparison of the percentage of patients with improvement which meets or exceeds MCID (91).

In the phase 3 abetimus sodium trial, definitions of MCID in SF-36 domains and summary scores were based on a 15-point global change scale, after Guyatt et al., corresponding to improvement by a score of 6: “a little better” and worsening by a score of 10: “a little worse” (92). MCID was determined to range from 6.7 to 11.4 points in domain scores and 3.4 to 3.9 in PCS scores, consistent with literature reported values in RA and OA and other chronic diseases (82). Of interest, clinically important worsening ranged from -14.7 to 1.7 for domains and -2.1 and -0.8 for MCS and PCS, respectively—demonstrating that MCID was not symmetrical. Although it has yet to be determined how significant changes in patient-reported HRQOL should be predefined in a RCT, definitions of clinically meaningful improvement, which meet or exceed MCID, or stabilization (“lack of deterioration”) may offer another useful means to support the efficacy of a new therapy.

Disease-specific HRQOL instruments are currently under development in SLE and include:

- A symptom checklist published in quality of life research in 2003/2004 (93)
- An instrument developed by Leong et al. published in *Rheumatology* in 2005 (94)
- The SLE-QOL: an instrument from UK researchers, reported in abstract form at the 2004 International Society of Quality of Life Research meeting (95 ,96)

Use of both generic and disease-specific measures of HRQOL are complementary and important in RCTs; as well as supporting economic analyses. Generic instruments facilitate comparisons across diseases but may not measure all domains of interest to an SLE patient; disease-specific instruments reflect the more important aspects of HRQOL and are likely more sensitive to change.

Responder Analyses

A well-constructed SLE responder index would merge the information from the various DAIs, SDI (damage), and HRQOL measures into a single definition that would identify a patient as either a “responder” or “nonresponder.” Responder indices are presented on a per-patient basis, facilitate comparisons across treatments, are easy to use and report, and gain statistical power with repeated use. But a responder index without prospective, objective validation in RCTs is not reliable as a measure. Several responder analyses have been proposed in recent trials but without supportive data from prior RCTs to indicate their validity.

The response index for lupus erythematosus (RIFLE) was first proposed for use in a placebo RCT evaluating anti-CD40L, where the active treatment failed to differentiate from placebo by SELENA SLEDAI or other secondary measures: BILAG, physician and patient global disease activity, time to flare, KFSS and SF-36 (75 ,97). An initial placebo RCT examined whether prasterone would allow reduction of corticosteroid use in steroid-dependent patients with SLE. “Responders” were defined as those receiving approximately 7.5 mg/day prednisone for a least 2 months including the last observation over the 7- to 9-month treatment period (74). In those with active disease, defined as SLEDAI scores greater than 2 (omitting scoring for anti-dsDNA Abs and complement levels), a significant number of patients receiving active therapy were classified as responders compared with placebo. In a second prasterone trial, a “responder” definition proposed in collaboration with the FDA required that patients could not have developed new adverse organ system manifestations, either because of treatment or their underlying disease, based on SDI (damage) (71). If these criteria were met, then patients were assessed for “improvement and/or stabilization” by two physician-assessed DAIs: SLEDAI and SLAM, and two patient-reported measures: global disease activity and KFSS (fatigue). In the large subset of patients with active disease at baseline, statistically more patients receiving active treatment were responders than with placebo.

Another important point is that improvement and/or stabilization, e.g., “lack of deterioration” should be considered a response, especially in SLE with a relapsing and remitting course, characterized by heterogeneous and unpredictable organ system involvement. Statistical definitions of no change or improvement must account for test-retest variability in these measures, which can be large. For example, differences in screening and baseline values for SLEDAI, SLAM, KFSS, and patient global assessed 7 to 14 days apart in patients with “stable” disease and no change in treatment ranged from 0.5 for SLEDAI and KFSS to 1 .0 for SLAM and 10 mm for patient global assessment by VAS (71). And “lack of deterioration” implies that patients cannot have significant worsening during the trial, even over a short period of time (e.g., >30 days, requiring change in therapy).

Systemic Lupus Erythematosus (SLE) Guidance Document

The U.S. FDA recently released a draft *Guidance for Industry Systemic Lupus Erythematosus—Developing Drugs for Treatment*, discussing the development of new therapies for SLE designed to offer useful guidelines for clinical trial development (54). It was developed after several meetings of the Arthritis Advisory Committee discussing trial design in SLE. Written in the absence of a regulatory precedent, it is meant to be advisory, to help develop a roadmap for promising new therapies. It is published in the Federal Register and posted online, where comments are invited: http://www.fda.gov/cder/guidance/index.htm. The document defines treatment, as well as disease-induced damage and queries whether the SDI (damage) could identify all treatment associated toxicities, noting that distinguishing between disease and treatment associated damage would greatly help understand the safety of new therapies. It suggests the definition of “major SLE flare” to be useful and states that serologies and/or surrogate markers may function as supportive evidence of efficacy, although none as yet have been validated. It adds patient global assessment of disease activity to the list of recommended outcome measures and suggests that fatigue and HRQOL are important measures to assess.

Claims for Approval from the FDA *Draft* Guidance Document

The FDA SLE Guidance Document outlines five proposed claims for treatment, presented below, with selected pertinent comments.

- ‘1. Reduction in Disease Activity

  Because the BILAG evaluates patients based on the need for additional treatment, the clinical interpretation of a change in score is apparent. For other indices, deciding whether changes in score are clinically

meaningful may be more complicated. If a disease activity measure other than the BILAG is chosen, confirmation of a positive result with two different DAIs would be important to confirm the findings.

- 2. Treatment of Lupus Involving a Specifically Identified Organ

  For products being proposed for use in the manner of a specified short course of treatment leading to induction of a sustained remission, studies of 3 to 6 months' duration may be acceptable with longer-term follow-up for safety and durability of response. For products being proposed for chronic use, studies as short as 1 year may be considered.

- 3&4. Complete Clinical Response/Remission

  Complete absence of disease activity at all sites for at least 6 consecutive months. This response is termed complete clinical response if the subjects continue to receive SLE-directed therapies. Remission occurs if subjects were receiving no ongoing therapy for their SLE. A trial in support of the claim of complete clinical response should be at least 12 months in duration and demonstrate an increase in the proportion of subjects in whom a disease activity measure achieves zero.

- 5. Reduction in Flares

  Proposals for clinical trials using renal and/or major SLE flare as an endpoint should: (1) provide a clear and accepted definition for flare, and data supporting the choice of that definition; (2) provide evidence that reducing flare incidence by that specific definition of flare would be expected to translate into a clinical benefit to the patient; and (3) assess the durability of the clinical benefit. A successful clinical trial could be defined as an increase in the time-to-flare or as a decrease in the number or severity of flares over the course of a 1-year trial.”

Trial Design and Analysis

Although the major precedent for SLE trials remains the combined NIH experience in nephritis, it is difficult to design RCTs for organ specific damage as most patients have multisystem disease. Thus trials designed to focus only on selected organ system involvement must also assess global health/HRQOL.

Protocol mandated treatment regimens with early rescue—a predefined endpoint of “treatment failure”—are preferred to individual patient management within a protocol. Definitions for when to end a trial because of unforeseen adverse effects or other patient safety concerns must be predetermined.

In designing trials with time-to-flare analysis as an endpoint, all patients should be exposed to the same duration of treatment, which can be difficult to justify if treatment benefit is evident in one group but not another. Stopping studies when a sufficient number of events have accrued may be risky; not knowing their distribution between active and placebo treatment.

Patients cannot be denied standard of care. Therefore, new medications must be tested in an add-on or head-to-head comparison design. Placebo controls are additionally difficult to use except in the presence of background therapy, which leads to confounding polypharmacy. Pharmacokinetic and pharmacodynamic interactions between existing and additional treatments require documentation. An accepted standard of care within the protocol needs to be clearly delineated for the protection of patients.

Studies to Show Superior Safety or Comparable Efficacy

These trials aim to provide the superiority of a new treatment over an existing one. Promising therapies may be compared to accepted therapy, to show superiority or noninferiority. If the goal is only comparable efficacy, then a nonequivalence design may be utilized, which will usually allow a smaller sample size.

Currently only hydroxychloroquine, aspirin, and prednisone are approved for use in SLE. Although not specifically labeled for treatment of SLE, cyclophosphamide is considered standard of care for nephritis. Treatment regimens omitting cyclophosphamide are gaining rapid acceptance and may be used as the active comparator—azathioprine has been widely utilized in Europe, as confirmed in the EURO LUPUS trial, and several RCTs have shown promising results with mycophenolate mofetil (51 ,77 ,78 ,79 ,98).

Alternatively, if superior efficacy to accepted standard of care can be demonstrated for a new therapy, priority review may be considered under the US Code of Federal Regulations (CFR), which govern the regulatory role of the FDA: 21 CFR 314, subpart H or 21 CFR 601, subpart E (99 ,100). These regulations provide that the agent must treat a serious or life-threatening disease, provides meaningful therapeutic benefit over existing treatments, and then require further studies post approval to verify the clinical benefit. This precedent was established with therapies for AIDS, and failure to show benefit in phase 4 may lead to expedited withdrawal. It can be very difficult to demonstrate statistical superiority of a treatment in an active controlled trial, especially when only limited RCT data are available to support the efficacy of active comparators in SLE, and only three agents are currently labeled for use. Demonstration of superiority may therefore require a combined analysis of safety as well as efficacy.

It is also important for trials to be sufficiently powered to demonstrate that if a new product is not inferior to an accepted therapy that it has at least as good or improved safety profile. The two recently published SELENA-SLEDAI RCTs demonstrated the noninferiority of hormone replacement therapy and oral contraceptives to placebo by the number of disease flares in patients with SLE (30 ,32).

Similarly, it is appropriate for steroid-sparing agents to demonstrate not only that reduction in steroid use is statistically significant, but that these reductions are clinically meaningful as well as reflecting an improved safety profile.

Past definitions of clinically meaningful changes include sustained reductions in daily prednisone dose to approximately 7.5 mg—tapering regimens have never been agreed upon or strictly adhered to in an RCT. As with DAIs developed by Delphi process, consensus proposed tapering regimens may be difficult to adhere to when managing a heterogeneous protocol population (101). To demonstrate an improved safety profile is even more challenging as it is difficult to know how to adequately power trials to show statistical differences in safety.

Phase 2 Trials

Phase 2 trials are used to explore the dosing, activity, and toxicity of prospective treatments. Safety of patients needs to be of concern and possible interactions with background treatments need to be evaluated. Outcome measures in phase 2 trials should be carefully evaluated for validity and sensitivity for use in phase 3 trials, as information about the new therapy is most likely incomplete at this point in its development. It is important to note that small phase 2 trials in SLE have substantial risk for being underpowered, given the heterogeneity of the disease population, organ system involvement, requirement for background therapy, and so on.

Phase 3 Trials

Concomitant medications pose a complication for RCT designs in SLE. Acceptable baseline levels of medication and acceptable treatment changes should be defined. Rescue medications and patient withdrawal from the study must also be considered. All RCTs must be adequately blinded to ensure lack of bias. Extension studies should be considered for long term evaluation, but in general, most trials should be at least 12 months long in duration.

Candidate Biomarkers/Surrogate Markers as Endpoints

Biomarkers or “early markers” indicate when a therapeutic agent has been successfully delivered, and has the desired pharmacodynamic effect, which may ultimately reflect potential clinical benefit. Surrogate markers substitute for a clinically meaningful endpoint, and are laboratory measurements or physical signs which have been shown to directly correlate with, and predict clinical outcome.

Biomarkers are an appealing idea for early detection of disease and treatment evaluation, and there is scientific interest in exploring when biomarkers may substitute for clinical endpoints in phase 3 trials, especially in a challenging indication such as SLE. At an NIH workshop held in 1998, participants agreed this primarily applied to situations where trials using clinical endpoints were not feasible, as in the case of ESRD or mortality (102). That no RCT has successfully led to regulatory approval of a new treatment for SLE again raises the question of whether the therapy or the outcome measures failed in these trials.

Table 68-4: Promising Biomarkers in SLE

Class	Examples
Autoantibodies	Anti-dsDNA Abs
Complement and complement split products	C3, C4, CH_{50} Erythrocyte surface CR1/C4d ratios Reticulocyte surface C4d levels
Alterations in circulating B and plasma	CD27 high-plasma cells,
Cell subsets	CD19+, CD20+ B cell subsets
Interferon-α “signature”	IFN-α gene products
Other cytokines	sIL-2R, sTNF-R, IL-6, and IL-10

As there are no currently accepted biomarkers for SLE clinical trials, to use the term “surrogate markers” is premature. In other areas of clinical evaluation, experience has shown that identifying biomarkers and surrogate markers is very difficult and requires a large combined experience of many RCTs (9). Nonetheless, “early markers” of disease activity based on the biologic effects of a therapy should and can be used in SLE trials, and have been extensively reviewed by Illei and Lipsky (103 ,104). Such markers can be particularly useful in phase 2 studies, prior to definitive demonstration of efficacy. Ongoing efforts are underway to identify SLE biomarkers, supported in part by NIH NIAMS, as well to validate and standardize their means of identification (105).

Approval may be based on a validated surrogate endpoint. If the surrogate is not validated, but appears to be reasonably likely to predict a clinical benefit, accelerated approval may be considered under 21 CFR 314, subpart H or 21 CFR 601, subpart E (99 ,100). In this case, approval would be contingent upon a phase 4 study to verify the clinical benefit. Supporting the proposition that the surrogate is reasonably likely to predict clinical benefit is essential to this approach.

Although there are no regulatory precedents at this time, there are biomarkers, which may be suitable to suggest to the FDA for inclusion as examples to support a subpart H or E discussion and are presented below. Importantly, biomarkers may also serve to prospectively identify a patient population with active disease who may best respond to a new therapeutic intervention (Table 68-4).

Anti-dsDNA Antibodies

Anti-dsDNA Abs are the leading biomarker candidate based on published evidence that increasing anti-dsDNA Abs levels may predict disease flares in at least a subset of patients with SLE. Prospective studies have shown anti-dsDNA Abs often rise well before a major SLE flare and decrease at the time of or following a flare (106). Several studies suggest that increases in anti-dsDNA Abs can be used to initiate

pre-emptive treatment to reduce renal flares. Swaak et al. followed 143 SLE patients for as long as 6 years demonstrating that twofold increases in antidsDNA Abs predicted 22 major disease exacerbations (21 renal, 12 nonrenal) and no flares in those with stable anti-dsDNA Ab levels (107). ter Borg et al. followed 72 SLE patients showing 24 of 33 exacerbations were predicted by significant increases in anti-dsDNA Abs levels 8 to 10 weeks prior to flare, a more sensitive measure than complement 3 or 4 levels for predicting exacerbations (108). In two subsequent series, anti-dsDNA Abs were measured monthly; patients with predefined increases (with or without accompanying symptoms) were randomized to conventional treatment or prospective addition of 30 mg prednisone or MMF daily (109 ,110). In both reports, clinical relapses at 6 months were significantly less in patients receiving expectant therapy. Using anti-dsDNA Abs as an indication to treat, only 2 of 22 with active treatment relapsed, versus 20 of 24 with placebo. These observations are consistent with series of “clinically quiescent, serologically active” patients described by Gladman et al., and recently by Buyon et al., where expectant treatment resulted in fewer disease exacerbations (111 ,112).

In an open label series of patients receiving the anti-CD40L mAb BG9588, reductions in anti-dsDNA Ab levels were associated with decreases in identified anti-dsDNA Ab-producing B cells, increased complement 3 levels, and decreased hematuria (113 ,114). In two placebo RCTs in 487 SLE patients, Linnik et al. confirmed that decreases in anti-dsDNA Abs correlated with increases in complement 3 levels and less risk of renal flare over time (76). Fifty percent reductions in anti-dsDNA Ab levels were associated with 52% (95% confidence interval [95% CI], 26%–68%, nominal p <0.0007) and 53% reductions (95% CI, 33%–69%, nominal p <0.0001) in the risk of renal flare in the two trials, respectively. As discussed previously, sustained reductions in anti-dsDNA Abs were associated with improvement in patient reported HRQOL in these trials whether in patients receiving active therapy or placebo superimposed on background therapy. As anti-dsDNA Abs may mediate at least some of the brain damage observed in neuropsychiatric SLE; this mechanism may help to explain these findings (115).

The data support the use of anti-dsDNA Ab titers as a biomarker, viewed in the context of corresponding improvements in complement 3 levels and HRQOL and fewer SLE and renal flares in patients with sustained reductions, but only in the subset of patients with these autoantibodies (116). To be used as a valid and reliable biomarker, standards need to be developed for measuring anti-dsDNA Abs, including when sampling should occur, the relationship between increases in Ab levels and clinical flares, as well as definitions utilized to identify prospective changes. Utilizing a central lab and the correct assay method is critical. For example, the Farr assay is preferable to other ELISA based tests to determine anti-dsDNA Abs, despite its expense, technical requirements, and use of radioactive material (117).

Complement and Complement Split Products

Erythrocyte CR1/C4d Ratio

Complement consumption is a hallmark of active SLE, although historically assays have been insensitive to change until complement synthesis is outstripped by activation with persistent immune complex formation and deposition. Manzi and Ahearn et al. have shown that ineffective clearance of complement-bearing immune complexes by erythrocytes expressing complement receptor 1 (CR1) leads to persistently decreased erythrocyte CR1 and elevated complement 4 split product, C4d, levels with high diagnostic sensitivity and specificity for SLE (118 ,119). In pilot, cross-sectional studies, two color-flow cytometric analyses of erythrocyte C4d (E-C4d) and E-CR1 levels show little change in normal individuals over time; abnormally high E-C4d and low E-CR1 levels are 81% sensitive and 91% specific for SLE compared with healthy individuals, and within an individual SLE patient fluctuate over time and appear to correlate with disease activity (120). Because erythrocytes have a lifespan of approximately 120 days, E-C4d levels likely reflect cumulative complement activation and disease activity over that range of time; reticulocyte bound C4d (R-C4d) may serve as a better reflection of current or impending disease flares and are elevated in patients with SLE compared with normals and other diseases; fluctuations correlated with disease activity as measured by SLEDAI and SLAM. Once this assay is commercially available for pragmatic use in RCTs it may prove to be a very promising biomarker.

Although no RCTs have been performed in SLE with specific complement inhibitors, promising data have been reported with a mAb to complement 5 (eculizumab) in paroxysmal nocturnal hemoglobinuria, demonstrating excellent correlations between improvement in complement levels, measures of hemolysis, and decreased transfusion requirements (121).

Alterations in Circulating B and Plasma Cell Subsets

Although T cells and dendritic cells play well-documented roles in SLE, a central role for B cell hyperactivity has been recently clarified by several open label series with promising therapeutic agents. Specific alterations in circulating B and plasma cell subsets in patients with active SLE and normalization after treatment may serve as useful biomarkers. CD27 is expressed on memory B cells, and a subset of plasma cells, which have been shown to be greatly expanded in peripheral blood of patients with active SLE (122). Flow cytometric analysis of CD27hi plasma cells may be a reliable assessment of disease activity (123).

Circulating T and B cells in patients with active SLE spontaneously express CD40L or CD1 54, suggesting that activated lymphocytes are being released from germinal centers (GCs), which facilitate autoantibody production. Grammer et al. studied CD1 9+ peripheral B cells before

and after treatment with humanized anti-CD40L mAb (BG9588, 5c8) (124). CD38 plasmablasts not found in normal individuals were evident in the circulation, which disappeared following treatment, as did CD38hiIgD^{+} and CD38^{+}IgD^{-} B cell subsets. Disappearance of the bright CD38 plasma cells was associated with decreases in anti-dsDNA Abs, proteinuria, and SLEDAI scores.

Tocilizumab

In a pilot open-label study of tocilizumab, a humanized anti-IL-6 receptor mAb in patients with active SLE, ESR levels fell, and disease activity improved (125). Abnormal circulating CD19lowIgD- plasma cells decreased with treatment: IgD+ B cells, functionally anergic, disappeared and increased levels of naïve CD19hiIgD^{+}CD27^{-}CD21^{+}CD23^{-} B cells normalized, with associated increases in CD19hiIgD^{+} CD27^{-}CD21^{+}CD23^{+} B cells.

Rituximab

Rituximab, a chimeric anti-CD20 mAb, depletes circulating B cells, with more rapid and complete depletion in SLE patients with a specific FcγIIIR polymorphism (126 ,127 ,128). In patients who were “good depletors,” remaining B cells expressed a homogenous memory phenotype, whereas a heterogeneous population of naïve and memory B cells, as well as a high percentage of pre-GC CD38 cells, remained in “poor depletors.” In several recent open-label series, B cell depletion with rituximab led to a sustained clinical response with some reports of impressive disease improvement and variable effects on anti-dsDNA Abs (129 ,130 ,131).

Epratuzumab: Epratuzumab is a humanized mAb to the CD22 surface antigen on B cells that negatively regulates BcR signal transduction and B cell homing, which has been shown effective in more than 300 patients with NHL. An open-label series in 14 SLE patients with BILAG “B” activity in one or more organ systems was positive, demonstrating B cell depletion without immunogenicity (132).

B Lymphocyte Stimulator (BLyS) Antagonists

BLyS is a vital B cell growth factor released by activated monocytes and macrophages, which binds to B cell receptors and promotes antibody production (133). A variety of antagonists to BLyS are in development, including anti-BLyS mAb (belimumab). Preclinical and clinical results to date show that belimumab reduces circulating CD20^{+} B cells, activated B cell subsets and immunoglobulin levels. An observational study of 244 SLE patients over 2 years found 35% of patients had elevated BLyS at one or more time points which statistically correlated with SLEDAI scores, IgG levels and anti-dsDNA Abs (134). A phase 1 study using belimumab in SLE demonstrated selective depletion of B cells with no overt toxicity (135).

Together, the body of data following administration of promising therapeutics, targeting different cell surface antigens, growth factors and cytokines, suggest that alterations in circulating B- and plasma cell subsets will function as useful biomarkers both to ascertain successful delivery of the agent and to correlate with improvements in clinical status.

Interferon-a “Signature”

IFN-α gene expression is increased in SLE and correlates with both disease activity and severity in a subset of patients (136 ,137). Plasmacytoid dendritic cells, a source of type I IFNs, are decreased in SLE plasma but elevated in involved skin and kidney. Oligonucleotide microarray profiling of peripheral blood mononuclear cells in patients with active and inactive SLE has revealed a distinct IFN-α gene product profile or “signature,” which seems to correlate with active disease manifestations and reflects response to treatment with high dose glucocorticoids (138 ,139). Patients with high levels of IFN-α gene products had a higher prevalence of renal disease and SDI (damage) with low C3 levels and Sm and RNP autoantibodies rather than anti dsDNA Abs (140).

As DNA in anti-dsDNA complexes and apoptotic debris activate IFN-α via Toll-like receptors, it is unclear whether the interferon “signature” of induced gene products is responsible for activation of disease or a pathologic marker of disease activity (141). A variety of agents, including mAbs to IFN-α and IFN-α/ßR, mAbs to FcγIIa, IL- 10 and IL- 18, and mAbs to BDCA2 on plasmacytoid dendritic cells inhibit ongoing IFN-α production and are being explored as therapeutic options in SLE (142). Identification of an increased IFN-α “signature” may represent a promising biomarker to identify patients with impending flares, or active SLE, as well as responses to treatment.

Other Cytokines

Unregulated cytokine production, including TNF-α, IL-6, IL-18, and IFNs are overexpressed systemically and locally and play a large role in the inflammatory response in SLE that leads to irreversible organ damage. IL-6 plays a critical role in the B cell hyperactivity and immunopathology of human SLE, and may have a direct role in mediating tissue damage (143). Serum IL-6 levels do not predict disease activity in patients with SLE, although urinary IL-6 may identify active nephritis (144). Increased serum IL-10 and IL-6 levels have been repeatedly shown in patients with active SLE, as well as first-degree relatives (145). Serum IL-10 levels correlated with anti-dsDNA Ab titers, with a weak correlation between circulating IL-10 levels and disease activity as measured by SLEDAI but not SLAM (146). IL-6 and IL-10 levels may play a role as biomarkers in the future; inhibitory agents including monoclonal antibodies targeting their effects will likely better clarify their actions.

Several series have shown that increases in soluble IL-2 receptor (sIL-2R) levels occur during flares of SLE and

decrease with treatment and clinical improvement, especially in patients with nephritis (147 ,148). Circulating levels of soluble p55 and p75 TNF-α receptors have been reported to be increased in patients with active SLE and may also serve as potential biomarkers of disease activity. An open label series administering the anti-TNF mAb, infliximab, led to improvement in arthritis and proteinuria, although was associated with increased anti-dsDNA Abs in a few patients who received re-treatment (149 ,150 ,151).

In summary, the variety of symptomatology and cyclical nature of SLE indicate that consistent biomarkers across patient populations may be difficult to validate. Sensitive and reproducible measures of anti-dsDNA Abs and/or complement activation/depletion, presence of circulating abnormal B cell subsets including preplasma and plasma cells and/or elevated levels of IFN-α, IL-6, and IL-10, or their gene products may serve as biomarkers of active disease as well as potential targets for therapeutic intervention. A variety of multiplexed assays are now available which efficiently analyze hundreds or thousands of samples simultaneously, which should significantly further efforts to identify promising biomarkers (152).

