Disease in MRL-Fas(lpr) mice has been successfully suppressed by the administration of cholera toxin (654) and of

a platelet activating-receptor antagonist (655). Administration of a single dose of thalidomide to NZB, MRL/n, and MRL-Fas(lpr) mice reduced the production of IgM and/or IgG, probably by reducing the numbers of $CD5^+$ B cells (656). Treatment of BW mice with lithium chloride prolonged survival through unknown mechanisms (657). The value of these strategies (and of others not mentioned here) will depend on whether these findings can be confirmed and the role of these compounds in altering disease elucidated.

Lupus in Domestic Animals

Spontaneous lupus-like disease has been reported in several animal species other than mice, including dogs, cats, rats, rabbits, guinea pigs, pigs, monkeys, hamsters, and Aleutian minks (658 ,659 ,660 ,661 ,662 ,663 ,664 ,665 ,666 ,667 ,668 ,669 ,670 ,671 ,672). The largest body of literature addresses SLE in dogs.

Spontaneous Canine SLE

The canine lupus model is particularly interesting because of its clinical similarity to human SLE. Like human SLE, canine lupus is a chronic disease with alternating periods of remission and relapse. In contrast, such a cyclic evolution is not observed in mice with lupus, where the disease steadily progresses to its terminal stage (673). Frequent manifestations in canine lupus include fever, polyarthritis (91%), glomerulonephritis (65%), mucocutaneous lesions (60%), lymphadenopathy, and splenomegaly (671). Other infrequent manifestations include hemolytic anemia, thrombocytopenia, and clotting (667 ,669 ,670 ,671 ,672 ,674 ,675 ,676). Bullous, discoid, and systemic type skin lesions can occur. The predominant autoantibodies, occurring in more than 90% of dogs with SLE, are ANAs and antibodies directed against individual histones. Antibodies against ssDNA, dsDNA, Ro/SSA, Sm, RNP, lymphocytes, and platelets are found, but in less than 30% (664 ,670 ,675 ,676 ,677 ,678 ,679). The H130 Id that is characteristic of anti-DNA from MRL-Fas(lpr) mice has been found on anti-DNA in dogs (680). Effective interventions include glucocorticoids, levamisole, apheresis, and tetracyclines. Most dogs respond.

In dogs, the disease can be sporadic or familial. A colony of dogs particularly susceptible to SLE was created by breeding a male and female German shepherd, each of which had SLE. As healthy sires were introduced to mate with F1 and F2 generations, the disease prevalence declined (666 ,667). There is a genetic association with MHC, as in mice and in humans (reviewed in (681)). The DLA-A7 MHC class I gene confers a relative risk of approximately 12 for SLE whether it is found in sporadic or familial disease; DLA-Al and B5 are negatively correlated with disease (668).

Because of concern that SLE may be transmitted by viruses, studies have been done to determine whether SLE in humans is more common among owners of dogs with SLE. A study of 83 members of 23 households with 19 dogs that had high-titer ANAs showed no excess in the number of cases of human SLE (682).

Induced Model of Canine SLE

Normal dogs immunized with heparan sulphate, the major glycosaminoglycan of the glomerular basement membrane, develop antinuclear antibodies, proteinuria and skin disease, and marked deposition of IgM and C3 in the dermal–epidermal junction of skin (683). Cutaneous signs associated with SLE included alopecia, erythema, crusting, scaling, and seborrhoea. Three of eight dogs showed lameness. Therefore, the heparan sulfate-immunized dog can be useful as a canine SLE model for studying immune-mediated skin disease and autoimmunity.

SLE in Cats, Monkeys, and Horses

SLE in cats usually is a spontaneous disease (684). Analyses of clinical features in 22 cases showed that glomerulonephritis (in 10 cases), neurological signs (in 9 cases), arthritis (in 9), anemia (in 8) and dermatological signs (in 7 cases) were frequent manifestations (685). Other manifestations included fever, lymphadenopathy, mucocutaneous ulcers and thrombocytopenia. In addition to spontaneous diseases, there has been interest in a series of experiments in which the administration of propylthiouracil to cats induces autoantibodies and autoimmune hemolytic anemia (686).

SLE in monkeys can be induced by feeding macaques alfalfa seeds, probably because of the immunostimulatory properties of the L-canavanine nonprotein amino acid that the seeds contain (631 ,632 ,633 ,634).

SLE is rarely reported in horses. In these cases, horses were reported to manifest with polyarthritis, proteinuria, thrombocytopenia, and a positive ANA in one case (687) and weight loss, Coombs' positive anemia, alopecia, ulcerative glossitis, generalized lymphadenopathy, and skin inflammation with dermoepidermal Ig deposits on biopsy in another case (688).

Attempts have been made to induce SLE in animals by transferring plasma from patients with SLE. Histologic evidence of glomerulonephritis was produced by repeated infusions of human plasma containing LE factors into healthy dogs in one set of experiments (689) but not in another (690). Similar experiments were unsuccessful in guinea pigs.

Efforts to induce lupus-like disease in various animals by administering lupus-inducing drugs have been largely unsuccessful. Hydralazine and procainamide have been given to dogs, guinea pigs, swine, and rats, but with little evidence of autoimmune responses (691). On the other hand, immunization of rabbits, mice, and baboons with protein or oligopeptide autoantigens (from Sm B/B8, Ro 60-kd peptides, and La/SS-B) have induced epitope spreading, antinuclear antibodies and proteinuria in a proportion of animals (466 ,467 ,468 ,469 ,470). Differences in proportions of animals that develop autoantibodies in different experiments may reflect differences in environmental stimuli to which animals are exposed in different laboratories.

Finally, dogs have been studied for evidence of vertical transmission of infectious agents that cause SLE. In breeding studies performed by Lewis and Schwartz (665), the incidence of positive LE-cell tests in inbred backcrosses and outcross

matings was not consistent with any conventional mechanisms of inheritance. The investigators concluded that the results could be explained by vertical transmission of an infectious agent in a genetically susceptible individual. Cell-free filtrates of tissues from seropositive dogs also have been injected into newborn mice (665), and these mice developed ANAs and, in some cases, lymphomas. Passage of cells or filtrates from the tumors to normal newborn puppies resulted in ANA production or positive LE-cell tests. C-type RNA viruses were identified in the tumors. In cats, autoimmunity is highly associated with the feline leukemia virus (662). It may be that autoimmune disease similar to human SLE is more closely linked to viral infections in dogs and cats than in humans.

Use and Analysis of Animal Strains for Lupus Research

A variety of animal strains develop lupus-like disease, each with particular clinical manifestations and pathogenesis, representing different stages or subsets of SLE. Whereas selection of the model that truly represents human SLE remains debated, investigators have chosen models based on the clinical manifestation or phenomena of interest within the lupus autoimmune spectrum. For example, NZB/Bl mice may be most suitable to study autoimmune hemolytic anemia; BW and NZM strains have been extensively studied for anti-dsDNA antibody production, T cell autoreactivity and typical progressive lupus nephritis. MRL-lpr/lpr mouse, on the other hand, can serve as a model for a more multisystem disease such as lupus dermatitis, arthritis, fulminant interstitial nephritis, and lymphadenopathy and autoantibodies against multiple antigens. Although not extensively investigated, canine SLE may serve as a model for relapsing-remitting disease with clinical manifestations that more closely mimic human SLE. Induced SLE models such as hydrocarbon oil-induced lupus in otherwise normal mouse strains may be particularly useful in investigating the role of various genes in the pathogenesis of lupus using gene-targeted strains that are not normally lupus-prone, as it may save the 2 years or more that is required to backcross the null genotype from the stock strains (usually C57BL6/Sv129) on to the lupus-prone backgrounds. Materials and methods required for analyses of autoantibodies and disease profile are nicely outlined in a recent review (5).

Translation of Lessons from Animal Models in to Human Disease: Successes and Failures

Parallel developments in human disease observations and animal model investigations have helped in tracing some pathogenetic steps leading to manifestations of lupus. Some observations made in animal models are already being translated onto human clinical trials. For example, more than 30 years ago, Borel et al. showed that it is possible to prevent lupus in an animal model by inducing tolerance to denatured DNA (570). About 15 years later, this finding was translated onto human disease by showing that a DNA-human IgG conjugate inhibits the formation of anti-dsDNA in vitro by lymphoid cells from SLE patients (692). Such studies eventually led to a clinical trial to evaluate a dsDNA-directed B cell tolerogen, a synthetic molecule with the ability to bind dsDNA antibodies leading to anergy or apoptosis of B cells, which has shown delayed renal flares and reduction of anti-dsDNA antibodies in a subset of SLE patients (577 ,693). Similarly, identification of anti-DNA Ig-derived peptides as T cell epitopes in murine lupus in early 1990s led to a clinical trial using anti-DNA Ig-derived peptides in human SLE by Teva Pharmaceuticals. However, past experience has taught us that rush to clinical trials must not occur without full realization that the biological basis by which an intervention may suppress disease in an animal model may not be directly translatable to humans. Thus, while the full elucidation of human lupus pathogenesis and the most effective therapies to suppress or prevent disease will clearly require intense investigations using current model systems and development of newer models that are more representative of human disease, a more intensive effort will be needed to translate this knowledge towards the development of disease stage-specific biomarkers and treatments for human disease.

Chapter 19

Pathogenesis of Atherosclerosis in Lupus

Maureen McMahon

Jennifer Grossman

Introduction

Premature atherosclerosis (ATH) is a major comorbid condition in systemic lupus erythematosus (SLE). While typical features of SLE such as nephritis and vasculitis have been the traditional focus of treatment, the identification of comorbid conditions such as atherosclerosis has become more important as the treatments for SLE improve and patients live longer. In a landmark study, Urowitz et al. described a bimodal mortality curve where early mortality (first 10 years after diagnosis) was primarily because of lupus-related causes and infection, while late deaths (more than 10 years after diagnosis) were primarily attributable to atherosclerotic and thrombotic disease (1). The mortality rate from atherosclerosis in SLE patients has been between 6% to 16% in various recent series (2). The incidence of subclinical atherosclerosis in SLE is also increased; in a recent study using carotid ultrasounds, a 37% prevalence of carotid atherosclerosis was found in lupus patients compared to 15% of controls ($p < 0.001$) (3). Manzi et al. found a prevalence of subclinical carotid atherosclerosis of 40% in their cohort (4). Asanuma et al. also found an increased prevalence of subclinical atherosclerosis when electron beam computerized tomography was used as the screening instrument, with coronary calcification present in 31% of SLE patients compared to 9% of controls (5).

The traditional risk factors of hypertension (2 ,6 ,7), hypercholesterolemia (1 ,7 ,8), diabetes mellitus (1 ,7), older age (2 ,7 ,8), and postmenopausal status (2 ,8) have all been associated with atherosclerotic disease in SLE patients. Case control studies have suggested that independent factors associated with SLE are also risk factors. Manzi et al. compared age-specific incidence rates for coronary artery disease (CAD) for SLE patients and controls from the Framingham Offspring Study (8). Women with SLE between ages 35 to 44 were 50 times more likely to have a myocardial infarction (MI) than controls. In a Canadian cohort after controlling for gender, blood pressure, diabetes, cholesterol, smoking, and left ventricular hypertrophy, the relative risk attributed to SLE for MI was 10.1 and 7.9 for stroke (9). Thus, while SLE patients are subject to the same traditional risk factors as the general population (9 ,10 ,11), these factors do not adequately account for the significantly increased level of cardiovascular disease. The mechanisms of the increased and accelerated atherosclerotic risk for SLE patients remain to be determined. It is likely that multiple mechanisms are operative, including inflammation of arteries, degeneration of intimae and media of arteries, and prothrombotic states (12 ,13). To further understand the pathogenesis of atherosclerosis in SLE, it is important to first develop an understanding of the development of atherosclerosis in the general population, and the role played by inflammation.

Inflammation and the Pathogenesis of Atherosclerosis

For many years, atherosclerosis was regarded as a passive accumulation of lipids in the vessel wall. Recently, however, it has been realized that inflammation plays a role not only in the development of the atherosclerotic lesion, but also in the acute rupture of plaques that occurs during acute myocardial ischemic events (12 ,13). As in the pathogenesis of SLE itself, the interplay of multiple inflammatory mediators, including leukocytes, cytokines, chemokines, adhesion molecules, complement, and antibodies, results in the formation of atherosclerotic plaques (14).

Adhesion Molecules and Leukocyte Recruitment

Atherosclerotic lesions begin with the recruitment of inflammatory cells such as monocytes and T cells to the endothelial wall. First, the endothelial cells are stimulated to express leukocyte adhesion molecules, including E-selectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1) (14). These cell-surface proteins are upregulated during periods of inflammation. For example, the expression of adhesion molecules can be induced by pro-inflammatory cytokines such as TNF-α and IL-1, which upregulate leukocyte adhesion molecules in an NF-κB dependent process (14). Also, VCAM-1 can be induced in response to exposure of the endothelial cells to the lipopolysaccharides of Gram-negative bacteria, lysophosphatidylcholine (LPC) and oxidized phospholipids such as oxidized LDL (OxLDL) (15 ,16). Additionally, the expression of ICAM-1 can be induced in response to hemodynamic stress, as in cases of hypertension (17). High Density Lipoproteins (HDL) are capable of inhibiting the

expression of these cell surface adhesion molecules (18 ,19), likely through inhibition of endothelial cell sphingosine kinase, an enzyme that catalyzes a step in the pathway by which TNF stimulates the expression of endothelial cell adhesion molecules (20).

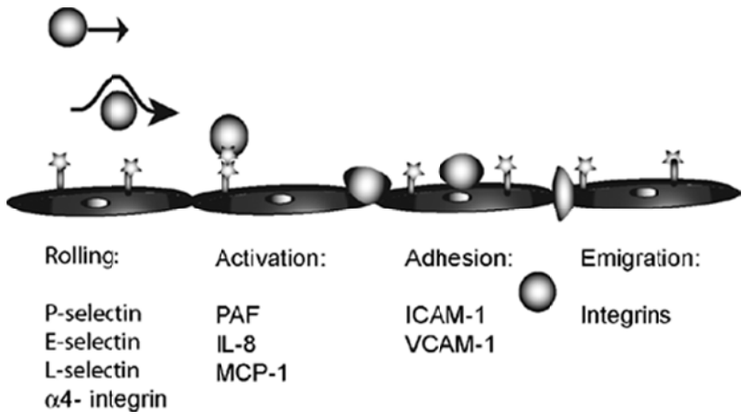

Figure 19-1. Adhesion molecules are involved in the adhesion of monocytes to activated endothelial cells. Monocytes randomly contact endothelial cell adhesion molecules. Selectins such as E-selectin slow the monocyte and induce rolling of the monocyte along the endothelial surface. Next, the monocyte firmly attaches to the surface by binding to vascular cell adhesion molecule 1 (VCAM-1) or intercellular adhesion molecule 1 (ICAM-1), which interact with integrins on the monocyte surface. Once the monocyte is tightly bound, it then migrates between endothelial cells in response to MCP-1.

The process of leukocyte adhesion occurs in several steps. First, E-selectin mediates the rolling and loose tethering of leukocytes on the endothelial cell surface, before they are more tightly bound by VCAM-1 and ICAM-1 (Fig. 19-1) (21). The importance of these adhesion molecules in the development of atherosclerosis is highlighted by the fact that atherosclerosis-prone apoE deficient mice who are also deficient in E-selectin develop fewer plaque lesions (22). Also, soluble levels of VCAM-1 can be detected in the systemic circulation, and elevated levels of this adhesion molecule have been found in humans with coronary artery disease (CAD) (23 ,24). In one cross sectional carotid ultrasound study of SLE patients, however, neither levels of soluble VCAM-1 nor ICAM-1 were significantly associated with carotid plaque (3).

Leukocyte Migration into the Intima

After leukocytes adhere to the cell surface, they migrate through the endothelium and into the intima (14). This transmigration is influenced by several factors; first, several chemotactic proteins such as monocyte chemotactic protein-1 (MCP-1) are produced by the endothelial and smooth cell layers (25). The expression of MCP-1 in smooth muscle cells and endothelial cells can be induced by both cytokines such as TNF-α and IL-1 and by OxLDL (25 ,26 ,27). Additionally, some of the components released in the complement cascade, such as C5a, are strongly chemotactic for monocytes, and can also stimulate endothelial cells to express MCP-1(25 ,28). Conversely, normal HDL inhibit the expression of MCP-1(20). The importance of MCP-1 in the development of the atherosclerotic plaque is emphasized by the fact that atherosclerosis-prone mice who are also deficient in MCP-1 or its receptors have drastically reduced atherosclerotic plaque burdens compared to mice with normal MCP-1 levels (29 ,30). Elevated circulating levels of MCP-1 are also positively related to increased carotid artery intimal-medial thickness intimal-medial thickness (IMT) in humans (31).

Low-Density Lipoproteins and the Development of Foam Cells

Next, low-density lipoproteins (LDLs) are transported in a concentration dependent manner into artery walls (32). These LDLs become trapped and bound in the extracellular matrix of the subendothelial space (33), and seeded with oxidant waste products from nearby artery wall cells. These trapped and seeded LDLs then accumulate additional reactive oxygen species from nearby artery wall cells. When a critical threshold of reactive oxygen species is reached, LDL phospholipids become oxidized, resulting in the formation of specific pro-inflammatory oxidized lipids (POVPC, PAPC, PGPC, and PEIPC). When endothelial cells (34) are exposed to these pro-inflammatory oxidized lipids, they release cytokines such as monocyte chemotactic protein-1, macrophage colony-stimulating factor (M-CSF), and growth-related oncogene (GRO), resulting in monocyte binding, chemotaxis, and differentiation into macrophages (34). (HDL) cholesterol are capable of inhibiting the transmigration of leukocytes in response to OxLDL (35). The OxLDL are phagocytized by infiltrating monocytes/macrophages, which then become the foam cells around which atherosclerotic lesions are built (32).

Monocytes and T cells infiltrate the margin of the plaque formed by foam cells. Muscle cells from the media of the artery are stimulated to grow (36). These muscle cells encroach on the lumen of the vessel and ultimately lead to fibrosis, which can render the plaques brittle. The occlusion that results in myocardial infarction can occur when one of these plaques ruptures, or when platelets aggregate in the narrowed area of the artery (36).

Inflammatory Changes in the Endothelium

As noted above, changes in the endothelium can accelerate the formation of the atherosclerotic plaque. For example, when exposed to oxidized LDL, interleukin-1, and tumor necrosis factor (TNF), the vascular endothelium undergoes a series of inflammatory changes, resulting in endothelial cell activation (ECA) (37). When ECA occurs, there is an up-regulation of leukocyte adhesion molecules such as VCAM-1, ICAM-1, and E-selectin (37). There is a loss of vascular integrity, and the endothelium becomes leaky. Additionally, ECA can result in prothrombotic changes, including enhanced plasminogen activator inhibitor type-1

release, the production of platelet activating factor, and the expression of tissue activating factor (37). Chemoattractant cytokines such as monocyte chemoattractant protein-1 (MCP-1), interleukin-6 (IL-6), and interleukin-8 (IL-8) are also expressed (37). Thus, exposure to OxLDL induces a cascade of pro-inflammatory, pro-atherogenic changes in the endothelium (38).

HDL Clears OxLDL from the Endothelium

There are many mechanisms designed to clear OxLDL from the subendothelial space, such as macrophage engulfment using scavenger receptors (39 ,40), and enhanced reverse cholesterol transport mediated by HDL (41 ,42). In addition, HDL has also been shown to both prevent and reverse LDL oxidation (43 ,44). When Watson and colleagues incubated LDL with HDL, there was an 80% decrease in the biological activity of the LDL (45). Both HDL and its major apolipoprotein constituent, apolipoprotein A-1 (apoA-I) have been shown to prevent LDL oxidation (34 ,46). In addition to the enhancement of reverse cholesterol transport (41 ,42 ,47 ,48), HDL and apoA-I exert their beneficial effects by removing reactive oxygen species from LDL, thus preventing the oxidation of LDL and subsequent recruitment of inflammatory mediators (34 ,49). In addition to apo A-I, HDL contains several enzymes that can prevent or destroy the formation of the oxidized phospholipids in OxLDL that induce the inflammatory response (50). These enzymes include paraoxonase (51), platelet-activating factor acetylhydrolase (PAF-AH) (45), and lecithin-cholesterol acyltransferase (LCAT) (52) (Fig. 19-2).

Thus, it is not solely the amount of HDL present that determines atherosclerotic risk, as HDL function is equally significant (17). For example, during the acute phase response HDL can be converted from their usual anti-inflammatory state to pro-inflammatory. Van Lenten and colleagues studied HDL taken from humans before and after elective surgery (53). Before surgery, HDL were able to inhibit LDL oxidation and LDL-induced monocyte chemotactic activity in a human artery wall cell coculture model. Three days after surgery, however, at the peak of the acute phase response, HDL promoted LDL oxidation and monocyte chemotactic activity; HDL returned to an anti-inflammatory state 1 week after surgery (53). Thus, acute phase HDL can be described as pro-inflammatory. Van Lenten et al. also found that levels of anti-inflammatory components of HDL such as apoA-I and HDL-associated paraoxonase activity were reduced in the acute phase response (53). Additionally, acute phase HDL was greatly enriched in acute phase reactants such as serum amyloid A (53). Thus, HDL can be described as a “chameleon like lipoprotein;” anti-inflammatory in the basal state and proinflammatory during the acute phase response (32) (Fig. 19-3). This acute phase response, however, can also become chronic (54), and may be a mechanism for HDL dysfunction in SLE.

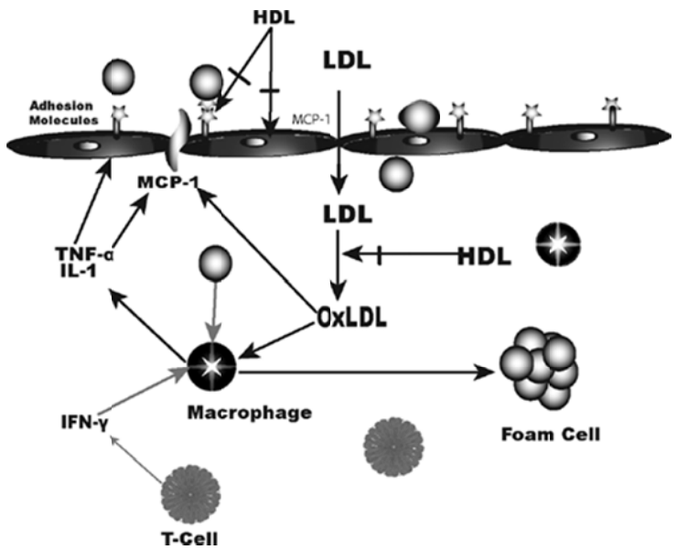

Figure 19-2. Atherosclerosis is an inflammatory disorder that is initiated by the interplay of cytokines, lipids, oxidation products, and leukocytes. The process begins when LDL enters and is trapped in the arterial intima. LDL is oxidized and transformed into oxidized LDL (OxLDL). OxLDL then activates endothelial cells to express monocyte chemotactic protein 1 (MCP-1), which attracts monocytes from the vessel lumen and into the subendothelial space. OxLDL then promotes the differentiation of monocytes into macrophages. Macrophages in turn release a variety of chemicals, including cytokines. Of these cytokines, tumor necrosis factor α (TNF-α) and interleukin-1 (IL-1) activate endothelial cells to express adhesion molecules that bind monocytes, making them available for recruitment into the subendothelial space by MCP-1. Normal functioning HDL inhibits the formation of oxidized LDL, the expression of endothelial cell adhesion molecules and MCP-1, and promotes the efflux of cholesterol from foam cells.

The Role of Cytokines in Atherosclerosis

T cells, primarily of the Th1 subtype, are also abundant in atherosclerotic lesions, and may play a role in the formation of plaque through the cascade of cytokines that is initiated by their activation (55). Vascular endothelial and smooth muscle cells are important targets for inflammatory cytokines, and these cells can produce additional cytokines when stimulated (13). At least two stimuli for Th1 differentiation are present in the atherosclerotic plaque. IL-12 is expressed by macrophages, smooth muscle cells, and endothelial cells, and is an important stimulus for Th1 differentiation (56). Elevated levels of IL-12 have been found in atherosclerotic plaques (56), and the inhibition of IL-12 using a vaccination technique that fully blocks the action of IL-12 has been shown to decrease atherosclerosis in mice (57). IL-12 production is upregulated in monocytes exposed to oxidized LDL (56).

IFN-γ has also been detected in human plaques (14). It is a powerful growth inhibitor for smooth muscle cells, endothelial cells, and collagen production, and thus promotes plaque instability (58). Additionally, IFN-γ induces the expression of secretory phospholipase A2, leading to the

production of inflammatory lipid mediators such as LPC, PAF, and eicosanoids (59). INF-γ also improves the efficiency of antigen presentation, and leads to increased synthesis of TNF-α and IL-1 (60). All of these actions contribute to the formation of the atherosclerotic plaque, and indeed, in atherosclerosis-prone apoE knockout mice who are also lacking IFN-γ, atherosclerosis is decreased by nearly 60% (61 ,62). The administration of IFN-γ also accelerates atherosclerosis in apo-E knockout mice. Increased levels of both IFN-γ and IL-12 have been found in humans with unstable and stable angina compared with controls (63).

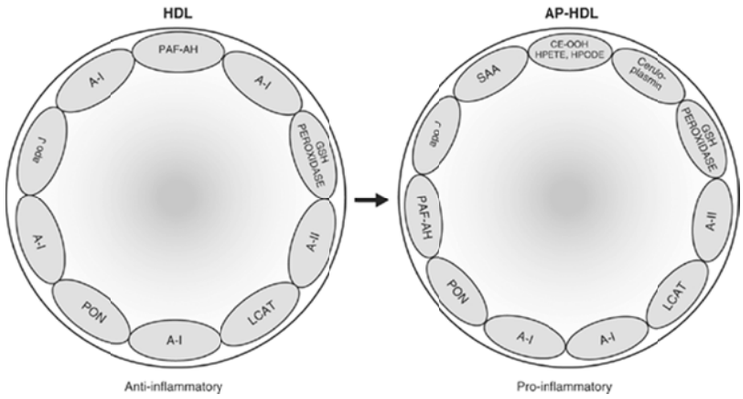

Figure 19-3. The acute-phase (AP) reaction favors the formation of proinflammatory HDL and mildly oxidized LDL. **A,** In the basal state, HDL contains apoA-I and apoJ as well as 4 enzymes, PON, PAF-AH, lecithin:cholesterol acyltransferase (LCAT), and plasma reduced glutathione selenoperoxidase (GSH peroxidase) that can prevent the formation of or inactivate the inflammatory LDL-derived oxidized phospholipids found in mildly oxidized LDL. As a result, in the basal state, HDL may be considered anti-inflammatory. During the acute-phase reaction, A-I may be displaced by the pro-oxidant acute-phase reactant SAA. Another pro-oxidant acute-phase reactant, ceruloplasmin, associates with HDL as does the anti-oxidant acute phase reactant apoJ. PON, PAF-AH, and LCAT decrease in HDL during the acute-phase reaction, and the lipid hydroperoxides HPETE, HPODE, and cholesteryl linoleate hydroperoxide (CE-OOH) increase in HDL. A-II and GSH peroxidase are shown as unchanged during the acute-phase reaction although there are no data on the latter. The net effect of the changes in HDL during the acute-phase reaction is the production of pro-oxidant, proinflammatory HDL particles (AP-HDL). (From Navab M, Berliner JA, Subbanagounder G, et al. HDL and the inflammatory response induced by LDL-derived oxidized phospholipids. *Arterioscler Thromb Vasc Biol* 2001;21(4):481–488.)

As noted above, TNF-α and IL-1 are also present in human atherosclerotic lesions. Like IFN-γ, they also affect smooth muscle proliferation. TNF-α and IL-1 induce local inflammation in blood vessels by stimulating the activation of macrophages (17), inducing the secretion of matrix metalloproteinases (64), and promoting the secretion of cell surface adhesion molecules (14). TNF-α can also upregulate the expression of cell surface adhesion proteins; normal functioning HDL can inhibit this upregulation (65). TNF-α and IL-1 can also inhibit lipoprotein lipase, an enzyme important in the metabolism of triglycerides and very low-density lipoprotein (VLDL) (66 ,67). Additionally, TNF-α and IL-1 enhance production of M-CSF, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) by smooth muscle cells, endothelial cells, and monocytes. These mediators activate monocytes and stimulate their transformation into macrophages and foam cells (68). Inhibition of TNF-α decreased the progression of atherosclerosis in apoE knockout mice (69). Elevated levels of TNF-α may also play a role in the increased risk of atherosclerosis in the general population (70). TNF-α has been linked to vascular injury in both acute and chronic inflammatory conditions. TNF-α has been identified in human endothelial and smooth muscle cells in all stages of atherosclerosis, from early intima thickening to established occlusive atherosclerosis (71 ,72).

In addition to TNF-α and IL-1, the pro-inflammatory cytokine pathway also involves the expression of IL-6 (14). Circulating IL-6 is another cytokine marker that is a strong independent marker of increased mortality in unstable CAD (73). IL-6 stimulates hepatocytes to produce CRP and other markers of inflammation (74). CRP is not only a marker of

acute phase reaction, but may also have a direct effect on leukocyte recruitment and apoptosis in vessel walls (75 ,76). IL-6 is also required for short-term regulation of paraoxonase (PON), an anti-oxidant enzyme present in HDL (77). LDL-derived phospholipids such as oxidized palmitoyl arachidonyl phosphatidyl choline (OxPAPC) induce the expression of IL-6, which in turn down regulates PON mRNA levels (73). Patients with unstable coronary syndromes have elevated levels of both IL-6 and CRP (78 ,79). Additionally, IL-6 has been described as an independent predictor of endothelial dysfunction in rheumatoid arthritis (RA) patients (80).

TGF-β, in contrast, likely plays a protective role against atherosclerotic plaque formation, as discussed in several publications (39 ,70 ,71 ,72 ,73 ,74 ,75 ,76). Thus, the balance of pro-inflammatory and anti-inflammatory cytokines and their interactions with inflammatory cells and lipid components contributes to the formation and maintenance of the atherosclerotic plaque (Table 19-1).

Table 19-1: Some Atherogenic Cytokines and Their Mechanisms

Cytokine	Expressed By	Induced By	Biological Function	Evidence fo Role in ATH	References
MCP-1	Smooth muscle cells, foam cells	TNF-α IL-1 OxLDL Complement Elevated Homocysteine Inhibited by HDL	Chemotactic factor for monocytes	Increased MCP-1 levels related to carotid artery IMT	(25,26,27,29,30,31,37)
TNF-α	Endothelial cells,	IL-6	Activate Macs	Increased	(14,17,64,65,66,67,68,69,70,71,72)
IL-1	Macs, T-cells, foam cells	Inhibited by HDL	Increase adhesion molecules Inhibit LPL Increase SAA Increase MCP-1 Increase CD40L	TNF-α levels increase ATH risk	
IFN-γ	T-cells, foam cells		Inhibit SMCs, EC, collagen Increase plaque instability Increase TNF-α IL-1 Inhibit LPL Prime Macs for activation Increase CD40	Increased IFN-γ in unstable angina	(14,58,59,60,61,62,63)
IL-6	Smooth muscle cells, ECs, foam cells	OxLDL TNF-α IL-1 IFN-γ	Increases SAA Stimulates hepatocytes to produce CRP Regulates paraoxonase	Predictor of unstable angina, endothelial dysfunction	(14,37,73,74,75,76,77)
IL-12	Macs, SMCs, ECs	OxLDL	Th1 differentation	Increased levels seen in ATH plaques	(56,57,63)

ATH, atherosclerosis; CRP, C-reactive protein; EC, endothelial cell; LPL, lipoprotein lipase; Macs, macrophages; OxLDL, oxidized LDL; SMC, smooth muscle cells.

Abnormalities in SLE

Many of the inflammatory mediators described above are also actively involved in the pathogenesis of SLE, and are thus likely to play a role in early atherogenesis. Several of these inflammatory risk factors for atherosclerosis, as well as traditional risk factors, have been demonstrated in patients with SLE.

Dyslipoproteinemia and SLE

Hyperlipidemia is a well established risk factor for coronary artery disease in the general population. Hyperlipidemia is also common in SLE, and has been described in more than 50% of lupus patients (7). Secondary causes of hyperlipidemia, such as the nephrotic syndrome (81) and medications such as corticosteroids (82) do play a role in SLE (83). The disease activity of lupus itself, however, has also been associated with dyslipidemia. High levels of VLDL and triglycerides

(TG) and low levels of HDL have been described as the “lupus pattern,” and are more strikingly noted in patients with active disease (84). Further investigation has suggested that the interplay between blood lipids and chronic inflammation may be one contributing factor to atherosclerosis in SLE (85).

Oxidized Low-Density Lipoproteins

As noted above, the oxidation of LDL is a triggering mechanism in the pathogenesis of atherosclerosis. In fact, elevated levels of circulating oxidized LDL are strongly associated with documented coronary artery disease in the general population (86). Elevated levels of circulating OxLDL have also been described in SLE patients, especially in those with a history of cardiovascular disease (87 ,88). Levels of the oxidized phospholipid OxPAPC have also been associated with thickened IMT on carotid ultrasound (89). Interestingly, renal manifestations of SLE have also been associated with higher levels of circulating OxLDL (88).

Circulating antibodies to OxLDL (anti-OxLDL) have also been described, although the relationship to the development and progression of atherosclerosis is unclear. Elevated levels of antibodies against OxLDL have been described in the general population, and in some studies are predictive of myocardial infarction and the progression of atherosclerosis (90 ,91). Other studies, however, have not found any such correlations (14 ,92). Similarly, the presence of antibodies to OxLDL has been described in subjects with SLE. Anti-OxLDL have also been described in up to 80% of patients with SLE and antiphospholipid antibody syndrome (86 ,93 ,94 ,95). Some studies have demonstrated that autoantibodies to oxidized LDL are more common in SLE patients who have a history of cardiovascular disease than in SLE controls or normal subjects (87), although in two other studies, anti-OxLDL and arterial disease were not associated (96 ,97). Titers of antibodies to OxLDL have also been associated with disease activity in SLE (98).

There is some speculation that the increased risk of thrombotic and atherosclerotic events seen in patients with SLE and antiphospholipid antibodies may be due in part to a cross-reactivity between anticardiolipin and OxLDL (93). Cardiolipin is a component of LDL, (99) and indeed, a cross-reactivity between anti-cardiolipin and anti-OxLDL antibodies has been demonstrated (93 ,94). Additionally, β_2-glycoprotein I (β_2GPI) has been shown to bind directly and stably to oxidized LDL (100). These OxLDL-β_2GPI complexes have been found in patients with SLE and/or APS, and are associated with a risk of arterial thrombosis (101).

Lipoprotein (a)

In addition to oxidized LDL, lipoprotein (a) (Lp[a]) has also been implicated in the pathogenesis of atherosclerosis in both the general and SLE populations (86). Lp(a) is structurally related to LDL, but also contains apo(a) that is covalently linked to apolipoprotein B-100 (102). Lp(a) is rich in cholesterol, and is structurally similar to plasminogen (103 ,104). In the general population, elevated Lp(a) levels have been associated with a two-fold increased relative risk of myocardial infarction (104 ,105). Although the mechanism by which Lp(a) contributes to the pathogenesis of atherosclerosis is not well understood, Lp(a) has been shown to physically associate with pro-inflammatory oxidized LDL (106), and circulating plasma levels of both Lp(a) and OxLDL have been associated with coronary artery stenosis (86).

Several researchers have found elevated levels of Lp(a) in SLE patients (107 ,108 ,109). One study reported that serum Lp(a) levels were increased in lupus patients with renal disease and hypoalbuminemia, and that treatment with corticosteroids reduced the elevated Lp(a) levels (109). Another group reported, however, that Lp(a) levels are not influenced by corticosteroids or disease activity (108). Patients with high serum Lp(a) concentrations also had higher levels of circulating IgM OxLDL-containing immune complexes (110).

High-Density Lipoproteins

As noted above, normal HDL perform many anti-inflammatory, protective functions. HDL enhance reverse cholesterol transport by promoting the efflux of cholesterol from the artery wall (41 ,42 ,47 ,48). HDL and its major apolipoprotein constituent, apolipoprotein A-I (apo A-I), have also been shown to prevent LDL oxidation (34 ,46). They are capable of removing “seeding molecules” from LDL, thus preventing the oxidation of LDL and subsequent recruitment of inflammatory mediators (34 ,49). Additionally, normal anti-inflammatory HDL are capable of inhibiting the expression of cell surface adhesion molecules, (18 ,19), the expression of MCP-1 (20), and the synthesis of platelet-activating factor by endothelial cells (111). HDL also modulate endothelial function, likely by stimulating endothelial nitric oxide production (112 ,113).

Levels of HDL have been found to be reduced in many patients with SLE (107). In one study, HDL levels were reduced in 79% of patients with active SLE and 29% of patients with inactive disease when compared to controls (84). Additionally, decreased levels of HDL have been associated with increased TNF-α and soluble TNF receptors in SLE patients (85). Reduced levels of HDL have also been found in SLE patients with IgG anti-cardiolipin antibodies (114 ,115).

As previously noted, however, it is not solely the amount of HDL present that determines atherosclerotic risk, as HDL function is equally significant (17). Abnormal functioning, pro-inflammatory HDL has been associated with atherosclerosis in the general population. In one study of patients with documented coronary artery disease and normal HDL cholesterol levels, 19 of 20 atherosclerosis patients had pro-inflammatory HDL, compared to 2 of 20 controls (116). HDL function has also been described as abnormal in subjects with SLE. Our group has found that 45% of women with SLE, compared to 20% of RA patients and 4% of controls, had pro-inflammatory HDL that was not only unable to prevent oxidation of LDL but caused increased levels of oxidation (117). In this study, 4 of 4 SLE patients with a history of documented atherosclerosis had

pro-inflammatory HDL, further suggesting that HDL play an important role in the pathogenesis of atherosclerosis.

Abnormalities of the functional components of HDL may also contribute to the pathogenesis of ATH in SLE. Many of these abnormalities have been described in patients with SLE, including apoA-I, paraoxonase, serum amyloid A, and ceruloplasmin, and are described in detail below.

ApoA-I

ApoA-I is the major apolipoprotein component of HDL. Even when apoA-I is isolated from HDL particles, it has been shown to prevent LDL oxidation both in artery wall coculture studies and in cell-free systems (34 ,46). As a component of HDL, apoA-I exerts its beneficial effects through the enhancement of reverse cholesterol transport (41 ,42 ,47 ,48). HDL also removes “seeding molecules” from LDL, thus preventing the oxidation of LDL and subsequent recruitment of inflammatory mediators (34 ,49). Nearly 100% of ApoA-I is carried in plasma on HDL molecules.

Reduced levels of both HDL and apoA-I have been found in SLE patients with IgG anticardiolipin antibodies (95). In the general population, antibodies to apoA-I have been found in up to 21% of patients with acute coronary syndromes who have no other features of autoimmune disease (118). Antibodies to apoA-I have also been described in SLE; in one study, antibodies to apoA-I were found in 32.5% of patients with SLE and 22.9% of patients with primary antiphospholipid syndrome (APS) (115). It is unclear, however, how the presence of these antibodies affects the function of apoA-I in either SLE or acute coronary syndrome patients.

Paraoxonase

Serum paraoxonase (PON) is a serum esterase that is secreted primarily by the liver, and is associated with HDL in plasma. PON has been identified as one of the important components of HDL that prevents lipid peroxidation (119) and blocks the pro-inflammatory effects of mildly oxidized LDL (120). Decreased levels of PON activity have also been associated with atherosclerosis in the general population. One study demonstrated that PON activity in HDL was significantly lower in patients with documented coronary artery disease than in controls (49). Altered levels of PON activity have also been seen in patients with SLE. In one study, PON activity was reduced in SLE and antiphospholipid syndrome patients compared to controls, although there was no reduction in the total antioxidant capacity of the plasma (121). In that study, antibodies against HDL and ß2GPI were associated with the reduction in PON activity (121). Similarly, in patients with anticardiolipin antibodies, PON activity was reduced when compared to healthy controls (122). Although further investigation is necessary, it is possible that the antibodies against HDL and $ß_2$GPI contribute to the oxidation of LDL through a cross-reactive, inhibitory effect on PON activity (121).

Serum Amyloid A

Serum amyloid a (SAA) is an acute phase reactant that may be associated with HDL during periods of acute inflammation, and may serve as a transient cholesterol binding protein (123 ,124). ApoA-I levels bound to HDL decrease by 73% as SAA levels increase in acute inflammatory phase HDL (53). This SAA-HDL is more likely to be rapidly removed from circulation (125), and has decreased enzymatic activity compared with normal HDL (126). Inflammatory cytokines such as IL-1 and IL-6 have been shown to upregulate SAA hepatic synthesis (127 ,128). Additionally, antibodies to apoA-I have been inversely correlated to plasma SAA levels in patients with acute coronary syndromes (118). SAA levels have been shown to be elevated in SLE patients with active disease, although the relationship of SAA levels to other abnormalities of lipid metabolism in SLE has not been explored (129 ,130).

Ceruloplasmin

Ceruloplasmin is another acute phase reactant that can be associated with HDL during periods of acute inflammation. Elevated levels of ceruloplasmin, which normally carries about 95% of plasma copper (131), have been demonstrated in patients with CAD (132). HDL that have been enriched with ceruloplasmin demonstrate altered ability to inhibit LDL oxidation (133). The relationship of ceruloplasmin levels and atherosclerosis has not been described in SLE. One study of 27 SLE subjects and 20 controls did note, however, that serum ceruloplasmin levels were higher in SLE subjects than in controls (134).

Triglycerides

Triglyceride molecules also have been felt to play a role in the pathogenesis of ATH (135). Triglyceride levels are often elevated in patients with SLE (83 ,84 ,136). Several abnormalities in lipid and chylomicron metabolism that may explain these elevated triglyceride levels have been found in SLE. Chylomicrons are the triglyceride-rich lipoproteins that carry dietary lipids absorbed in the intestine (137). Chylomicron triglycerides are broken down by the enzyme lipoprotein lipase (LPL) (138). The chylomicron remnants are then removed from circulation by the liver using apoE as a ligand (138 ,139).