Lessons Learned and Future Directions

Designing successful RCTs for SLE is quite difficult. Specifically, outcome measures are complicated to define and reproduce in such a variable disease. Because of the cyclic nature of the disease it can be difficult to assess clinical endpoints over fixed time intervals. Often in SLE, there are poor correlations between patient and physician assessments of disease activity. Responder analyses do not function well if they are used before validation in early RCTs. Repeatedly in SLE, it has been difficult to replicate findings from one promising trial in a larger confirmatory trial—changes in medical practice at both an individual and group level may confound treatment effects. Objective outcome measures are well defined in renal and hematologic disease, and proposed for other manifestations, but few SLE patients have isolated organ system involvement at any one time. And it is critical to always assess patient reported outcomes.

Attainment of predefined endpoints may require prolonged therapy. If a benefit is conferred over short term or extension trials, a control group becomes unethical, even with background therapy. Yet, there is a need for a control group, although background therapy—even if stable for a period of time prior to enrollment—may well confound treatment effects. Research designs must include definitions for increasing, tapering, or stopping of glucocorticoid doses, as well as criteria for removing patients from the trial if their treatment requires prohibited medications or other nonprotocolized management. Thus trial designs must anticipate treatment of emergent disease manifestations and changes in disease course. Definitions of increased disease activity, flare, and allowed concomitant treatment must be established before trial initiation and strictly adhered to. Protocol mandated treatment regimens should therefore offer early rescue when a predefined endpoint of treatment failure is reached, rather than allowing individualized patient management within a protocol.

Patient selection criteria must also take into account demographics and disease activity and/or damage levels that contribute significantly to the heterogeneity of the SLE population. Although it is appealing to try and define specific criteria to identify a more homogeneous and responsive population, these have so far eluded us. Hopefully data from ongoing and future RCTs will help to inform these efforts, including the use of promising biomarkers.

Although there is a limited body of evidence derived from RCTs, early markers of treatment response have correlated with longer term clinical outcomes and may facilitate future treatment development. Some potential candidates have been discussed in this chapter. If they are biomarkers, it is crucial to use validated methods and a central lab to assure consistency and reproducibility of the assays. Importantly, biomarkers may prospectively identify a patient population with active disease who may best respond to a new therapeutic intervention.

Acknowledgments

The author would like to thank Paul Brunetta, MD, Marc Chevrier, MD, Dafna Gladman, MD, David Isenberg, MD, Maarten Kraan, MD, Joan Merrill, MD, Barbara Mittleman, MD, Michelle Petri, MD, Joel Schiffenbauer, MD, Jeff Siegel, MD, Josef Smolen, MD, and and Julian Thumboo, MD for their detailed reviews and helpful comments.

Chapter 69

Prognosis, Mortality, and Morbidity in Systemic Lupus Erythematosus

Dafna D. Gladman

Murray B. Urowitz

The concept of the clinical spectrum of systemic lupus erythematosus (SLE) has evolved over the last 50 years. Before identification of the LE-cell phenomenon in 1948, the diagnosis of this condition was difficult. In 1971, the preliminary criteria for the classification of SLE, based on knowledge of the disease at the time, were described (1), but they included few laboratory tests. These criteria were revised in 1982 (2) and again in 1997 (3) to include serologic tests that had become more generally available. Many patients who had been labeled as having lupus in earlier studies would not meet the current criteria for diagnosis of the disease; on the other hand, mild cases of SLE in the past would have been overlooked. A recent study documented that the application of the 1997 criteria would have excluded two patients from a longitudinal cohort study because of the removal of the LE cell preparation, while the addition of the anticardiolipin antibody to the criteria set would not have affected the inclusion of patients had the LE cell test remained (4). Therefore, early survival studies included only those patients with severe SLE who could be diagnosed by biopsy or at autopsy; thus, long-term survival was unusual. After the introduction of corticosteroids in 1948, the reported survival times in SLE improved significantly. All of these factors have conspired to produce an improved survival in SLE over time. This chapter examines survival in SLE, predictors for mortality, and causes of death. Other important prognostic outcomes that contribute to morbidity in patients with SLE also are discussed.

Survival Analysis

Early studies of survival in patients with SLE reported that no more than 50% survived the first 3 years of their illness (5 ,6). Merrell and Shulman (7) introduced the life-table method to describe survival in SLE and defined the time of diagnosis of SLE as the start point for calculating disease duration. In their classic 1955 study (7), data extrapolated from 99 cases of SLE predicted that 78% of these patients would be alive 1 year after diagnosis, 67% after 2 years, and 51% after 4 years. Patients who were diagnosed within 2 years of the onset of symptoms had a poorer survival. Subsequent studies demonstrated better survival in the 1960s than in the previous decade (8 ,9 ,10 ,11). Dubois' group pioneered large-scale survival studies with reports in 1956 and 1963 (12 ,13) that included 163 and 520 patients, respectively. In the 1956 survey, the 5-year survival rate was 40%. Of the 60 patients from the presteroid era, or those who were inadequately treated, 50 succumbed within 2 years after diagnosis. The duration of disease from diagnosis to death was divided by Dubois into three periods of observation: (1) 1950 to 1955, (2) 1956 to 1962, and (3) 1963 to 1973. This was not an artificial division; 1956 marked the first time that central nervous system (CNS) lupus was treated with high doses of steroids, and 1963 marked the general availability of procedures such as the use of potent nonmercurial diuretics and peritoneal dialysis. The median duration of disease (until death) in the group treated before 1955 was less than 2 years, and by 1973, it had increased to 8.5 years (14).

In 1966, Leonhardt (15) studied 54 Swedish patients with SLE and obtained survival curves from the time of diagnosis of about 90% at 1 year and 70% at 5 years whereas matched normal individuals had 97% and 94% 5-year and 10-year survivals, respectively. Estes and Christian (16) used Merrell and Shulman's methods on 150 patients who were seen between 1962 and 1970, 90 of whom received steroid therapy. The 5-year and 10-year survival rates were 77% and 59%, respectively. Urowitz et al. (17) reported a 5-year survival rate of 75%, whereas the 10- and 15-year survival rates dropped to 63% and 53%, respectively. In a subsequent evaluation by Lee et al. (18), the first- and second-year survival rates were estimated at 93.1%, and by 5 years, the survival rate decreased only to 91.2%.

Tremendous improvement in survival was evident throughout the 1970s. Urman and Rothfield (19) evaluated the survivorship of 156 patients who were treated at the University of Connecticut between 1968 and 1976, and they compared it with that of 209 of Rothfield's New York City patients who were treated from 1957 to 1968. Although the validity of comparing two such totally disparate groups has been questioned, the 5-year survival rates were 93% and 70%, respectively. Over 90% received steroids, but less than 1% were treated with immunosuppressive drugs. Improved survival was attributed to better disease understanding, newer antibiotics, use of C3 and anti-DNA to monitor activity, and judicious adjustment of steroid

doses. The prevalence of CNS disease decreased significantly between the two groups.

In 1981, Wallace et al. (5 ,20) evaluated the course of 609 patients who had been followed in Dubois' private practice since 1950. The overall 5-, 10-, and 15-year survival rates were 88%, 79%, and 74%, respectively. Overall survival improved only in those who were diagnosed since 1970. Patients older than 50 years of age had a benign course, and children did well (100% 10-year survival) only if renal disease was not present. At least 100 of the 609 patients were off all medication and in complete remission for at least 5 years. These findings are consistent with those in a report by our group (21) of several patients with severe multisystem disease who were off all medications and were asymptomatic a mean of 75 months later.

Ginzler et al. (22) reported the results of a nine-center study of 1,103 patients in 1982. The 5- and 10-year survival rates were 86% and 76%, respectively. (Note the similarity to the Wallace data.) No improvement in survival was noted in the patients entered between 1965 and 1970 compared with those entered between 1971 and 1976. One-half of the patients received public funding, and they had a significantly lower survival rate. Overall, whites lived longer than African Americans, but this difference was not noted in the privately funded patients.

Other investigators have reported better survival rates in patients with SLE than those found in the Wallace and Ginzler studies. At the Johns Hopkins Hospital, 140 subjects had 94% and 82% 5- and 10-year survivals, respectively (23). A British group (24) observed 98% 5-year survival among 50 patients who were followed for 29 months. Fries and Holman (25) reported that more than 90% of their 193 patients survived for 10 years. Jonsson et al. (26) identified 133 patients with SLE out of 158,572 Swedish individuals. Only nine deaths occurred in these patients, and the 5-year survival rate was 95%. In India, however, patients with SLE have not fared as well, with survival rates of 68% at 5 years and only 50% at 10 years (27). In a large, hospital-based Danish study (28 ,29), 39 deaths occurred between 1965 and 1983, and an 80% 10-year survival rate was reported, which did not change when patients were divided into those diagnosed before and those diagnosed after 1973. Similarly, a Dutch group (30) that followed 110 patients between 1970 and 1988 noted only 14 deaths, with survival rates of 92% and 87% at 5 and 10 years, respectively. Reveille et al. (31) examined survivorship in 389 patients who were seen at the University of Alabama hospitals between 1975 and 1984. The 89 deaths in this group provided 89% and 84% 5- and 10-year survival rates, respectively. In another southeastern U.S. study of largely publicly funded patients, Studenski et al. (32) reported the outcomes of 411 patients who were observed between 1969 and 1983 at Duke University hospitals in North Carolina. Only patients who were seen within 2 years of diagnosis were considered. The 81 deaths in this group allowed 84% 5-year and 82% 10-year Kaplan-Meier survival curves to be devised. A subsequent analysis of the Duke University cohort followed between 1969 and 1983 revealed slightly lower survival rates of 82%, 71%, and 63% for 5-, 10-, and 15-year survival (33).

In the nineties, there was continued improvement in the survival rates of patients with SLE in the Western world. In a study of 66 patients from Finland (34), the 10- and 15-year survival rates were 91% and 81%, respectively. Pistiner et al. (35), reviewing data collected in a single practice in Los Angeles, California, reported survival rates of 97% at 5 years, 93% at 10 years, and 83% at 15 years. These authors clearly demonstrate the improved survival in the past decade, because their previous survey (20) demonstrated 88%, 79%, and 74% survival at 5, 10, and 15 years, respectively. Information from the Arthritis, Rheumatism, and Aging Medical Information System (ARAMIS) data bank reveal similar results (36). Data from the University of Toronto Lupus Clinic published in 1995 revealed rates of 93%, 85%, 79%, and 68% for 5-, 10-, 15-, and 20-year survival in a cohort of 665 patients (37). The most recent survival data from the University of Toronto Lupus Clinic provide 5-, 10-, 15-, and 20-year survival rates of 95%, 90%, 84%, and 75%, respectively. Almost identical survival rates were reported by Tucker et al. (38) for a cohort of 165 patients followed at Bloomsbury Rheumatology Unit in London, England. A study of 658 patients from Mexico City provides excellent overall survival rates of 96% at 5 years and 92% at 10 years when measured from the time of first symptom. However, the 5-year survival from entry to the cohort was only 91% (39) (unfortunately, the survival was not calculated from the time of diagnosis and therefore is not comparable to the other reported series). A study of 306 European Spanish patients revealed similar 5-, 10- and 15-year survival rates of 90%, 85% and 80% (40). Among the population of Manitoba, Canada, survival rates at 5, 10, and 15 years were 98%, 96%, and 90% for Caucasians, and 94%, 80%, and 75% for Indians, respectively (41). A multicenter cohort of 513 Danish patients identified survival rates of 91%, 76%, 64%, and 53% for 5, 10, 15, and 20 years, respectively (42). Similar observations for 5- and 10-year survival rates of 92% and 75% were noted for an incident cohort of patients in northern Norway (43). Uramoto et al. (44) compared patients with SLE diagnosed at the Mayo Clinic between 1981 and 1982 to those diagnosed between 1950 and 1979 and found a significant improvement in the survival rates over time. Their patients are older (49 and 46 years at diagnosis) than those included in other cohorts (early thirties). A study from Lund, Sweden demonstrated 93% 5-year survival and 83% 10-year survival (45). The median age at diagnosis for the Swedish cohort was similar to that noted at the Mayo Clinic. Five-year survival rates were similar to the general population, however, the 10-year survival in the SLE cohort was reduced compared to the rate of 96.3% in the general population. A recent study of 245 patients from Barcelona documented a 5-, 10-, and greater than 10-year survival at 97%, 94%,

and 90% respectively (46). Cervera et al. (47) recently reported a 10-year survival of 92% among a cohort of 1,000 European patients with SLE. However, this was based on duration of follow-up and is not comparable to previous studies, as the patients entered this multicenter study with an average disease duration of 101 months. A survival analysis of a German cohort of 338 patients revealed a 97% 5-year survival and 90% 10-year survival (48). Japanese patients with SLE have also demonstrated improved survival in the past 2 decades (49). The 5-year survival rate for patients diagnosed between 1955 and 1969 was 71%, those diagnosed between 1970 and 1979 was 91% and for those diagnosed between 1980 and 1990 it climbed to 96%. A cohort of 178 SLE patients was identified in a population study in northwest Greece between January 1982 and December 2001. Survival in this cohort was excellent with rates of 97% and 90% for 5- and 10-year survival (50). In a multicentered study of 1214 SLE patients from South America (the GLADEL study) the 4-year survival was documented at 95% (51).

The improved survival typical of the Western world has not been noted worldwide. It has been suggested that the survival of patients with SLE from India has not improved at all during the 1980s (52). A comparison of patients with SLE who were registered between 1981 and 1985 with those who were registered between 1986 and 1990 revealed that these two groups were similar in demographics and disease characteristics, and in their mortality rates (72% and 78% at 5 years, respectively). Of note, mortality was higher in the first 2 years of disease. Five- and 10-year survival rates for SLE patients in Singapore during the period of 1970 to 1980 were 70% and 60%, respectively (53). Similar survival rates were noted in Japanese patients with SLE prior to 1980. An additional study from India (54) including patients followed from 1981 to 1993 revealed a cumulative survival of 77% at 5 years and 60% at 10 years. Among black Caribbean patients, poorer survival of only 56% at 5 years has been recorded (55), and a study from Chile (56) showed that 10-year survival of Chilean patients with lupus is somewhat lower than that of patients in several North American centers. In Malaysia, the overall 5- and 10-year survival rates were reported to be 82% and 70%, respectively. The results were lower for Asian Indian patients (70% and 65%, respectively) but were similar in Chinese and Malay patients (83% and 75%, respectively) (57). Similar survival rates of 84% and 75% were noted in cohort of 349 Thai patients (58). A study of Tunisian lupus patients followed between 1987 and 2001 revealed survival rates of 85% at 5 years (59).

In summary, the survival of patients with SLE has improved from 50% at 2 years in 1939 to 5- and 10-year survivals of 70% and 50%, respectively, after the introduction of corticosteroids in the 1950s; to 90% and 80% 5- and 10-year survivals, respectively, in the 1980s; and to almost 70% survival at 20 years in the 1990s (Fig. 69-1 and Table 69-1).

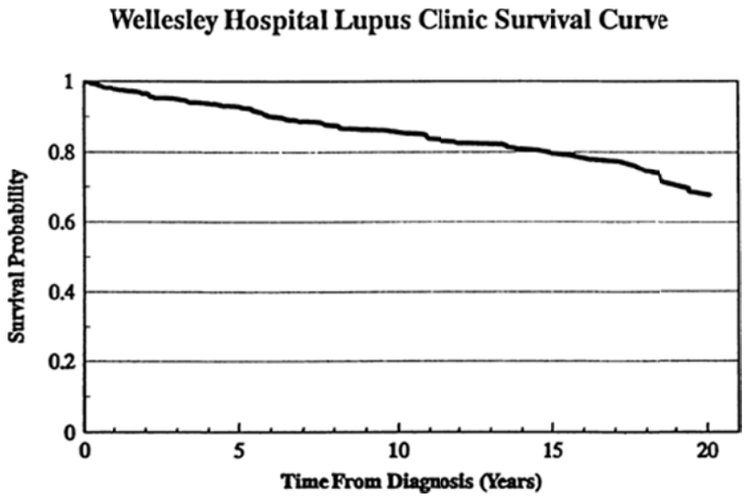

Figure 69-1. Survival in SLE, University of Toronto Lupus Databank. From Abu-Shakra M, Urowitz MB, Gladman DD, et al. Mortality studies in systemic lupus erythematosus. Results from a single centre. I. Causes of death. *J Rheumatol* 1995;22:1259–1264, with permission.

Reasons for Improved Survival in Patients with SLE

It may be concluded that the major contributing factors toward improved survival since 1950 are the availability of dialysis, corticosteroids, and improved antibiotic and antihypertensive agents. Further improvement in subsequent decades may have resulted from earlier diagnosis and the inclusion of milder cases in the more recent studies. Wallace et al. (20) found a mean interval of 4 years from onset to diagnosis in the 1970s; in 1990, this interval was 2 years (34). This is not supported, however, by the patterns of disease that have been seen over the past two decades (5 ,43) or by a recent study from Curaçao (55), in which the delay of diagnosis was only 18 months and the patients fared poorly.

The authors of a Dutch study analyzed the pattern of clinical features in patients with SLE over the past two decades (60). They divided their 110 patients, who were followed prospectively in their lupus clinic, into three groups based on their year of diagnosis. Group A included patients who were diagnosed before 1975, group B included patients diagnosed between 1975 and 1979, and group C included patients diagnosed between 1980 and 1985. There were no differences in the age at diagnosis, the age at onset of symptoms that could be related to SLE, or the interval between onset of symptoms and diagnosis in these groups. Moreover, there were no significant differences in the frequency of clinical features at the time of diagnosis. The number and types of exacerbations in these groups were not different after correction for disease duration. Thus, the authors concluded that the use of American College of Rheumatology (ACR) criteria for the classification of SLE, or the availability of laboratory tests for the diagnosis of the disease, have not led to earlier diagnosis of SLE or a change in its clinical pattern during the past two decades.

A study from Toronto (61) further investigated the reasons for the improved survival noted among patients with SLE

over a 24-year period. These authors had documented the increased survival rates for their patients over that period of time. They divided their patients into three groups, reflecting three periods of admission to their lupus clinic, and compared the survival rates in these groups to those recorded for the general population over the same periods of time. The improved survival in their patients with SLE did not reflect only the general improvement in survival in the population, because the standardized mortality rates decreased over the three periods, from 7.74 in the early 1970s, to 3.02 in the late 1980s and early 1990s. Analysis of variance did not reveal significant differences in the age at diagnosis or at enrollment into the clinic, or in disease activity at presentation as measured by the SLE Disease Activity Index (SLEDAI). Although there was a reduction in deaths because of infection and other morbidity, there were no differences in deaths related to lupus disease activity. The authors concluded that the improved survival in their patients was not the result of earlier diagnosis and/or a milder form of the disease. Because no new medications for SLE were instituted during the period of study, new treatments could not be considered as the reason for improvement. More appropriate use of conventional therapy was a more likely explanation.

*4-year survival; **Unpublished observations.

In Chile, Massardo et al. (56) also noted that patients whose disease onset was after 1980 fared better than those who were diagnosed earlier, but they did not compare their

patient population with the overall Chilean population. In India, the lack of improvement in survival in their population was thought to result from the general standard of medical care. This lends support to the notion that the improved survival in patients with SLE may have resulted from advances in medical therapy in general, such as improved antibiotics, antihypertensive agents, and the availability of renal dialysis and transplantation, as well as from more judicious use of lupus-specific therapy.

Uramoto et al. (44) demonstrated that although the incidence of SLE tripled over four decades between 1950 and 1990, the survival of patients with SLE has improved. They suggested that recognition of mild disease and better approaches to therapy may contribute to the improved survival, but this is not supported by the literature.

Bjomadai et al. (62) also demonstrated reduced mortality hazard ratios in Sweden for hospitalized SLE patients identified in the three decades ending in 1994. They identified a decline only in causes related to SLE, suggesting that the disease process was better treated. Unfortunately, there was no information on the actual disease manifestations or treatment provided these patients.

Although it is not clear exactly what has been associated with improved survival in SLE, it is possible that the tendency to follow patients with SLE in specialized clinics has contributed to this improvement. Ward recently documented the role of the experience of an individual physician in looking after SLE patients in the observed reduced mortality (63). After adjustment for demographic characteristics, severity of illness and hospital characteristics, the mortality risk was reduced by 20% and 42% for physicians with 1 to 3 or greater than 3 SLE admissions per year compared to less than 1. This was most noticeable for patients with lupus nephritis, for whom the adjusted odds of mortality were 60% lower among those in the highest category of physician volume.

Urowitz et al. (64) have also noted that specialty care may be advantageous for patients with lupus, even when their disease is under control.

Mortality Rates

Several published reports allow trends in overall mortality rates among patients with SLE to be interpreted. Data from the studies by Cobb (65) and Siegel et al. (66) demonstrate surprisingly low death rates. Between 1968 and 1972 (67) and between 1972 and 1977 (68), improvements in mortality rates were seen in all subsets; both of these studies suggest that mortality in African Americans is accentuated in early adulthood and then declines and that mortality in whites consistently increases with age. Death rates increased earlier in females than in males. These figures cannot be interpreted to imply a greater incidence of SLE in African Americans than in whites, however, because socioeconomic differences between the groups are still large and consequently, influence mortality.

Kaslow (69) also studied mortality patterns in 12 U.S. states that include 88% of all Americans of Asian ancestry. Between 1968 and 1976, the mortality rate for Asian Americans was 6.8 per million person-years, compared with 8.05 for African Americans and 2.8 for whites. Serdula and Rhodes (70) noted the mortality rate in Hawaii (1970–1975) to be 1.89 per million person-years for whites and 14.46 for nonwhites who were almost entirely of Asian ancestry. This finding also implied greater disease severity, increased incidence of SLE, or more socioeconomic hardships among Asian Americans, but these contentions remain to be proven.

Several reports have addressed mortality rates of SLE in Europe. Helve (71) derived a 4.7 per million person-years mortality rate among patients with SLE in Finland, but this study considered only hospitalized patients. Hochberg (72) accessed the Office of Population Censuses and Surveys data from 1974 to 1983 for England and Wales. He concluded that females have a fourfold higher mortality rate than men and that the highest mortality rates were in the 65- to 74-year age group. The annual mortality rate among females fell from 4.47 to 2.99 per million person-years between 1974 and 1983. These mortality patterns are similar to those observed in the United States. In the Danish multicenter cohort (43), the overall mortality rate was 2.9% per year, with a standardized mortality ratio of 4.6. This standardized mortality ratio is identical to that reported for the Toronto cohort, as well as to a British cohort (37 ,73). A study from Mexico City also identified the mortality rate at 2.4% per year, but does not provide comparative data for the Mexican population (39). Mortality rates in Greece and Germany were found to be lower than those in other centres, with standard mortality ratios (SMRs) of 1.2 and 2 respectively (48 ,50).

Ward demonstrated that in-hospital mortality among patients with SLE admitted through the emergency room is lower at hospitals in which there is more experience caring for patients with SLE (74). Mortality for emergency admissions as a result of SLE was 1.7% for hospitals with high experience compared to 10% for hospital with less experience. Ward further demonstrated that for patients with private insurance there was no difference in mortality rates related to hospital experience (75). However, patients without private insurance had much lower mortality rates if hospitalized in experienced hospitals. Differences in mortality between the highly experienced and less experienced hospitals was likely not related to general medical care since the difference was not seen for all subgroups of patients with SLE, nor for all reasons for hospitalization. It is more likely related to better management of the SLE itself. This is further documented in the fact that death rates were lower when experienced physicians were looking after the patients (63).

A U.S. study revealed geographical variation in mortality associated with SLE (76). The study identified increased mortality in Alabama, Arkansas, Louisiana, and New Mexico. Rates were higher in all racial groups but relative risks were lower in whites than other racial groups, and were higher in women than in men. Minnesota, Vermont, Virginia, and Washington had lower than expected SLE deaths. Clusters with elevated mortality had higher poverty rates and/or greater concentrations of ethnic Hispanics than those with lower mortality.

In the LUMINA (Lupus in Minority populations: Nature versus nurture) study, which includes patients who are seen within 5 years of disease onset, there were 34 deaths (11.8%) among the first 288 patients within the first 5 years of observation. Mortality was higher among Hispanics (12.2% and African American (15%) than Caucasians (7%) (77).

Causes of Death

Despite their improved survival, patients with SLE still die at a rate that is three to four times that of the general population (61 ,62 ,73). Causes of death may be divided into those related to the SLE disease process itself, those related to therapy, and those from unrelated causes (Table 69-2). Causes related to the SLE include active disease, including nephritis, vasculitis leading to CNS disease or intestinal perforation, intractable bleeding, and end-organ failure (e.g., renal, cardiac, or pulmonary). These certainly have improved with the more appropriate use of steroid therapy, the introduction of antimalarials, and immunosuppressive therapy. Better treatment for hypertension as well as cardiac and pulmonary failure, and the advent of renal dialysis and transplantation, may have averted some of the deaths that otherwise would have resulted from intractable organ failure in these patients.