Disturbances in chylomicron metabolism, including decreased lipolysis and slowed chylomicron removal, have been observed in patients with SLE (140). One explanation for the decreased lipolysis of chylomicrons is the presence of antibodies to lipoprotein lipase. One study found that antibodies to LPL were found in 47% of patients with SLE (141). Another study described antibodies to LPL in nearly 40% of SLE patients; triglyceride levels were significantly elevated in the anti-LPL+ group (142). Studies are currently underway to determine if these antibodies are associated with an increased risk of atherosclerosis in SLE patients.

In addition to antibody formation, inflammation may induce other mechanisms that result in the elevation of triglycerides in SLE patients. TNF-α, IL-1, and IFN-γ have all been shown to decrease LPL enzymatic activity (66 ,67 ,143). In lupus patients, a strong positive correlation between TNF-α and plasma triglycerides has been described (144).

Endothelial Function

A number of abnormalities of the vascular endothelium have been described in association with SLE. Endothelial function can be measured by examining endothelium-dependent (flow mediated) dilation (FMD) of the brachial artery in response to reactive hyperemia. FMD is thought to be dependent on the production and release of nitric oxide (37). Endothelial dysfunction has been described as an early abnormality in the development of atherosclerosis (145), and is predictive of subsequent cardiovascular events (146) in the general population. Increased endothelial dysfunction has also been described in women with SLE. In one cohort, SLE subjects had greater endothelial dysfunction that correlated with increased carotid intima-medial thickness, even after controlling for traditional cardiac risk factors (147). One pediatric population with SLE, however, demonstrated normal endothelial function (95).

Antibodies to endothelial cells have also been described in up to 63% of subjects with SLE (148). Patients with these anti-endothelial cell antibodies were also found to have an increased prevalence of vascular lesions (including arterial and venous thrombosis and vasculitis), lupus nephritis, and anticardiolipin antibodies (148). Endothelial cell activation can also be induced by antiphospholipid and anti-$ß_2$GPI antibodies (149).

Circulating endothelial cells (CECs) in patients with SLE are associated with increased levels of complement split products, suggesting that they are a surrogate marker for the injury of the vascular endothelium that is due to complement activation (150). Elevated levels of circulating apoptotic endothelial cells have been described in SLE subjects. Apoptotic endothelial cells in this group were strongly correlated with abnormal brachial artery FMD (151).

Immune Complexes

Immune complexes (IC) have also been described as a risk factor for atherosclerosis in the general population. In one prospective study of 257 healthy men, the levels of circulating immune complexes at age 50 correlated with the future development of MI (152). Other studies have demonstrated increased levels of immune complexes containing both Lp(a) (153) and LDL (154) in patients with CAD. In vitro studies have also suggested that LDL containing immune complexes may play a role in atherogenesis. Macrophages that ingest LDL-IC become activated, and release TNF-α, IL-1, oxygen-activated radicals, and matrix metalloproteinase-1 (154). LDL-containing immune complexes have been examined in several studies of SLE subjects, with varying results. In one study of a pediatric SLE population, there was an increase in levels of IgG LDL-immune complexes in SLE subjects compared to healthy controls, although there was no association with endothelial dysfunction (95). Another study of an adult SLE population, however, demonstrated no difference from controls in levels of IgG or IgM LDL-containing IC (88).

IC containing C1q have also been implicated in atherosclerosis. C1q containing IC can bind to C1q receptors on endothelial cells, stimulating the expression of VCAM-1. C1q-IC may also contribute to atherosclerosis by interfering with cholesterol metabolism in the arterial wall. Cholesterol 27-hydroxylase is a P450 enzyme that is present in arterial endothelial cells and macrophages, and is responsible for the first step of cholesterol metabolism to 27-hydroxycholesterol. 27-hydroxycholesterol is more soluble, and thus more easily transported out of the arterial wall and into the liver. 27-hydroxycholesterol is also anti-atherogenic in other ways, as it can down-regulate cell surface LDL receptors, and suppress smooth muscle cell proliferation (155 ,156). C1q-IC have been shown to inhibit cholesterol 27-hydroxylase, and thus may contribute to atherogenesis (157). No studies to date have examined the relationship of C1q-IC to atherosclerosis in subjects with SLE.

CRP

CRP is an acute phase reactant that is synthesized in the liver in response to interleukin-6. It has been well established as a predictor of cardiovascular events in the general population; when both CRP and cholesterol levels are high, a person's overall risk of developing a future cardiovascular event is increased up to ninefold (74). There is evidence that CRP is not solely a marker of systemic inflammation, but rather may play a direct role in the pathogenesis of atherosclerosis. For example, CRP has been shown in vitro to activate endothelial cells to express ICAM, VCAM, and E-selectin (158). CRP has also been shown to activate complement (159), induce endothelial cells to produce MCP-1 (75), and mediate macrophage uptake of LDL (160). In SLE subjects, however, the role of CRP as a predictor of atherosclerosis is less clear. In one cross-sectional study, Manzi et al. found that CRP was significantly associated with focal plaque, although this effect did not persist in the logistic regression models (4); in a separate cross-sectional study, the same group found that high CRP levels >4 mg/mL were independent determinants of IMT (161). Roman et al., however, did not find an association with plaque and CRP (3).

Homocysteine

Homocysteine is another predictor of atherosclerosis in the general population (162). Homocysteine is a metabolite in methionine production, and may play a direct role in the pathogenesis of SLE through its toxic effects on the endothelium (163). Homocysteine is also prothrombotic (164), and decreases the availability of nitric oxide (165). High levels

stimulate monocytes to secrete MCP-1 and IL-8 (166). The thiolactone metabolite of homocysteine combines with LDL to enhance foam cell formation in vessel walls (167). The molecule releases free oxygen radicals that can damage tissue (168), and there are several prothrombotic actions on platelets and endothelial cells (169). Hyperhomocysteinemia can result from genetic and/or dietary factors. As previously noted, population studies have identified an association between high homocysteine levels and atherosclerosis in the general population (167). Petri has prospectively demonstrated that elevated homocysteine levels may also be a risk factor for the later development of CAD in SLE patients (170). In several studies, elevated levels of homocysteine have also correlated with ATH in SLE (10 ,87 ,171 ,172). In other recent studies of SLE, however, homocysteine has not correlated with evidence of plaque on carotid ultrasound (3 ,5 ,173).

CD40-CD40L Interactions

The overexpression of CD40 ligand (CD40L) has also been implicated in the pathogenesis of atherosclerosis in the general population (174). The interaction between CD40L, expressed on T cells, and its receptor, CD40 on B cells is involved in the mediation of B cell activation and the production of autoantibodies (175). CD40L is also expressed on macrophages, endothelial cells, activated platelets, and macrophages. Ligation can result in the induction of VCAM-1, ICAM-1, and E-selectin by endothelial cells (176), expression of tissue factor by macrophages (177), and the elaboration of cytokines such as interleukin-1SS (178). The overexpression of both CD40 and CD40L has been demonstrated in human atherosclerotic lesions (174). Additionally, healthy women with high levels of soluble CD40L have a higher incidence of cardiovascular events (179). Women with SLE also have abnormally high levels of CD40L (175). Additionally, CD40 expression is upregulated on endothelial cells of women with lupus nephritis (180). In one recent study of SLE, however, CD40 levels did not correlate with evidence of atherosclerosis on carotid ultrasound (3).

Antiphospholipid Antibodies

The role of antiphospholipid antibodies (APL) in atherosclerosis in SLE is controversial. Because these antibodies are associated with an increased risk of arterial and venous clots, it seems logical that these antibodies would also be associated with atherosclerosis. In fact, several studies in men have shown that antiphospholipid antibodies are associated with an increased risk of future myocardial infarctions (90 ,181). Also, in renal transplant patients, the presence of APL was associated with a relative risk of an atherosclerotic event of 2.82 (182). Similarly, patients with primary antiphospholipid antibody syndrome had thicker carotid artery IMT than controls, especially those older than 40 (183). Interestingly, these findings have not been convincingly replicated in SLE studies. Many lupus cohorts have not shown a consistently significant association with APL and atherosclerosis (3 ,4). Coronary calcification scores were associated with APL positivity in a univariate analysis; however, the association was no longer significant when adjusted for age and sex (5).

In a prospective Hopkins Lupus Cohort, 37 of 380 lupus patients developed myocardial infarctions; patients with a positive lupus anticoagulant (LAC) were more likely to develop a myocardial infarction than those without (184). This association, however, was not seen with anticardiolipin antibodies (ACL), and neither LAC nor ACL were associated with subclinical atherosclerosis as assessed by carotid ultrasounds. Conversely, several studies have demonstrated an association between the presence of APL and atherosclerosis in SLE. In the LUMINA study, 34 patients (6.2%) experienced a cardiovascular or cerebrovascular event after entering the cohort (185). The authors did find that APL were an independent risk factor for having an event in this cohort (185). Similarly, a cross-sectional study from England found that APL were associated with plaque seen on carotid ultrasound (147).

Animal studies evaluating the role of APL in atherosclerosis likewise remain contradictory. George and colleagues immunized LDL receptor deficient mice with $ß_2$-GPI and found that fatty streak formation was accelerated (186). They were also able to accelerate atherosclerosis by passively transferring $ß_2$-GPI reactive lymphocytes. In a follow-up study, the authors fed $ß_2$-GPI to LDL receptor deficient mice to induce oral tolerance. They were able to show that the mice that received the $ß_2$-GPI had less atherosclerosis, and that the oral tolerance was successful as assessed by a inhibition of lymph node proliferation to $ß_2$-GPI in these mice (187).

Other authors, however, have suggested the APL may play a protective role in the pathogenesis of atherosclerosis. Immunization of rabbits (188), LDL receptor deficient mice (189) and apoE deficient mice (190) with LDL and/or OxLDL inhibited the progression of atherosclerotic lesions. Furthermore, passive administration of a monoclonal IgG cardiolipin reactive antibody to LDL receptor deficient mice reduced plaque formation (191).

There are a number of mechanisms by which APL could exert their influence on atherosclerosis. As noted in the sections above, APL may cross-react with a variety of compounds that are involved in plaque formation (Table 19-2). Some studies have shown that persons without autoimmune diseases that have elevated levels of both anti-OxLDL and anticardiolipin have an increased risk atherosclerosis (90). Similarly, in one study, both anti-HDL and anti-$ß_2$-GPI antibodies were found in patients with SLE and primary APS (121). Furthermore, APL may participate in the process of atherosclerosis by binding to and activating endothelial cells (149). Additionally, APL have been shown to bind Annexin V, an antithrombotic protein, and in turn decrease the binding of Annexin V to the endothelium. Decreased Annexin V binding was noted in SLE with cardiovascular disease compared with SLE without cardiovascular disease (192). Further studies are needed to explore the contributions of antiphospholipid antibodies to atherosclerosis.

Table 19-2: Potential Cross-Reactivities of Antiphospholipid Antibodies and Factors Affecting Atherosclerosis

Factor	Reference
LDL	(99,191)
OxLDL	(90,93,94,100,101)
HDL	(101,121)
Paraoxonase	(121,122)
Annexin V	(192)
Apo A-1	(101,115)
Endothelial cell activation	(149)
Antiendothelial cell antibodies	(148)

Summary

Atherosclerosis is a complicated inflammatory process characterized by the interactions of numerous different moieties including lipids, enzymes, endothelial cells, cytokines, and peripheral blood mononuclear cells. The prevalence of atherosclerosis is higher in SLE and occurs at an earlier age. The lupus related factors that account for this increased risk are likely numerous and related to the factors described in this chapter. Expanding our understanding of the pathogenesis of atherosclerosis in SLE is critical if we are to improve the quality of care and improve mortality in this vulnerable population.

Chapter 20

Autoantigens and Defects in Immune Tolerance in Lupus

Ram Raj Singh

Shweta Dubey

Introduction

Presence of autoantibodies against a variety of ubiquitous self-antigens is a hallmark of systemic lupus erythematosus (SLE) (1). While primary impairments in B cells that can produce autoantibodies have been described in lupus, T cell help is paramount for the production of pathogenic autoantibodies (2). Thus, delineation of mechanisms of autoantibody production would require thorough understanding of loss of self-tolerance in both T and B cells. In this chapter, we will introduce concepts of normal immunologic tolerance, and review potential mechanisms that lead to breakdown of tolerance in lupus. We will then describe various autoantigens that have been implicated in the induction of lupus-like autoimmunity. Several groups have used ingenious and arduous approaches to map T cell epitopes (fragments of autoantigens which can activate T cells capable of eliciting or suppressing autoantibody production by B cells) in these autoantigens. Peptides containing these autoantigenic epitopes have been administered in ways that can induce immune tolerance and prevent disease in animal models of lupus. Efforts are underway to translate these findings from model systems into human disease to develop antigen-specific therapies. These and other methods of re-establishing immune tolerance in lupus will also be discussed.

Immune Tolerance

Lymphocyte Homeostasis and Immune Tolerance

The immune system is unique in its ability to maintain a state of equilibrium despite its continuous exposure to self-antigens and mounting an adequate response to a variety of foreign antigens. After responding to an antigen the immune system returns to its original state, so that the numbers and functional status of lymphocytes are reset at roughly the original state. This process known as lymphoid homeostasis allows the immune system to respond to new antigenic challenges. The size and content of the preimmune lymphocyte repertoire are tightly regulated, as new emigrants from the lymphoid organs compete for “space” with resident cells (3). Several groups have tried to define factors that control naïve and memory T-cell homeostasis under lymphoproliferative or lymphopenic conditions (4 ,5). There has been a recent interest in the hypothesis that in lymphopenic conditions, T cells expand to re-establish homeostasis by a process dependent on self-major histocompatibility complex (MHC)-peptide recognition and on the availability of cytokines that can promote the proliferation and survival of lymphocytes. Such lymphocyte expansion is believed to be a normal physiologic process. The chronic recurrence of this process, however, might lead to selection and accumulation of high affinity self reactive T cell clones and ensuing autoimmune disease (6). A recent study indeed provides experimental support for this hypothesis (7). This study showed that autoimmune nonobese diabetic (NOD) mice have reduced number of CD4 T and B cells as compared to control mouse strains. Increasing T cell numbers such as by immunization with complete Freund's adjuvant (CFA) increases B and T cell numbers and protects these mice from autoimmune diabetes. Interestingly, self-reactive T cell receptor (TCR) transgenic T cells expand in the lymphopenic NOD mice, but not in NOD mice “filled” (reconstituted) with syngeneic T cells, in CFA-immunized NOD mice, and in congenic B6.idd3.NOD mice that have normal T and B cell numbers. Thus, lymphopenia and the resulting compensatory homeostatic expansion of effector lymphocytes reactive with self antigens may precipitate autoimmunity (7). Other examples of lymphopenia-induced autoimmunity in rodents include the development of autoimmunity after neonatal thymectomy, discontinuation of cyclosporine treatment or total lymphoid irradiation (8 ,9). Lymphopenia also accompanies human autoimmune diseases, such as SLE and Sjogren' syndrome (10).

Lymphocytes with receptors specific for self-antigens are generated continuously in the body, yet most individuals maintain a state of unresponsiveness to their own antigens, a process referred to as self-immune tolerance. Thus, immune tolerance can be broadly defined as a physiologic state in which the immune system does not react harmfully against the components of an organism that harbors it or against antigens that are introduced to it (11). Harmful responses are prevented by a variety of mechanisms that operate during development of

the immune system and during the generation of each immune response. These mechanisms can be broadly classified into four major groups, which are: (1) Central tolerance, which implies induction of tolerance in developing lymphocytes when they encounter self-antigens in the thymus or bone marrow. This process ensures tolerance to self-antigens that are present in high concentrations in the bone marrow and thymus. This process occurs by induction of apoptosis of self-reactive lymphocytes also known as clonal deletion. (2) Peripheral tolerance is maintained by mechanisms that operate on mature lymphocytes once they exit the primary lymphoid organs. Some self-antigens may not be able to induce central or peripheral tolerance. (3) Clonal ignorance may be the mechanism of tolerance for these self-antigens, which is believed to operate when the self-antigen is sequestered in anatomical sites, which are inaccessible to lymphocytes. (4) Clonal anergy is another mechanism of lymphocyte tolerance in which the lymphocyte is functionally unresponsive following antigen encounter but remains alive for extended periods of time in a hyporesponsive state (12). Self-antigen recognition without costimulatory signals is widely believed to induce lymphocyte anergy. However, the conditions or factors that determine whether a self-antigen can be functionally ignored or induces anergy remain to be fully understood. More importantly, so far we do not know which self antigens can induce which form of self-tolerance or what is the relative contribution of each of these mechanisms in shaping the normal immune repertoire. There is also no proper understanding of what are characteristics of a self-antigen that can lead it to undergo central tolerance, peripheral tolerance, clonal ignorance, or clonal anergy. Nevertheless, substantial progress has been made in unraveling these basic tolerance mechanisms that are common to both B and T lymphocytes. Since current knowledge supports loss of tolerance in both B and T cells in eliciting pathologic autoimmunity, we will discuss them separately (Table 20-1).

Mechanisms Underlying T Cell Tolerance

Tolerance of self-reactive T cells occurs in both a central tolerance mode occurring in the thymus, and in peripheral tolerance mode occurring in the peripheral lymphoid organs. Figure 20-1A depicts the sites of tolerance and potential mechanisms.

Table 20-1: Mechanisms of Self-Tolerance in T and B Cells

	T cells	B cells
Clonal deletion	Yes	Yes
Ignorance	Yes	Yes
Anergy	Yes	Yes
Immune deviation	Yes	
Regulatory T cells	Yes	
Receptor editing		Yes

Thymic Selection

The recognition of self-peptides, in association with self-MHC molecules, presented to differentiating T cells by antigen-presenting cells (APC) present in the thymus results in thymic selection of T cells (11). This thymic selection process ensures that mature T cells are both self-MHC restricted and self-tolerant. When the TCRs on a pre–T cell thymocyte are engaged, the thymocyte can be either positively or negatively selected depending on the balancing effects of several other factors regulating this process. Thymic selection begins at the double positive (DP, $CD4^+CD8^+$) stage in the thymus (when the alpha and beta chain genes are expressed) and beyond. This process has two important outcomes: MHC restriction (positive selection) and central tolerance (negative selection). Thymic cortical epithelial cells function as the effector cells in a process known as positive selection. In positive selection, T cells that bear a TCR that can bind self-MHC are selected to survive and proliferate. T cells that are not positively selected are triggered to undergo apoptosis. Positively selected thymocytes must go through a second phase of selection known as negative selection. During negative selection, any T cell that is presented with antigenic peptide bound to MHC within the thymus is triggered to undergo apoptosis. The self-peptides encountered in the thymus are derived from proteins expressed in thymus as well as other proteins brought to the thymus via the blood stream. Negative selection can apparently be mediated by a variety of different cell types, including thymic dendritic cells (DC) and macrophages. The surviving T cells migrate to the medulla where they continue maturation and finally leave the thymus through the postcapillary venules or efferent lymphatics.

Although thymic selection should enable the deletion of all self-reactive T cells, this process is not perfect because not all peptides that an organism may encounter in the lifetime are presented in the thymus. Other variables such as peptide concentrations, affinity of TCRs or state of APCs in the thymus may all determine whether the threshold for receptor occupancy is reached for the positive or negative selection to occur. Potentially self-reactive T cells that escape central tolerance can still be tamed through several backup mechanisms for maintenance of self-tolerance. These peripheral tolerance mechanisms include antigen-specific unresponsiveness or anergy, immune deviation, and elimination after repeated activation (13). Variables that determine whether peripheral deletion proceeds efficiently include extent of TCR occupancy, affinity of antigenic peptide for the MHC and affinity of TCR for the antigen peptide complex. High antigenic dose and chronic stimulation favor elimination both in CD4 and CD8 T cells. The silencing of T cells upon persistent activation in the periphery may thus represent a continuous process, ranging from the activation to unresponsiveness to deletion, with T cell signal strength and exposure time together determining the outcome. A major mechanism for peripheral deletion of activated T cells involves activation-induced cell death (AICD) via the Fas-FasL pathway, as suggested by studies in mouse models, where mutations in these molecules are

associated with the development of autoimmunity. Mouse deficient in Fas (MRL-FAS$^{lpr/lpr}$ [MRL-lpr]) or FasL (gld mice) develops severe lymphoproliferative autoimmune disease caused by accumulation of activated T cells. Mutations in Fas are associated with autoimmune disease in humans as well (14). Some mouse strains carrying gld or lpr mutations develop arthritis or nephritis, whereas the same mutations on other genetic backgrounds cause only excessive lymphoproliferation (15 ,16 ,17). In humans, not all subjects carrying mutations in Fas or FasL develop autoimmune disease (14 ,18). This suggests that other genetic parameters and additional mechanisms contribute for peripheral tolerance of autoreactive T cells.

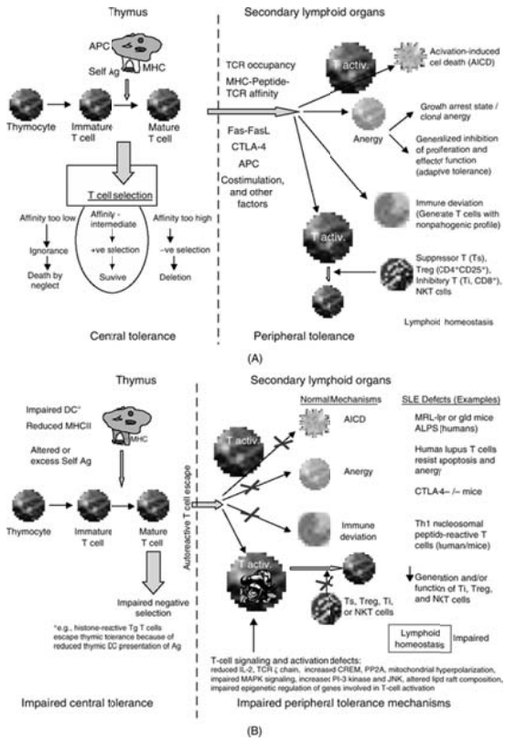

Figure 20-1. T-cell tolerance. **A,** Normal tolerance mechanisms. Immune tolerance is a physiological state in which the immune system does not react harmfully against the components of an organism that harbors it or against antigens that are introduced to it. Self-reactive T cells undergo negative selection in the thymus; those that escape thymic tolerance are subjected to multiple peripheral tolerance mechanisms at many levels. **B,** Breakdown of T-cell tolerance in SLE. T cells may escape negative selection in thymus by impaired presentation of self-antigen by thymic APC. The affinity of self-epitopes can also prevent them from undergoing negative selection. Self-reactive T cells exit the thymus and get activated by self-antigen presented on APC, which induces a hyper-responsive phenotype coupled with resistance to induction of anergy and/or apoptosis. Immune deviation and activation of Treg and Ti cells, which are additional mechanisms to control autoreactive T cells, fail to suppress them, thereby leading to the expansion and survival of autoreactive T cells. SLE T cells also exhibit an overexcitable phenotype which further contributes to increased T-cell activation and TCR mediated signaling.

Another molecule, CTLA-4, has been implicated in peripheral deletion. Whereas ligation of Fas on activated T cells is sufficient for the induction of cell death, CTLA4-induced cell death is dependent on the simultaneous triggering of the TCR. The importance of this pathway is illustrated in studies where targeted disruption of the CTLA-4 gene in mice results in massive accumulation of activated lymphocytes in lymphoid organs, infiltration of multiple tissues with activated lymphocytes, autoimmunity, and fatal multi-organ inflammation (19 ,20 ,21). However, there has been no direct demonstration that the infiltrating lymphocytes actually recognize self-antigens in these mice.

Induction of anergy is another mechanism of lymphocyte tolerance in which the lymphocyte is functionally unresponsive following antigen encounter but remains alive for extended periods of time in a hyporesponsive state (12). Two different forms of T cell anergy have been described. One is principally a growth arrest state that has been termed as clonal anergy and the other represents a generalized inhibition of proliferation and effector functions called adaptive tolerance or in vivo anergy (22). According to the two-signal model of T cell activation versus anergy, the APCs having the ability to offer T cells the prerequisite triggering of TCRs (signal 1) and costimulation (CD28/B7, the signal 2) induce T cell activation. However, not all APCs have the ability to offer T cells both of these signals, and signaling through the TCR alone induces a state of functional unresponsiveness or clonal anergy. This could happen via two pathways: one is the direct inhibition of CD28 signaling by “anergy factors” and the other involves indirect effect on cell cycle progression through growth factors such as IL-2 (23 ,24). Recent work has led to a better understanding of the cell-intrinsic program that establishes T cell anergy. During the induction phase of anergy, “incomplete” stimulation of T cells (TCR triggering without costimulation) leads via calcium influx to an altered gene expression program that includes upregulation of several E3 ubiquitin ligases. When the anergic T cells contact APCs, intracellular signaling proteins are monoubiquitinated and targeted for lysosomal degradation, thus decreasing intracellular signaling and also resulting in decreased stability of the T cell-APC contact (25). Ubiquitin ligases that have been implicated in T cell anergy are c-Cbl, Cbl-b, GRAIL, ITCH, and Nedd4 (26). Interplay of these ubiquitin ligases has been shown to regulate T cell anergy.

Immune Deviation

The immune system has also evolved to have a functional mechanism of tolerance in the face of persistent T cell activation. Skewing of a T cell response into a lineage that does not mediate disease and which prevents development of harmful T cell responses is called immune deviation. In certain autoimmune models, animals have tissue infiltration with autoreactive T cells that bear an activated phenotype but the animals do not develop clinical manifestations of disease (27). Studies have shown that T cells from nonautoimmune animals can respond to autoantigens in vitro as strongly as T cells from the autoimmune-prone animals do (28). In

NOD mice, which spontaneously develop diabetes, presence of Th1 cells in islets was found to be associated with the clinical disease, whereas resistance to disease is associated with predominance of cells producing Th2-like cytokines (29). Similarly, in EAE models the Th1 responses are generally pathogenic, whereas Th2 responses are protective. Specific mechanisms, which allow skewing of T cell immune deviation, are still not clearly understood. Several explanations for the apparent dichotomy have been proposed, including the role of the type of APCs participating in the immune response, modulation of the costimulatory molecules, and signal transduction pathways.

Regulatory T Cells

A number of studies have shown existence of a number of T cell subsets, which can regulate autoimmunity. Such subsets of T lymphocytes are called regulatory T cells. One of the most studied subset of regulatory T cells (Treg) is $CD4^+CD25^+$ cell, also called the natural T_{regs}, which are derived as a functionally mature population from the thymus. Natural Tregs comprise approximately 5% to 10% of the peripheral CD4 T cells in humans and mice. Their importance in the regulation of autoimmunity was initially realized in studies where passive transfer of T cells lacking in $CD4^+CD25^+$ subset into athymic nude mice resulted in spontaneous development of various T cell–mediated autoimmune diseases (30). Recent advances in the identification of markers to identify these cells and in understanding of their function at the molecular level have begun to pinpoint their roles in self-tolerance and autoimmune disease (31 ,32 ,33). As described below in section 2, $CD8^+$ inhibitory T cells that produce TGF-ß prevent or suppress autoimmunity (34) and may play a role in maintaining self-tolerance. Another regulatory T cell population, called natural killer T (NKT) cell, has also been proposed to play a role in the induction of self-tolerance in periphery (35 ,36 ,37).

Mechanism of B Cell Tolerance

As with T cells, tolerance of self-reactive B cells occurs in both a central tolerance mode occurring in the bone marrow, and in peripheral tolerance mode occurring at different stages of maturation of B cells as well as at the level of mature B cells. Figure 20-2 depicts the sites of B cell tolerance and potential mechanisms.

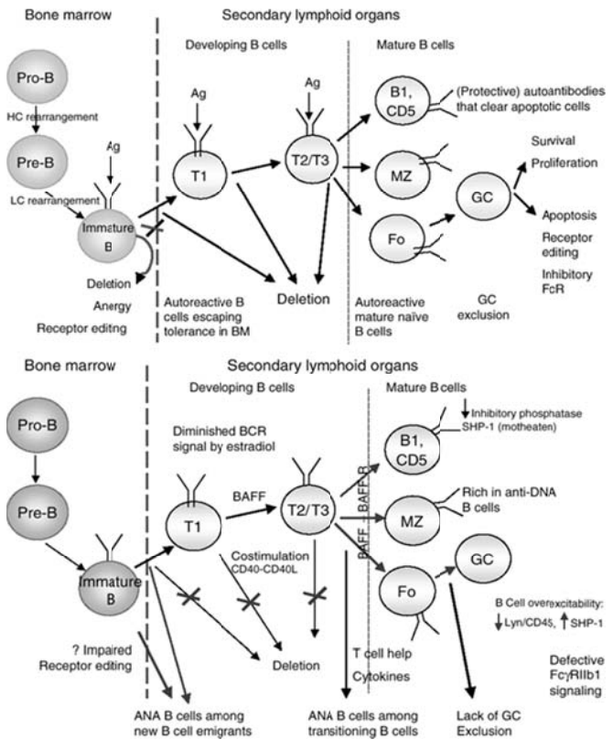

Figure 20-2. B-cell tolerance. **A,** Normal B-cell tolerance checkpoints. There are three distinct tolerance checkpoints in B cells. First, there is an initial checkpoint during the maturation of B cells in the bone marrow; second, there are many checkpoints during B-cell development in the periphery, and finally, there are checkpoints involving mature B-cell subsets. Fo, follicular; GC, germinal center; HC, heavy chain; LC, light chain; MZ, marginal zone; T, transitional. Details on the mechanisms involved at each of these stages are provided in the text. **B,** Breakdown of B-cell tolerance in SLE, as described in section 2.4.

More than half of all newly generated immature B cells in the bone marrow of healthy individuals appear to be polyautoreactive and capable of binding self-antigen including nuclear antigens (38 ,39). Elaborate control mechanisms must therefore exist to remove such potentially autoreactive B cells ensuring self-tolerance. In fact, extensive studies in mouse models and some in humans with regard to B cell selection suggest that there are number of distinct tolerance checkpoints during B cell development and maturation (38 ,40), which can be broadly categorized into three stages. First, there is an initial checkpoint during the maturation of B cells in the bone marrow; second, there are many checkpoints during B cell development in the periphery, and finally, there are checkpoints involving mature B cell subsets (Fig. 20-2A).

The majority of polyreactive and antinuclear antibody B cells are removed at the immature B cell stage in the bone marrow (38). Essentially three mechanisms have been described to silence developing autoreactive B cells in the bone marrow: deletion, anergy, and receptor editing (39 ,41 ,42 ,43). B cell receptor (BCR) signaling strength and the physical nature of the self-antigen (soluble versus membrane-bound) play major regulatory roles in the selection process (44 ,45). Immediately after rearrangement of light chain genes, the newly generated immature B cells

express BCR, which upon contact with the antigen results in maturational arrest of B cells, reexpression of rag-1 and rag-2, and resumption of rearrangement of light chain loci. This process has the potential to delete the initially successfully rearranged light chain gene and create newly arranged light chain gene. This regulatory event is known as receptor editing. It is presumed that immature B cells that are no more self-reactive can now mature and leave the bone marrow. The immature self-reactive B cells are destined to undergo clonal deletion or clonal anergy depending upon the affinity of the antigen to the BCR.

In the periphery, most remaining potentially autoreactive B cells are removed when newly emigrant B cells transition into naïve immunocompetent lymphocytes (38). To develop from the immature state in the bone marrow to the mature naive state in the peripheral lymphoid organs, a B cell must survive several checkpoints (40). The first checkpoint is between the immature cell in the bone marrow and the transitional T1 cell in the spleen. The second is between the T1 and more mature T2/3 state, and the third is between the T2/T3 stage and mature B cells. Tolerance mechanisms are less clear at these checkpoints, and both positive and negative selection mechanisms have been proposed (46 ,47 ,48). Negative selection that is mediated by BCR signaling is generally considered to be a B cell intrinsic property. The transitional B cells can be rescued from negative selection by costimulatory signals. For example, CD40 engagement by CD40 ligand (CD40L) can rescue B cells destined to undergo BCR-mediated apoptosis. Further, B cell activating factor of the tumor necrosis factor family (BAFF) can enhance the survival of transitional B cells.

B cells that escape tolerance mature into immunocompetent B cells having the phenotype of the following B cell subsets, namely B1 B cells, marginal zone (MZ) B cells, short-lived plasma cells, or germinal center–matured long-lived plasma cells. The B1 cells express CD5, are restricted in diversity, and fail to generate a memory population. Self-reactive B1 cells bearing low affinity BCRs normally home to peritoneal cavity (in mice) and produce autoantibodies that are thought to help avoid pathogenic autoreactivity by clearing apoptotic cells (49). Human equivalent of B1 cells, which express CD5, are normally present in the naïve repertoire, but they are usually excluded from the germinal center reactions (50). Thus, germinal center exclusion of potentially autoreactive B1 subsets may be one essential checkpoint in mature B1 cells. The MZ B cells that mature rapidly into plasmablasts can produce autoantibodies (51). How tolerance is regulated in the MZ B cell subset is unclear. The follicular B cells, after they encounter antigen and receive T cell help, generate germinal centers to mount an affinity-matured antibody response and generate memory B cells. The germinal center serves as a major checkpoint in establishing follicular B cell tolerance, where a stringent balance of proliferative and apoptotic signals is required to prevent the survival of self-reactive B cells while ensuring expansion of the normal B cell repertoire. Mechanisms of positive and negative selection at the level of germinal center are not well understood. Receptor editing might contribute to negative selection at this stage (52) and inhibitory Fc receptor Fcγ2RIIB may regulate B cell survival in the germinal center (53), whereas T cells may serve to mediate positive selection of germinal center B cells.

Thus, tolerance of self-reactive B cells occurs in the bone marrow, and in the periphery at different stages of maturation of B cells as well as at the level of mature B cells (Fig. 20-2A). Peripheral tolerance of B cells generally results from contact with antigen in a way that does not promote full activation, either because the B cell is still immature and hence less responsive to B cell activation pathways or because the B cell contacts the antigen in absence of costimulatory molecules. If the antigen is a weak one, the B cell becomes anergic.

Thus, elaborate mechanisms of T and B cell tolerance act in concert to maintain normal lymphocyte homeostasis and avoid pathologic autoimmunity. Elucidating the nature of these mechanisms may lead to better approaches for sustaining a balanced response to self and promoting reactivity to non-self at the same time. How tolerance mechanisms fail resulting in pathologic autoimmunity will be discussed in the following section.

Immune Tolerance Defects in Lupus

While substantial progress has been made in understanding fundamental mechanisms of self-tolerance, how impairment in this process causes autoimmune disease remains largely unclear. A number of mechanisms have been proposed, and a few have been demonstrated in animal models of autoimmunity. As summarized in Table 20-2 , some of these mechanisms depend on alterations in autoantigen itself (54 ,55 ,56), some on changes in the processing and presentation of autoantigen at the level of APCs, some on changes in the T and B cells, and some on the aberrant immune regulation. Based on our current understanding, it appears that alterations at different levels may account for loss of self-tolerance in different animal models and probably in different subsets of SLE, and that multiple impairments could well account for the loss of self-tolerance in a single model or patient (54). This concept is certainly consistent with the complex multigenic nature of the genetic predisposition of SLE.

Abnormalities at the Level of Autoantigens in Tolerance Breakdown in Lupus

That only certain self proteins frequently elicit an autoimmune response has intrigued many investigators to speculate that autoimmunity might occur as a result of altered self or modified self serving as a potential source of autoantigen. Several mechanisms have been proposed to account for such modifications.

Mutations in a self-antigen creating a neo-epitope might trigger autoimmunity. For example, in a cDNA library made from peripheral blood lymphocytes of a patient with primary

Sjogren' syndrome, one study identified a deletion of an (A)-residue in a cDNA encoding for the nuclear autoantigen La (SS-B). This leads to a frame shift mutation and a premature stop codon within one of the protease sensitive regions of the La protein (57 ,58 ,59). The region where the deletion occurred, represents a hot spot region in the La gene(s), which is located in one of the major autoepitope regions of the La antigen. Translation of the patient's mutant La mRNA in transfected mouse cells resulted in a C-terminally truncated La peptide. Because of the lack of the nuclear location signal the La peptide remained in the cytoplasm. The modified La peptide shared homology with (1) La protein itself and (2) a series of DNA binding proteins including other autoantigens and viral proteins such as topoisomerase I, RNA dependent RNA polymerase of influenza virus and reverse transcriptase. The mutant La peptide represents a putative neo-epitope that could be involved in triggering of the autoimmune response.

Table 20-2: Potential Mechanisms for Loss of Self-tolerance in the Development of Lupus

	Site of Alteration	Alterations	Ref.
1.	Autoantigen	a) Altered self	
		i) Mutations in autoantigens	(57,58,59)
		ii) Excessive polymorphisms of autoantigens	(60)
		iii) Noncanonical alternative mRNA splicing at high frequency	(63)
		iv) Post-translational modifications of autoantigens	(68,70)
		v) Direct modification of host proteins by viruses	(89)
		b) Molecular mimicry	(76)
		c) Excess:	(87,88)
		– Altered proteolytic cleavage of autoantigens	(55,317)
		– Inducible autoantigen expression by cytokines such as IFN-α	(79)
		Reduced clearance	(82)
		d) Activation of TLR ligands (e.g., chromatin as an endogenous ligand for TLR9)	(89)
		e) Altered recognition in endomembrane traffic	
2.	APC	a) Altered antigen processing	(87,85,86)
		b) Altered MHC class II expression and presentation	(90,91,92)
		c) Altered migration of APCs to sites of tolerance induction	(90)
3.	T cells	a) Disturbed homeostasis	(10)
		b) Reduced apoptosis	(100)
		c) Loss of anergy	(107)
		d) Enhanced constitutive signaling	(125,137,138,155,318)
		e) Immune deviation	
4.	B cells	a) Impaired tolerance at the early immature stage in bone marrow	(40,142)
		b) Impaired tolerance during transition to mature stages in the periphery	(40,142)
		c) Impaired regulation at the level of mature B cells	(40)
		d) Defective follicular exclusion	(154)
		a) Impaired receptor editing	(142)
		b) Apoptosis	(319)
		c) Enhanced constitutive signaling	(158,160)
		d) Presentation of autoantigens by B cells	(166)
5.	Regulatory T cells and cytokines	a) Reduced induction or activation of $CD8^+$ inhibitory T (Ti) cells	(34,169,170,320)
		b) Reduced function of $CD4^+CD25^+$ Treg cells	(184,321)
		c) Insufficiency of natural killer T (NKT) cells	(322,323)
		d) Reduced production of immunoregulatory cytokines such as TGF-ß	(34,182)

Stadler et al asked whether alterations in self-proteins might actually be genetic polymorphisms. To address this question, they analyzed sequence variability in the known human autoantigens (*n* = 348) and compared it with other human genes (*n* = 14,881). Remarkably, the autoantigens contain significantly more single nucleotide polymorphisms (SNP) within coding regions than other human genes do. Autoantigens had 7.2 SNPs per gene as compared to 3.6 SNPs in the control gene. Such increase in polymorphisms in a protein may have important outcomes for the protein structure, function and antigenicity (60). Indeed, human Ro52, a major autoantigen in rheumatic diseases, contains two synonymous and three nonsynonymous SNP, and one of the nonsynonymous SNP is located in the central immunodominant region of the autoantigen (61). Further, an intronic SNP that leads to aberrant splicing of Ro52 mRNA resulting in the generation of a shortened version of the

Ro52 protein is strongly associated with anti-Ro52 autoantibodies in primary Sjogren syndrome (62).

Some autoantigens can be differentially immunogenic because of existence of alternatively spliced isoforms (63). A recent study used a bioinformatics approach to analyze the extent of alternative splicing within 45 randomly selected self-proteins associated with autoimmune diseases as compared to 9554 randomly selected proteins in the human genome. They found occurrence of alternative splicing in 100% of the autoantigen transcripts, which is significantly higher than the approximately 42% rate of alternative splicing observed in the randomly selected human gene transcripts. Within the isoform-specific regions of the autoantigens, 92% and 88% encoded MHC class I and class II-restricted T cell antigen epitopes, respectively, and 70% encoded antibody binding domains. Furthermore, 80% of the autoantigen transcripts underwent noncanonical alternative splicing, which is also significantly higher than the less than 1% rate in randomly selected gene transcripts.

Posttranslational modifications in a protein could also act a means to promote autoreactivity (56 ,64). The immune system normally utilizes posttranslational modifications to control its function. Essentially all immunoglobulin molecules undergo these modifications. Posttranslational modifications are also documented for TCR molecules. For example different glycosyl groups are present on TCR in different stages of development. Posttranslational modifications are also reported for cytokines like IL-2 and IL-6. When such modifications occur in self-antigens, they exert more subtle effects through altering the susceptibility of a protein to proteolytic cleavage during antigen processing. Since these modifications occur after the lymphocyte has undergone negative selection, the existing B and T lymphocytes can recognize the modified antigens causing their loss of tolerance. This process may spread to the unmodified self-protein through epitope spreading, and autoimmunity is sustained through the continuous supply of unmodified protein (64). Posttranslational modifications in several self-antigens as well as immune responses directed toward posttranslationally modified self-antigens have been noted in autoimmune diseases, such as SLE, rheumatoid arthritis, and multiple sclerosis (64 ,65 ,66 ,67). For example, the spontaneous conversion of an asparagine residue or aspartic acid residue to an isoaspartyl residue renders cytochrome c and snRNP D peptides immunogenic in murine models of SLE autoimmunity (68). Mice develop T cell responses to the isoaspartic acid peptides but not to the native aspartic acid containing peptides. However, mice also develop autoantibodies that recognize both the isoaspartic peptides and the native aspartic acid peptides. These autoantibodies can diversify to recognize other antigens such as dsDNA. Additionally, isoaspartic acid residues have been found in histone H2B, a common autoantigen in spontaneous and drug-induced lupus (69). Finally, patients with SLE have been shown to have autoantibodies that react to the C-terminus of snRNP, which contains symmetrical dimethyl arginines (70) as well as phosphorylated serine/arginine-rich residues of the SR protein (a family of pre-mRNA splicing factors). Interestingly, some autoantibodies were directed at dephosphorylated SR proteins that normally would exist in a phosphorylated state (71).