The primary cause of death may at times be difficult to determine, but early studies followed the detailed protocols that were given in Klemperer's classic paper of 1941 (78). Before 1962, the most common cause of death was progressive renal failure and its associated complications. The incidence of uremia increased from 5% of patients who were treated in the 1930s to as high as 36% in Estes and Christian's report in the 1960s (16), before declining in the 1970s. Since then, uremic demise has occurred much less frequently as a result of better care for patients with end-stage renal disease, including dialysis and the use of cytotoxic therapy for lupus nephritis. Between 1956 and 1973, it decreased from 36% to 14% for all causes of death. The second most common clinical pattern was evidence of active CNS lupus, but with high-dose steroid therapy, CNS lupus became a much less frequent cause of death after 1956 (78). In Dubois' series (79), it decreased from 26% to 8% between 1956 and 1973. The more recent multicenter study (80) revealed mortality because of CNS disease to be reduced to 7%, and in the most recent study from Toronto (37), CNS disease contributed to 5% of deaths.

Table 69-2: Primary Causes of Death and Their Contributing Factors in SLE

	Primary Cause N (%)	Contributing Factors N (%)
I. Active SLE	20 (16)	38 (30.6)
II. Infections	40 (32)	12 (9.7)
III. Other morbidity related:	38 (31)	2 (1.6)

From Abu-Shakra M, Urowitz MB, Gladman DD, et al. Mortality studies in systemic lupus erythematosus. Results from a single centre. I. Causes of death. *J Rheumatol* 1995;22:1259–1264, with permission.

Most patients in Klemperer's series (78) died from infections because of low resistance and the unavailability of antibiotics. Common bacterial pathogens and tuberculosis accounted for most of these infections (16 ,81 ,82 ,83); opportunistic organisms were rare in the presteroid era. By 1975, despite the benefits that may follow steroid or cytotoxic therapy, the primary cause of death remained progressive renal damage. The second most common cause was infection, particularly bronchopneumonia caused by opportunistic pathogens. Ropes (84) emphasized that the major causes of death before 1949 were infection, active lupus, and uremia, but that by 1964, they were uremia, infection, and CNS disease.

In 1976, Urowitz et al. (17) demonstrated a bimodal mortality pattern in SLE. Of 81 patients who were studied, 11 died, and six of these died within a year of diagnosis, usually from complications of active lupus or sepsis. All were on high-dose steroids. The remaining five patients died a mean of 8.6 years after diagnosis. None had active nephritis or sepsis. The mean dose of steroids was minimal, and four patients had myocardial infarctions. Their follow-up studies (37 ,85), as well as the work of others cited in this section, confirmed these findings.

Urman and Rothfield (19) also demonstrated a change in the causes of death as patients with SLE age. Among 209 patients who were studied in New York City from 1957 to 1968, the main cause of 49 deaths was active lupus (excluding uremia; 39%), lupus nephritis (27%), and infection (22%). In 19 deaths among their 156 Connecticut patients who were followed from 1968 to 1976, the causes were lupus nephritis (42%), active lupus (excluding uremia; 21%), and infection (16%).

The multicenter study of 1,103 patients by Rosner et al. (80) reported 222 deaths between 1965 and 1976. As in Urman and Rothfield's report (18), no patient died from a malignancy. The major causes were infection (18%), renal disease (18%), CNS disease (7%), and cardiovascular disease (6%).

Karsh et al. (86) reviewed 94 deaths in 428 patients with lupus nephritis who were seen at the National Institutes of Health (NIH) between 1954 and 1977. The bimodal pattern first reported by Urowitz et al. (17) was observed. The causes of death were renal complications (40%), vascular disease (25%), and infection (16%). Only one death occurred from cancer, although most of the patients were treated with immunosuppressive drugs.

In a similar study of 138 patients with lupus nephritis who were followed at Guy's Hospital in London between 1964 and 1982 (87), 42 died. Of these, 12 died, usually from active lupus or infection, within a month of starting dialysis. The bimodal curve with late vascular deaths was borne out.

Wallace et al. (20 ,88) reported their experience with 128 deaths among 609 private patients who were seen between 1950 and 1980. Only 38 of those in the group had kidney disease, but they accounted for 67% of the deaths. The most common causes of death without nephritis were cardiovascular disease (primarily atherosclerotic; 30%), CNS disease (mostly vasculitis; 24%), and sepsis (17%). These authors confirmed Urowitz's finding that most early deaths result from active SLE, and that the preponderance of later deaths result from cardiovascular complications (17).

Information was available on 55 of 67 patients with SLE who died at the University Hospital in Jamaica between 1972 and 1985 (89). Of these, 23 were early demises, and 32 were late. Deaths were caused by infection (37%), renal disease (24%), hemorrhage (17%), and CNS disease (17%). Of 88 deaths observed in a SLE cohort by Studenski et al. (32) at Duke University, 71 resulted from the disease. Reveille et al. (31) reviewed the charts of 389 patients with lupus at the University of Alabama who were seen between 1975 and 1984. Of the 89 patients who died, 74 had a determinable cause of death. The principal causes of death were infection (39%), active SLE (11%), and cardiovascular disease (9%). Pistiner et al. (35) completed a 10-year update of 570 patients with lupus who were seen between 1980 and 1989. None of the patients with discoid or drug-induced lupus died. The most common causes of deaths among patients with SLE were active disease (35%), sepsis (19%), stroke (15%), and cardiovascular disease (15%).

Cardiovascular disease emerged as a major cause of death in a population study from Sweden (62). Mortality risk because of heart disease was highest in the 20- to 30-year age group. Other important cause of death was malignancy. This study was based on an administrative database and based on hospital discharges. Nonetheless, it supports the concept that active lupus is decreasingly recognized as a cause of death in SLE.

Sepsis, advanced renal failure, left-ventricular failure, and pulmonary embolism were the leading causes of death in the study reported from India (52). Causes of death among 48 Chilean patients with SLE (56) included active SLE in 31 patients, with renal and CNS disease being most prominent. Seventeen patients died with inactive lupus. Four of these 17 deaths resulted from infection, with the others generally resulting from complications of the disease or its therapy. Infection contributed to death in 27 patients. A survey of African blacks who were hospitalized with SLE between 1984 and 1990 in Durban, South Africa, revealed a high mortality rate (90). Causes of death among the 23 patients who died in the hospital included a combination of infection (47%), renal failure (37%), cardiac failure (21%), and neurologic disease (16%). Other causes included pulmonary embolism, diabetic coma, and cardiovascular collapse. Infections and active lupus were the most common causes of death among SLE patients in Singapore (53). These were also the most common causes of death in the European Working Party study (44), in the Danish study (43), as well as in the LUMINA study, which reported deaths within the first 5 years of study onset (77). Infection was the most common cause of death in the cohort from London reported by Tucker et al. (38). These authors also reported on four of 16 deaths related to complications of malignancy. A more recent British study also highlights malignancy as an important cause of death among their patients with SLE (73).

Abu-Shakra et al. (37) reviewed the causes of death in 124 patients with SLE who died during follow-up at the University of Toronto Lupus Clinic between 1970 and 1994. Active SLE and infection were both primary and contributing factors in a large proportion of the patients (Table 69-2). Patients who died within the first 5 years of diagnosis were more likely to die of active disease, whereas patients who died late in the course of their disease tended to die of atherosclerotic complications, thus demonstrating the bimodal mortality once again. Of the 124 patients who died from 1970 to 1993 in that clinic, 40 have had postmortem examinations (37). Of these, 21 (40%) had evidence of moderate to severe atherosclerosis at the time of death either as a coexistent finding or as a primary cause of

death. This same group of investigators demonstrated that although mortality risks from SLE have decreased over the past 25 years, there was a decrease in mortality related to infection there no decreased mortality because of active SLE. Ståhl-Hallengegre et al. (45) also demonstrated that late deaths among patients with SLE were related to atherosclerosis.

Hernandez-Cruz et al. (91) identified 76 SLE in-patients who died and had autopsies in their institution between 1960 and 1994 and matched them with SLE in-patients on the basis of age, decade of SLE onset, and disease duration. Major causes of death included infection, lung hemorrhage, CNS hemorrhage, and active SLE. Myocardial infarction as a cause of death was noted only after 10 years of disease.

Accelerated atherosclerosis has been identified as a major cause of mortality and morbidity in SLE. Studies at the University of Toronto cohort revealed that at any point in time 10% of the patients will have features of clinical atherosclerosis either manifesting as angina, myocardial cardiac infarction, or peripheral vascular disease alone or in combination. This is comparable to the prevalence of myocardial infarction and angina noted in other established lupus cohorts including Pittsburgh (6.7%) and Baltimore (8.3%) (92 ,93). Ward (94) also has identified atherosclerotic morbidity and mortality among patients with SLE. Bruce et al. (95) further demonstrated that persistent hypercholesterolemia in the first 3 years of SLE was a risk factor for mortality in their inception cohort.

Factors Associated with Mortality and Morbidity in SLE Demographic Factors

Several specific factors have been implicated as predisposing factors for mortality in patients with SLE (Table 69-3). These include demographic features, which are unrelated to the disease process itself, such as race, gender, age at onset, and socioeconomic status, including the type of healthcare delivery system that is available.

Race

Race distribution and its influence on SLE diagnosis is discussed in Chapter 4 , The Epidemiology of Systemic Lupus Erythematosus, and in the previous sections of this chapter. Siegel et al. (96 ,97) analyzed the relationship between survival and race among a black, Puerto Rican, and white population in a series of 292 cases in the 1960s, and they observed no differences. The 5-year survival rates by group ranged from 62.7% to 65.1%.

Table 69-3: Factors Associated with Mortality

Non-SLE-related factors	SLE related factors
Demographic	Year at diagnosis
Race	Time of Onset to diagnosis
Gender	Disease manifestations
Age at onset	Disease activity
Socioeconomic status	at presentation
Health care delivery system	Treatment
Environmental	
Geographic	

In general, whites have a better outcome than nonwhites, with mortality rates being three times higher in nonwhites than in whites (55 ,57). Although race did not appear as an important prognostic factor in a logistic regression analysis of the multicenter study published by Ginzler et al. (22), it was found to be a factor adversely affecting survival of patients with SLE when Cox multivariate analysis was applied to a group of 389 patients by Reveille et al. (31), and was also an important factor in the LUMINA study (77). It has been difficult to separate the effects of race and socioeconomic status, particularly regarding the differences between white and African-American patients in the United States. In Reveille et al.'s study (31), white patients with private insurance fared better than African-American patients with private insurance; however, there was no difference in outcome when African-American patients with and without private insurance were compared. Studenski et al. (32) found that nonwhite race and socioeconomic status contributed independently to mortality. Also, although the overall survival was better for whites than for African Americans in a recent report from Duke University (33), this was related to the socioeconomic status, which was poorer among the African Americans. Abu-Shakra et al. (98) analyzed the factors associated with mortality in patients with SLE who were followed at a single centre. Race was not found to be associated with mortality. Levy et al. (99) identified high unfavorable outcomes among their black and North African patients. This was based on a descriptive analysis, not on a formal statistical evaluation. They suggest that although this may be related to poor socioeconomic status, noncompliance with medical treatment is another factor. Thus, although there may be racial differences in the expression of this disease and its outcome, the effect of race has been confounded by other factors. Wang et al. (57) demonstrated a reduced survival among Asian Indian patients compared to Chinese and Malay patients in Malaysia. Ward found that hospital mortality was mostly affected by the experience of the physician regardless of ethnicity (75). However, in a subsequent study Ward found that among whites, higher education levels were associated with lower mortality becuase of SLE. The same associations were not noted among ethnic minorities and it was suggested that underascertainment may represent underreporting of SLE on death certificates or underdiagnosis of SLE in ethnic minorities with low education levels (100).

Just as with survival studies it has been difficult to isolate the role of race in morbidity in SLE. A recent study from Toronto shows that among patients followed in the same centre with the same health care availability there were some differences in morbidity, although not in mortality (101). Similarly among SLE patients in Manitoba, although Caucasians had slightly higher survival rates, they were not substantially different from Manitoba Indians (41).

Gender

The relationship between gender and prognosis has been controversial. Although Kaslow suggested higher mortality in females than in males with SLE (69), Wallace et al. (20) and Kaufman et al. (102) demonstrated the opposite: a better prognosis for women than for men. Kellum and Haserick (8) also reported that male SLE was more severe: 34.5% of men were alive at 8 to 10 years, compared with 56.3% of women. Swaak et al. (30), a Soviet group (103), as well as a study by Ward et al. (33), have confirmed these findings. On the other hand, gender did not appear to be a significant predictor in the statistical analysis performed by Ginzler et al. (22). Chang et al. (104) found no statistically significant differences in survival between male and female patients in Taiwan. Abu-Shakra et al. (98) found no effect of gender on prognosis. Miller et al. (105), Ward and Studenski (106), and Wang et al. (57) concluded that the spectrum and severity of SLE tended to be the same in males and females. In a cohort of patients from Puerto Rico men had more sever disease as manifested by a higher prevalence of serositis, proteinuria and renal insufficiency, higher accumulation of damage, and more deaths (107). Although a similar increase in disease manifestations among Mexican SLE male patients compared to female patients was noted, there was no increased mortality among these men (108). Thus, the issue of the effect of gender on prognosis in SLE remains unanswered.

Age at Onset

Age at onset of SLE was found to be a significant predictor of survival at both 1 and 5 years in the U.S. multicenter study (22), with better survival rates in older patients. Onset of SLE in the pediatric-age group has been associated with a worse prognosis, probably because these patients still may die earlier than their counterparts with older-onset disease (109). Studenski et al. (32) found no significant effect of age on survival (cutoff at 55 years). On the other hand, Reveille et al. (31) found that increasing age of onset adversely affected survival. A comparison with the estimated survival of the age-matched segment of the U.S. population showed that patients with SLE fared worse at all age groups. Abu-Shakra et al. (98) found that older patients (≥50 years) at diagnosis or presentation to the Lupus Clinic were at a slightly higher risk for death than patients who were diagnosed before age 50. Older age also was associated with decreased survival in the study reported by Ward et al. (33). Hagelberg et al. (110) reported the survival of a pediatric cohort with lupus nephritis to be 94% at 11 years. However in an Indian pediatric cohort the survival was not as good, with only 68% of the patients surviving at 3.2 years (111). It is of interest that when experimental lupus was induced in young and old BALB/c mice by immunization with 16/6 idiotype in complete Freund adjuvant, old mice produced fewer antibodies and demonstrated a milder renal lesion than young mice, suggesting that aging modifies development and expression of the autoimmune disease (112). Rood et al. (113) recently observed a significantly higher mortality in patients who developed SLE during reproductive years than in patients who developed lupus in the nonreproductive years. Whether this is an effect of age or hormonal status is unclear. Age at enrollment was not a significant predictor of mortality in the LUMINA study (77).

SLE in Children

Childhood SLE is characterized by more organ-threatening disease than adult-onset SLE (38). In the past childhood SLE was thought to be associated with a poorer prognosis (1). Lupus in children is managed the same way as in adults (114), with particular attention being given to their specific psychosocial needs and special problems (see Chapter 6 , Serum and Plasma Protein Abnormalities and Other Clinical Laboratory Determinations in Systemic Lupus Erythematosus). All studies from before 1977 were associated with a less than 50% 10-year survival rate (115 ,116 ,117 ,118 ,119 ,120). Because of the more widespread use of cytotoxic agents, improved antihypertensive agents, dialysis, renal transplantation, cyclosporine, and other diagnostic advances, the 10-year survival now has improved to an average of 85% for children who are treated in optimal settings (110 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129). In China, the survival rates are lower, with most recent data revealing a 5-year survival rate of only 76.3% (128), and in India the survival at 3 years was only 68% (111). A practice containing largely indigent African-American and Hispanic patients in Brooklyn reported a 25% 5-year mortality rate and a 25% 5-year rate of renal failure requiring dialysis (129). Lehman's group in Los Angeles was unable to find any prognostic differences among patients with onset at an age of less than 10 years versus 10 to 20 years (109). Wallace et al. (20) could not find any differences in survival between 55 patients who survived to adulthood and who were diagnosed before 20 years of age versus 409 patients who were diagnosed at a later age. Tucker et al. (38) identified identical 5-year survival rates of 94% among the childhood-onset and adult onset SLE patients.

In summary, the bleak prognosis for childhood SLE that was reported in the 1960s and 1970s has improved substantially. Children now have only a slightly worse outcome than adults.

Older Adults

Idiopathic SLE developing in individuals after the age of 50 years as compared with adults with onset before the age of 50 is characterized by a milder serologic picture, infrequent renal disease, and more serositis and arthritis (130). These patients with older-onset SLE had 92% and 83% 5- and 10-year survival rates, respectively, in Wallace et al.'s 1980 survey (20) and in a study by Baker et al. (131). Fewer elderly patients required corticosteroids, and and when they did, lower doses were needed, and for shorter durations (132). Nephritis did not appear to alter overall survival (20). However, Reveille et al. (31) noted that older age of onset was associated with a poorer outcome, and Abu-Shakra et al. (98) noted that patients who were diagnosed or presented at 50 years of age or older had a slightly higher risk for mortality.

A comparison of 47 patients with late onset SLE (greater than age 50 at diagnosis) and 114 patients with age of onset younger than 50 revealed that there were more men among patients with late onset SLE. The disease appeared milder with less evidence of renal involvement and arthritis, less serological abnormalities. Survival was better in patients with early onset SLE 95% at 5 and 10 years and 92% at 15 years, compared with 85%, 71% and 59% for 5, 10, and 15 years respectively in the older age group (132). The authors performed a pooled data analysis and found that serositis, pulmonary involvement, rheumatoid factor positivity were more common among late onset than early onset SLE patients.

Socioeconomic Factors

Dubois et al. (14) concluded that patients who were treated in his private practice did better than those who were treated in publicly funded clinics where he worked. Studenski et al. (32) found that patients with lower socioeconomic background had a worse prognosis; they used Medicaid insurance as a marker of low socioeconomic status, which is not necessarily the case in other practices. The issue of noncompliance with medical therapy was proposed by Levy et al. (99) to be as a factor that must be separated from socioeconomic status. Bruce et al. (133) recently demonstrated that poor compliance was associated with poor outcome with respect to renal disease, but suggested that cultural differences may contribute to noncompliance with medications. Petri et al. (134) demonstrated that both noncompliance and type of medical insurance were important factors in the morbidity of SLE. Karlson et al. (135) studied the relationship between lupus morbidity (defined as disease activity measured by the Systemic lupus activity measure [SLAM]) and socioeconomic predictors in five centers; they found that higher education, private insurance/Medicare, and higher income were associated with less disease activity at diagnosis. The GLADEL cohort documented that mortality was associated with lower education and poor medical coverage among Hispanics (51).

Methods of Healthcare Delivery

Patients who are treated in different healthcare settings (e.g., private practice, university medical center, prepaid health plan, local clinic, or within a government-controlled system such as the Veterans Administration) probably are different. Therefore, the healthcare setting from which a series of patients with SLE is obtained can influence prognosis. The availability of services and specialists varies widely. Sicker patients often are funneled into tertiary university centers, thus lowering their reported survival curves for SLE (136). As noted earlier, patients from India, Chile, and the island of Curaçao fared worse in terms of survival than patients from North American centers. Whether this is related to a lack of specialists or to poorer standards of medical care in general is not clear.

In the United States, healthcare is funded by private insurance (e.g., fee for service, managed care, or prepaid health maintenance plan), Medicare, Medicaid (i.e., an extension of the welfare system), cash, or local governments that provide subsidized care to indigent patients. Fessel (137), working with middle-class patients who had at least one family member employed and therefore enrolled in the Kaiser-Permanente prepaid health plan, reported good survivals in patients with SLE. Ginzler et al. (22) studied 1,103 patients with SLE at nine centers and found that privately funded patients had better survival rates than those receiving public funding. Reveille et al. (31) documented that African Americans with private insurance have improved survival compared with those without it.

Reports of patient outcome also probably are influenced by the specialty of the physician who is analyzing the data. For example, Wasner and Fries (138) found that rheumatologists and nephrologists usually agree with each other on general treatment approaches for SLE, but that nephrologists place more emphasis on renal biopsy and use immunosuppressive drugs more frequently. Stewart and Petri (139) recently suggested that patients followed in a health maintenance organization had higher creatinine levels, and less were treated with immunosuppressive agents compared to patients followed by an academic rheumatologist. Ward demonstrated that in-hospital mortality among patients with SLE is lower in hospitals that have more experience in looking after patients with SLE (74).

Wallace's group (20 ,34) has observed higher mortality rates in their clinic patients compared with their private-practice patients. Esdaile et al. (140), on the other hand, found that socioeconomic status had no correlation with health outcomes among Canadian patients with SLE, but all of them had health insurance. Ward also found that hospitalized SLE patients who had private insurance fared better than those who did not (63 ,74).

Environment

Environmental considerations, such as climate, occupation, exposure to chemicals, diet, lifestyle, exercise, and drug-induced SLE, are described in Chapter 3 , Environmental Aspects of Lupus, Chapter 4 , The Epidemiology of Systemic Lupus Erythematosus, and Chapter 59 , Antimalarial Therapies. Whether they influence prognosis is uncertain.

Geography

Geography may be a factor in survival patterns. Chapter 4 discusses the incidence and prevalence of SLE in various parts of the world. Generally, Canadian, Japanese, and European patients with SLE have outcomes similar to those of patients in the United States. SLE might present differently in certain locales, which may alter prognosis. For example, black patients with SLE in Zimbabwe have an unusually high incidence of renal disease and a low incidence of photosensitivity (141). In India (27), Egypt (142), and Thailand (143), mortality rates are high. However, as noted

earlier, the differences in survival that have been noted among patients from India, Chile, or the Caribbean may be related to general medical care and not to certain features related to SLE itself.

Systemic Lupus Erythematosus-Related Factors

SLE factors that may affect prognosis include time between the onset of symptoms and the diagnosis of SLE, change in disease expression over time, presence of specific disease manifestations, overall disease activity, and use of therapeutic modalities.

Year of Diagnosis

The year of disease onset is a critical factor in the prognostic equation. As noted earlier, the overall survival of patients with SLE has improved dramatically over the last 50 years. Treatment practice has changed and varied depending on the year and location of treatment and the source of healthcare delivery. For example, corticosteroids were used at higher doses and for longer periods in the 1950s; similarly, certain immunosuppressive agents were used more extensively in the late 1960s and early 1970s than they are at present. The advent of steroids, dialysis, newer antihypertensives and antibiotics, and parenteral cyclophosphamide has had an impact on patient survival as well (144).

Time from Onset to Diagnosis

The time difference between onset of symptoms and the diagnosis of SLE has not been formally used as a predictor of survival in SLE. It has, however, been considered as a factor in the calculation of survival rates, because there would be a prolonged survival in those instances where the date of onset of symptoms has been used as the entry point of a survival study. Seleznick and Fries (36) actually demonstrated the point by providing survival rates calculated from first symptom (99%, 96%, and 89% for 1, 5, and 10 years, respectively) and from first visit (96%, 88%, and 64% for 1, 5, and 10 years, respectively). Similar observations were made by Drenkard et al. (39) who showed 96% and 92% 5- and 10-year survival rates calculated from the onset of symptoms as opposed to only 91% 5-year survival calculated from the first visit. Wallace et al. (20) pointed out that the time lag between onset of symptoms and diagnosis in their population did not vary significantly in the three decades of their study and, therefore, might not have influenced the improved survival that was noted over that time period. Their 1990 analysis of 464 patients suggested that the time from onset of symptoms to diagnosis in those older than 60 years is 3.2 years, the longest of any age group (35). Urowitz et al. (61) showed that disease duration to first visit did not vary significantly in the three epochs of their study (i.e., early 1970s, late 1970s to mid 1980s, late 1980s to early 1990s). Most investigators calculate survival rates from the time of diagnosis particularly because not all patients who present with symptoms of SLE go on to develop clear-cut lupus (7). Only one third of the patients with latent lupus described by Ganczarczyk et al. (145) went on to develop clear-cut SLE. Similarly some 20% of 122 Dutch patients (146) and 57% of 28 Swedish patients (147) with “incomplete lupus” went on the fulfill criteria for SLE. If the remaining patients with “incomplete” or “incipient” lupus are included in an analysis of survival, they might yield higher survival rates for the sample population. Of interest in this regard is a paper describing SLE in Iceland (148), which describes a nationwide survey allowing the investigators to include milder cases; the mortality rates in this study are similar to those in other reports. Hernandez-Cruz et al. (91) also found that their patients who died had a longer delay between symptoms and diagnosis compared to those who survived.

Change in Disease Expression over Time

Another important issue is whether the nature of SLE has changed with time. Hashimoto et al. (149) conducted a comparison by decades of 229 Japanese patients who were studied since 1955. They concluded that the incidence of Raynaud phenomenon, alopecia, oral ulcers, and nephritis has increased in the last decade. In contrast, Wallace's (35) group compared 464 U.S. patients with SLE (diagnosed between 1980 and 1989) with the 520 patients who were seen by Dubois (diagnosed between 1950 and 1963) in the same office. The percentage of patients with organ-threatening disease decreased from 65% to 52%, and acute CNS vasculitis practically disappeared. This might be attributed to earlier recognition and treatment of the symptoms and signs of SLE, an evolutionary change in the disease process, changes in referral patterns, and/or the availability of antinuclear antibody (ANA) testing and other serologic procedures that can help to identify milder cases. Urowitz et al. (95) found that the disease expression did not change in an SLE cohort over a 24-year period; thus, survival could not be attributed to milder disease. Moreover, there was a similar delay from diagnosis to presentation to clinic in patients who were seen in the early 1970s compared with late 1980s.