The above mechanisms, including somatic mutations, genetic polymorphisms, alternative splicing, and posttranslational modifications could generate epitopes for which the immune system is not tolerized (63). The modified antigens can be taken up, processed and presented by APCs and recognized by existing potentially self-reactive B and T cells resulting in breakage of tolerance and induction of autoimmunity.

Bacterial, viral and parasitic infections are known to induce and exacerbate autoimmune diseases, presumably via eliciting molecular mimicry. Association between the development of SLE and viruses such as Epstein Barr virus (EBV), coxsackie virus and retroviruses like HTLV have been described (72 ,73 ,74 ,75). For example, analysis of autoantibody responses in patients with SLE prior to the onset of clinical disease led to identification of an initial autoantigenic epitope that appears in some patients positive for antibodies to 60 kD Ro antigen. This initial epitope cross-reacts with a peptide from the latent viral protein EBV nuclear antigen-1 (EBNA-1). Animals immunized either with the initial epitope of 60 kDa Ro or with the cross-reactive EBNA-1 epitope progressively develop autoantibodies binding to multiple epitopes of Ro and spliceosomal autoantigens. The immunized animals eventually develop clinical symptoms of lupus such as leukopenia, thrombocytopenia, and renal dysfunction. This study provides a strong evidence for association of EBV infection and development of SLE (76).

Defective apoptosis can also result in the generation of neoepitopes. Proteolytic cleavage by caspases of lupus associated autoantigens, like poly (ADP-ribose) polymerase and catalytic subunit of DNA-dependent protein kinase (DNA-PKCs), has been shown to disturb homeostasis and cause increased apoptosis (77). As a result of nuclear fragmentation and membrane blebbing in apoptosis, autoantigens that are targeted in SLE are reorganized and transported to cell surface (78). A recent study suggested that secondary necrosis can be an additional source of proteolytically modified form of specific autoantigens (79). These investigators treated Jurkat cell lines with different apoptosis inducers. During the initial apoptotic stages, several autoantigens, including polyADDP ribose, polymerase, and topoisomerase were cleaved into apoptosis fragments. These apoptotic cells underwent secondary necrosis in the absence of phagocytosis with additional proteolytic modifications of autoantigens (79). This process may further contribute to increased presentation of altered self-peptides by DCs to autoreactive T cells.

Apoptotic defects and impaired removal of apoptotic cells could contribute to an overload of autoantigens (particularly nucleosomes) in circulation or in target tissues that could become available to initiate an autoimmune response. Nucleosomes are formed during apoptosis by organized cleavage of chromatin. These nucleosomes together with other autoantigens cluster in apoptotic bodies at the surface of apoptotic cells. Systemic release of these autoantigens is

normally prevented by swift removal of apoptotic cells. However, if excessive apoptosis exceeds the rate of removal of apoptotic bodies, nucleosomes are released. Furthermore, during apoptosis these autoantigens may undergo posttranslational or posttranscriptional modifications, which make them more immunogenic.

Activation of toll-like receptors (TLRs) by autoantigens can amplify the autoimmune response by activating the innate immune component. Chromatin-containing CpG motif-rich DNA or RNP antigens containing double-stranded RNA (dsRNA) can potentially trigger lupus-like autoimmune responses by providing accessory signals through TLR9 on DCs, macrophages or B cells, or through TLR3 on DCs (80 ,81). Further, immune complexes containing IgG bound to chromatin can activate murine DCs through both TLR9-dependent as well as TLR9-independent pathways (82), which may affect autoimmune responses. Indeed, TLR9-deficiency specifically reduces the generation of anti-dsDNA and antichromatin autoantibodies in MRL-lpr mice (83). The viral dsRNA can also activate DCs via TLR3 to induce the production of type I interferons and other cytokines associated with disease activity in SLE. Consistent with the role of TLR3 in lupus, TLR3 expression is increased in infiltrating antigen-presenting cells as well as in glomerular mesangial cells in kidney sections of MRL-lpr mice (84).

Altered processing and presentation of self epitopes can also lead to generation of new autoantigens for which the immune system is not tolerized. A recent study examined whether some epitopes in a native protein, mouse lysozyme-M, can be cryptic because of the unavailability of a proteolytic site, and whether it could be reversed to immunodominance by introduction of a novel cleavage site in the flanking region of the epitope. Using site-directed mutagenesis, they created the dibasic motif (RR or RK; R = arginine, K = lysine), a target of intracellular proteases, in the region adjoining one of the three cryptic epitopes (located at 46–61, 66–79, or 105–119) of mouse lysozyme-M. Interestingly, the mutated lysozyme proteins, but not unmutated mouse lysozyme-M, were immunogenic in mice. The T cell response to the altered lysozyme was attributable to the efficient processing and presentation of the previously cryptic epitope, and this response was both epitope- and MHC haplotype-specific (85). In xenobiotic models of lupus-like autoimmunity, cell death following exposure to autoimmunity–inducing agents leads to generation of novel protein fragments that may activate self-reactive T lymphocytes (86). During apoptosis, interaction of several autoantigens with granzyme B has been shown to generate unique protein fragments which are not observed during any other form of cell death. Interestingly, nonautoantigens are either not cleaved by granzyme B or are cleaved to generate fragments identical to those formed in other forms of apoptosis. Therefore the ability of granzyme B to generate unique fragments appears to be an exclusive property of autoantigens (87 ,88).

One study suggested that the altered recognition of autoantigens in endomembrane traffic might elicit autoimmunity (89). They showed that the RNA transcription termination factor La, a frequent target of Sjogren autoantibodies, appears in the acinar cell cytoplasm and plasma membranes during viral infection and during in vitro exposure to cytokines. The endomembrane compartments where proteolysis occurs contain La, galactosyltransferase, cathepsin B, and cathepsin D. MHC class II molecules cycle through this compartment. This traffic may permit trilateral interactions in which B cells recognize autoantigens at the surface membranes, and CD4 T cells recognize peptides presented by MHC II, the B cells provide accessory signals to CD4 T cells, and CD4 T cells provide cytokines that activate B cells.

Impaired APC Functions in Tolerance Breakdown in Lupus

We have recently found that Langerhans DCs in skin of lupus-prone MRL-lpr mice display reduced MHC class II molecule expression and impaired migration capacity to draining lymph nodes, when compared with normal strains (90). Importantly, correction of these defects results in improved lupus dermatitis, suggesting a possible role of reduced APC function in the induction of peripheral T cell tolerance (to skin-specific autoantigens in this case) and in the development of lupus (dermatitis in this case) (90). This point was more elegantly made in a recent study, which used a nucleosome-specific TCR transgenic mouse model to infer that thymic DCs from lupus mice are less efficient than those from normal mice in presenting naturally processed nucleosomal peptides in the steady state (91). This impairment is probably owing to lesser amounts of MHC class II and costimulatory molecules on thymic DC of lupus mice than on their normal counterparts. Thus, a relative deficiency in the natural display of self-epitopes by thymic DCs may account for the positive selection of autoreactive Th cells in lupus-prone mice, and/or absence of negative selection. Similarly, deficiency in the natural display of autoepitopes by Langerhans cells may account for the loss of peripheral tolerance to skin autoantigens.

Another study, however, has found increased maturation of DCs and macrophages in a mouse model, where introgression of the SLE3 lupus-susceptibility locus from lupus-prone mice onto a normal B6 background causes T cell hyperactivity (92). Such T cell hyperactivity was thought to be because of the presence of a more mature, less apoptotic, and more pro-inflammmatory APCs in the autoimmune congenic mouse B6.SLE3 (92). Monocytosis in lupus-prone BXSB mice (93 ,94) and increased macrophages in (NZB/NZW)F1 and MRL-lpr mice (95) have also been implicated in the development of lupus. Other studies have postulated imbalance in DC homeostasis as a contributing factor in SLE. According to this idea, cytokines such as IFN-α/β drive differential differentiation of distinct subsets of DCs in SLE. In fact, serum from SLE patients induces normal monocytes to differentiate into DCs, which is dependent on the actions of IFN-α. Thus, unabated induction of DCs by IFN-α may drive autoimmune

responses in SLE (96). In fact, plasmacytoid DCs that are primary producers of IFN-α are present in large numbers in most lupus-affected, but not in normal, skin tissue specimens. The role of increased plasmacytoid DCs in peripheral tissue sites (97) in breaking local T cell tolerance remains unclear.

B cells may also serve as important APC in breaking T cell tolerance. Using anti-snRNP Ig transgenic mice, Mamula and colleagues showed that whereas both normal and autoimmune (MRL-lpr) mice harbor autoreactive T cells, transgenic B cells can tolerize autoreactive T cells in the periphery of normal mice only (98). Thus, B cells (anti-snRNP transgenic B cells in this case) served as important APCs for T cell tolerance in normal mice and for T cell activation in MRL mice. The study further suggested that anti-snRNP B cell anergy in normal mice could be reversed by autoreactive T cells from autoimmune mice in a cognate manner, indicating an important role of T cells in the development of lupus (as described below).

T Cell Abnormalities Contributing to Tolerance Breakdown in Lupus

As described in the following subsections, different laboratories have used various animal models of lupus or T cells from patients with SLE to investigate tolerance abnormalities in T cells. These studies have detected different impairments occurring at almost every level of central or peripheral tolerance mechanisms (Fig. 20-1B).

Impaired Clonal Deletion of Lupus Autoreactive Th Cells

Several approaches have been used to determine if lupus T cells arise as a consequence of failed negative selection. Using transgenic mice expressing TCR of a pathogenic autoantibody–inducing Th cell that was specific for nucleosomes and its histone peptide H4 (71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94), one group reported that whereas introduction of the lupus TCR transgene causes marked deletion of transgenic thymocytes in the normal mouse backgrounds, such deletion is not detected in the lupus-prone (SWR × NZB)F1 (SNF1) thymus (91). Thus, impaired central tolerance may contribute to the positive selection of autoreactive pathogenic Th cells in lupus (Fig. 20-1B). This idea is further supported in studies where a drug procainamide-hydroxylamine that induces lupus in humans interferes with central tolerance mechanisms in the thymus, resulting in the emergence of chromatin-reactive T cells followed by humoral autoimmunity in C57BL/6 × DBA/2 F1 mice (99). To address this issue in humans, T cells from SLE patients were cultured with thymic stromal cells. In these experiments, T cells from SLE patients are more resistant to induction of apoptosis by thymic stromal cells than normal T cells. Thus, SLE T cells have intrinsically acquired a mechanism to evade central tolerance mechanisms in SLE, whereby interactions between thymic stromal and lymphoid cells leads to subsequent survival of autoimmune T cells (100). Other studies, however, suggest that central tolerance mechanisms are intact and that perturbation in peripheral tolerance mechanisms contributes to autoimmune response in lupus.

Neonatal and Adult Tolerance to Exogenously Administered Peptide Antigens in Lupus

To understand mechanisms and outcome of tolerance induction in lupus, we administered MHC class II-binding foreign or self peptides, namely hen egg lysozyme (HEL) 106–116 or self immunoglobulin A6.1 VH58–69, to newborn lupus (NZB/NZW F1) or normal (BALB/c) mice (101). A comparable level of tolerance, as measured by peptide-specific T cell proliferation and IL-2 production in response to subsequent peptide challenge, was induced in both lupus-prone and normal mice. Lupus-prone mice, however, had increased anti-DNA antibody production in response to a neonatally administered self VH peptide. Comparable levels of tolerance were also induced in adult lupus-prone and normal control mice, when peptide antigens were administered IV in high doses of soluble form or intraperitoneal (IP) in high doses of emulsified form (102 ,103 ,104). The older lupus-prone animals, however, tend to have relatively more leakiness in tolerance, particularly in T helper (Th) functions and peptide-specific antibody responses (Singh RR, unpublished data). These studies demonstrate lack of a major tolerance defect in the induction of experimental tolerance in lupus-prone mice.

Intact Central Tolerance, but Impaired Peripheral T Cell Control Mechanisms

Several groups have studied mechanisms and outcome of tolerance induction in lupus using transgenic mice expressing TCR of a T cell–specific for a conventional peptide antigen (for example, pigeon cytochrome C [PCC]). In the PCC peptide TCR transgenic model, the relevant antigen exposure results in intrathymic deletion of immature $CD4^+CD8^+$ DP thymocytes, TCR downregulation and thymocyte apoptosis, which are comparable between a nonautoimmune mouse strain (B10.BR) and an autoimmune–prone MRL-MpJ strain (105). Thus, central tolerance to a conventional antigen is intact in lupus-prone MRL mice. Using the NZB model, another study inferred that there is no generalized T cell tolerance defect in lupus-prone mice (106). Similar conclusions have been reached in many studies. Thus, autoreactive T cells in lupus mice may arise because of defects in peripheral control mechanisms. Further, lupus T cells may be abnormally activated in the setting of incomplete but normal tolerance.

Using elegant gene microarray profiling, functional, and biochemical studies, a recent study showed that activated T cells of patients with SLE resist anergy and apoptosis (Fig. 20-1B) by upregulating and sustaining cyclooxygenase-2 (COX-2) expression, along with the anti-apoptotic or survival molecule c-FLIP (cellular homolog of viral FLICE inhibitory protein)

(107). Inhibition of COX-2 causes apoptosis of the anergy-resistant lupus T cells by augmenting Fas signaling and reducing c-FLIP. Studies with COX-2 inhibitors and COX-2–deficient mice confirmed that anergy-resistant lupus T cells, and not cancer cells or other autoimmune T cells, selectively use this COX-2/FLIP antiapoptosis program. Thus, an imbalance in the proapoptotic/antiapoptotic mechanisms may contribute to the persistence of autoreactive clones (107).

Studies in mouse models also show that CD4 T cells from lupus mice are more resistant than nonautoimmune mice to anergy induction (Fig. 20-1B). Anergy avoidance in the periphery may be one of the causes for abnormal T cell activation in response to self-antigen in SLE (108). Indeed, T cells from SLE patients and lupus-prone mice display phenotypes of in vivo activation, such as CD25, HLA-DR, and high levels of CD40L (109 ,110). Furthermore, CD8 T cells from SLE patients have been found to have high expression of perforin and granzyme (111), which correlate with disease activity. We have also observed increased percentage of $CD44^{hi}CD62L^{lo}CD69^{+}$ T cells in the spleen of MRL-lpr mice (Dubey S and Singh RR, unpublished data). Therefore, there is ample evidence in both human and murine systems that T cell activation is a hallmark of disease development in SLE. However, the mechanisms that cause T cells to become hyperactivated or overexcitable have not been well defined.

Heightened response to peptide antigens, particularly those with low affinity for TCR, appears to drive the polyclonal T cell activation seen in lupus mice (112). Several studies have also demonstrated the presence and role of intrinsic T cell abnormalities, such as diminished activation thresholds, in T cells from patients and mice with SLE. The following sections narrate efforts of several laboratories trying to define such intrinsic T cell abnormalities in lupus.

T Cell Signaling Defects in SLE

T cells use a cell surface multisubunit structure, the TCR/CD3 complex, as an antigen specific recognition site. The TCR α/ß or γ/δ are the antigen-binding sites but because of having very short cytoplasmic domains they are not capable of any signal transduction that is carried out by the CD3 complex. Human and murine SLE T cells, when stimulated through the TCR/CD3 complex, exhibit several abnormalities in T cell signaling (Fig. 20-1B). These include aberrant tyrosine phosphorylation, altered calcium flux, and heightened mitochondrial potential. A major and well studied outcome of this aberrant signal transduction in SLE T cells is reduced IL-2 production, a phenotype of lupus T cells observed more than 20 years ago (113 ,114 ,115). Reduced response to IL-2 by T cells accompanied reduced IL-2 production in some SLE patients (113). Linker-Israeli and colleagues noted a severe defect in IL-2 production by mononuclear cells from all 19 SLE patients regardless of the stimulant used and irrespective of the patients' disease activity (116). Another study in 32 SLE patients and 27 healthy volunteers, however, found a correlation between degree of IL-2 depression in PHA stimulated cells and disease activity (117). This study also showed that IL-2 production was restored in SLE patients by addition of either phorbol myristate acetate (PMA) or ionomycin to cultures (118). Defective IL-2 production has also been reported in mouse models of lupus, including MRL-lpr, BXSB, and BWF1 mice (114 ,119 ,120 ,121). In MRL-lpr mice, reduced IL-2 production precedes the onset of clinical illness and becomes increasingly severe with age (121) (Dubey and Singh, unpublished data). Spleen cells from MRL-lpr mice also fail to respond normally to IL-2 (121). It is therefore important to focus on the IL-2 defect in SLE T cells, since it acts as an essential regulator of immune response by promoting activation of immune system and terminating it when required by inducing activation-induced cell death of autoreactive T cells. In fact, treatment of MRL-lpr mice with *Il2* gene delivered via vaccinia virus or attenuated salmonella vectors results in significant improvement in lupus disease (122 ,123). Consistent with reduced IL-2 production, proliferative responses of T cells from SLE patients when cultured with thymic stromal cells are lower than their normal counterparts (100).

Several mechanisms have been proposed to explain defective IL-2 production in SLE. Reduced phosphorylation and expression of the TCR/CD3ζ chain (124) is one such mechanism. Two SLE patients have been shown to harbor a 36bp exon 7 deletion in the TCR ζ mRNA. Many other mutations found in SLE patients have been mapped to the third immune coreceptor tyrosine-based activation motif (ITAM) motif or the GTP/GDP binding site in the TCR ζ molecule. These mutations have been implicated in the downregulation of TCR ζ chain and consequent reduced IL-2 production in SLE patients (125). Furthermore, transfection of SLE T cells with TCR ζ chain increases surface expression of TCR and normalizes TCR/CD3-induced free intracytoplasmic calcium (124 ,126).

Under physiologic conditions, the signal generated by the CD3 complex triggers phosphorylation of phospholipase C (PLC-γ) on Tyr and Ser residues, hydrolysis of phosphatidylinositol 4,5 biphosphate to phosphatidylinositol 1,4,5 biphosphate and a rapid rise in intracellular Ca^{2+}. The rise in intracellular calcium upon activation has been reported to be higher in SLE T cells than in control T cells (127). This increase in calcium flux in T cells, however, did not correlate with disease activity. The aberrant calcium flux is probably because of an IgG anti-TCR/CD3 complex antibody in human SLE serum (128). Tsokos et al. have recently shown that this anti-TCR/CD3 complex antibody stimulates translocation of Ca^{2+} Calmodulin kinase from the cytosol to the nucleus. This event induces upregulation of CREM (cAMP response element CRE modulaor) transcript and protein, phosphorylation of CREM and binding of pCREM homodimers to -180 site of IL-2 promoter, thus leading to decreased IL-2 production. Further studies from this group suggest that protein phosphatase2A (PP2A), the primary enzyme that dephosphorylates CREB in T lymphocytes, is involved in the suppression of IL-2 production. Thus, PP2A represents a negative regulator of IL-2 promoter activity. Consistent with

this idea, the mRNA, protein, and catalytic activity of PP2A are increased in patients with SLE regardless of disease activity and treatment (128).

Perl et al. have suggested another mechanism of altered calcium flux in lupus T cells. They have shown nitric oxide-dependent mitochondrial hyperpolarization to be responsible for higher calcium flux in lupus T cells (129). In contrast to above studies showing increased calcium flux in SLE T cells, Sierakowski et al. found lower calcium flux upon anti-CD3 stimulation in SLE patients than in controls. Ionomycin-induced calcium flux, however, is similar between SLE patients and controls. The reduced calcium flux upon TCR stimulation in T cells was also seen in patients with mild disease or in those whose T cells produced normal amounts of IL-2 (117). We have observed reduced calcium flux upon TCR signaling in T cells from autoimmune MRL-lpr mice at an age (≥8 weeks) when they begin to develop disease. At this time point, however, B cells when stimulated through their receptor exhibit higher calcium flux. Interestingly, T cells from these mice display a split activation phenotype, i.e., whereas these T cells show evidence of in vivo activation as exhibited by increased expression of activation markers and IFN-γ production, they have reduced IL-2 production and calcium flux upon TCR stimulation (Dubey and Singh, unpublished data).

Two cytoplasmic intracellular signaling pathways important in T cell activation, differentiation, and effector function are the mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3c-kinase (PI3-K). There are three major groups of MAP-kinases in mammalian cells (130): extracellular signal regulated kinases (ERK), p38 MAP kinases, and c-Jun N-terminal kinases (JNK). Defects in MAPK signaling pathway in T cells have been shown to account for reduced IL-2 production by SLE T cells. For example, the activity of ERK-1 and ERK-2 is diminished in resting as well as TCR-stimulated peripheral blood T cells from SLE patients, which can lead to diminished translocation of nuclear factor AP-1, resulting in altered coordination of signals needed for normal IL-2 production and maintenance of tolerance in T cells (131). Studies using the graft versus host disease (GVHD) model of murine lupus have found increased activity of PI3-K and JNK, but not for raf-1, p38 MAPK, or ERK-1. Increased PI3-K activity in the chronic GVHD model is consistent with a role for persistent T cell activation in lupus-like disease, as evidenced by increased phosphorylation of TCR-associated Src-family kinases (Lck and Fyn) (132). Consistent with these data, treatment with a PI3-K inhibitor improves disease in MRL-lpr lupus mice (133).