Effect of Disease Manifestations

The presence of certain disease manifestations may predispose patients to mortality. Between 1973 and 1985 at the University of Mississippi, 50 deaths occurred in patients with SLE (150). Serositis, nephritis, CNS disease, and leukopenia were associated with a fatal outcome, and the mean interval from diagnosis to death was 4.1 years. Reveille et al. (31) found that thrombocytopenia, nephritis, CNS disease, anemia, and hypertension were associated with a poorer outcome. In the Toronto study (98), renal damage, thrombocytopenia, cardiac complications, hypertension, and lung involvement were associated with mortality by univariate analysis, but the best-fitting multivariate model included renal damage, thrombocytopenia, SLEDAI of 20 or higher at presentation, lung involvement, and age older than 50 years at presentation. In the Mexican autopsy study lung involvement, severe thrombocytopenia

and heart involvement were features that were statistically different between cases and controls (91).

Although CNS disease commonly was found in patients who died with active lupus (37) and has been found to be associated with decreased survival (22), most studies have not confirmed the role of CNS disease as a predictor for mortality. On the other hand, the presence of nephritis carried a poor prognosis for patients with lupus who were followed in hospital centers (20 ,22 ,31 ,137) as well as in outpatient facilities (31). The presence of proliferative and chronic lesions on kidney biopsy specimens was associated with a higher risk of all-cause mortality, particularly in patients with normal serum creatinine (151). Similar results were obtained by Esdaile et al. (152) using the conventional Cox model, although when a time-dependent model was developed, only subendothelial deposits were contributory. Massardo et al. (56) also found that survival curves for World Health Organization (WHO) types II and III were better than for type IV on univariate analysis. It is of interest that the survival rates calculated for the subgroup of Chilean patients who underwent kidney biopsy was somewhat lower than that of the total population, with rates of 89%, 72%, and 58% for 1, 5, and 10 years, respectively. However, renal disease did not remain significantly associated with prognosis on multivariate analysis once disease activity was in the model. Additionally, the Lupus Nephritis Collaborative Group did not find that renal activity or chronicity indices predicted either death or renal failure (153).

Overall Disease Activity as a Predictor of Mortality

The assessment of disease activity in SLE has become easier with the development and validation of a number of instruments over the past several years. The most commonly used instruments include: the SLEDAI (154), the SLAM (155), the British isles lupus assessment group (BILAG) (156), the Lupus activity index (LAI) (157), and the European consensus lupus activity measurement (ECLAM) (158). These indices have been shown to be comparable (159 ,160). Thus, overall disease activity now can be evaluated as a prognostic factor in SLE.

Indeed, overall disease activity at the time of renal biopsy has been shown to be a prognostic factor for mortality in two cohorts of patients (151 ,161). It also was demonstrated to be the most important predictor of mortality in other cohorts of patients with SLE (162). Disease activity (as measured by the SLEDAI) at the time of presentation to the Lupus Clinic was a predictor for mortality in a recent study (98). Although high SLEDAI (>10) was not a predictor among black Caribbean patients, a high-weighted SLEDAI score, depicting disease activity over the course of disease, was associated with decreased survival in both univariate and multivariate analyses (55). The disease activity index had the strongest association with outcome in Chilean patients with SLE (56). Disease activity, although evaluated by an unvalidated measure, was also associated with mortality in patients from Mexico (39).

Cook et al. (163) found that in a univariate analysis total SLEDAI score was highly prognostic for mortality within 6 months of the last clinic visit. Increasing relative risks were obtained for increasing SLEDAI scores (1.28 for SLEDAI 1–5, 2.34 for SLEDAI 6–10, 4.74 for SLEDAI 10–19 and 14.11 for SLEDAI ≥20 compared to SLEDAI = 0). A time-dependent Cox regression analysis identified the individual components of SLEDAI as risk factors for death, including organic brain syndrome, retinal changes, cranial nerve involvement, proteinuria, pyuria, pleurisy, fever, thrombocytopenia, and leucopenia.

Ibañez et al. (164) developed a method to describe disease activity over time in patients with SLE. The adjusted mean SLEDAI (AMS) was found to be a strong predictor for mortality.

The effect of the various factors on survival in SLE is summarized in Table 69-4 .

Effect of Treatment on Mortality

Treatment may be an important factor affecting mortality. Improved therapeutic approaches for SLE may provide better disease control through suppression of the inflammatory process and thus reduce mortality that is related to active disease. There have not been many prospective, randomized, controlled drug trials in SLE. The Canadian Hydroxychloro-quine Study Group published its findings of a randomized trial of withdrawal of hydroxychloroquine in patients with stable SLE (165). They found that hydroxychloroquine is effective in controlling disease exacerbations in SLE; patients who continued to take the drug were less likely to have clinical flares than those who were taken off the drug. However, they did not study its effect on mortality.

That steroids have made a difference in the control of SLE is widely accepted, such that it is considered to be unethical to perform a placebo-controlled trial of steroid therapy in SLE. On the other hand, the contribution of steroid therapy to the changing pattern of mortality and morbidity in SLE has been noted (166). Sturfelt et al. (167) noted that prolonged corticosteroid therapy was associated with valvular abnormalities and myocardial infarction in their prospectively studied patient population. Because atherosclerotic complications are a major cause of death, particularly late in the disease, this is an important observation. Petri et al. (168) further demonstrated that an increase in prednisone dose of 10 mg was associated with an increase in cholesterol levels of 7.5, thus predisposing patients to coronary artery disease, whereas hydroxychloroquine therapy was associated with a lower serum cholesterol level, possibly protecting patients from coronary-artery disease. Use of medications did not appear as a predictive factor in the analysis performed by Abu-Shakra et al. (98).

The role of treatment as a potential confounder of the relationship between major predictors and mortality was investigated by McLaughlin et al. (151). They found that when the treatment variable was added to the baseline model, the relative risk estimates did not change significantly, suggesting that these estimates were not confounded by the treatment variables that were considered, which included steroid and immunosuppressive drugs.

Spontaneous Remissions

During periods of remission, either no symptoms or minor complaints, such as slight morning stiffness or occasional pleuritic discomfort, may occur. Laboratory abnormalities such as leukopenia, elevated sedimentation rate, and positive ANA may persist or disappear.

SLE can spontaneously improve and remit. Dubois (169) reported that 35 of 520 patients had multiple spontaneous remissions of varying lengths of time not associated with treatment. Some were of 10 to 20 years' duration. Ropes (8 ,9) noted spontaneous remissions of a few months to several years in 70 of 72 patients. Tumulty (170) in 1954 observed spontaneous remission in 19 of 34 patients who were treated symptomatically. Tozman et al. (21) remarked that four of 160 patients with SLE with a history of severe organ involvement who were followed for a mean of 75 months had no treatment and no disease activity. Heller and Schur (171) noted that 13 of their 305 patients (4%) developed clinical and serologic (with ANA becoming negative) remissions between 1967 and 1981 and lasting for at least 18 months; only 8 of 13 patients, however, were off all medications. Drenkard et al. (172) defined remission as “at least 1 year during which lack of clinical disease activity permitted withdrawal of all treatment for lupus proper.” The period of remission was considered from the time the patient stopped all medications. They did not use a validated disease activity measure to describe disease activity. Of their 667 patients followed for a median of 3.7 years, 156 fulfilled their definition of remission, and 62 went into remission within the first 2 years of disease, and 81 were still in remission at the time of the analysis. The mean duration of first remission was 4.6 years (range, 1 to 21 years). Patients who achieved a remission period had increased survival, independently of the effect of other disease manifestations that were associated with increased mortality among their patients. They concluded that lupus was a milder disease than previously considered, and that remission was common. Urowitz et al. (173) found that of the 703 patients followed in their clinic between 1970 and 1997 who had not been absent from the clinic for more than 18 months 46 (6.5%) achieved complete remission for at least 1 year, whereas only 12 patients (1.7%) had prolonged complete remission of at least 5 years on no treatment. Although the frequency of disease manifestations was similar to the nonremission patients, the 5-year remission group was distinguished by lower overall disease activity as measured by the adjusted mean SLEDAI (AMS), the lower prevalence of anti-DNA antibodies, and lower use of steroids and antimalarials.

Overall, it seems that 2% to 10% of patients who fulfill ACR criteria for SLE can enter true disease remissions that can last for months to years; in other words, they have no symptoms and require no therapy for SLE. This must be remembered when considering therapy for the individual patient or when evaluating the efficacy of treatment.

Other Outcome Measures of Prognosis in Systemic Lupus Erythematosus

Cumulative Organ Damage

As patients with SLE live longer, their prognosis needs to be assessed by other outcome measures. Individual organ damage, most notably the presence of end-stage renal disease, has been used as an outcome (174). More recently, a global measure of damage namely, the SLICC/ACR damage index for SLE has been introduced as a measure of outcome in SLE (175). This measure includes descriptors of nonreversible change that occur after the onset of SLE, whether or not they are related to

the disease process or its treatment (Table 69-5). This instrument has been shown to be valid and reproducible (176).

The SLICC/ACR damage index may serve as a predictor for other outcomes, or may be an outcome of morbidity in itself (178). Early damage, measured by the SLICC/ACR Damage Index within the first year of disease was found to be a predictor of mortality in SLE in the Toronto Cohort (177). The presence of a SLICC/ACR damage score of two or more within the first 5 years of SLE was found to be highly predictive of mortality in a Swedish cohort (179). An increase in SLICC/ACR damage index score within the first 3 years of follow-up in a Chinese cohort was also associated with mortality risk (180). Stoll et al. (181) identified renal damage at 1 year to be predictive of end-stage renal disease, and pulmonary damage to be predictive of death within 10 years. This study also demonstrated that Afro-Caribbean and Asian patients accumulated more damage than Caucasian patients, suggesting a racial influence on disease expression in this disease. A study of the Montreal cohort, which included only Caucasian patients, revealed that the SLICC/ACR damage index scores predicted poor outcomes defined as either death or hospitalization (182). Nossent (183) found that over an observation period of 71 months the median Damage Index score was 2.4 in a population of

patients from Curaçao. Despite the higher SLICC/ACR Damage Index scores in this patient population, there was no demonstrable association with poorer survival in that study. The LUMINA study showed that deceased patients experienced more active disease and accrued more damage from the outset of their disease compared to survivors (77). Zonana-Nacach et al. (184) used the SLICC/ACR Damage Index to assess damage among 210 Mexican patients with SLE. They found that damage increased with disease duration so that after 10 years of disease 70% of their patients demonstrated damage recorded by the SLICC/ACR. A Danish study (185) also demonstrated that deceased patients had accrued more damage than patients who remained alive. In a recent multicenter cohort of patients with SLE there was evidence of damage within a mean of 3.8 years after onset. Although race and socioeconomic status did not influence early damage, older age at diagnosis of SLE, greater disease activity at diagnosis, and longer disease duration were associated with damage (186). Maddison et al. found that older patients were at higher risk of accumulating damage than younger patients with SLE (187).

Table 69-5: SLICC/ACR SLE Damage Index

Item	Score
Ocular (either eye, by clinical assessment)	
Any cataract ever	1
Retinal change OR optic atrophy	1
Neuropsychiatric	
Cognitive impairment (e.g. memory deficit, difficulty with calculation, poor concentration, difficulty in spoken or written language, impaired performance level)	
OR major psychosis	1
Seizures requiring therapy for 6 months	1
Cerebral vascular accident ever (Score 2 if >1)	
OR surgical resection not for malignancy	1 2
Cranial or peripheral neuropathy (excluding optic)	1
Transverse myelitis	1
Renal	
Estimated or measured GFR <50%	1
Proteinuria 3.5 g/24 hours	1
OR end-stage renal disease (regardless of dialysis or transplantation)	3
Pulmonary	
Pulmonary hypertension (right ventricular prominence, or loud P2)	1
Pulmonary fibrosis (physical and radiograph)	1
Shrinking lung (radiograph)	1
Pleural fibrosis (radiograph)	1
Pulmonary infarction (radiograph)	
OR resection not for malignancy	1
Cardiovascular	
Angina	
OR coronary artery bypass	1
Myocardial infarction ever (Score 2 if >1)	1 2
Cardiomyopathy (ventricular dysfunction)	1
Valvular disease (diastolic murmur, or a systolic murmur >3/6)	1
Pericarditis × 6 months,	
OR pericardiectomy	1
Peripheral Vascular	
Claudication × 6 months	1
Minor tissue loss (pulp space)	1
Significant tissue loss ever (e.g., loss of digit or limb) (Score 2 if >one site)	1 2
Venous thrombosis with swelling, ulceration, **OR** venous stasis	1
Gastrointestinal	
Infarction or resection of bowel below duodenum, spleen, liver or gall bladder ever, for whatever cause (Score 2 if >one site)	1 2
Mesenteric insufficiency	1
Chronic peritonitis	1
Stricture	
OR upper gastrointestinal tract surgery ever	1
Pancreatitis	1
Musculoskeletal	
Muscle atrophy or weakness	1
Deforming or erosive arthritis (including reducible deformities, excluding avascular necrosis)	1
Osteoporosis with fracture	
OR vertebral collapse (excluding avascular necrosis)	1
Osteonecrosis (Score 2 if >1)	1 2
Osteomyelitis	1
Ruptured tendon	
Skin	
Scarring chronic alopecia	1
Extensive scarring or panniculum other than scalp and pulp space	1
Skin ulceration (not because of thrombosis) for more than 6 months	1
Premature Gonadal Failure	1
Diabetes (regardless of treatment)	1
Malignancy (Exclude dysplasia) (Score 2 if >one site)	1 2

Note: Damage (nonreversible change, not related to active inflammation) occurring since onset of lupus, ascertained by clinical assessment and present for at least 6 months unless otherwise stated. Repeat episodes mean at least 6 months apart to score 2. The same lesion cannot be scored twice.

Non-Caucasian race, longer disease duration, higher disease activity, and lower level of education were associated with more organ damage in SLE in two cohorts of patients from the United Kingdom (188). A study of patients followed for at least 15 years documented increases in SLICC/ACR Damage Index over time, and identified corticosteroids as important contributors to damage (189). Similarly Stoll et al. (190) found that patients accumulated damage over a 5 year period and that disease activity was contributing to the damage. Patients followed in the LUMINA study who did not have damage at presentation were studied to determine the predictors for the occurrence of initial damage (191). Independent predictors of a shorter time to initial damage were Hispanic ethnicity from Texas (HR 2.11, 95% confidence interval [CI], 1.15–3.88), greater disease activity according to the Systemic Lupus Activity Measure (HR 1.09, 95% CI, 1.04–1.15), the occurrence of thrombotic events (HR 7.66, 95% CI, 2.13–27.51), and prednisone at a dosage of less than 10 mg/day (HR 2.53, 95% CI, 1.15–5.55). A dose of prednisone 10-30 mg/day was found to be protective (HR 0.46, 95% CI 0.22-0.96). Antiphospholipid syndrome was found to be important to the development of damage in a Spanish study (192). Ibañez et al. (193) documented that the risk of damage increases with increases in AMS, age at diagnosis, disease duration, and use of corticosteroids and immunosuppressive medications but is not affected by sex, SLEDAI at presentation or use of antimalarials (193).

Thus the assessment of damage in SLE is important both as a predictor of mortality and as an important outcome.

Specific Organ Damage in Systemic Lupus Erythematosus

Although the overall SLICC/ACR Damage Index provides a global measure of accumulated damage in SLE, it also identifies damage in individual organ systems. Individual organ damage is described elsewhere in this book in the appropriate chapters.

Malignancies in Systemic Lupus Erythematosus

Data concerning the incidence of malignancies in SLE are of great interest, because it is believed that the failure of immune surveillance is a cause of the induction and spread of tumors. In SLE, two reasons for faulty immune mechanisms are known. One involves abnormalities in immune regulation that are associated with the disease process. The second involves long-term treatment with cytotoxic agents, which increases the risk of developing cancer. In fact, cancer is an extremely infrequent cause of death in SLE. Eight large surveys (17 ,19 ,20 ,28 ,31 ,32 ,80 ,86) were composed of 3,683 patients, and of the 667 who died, 16 had malignancies, representing 2.5% of patients. Approximately 1,000 of the total number of patients had received some type of immunosuppressive treatment; however, these studies did not compare the frequency of malignancy to the general population. In a study of 205 patients with SLE who were followed over 2,340 patient-years, Petterson et al. (194) found a 2.6-fold increased risk for all cancers as compared with that of the total Finnish population. Sweeney et al. (195) did not find an increased frequency of cancers among their cohort of patients with SLE, but follow-up was short. In a more recent study of malignancy in 724 patients with SLE who were followed prospectively for 24 years at a single lupus clinic in Toronto, 24 cancers were identified in 23 patients (3.2%) during 7,233 patient-years of follow-up (196). The most frequent cancer types/sites were hematologic. None of the six patients with hematologic malignancies received cytotoxic drugs before the diagnosis of cancer. Compared with the general population in Toronto, the overall estimated risk for all cancers was not increased in the lupus cohort (SIR, 1.08; 95% CI, 0.70 to 1.62). A 4.1-fold increased risk for hematologic cancers was observed; however, when these malignancies were analyzed separately, only non-Hodgkin lymphoma was associated with an increased risk (SIR, 5.38; 95% CI, 1.11 to 15.7). Using the cancer rates in patients with rheumatoid arthritis or systemic sclerosis who were in the same geographic area, the risk for cancer was found to be significantly lower in the SLE cohort compared with that of patients with rheumatoid arthritis (SIR, 0.65; 95% CI, 0.41 to 0.96) and patients with systemic sclerosis (SIR, 0.4; 95% CI, 0.26 to 0.60). An increased frequency of non-Hodgkin lymphoma among patients with SLE also was reported from Denmark (197). Ramsay-Goldman et al. (198) found an increased risk for malignancy in their lupus cohort. Breast, lung, and gynecologic malignancies were the most common malignancies observed in the cohort and breast cancer was significantly increased in Caucasian women.

Bernatsky et al. (199) assembled a multisite (23 centers) international cohort of 9,547 patients diagnosed as having SLE and observed for a total of 76,948 patient-years. Patients at each center were linked to regional tumor registries to determine cancer occurrence. Standardized incidence ratios (SIRs) were calculated. Within the observation interval, 431 cancers occurred. For all cancers combined, the SIR estimate was 1.15 (95% CI, 1.05–1.27); for all hematologic malignancies, it was 2.75 (95% CI, 2.13–3.49), and for non-Hodgkin lymphoma, it was 3.64 (95% CI, 2.63–4.93). The data also suggested an increased risk of lung cancer (SIR 1.37; 95% CI, 1.05–1.76), and hepatobiliary cancer (SIR 2.60; 95% CI, 1.25, 4.78). These results support the notion of an association between SLE and cancer and more precisely define the risk of non-Hodgkin lymphoma in SLE. It is not yet known whether this association is mediated by genetic factors or exogenous exposures

Quality of Life in Patients with Systemic Lupus Erythematosus

In addition to disease activity and damage, quality of life and disability also are considered important outcomes in patients with SLE (200). These have been measured by the Medical Outcome Study (MOS) Short Form 20 (SF-20) as well as by the SF-36. The quality of life of patients with SLE was found to be reduced compared to healthy controls (201 ,202 ,203 ,204 ,205 ,206). Although fibromyalgia has been shown to be a contributor to the reduced quality of life in patients with SLE (202 ,204), disease activity and damage have been reported to contribute by some investigators (201 ,205), but not all (202 ,203 ,206). It seems that the investigators who used either the SLAM or the BILAG as their disease activity measures were more likely to find a relationship between quality of life and disease activity or damage. This may be related to the fact that these two instruments include items that reflect quality of life as well as damage.

Early work disability was reported in 40% of patients with SLE and was related to low education level, higher physical demands of the job, and higher disease activity at diagnosis (207). Ward et al. (208) suggest that patients who participate in their own care tend to have less morbidity. This is an important concept when considering the prognosis of patients with SLE.

Summary

The information in this chapter can be summarized as follows:

- Overall survival and duration of disease:
  - More than 90% of patients with SLE survive for at least 2 years after diagnosis, compared with 50% of such patients 50 years ago. More recent surveys reveal a 80% to 90% 10-year survival rate and 80% at 20 years. The mechanism for improved survival over the past five decades is unclear.

- SLE can become inactive for many years; 15% to 20% of patients at any time have no evidence of clinical activity and are on minimal or no medication.
- African Americans, males, children, patients who receive care in publicly funded systems, and those with thrombocytopenia have a poorer prognosis, especially if nephritis is present.

- Mortality rates and causes of death:
  - A bimodal mortality curve in SLE is prevalent. Patients who die within 5 years of disease onset usually have active SLE, high steroid requirements, and infections. Patients who die later usually have evidence of atherosclerotic cardiovascular disease; in contrast, active SLE, infection, and high steroid requirements are uncommon.
  - Most patients with SLE die from active SLE, nephritis, sepsis, and cardiovascular disease. Mortality from CNS disease or malignancies rarely occurs.
- Other outcome measures in SLE

With improved survival, morbidity and damage related to the disease process or its treatment become important outcomes, as is the quality of life and functional disability of patients with SLE.

Chapter 70

Biologics and Stem Cell Therapies for Lupus

Daniel J Wallace

Bevra Hannahs Hahn

Despite all of the advances in therapy of SLE over the last few years, half of our patients with organ-threatening disease (which is half of the lupus population) succumb within 20 years. For the 75% with SLE who survive 20 years, quality of life is usually less than optimal. There has not been a drug approved for the treatment of SLE in the United States since 1966. The reasons for this are many. The first problem is the length of duration of studies to show prevention of end-stage renal disease (the landmark NIH nephritis study in the 1970s and 1980s showed it took 5 years for prednisone with parenteral cyclophosphamide to demonstrate a superior response to prednisone alone (1)). Pharmaceutical companies took note and decided they simply cannot afford to fund studies of that duration, particularly if the product being tested is not more effective than standard treatments. A second problem is the heterogeneity of the disease, presenting problems in studying outcomes—can the same study include SLE patients with nephritis and others with no nephritis, but hematologic disease or CNS disease? In this regard, it has taken a long time for the lupus investigator community to devise, test, and validate a set of measures to assess the responses and outcomes of new therapies studied in different organ systems. The recently published Food and Drug Administration (FDA) Guidance Document represents a major effort to bridge these failings and provide the pharmaceutical industry a roadmap that specifies what is expected in a clinical trial, which might lead to a drug's ultimate approval for a lupus indication (see Chapter 68) (2).

The search for innovative therapies that are targeted, safe, and effective is well underway. The majority of approaches involve the use of biologics. The 1990s saw the development and approval of a group of highly effective agents used to manage rheumatoid arthritis (RA) and other inflammatory disorders, but not lupus. Now that investigators have largely agreed that clinical activity assessments, response metrics, damage indices, quality of life assessments, organ specific measures, and safety issues are available valid and reliable in a clinical trial, no fewer than 10 biologics are in various stages of testing in humans with SLE as of this writing (July 2006). A major effort is underway to evaluate and screen a variety of surrogate markers and biomarkers that could accelerate the approval process by shortening the length of a study.

This chapter will address biologics and stem cell transplantation and their potential use in lupus. It will largely restrict itself to agents that have been tested in humans. Chapters 61 and 66 discuss niche therapies and miscellaneous immune suppressive drugs with uses applicable to lupus.

Early Human Trials

Credit for early testing of a biologic in patients with SLE goes to Richard Weisbart, Debra Zack, and their colleagues at UCLA who synthesized MAb3E10, a murine anti-double-stranded (ds) deoxyribonucleic acid (DNA) monoclonal antibody in the early 1990s. A phase I study in 9 patients showed that vaccination with the mAb produced an anti-idiotypic response (probably desirable to suppress the idiotype-bearing anti-DNA) and was safe (3 ,4). Biologics being tested for rheumatoid arthritis were studied in a small number of lupus patients. Lipsky's group and Klippel's group at the National Institutes of Health (NIH) treated a total of 10 patients with anti-CD5 ricin A chain immunoconjugate (Xoma) (5 ,6). Modest T cell depletion and transient $CD5^{+}$B cell depletion occurred. Over a 10-year period, a cell-depleting anti-CD4 antibody (MAX.16H5) was given to 35 German lupus patients. The synthesis of IL-6 was significantly decreased. However, in RA trials, tachyphylaxis occurred; safety concerns caused abandonment of this approach (7 ,8). Finally, Klippel's NIH unit also performed a phase 1b, randomized, double-blind, placebo-controlled trial of recombinant human Dnase I in lupus nephritis in an attempt to inhibit antibody deposition (9). Although safety was demonstrated among the 17 patients entered, clinical effects were slight, and achieving sustained therapeutic concentrations was problematic.

Recent Targeted Therapies in Human SLE Trials

See Table 70-1 and Table 70-2 .