T cell abnormalities in lupus can also be explained by the altered lipid raft composition and dynamics. The organization of signaling molecules into discrete membrane associated microdomains, called lipid rafts, is vital for regulation of T lymphocyte activation pathways (134 ,135). Lipid rafts play a central role in signal transduction, in the immune response and in many pathological conditions on the basis of two important raft properties, their capacity to incorporate or exclude proteins selectively, and their ability to coalesce into small domains. As reported recently, SLE T cells contain larger pools of lipid rafts compared with normal T cells and produce lipid rafts more robustly upon anti-CD3 treatment than normal T cells. These changes are accompanied by a qualitative alteration in the composition of lipid rafts in SLE: whereas CD3ζ and LAT (linker of activated T cells) are uniformly distributed on the surface of normal T cell membrane, these molecules are organized in discrete clusters on membrane of SLE T cells. Unlike normal T cells, lipid rafts from SLE T cells contain FcRγ and activate Syk kinase (136).

The localization of Lck to lipid rafts is essential for normal TCR-mediated signaling. Lck is significantly reduced in both lipid rafts and nonraft portions of T lymphocytes from SLE patients. Reduced expression of Lck in lupus T cells occurs because of increased ubiquitination and subsequent degradation of Lck, so that T cells become unresponsive to TCR-mediated signals (137). These findings imply chronic in vivo activation of T cells in SLE. However, the direct pathogenetic implications of reduced Lck in lupus T cells as well as factors that regulate Lck homeostasis in lipid raft domains and cause degradation of Lck in lupus T cells remain to be clarified. Further studies have shown increased expression of raft-associated ganglioside GM1 in SLE T cells. CD45, a tyrosine phosphatase that regulates Lck activity, is also differentially expressed and its localization into lipid rafts is increased in SLE T cells. Such altered association of CD45 with lipid raft domains may regulate Lck expression in SLE T cells. The altered lipid raft occupancy is not induced by serum factors from patients with SLE, but cell-to-cell contact is required to activate proximal signaling pathways (138).

While most studies have focused on identifying genes associated with altered T cell functions in SLE, epigenetic regulation of gene expression, such as histone acetylation and methylation, may also contribute to impaired SLE T cell function (139). In fact, treatment with histone deacetylase inhibitors, such as trichostatin A, which corrects these impairments and suppresses lupus in mice (140), holds promise for humans.

B Cell Abnormalities Contributing to Tolerance Breakdown in Lupus

Breaking the B Cell Tolerance Checkpoints

Appearance of self-reactive antibodies precedes the onset of clinical manifestations in humans and animals with SLE (141). Where in the B cell pathway tolerance is first broken and which mechanisms account for such breakdown remains to be determined, however (Fig. 20-2B). As described above, there are many B cell tolerance checkpoints that can be located at three broad steps of B cell pathway, namely immature state in the bone marrow, then in the periphery from the immature state to mature naïve state, and finally at the level of mature B cell subsets (Fig. 20-2A). At the immature B cell stage in the bone marrow, most polyautoreactive and antinuclear B cells in healthy individuals are silenced through clonal deletion, anergy, or receptor editing (38). Although there is evidence that

receptor editing occurs in SLE patients, whether it functions to eliminate autoreactivity appropriately is not known (40).

A recent study examined the B cell repertoire at the transitional and naïve stage in the peripheral blood of three newly diagnosed, untreated SLE patients (142). All three patients had increased numbers of naïve B cells expressing self-reactive antibodies as measured by reactivity to Hep-2 antigens. One of the three patients had a high frequency of self-reactive B cells among new B cell emigrants, implying a defect in early B cell tolerance in the bone marrow in some SLE patients (Fig. 20-2B).

As described above, self-reactive B cells that escape tolerance in the bone marrow are subject to removal in the peripheral lymphoid organs when they transition from the immature state in the bone marrow to the mature naïve state. B cell tolerance is impaired at this step in at least some patients with SLE, as in two of the three SLE patients studied autoreactive B cells failed to be removed during their maturation from the transitional to the mature naive stage (142) (Fig. 20-2B). Studies in mouse models suggest that negative selection mediated by BCR signaling confers B cell tolerance at the transitional stages in the periphery. In fact, evidence shows that clonal deletion of B cells at their T1 stage of development is defective in murine lupus (143). In NZB mice, IgM crosslinking in resting or isolated T1 B cells prevents mitochondrial membrane damage and apoptosis induction (143 ,144). Since T2/T3 cells can be rescued from negative selection by costimulatory signals, increased expression of costimulatory molecules in SLE patients (145) can rescue transitional B cells destined to undergo BCR-mediated apoptosis. BAFF that can also enhance the survival of autoreactive transitional B cells (146) is increased in the circulation of some patients with SLE (147). Extrinsic factors such as the sex hormone estradiol can also diminish the BCR signal and thereby potentially diminishes the negative selection of autoreactive B cells (148) (Fig. 20-2B). This might be one explanation for the predominance of SLE and several other autoimmune diseases in women.

SLE patients have high numbers of naïve B cells that can secrete polyreactive antibodies that react with ssDNA, dsDNA, insulin, and LPS (142). It is not clear whether the polyreactive autoreactive B cells reflect a defect in negative selection that correlates with development of disease or they represent precursors of the B cells that produce pathogenic autoantibodies (40). Although lupus patients have cross-reactive antibodies, the polyreactivity is usually restricted to a set of nuclear and nucleoprotein antigens. Thus, it will be important to know when the generalized polyreactivity is converted to restricted cross-reactivity in patients with SLE.

Finally, self-reactive B cells that escape tolerance processes throughout their transitional stages may mature to be autoantibody-secreting B cells. These mature autoantibody–secreting cells may assume the phenotypic characteristics of any B cell subset: B1, marginal zone (MZ) B cells, and follicular B cells (40) (Fig. 20-2B). However, it is unclear which of these B cell subsets contribute to disease pathogenesis in mice and which B cell subsets are responsible for autoantibody production in humans with SLE.

In mouse models, all three subsets can produce pathogenic autoantibodies. For example, B1 cells produce high-affinity IgM anti-dsDNA autoantibodies in the moth-eaten mouse strain that is deficient in the inhibitory phosphatase SHP-1 (148). The human equivalent of murine B1 cells, CD5-expressing B cells, generally produce polyreactive, low-affinity IgM autoantibodies using germline-encoded V genes. However, somatic mutation has been described in human autoreactive $CD5^+$ B cells (149), which can some times differentiate into cells with features of germinal center cells (150). Thus, impaired generation or regulation of B1 B cells may be involved in the pathogenesis of SLE. In fact, VH4–34-expressing, $CD5^+$ B cells that produce pathogenic IgM antilymphocyte antibodies are normally excluded from germinal center reactions, but these cells enter germinal centers in patients with SLE and contribute to the memory B cell pool (50).

The MZ B cells have several features required to break T cell tolerance. For example, they can act as APCs as they express costimulatory molecules and can activate T cells (151). These cells are easily activated by DC and mature rapidly into plasmablasts (51). MZ B cells can also generate T cell–independent autoimmune responses and undergo heavy chain class switching and somatic mutation in extrafollicular regions of the spleen in lupus-prone mice (152). MZ B cell can also initiate germinal center formation (51). In humans these cells are present in circulation as $IgD^{low}IgM^+CD27^+$ and can populate all secondary lymphoid organs. The factors that regulate differentiation and entry of MZ B cells to germinal center or extrafollicular foci of antibody production are not known. MZ B cell development depends on BAFF that is upregulated in SLE. In fact, MZ B cells can produce pathogenic autoantibodies in lupus-prone (NZB/NZW) F1 mice (153).

After antigen encounter and T cell help, follicular B cells normally generate germinal centers where they mount an affinity-matured antibody response and generate memory B cells. Since lupus autoantibodies are mostly somatically mutated and class-switched IgGs, they are likely to be produced by antigen-experienced B cells, implicating abnormalities in tolerance in late stage, germinal center-matured B cells. Mechanisms of negative and positive selection in germinal centers are not well understood. Presence of autoreactive T cells and lack of inhibitory mechanisms such as inhibitory Fc receptor Fcγ2RIIB on the B cells may contribute to positive selection and differentiation of autoreactive B cells at this stage.

To understand B cell tolerance in SLE, a recent study analyzed autoreactive B cells in tonsil biopsies from patients and normal individuals (154). They show that autoreactive B cells exist but do not secrete IgG in normal subjects, but these cells expand and secrete IgG in patients with SLE. In SLE, but not in RA, 9G4 B cells escape normal censoring and actively participate in productive germinal center reactions, leading to the generation of increased levels of IgG memory and plasma cells. The specific peripheral tolerance checkpoint

that is broken occurs at an early point in the germinal center reaction during the transition from the pregerminal center to the centroblast stage, thus implicating faulty germinal center exclusion of autoreactive B cells in the pathogenesis of SLE (Fig. 20-2B).

B Cell Receptor Signaling Defects, Hyperactivation, and Loss of Tolerance in SLE

The strength and the duration of B cell response largely depend on the integrity of BCR and availability of costimulatory (CD19, CD21) or inhibitory receptors. Patients with SLE manifest B cell abnormalities that include B cell proliferation, increased calcium flux, hyperresponsiveness to physiologic stimuli, and altered production and response to cytokines (155 ,156). One cause of the B cell overexcitability in lupus is supposed to be increased signaling through the BCR. In this context, expression of lyn protein, a key negative regulator of B cell signaling, is reduced in B cells from a majority of patients with SLE. SLE B cells also have altered translocation of Lyn to lipid rafts. This altered Lyn expression is associated with heightened spontaneous proliferation, anti-dsDNA autoantibodies, and elevated IL-10 production (157). Another study reported persistently reduced tyrosine phosphatase CD45 and elevated protein tyrosine phosphatase SHP-1 in the BCRs from SLE patients. Since Lyn and SHP-1 act in concert within a negative signaling pathway in which CD45 counteracts SHP-1 mediated regulation, altered expression of these molecules may contribute to defective feedback regulation in SLE B cells.

B cells preferentially express the FcγRIIb1 (CD32) isoform, cross-linking of which in normal B cells suppresses the B cell signal transduction. Defective inhibitory signaling via FcγRIIb1 is purported to cause increased calcium flux in SLE B cells (158). Furthermore, germline deficiency of Fcγ2RIIB causes an accumulation of plasma cells secreting anti-DNA antibodies in mice (53), suggesting a role of this Fc receptor in regulating B cell differentiation at the germinal center stage. In fact, Fcγ2RIIB polymorphisms have been associated with autoimmunity in mice and man. For example, a polymorphism in the FcγRIIb1 gene, FCGR2B c.695T > C that results in the non-conservative replacement of 232Ile at the transmembrane helix to Thr, is associated with susceptibility to SLE in Asians. This polymorphism (Fcγ2RIIB 232Thr) is less potent than wild-type molecule (Fcγ2RIIB 232Ile) in inhibiting BCR-mediated phosphatidylinositol-3,4,5-trisphosphate accumulation, Akt and PLCγ2 activation, and calcium mobilization after IgG Fc-mediated coligation with BCR. Further, the Fcγ2RIIB 232Thr is less effective than wild-type Fcγ2RIIB 232Ile in its localization to detergent-insoluble lipid rafts (159). Thus, altered balance between positive and negative signaling molecules may modify the BCR signaling thresholds and contribute to disruption of B cell tolerance (158 ,160).

B cell activating factor (BAFF) and BAFF receptors appear to affect many stages of B cell differentiation, ranging from the development, selection, and homeostasis of naïve B cells to antibody producing plasma cells. Excessive BAFF rescues self-reactive B cells from anergy, thereby breaking B cell tolerance (161). Mice overexpressing BAFF exhibit increased B cell numbers in spleen and lymph node and autoimmune phenotype similar to that observed in patients with SLE (146 ,162). Inhibition of BAFF by TACI-Ig and BAFFR-Ig has been proven to be beneficial in murine model of SLE (163). Elevated serum levels of BAFF have been detected in some SLE patients (164). BAFF-R is consistently occupied on blood B cells in SLE patients. Dysregulation in expression of these molecules may contribute to breakage of B cell tolerance in SLE. To delineate the mechanism of B cell tolerance by BAFF, one study used anti-HEL–specific BAFF transgenic mice and showed that self-reactive B cells upon which deletion is stringently enforced in early stages of development are mostly unaffected by BAFF. However, self-reactive B cells that are destined for deletion during later stages of maturation are rescued by BAFF from undergoing apoptosis (146). Thus, increased BAFF expression in SLE-prone individuals may precipitate autoimmunity through positive selection of B cells at their late stages of maturation.

B Cell Role in Breaking T Cell Tolerance

Role of B cells has been recently explored beyond their traditional function of autoantibody production. B cells process and present self-antigens to naïve T cells (165). Mamula et al. reported that mice are normally unresponsive to immunization with native mouse snRNP (a lupus autoantigen), suggesting that the tolerance to this self-antigen is intact in these animals. Such tolerance can be broken, however, if the animals are immunized with native foreign (human) snRNPs, as evident by presence of T cells and crossreactive anti-snRNP antibodies. When mice are immunized with human and mouse snRNPs together in adjuvant, T cells specific for mouse snRNPs can be elicited. Furthermore, B cells purified from mice immunized with foreign antigen (human A protein), when transferred into naive mice, can present self-antigen (mouse snRNP) and activate self-reactive $CD4^+$ T cells specific for mouse antigen (166). Similarly, B cells induced to make autoantibody by immunization of mice with the nonself-protein human cytochrome c can present self-antigen mouse cytochrome c to activate autoreactive T cells. This mechanism of breaking T cell self tolerance can account for the role of foreign antigens in breaking not only B cell but also T cell self tolerance, leading to sustained autoantibody production in the absence of the foreign antigen. In consonance with these observations, B cell–deficient MRL-lpr mice have fewer numbers of CD4 and CD8 memory cells than their B cell-intact counterparts (167), whereas secreted Ig-deficient, but B cell–intact MRL-lpr mice continue to have spontaneous T cell activation and expansion (168). Thus, B cells serve as an important role as APCs in inducing spontaneous activation of T cells in autoimmunity.

Impairments of Regulatory T Cells and Factors as Mechanisms of Loss of Tolerance

T and B cells are normally self-tolerant. We have reported that this tolerant state can be broken in otherwise healthy, nonautoimmune mice by in vivo stimulation of the Th cells that are capable of promoting autoantibody production, e.g., by immunization with autoantigenic peptides (such as anti-DNA VH peptides). This state of loss of tolerance (or autoimmunity) is short-lived, however. Recovery from autoimmunity in these mice correlates temporally with the appearance of certain $CD8^+$ and $CD4^+$ T cells that are capable of suppressing autoantibody production (34 ,169 ,170). In fact, $CD8^+$ regulatory T cell lines derived from nonautoimmune mice can suppress in vivo autoantibody production and nephritis when implanted into lupus-prone (NZB/NZW) F1 mice (171). Thus, self-reactive B and Th cells exist in the normal immune repertoire but are kept in control to avoid pathologic autoimmunity. These control mechanisms are defective in lupus mice, which have impaired activation of such inhibitory, suppressor and Treg cells (34 ,169). Impairments in $CD8^+$ T cell suppressor functions have also been described in human SLE (172). These observations might have therapeutic implications because we can correct this impairment in lupus mice by modifying the delivery of peptide antigens, for example, by DNA vaccination with minigenes that encode certain T cell epitopes derived from anti-DNA variable regions (173). Vaccination with nucleosome-derived peptides can also induce suppressor $CD8^+$ and $CD4^+CD25^+$ T cells, as can administration of an Ig-derived peptide, which suppress disease in lupus mice (174). Because similar T cell epitopes exist in humans, strategies described here might be useful in therapy of the human disease.

The VH peptide-reactive $CD8^+$ inhibitory T (Ti) cells described above produce TGF-ß (34 ,169 ,171 ,173). Recent studies have further demonstrated a role of TGF-ß in Ig peptide-mediated suppression of lupus-like autoimmunity in (NZB/NZW) F1 and other models of lupus (175 ,176 ,177). TGF-ß and other cytokines play an important role in maintaining self-tolerance (178 ,179), as TGF-ß1 knockout mice develop lethal systemic inflammation and autoantibodies (180 ,181). This TGF-ß–mediated self-tolerance appears to act via controlling T cell activation, as the deletion of the TGF-ß receptor type II gene in T cells alone can cause severe autoinflammatory disease (Adams and Singh, unpublished). TGF-ß is also required for the normal functioning of Treg and Ti cells. The regulatory role of TGF-ß in the development of lupus-like autoimmunity is further supported in studies which have shown reduced production of TGF-ß by immune cells from patients with SLE; addition of TGF-ß to the lupus PBMC cultures reduces production of autoantibodies (182). However, TGF-ß production is increased in SLE patients having advanced disease with tissue fibrosis. For example, SLE patients who have congenital complete heart block that is believed to occur as a result of fibrosis of cardiac conduction system have a TGF-ß1 genotype that is associated with increased fibrosis. Further, their PBMCs produce increased spontaneous and mitogen-stimulated TGF-ß1 secretion (183). Thus, TGF-ß may play dual, seemingly paradoxical, roles during the development and progression of lupus disease (2): In early stages of disease development TGF-ß deficiency may predispose to immune dysregulation, breakdown of immune tolerance, and development of autoimmunity, whereas in late stages of disease increased TGF-ß production in local tissues may predispose to impaired tissue repair and remodeling and development of tissue fibrosis.

The VH peptide-reactive $CD4^+CD25^+$ Treg cells can also inhibit autoantibody production in vitro in (NZB/NZW) F1 mice (184). To test the role of such Treg cells on lupus disease in vivo, Bagavant et al. performed thymectomy on day 3 of life, which is known to cause deficiency of $CD4^+CD25^+$ Treg cells and generalized autoimmune disease in normal background, in the NZM2328 model of lupus (185). Indeed, the day 3-thymectomy accelerated anti-dsDNA antibody production and proliferative glomerulonephritis and sialoadenitis and induced severe prostatitis, thyroiditis, and dacryoadenitis. To test whether “refilling” these thymectomized mice with Treg cells will obviate lupus exacerbation, they transferred $CD25^+$ T cells from young, healthy NZM2328 mice into syngeneic mice 4 to 7 days after thymectomy. Such transfer prevented the development of prostatitis, thyroiditis, and dacryoadenitis, abolished the accelerated dsDNA antibody response, but had little or no influence on the accelerated development of lupus nephritis and sialoadenitis (185). Thus, a deficiency of $CD4^+CD25^+$ Treg cells may contribute to abnormal immunoregulation in NZM2328 mice, but it may not be sufficient to cause lupus nephritis.

That regulatory mechanisms constitute an important checkpoint against the development of pathologic autoimmunity was also demonstrated in a recent study, where introduction of a transgenic TCR specific for a pathogenic nucleosome-specific T cell in a lupus-prone strain caused suppression of autoimmune disease despite positive selection of autoreactive Th cells. The autoimmune disease suppression in TCR transgenic lupus mice was associated with a marked downregulation of the transgenic TCR, upregulation of endogenous TCRs in the periphery, and induction of potent regulatory T cells. Thus, presence of autoreactive Th cells in large numbers since birth may elicit regulatory mechanisms to preempt pathologic autoimmunity (91).

Autoantigens in SLE

Common Autoantigens in Lupus

Autoimmunity in SLE is directed to some highly conserved intracellular molecules particularly against nuclear and cell membrane phospholipid components (186). Most studies have focused on autoantibody responses to functionally related nucleic acid–containing macromolecules such as chromatin or ribonucleoprotein (RNP) particles, since autoantibodies to double-stranded DNA (dsDNA) and Sm antigens of the U-1 small nuclear RNP (snRNP) complex

are considered pathognomic of SLE (187). These and other autoantibodies and characteristics of the relevant autoantigens are described in detail in other chapters.

In brief, high-affinity antibodies to dsDNA are hallmarks of SLE. Some subsets of these autoantibodies cause renal and vascular injury (1 ,188). The common features of such pathogenic autoantibodies, such as class-switched IgGs and somatic mutation, indicate that anti-dsDNA antibodies arise as a result of an antigen-driven process. The antigenic stimuli driving the production of anti-dsDNA autoantibodies remain elusive, but recent studies provide some possible candidates. Since nucleic acids are poor or not immunogenic, DNA-binding protein in complex with DNA is purported to break tolerance to DNA (189). One possible explanation is that some peptides can serve as surrogate anti-dsDNA epitopes thus activating T cell help for the production of anti-dsDNA antibodies (190 ,191). Another possibility supports a hapten-carrier like mechanism, where T cells specific for peptides derived from the DNA-binding proteins (such as histones) provides help to DNA-specific B cells. For example, immunization of animals with DNA-protein complexes, rather than with protein-free DNA, induces robust anti-dsDNA antibody response (189). A third possibility is that anti-dsDNA antibody response could occur during the autoantibody response toward the protein constituent of the ribonucleoprotein autoantigens such as nucleosomes or snRNPs (186).