Table 70-1: Summary of Drugs for SLE Recently Studied in Human Clinical Trials

1. Therapies that target T/B/APC cell interactions
   a. Anti-CD40L (Biogen/IDEC)
      i. One product was safe, but not effective and another was thrombogenic; new products being developed
   b. CTLA4Ig (Bristol Myers Squibb)
      i. Approved for RA (2006) lupus trials underway
2. Targeting the activation of complement
   a. Anti-C5a and SLE (Alexion)
      i. Improves paroxysmal nocturnal hemoglobinuria, modestly effective in RA, phase I trial documents safety in SLE
3. Inducing immune tolerance
   a. LJP 1082 (La Jolla Pharmaceuticals)
      i. Binds to $ß_2$-glycoprotein I; safety documented in phase I trial
   b. LJP 394 (La Jolla Pharmaceuticals)
      i. An anti-DNA B cell tolerogen; tested in nearly 1,000 patients and has received an approvable letter from the FDA
   c. Edratide (TV4710, TEVA)
      i. A peptide tolerogen that inhibits anti-DNA production probably by inducing regulatory T cells. Safety demonstrated in phase I study; phase II-III trial in progress
4. Agents that target B cells
   a. BlyS protein stimulator protein antagonists and related compounds (Human Genome Sciences <HGS>, Amgen, Lilly, Serono, Biogen)
      i. HGS product safe in phase I trial, improves lupus if seropositive in Phase III trial. Other agents in phase I trials.
   b. anti-CD20 (Rituximab—Genentech)
      i. Approved for lymphoma, RA. Phase III lupus trials in progress, many promising case reports, fully humanized versions being studied (Genmab, Trubion, Genentech)
   c. anti-CD22 (Epratuzumab—Immunomedics)
      i. Phase I trial demonstrates safety in lupus and Sjogren; phase III trial in progress for lupus, Sjogren, and lymphoma
5. Agents that remove autoantibodies from the circulation
   a. Antibody to CR1 linked to a DNA antigen (Elusys, ETI 201)
      i. Promotes clearance of anti-DNA, phase I trial demonstrated safety
6. Agents that target cytokines
   a. TNF blockers: Infliximab (Remicade-Centocor/Schering)
      i. Approved for RA, articles suggest efficacy in selected cases of SLE, but may increase autoantibody production
   b. Agents that target interleukins: anti IL-1Ra (Kineret-Amgen), anti IL-6 (Roche), and IL-10 (Schering)
      i. Approved for RA, Kineret is disappointing in lupus, NIH trial of anti-IL-6 suggests efficacy, 6 patients given anti IL-10 had a modest response
   c. Agents that target interferons—in development

NIH, National Institutes of Health; RA, rheumatoid arthritis.

Therapies That Target T/B/APC Cell Interactions

Anti-CD40L Monoclonal Antibodies

CD40 is expressed constitutively on B cells, antigen-presenting cells (APCs), endothelial, and epithelial cells and interacts with CD40L (CD154, gp39) induced on activated T and B cells, basophils, and eosinophils. CD40/CD40L interaction is necessary for normal immune functions such as T cell activation, B cell differentiation and activation, apoptosis, germinal center formation, and antibody isotype switching (10 ,11). $CD4^+$ and $CD8^+$ T and B cells from SLE mice and patients express increased quantities of CD40L compared to healthy controls. CD40 knockout mice have defective humoral immunity. Glomeruli from lupus nephritis patients show upregulated CD40 and CD40L expression. Inhibition of the interaction of CD40-CD40L should inhibit T cell activation, B cell responses, and autoantibody production. In murine lupus, anti-CD40L therapy can delay, but not prevent development of disease, if given prior to the onset of disease. Early therapy prevents antibody production, whereas later therapy prevents tissue damage (12).

A phase I clinical trial of a humanized monoclonal antibody against CD40L (IDEC 131) showed that the antibody binds to CD40L on T cells, prevents CD40 signaling in B cells, and is safe and well tolerated (13). A phase II randomized, double-blind, placebo-controlled trial of 85 patients with mild to moderately active SLE who received six infusions over 6 weeks showed improved SLEDAI scores in both treatment and placebo groups; the differences were not statistically significant. Many patients clearly improved

on the drug; the study design might have been improved regarding entry criteria, dose of mAb, and so on (14). On the other hand, 28 patients with active proliferative nephritis who received a different mAb anti-CD40L (BG9588) showed mean reduction in anti-DNA antibody, improved C3 complement, and diminished hematuria (15). The trials were halted when several patients in SLE and in transplantation trials developed thromboembolic events. CD40-CD40L interactions occur on endothelial cells and on platelets; these effects might account for the prothrombotic properties of at least one of these mAb (16). Further work regarding these interactions will be required before anti-CD40-CD40L blocking agents are tested further in humans.

Table 70-2: Additional Approaches Likely to Be Utilized in Human Trials

1. T cell vaccination
2. Agents that target chemokines
3. Blockade of the alternative complement pathway
4. Peptide tolerogens to HLA molecules, Sm, and immunoglobulins
5. Promotion of T regulatory cells
6. Approaches that block interferon-α
7. Gene therapies
8. Upregulation of TGF-ß
9. Targeting toll receptors that promote inflammation
10. Targeting Fc receptors
11. Developing gene transcriptional regulators
12. Inhibition of IL-12,15, 17, or 18
13. Induction of anergy in helper T cells

CTLA4Ig (Cytotoxic-T-Lymphocyte Antigen 4 Fused with a Portion of Immunoglobulin)

The CD80/86 (B7.1/2)-to-CD28 pathway is the major second signal that causes T cell activation, proliferation, survival, and cytokine production (17 ,18 ,19). CD28, which is constitutively expressed on T cell surfaces, binds CD80/86 on APCs and cell signaling resulting in cytokine production and proliferation ensues. Once T cells are activated, they express surface CTLA4. This molecule is structurally related to CD28, but binds B7 molecules with a much higher avidity than CD28. CTLA4/CD80/86 interactions usually generate a negative signal to T cells, downregulating proliferation and cytokine production. The biologic agent CTLA4Ig, a soluble recombinant humanized fusion protein with an IgG-Fc portion, mops up CD80/86. Therefore, CD80/86 molecules are not available to bind CD28; T cell activation to proliferation and cytokine secretion cannot occur. CTLA4Ig administration inhibits predominantly naïve and $CD4^+$ T cells with little or no effect on $CD8^+$ T cells. Thus, the undesirable, rapidly proliferating $CD4^+$ helper T cells driving B cells to make autoantibodies are inhibited, and a variety of both pro-and anti-inflammatory cytokines fall in quantity. The magnitude of effect varies depending on the APC cell with different effects on dendritic and B cells.

CTLA4Ig inhibits T cell–dependent B cell maturation in NZB/NZW F1 mice, and delays the onset of nephritis when administered early in life. Importantly, it can suppress established lupus nephritis when combined with cyclophosphamide or anti-CD40L therapy (19). In lupus, it is thought that the administration of CTLA4-Ig may additionally induce tolerance and skew the cytokine profile toward Th2.

Abatacept (a commercial preparation of CTLA4Ig; Bristol Myers Squibb) ameliorates disease activity in psoriasis and in RA in combination with methotrexate (20). It has not been compared directly to anti-TNF therapies in these diseases. In February, 2006, Abatacept (Orencia) was approved by the FDA for the treatment of rheumatoid arthritis. Clinical trials with abatacept in SLE were initiated in 2005 and another CTLA4-Ig product has entered phase I trials in SLE patients.

Targeting the Activation of Complement

Anti-C5a and SLE

Formation of the terminal components of complement has been inhibited by targeting C5 (21 ,22 ,23). Anti-C5 antibodies improved survival and delayed the progression of renal disease in murine lupus (24). Eculizumab binds specifically to C5, inhibiting its cleavage into C5a and C5b, preventing the release of C5a and formation of C5b-9. In a phase I trial, intravenous administration of eculizumab (humanized recombinant anti-C5a antibody hbG1.1, Alexian) blocked C5 activation for up to 10 days and was safe and well tolerated (25). Eculizumab treatment diminished transfusion requirements, hemolysis, and improved quality of life in 11 patients with paroxysmal nocturnal hemoglobinuria, a disorder characterized by a deficiency of surface proteins, which protect the cells against attack by the complement system (26). Disappointingly, a phase II trial of eculizumab in RA showed it to be no more effective than methotrexate and funding for future lupus initiatives have been put on hold by the manufacturer, whereas development for use in paroxysmal nocturnal hemoglobinuria continues (24).

Complement Inhibition Prevents Fetal Loss from Antiphospholipid Antibodies in Mice

Experiments in pregnant mice infused with human anticardiolipin (anti-CL) have shown that activation of C3 and C5 complement are required for antiphospholipid-induced pregnancy loss (27). Furthermore, the thrombogenic properties of antiphospholipid antibodies are reduced in C3 and C5 knock out mice (28). Holers and Salmon demonstrated that administering an anti-C5 monoclonal antibody to anti-CL–infused pregnant mice significantly reduces fetal loss (27). Similarly, administration of an antibody that prevents alternative pathway activation (Factor B interaction with complement to form the C3bBb complex), is also effective (29). Heparin, which inhibits complement activation

(probably via charge) is effective in reducing fetal loss in the model, but fondaparinux and hirudin, anticoagulants that do not inhibit complement activation, are not effective (30). Therefore, for prevention of antiphospholipid–induced fetal loss in mice, treatment that inhibits complement activation is more effective than treatment that simply anticoagulates.

Inducing Immune Tolerance

Inhibiting Antiphospholipid Syndrome by Tolerizing B Cells Making the Antibody

Another approach to inhibiting antiphospholipid syndrome is to tolerize B cells so they cannot make the antibody. LJP 1082 (La Jolla Pharmaceuticals) has a polyvalent antigenic structure aimed at cross-linking surface immunoglobulin that binds $ß_2$-glycoprotein 1 ($ß_2$GPI) (a target of most anticardiolipin antibodies). The antigen is small; therefore, B cell receptors can be linked with antigen without simultaneous binding of Fcγ receptors. Thus, the B cell receives the first activating signal but not the second; the B cell should be rendered anergic (tolerized). In a phase I trial in patients with antiphospholipid antibodies, a single intravenous dose of LPJ 1082 was safe. Further development of this promising agent depends upon the availability of funding (31 ,32).

Inhibiting Anti-DNA Production by Tolerizing B cells: LJP 394 (La Jolla Pharmaceuticals; Riquent)

LJP 394 is a synthetic compound that is designed to act as B cell tolerogen for cells with DNA-binding BCR. The active drug substance is a water-soluble conjugate composed of four oligodeoxyribonucleotides (B cell epitopes) attached though a linker to a triethylene glycol-base central branched structure or platform. LJP 394 provides multivalent epitopes capable of cross-linking surface antibody (B cell receptors that bind DNA, thus on a B cell that can make anti-DNA). The antigen is small, so that BCR can be cross-linked, but not FcγR. Therefore, there is first signal without second signal, and the B cell becomes anergic, unable to proliferate or secrete antibody. LJP394 is neither immunogenic nor antigenic; it does not affect natural killer cell activity or T cell–mediated delayed-type hypersensitivity. No anaphylaxis has been observed, and it activates complement poorly, if at all (33).

LJP 394 has been studied in 14 randomized controlled studies enrolling approximately 900 patients since 1996 (34 ,35 ,36). Administered as a 90-second intravenous push as often as every week, the agent has had no apparent safety issues or adverse reactions. The principal conclusions of the trials demonstrated: (a) significant reduction in serum levels of anti-dsDNA and increases in levels of C3 complement, (b) improvement in quality of life indices, (c) a trend toward reduction of renal flare rates and time-to-renal flare, (d) greatest efficacy in patients whose anti-DNA binds the LJP394 oligonucleotide epitope with high affinity. Riquent has received an approvable letter from the FDA pending results of an additional clinical trial.

Inhibiting Anti-DNA Production by Tolerizing T Cells: Peptide Tolerogens

There are several examples of small peptides (9 to 34-mers) from autoantigens or autoantibodies that bind to HLA/MHC Class II and/or HLA/MHC Class I molecules—complexes that then can engage T cell receptors (TCR) that recognize the MHC/peptide complex on $CD4^+$ T or $CD8^+$ T cells. Mechanisms of tolerance induced by IV or subcutaneous inoculation of such peptides include induction of: (a) anergy in $CD4^+$ helper T cells, (b) $CD4^+$ regulatory T cells that by secretion of IL-10 suppress proliferation in $CD4^+$ helper T cells, (c) $CD4^+CD25^+$ regulatory T cells that on contact inhibit proliferation in $CD4^+$ helpers and/or Ig synthesis by B cells, and (d) $CD8^+$ inhibitory cells that inhibit $CD4^+$ proliferation by secretion of TGF-ß. Hahn and Singh, working in the NZB/NZW F1 mouse model of lupus, have shown that the administration of high doses of selected peptides, including an artificial peptide, pConsensus, that contains T cell epitopes that can activate both $CD4^+$ T cells through I-Ed (MHC class II) and $CD8^+$ T cells through Kd (MHC class I) can delay or suppress anti-DNA production and nephritis (37). T cell anergy and induction of peptide-binding $CD4^+CD25^+$ regulatory T cells and $CD8^+$ TGF-ß-secreting cells occur in that system (38 ,39). Datta et al. have shown similar results in murine lupus with peptides selected from the histones in nucleosomes (40); both $CD4^+CD25^+$ and $CD8^+$ regulatory/inhibitory T cells are induced in that system; high doses and very low doses (nanomolar quantities) are effective (41). Reimekasten et al. (42) have shown similar results after administration of a peptide from the Sm-D antigen, with IL-10 secreting $CD4^+$ T cells as major regulators.

Mozes et al. have brought this idea to human trials. They constructed a peptide (Edtratide: TV4710, Teva Pharmaceuticals), which contains amino acid sequences from a human mAb Ig hypervariable region. Similar peptides from murine anti-DNA suppress autoantibodies and autoimmune disease in murine lupus (43). Administration of the peptide also prevents anti-DNA synthesis by human B cells transferred to SCID mice (severe combined immunodeficiency mice, which lack thymus, and therefore, most T cells) (44). In a phase I safety and dose-finding trial, Edratide was administered subcutaneously to patients with SLE. Safety and tolerability were good. Phase II/III trials are enrolling SLE patients (45).

Agents That Remove Autoantibodies from the Circulation

Elusys has developed a heteropolymer (ETI-201) that consists of a murine antibody to CR1 (CD35) linked to DNA antigen. CR1 receptors (also called C3b C4b receptor) on erythrocytes of primates, including humans, bind C3b produced by complement activation. As complement is activated within immune complexes, the complexes bind to CR1 via C3b and are carried by erythrocytes to liver, where they are phagocytized and cleared. The heteropolymer should produce immediate clearing of anti-DNA; its DNA portion is recognized by a patient's anti-DNA, and because

the polymer is already bound to CR1 via anti-CR1, clearing of the undesirable antibody should occur promptly. In SLE patients, phase I trials have demonstrated that ETI-201 can lower anti-dsDNA (both high avidity and total anti-DNA) and appears safe (46). From published data, it is not clear how frequently the heteropolymer has to be administered to produce long-lasting reduction of anti-DNA quantities.

Agents That Target B Cells

B Lymphocyte Stimulator (BLyS) Protein Antagonists and Related Compounds

A member of the TNF superfamily, BlyS protein (also known as BAFF, TALL-1, THANK, TNFSF20, zTNF4) is a 285 amino acid protein that upon binding to receptors on B cells promotes survival, expansion, and differentiation of those cells (47 ,48 ,49 ,50). There are three receptors that bind BlyS—BCMA, BAFF-R, and TACI. First described in 1999, BLyS expression is highly restricted to myeloid lineage cells (e.g., monocytes, macrophages, dendritic cells) and some activated T cells. Mice that develop spontaneous lupus have increased serum levels of BLyS; transgenic mice overexpressing soluble BlyS develop a lupus-like disorder (49 ,50). Many patients with SLE, RA, lymphoma, and Sjogren syndrome have elevated serum levels (51 ,52 ,56). BlyS is 35% homologous with APRIL, a 250 amino acid protein that binds to BlyS receptors BCMA and TACI but not BAFF-R. In some systems, signaling through APRIL results in downregulation of B cell expansion. Levels of APRIL inversely correlate with anti dsDNA (53).

Human monoclonal antibodies against BLyS and its related proteins have been developed. In a phase I study, 75 patients with SLE received anti-BlyS (LymphoStat B, Human Genome Sciences). The product reduced quantities of circulating B cells and had acceptable safety and tolerability (54). Anti-BLyS is modestly effective for RA (55). In a phase II SLE trial, the efficacy outcomes of reduced disease activity measured by SLEDAI, and reduced numbers of flares, compared to placebo, were not met (55). However, a subset of patients could be identified that had good responses, and there was significant reduction of anti-DNA in the treated groups. The manufacturer has announced that it intends to pursue phase III trials, with modifications that will concentrate on the subset of patients most likely to be responsive. Other agents in development include fusion proteins of soluble BAFF-R (Biogen) and soluble TACI (Serenoa, Amgen). These should mop up soluble BlyS, preventing it from binding to receptors on B cells, thus preventing full B cell expansion and maturation in marginal zones of lymphoid tissues.

Rituximab (Anti-CD20 Therapy)

CD20 protein consists of 44 amino acids exposed in the extracellular space of pre-B lymphocytes and mature B lymphocytes but not hematopoietic stem cells, pro-B lymphocytes and plasma cells. Antibodies to CD20 thus specifically eliminate B cells without preventing their regeneration. A chimeric anti-CD20 whose variable region is derived from a mouse antibody contains a human IgG1 κ constant region and a variable region from a murine antibody IDEC-C2B8, which binds with high affinity to cells expressing the CD20 antigen. It is thought to have anti-inflammatory actions in rheumatic diseases via five mechanisms. These include activation of complement with lysis of the targeted cell, antibody-dependent cell-mediated cytotoxicity, alteration of the ability of B cells to respond to antigen (with decreases in B cell derived IL-6 and IL-10), decreases in T helper cell activation via down regulation of the T cell CD40L costimulatory pathway, and promotion of apoptosis. Since its introduction in 1997, rituximab (Rituxan) has been given to over 750,000 lymphoma patients (56 ,57).

Rituximab has therapeutic effects in RA (especially in combination with methotrexate) in several large trials. As of this writing approximately 120 patients with SLE given rituximab have been published in case reports and open label trials (58 ,59 ,60). It appears to reduce the quantities of B cells acting as APC to activate helper T cells (59), without drastically lowering autoantibody titer, quantitative immunoglobulins or anti-dsDNA. Quantities of circulating B cells nadir 1 to 2 months posttreatment and correlate well with higher serum rituximab levels and the Fc-γRIIIa genotype (61 ,62). In uncontrolled, open trials in patients with SLE, disease activity indices (e.g., SLEDAI, SLAM) improved in 40% to 80% of patients and remain favorable in most for 2 to 6 months. The dosing in these reports ranges from a total of 1,000 mg/m^2 to 1,500 mg/m^2 given intravenously one to four times over 4 weeks. Concomitant therapies have included corticosteroids (which if given intravenously as methylprednisolone with rituximab decreases infusion reactions), and in some series cyclophosphamide or other immune suppressives. Nearly all manifestations of SLE improve, especially if autoimmune hemolytic anemia, thrombocytopenia or nephritis are present. The treatment produces fever, chills, asthenia, and headaches the first day or so, but these effects are short-lived. Such reactions are most common during and after the first infusion of Rituximab. The emergence of inactivating antibodies to the Rituximab mouse/human chimera probably accounts for the general observation that Rituximab's effects diminish with repeated dosing several months later (63 ,64). Several humanized versions of Rituximab are being studied in clinical trials in RA (Trubion, Amgen, Genmab, Genentech) and in SLE and a large-scale trial with rituximab in SLE has been initiated (Genentech).

Epratuzumab (hLL2; Immunomedics, UCB) Therapy

CD 22 is a B cell restricted, 130 to 140 kd transmembrane glycoprotein expressed in the cytoplasm of pro-B, pre-B, and mature B cells, but not plasma cells (65 ,66). It internalizes rapidly followed by degradation in lysosomes, without detectable recycling. The binding of CD22 to endogenous ligands triggers B cell activation and proliferation.

Epratuzumab (hLL2; Immunomedics) is a humanized anti-CD22 monoclonal antibody that binds with high affinity to the third loop of CD 22, and blocks binding of natural ligands. It inhibits B cell receptor mediated signals, elicits moderate antibody-dependent cellular cytotoxicity, promotes apoptosis, activates sialic acid bearing ligands, and decreases CD 22 cell surface expression. These actions play an important role in SLE. Epratuzumab causes a temporary, moderate B cell depletion, which is less than noted with its closely related cousin, rituximab.

Epratuzumab has been studied in lymphoma, Sjogren syndrome, and SLE (67 ,68). Intended to be given weekly for 4 weeks every 3 months for 1 year in its uncontrolled clinical trial for lupus that began in 2005, the agent improved salivary and lacrimal gland flow, fatigue, and tender joint counts in 14 Sjogren patients, and appeared safe and well tolerated among 15 lupus patients. In the latter group, it appeared to improve disease activity in those with mild to moderate inflammation as defined by BILAG scores.

Agents That Target Cytokines

TNF-a Inhibition

The widespread availability of etanercept, infliximab, and adalimumab for RA has led to its off-label use in patients with SLE who were refractory to standard therapies. There is considerable evidence that TNF-α plays a pro-inflammatory role in lupus; renal biopsies contain significant amounts of TNF-α, and serum levels are elevated in some patients. However, caution has been advised, because 10% to 45% of patients with RA, Crohn disease, or psoriasis receiving TNF-α inhibitors have developed antinuclear antibodies, anti-dsDNA and/or anticardiolipin antibodies (69 ,70 ,71). Disease flares have been reported in this setting and about 1% developed drug-induced lupus (reviewed in Chapter 44). Smolen's group has reported improvements in synovitis and proteinuria in lupus patients receiving infliximab even though anti-dsDNA and antiphospholipid titers increased in some of the patients (71 ,72). At the time of this writing (July 2006), the safety and efficacy of TNF-α inhibitors in SLE is not clear.

Agents That Target Interleukins

Anakinra (Kineret) is an anti–IL-1RA therapy that has transient but unimpressive effects in SLE (73). IL-6 plays a critical role in B cell hyperactivity in SLE (74). Preliminary work at the NIH suggests that mononuclear cells from lupus patients might be inactivated by treatment with a humanized anti IL6-R monoclonal antibody (75 ,76). The therapy has been impressively effective in children with Still disease in Japan (77). Six patients given an anti–IL-10 murine antibody intravenously for 21 days showed a reduction in SLEDAI score, cutaneous lesions, and joint symptoms, but all developed antibodies against the agent (78).

Agents That Target Chemokines

Although antagonism to monocyte chemoattractant protein 1 failed to improve human rheumatoid arthritis, since it retards nephritis and renal vasculitis in MRL/lpr mice, studies in human SLE are anticipated (79 ,80).

T Cell Vaccination

Li et al. successfully vaccinated six patients with autoreactive T cell clones, which resulted in decreases in SLEDAI scores and steroid dose reduction (81).

Stem Cell Transplantation and SLE

In the early 1990s, the idea arose of treating patients with severe SLE who were unresponsive to conventional therapies with immunoablation followed by infusion of autologous hematoprogenitor stem cells (82 ,83).The theoretical benefits would be (1) the procedure would “debulk” the immune system of its autoreactive cells, providing the opportunity for normal regulatory networks to exert control of autoimmune disease; (2) “new” immune cells would develop in the environment of upregulated display of self-antigens to which the person had reacted previously, and such cells would “learn” to be tolerant to those self-antigens. Against these potential benefits would be the fact that the cells repopulating the immune system have the same genetic content as the original cells; therefore if SLE depends as much or more on genetic predisposition as on unfortunate environmental “hits,” the results would be recurrence of SLE.

Supporting the potential benefits were observations that in several patients with cancers treated with autologous bone marrow transplantation, concurrent SLE improved (84 ,85). These reports were followed by reports of one or a few cases of SLE treated with high dose immunosuppressive with bone marrow rescue by autologous stem cells (86 ,87 ,88). With this encouraging beginning, U.S. and European centers began treating larger numbers of SLE patients and recording results in widely available databases (88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96). As of October 2004, 66 patients with SLE had been treated, followed for at least 36 months, and enrolled in the EBMT/EULAR autoimmune disease database. In the United States as of November 2004, Burt and Traynor have treated 33 patients with follow-up for at least 12 months.

From data published to date, the authors have reached the following conclusions:

- Aggressive immunoablation plus myeloablation is unnecessary for response and carries a high morbidity/mortality. At the time of this writing (November 2005), most phase II/III studies are designed with immunoablation alone, generally built around a dose of cyclophosphamide of 200 mg/kg given over 4 days before autologous stem cells are administered, plus high-dose corticosteroids during the first few weeks, and GM-CSF administered after stem cell transplant to

speed the reappearance of granulocytes in the circulation.

- The conditioning regimen (to expand stem cells prior to harvest) is somewhat risky and involves administration of cyclophosphamide 2 g/m^2 and G-CSF to mobilize hematopoietic stem cells, which are then isolated by CD34$^+$ selection. To carry out transplantation, the stem cells must expand in vitro to an appropriate number to maximize repopulation of the bone marrow.
- Removal of T lymphocytes from the host gives better responses and lower GVH-like adverse events. This is achieved in most protocols by administration of ATG 90 mg/kg divided over 3 days prior to the infusion of the stem cells.
- All the regimens include standard antibiotics, antifungal, and antiviral preventive measures during the period of agranulocytosis that follows immunoablation.
- Failure of the stem cells to engraft is rare, but occurs (97).
- Autoantibodies and autoimmune syndromes that are previously absent can occur after autologous stem cell transplantation; these include autoimmune thyroid disease, hemolytic anemia, thrombocytopenia, and antiphospholipid antibodies and syndrome.
- Mortality rates in the United States, Europe, and Asia among SLE patients treated with various regimens and autologous stem cell transplantation is 5% to 15%. Deaths occur from sepsis, bleeding, new lymphoproliferative disorders, active progressive SLE unresponsive to treatment (or relapsing), and new autoimmune events.
- The rate of remission (defined variously, most commonly as (a) SLEDAI less than or equal to 3, (b) prednisone requirement less than or equal 10 mg per day and (c) no new immunosuppressive drugs) is approximately 66%. An additional 10% to 15% have a response that is not complete.
- The rate of relapse among good or partial responders is approximately 33% over a period of 3 years.
- Several manifestations of SLE in patients that have been resistant to standard therapies can respond well to these regimens of autologous hematopoietic stem cell transplantation, including nephritis (if a reversible component is present), central nervous system lupus, pulmonary lupus, and antiphospholipid syndrome (98 ,99).

The most important factor in determining whether this intervention is successful is patient selection. Death rates in the European/Asian experience were highest in patients with very active SLE (SLEDAI scores >20) (96). On the other side of the coin, a treatment associated with a 5% to 15% mortality rate is not appropriate for patients whose SLE is not life-threatening, unless they choose to take this rather large risk because their quality of life is quite poor. Finally, the patients must have reversible disease to benefit; determining that is not always easy, particularly when the major disease manifestations are extrarenal and tissue is not readily available for biopsy.

In summary, with durable remission possible in approximately 50% of SLE patients with severe disease who have entered these trials, most experts feel that additional trials are warranted. At this time (November 2005), we are aware of controlled phase II trials underway at the facilities of the NIH in Bethesda, MD, and a larger multicenter trial supported by the NIH is scheduled to begin in 2006.

Many experts think that developing safe methods of allogeneic bone marrow/stem cell transfer to patients with SLE would be a better strategy than autologous stem cells, since the donor would not have a lupus-prone genetic background. The major hazard of this approach is graft-versus-host disease. However, a method that employs small and infrequently repeated doses of allogeneic human donor T cells to SLE patients is being studied. A recent open study by Burt RK et al. (*JAMA* 2006:295:559–560.) in SLE patients in the USA showed at 5 years probability of 84% survival and 50% disease free survival.

Targeted Therapies in Development (Not yet used in Humans)

Approaches that Block Interferon-a

Using global gene expression profiling, a majority of lupus patients show dysregulated expression of genes in the interferon pathway. This signature serves as a marker for more severe disease activity (100 ,101 ,102). α-Interferon promotes B cell, T cell, and dendritic cell activity and increased MHC expression. Plasmacytoid dendritic cells are a potent source of type 1 interferons (103). Therapeutic approaches that block the activation of interferon-α include those that interfere with its production, effects on cytokines, effects on other immune cells, agents that inhibit its signaling pathway or drugs that neutralize it directly. Agents that block this pathway have potential uses in managing lupus. MedImmune is studying antibodies against interferons and interferon receptors as potential therapies for SLE (104).

Gene Therapies for Lupus

Since the tragic death in 1999 of a young man undergoing gene therapy in the United States, most human trials have stopped. However, in murine models of lupus, there continues to be important work in gene therapy. Most of the treatments have targeted cytokines, T/B/APC interactions, or induction of regulatory T cells. With regard to cytokines, there is substantial evidence that an imbalance between helper and regulatory cell functions is characteristic of SLE. Increasing IL-2 levels via administration of the construct in vaccinia virus or in oral attenuated Salmonella typhimurium to MRL/lpr mice reduced autoantibody production and renal damage (105 ,106), but administration of a construct as cDNA given IM enhanced autoantibody production and shortened survival (107). In a human experiment, transfection of p65 (a subunit of the NF-κB transcription factor that regulates IL-2 production) into cultures containing T cells from SLE patients increased IL-2 promoter activity in the cells (108).

Upregulation of TGFbeta has also had mixed results—improving MRL/lpr disease given in plasmid (109), or as cDNA injected intramuscularly (106) but not when delivered

orally in *Salmonella* (107). Administration of adenovirus vector containing DNA encoding human TGF-ß receptor showed expression of the protein in glomeruli, and a brief period during which mesangial proliferation and fibrosis in glomeruli and interstitium was reduced, but the benefit was not maintained (110). Administration of plasmid containing DNA encoding IL-12 to MRL/lpr mice increased levels of IL12 and was beneficial (111). Inhibition of IFN-γ by IM injections of plasmids with cDNA encoding IFN-γR/Vc, or naked DNA from such plasmids, retarded both onset and progression of SLE in MRL/lpr mice (112).

Prevention of T/B crosstalk was induced by administration of adenovirus containing CTLA4IgG gene IV, which improved lupus nephritis in MRL/lpr (113). A single injection of an adenoviral construct for transmembrane activator and CAML interactor receptor that produces high serum levels of TACI-Fc fusion protein reduced B cell numbers and blocked autoantibody production in B6.lpr/lpr mice, and reduced B cells and nephritis in MRL/lpr. However, NZB/NZW F1 mice were not responders because they made antibodies to the TACI and did not reduce B cell numbers or disease (114).

Finally, gene therapy has been used to induce regulatory/inhibitory T cells. First, nucleosome-specific regulatory T cells were induced in NZB/NZW F1 mice by multiple gene transfer than included TCR-α, TCR-ß, of a histone of peptidereactive T cell and CTLA4Ig, with resultant suppression of nephritis (115). A second approach was designed to induce anti-DNA-immunoglobulin-derived-peptide-specific $CD8^+$ cytotoxic T cells that could kill B cells making anti-DNA. A minigene encoding Ig-derived peptides that are presented by MHC class I molecules in NZB/NZW F1 mice was inoculated into young mice. The immunized mice developed $CD8^+$ T cells cytotoxic for B cells with BCR that bind DNA. Thus, the gene therapy specifically targeted production of anti-DNA. Proteinuria was delayed and survival increased (116).

In summary, gene therapy for SLE is in an early stage (117). The ideal DNA constructs, vectors, routes of administration, and dosage schedules have not been completely worked out, particularly for human use. This is an exciting future direction.

Other Strategies

Innovative strategies that can improve lupus may employ novel approaches, but have not been attempted in humans. Some of these include:

- The promotion of regulatory cells that are deficient in SLE, such as $CD4^+CD8^-CD25^+$, which may be accomplished by “educating” peripheral blood mononuclear cells with IL-2 and TGF-ß (118), or by peptide tolerization or gene vaccination discussed above (38 ,39 ,41 ,43).
- Developing gene transcriptional regulators, such as histidine deacetylases (HDAC) inhibitor Trichostatin A, coactivators, corepressors, or nuclear hormone receptors (119).
- Targeting Fc receptors that couple antigen-antibody complexes to effector cells and initiate the inflammatory cascade (120).
- Targeting toll receptors that promote inflammation as part of our innate immunity. For example, dendritic cell activation by chromatin-immunoglobulin G complexes is Toll-like receptor 9–dependent and is probably relevant to maintaining immune activation in patients with SLE (121).

Section VII:
Appendices

Appendix I: A Patient's Guide to Lupus Erythematosus

Daniel J. Wallace

Bevra Hannahs Hahn

Francisco P. Quismorio Jr.

Purpose of This Appendix

When first told they have lupus erythematosus (LE), many patients have never before heard the term. This appendix is intended to help you understand what lupus is, how it may affect your life, and what you can do to help both yourself and your physician in the management of the illness. It will not replace your physician's advice. Because each case of LE is different, only your physician can answer specific questions about your individual situation. It is hoped that by learning facts about LE in nontechnical terms, you may increase your knowledge of the disease. In addition to explaining what lupus is, we have tried to answer other questions that you, your relatives, and your friends may have, such as what causes LE, the difference between cutaneous LE (CLE) and systemic LE (SLE), how the diagnosis is made, and how the illness is treated.

We use easy-to-understand terms throughout this appendix. We also have provided a glossary at the end to explain the more complicated words.

Because many of the most significant studies of LE are fairly recent and are constantly in various stages of exciting change and progress, much of the information that is available is already out of date. If you look up LE in an encyclopedia or medical book, you likely will be confused and maybe even frightened. You do not need to be frightened, and it may interfere with your seeking proper diagnosis and treatment.

A Brief History of LE

Lupus means *wolf* in Latin, and erythematosus means *redness*. The name was first given to the disease because it was thought that the skin damage resembled the bite of a wolf.

LE has been known to physicians since 1828, when it was first described by the French dermatologist Biett. Early studies were simply descriptions of the disease, with emphasis on the skin changes. Forty-five years later, a dermatologist named Kaposi noted that some patients with LE skin lesions showed signs that the disease affected internal organs.

In the 1890s, Sir William Osler, a famed U.S. physician, observed that systemic LE (also called SLE) could affect internal organs without the occurrence of skin changes.

In 1948, Dr. Malcolm Hargraves of the Mayo Clinic described the LE cell, which is a particular cell found in the blood of patients with SLE. His discovery enabled physicians to identify many more cases of LE by using a simple blood test. As a result, the number of SLE cases that have been diagnosed during the succeeding years has steadily risen. Since 1954, various unusual proteins (or antibodies) that act against the patient's own tissues have been found to be associated with SLE. Detection of these abnormal proteins has been used to develop more sensitive tests for SLE (i.e., antinuclear antibody [ANA] tests). The presence of these antibodies may result from factors other than SLE.

What is LE?

LE usually appears in one of two forms: (1) cutaneous lupus erythematosus (the skin form, CLE); or (2) systemic lupus erythematosus (the internal form, SLE).

Chronic cutaneous lupus (CLE, formerly known as discoid lupus) LE has a particular type of skin rash with raised, red, scaly areas, often with healing in the centers or with scars. These eruptions most commonly are seen on the face and other light-exposed areas. Usually, patients with DLE have normal internal organs. A skin biopsy of the lesion may be helpful in confirming the diagnosis.

Subacute cutaneous lupus erythematosus (SCLE) is a nonscarring subset of lupus that is characterized by distinct immunologic abnormalities and some systemic features.

SLE is classified as one of the autoimmune rheumatic diseases, in the same family as rheumatoid arthritis, and usually is considered to be a chronic, systemic, inflammatory disease of connective tissue. Chronic means that the condition lasts for a long period of time. Inflammatory describes the body's reaction to irritation with pain and swelling. LE involves changes in the immune system, so that elements of the system attack the body's own tissues. Different organs are affected in each person, and joints usually are inflamed.

Inflammation also can involve the skin, kidney, blood cells, brain, heart, lung, and blood vessels. The inflammation can be controlled by medication.

SLE can be a mild condition, but because it can affect joints, skin, kidneys, blood, heart, lungs, and other internal organs, it can appear in different forms and with different intensities at different times in the same person. A large number of people with SLE have few symptoms and can live a nearly normal life. Therefore, while reading about the symptoms, you should not become unnecessarily worried, because all of the symptoms usually do not occur in one person.

How serious lupus is varies greatly from a mild to a life-threatening condition. It depends on which parts of the body are affected. Even a mild case can become more serious if it is not properly treated. The severity of your LE should be discussed with your physician.

In addition to CLE and SLE, there are other variants of lupus. Drug-induced lupus afflicts 15,000 Americans each years and results from over 70 different drugs. Fortunately, it goes away when the medicine is discontinued. Neonatal lupus reflects the presence of a lupus rash or abnormal heart pacing system in a newborn whose mother has certain lupus autoantibodies. The rash disappears within a few weeks and the children do not have lupus. Mixed connective tissue disease or crossover or overlap syndromes imply the presence of lupus as well as another autoimmune disorder such as scleroderma (i.e., hardening and thickening of the skin), rheumatoid arthritis or polymyositis (i.e., inflammation of the muscles). Finally, undifferentiated connective-tissue disease (UCTD) patients often have features of lupus, such as a positive ANA with swollen joints, but do not fulfill the criteria for SLE. Over time, one third evolve lupus or another autoimmune disorder, one third stay as a UCTD, and the process disappears in another third. LE is not infectious or contagious. It is not a type of cancer or malignancy. LE is not related to acquired immunodeficiency syndrome (AIDS).

Frequency of LE

No one has made an accurate estimate of the number of patients with CLE because many people have mild cases and probably do not know it. There may be as many as 1 million people with SLE in the United States.

The number of new cases of SLE diagnosed by physicians is definitely increasing, for several reasons. After the LE cell test came into use, physicians were able to diagnose the illness correctly in patients who were believed to have other rheumatic diseases, or who were thought to have neurotic complaints. Tests for ANAs and other antibodies, which usually are positive in SLE, have helped physicians to discover even more patients with milder cases, but the tests might be positive in patients without SLE.

Seven of ten patients with CLE and 90% with SLE are women, most of them developing their first symptoms between 15 and 30 years of age. LE is rare in children under the age of 5. It is found throughout the world, however, and affects all ethnic groups and religions.

SLE is more common than rheumatic fever, leukemia, cystic fibrosis, muscular dystrophy, multiple sclerosis, hemophilia, and several other well-known diseases.

What Causes LE?

The cause of CLE is unknown. In most cases, the cause of SLE also is unknown, although it is believed that many factors may be involved, including genetic predisposition and environmental factors such as excessive sun exposure, certain medicines, and infections. In families of patients with SLE, it is known that there is an increase in the number of relatives with SLE and rheumatoid arthritis compared with the normal population. Many of the relatives have abnormal proteins, such as ANAs, in their blood, although they may not have any symptoms of the disease. Using sera from new recruits to the U.S. Armed Forces, it has been shown that those who develop SLE possess lupus autoantibodies years before they have symptoms or are diagnosed.

A critical “dose” of 30 thus far identified susceptibility genes causes enough immune response abnormalities to sustain the production of antibodies to self and immune complexes (antigen and antibody complexes). The genes are “turned on” by infections, increased exposure to ultraviolet light or other environmental toxins, at least 70 known prescription drugs, increased exposure to exposure to increased estrogen or other sex hormones and severe stress. Antigens are formed which promote an immune reaction, mimic microbes, or react to debris from dead cells. There are intrinsic abnormalities of B and T lymphocytes. These cells are activated by lower concentrations of antigen than normal, have sustained surface expression of activation markers, and are relatively resistant to dying cell debris, which allows them to escape regulation. There is a consequent release of cytokines by these cells which results in inflammation. In this milieu, autoantibody subsets become pathogenic and more antibody production occurs. Immune complexes (consisting of antigen and antibody) are formed, which favor capture rather than elimination and tissue is further damaged.

In perhaps 10% of patients with SLE-type symptoms, the disease may have been caused by medications. The most common of these is procainamide (Pronestyl), which often is used to treat heart irregularities. It is essential that your physician be told of all medications you are taking, including birth control pills and estrogens for menopause, as well as medications purchased over the counter or at health-food stores. Sometimes, medication can flare lupus; for example, sulfa antibiotics can make you more sun-sensitive and susceptible to developing rashes.

Diagnosis

The skin rash of CLE may be so typical that an experienced doctor can make the diagnosis by the history and appearance of the rash. If there is any question, a skin biopsy usually helps. It is essential that each patient with CLE

have a thorough physical examination, including laboratory tests, to check the possibility of SLE being present.

Diagnosing SLE is more difficult. Finding a definite answer may take months of observation, many laboratory tests, and sometimes a trial of drugs. Because of many different symptoms, some patients are thought to have another disease, rheumatoid arthritis, with swelling of a few or many joints of the hands, feet, ankles, or wrists. If typical skin lesions are present, they are helpful in making the diagnosis. Other findings, such as fever, pleurisy (i.e., painful breathing), or kidney disease, also point to the diagnosis of SLE.

In addition to a complete medical history and physical examination, routine tests are done to learn what internal organs are involved, for example, a blood count to see if there are too few red cells, white cells, or platelets (i.e., cells that are necessary for clotting). A routine analysis of the urine is always done, and a kidney function test is obtained. A chest radiograph electrocardiogram, or echocardiogram may be recommended if clinical evidence of problems in the lung or heart is found.

Diagnostic Criteria and Autoantibody Testing

In 1997, the American College of Rheumatology (ACR) established new diagnostic criteria for SLE. After excluding rheumatoid arthritis, scleroderma, and polymyositis, a diagnosis of SLE can be made if four of the following 11 criteria are met:

- Butterfly rash on cheeks
- Cutaneous (discoid) lupus
- Sensitivity to sunlight
- Mouth or nose sores
- Arthritis (i.e., swelling or inflammation of several joints)
- More than 0.5 g of protein in the urine per day, or cellular casts in a urinalysis
- Seizures or psychosis
- Pleuritis or pericarditis
- Low white blood count, low platelet count, or hemolytic anemia
- Antibody to DNA or to Sm antigen (i.e., a fairly specific antibody found in about one fourth of patients with lupus), or to antiphospholipid antibody (a false-positive syphilis test, anticardiolipin antibody, or lupus anticoagulant)
- Positive ANA test

Table APPI-1: Principal Immune Serologies and Their Value in SLE

Autoantibody	% in SLE	% in Normals	Comment
Antinuclear	98	5-10	If absent, it's probably not lupus
Anti-DNA	50	<1	Suggests more serious disease
Anti-Sm	25	<1	The most specific test for lupus
Anti-RNP	25	<1	Many also have MCTD
Antiphospholipid	33	5	1/3 have thromboembolic events
Anti-Ro/SSA	30	<1	Associated with Sjögren's, neonatal lupus, sun sensitivity
Anti-La/SSB	15	<1	Always seen with anti-Ro; may diminish pathogenicity of anti-Ro
Antineuronal	20	<1	Putative marker for CNS vasculitis
Antiribosomal P	20	<1	Seen with psychosis, hepatitis
Low serum complement	50	5	Decreased with inflammation

MCTD, mixed connective tissue disease.

To help confirm the diagnosis, special tests for SLE are performed that measure blood antibodies. These include examinations for ANA, which is the most sensitive test for the disease. Serum complement (i.e., a protein that is decreased during active phases of autoimmune illness) often is measured. Anti-DNA antibody is a specific type of ANA that often is present in the blood of patients with SLE; its presence is helpful in confirming the diagnosis of SLE. Moreover, when the disease is active, especially if the kidneys are affected in SLE, anti-DNA antibodies usually are present in high amounts in the blood. Thus, tests for anti-DNA antibody can be useful in monitoring disease activity in SLE. Again, none of these tests is specific for SLE, and different medical centers may use other diagnostic tests depending on their individual experience tests; consequently, obtaining such a result does not confirm the diagnosis of SLE. All tests must be evaluated by the physician in regard to the signs and symptoms of the patient. Table APPI-1 lists some of the autoantibodies ordered by musculoskeletal specialists concerned about diagnosing or following SLE.

Some patients with a negative ANA may still have SLE. Usually, these patients have anti-Ro/SSA antibody or a positive, nonlesional (i.e., skin that looks normal) skin biopsy using immunofluorescence (i.e., lupus band test), or have taken steroids or given chemotherapy in the past. Patients with CLE often have a negative ANA and a positive biopsy from the skin rash.

Resemblance to Other Diseases

One problem in diagnosis is that there is no single set of symptoms or pattern of disease. Also, SLE can mimic the symptoms of many other diseases, such as cancers, infections, and hormonal problems, and it can strike many different parts of the body, sometimes confusing even the most experienced physicians. The musculoskeletal pain of SLE often is difficult to differentiate from a syndrome known as fibromyalgia. Formerly termed fibrositis, fibromyalgia is associated with poor sleeping habits, fatigue, tension headaches, numbness and tingling, and irritable bowel symptoms, in addition to spasm and pain in the muscles, especially in the upper neck and back and coexists with lupus.

Symptoms and Course

The patient with SLE may have periods of severe illness (i.e., flare or exacerbation) with extreme symptoms, intermingled with periods of no illness and complete freedom from symptoms (i.e., remission). The illness comes and goes so unpredictably that no two cases are alike. Even before the discovery of corticosteroids, some patients made a full recovery with treatment by aspirin and rest alone. Although causes for disease flare-ups may be recognized and prevented by the patient, at other times their cause is unknown. Some possibly preventable causes of flare-ups are excessive sun exposure, injuries, insufficient rest, stopping medications that have been controlling the disorder, irregular living habits, and emotional crises. It cannot be emphasized too strongly that abruptly stopping medication, particularly large doses of corticosteroid derivatives such as prednisone, can lead to severe flare of the disease or even a fatal outcome.

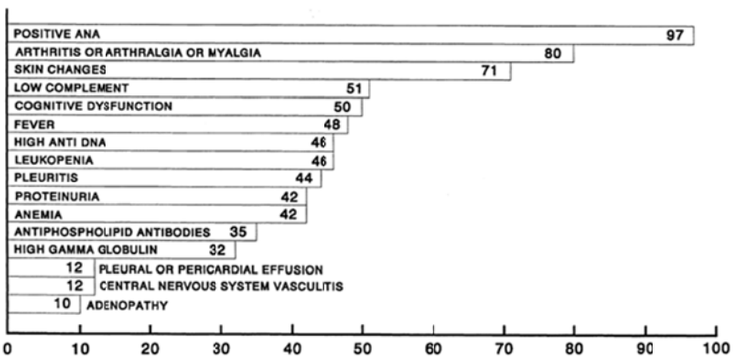

Figure APPI-1. Cumulative percentage incidence of 16 clinical and laboratory manifestations of systemic lupus erythematosus (SLE) based on major studies involving nearly 2,000 patients evaluated in seven studies since 1975.

Symptoms of the Disorder

The symptoms of SLE are varied, and no two patients have exactly the same ones. Any part of the body can be involved, so symptoms may include one or more of the following in any combination: joint and muscle pain, fever, skin rashes, chest pain, swelling of hands and feet, and hair loss (Fig. APPI.1). Joint involvement in SLE usually is less severe than that occurring in rheumatoid arthritis and usually is nondeforming. You should remember that in most patients, most of the symptoms disappear. This clearing of symptoms is called a remission. Medications usually are necessary to cause remissions, but sometimes they occur spontaneously (i.e., without treatment).

Physicians use the term remission or controlled rather than cure in speaking of the periods when patients are free of symptoms, because both doctors and patients then can be watchful for signs and symptoms, which may be a warning that a flare is beginning. Treatment then can be started before unnecessary damage occurs.

General Symptoms

Generalized aching, weakness, tiring easily, low-grade fever, and chills commonly are associated with active SLE. Although these symptoms usually are particularly noticeable during flare-ups of the disease, some patients give a lifelong history of low energy, malaise (i.e., generalized discomfort), and inability to keep up an active work schedule. A low-grade rise in temperature (99.5°F to 100.5°F), usually in the late afternoon, may be a sign of smoldering LE activity and may appear several days before the patient feels really ill. In the patient with SLE, loss of energy, development of weakness, low-grade fever, or tiring easily is each considered to be a danger sign. It may indicate that new

activity of the disease is developing. When any of these early warning signs develop, patients should consult their physician immediately, so that an examination can be made and further treatment prescribed if necessary.