Autoantibody against the Sm autoantigens of the snRNP complex is also pathognomic of SLE. The snRNPs are ubiquitous self-antigens that are components of the spliceosome complex, which normally functions to excise intervening introns and generate mature messenger RNA transcripts. In most snRNP particles, seven core proteins, B, D1, D2, D3, E, F, and G, form a heptamer ring, with the snRNA passing through the centre. The Sm epitopes are distributed on the outside surface of the ring. James et al. used overlapping octapeptides spanning the full length of the B/B' protein to identify an epitope, PPPGMRPP, within the C-terminus of SmB'/B, that is recognized very early in animal models and in some SLE patients (192). Over time, the immune response spreads beyond this initial epitope to other snRNP autoantigens including U1-specific RNP epitopes frequently targeted by antibodies present in patients with mixed connective tissue disease (192). Most Sm-precipitin–positive lupus sera, however, recognize certain SmD polypeptides, such as the glycine–arginine (GR)-rich carboxyl region of SmD1 (193 ,194). The levels of the anti-SmD83–119 strongly correlate (as does antinucleosome) to disease activity. Levels of anti-dsDNA and anti-SmD183–119 strongly correlate with lupus nephritis (195 ,196).

Potential mechanisms that make an antigen an autoantigen are described above and have been recently reviewed by several authors (54 ,56 ,186 ,197 ,198). Table 20-3 summarizes briefly some common features. Not all features described in this table are applicable to all autoantigens. In addition to their being evolutionary conserved and ubiquitously expressed, lupus autoantigens are highly diverse, yet this diversity is restricted to certain set of autoantigens causing a “restricted polyclonality” of autoimmune response in lupus. Several mechanisms have been proposed to explain this phenomenon, which have been reviewed in several publications (199 ,200 ,201 ,202 ,203). According to a unique mechanism that we have suggested (204), T cell epitopes (amino acid sequences that can serve as T cell determinants) are shared among variable regions of different lupus-related autoantibodies but not among other antibodies. Thus, a T cell epitope present in an anti-DNA Ig may activate T cells that can deliver help to B cells specific for antiphospholipid or anti-red blood cells or other related autoantigens, but not to B cells specific for an unrelated antigen. This is one explanation why lupus autoantibodies are polyclonal, yet restricted to a recurring set of autoantigens. The shared T cell epitopes in autoantibodies may originate as a result of replacement mutations in mutationally “cold” framework regions, which do not affect the binding of antibody to its antigen but create T cell epitopes (205 ,206). In fact, while mutations in normal Ig involve hot spot areas, mutations in lupus Ig occur in nonhot spot areas, which might be responsible for creating T cell epitopes (207).

Table 20-3: Some Common Features of Autoantigens Described in Lupus

		Ref.
1.	Ubiquitously present	(54,186)
2.	Evolutionary conserved	(56,186)
3.	Genetically polymorphic	(54,60)
4.	Expressed in apoptotic blebs	(319)
5.	Restricted polyclonality, i.e., against autoantigens that are structurally or functionally related	(292)
6.	Restricted polyclonality through shared T-cell determinants among variable region of different autoantibodies	(200,204)
7.	Posttraslationally modified	(68,71)
8.	Substrates of apoptotic enzymes (caspases)	(86,88)
9.	Mutated somatically	(57,58,59)
10.	Charged or coil-coil structure	(54)
11.	Molecular mimics of infectious agents	(72,76)
12.	Able to interact with TLR or other receptors	(80,81,324)

The lupus autoantigens are presumed to initiate and perpetuate the autoimmune response in T and B cells, but the exact mechanisms as to how and when this occurs is still not understood. These mechanisms are discussed in other sections of this and other chapters. In brief, autoreactive T cells such as nucleosome-specific T cells have been identified in SLE patients, which drive the formation of anti-dsDNA and antihistone antibodies (208 ,209).

Identification of Autoantigenic Epitopes in Lupus: Studies in Animal Models

Work in the late 1980s suggested that autoantibody production in humans and mice with SLE is antigen-driven and is dependent on Th cells that are mostly $CD4^+$ (210 ,211 ,212 ,213). To identify the nature and specificity of such autoreactive Th cells, several laboratories have used diverse approaches, including T cell pepscanning of candidate autoantigens, isolating autoreactive T cell clones and deducing potential autoantigens, screening phage display libraries, and eluting naturally processed self-peptides from MHC class II molecules. These approaches have led to identification of epitopes that activate autoreactive Th cells in humans and mice with lupus and modulate disease in lupus mice (Table 20-4).

T Cell Epitope Mapping by Pepscan of Potential Autoantigens

Ig VH Peptides as Autoantigenic Th Epitopes

Early work in late 1980s and early 1990s suggested that human or murine B cells can process Ig molecules and present Ig-derived peptides in the context of their surface MHC class I and class II molecules (206 ,214 ,215 ,216 ,217 ,218 ,219). Moreover, Ig-derived peptides are eluted from MHC class II molecules, suggesting that they are naturally processed (220 ,221). An evidence for functional role of Ig peptide-reactive T cells came from studies in a transgenic mouse: T cells from mice expressing a transgene encoding a TCR specific for an Ig-derived peptide provided help for B cell production of antibodies (222). Furthermore, Ig peptide-reactive T cells follow rules of conventional T cell tolerance and activation. This was elegantly shown using a TCR transgenic mouse strain that expresses a TCR specific for a κ variable region peptide in mAb 36–71, and another double transgenic mouse strain that expresses both the TCR transgene and the κ chain of mAb 36–71 (223). The TCR transgenic T cells undergo central deletion in thymus in double transgenic mice that have been exposed to the antigen (κ chain of mAb 36–71) since birth. In contrast, adoptive transfer of transgenic T cells into κ (Ig) transgenic recipients results in T and B cell activation, lymphadenopathy, splenomegaly, antichromatin antibody production, and lupus nephritis. It is believed that normal as well as lupus-prone mice generally attain T cell tolerance to germline-encoded antibody sequences (206 ,224 ,225), whereas somatically mutated antibody sequences can activate T cell help because they arise in rare B cells at a late stage of T and B differentiation thus creating neoepitopes (206). Interestingly, this group found that clonal expansion of a spontaneous autoreactive B cell lineage from a lupus mouse correlated with VH somatic mutations in mutationally “cold” framework region. While these mutations did not affect the affinity of the antibody product for chromatin, one of them created a MHC class II–restricted T cell epitope. This mutation was shared by all seven members of the lineage, thus making a point of massive clonal expansion (205).

The above observations led us to postulate that SLE B cells process their endogenous or surface Ig into peptides that are presented on MHC class II molecules. These peptide-MHC complexes then activate autoreactive Th cells, which, in turn, stimulate B cells for the increased production of autoantibodies (102 ,204 ,226 ,227). To map the T cell epitopes in anti-DNA mAb VH regions, over 400 overlapping peptides from anti-dsDNA monoclonal antibodies were cultured with naïve splenocytes from young (NZB/NZW)F1 mice; T cell proliferation and anti-DNA antibody forming cells (Elispots) were estimated. Several peptides consistently induced T cell proliferation and/or help for anti-DNA antibody production (102 ,227). These peptides bound different MHC class II molecules; some peptides bound more than one MHC molecule (226). Some epitopes were dominant; others were subdominant or cryptic in the context of whole Ig molecule or its heavy chain (226).

Several lines of evidence support the role of these peptides in autoantibody production and lupus. First, many peptides increased anti-dsDNA antibody production in vitro when cultured with syngeneic splenocytes (204). Secondly, adoptive transfer of peptide-specific T cell lines or immunizations with peptide/adjuvant emulsions increased serum IgG anti-dsDNA antibody levels, accelerated nephritis, and decreased survival (226). More importantly, IV treatment with high doses of a combination of three peptides significantly decreased anti-DNA antibody levels, serum creatinine, and proteinuria, and improved survival (102). The treatment was effective when initiated in the prenephritic age group (102). Minimal or no diminution of anti-DNA antibodies and clinical disease was observed when treatment was initiated in older lupus mice that already have large numbers of highly activated T and B cells (Singh, unpublished observations) (Table 20-5). Apparently, antigen-primed memory T cells, which are abundant in lupus mice that have established disease, are relatively resistant to tolerance induction (228).

The limitations may be overcome by using a peptide that can target a broad repertoire of T cells responding to early and late appearing T cell epitopes. To design such a “consensus” peptide that would contain optimal or best-fit residues in a T cell epitope, we statistically analyzed more than 400 overlapping peptides for the presence of residues that were associated with T cell activation at each of 15 amino acid positions in a peptide. A peptide based on this analysis (Table 20-4) more strongly stimulated T cell help for anti-DNA antibodies than most wild type peptides (229). A tolerogenic regimen of this peptide in young (NZB/NZW)F1 mice was highly effective in delaying the development of anti-DNA antibodies and nephritis. This peptide was also effective when injected into 20-week-old (NZB/NZW) F1 mice that already had high levels of circulating anti-DNA antibodies. Strikingly, treatment with this peptide decreased anti-DNA antibody as well as antibodies that bind nucleosome and cardiolipin (230).

Findings supporting the role of Ig-derived peptides in the pathogenesis of (NZB/NZW) F1 disease have been recently reported from two other laboratories. Jouanne et al. (231)

reported that injection of a peptide corresponding to the VH complementarity determinant region (CDR) 3 region of natural polyreactive autoantibody to young pre-autoimmune (NZB/NZW)F1 mice delayed development of proteinuria and 50% survival rate (231). In another study, Brosh et al. (232) showed that splenocytes from the naïve or immunized (NZB/NZW) F1 mice proliferated in response to a CDR3-based peptide derived from a mAb anti-DNA, 5G12. This peptide also modulated lupus in (NZB/NZW) F1 mice when administered in young age (233). In the SWR/NZB F1 mice, however, treatment with peptides corresponding to CDR1 or CDR2 of anti-DNA monoclonal antibodies did not have any significant effect on the incidence of nephritis (234).

T Cell Pepscan of U1–70K snRNP Autoantigen

Muller et al. tested a series of overlapping peptides to identify an epitope present in residues 131–151 of the spliceosomal U1–70K small nuclear ribonucleoprotein (snRNP) (235 ,236 ,237). This peptide is recognized very early by IgG antibodies and $CD4^+$ lymph node T cells in lupus-prone MRL-lpr and (NZB/NZW) F1 mice (238 ,239). The ability of this peptide to stimulate T cells from mice bearing different MHC haplotypes (H-2^k of MRL-lpr and H-$2^{d/z}$ of (NZB/NZW) F1) correlated with its binding to I-A^k, I-E^k, I-A^d, and I-E^d murine MHC molecules.

Interestingly, an analog of peptide 131–151 sequence phosphorylated on Ser140 (named peptide P140) is strongly recognized by lymph node and peripheral $CD4^+$ T cells and by IgG antibodies from MRL-lpr mice (210 ,239). Whereas IV treatment of young MRL-lpr mice with the phosphorylated analog P140 peptide but not with the parent peptide 131–151 in saline reduces proteinuria and dsDNA IgG antibody levels and enhances the survival (240), subcutaneous administration of P140 in Freund adjuvant accelerates lupus nephritis. The therapeutic effect of IV administered P140 correlates with transient abolition of T cell intramolecular spreading to other regions of the U1–70K protein (203), which is important because the conserved T cell epitope sequence contains an RNA-binding motif called RNP1 that is also present in other sn/hnRNPs and often targeted by antibodies from lupus patients and mice (203 ,237). Thus, modifying responses to this promiscuous and conserved epitope may target a broad autoreactive Th cell repertoire in different models and patients.

T cell Pepscan of Histone Autoantigen in (NZB/NZW) F1 Mice

A panel of overlapping peptides spanning the whole sequences of H4 and H3 were cultured with $CD4^+$ T cells from unprimed (NZB/NZW) F1 lupus mice (241). None of the 11 H4 peptides stimulated $CD4^+$ T cells in these mice, whereas several H3 peptides representing sequences 53–70, 64–78, and 68–85 elicited proliferation and induced secretion of IL-2, IL-10, and IFN-γ. The H3 peptides 56–73 and 61–78 induced the production of IFN-gamma and IL-10, respectively, without detectable proliferation, suggesting that they may act as partial agonist of the TCR. Moreover, they found that this conserved region of H3, which is accessible at the surface of nucleosomes, is targeted by antibodies from (NZB/NZW) F1 mice and lupus patients, and contains motifs recognized by several distinct HLA-DR molecules. It might thus be important in the self-tolerance breakdown in lupus.

Cloning Autoreactive Th cells That Induce Nephritis, and Deducing Autoantigens That Can Activate These Autoreactive T Cells

Nucleosome Core Histone Peptides as Th Auto-Epitopes

Datta et al. cloned Th cells from the SWR/NZB F1 mouse model of lupus. Some of these Th cells initiate and sustain the production of pathogenic autoantibodies, induce lupus nephritis, and recognize nucleosomes (242). In subsequent work they stimulated these autoreactive lupus Th cells with 145 overlapping peptides spanning the four core histones H2A, H2B, H3, and H4. From these studies, they localized the critical lupus epitopes in the core histones of nucleosomes at amino acid positions 10–33 of H2B and 16–39 and 71–94 of H4 (243) (Table 20-4). Autoimmune T cells of SWR/NZB F1 mice are spontaneously primed to these epitopes from early life. Moreover, immunization of preautoimmune SWR/NZB F1 mice with these peptides precipitates lupus nephritis (243).

More importantly, a brief therapy with the nucleosomal core histone peptides, administered IV to 3-month-old prenephritic mice already producing pathogenic autoantibodies, markedly delayed the onset of severe lupus nephritis. Chronic therapy with the peptides injected into 18-month-old mice with established glomerulonephritis prolonged survival and halted the progression of renal disease (Table 20-5) (234).

Selecting Candidate Peptides in an Immunogen Used to Induce Lupus in Normal Strains

SLE-like disease can be induced in normal mice by injecting human or murine anti-DNA monoclonal antibodies that bear a 16/6 Id that is frequently present on Ig of mice and humans with SLE (244). Using this model, Mozes et al. found that two peptides representing regions of FR1/CDR1/FR2 (termed as “pCDR1”) and FR3/CDR3 (termed as “pCDR3”) of the VH of a mAb, 5G12, stimulated T cell proliferation in BALB/c and SJL mice, and induced proteinuria, leukopenia, and glomerular Ig deposits (245) (Table 20-4). A T cell line reactive with pCDR3 also induces experimental lupus in naïve mice (246 ,247). Neonatal administration of these peptides prevented anti-DNA antibody production in this monoclonal antibody-induced model of SLE (Table 20-5). Further studies from this group have continued to demonstrate the immunomodulatory effects of these peptides in other models of lupus as well as on human cells, as described below. These findings along

with results described above (102 ,204 ,226 ,227) further indicate an important role of Ig-derived peptides in murine models of lupus.

Screening Phage Display Library to Identify Peptides That Bind Anti-DNA Antibody

An entirely different approach was used by Gaynor et al. (248) to identify nephritogenic peptides. They screened a peptide display phage library with mouse monoclonal antibodies that bind dsDNA and cause nephritis, and identified a decapeptide DWEYSVWLSN that specifically binds an anti-dsDNA monoclonal antibody, R4A. Immunization with this peptide induced IgG Antibodies that bind DNA, cardiolipin, and Sm/RNP, and caused Ig deposition in glomeruli (191 ,249). Administration of this peptide in soluble form protected mice from renal deposition of the anti-DNA antibody in vivo (248) (Table 20-5).

Another study demonstrated potential utility of a peptide DNA surrogate in inhibiting human anti-DNA antibodies. Using the anti-dsDNA antibodies to screen a phage peptide display library, Zhang and Reichlin demonstrated that purified polyclonal anti-dsDNA antibodies and a monoclonal anti-dsDNA antibody specifically bind a 15 mer peptide ASPVTARVLWKASHV (250). This 15-mer peptide can inhibit anti-dsDNA antibodies binding to dsDNA antigen in immunoassays and in the *Crithidia luciliae* assay.

Eluting “Naturally Processed” MHC Class II–Bound Self Peptides

All four approaches mentioned in the preceding sections have examined the T cell activation or mAb binding by peptides in vitro or ex vivo. These approaches, however, do not directly address if these peptides are naturally processed in vivo during the development of autoimmune response. To address this issue, efforts have been made to elute self peptides bound to MHC class II molecules present on APCs. In one study, a number of peptides from diverse source of antigens, including histones, small nuclear RNP, RNA processing enzymes, Ig γ1, IgG γ2b, lysozyme, and 26S proteasome, were identified in the eluates of MHC class II molecules I-A^k and I-E^k isolated from the lymph nodes of MRL-lpr mice, but not from non-autoimmune C3H animals (251) (Table 20-4). Identification of multiple peptides from several different protein donors in the MRL-lpr but not in C3H mice raises a possibility that the autoimmunity in lupus may not be limited to a few autoantigens. It is possible that one or a few epitopes initiate the autoimmunity, which later spreads to other epitopes in the same or the other antigens. Isolation of MHC-bound peptides at an early versus late stage of disease in lupus mice should be able to address this issue.

Further studies revealed that 11 of these peptides identified in these eluates could stimulate proliferation of T cells in both lupus and nonautoimmune mice. However, only four of them (peptides 4–23 of SRp20, 84–103 of H2A, 42–59 of $ß_2$-microglobulin and 110 of I-A^k induced proliferation of T cells in lupus mice (252). It remains to be determined whether these eluted peptides serve as natural autoantigens in lupus.

In another study, a murine lupus APC line was fed with crude chromatin, and the processed peptides were eluted from MHC class II molecules isolated from these APCs. The eluted peptides were then tested for their functional ability to stimulate autoimmune Th clones (253). Of the three major eluted peptides, peptide homologous to histone H122–42 stimulated autoimmune Th cells to augment the production of antinuclear autoantibodies. This peptide potently accelerated lupus disease in SNF1 mice and stimulated T cells from young unprimed SNF1 mice. T cells reactive with this peptide cross-reacted with other core histone epitopes, but not with other lupus autoantigens.

Employing Professional APCs to Assist in Mapping of Th Auto-Epitopes

One group pulsed bone marrow-derived DCs with lupus autoantigens U1A protein (254) or nucleosome (255) and tested in vitro recall T cell responses to individual epitopes. The authors found this approach to be highly efficient for detecting in vitro responses of freshly isolated T cells from unprimed lupus ((NZB/NZW)F1) mice. Several potential auto–T cell epitopes of core histone proteins (H2A, H2B, H3, and H4) were identified using this approach. Intradermal immunization with one of these peptides, H3(111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129 ,130), suppressed anti-dsDNA and anti-ssDNA IgG levels and delayed the progression of glomerulonephritis in lupus-prone (NZB/NZW)F1 mice. These investigators are also using bone marrow-derived DCs to modulate in vivo T cell responses in lupus mice. Thus, nucleosome-pulsed bone marrow-derived DCs elicit release of IL-4 and IFN-γ, representing a Th0 (i.e., mixed Th1 and Th2) pattern of cytokine production. Such modulation of T cell responses to autoantigens might be of therapeutic benefit.

Identification of Self-Epitopes in Human SLE

Human T cells reactive with several lupus autoantigens including DNA-histones, the snRNP antigenic proteins Sm-B, Sm-D, U1–70kD, and U1-A, and heterogeneous RNP (hnRNP) A2 have been isolated from the peripheral blood of SLE patients, as summarized in a recent review (256). Datta et al. first described T cell lines from patients with SLE, which augmented the production of IgG anti-DNA antibodies ex vivo (257). Subsequent characterization of lupus autoantibody-promoting T cells by this group showed that these cells are usually $CD4^+$, can provide help to anti-DNA and anti-histone B cells, and use restricted CDR3 characteristic of antigen selection (258). In a further study (259), they tested 154 peptides spanning the entire length of core histones of nucleosomes for the ability to stimulate an anti-DNA autoAb-inducing Th clone, as well as $CD4^+$ T cell lines and freshly isolated T cells in PBMCs from 23 patients with SLE. In contrast to normal T cells, lupus T cells responded vigorously

to certain histone peptides, irrespective of the patient's disease status (Table 20-4). Interestingly, most of the peptides that activated human T cells from lupus patients were previously identified as T cell epitopes in lupus-prone mice (Table 20-4) (243 ,259). Several additional epitopes, including peptides 34–48 of H2A, 91–105 and 100–114 of H3, and 49–63 of H4, were also found to activate human T cells from lupus patients. Most of these sequences are located in the regions of histones that are accessible at the surface of nucleosome and that contain B cell epitopes targeted by lupus autoantibodies. Importantly, most T cell epitopes have multiple HLA-DR binding motifs, i.e., they are promiscuous with regard to their binding to HLA molecules. Thus, peptides containing these epitopes could potentially be used to treat many patients obviating the need for the development of individualized therapy.

To determine if Ig-derived peptides activate T cells from SLE patients, Williams et al. cultured PBMCs from 28 lupus patients and 13 healthy individuals with selected 16-mer peptides from two anti-DNA autoantibodies, B3 and 9G4 (260). Three of 13 healthy individuals (23%) versus 17 of 28 SLE patients (61%) had T cells that proliferated in response to at least one V region peptide. In another study, Linker-Israeli et al. (261) cultured 12-mer overlapping peptides from the VH of two anti-dsDNA antibodies, B3 and F51, with PBMCs from patients with SLE, their first-degree relatives or unrelated healthy individuals. The expression of early T cell activation markers, CD25 and CD69, and cytokines were determined by flow cytometry. SLE patients had significantly increased T cell activation markers and IL-4 secreting cells than either first-degree relatives or unrelated controls. A subsequent study was done by these investigators in a larger cohort (31 patients and 20 matched healthy controls) to analyze cytokine release by PBMCs in response to seven peptides from the CDR1/FR2 to CDR2/FR3 VH regions of human anti-DNA monoclonal antibodies (262) PBMCs from significantly higher proportions of SLE patients than controls responded to VH peptides by generating IFNγ and IL-10. Three peptides were more stimulatory in the SLE patients than controls. There was a skewing of the immune response to Th2 bias as the disease progressed from early to later stage. Although none of the peptides was restricted by any particular MHC class II allele, among responders there was increased prevalence of HLA-DQB1*0201 and/or DRB1*0301, alleles known to predispose to SLE. Thus, responses to some VH peptides are more frequent in SLE and vary with disease duration. Increased peptide presentation by SLE predisposing HLA molecules might permit brisker increased T cell responses to autoantibody peptides, thus increasing risk for disease.