The following symptoms and signs are typically found in SLE:

- Skin: A reddish rash or flush may appear involving the cheeks and nose in a so-called butterfly pattern. Other eruptions resembling CLE may occur in light-exposed areas of the body. Some patients are particularly sensitive to cold. After exposure to cold, the skin of their hands and feet may show several distinctive changes in color. Other patients may notice red, scaling changes on the back of the hands and on the fingers between the knuckles. Small areas of scarring on the scalp may produce baldness, and small red areas on the lips and the lining of the mouth may be related to SLE. Some patients have a definite sensitivity to ultraviolet rays of the sun, and even small amounts of sunlight may make these patients much worse. Easy bruising or pinpoint bleeding into the skin sometimes is related to SLE.
- Chest: Pleurisy, or irritation of the membranes lining the chest, causes painful breathing and is common in patients with SLE. Shortness of breath or rapid heartbeat sometimes is a related symptom. There may be an accumulation of fluid in the chest cavity from inflammatory changes.
- Muscular system: Tiring easily and weakness often are the first symptoms of SLE. Indeed, without these complaints, the diagnosis of systemic involvement in LE is open to doubt. Because they also are common in many other diseases and with plain nervous exhaustion, it is best to let your physician decide on their importance. Weakness occasionally can be caused by corticosteroid drugs. In these cases, a change in medication dose or type often is all that is necessary to return muscle strength.
- Bones and joints: Arthritis, joint swelling, and stiffness are common signs of SLE activity. These may involve only one joint, may move from one region to another, or, rarely, may progress to a deforming arthritis. This, however, rarely is disabling, and it is less frequent than in rheumatoid arthritis. Softening of bone (i.e., osteoporosis) can result from physical inactivity when you are ill and from corticosteroid drugs. Strategies are available to reduce these effects, including calcium, vitamin D, bisphosphonates, and hormonal replacement therapies for menopause or parathyroid disease.
- Blood: Anemia, or a low red-blood-cell count, is common in patients with LE. There may be a decrease in white blood cells, usually to around 2,500 to 4,000 per mL (normal is 4,500 to 10,000 per mL). The blood platelets, which are necessary for clotting, may become affected. Frequently, abnormalities of proteins in the blood are present as well; sometimes, a false-positive reaction for syphilis occurs when the blood is tested. Of course, this does not mean that the patient has syphilis, because this false reaction is only a manifestation of SLE.
- Heart: In some patients with SLE, swelling of the feet and ankles may occur, as well as shortness of breath or difficulty in breathing after exertion or when lying down. These symptoms may mean that the heart is affected. Fluid may collect in the pericardial sac surrounding the heart; sometimes heart muscle or valves become inflamed. The patient should remember that LE involvement does not always damage the heart permanently, because such changes disappear can completely with treatment. SLE patients are susceptible to developing accelerated atherosclerosis, even if they never took corticosteroids and should be screened for blood pressure and lipid profiles.
- Stomach and intestinal tract: Pain in the abdomen, nausea, vomiting, diarrhea, or constipation sometimes are associated with SLE. These symptoms may be so severe as to imitate acute appendicitis, a stone in the kidney, or some other condition requiring surgical treatment. If these symptoms appear, it is important for the patient to tell the surgeon that he or she has SLE as well as the type and dosage of medication being taken.
- Kidney and bladder: The kidney serves as the filtering plant of the body, filtering out waste products while preserving the many chemical parts of the blood that are essential for good health. Involvement of the kidney by SLE may cause loss into the urine of some of these essential chemical components, and there may be poor excretion of the waste products that usually are discarded in the urine. Retention and accumulation of the waste products can produce further symptoms or signs (such as foam in the urine or swelling) that may require specialized treatment. The development of SLE kidney involvement is painless and should be checked by urinalysis every few months. Kidney biopsy (i.e., removal of a bit of tissue for study under the microscope) may be helpful in confirming the diagnosis or choice of treatment.
- Lymph glands, spleen, and liver: Occasionally, the lymph glands of the neck, under the arms, and in the groin become enlarged. The spleen (an internal organ) also may become enlarged, and SLE hepatitis (i.e., an inflammation of the liver) sometimes develops.
- Nervous system (brain, spinal cord, and nerves): Temporary seizures that resemble epilepsy may be early evidence of SLE, and the diagnosis of SLE is suggested only after other symptoms appear. Mental depression, excitability, unusual worry, headache, mental confusion, forgetfulness, nerves, or even a nervous breakdown can be caused by SLE. Some patients have transient paralysis, stroke, neuritic pains, or poor bladder control related to their disease. Cognitive impairment (difficulty in thinking clearly) is common.
- Menstrual periods: Menstrual periods may become irregular, more or less frequent, or even stop completely for several months. This usually is related to the activity of SLE or to side effects of glucocorticosteroids.

When the disease is brought under control, menstrual periods may return to normal.

Thus, a wide range and variety of symptoms may announce the onset of SLE. Some patients, through the entire course of their illness, have symptoms involving only one organ. Others may have symptoms that come and go, and some may begin with one group of symptoms and acquire others as new parts of the body become involved with the SLE process. Remember that before the discovery of cortisone derivatives, 40% of patients improved with rest and aspirin alone.

Other Considerations

Early warnings that may indicate a flare-up include chills, fatigue, loss of pep, new symptoms, and fever, such as change from the normal daily temperature to a slight afternoon fever of 99.5°F to 100.5°F. If any of these changes occur, the physician should be notified.

The patient with SLE without organ-threatening disease generally can return to his or her regular occupation. Usually, after the illness is well controlled, it does not interfere with full-time work as long as the patient does not become too tired or stressed.

Childbearing

Patients with SLE usually can have successful pregnancies, provided they do not have too much kidney or heart disease. Although many women with SLE feel better during pregnancy, an occasional flare-up can occur. Physicians cannot predict the effect of pregnancy on a particular individual. Whether pregnancy is advisable in your own case should be discussed with your physician before you become pregnant.

Patients with DLE usually have no problems with pregnancy. The safety of many common medications in pregnancy, however, is not well established. Glucocorticoids (i.e., steroids) generally are safe for the fetus and can be continued throughout pregnancy and delivery if needed for disease control. Nonsteroidal anti-inflammatory drugs (NSAIDs) and high-dose aspirin can be used cautiously if necessary. Hydroxychloroquine is generally safe. Active SLE is associated with fetal loss.

A subset of patients with LE and antiphospholipid antibodies (especially those with high levels of anticardiolipin antibody) has been shown to have spontaneous recurrent fetal loss. They also may be at risk for developing blood clots. Children of mothers with SLE who have Ro/SSA antibody are at a slight risk for developing neonatal lupus or congenital heart block.

Contraception

The safest methods of contraception are the use of barrier methods such as diaphragm and jelly, foam, sponges, or condoms. Although birth control pills are safely used by many patients with SLE, the incidence of pill-related complications appears to be higher in these patients than in the normal user, especially in individuals with migraine headaches, high blood pressure, very high cholesterol, and antiphospholipid antibodies. Intrauterine devices are not advisable because of the high incidence of infections connected with their use.

Hormone Replacement Therapy

When women with SLE enter the menopause, either naturally or from the chemotherapy-type medications that sometimes are used to treat SLE, the question of taking estrogen and/or progesterone type hormones arises. Advantages include controlling hot flashes, prevention of dryness and mood swings, and reduced risk of heart attacks, osteoporosis, and fractures. Disadvantages include risking a lupus flare, risks of increased clotting and gallstones, weight gain, fluid retention, and higher blood pressure, as well as a slightly increased risk for breast cancer. Women with lupus and their doctors should weigh the pros and cons before starting this treatment. Treatment always can be stopped if problems do occur.

Treatment of LE

Several effective methods of treatment are available. Unfortunately, all of the medications that are used to treat SLE, including regular aspirin, have some potential dangers, but we must use them, optimally at low levels and for a short time. The one to be used in a particular individual depends entirely on the type of LE that is present. Patients with CLE may be treated with creams or ointments containing corticosteroid medications and sunscreens. With more extensive skin changes, antimalarial drugs often are effective.

Treatment usually is required for months to years. Stopping medication may produce a flare of skin lesions.

SLE is managed by local treatment for any skin eruptions plus various medications taken by mouth for symptoms such as arthritis, fever, rash, and kidney disease.

Aspirin and Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Aspirin and NSAIDs are not merely pain killers. When taken regularly and as often as prescribed, such as 8 to 16 five-grain tablets daily for adults, aspirin frequently controls fever, pleurisy (i.e., painful breathing), and joint discomfort. Aspirin and NSAIDs should be used with caution in patients who have had stomach ulcers; rarely, internal bleeding may result. When possible, it is advisable to stop these medications 1 week before surgery because of their tendency to slow down blood clotting. Taking the tablets with food often eliminates the stomach upsets that some patients experience. Antacids and a class of drugs known as frequently help to protect the stomach lining. NSAIDs such as indomethacin (Indocin), naproxen (Naprosyn), or ibuprofen (Motrin) frequently are effective for relieving

joint pains as well as pain at other sites of inflammation. Patients with kidney involvement should only take NSAIDs under close medical supervision, and all patients on NSAIDs or aspirin should have blood testing at 3- to 4-month intervals.

Antimalarial Drugs

This group of medications was first developed during World War II for the treatment of malaria when it became known that quinine, which then was standard treatment for malaria, was in short supply. It was discovered that many patients with LE, especially those who had skin changes of CLE, showed definite improvement after receiving the antimalarial drug quinacrine, although these chemicals also are helpful in systemic types of LE. It should be emphasized that there is no relationship between LE and malaria (which is caused by a small parasite transmitted by mosquitoes).

The exact mechanism of the antimalarial drugs in LE is not known, but by raising the pH of cells (i.e., making them more basic as opposed to acidic), inflammation is decreased. Immune responses also are reduced. In many patients with SLE, the antimalarials appear to make it possible to reduce the total daily dose of cortisone drugs. Another advantage of antimalarials is that they increase resistance to sun exposure and block the appearance of SLE rashes on exposure to ultraviolet light. Antimalarials are useful in managing skin, joint, and muscle symptoms, as well as fever, fatigue, and pleurisy. These agents often do not take effect for several months. Hydroxychloroquine (Plaquenil) is the only antimalarial approved by the U.S. Food and Drug Administration (FDA) for lupus and is the safest agent in its class.

Side effects of antimalarials in patients with LE do not often occur, but when they do, they can be important. The most common side effects usually involve the digestive system, with mild nausea, occasional vomiting, and diarrhea. Formerly, certain antimalarials, especially chloroquine (Aralen) and hydroxychloroquine (Plaquenil), were found to affect the eyes when used in doses twice as great as those now prescribed. Therefore, to be certain that no such bad effects occur, patients who are taking these medications must have eye examinations by an ophthalmologist at regular 6- to 12-month intervals. The risk of changes in the retina with Plaquenil is 3% after 10 years of continuous use. These changes are completely reversible with discontinuation of the drug and regular monitoring. Quinacrine (Atabrine) has not been reported to cause eye complications. Any changes in vision should be called to the attention of your physician.

Corticosteroids

The corticosteroid drugs (e.g., prednisone) are used primarily for treating the internal changes that are caused by lupus. However, they also help to heal the skin.

Cortisone and, later, prednisone were the first of the corticosteroid family to be used in medicine, and both they and their successors have been lifesaving in many thousands of patients with many different diseases. They are synthetic forms of hormones that normally are produced by the adrenal glands, which are the small glands above the kidneys. In addition to the beneficial effects of corticosteroids, however, these drugs have unwanted and undesirable side effects that may produce complications when they are taken for long periods.

In some cases of SLE, the physician may choose to prescribe different types of corticosteroid drugs or to prescribe them every other day instead of daily. This method reduces side effects considerably, but it may not be satisfactory for active cases.

The chief action of corticosteroid drugs is to decrease inflammation, so that these drugs control many of the symptoms and signs of SLE that are caused by inflammatory changes (e.g., arthritis and pleurisy). The drugs may be given by mouth in the form of tablets, or by injection into the muscle or joint or directly into the vein.

Another effect of the prednisone-like drugs is their shrinking effect on the adrenal glands. This occurs because the adrenal glands may stop producing the natural hormone, which is of special importance for two reasons. First, the synthetic hormone should not be stopped suddenly, because the adrenal glands may take several months to start production of natural hormone again. A sudden withdrawal of the synthetic hormone leaves the patient without this support and may cause a serious crisis. Therefore, the dosage of corticosteroids should be reduced gradually over several weeks or months, so that the patient's adrenal glands may increase their production of the natural hormone gradually over the same period. Second, any physical or mental stress, surgical procedure, dental extraction, or severe illness may increase the patient's need for large amounts of corticosteroids. When patients have taken corticosteroids for a long time, their own adrenal glands cannot satisfy this increased need, and larger, booster doses of the synthetic drug are required.

Persons who are taking corticosteroid drugs, or those who have taken them during the previous year, should carry with them an identification card or bracelet stating this fact for emergency use (much like the card carried by the diabetic person who must take insulin, or by a person who is extremely sensitive to penicillin).

Two points must be emphasized to every patient with SLE who is taking the corticosteroid groups of drugs. First, the drug should never be stopped suddenly if it has been taken for over 30 days; it should be reduced gradually over a long period (this is best done under the direct supervision of a physician). Second, when any patient is on long-term steroid therapy, he or she may need increased booster doses of the drug before, during, and after any period of general body stresses (e.g., surgery), and he or she should tell the physician or dentist of this possibility.

Because corticosteroids have an appetite-stimulating effect, an effort should be made to avoid excessive weight

gain. Damage to weight-bearing joints may occur following long-term steroid treatment and, occasionally, in some patients with untreated SLE. Additionally, steroids may induce diabetes, hypertension, cataracts, glaucoma, edema, avascular necrosis, bone demineralization (i.e., osteoporosis), poor wound healing, fragile skin that tears and bruises easily, susceptibility to infections, and ulcers. If the dose of steroids is greater than 10 mg of prednisone each day, people may have increased susceptibility to infections.

Immune Suppressives

Many powerful drugs, such as immune suppressives (e.g., antibody suppressors), are used in the treatment of severe SLE; these include azathioprine (Imuran), cyclophosphamide (Cytoxan), mycophenolate mofetil (CellCept), and methotrexate. These drugs most commonly are used in those with aggressive disease. Indications for these agents are the subject of a great deal of debate, both because they are toxic and their effectiveness has not always been demonstrated, and also because they may decrease steroid requirements. Evidence from the National Institutes of Health (NIH) suggests that intravenous, intermittent cyclophosphamide in combination with corticosteroids or mycophenolate mofetil represent the treatments of choice for severe lupus nephritis. Plasma exchange (i.e., plasmapheresis) is a very expensive, blood-filtering procedure whose results are only of uncertain benefit. Its use is reserved for those with life-threatening complications of lupus. Other agents that occasionally are used in LE are nitrogen mustard, retinoid derivatives, leflunomide, gamma globulin, danazol, chlorambucil, dapsone, and cyclosporine.

It is essential that once an effective treatment program has been started, the patient should continue the medication faithfully and not change it without the physician's advice. Severe flare-ups may occur suddenly in patients who stop their treatment abruptly.

Coping with LE: How Can You Help Yourself?

Physical Measures

- Be careful in the sun: Two thirds of lupus patients have a problem with ultraviolet A and B (UVA and UVB) radiation from the sun. If you're going to be outside for more than 5 minutes, use a sunscreen. Choose a preparation that has a sun protection factor (SPF) of at least 15 and blocks both UVA and UVB. UVB sun exposure is greatest at midday. Perform your outdoor activities earlier in the morning or later in the afternoon or in the evening. Wear protective clothing. Ultraviolet radiation is greater at higher altitudes. The exposure one gets at sea level in 1 hour is the same that one absorbs in 5 minutes a mile up, as in Denver or Mexico City or on the ski slope.
- Diet: Lupus patients should eat a nutritious, well-balanced diet. There are some suggestions that fish, or specifically eicosapentaenoic acid in fish oil, might have modest antiinflammatory properties. In double-blind controlled studies, eating the equivalent of two fish meals a week clearly helps rheumatoid arthritis pain. An amino acid, L-canavanine, is found in alfalfa sprouts and can activate the immune system and promote inflammation in lupus patients. Other members of the legume family have only a fraction of the L-canavanine that sprouts do and are safe to use. Lupus patients taking corticosteroids should watch their sugar, fat, and salt intake.
- When you hurt, apply heat: Moist heat soothes painful joints. Moist heat is superior to dry heat. Hot tubs, saunas, Jacuzzis, or hot showers are useful. We advise ice or cold applications only for acute strains or injuries for the first 36 hours.
- General conditioning exercises: Activities such as walking, swimming, low-impact aerobics, and bicycling help prevent muscle atrophy or wasting and decrease your risk for developing thin bones, or osteoporosis. On the other hand, if your joints are swollen or you have fibromyalgia, be careful before doing a lot of weigh lifting, rowing, high-impact aerobics, or engaging in tennis, bowling, or golf. If exercises tire you easily, pace yourself with frequent rest periods.
- Consult a rehabilitation specialist: Physical therapists assist patients in muscle strengthening programs, exercises, and gait training. Occupational therapists work to minimize stresses to painful areas, evaluate workstations (especially those with computers) to ensure proper body mechanics, and recommend a variety of assistive devices. Vocational rehabilitation counselors may train you for a job that involves less sun exposure or emphasis on repetitive motions involving an inflamed hand or other part of the body.
- Don't smoke: Tobacco smoke contains an aromatic amine, hydrazine, which can flare cutaneous lupus. Smoking also worsens Raynaud disease and impairs circulation to a greater extent in lupus patients that in otherwise healthy people.

Develop Preventive Coping Strategies

- Don't let the weather psych you out: Lupus patients are sensitive to changes in barometric pressure. If the weather goes from hot to cold or wet to dry, one might be a bit achier. This will pass. The best climate for lupus patients is one with the fewest changes in the barometer.
- Mastering fatigue: Fatigue in lupus is caused by inflammation, anemia, and chemicals known as cytokines, among other sources. Pace yourself. Have periods of activity alternating with periods of rest. Patients who stay in bed all day only become weaker. On the other hand, supermoms who put in a 20-hour day without a break can flare their disease.
- Have a good doctor-patient relationship: Make sure that your physician is accessible and will assist you

when it's important. Work out in advance what to do in case of an emergency. Will your physician advise you if pregnancy is contraindicated, whether or not you can take a birth control pill, know which antibiotics lupus patients need to be careful with, write a jury duty letter, or fill out a disability form if needed? In return, it's vital to keep your appointments, be honest with your physician, take medication as prescribed, and respect the physician's time.

- Genetic and prognosis counseling: Women with lupus have a 10% chance of having a daughter with lupus and a 2% of having a son with the disease, although there is a 50% chance their offspring will have a positive ANA. Twenty percent of patients with non-organ-threatening SLE will evolve organ-threatening disease, usually within the first 5 years after diagnosis. Patients with non-organ-threatening disease have a near-normal life expectancy if antiphospholipid antibodies are absent. The survival of organ-threatening lupus patients is 75% at 15 years.
- Pregnancy: 70% of lupus pregnancies are successful. Lupus patients are normally fertile but often don't conceive if they are inflamed. Kidney failure, severe hypertension, and myocarditis are relative contraindications to becoming pregnant. Patients with antiphospholipid antibodies who have miscarried may be given aspirin or heparin during a pregnancy. Mothers with anti-Ro (SSA) antibody should be advised of a 5% to 15% risk of their child being born with a transient lupus rash or a more serious heart problem that can be detected with ultrasounds at weeks 18 and 24. Find out what medicines are safe to take during a pregnancy. Most lupus activity cools down during the second trimester and mild postdelivery flares can occur.
- Address fevers or infections promptly: Call a doctor if your temperature is over 99.6°F. It could be a lupus flare or an infection. Be careful before taking sulfa-based antibiotics, which are usually prescribed for bladder and female infections. They tend to make lupus patients more sun sensitive and can lower blood counts, and up to 30% of lupus patients are allergic to sulfa drugs.
- Ask about cognitive therapy: Some lupus patients have difficulty remembering names and dates, balancing their checkbook, and processing thoughts. Termed cognitive dysfunction, cognitive impairment, or “lupus fog,” this is a reflection of vascular spasm in that insufficient amounts of oxygen are reaching the brain. These symptoms come and go. Cognitive therapists are psychologists, speech therapists, and physical therapists who can help patients cope with this by initiating biofeedback and specific strategies that improve concentration.
- Don't be afraid to ask for help: The Lupus Foundation of America (LFA) provides information about doctor referrals, lupus books, patient information brochures, and newsletters. Most local chapters have rap or discussion groups, sponsor guest speakers, and maintain a list of mental health professionals who can assist you.

Is There Hope of Conquering SLE?

There certainly is! A great deal of fast-moving research is going on throughout the world. Medical scientists are interested in SLE not only because they want to help those who suffer from it, but also because they want to find the key to other closely related rheumatic disorders, such as rheumatoid arthritis. We expect laboratory research to improve methods of treatment and, eventually, to provide a means of prevention and cure. Some of the approaches that are being studied include newer anti-inflammatory therapies with-, chemicals that block or accentuate the effects of a protein known as cytokines, hormones, vaccines with peptides, new forms of immune suppression used in transplant patients, and biologics that block specific parts of the immune system.

Glossary

ACR
American College of Rheumatology, a professional association of 5,000 U.S. rheumatologists, of whom 3,800 are board-certified; criteria, or definitions for many rheumatic diseases, are called the ACR criteria; Formerly known as the ARA (American Rheumatism Association)

Acute
Of short duration

Adrenal glands
Small organs located above the kidney that produce many hormones, including corticosteroids and epinephrine

Albumin
A protein that circulates in the blood and carries materials to cells

Albuminuria
A protein in urine

Analgesic
A drug that alleviates pain

Anemia
A condition resulting from low red blood cell counts

Antibodies
Special protein substances made by the body's white cells for the defense against bacteria and other foreign substances

Anticardiolipin antibody
An antiphospholipid antibody

Anticentromere antibody
Antibodies to a part of the cell's nucleus; associated with a form of scleroderma called CREST

Anti-DNA
Antibodies to DNA; seen in one half of people with SLE and sometimes associated with disease flares and kidney disease

Anti-ENA
Extractable nuclear antibodies that largely consist of anti-Sm and anti-RNP antibodies

Antigen
Self or foreign substance that stimulates antibody formation

Antiinflammatory
An agent that counteracts or suppresses inflammation

Antimalarials
Drugs originally used to treat malaria but that are helpful for lupus, such as hydroxychloroquine, chloroquine, and quinacrine

Antinuclear antibodies (ANAs)
Proteins in the blood that react with the nuclei of cells; seen in 96% of patients with SLE, 5% of healthy individuals, and in most patients with autoimmune diseases

Antiphospholipid antibody
Antibodies to a constituent of cell membranes; seen in one third of patients with SLE; in the presence of a cofactor, these antibodies can alter

clotting and lead to strokes, blood clots, miscarriages, and low platelet counts; also detected as the lupus anticoagulant

Anti-RNP

Antibody to ribonucleoprotein; seen in SLE and mixed connective tissue disease

Anti-Sm

Anti-Smith antibody; is found only in lupus

Anti-SSA

Antibody associated with Sjögren syndrome, sun sensitivity, neonatal lupus, and congenital heart block; also called the Ro antibody

Anti-SSB

Antibody almost always seen with anti-SSA; also called the La antibody

Apoptosis

Programmed cell death—a normal process for ridding the body of damaged cells

Artery

A blood vessel that transports blood from the heart to the tissues

Arthralgia

Pain in a joint

Arthritis

Inflammation of a joint

Aspirin

An antiinflammatory drug with analgesic properties

Autoantibody

An antibody to one's own tissues or cells

Autoimmune

Allergy to one's own tissues

Autoimmune hemolytic anemia

See hemolytic anemia .

B lymphocyte or B cell

A white blood cell that makes antibodies

Biopsy

Removal of a bit of tissue for examination under the microscope

Bursa

A sac of synovial fluid between tendons, muscles, and bones that promotes easier movement

Butterfly rash

Reddish facial eruption over the bridge of the nose and cheeks, resembling a butterfly in flight

Capillaries

Small blood vessels connecting between arteries and veins

Cartilage

Tissue material covering bone; the nose, outer ears, and trachea primarily consist of cartilage

Chronic

Persisting over a long period of time

CNS

Central nervous system

Collagen

Structural protein found in bone, cartilage, and skin

Collagen vascular disease

Antibody-mediated inflammatory process of the connective tissues, especially the joints, skin, and muscle; also called connective tissue disease

Complement

A group of proteins that are activated, promote, and are consumed during inflammation

Complete blood count (CBC)

A blood test that measures the amount of red blood cells, white blood cells, and platelets in the body

Connective tissue

The glue that holds muscles, skin, and joints together

Corticosteroid

Any natural anti-inflammatory hormone made by the adrenal cortex; also can be made synthetically

Cortisone

A synthetic corticosteroid

Creatinine

A blood test that measures kidney function

Creatinine clearance

A 24-hour urine collection that measures kidney function

CREST syndrome

A form of limited scleroderma characterized by C (calcium deposits under the skin), R (Raynaud phenomenon), E (esophageal dysfunction), S (sclerodactyly or tight skin), and T (a rash called telangiectasia)

Crossover syndrome

An autoimmune process that has features of more than one rheumatic disease (e.g., lupus and scleroderma)

Cutaneous

Relating to the skin

Cytokine

A group of chemicals that signal cells to perform certain actions

Dermatologist

A physician specializing in skin diseases

Dermatomyositis

An autoimmune process directed against muscles associated with skin rashes

Discoid lupus

A thick, plaque-like rash seen in 20% of patients with SLE; if patients have the rash but not SLE, they are said to have cutaneous (discoid) lupus erythematosus

DNA

Deoxyribonucleic acid; the body's building blocks; a molecule responsible for the production of all the body's proteins

Enzyme

A protein that accelerates chemical reactions

Erythematous

Reddish hue

Estrogen

Female hormone produced by the ovaries

Exacerbations

Symptoms reappear; a flare

False-positive serologic test for syphilis

A blood test that reveals an antibody that may be found in syphilis and is falsely positive in 15% of patients with SLE; associated with the lupus anticoagulant and antiphospholipid antibodies

FANA

Another term for ANA

Fibrositis or fibromyalgia

A pain amplification syndrome characterized by fatigue, a sleep disorder, and tender points in the soft tissues; can be caused by steroids and mistaken for lupus, although 20% of patients with lupus have fibrositis

Flare

Symptoms reappear; another word for exacerbation

Gene

Consisting of DNA, it is the basic unit of inherited information in our cells

Glomerulonephritis

Inflammation of the glomerulus of the kidney; seen in one third of patients with lupus

Hematocrit

A measurement of red blood cell levels; low levels produce anemia

Hemoglobin

Oxygen-carrying protein of red blood cells; low levels produce anemia

Hemolytic anemia

Anemia caused by premature destruction of red blood cells because of antibodies to the red blood cell surface; also called autoimmune hemolytic anemia

Hepatitis

Inflammation of the liver

Hormones

Chemical messengers made by the body that include thyroid, steroids, insulin, estrogen, progesterone, and testosterone

Human leukocyte antigen (HLA)

Molecules inside the macrophage that binds to an antigenic peptide; controlled by genes on the sixth chromosome; they can amplify or perpetuate certain immune and inflammatory responses

Immune complex

An antibody and antigen together

Immunity

The body's defense against foreign substances

Immunofluorescence

A means of detecting immune processes with a fluorescent stain and a special microscope

Immunosuppressive

A medication, such as cyclophosphamide or azathioprine, that treats lupus by suppressing the immune system

Inflammation

Swelling, heat, and/or redness resulting from the infiltration of white blood cells into tissues

Kidney biopsy

Removal of a bit of kidney tissue for microscopic analysis

La antibody

A Sjögren antibody; also called anti-SSB

LE cell
Specific cell found in blood specimens of most patients with lupus
Ligament
A tether attaching bone to bone and giving them stability
Lupus anticoagulant
A means of detecting antiphospholipid antibodies from prolonged clotting times
Lupus vulgaris
Tuberculosis of the skin; not related to systemic or discoid lupus
Lymphocyte
Type of white blood cell that fights infection and mediates the immune response
Macrophage
A cell that kills foreign material and presents information to lymphocytes
Major histocompatibility complex (MHC)
In humans, it is the same as HLA
Mixed connective-tissue disease
When a patient who carries the anti-RNP antibody has features of more than one autoimmune disease
Natural killer cell
A white blood cell that kills other cells
Nephritis
Inflammation of the kidney
Neutrophil
A granulated white blood cell involved in bacterial killing and acute inflammation
NSAIDs
Nonsteroidal anti-inflammatory drugs, agents that fight inflammation by blocking the actions of prostaglandin; examples include ibuprofen and naproxen
Nucleus
The center of a cell that contains DNA
Orthopedic surgeon
A doctor who operates on musculoskeletal structures
Pathogenic
Causing pathology, or abnormal reactions
Pathology
Abnormal cellular or anatomic features
Pericardial effusion
Fluid around the sac of the heart
Pericarditis
Inflammation of the pericardium
Pericardium
A sac lining the heart
Photosensitivity
Sensitivity to ultraviolet light
Plasma
The fluid portion of blood
Plasmapheresis
Filtration of blood plasma through a machine to remove proteins that may aggravate lupus
Platelet
A component of blood responsible for clotting
Pleura
A sac lining the lung
Pleural effusion
Fluid in the sac lining the lung
Pleuritis
Irritation or inflammation of the lining of the lung
Polyarteritis
A disease closely related to lupus that features inflammation of small- and medium-sized blood vessels
Polymyalgia rheumatica
An autoimmune disease of the joints and muscles seen in older patients with high sedimentation rates who have severe aching in their shoulders, upper arms, hips, and upper legs
Polymyositis
An autoimmune disease that targets muscles
Prednisone; prednisolone
synthetic steroids
Protein
A collection of amino acids; antibodies are proteins
Proteinuria
Excess protein levels in the urine; also called albuminuria
Pulse steroids
Giving very high doses of corticosteroids intravenously over 1 to 3 days to critically ill patients
Raynaud's disease
Isolated Raynaud phenomenon not part of any other disease
Raynaud's phenomenon
Discoloration of the hands or feet (they turn blue, white, or red, especially with cold) as a feature of an autoimmune disease
RBC
Red blood cell count
Remission
Quiet period, free from symptoms, but not necessarily a cure
Rheumatic disease
Any of 150 disorders affecting the immune or musculoskeletal system; approximately 30 of these also are autoimmune
Rheumatoid arthritis
Chronic disease of the joints marked by inflammatory changes in the joint-lining membranes, which may have positive rheumatoid factor and ANA tests
Rheumatoid factor
Autoantibodies that react with immunoglobulin G (IgG) that are seen in most patients with rheumatoid arthritis and 30% of patients with SLE
Rheumatologist
An internal medicine specialist who has completed at least a 2-year fellowship studying rheumatic diseases
Ro antibody
See anti-SSA
Scleroderma
An autoimmune disease featuring rheumatoid-like inflammation, tight skin, and vascular problems (e.g., Raynaud)
Sedimentation rate
Test that measures the precipitation of red cells in a column of blood; high rates usually indicate increased disease activity
Serum
Clear liquid portion of the blood after removal of clotting factors
Sjögren syndrome
Dry eyes, dry mouth, and arthritis observed with most autoimmune disorders or by itself (i.e., primary Sjögren)
Steroids
Usually a shortened term for corticosteroids, which are anti-inflammatory hormones produced by the adrenal cortex or synthetically
STS
False-positive serologic test for syphilis
Synovial fluid
Joint fluid
Synovitis
Inflammation of the tissues lining a joint
Synovium
Tissue that lines the joint
Systemic
Pertaining to or affecting the body as a whole
T cell
A lymphocyte responsible for immunologic memory
Temporal arteritis
Inflammation of the temporal artery associated with high sedimentation rates, systemic symptoms, and occasionally loss of vision
Tendon
Structures that attach muscle to bone
Thrombocytopenia
Low platelet counts
Thymus
A gland in the neck area responsible for immunologic maturity
Titer
Amount of a substance, such as ANA
Tolerance
The failure to make antibodies to an antigen
Uremia
Marked kidney insufficiency frequently necessitating dialysis to stay alive
Urinalysis
Analysis of urine
Urine, 24-hour collection
All urine passed in a 24-hour period is collected and examined for protein and creatinine to determine how well the kidneys are functioning
UV light
Ultraviolet light; its spectrum includes UVA (320–400 nm), UVB (290–320 nm), and UVC (200–290 nm) wavelengths
Vasculitis
Inflammation of blood vessels
WBC
White blood cell count

Appendix II: Lupus Resource Materials

Compiled by Jenny Thorn Allan on Behalf of the Lupus Foundation of America

What Organizations Provide Patient Support in the United States?

(Many such organizations exist; only those with a budget of over $1 million are listed.)

Lupus Foundation of America, Inc. (LFA), 2000 L. St. NW, Suite 710, Washington, DC 20036, 202–349–1155 or toll-free 800–558–0121, Spanish line, 800–558–0231. With a nationwide network of 267 chapters, branches and support groups, the LFA is the nation's leading nonprofit voluntary health organization dedicated to finding the causes and cure for lupus. The LFA's mission is to improve the diagnosis and treatment of lupus; support individuals and families affected by the disease; increase awareness of lupus among health professionals and the public; and find the causes and cure. The LFA publishes patient education brochures, fact sheets, articles, and a national magazine, *Lupus Now*®. E-mail: lupusinfo@lupus.org for health education information; info@lupus.org for general information; lupusnow@lupus.org for magazine information. Web site: http://www.lupus.org/.

Arthritis Foundation, P.O. Box 7669, Atlanta, GA 30357, toll-free 800–568-4045. The Arthritis Foundation is the only national not-for-profit organization that supports the more than 100 types of arthritis and related conditions with advocacy, programs, services and research. Chapters and support groups across the country provide research monies, publish literature, and offer patient support for arthritis and related conditions such as lupus. Web site: http://www.arthritis.org/.

American Autoimmune Related Diseases Association (AARDA), 22100 Gratiot Ave. E. Detroit, MI 48021, 586–776–3900 (national office); 750 17th Street, NW, Suite 1100, Washington, DC 20006, 202–466–8511 (Washington office). The AARDA is dedicated to the eradication of autoimmune diseases and the alleviation of suffering and the socioeconomic impact of autoimmunity through fostering and facilitating collaboration in the areas of education, research, and patient services in an effective, ethical and efficient manner. Literature request line: 800-598-4668; E-mail: aarda@aol.com; Web site: http://www.aarda.org/.

SLE Lupus Foundation, 330 Seventh Ave., Suite 1701, New York, NY 10001, 212–685–4118 or toll-free 800–74LUPUS (5–8787); Headquartered in New York City and Los Angeles, the SLE Lupus Foundation provides patient services, education, public awareness, and funding for lupus research. E-mail: lupus@lupusny.org; Web site: http://www.lupusny.org/.

In Addition to the above, Where Else Can Reliable Information about Lupus Be Obtained?

American College of Rheumatology (ACR) and Association of Rheumatology Health Professionals (ARHP), 1800 Century Place, Suite 250, Atlanta, GA 30345, 404–633–3777. The ACR is the professional organization to which nearly all U.S. and many international rheumatologists belong. The ARHP is a division of the ACR. Web site for both: http://www.rheumatology.org/.

National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), 31 Center Drive, Room 4C05, MSC 2350, Rockville Pike, Bethesda, MD 20892. Part of the National Institutes of Health, NIAMS funds $90 million dollars in lupus research each year at the Bethesda campus and elsewhere in the country. The Institute also sponsors conferences and publishes patient education pamphlets and booklets, including specific materials on lupus. Some materials are available in Spanish. E-mail: NIAMSWeb-L@mail.nih.gov; Web site: http://www.niams.nih.gov/.

The NIAMS Information Clearinghouse offers a wide variety of information on rheumatic diseases, including lupus (also information in Spanish). NIAMS Information Clearinghouse, National Institutes of Health, 1 AMS Circle, Bethesda, MD 20892, 301–495–4484 or toll-free 877–22-NIAMS. TTY 301–565–2966. E-mail: niamsinfo@mail.nih.gov. (Please include your mailing address and, if possible, a telephone number in your e-mail message.)

In Addition to the above, What Other Organizations Fund Lupus Research?

(Many such organizations exist; this list is restricted to those that give more than $1 million a year to lupus-related research at more than one institution.)

Alliance for Lupus Research, 28 West 44th Street, Suite 1217, New York, NY 10036 212–218–2840 or toll-free

800-867-1743, was founded in 1999 with the mission to support research into the cause, cure, treatment and prevention of systemic lupus erythematosus. E-mail: info@lupusresearch.org; Web site: http://www.lupusresearch.org/.

Lupus Research Institute, 149 Madison Ave., Suite 205, New York, NY 10016, 212-685-4118, was founded in 1998 to conquer lupus through identifying its cause, creating effective treatments and, ultimately, developing a cure. E-mail: lupus@lupusresearchinstitute.org; Web site: http://www.lupusresearchinstitute.org/.

Research and Education Foundation of the American College of Rheumatology. The research funding arm of the ACR funds rheumatology training and research programs that are vital to the care of patients suffering from rheumatic diseases. To find out more about the REF's programs, go to http://www.rheumatology.org/ref/, send an e-mail to ref@rheumatology.org or call 404-633-3777.

Rheuminations, Inc., 221 East 48th Street. New York, NY 10017, 212-593-5180, is a private, nonprofit foundation that has provided funding for lupus-related research and education to various institutions, including the Hospital for Special Surgery's LANtern (Lupus Asian Network) Program and Charla de Lupus Teen Chat Program, and its Barbara Volcker Center for Women and Rheumatic Disease. Web site: http://www.dxlupus.org/.

How Can I Find Out about Lupus Support Outside of the United States?

The Lupus Foundation of America is associated with approximately 75 international lupus groups. Call the LFA for information, or go to the LFA Web site for an up-to-date list. Some important groups are:

Canada

Lupus Canada (the national organization), 590 Alden Road, Suite 211, Markham, Ontario L3R 8N2 Canada. Phone: 905-513-0004; toll-free in Canada 1-800-661-1468; E-mail: lupuscanada@bellnet.ca; Web site: http://www.lupuscanada.org/ (in French and English).

Europe

European Lupus Erythematosus Federation. All efforts in Europe are coordinated through a central office of the ELEF. Affiliate groups are located in Belgium, Finland, France, Germany, Great Britain, Iceland, Ireland, Israel, Italy, Netherlands, Norway, Portugal, Spain, Sweden, and Switzerland. E-mail: elef@rheumanet.org; Web site: http://www.elef.rheumanet.org/.

Mexico

Fundación Mexicana de Lupus, c/o Dr. J. Humberto Orozco-Medina, Club de Lupus Centro Medico de Occidente, Pedro Buezeta 870-B, Tavascos 3469-306, 44660 Guadalajara, Jalisco, Mexico. Phone: 5233-1201-9790. E-mail: info@lupusmexico.org; Web site: http://www.lupusmexico.org/.

Latin America

Panamerican League of Associations For Rheumatology, University of Arkansas for Medical Sciences, 4301 West Markham, Division of Rheumatology, Slot 509, Little Rock, AR 72205. E-mail: Donato-Debra@Cooperhealth.edu. Web site: http://www.panlar.org/.

United Kingdom

Lupus UK, St James House, Eastern Road, Romford, Essex RM1 3NH England, 44-1708-731-251; E-mail: headoffice@lupusuk.org.uk; Web site: http://www.lupusuk.org.uk/.

How Can I Find Out about Organizations That Serve Patients With Lupus-Related Disorders?

Fibromyalgia Network, P.O. Box 31750, Tucson, AZ 85751 supports research through the American Fibromyalgia Syndrome Association. Call toll-free 800-853-2929; Web site: http://www.fmnetnews.com/.

Scleroderma Foundation, 300 Rosewood Drive, Suite 105, Danvers, MA 01923, Phone: 978-463-5843, toll-free 800-722-HOPE (4673); E-mail: sfinfo@scleroderma.org; Web site: http://www.scleroderma.org/.

Sjogren's Syndrome Foundation, 8120 Woodmont Ave., Suite 530, Bethesda MD 20814. Phone: 301-718-0300, toll-free 800-475-6473. Web site: http://www.sjogrens.com/.

What Are the Best Books on Lupus Written by Nonphysicians?

Phillips, RH. *Coping with Lupus*. Revised and Updated Ed. (Avery/Penguin Putnam, 2001). Written by an eminent psychologist and popular speaker, it is the best book on the subject. Available from the LFA and in bookstores.

Phillips RH. *Successful Living with Lupus: An Action Workbook.* Revised and Updated Ed. (Balance Enterprises, 2005). Learn to improve your emotional and social well-being, by emphasizing your positive potential. Also available as a CD-ROM. Available from the LFA.

Lupus Foundation of America, Inc. *Loopy Lupus Helps Tell Scott's Story About a Disease Called Lupus.* Written by a third-grade class after a classmate was diagnosed with lupus, this book is brightly colored and charmingly illustrated by the boy's sister. Includes information for adults on the left-hand pages with Scott's story in his own words on the right-hand pages. Available from the LFA.

Hospital for Special Surgery (HSS) Department of Patient Care and Quality Management. *For Inquiring Teens with Lupus: Our Thoughts, Issues & Concerns* (HSS 2003). This colorful teen-speak booklet is available free of charge by calling the Charla de Lupus (Lupus Chat) Program toll-free at 866-812-4494 or 212-606-1958 within New York City.

Hospital for Special Surgery (HSS) Department of Patient Care and Quality Management. *What Chinese-Americans*

and Their Families Should Know about Lupus (HSS 2003). This bilingual booklet is available free of charge by calling the Lupus Asian Network (LANtern) toll-free at 866–505–2253.

Are There Other Books About Lupus and Related Diseases Written by Physicians?

Lahita RG, Phillips RH. *Lupus Q&A: Everything You Need to Know* (Avery Press, 2004). This is the revised and updated version of the popular 1998 book, *Lupus: Everything You Need to Know.*

Lahita RG, Yalof I. *Woman and Autoimmunity: Your Body Betrayed* (Regan Press, 2004). Written in the style of a novel, this book details the lives of 15 women and their adventures with autoimmune disease, with lupus being one of the diseases highlighted. Additionally, the author explains the body's immune system and how autoimmune diseases happen.

Wallace DJ, Wallace JB. *Making Sense of Fibromyalgia* (Oxford University Press, 1999). This complex autoimmune disease is found in 20 percent of people with lupus, making this book a popular companion text to books about lupus.

Blau SP, Schultz D. *Living with Lupus: The Complete Guide*. 2nd Ed. Revised and Updated (Da Capo Press/Perseus Books Group, 2004). The authors discuss medications and therapies, current research directions, and potential disease complications. The book also offers tips for day-to-day coping, plus information on dealing with decisions on pregnancy and hormone replacement. Lupus in children and teens, possible causes of the disease, and the doctor-patient relationship also are covered.

Lehman TJA. *It's Not Just Growing Pains: A Guide to Childhood Muscle, Bone, and Joint Pains, Rheumatic Diseases, and the Latest Treatments* (Oxford University Press, 2004). In this comprehensive resource guide for parents and professionals, the author offers easy-to-understand information on the causes, symptoms, tests and treatments for a variety of rheumatic diseases and childhood pain.

Wallace DJ, Wallace JB, *Fibromyalgia: An Essential Guide For Patients and Their Families* (NY/London: Oxford University Press, 2003). In clear and accessible language the authors provide a concise explanation of the syndrome and its symptoms, and also outline the recent advances in treatments. This guide offers expert advice to sufferers and gives them the education they need to get the help they require.

Wallace DJ, Editor, *The New Sjogren's Syndrome Handbook* (3rd Ed.) (NY/London: Oxford University Press, 2005). This comprehensive and authoritative guide has been revised and expanded to provide readers with medical and practical information that brings together the current thinking about the disease. The book illuminates the major clinical aspects of the syndrome in an easily readable and understandable manner and is loaded with practical tips and advice to assist those seeking information.

Wallace DJ, Clauw DJ, *Fibromyalgia and Other Central Pain Syndromes* (Philadelphia: Lippincott Williams & Wilkins, 2005). This volume is the first comprehensive text devoted to fibromyalgia and other centrally mediated chronic pain syndromes. Chapters discuss the definition, epidemiology, and pathophysiology of chronic pain and fibromyalgia, the clinical presentations of fibromyalgia syndrome, and central sensitization syndromes associated with chronic neuromuscular pain. The contributors thoroughly examine various approaches to evaluation and management of patients with fibromyalgia and chronic pain. Other chapters focus on disability issues, prognosis, and future research directions. A critically reviewed listing of Web sites and other resources is included.

Wallace DJ, *The Lupus Book: A Guide for Patients and Their Families* (3rd Ed.) (NY/London: Oxford University Press, 2005). This revised and expanded edition is suitable for the motivated patient wanting a concise, practical overview of their disease. It contains new sections relating to disability, economic impact of the disease, biologics and other new drug treatments, clinical measures of disease activity, clinical trial methods, and proactive treatment strategies, while sections relating to inflammation and the causes of lupus have been significantly updated.

What about Rheumatology or Lupus Textbooks?

Wallace DJ, Hahn BH. *Dubois' Lupus Erythematosus*. 7th Ed. (Lippincott, Williams & Wilkins, 2007). The definitive text on the topic, this book can be ordered from the publisher's Web site: http://www.lww.com/.

Lahita RG. *Systemic Lupus Erythematosus.* 4th Ed. (Academic Press, 2004). Another excellent lupus textbook.

National Institutes of Health/NIAMS. *Lupus: A Patient Care Guide for Nurses and Other Health Professionals.* (National Institutes of Health/NIAMS, 2001, Bethesda, MD) A replacement for Terry Nass's Lupus Erythematosus: A Handbook for Nurses (1985). Books are available at no charge from the NIAMS Information Clearinghouse; see listing above.

The best general rheumatology textbooks are:

Hochberg MC, Silman AJ, Smolen JS, et al, eds. *Rheumatology.* Two-volume set, 3rd Ed. (Mosby 2003; previous edition, 1997, by J.H. Klippel).

Kelley WN, et al. *Textbook of Rheumatology.* Two-volume set, 7th Ed. E. Harris, ed. (WB Saunders, 2005; previous edition, 1997).

Klippel JH, ed. *Primer on the Rheumatic Diseases.* 12th Ed. (National Book Network, 2001).

Koopman WJ, Moreland LW. *Arthritis and Allied Conditions: A Textbook of Rheumatology.* Two-volume set. 15th Ed. (Lippincott, Williams & Wilkins, 2004).

Koopman WJ, Boulware DW, Heudebert GR, eds. *Clinical Primer of Rheumatology* (Lippincott, Williams & Wilkins, 2003).

Maddison PJ, Isenberg DA, Woo P, et al, eds. *Oxford Textbook of Rheumatology.* 3rd Ed. (Oxford Medical Publications, Oxford Press, 2004).

Appendix III: The Medical Outcome Survey Short-Form General Health Survey

Jennifer Grossman

Caroline Gordon

- In general, would you say your health is:

  1 = Excellent

  2 = Very good

  3 = Good

  4 = Fair

  5 = Poor

- *Compared to one year ago*, how would you rate your health in general now?

  1 = Much better now than one year ago

  2 = Somewhat better now than one year ago

  3 = About the same as one year ago

  4 = Somewhat worse now than one year ago

  5 = Much worse now than one year ago

- The following items are about activities you might do during a typical day. Does your health now limit you in these activities? If so, how much?

  1 = Yes, limited a lot

  2 = Yes, limited a little

  3 = No, not limited at all

  - *Vigorous activities,* such as running, lifting heavy objects, participating in strenuous sports
  - *Moderate activities,* such as moving a table, pushing a vacuum cleaner, bowling, or playing golf
  - Lifting or carrying groceries
  - Climbing *several* flights of stairs
  - Climbing *one* flight of stairs
  - Bending, kneeling, or stooping
  - Walking *more than one mile*
  - Walking *several blocks*
  - Walking *one block*
  - Bathing or dressing yourself

- During the *past 4 weeks,* have you had any of the following problems with your work or other regular daily activities *as a result of your physical health*? 1 = Yes, 2 = No
  - Cut down on the *amount of time* you spent on work or other activities
  - *Accomplished less* than you would like
  - Were limited in the *kind* of work or other activities
  - Had difficulty performing the work or other activities (for example, it took extra effort)
- During the *past 4 weeks,* have you had any of the following problems with your work or other regular daily activities *as a result of any emotional problems* (such as feeling depressed or anxious) 1 = Yes, 2 = No
  - Cut down on the *amount of time* you spent of work or other activities
  - *Accomplished less* than you would like
  - Didn't do work or other activities as *carefully* as usual
- During the *past 4 weeks*, to what extent has your physical health or emotional problems interfered with your normal social activities with family, friends, neighbors, or groups?

  1 = Not at all
  2 = Slightly
  3 = Moderately
  4 = Quite a bit
  5 = Extremely

- How much bodily pain have you had during the past 4 weeks?

  1 = None
  2 = Very mild
  3 = Mild
  4 = Moderate
  5 = Severe
  6 = Very severe

- During the *past 4 weeks* how much did pain interfere with your normal work (including both work outside the home and housework)?

  1 = Not at all
  2 = A little bit
  3 = Moderately
  4 = Quite a bit
  5 = Extremely

- These questions are about how you feel and how things have been with you *during the past 4 weeks*. For each question, please give one answer that comes closest to the way you have been feeling.

  1 = All of the time
  2 = Most of the time
  3 = A good bit of the time
  4 = Some of the time
  5 = A little of the time
  6 = None of the time

  How much of the time during the *past 4 weeks* ….

  - Did you feel full of pep?
  - Have you been a very nervous person?
  - Have you felt so down in the dumps that nothing could cheer you up?
  - Have you felt calm and peaceful?
  - Did you have a lot of energy?
  - Have you felt downhearted and blue?
  - Did you feel worn out?
  - Have you been a happy person?
  - Did you feel tired?

- During the past 4 weeks, how much of the time has your physical health or emotional problems interfered with your social activities (like visiting your friends, relatives, etc.)?

  1 = All of the time
  2 = Most of the time
  3 = Some of the time
  4 = A little of the time
  5 = None of the time

- How **TRUE** or **FALSE** is each of the following statements for you?

  1 = Definitely true
  2 = Mostly true
  3 = Don't know
  4 = Mostly false
  5 = Definitely false

  - I seem to get sick a little easier than other people.
  - I am as healthy as anybody I know.
  - I expect my health to get worse.
  - My health is excellent.

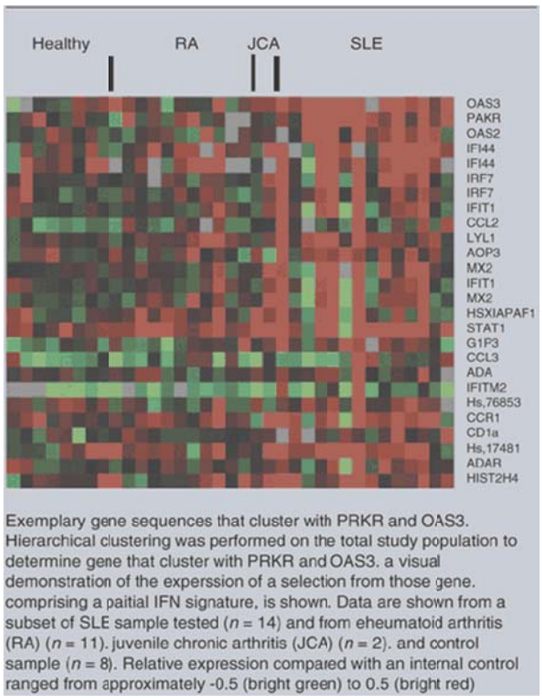
FIGURE 1.3. (See black and white image)



Exemplary gene sequences that cluster with PRKR and OAS3. Hierarchical clustering was performed on the total study population to determine gene that cluster with PRKR and OAS3. a visual demonstration of the experssion of a selection from those gene. comprising a paitial IFN signature, is shown. Data are shown from a subset of SLE sample tested ($n = 14$) and from eheumatoid arthritis (RA) ($n = 11$). juvenile chronic arthritis (JCA) ($n = 2$). and control sample ($n = 8$). Relative expression compared with an internal control ranged from approximately -0.5 (bright green) to 0.5 (bright red)