Guided by their findings in the 16/6Id murine model (see above), Mozes et al. examined immune responses of SLE patients to peptides encompassing CDRs of a monoclonal anti-DNA antibody with a 16/6 Id. In contrast to the above data showing increased responses to anti-DNA derived peptides (260 ,261 ,262), peripheral blood lymphocytes (PBL) from significantly fewer patients (37%) than controls (59%) proliferated in response to one of the anti-DNA peptides (263). A subsequent study by the same group reported in vitro proliferation of PBLs from 24 of the 62 SLE patients tested following stimulation with the human 16/6 Id (264). Interestingly, peptides from both the human and murine anti-DNA autoantibodies specifically inhibited the 16/6 Id-induced proliferation and IL-2 production. The latter inhibitions correlated with increased production of TGF-ß. This study suggested that certain anti-DNA peptides may downregulate autoreactive T cell responses in SLE patients. Indeed, treatment of severe combined immunodeficient (SCID) mice engrafted with PBLs of patients with SLE by repeated incisoproximal administration of a human monoclonal anti-DNA autoantibody peptide (hCDR1) suppressed human anti-dsDNA antibodies but not antitetanus toxoid antibodies (265). Such treatment also reduced proteinuria and renal deposits of human IgG and murine complement C3 in the engrafted SCID mice.

Human T cells reactive with various snRNP antigens, including Sm-B, Sm-D, U1–70kD, and U1-A, have been identified and characterized (256). Subsequent studies on snRNP-reactive human T cell clones showed that they typically exhibit TCRαß$^+$ CD4$^+$ CD45RO$^+$ phenotype, recognize antigen in the context of HLA-DR, and produce substantial amounts of IFN-γ, moderate quantities of IL-2, and variable amounts of IL-4 and IL-10 (266). Further, these cells can also provide help for relevant autoantibody production in vitro (267). Talken et al. (268 ,269) established two sets of T cell clones from patients with connective tissue diseases: one set reacted with Sm-B autoantigen and the others recognized U1–70kD polypeptide. Both sets of T cell clones had a highly restricted TCR CDR3 ß or α chain gene usage, respectively. Further analysis revealed that the Sm-B-reactive T cell clones recognized a peptide, Sm-B248–96 in the context of HLA-DR. Subsequent T cell epitope mapping studies of human T cell clones reactive with the snRNPs U1–70kD, Sm-B, and Sm-D revealed that there are limited T cell epitopes on these proteins and that almost all reside within functional regions of the protein; either within the Sm motifs for Sm-B and Sm-D or within the RNA binding domain for U1–70kD.

In another study, synthetic 15-mer overlapping peptides spanning the entire La sequence were cultured with PBMCs from patients with SLE and controls with a goal to identify T cell epitopes in the La antigen. They found significant, albeit a low-level, T cell proliferative response to a peptide (La 49–63) in HLA DR3$^+$ patients or healthy controls (270). This study highlights difficulties in identifying relevant pathogenic T cell epitopes using PBMC-based T cell proliferation read-out experiments. The study further suggests that the presence of self peptide-reactive T cells in the peripheral blood of healthy individuals is not uncommon. Thus, mechanisms other than loss of central tolerance might be involved in avoiding pathologic autoimmunity.

As described above, Muller et al. identified a CD4$^+$ T cell epitope in peptide sequence encompassing residues 131–151 of the spliceosomal U1–70K snRNP protein (RIHMVYSKRSGKPRGYAFIEY) and its analog phosphorylated at Ser140 (called P140; RIHMVYSKRS(P)GKPRGYAFIEY) in

the MRL-lpr and (NZB/NZW)F1 lupus models (238 ,271). Importantly, administration of the phosphorylated peptide P140 ameliorates the clinical manifestations of treated MRL-lpr mice (238 ,239). Since this peptide sequence that is completely conserved in the mouse and human U1–70K protein contains an RNA-binding motif often targeted by antibodies from lupus patients and mice, they investigated these peptides as potential candidates for the treatment of patients with lupus (271). Binding assays with soluble HLA class II molecules and molecular modeling experiments indicate that both peptides behave as promiscuous epitopes and bind to a large panel of human DR molecules. In contrast to normal T cells and T cells from non-SLE autoimmune patients, PBMCs, and/or $CD4^+$ T cells from 40% of SLE patients proliferate in response to peptide 131–151. Interestingly, the phosphorylated analog peptide P140 prevents $CD4^+$ T cell proliferation but not secretion of regulatory cytokine IL-10. Thus, P140 can serve as a "universal" immunomodulatory T cell epitope.

Thus, patients with SLE have circulating T cells that recognize diverse sets of autoantigenic peptides, which include core histone peptides, Sm-B, U1–70kD, and peptides derived from the V region of autoantibodies. The significance of these T cells in the disease pathogenesis remains to be fully understood. Such studies, particularly those identifying immunomodulatory epitopes in autoantigens, have potential to lead to antigen-specific therapies for SLE in humans.

Autoantigen-Based Vaccination and Peptide Therapies in Lupus

Current therapeutic modalities for lupus include immunosuppressive regimens, such as corticosteroids and cyclophosphamide, which are often administered at high doses. Although these treatments have been successful to a substantial degree in reducing mortality, they are associated with the development of numerous side effects and long-term complications. To avoid such drawbacks associated with immunosuppressive therapy several groups have focused on antigen-specific therapies.

Tolerizing DNA-Specific B Cells

Because many pathogenic autoantibodies bind DNA, there have been attempts to tolerize DNA-specific B cells. For example, more than 30 years ago, Borel et al. showed that it is possible to prevent lupus in an animal model by inducing tolerance to denatured DNA (272). About 15 years later, this finding was translated into human disease by showing that a DNA–IgG conjugate inhibits the formation of anti-dsDNA antibodies in vitro by lymphoid cells from SLE patients (273). Such studies eventually led to a clinical trial to evaluate a dsDNA-directed B cell tolerogen, a synthetic molecule with the ability to bind dsDNA antibodies, thus leading to anergy or apoptosis of B cells, which has shown delayed renal flares and reduction of anti-dsDNA antibodies in a subgroup of patients (274).

Tolerizing Lupus Th Cells

The above DNA-based tolerogen, however, has had a limited success in human SLE to date. Since strong evidence favors the requirement of T cell help for pathogenic autoantibody production (211 ,275), several groups have focused on strategies based on peptides that will specifically target autoreactive T and B cells. These approaches have mostly focused on identification of peptide sequences which can modulate autoimmune response, as summarized in Table 20-4 . Treatment with many of these peptides tolerizes pathogenic Th cells and/or induces regulatory or inhibitory T cells that suppress pathogenic Th or B cells. Such peptide-specific tolerance results in suppressed autoantibody production and lupus manifestations in murine models (102 ,173 ,275). Ongoing studies are trying to map such epitopes in humans (259 ,262). One clinical trial using an analogous peptide is in progress (264 ,265 ,275). Most studies using peptides to modulate lupus are described above and some are described in the following paragraphs. Table 20-4 provides a summary of these peptide and related therapies.

Degenerate recognition or cross-reactivity based on seemingly different peptides can occur in lupus. Thus, a single T cell hybridoma established from a (NZB/NZW)F1 mouse immunized with one self-Ig peptide recognizes several Ig-derived determinants, which had little sequence homology with the immunizing peptide (204). Such T cell recognition was not completely degenerate, as foreign peptides did not stimulate the self-reactive hybridoma. Such degenerate cross-recognition has also been described in humans with SLE. Thus, a single TCR on a human snRNP-reactive T cell clone can recognize two distinct snRNP autoantigenic peptides that have no apparent sequence homology (276). Similarly, a peptide SmD183–119 of SmD1 protein (D1 protein of the Smith [Sm] proteins, part of snRNP) activates T cell help for anti-dsDNA antibody production in (NZB/NZW) F1 mice (277). Importance of these studies is that tolerogenic treatment with one peptide should lead to tolerance in all cross-reactive T and B cells. Indeed, induction of high dose tolerance to the SmD183–119 peptide by IV injections of 600–1000 μg per month delays the production of autoantibodies including anti-dsDNA antibodies, postpones the onset of lupus nephritis, and prolongs survival (278). Tolerance to this peptide can be adoptively transferred by $CD90^+$ T cells, which also reduce T cell help for autoreactive B cells in vitro. The treatment was associated with increased frequencies of $IL\text{-}10^+/IFN\text{-}\gamma^+$ $CD4^+$ type 1 regulatory T cells, which can also prevent autoantibody generation and anti-CD3-induced proliferation of naive T cells.

Above studies on antigen-based therapies have mostly used parenteral routes of peptide administration. Mucosal delivery of peptides by oral feeding or nasal instillation can also induce strong peptide-specific tolerance in Th cells and suppress autoimmune diseases. The efficacy of mucosal tolerance has also been tested in lupus-prone mice (279). Nasal instillation of a histone peptide H471 that expresses a dominant T cell epitope in the histone protein H4 of mononucleosome induces a dose-dependent tolerance to the peptide H471 as well as to the whole mononucleosomes

in lupus-prone SNF1 mice. This is accompanied by an increase in IL-10 and suppression of IFN-γ production by lymph node cells. Furthermore, chronic nasal instillation of mice with the H471 peptide suppresses the development of autoantibodies and reduces the severity of glomerulonephritis in lupus-prone SNF1 mice. Such nasal tolerance restores the numbers of $CD4^+CD25^+$ Treg cells, which these authors found to be reduced in lupus-prone (NZB/NZW) F1 and SNF1 mice (280).

In preceding sections, we have described induction of tolerance in Th cells that mostly augment production of autoantibodies against nuclear and nucleoprotein antigens. Humans and mice with lupus also develop autoantibodies and T cells against cell- or tissue-specific protein antigens. For example, $CD4^+$ T cells from NZB mice respond to the anion channel protein band 3, a major target of the pathogenic red blood cell (RBC) autoantibodies in these mice. A band 3 peptide 861–875 is a dominant T cell epitope recognized by NZB T cells. Injection of NZB mice with the peptide 861–874, which is insoluble, accelerates the development of RBC-bound autoantibodies and autoimmune hemolytic anemia. Inhalation of this peptide also primes T cells for both peptide-specific and whole band 3 responses. By contrast, inhalation of a soluble analog (Glu861, Lys875) of this peptide deviated the autoimmune response toward a Th2 profile with increased IgG1 RBC-bound IgG, and reduced severity of anemia (281).

Other Non-T–Cell Based Peptide Therapies

Laminin Peptide Competitive Analogs to Inhibit Autoantibody Binding and Deposition in Tissues

Naparstek et al. have shown that murine pathogenic lupus autoantibodies bind to the laminin component of the extracellular matrix. Further analysis showed reactivity of these autoantibodies with a 21-mer peptide located in the globular part of the α-chain of laminin. Immunization of young lupus-prone mice with this peptide accelerated renal disease. They further found that the binding of lupus autoantibodies to the extracellular matrix could be inhibited in vitro by some competitive peptides that cross-react with the antilaminin antibodies. Treatment of MRL-lpr mice with these peptides prevented antibody deposition in the kidneys, ameliorated renal disease, and prolonged survival of the peptide-treated mice (282).

Mechanisms of Peptide-Based Therapies in Lupus

Neonatal Peptide Tolerance

Can peptide vaccines worsen lupus? Our initial attempts to tolerize lupus-prone mice met with difficulty. IP injections of a peptide emulsified in incomplete Freund adjuvant (IFA) were given to newborn mice. Most mice had excellent tolerance of type 1 T cell responses, but had activation of type 2 responses; peptide-specific T cell proliferation, and IL-2 and IFN-γ secretion was suppressed, but peptide-specific IgG antibodies, and secretion of IL-4, IL-5, and IL-10 was increased. This type of split T cell tolerance was associated with increased anti-DNA autoantibody production in (NZB/NZW) F1 mice (101). Induction of a similar split tolerance in adult mice was also associated with increased peptide-specific antibodies and type 2 cytokine production (Singh, unpublished observations).

Induction of "Direct" Tolerance in Th Cells

Subsequently, we found that IV administration of high doses of soluble peptides tolerizes both type 1 and type 2 T cell responses, and strongly suppresses peptide-specific T cell proliferation and antipeptide antibody responses, presumably through induction of apoptosis (102 ,283) (Singh, unpublished observations). This strategy successfully suppressed anti-dsDNA antibody production, delayed the onset of nephritis, and prolonged survival in young (NZB/NZW)F1 mice.

Inhibiting Determinant Spreading

Kaliyaperumal et al. (234) recently reported that IV administration of histone peptides in 18-month-old SWR/NZB F1 mice strongly suppressed autoantibody response to several antigens, a phenomenon they termed as "tolerance spreading." The anergy, deletion, suppression, or immune deviation that are classical mechanisms of tolerance induction did not appear to be operative in their system. Instead, they suggested that competition for MHC loading or modulation of some unknown signals involved in T-B cell interactions might have been responsible for tolerance induction in their model (234). In another study, Hahn et al. showed that treatment with a consensus anti-DNA variable region-based peptide not only reduced anti-DNA antibody levels, but also decreased the production of autoantibodies that bind nucleosome and cardiolipin (230), suggesting the spreading of tolerance to structurally unrelated lupus autoantigens.

There are also reports where treatment with autoantigenic peptides can accelerate disease spreading of pathogenic T cell responses to other epitopes or determinants. As a reminder, epitope or determinant spreading has been proposed as an important process, whereby the T cell responses spontaneously broaden from one part of an autoantigen to other parts of the same autoantigen as well as to other autoantigens during the progression of autoimmune diseases (201). In the NOD model of autoimmune diabetes, Tian J et al. found that treatment of newborn mice with an autoantigenic ß-cell peptide (in adjuvant) results in spreading of T cell response to other ß-cell autoantigen determinants, far in advance of when autoimmunity would have naturally arisen to these determinants. Thus, rather than limiting the loss of self-tolerance, immunotherapy caused the natural spreading hierarchy to be bypassed and autoreactivities to develop precociously (284). This study further underscores the need for caution in the clinical application of antigen-based immunotherapeutics in autoimmune disorders.

Induction of Regulatory T Cells and Cytokines

As discussed above, the nonautoimmune mouse strains can curtail pathologic autoimmunity by generation of autoantigenic peptide-reactive $CD8^+$ inhibitory T cells, which produce TGF-ß (34 ,169 ,172 ,174). TGF-ß produced by these cells appears to be important in their ability to inhibit autoantibody production, as the addition of an anti–TGF-ß antibody to cultures abrogates the inhibitory effect. Recent studies have further demonstrated an important role of TGF-ß in autoantigenic peptide-mediated suppression of lupus-like autoimmunity in (NZB/NZW) F1 and other murine models of lupus. Further studies have shown that such peptide-induced $CD8^+$ inhibitory T cells express regulatory T cell molecule Foxp3 and are more resistant to apoptosis than $CD8^+$ T cells from unprimed (NZB/NZW) F1 mice (177).

Most above studies have used high-dose peptide treatment regimens, which might induce allergic/anaphylactic reactions (285). To address this issue, a recent study showed that repeated low-dose treatment of lupus-prone (SWR × NZB)F1 (SNF1) mice by subcutaneous injections of 1 µg of highly conserved histone auto-epitopes suppresses IFN-γ responses of pathogenic lupus T cells, diminishes autoantibody production, delays nephritis and prolongs life span, without causing allergic/anaphylactic reactions or generalized immunosuppression (173). The protective effect is mediated through the generation of long-lasting, TGF-ß–producing $CD8^+$ and $CD4^+CD25^+$ Treg cells, which can suppress autoimmunity.

Induction of Cytotoxic T lymphocytes (CTL) That Ablate Autoreactive B Cells

Fan and Singh identified MHC class I–binding epitopes in the VH regions of anti-DNA monoclonal antibodies. The $CD8^+$ T cells reactive with these peptides elicit CTL responses against anti-DNA B cell hybridomas as well as B cells from diseased (NZB/NZW) F1 mice in vitro. This ablation of anti-DNA B cells occurs in a peptide-specific manner, as B cells that do not express Ig containing the relevant VH epitope are not subjected to killing. Induction of such CTLs in vivo is associated with reduced IgG anti-DNA antibody production (172).

Inhibiting T Cell Chemotaxis

In an experimental model of SLE induced in mice by immunization with a human anti-DNA mAb that expresses 16/6Id, treatment with a peptide located in the CDR1 of an anti-DNA mAb ameliorates the clinical manifestations of SLE and downregulates, ex vivo, the 16/6Id-induced T cell proliferation. The beneficial effects of the treatment with this peptide are associated with down-regulation of IFN-γ, IL-10, and TNF-α secretion and upregulation of the immunosuppressive cytokine TGF-ß in serum and in splenic cells cultured ex vivo (175 ,176 ,286). Further studies in this model suggested that TGF-ß–induced suppression may be mediated by downregulation of ERK phosphorylation, stromal cell-derived factor-1 α (SDF-1α; CXCL12)-induced T cell adhesion and migration, and expression and function of cell adhesion receptors LFA-1 (αLß2) and CD44 (287). The peptide-treated mice have reduced SDF-1α–induced T cell chemotaxis through fibronectin and collagen type I. SDF-1α is a pleiotropic CXC chemokine that affects the function of various cell types, including T cells, via its interactions with the CXCR4 receptor. The SDF-1α also regulates leukocyte proliferation, survival, and entry into sites of inflammation, and activation of T cells within blood vessels and in extravascular sites, where it can act either in its matrix-bound or soluble forms (288 ,289). Therefore in some models, the beneficial effects of peptide treatment may be mediated by affecting the chemotaxis and interaction with the extracellular matrix of autoreactive T cells.

Inhibiting Autoantibody Binding to Extracellular Matrix

As described above, treatment with certain laminin peptide analogs that cross-react with the antilaminin antibodies can suppress lupus disease in MRL-lpr mice. The authors suggested that the beneficial treatment correlates with the ability of these peptides to directly inhibit the binding of lupus autoantibodies to the extracellular matrix (282).

In summary, it appears that the mechanism of tolerance and peptide therapy depends on the nature of individual autoantigen or peptide, its form, dose, and route of delivery, and the state of T cell activation in the host. One peptide derived from anti-DNA IgG VH is in clinical trial at the time of this writing (January 2006). Generally, however, the variables listed would have to be individually worked out for different disease states and for autoantigens before other such therapy would be applicable to humans.

Will Peptide-Specific Treatment Ever Be a Reality, Since Patients with SLE Have a Highly Diversified and Polyclonal T and B Cell Repertoire?

Recent work from several laboratories suggest that, in contrast to the widely held notion that one autoimmune disease is caused by one or a few related autoantigenic epitopes, autoimmunity is fundamentally a continuously evolving process. The autoimmune responses shift, drift, and diversify with time not only to other epitopes in the original antigen but also to other antigens (101 ,290). Compared to many organ-specific autoimmune diseases, humans and mice with SLE develop a widespread polyclonal T and B cell activation (109 ,291). It is, therefore, not surprising that self-peptides of several different specificities are eluted from MHC class II molecules of lupus mice (251). Interestingly, the T cell activation although polyclonal is restricted to a set of autoantigens (204).

Several different mechanisms have been suggested to account for such “restricted polyclonality” in lupus. First, Craft et al. reported that it is the intrastructural organization of the autoantigenic complex that determines the restricted polyclonality in lupus mice (292). Secondly, Shi et al. (293) demonstrated a remarkable “promiscuity” in the recognition of histone peptides by T cells that induce pathogenic autoantibody production. Thirdly, we reported that Ig-derived T cell

epitope sequences are recurrent among lupus-associated autoantibodies of different specificities but are uncommon in the normal antibody repertoire (170 ,204). Based on this observation, we hypothesize that such sharing of T cell epitopes among various autoantibody V region sequences is responsible for restricted polyclonality in lupus. Thus, activation of T cells reactive with one or a few epitopes initially would drive activation of several B cells that display the shared peptide motif. These mechanisms are summarized in a recent review article (200).

Further complicating the issue of antigen therapies is the presence of polymorphisms in the HLA regions, thus requiring formulation and testing of expensive individualized therapy. Anticipating this problem, investigators are attempting to develop consensus and/or promiscuous autoantigenic epitopes that can bind many HLA molecules and modulate a broad repertoire of self-reactive T cells (170 ,200 ,230 ,293). For example, Kaliyaperumal et al. (234) used a set of highly promiscuous, nucleosomal epitopes that bind many MHC molecules across the species barrier and Hahn et al. (230) designed an artificial “consensus” Ig-based peptide that could suppress autoreactivities to several different autoantigens. Similarly, a $CD4^+$ T cell epitope in the spliceosomal U1–70K snRNP131–151 and its phosphorylated analog P140 can bind multiple HLA-DR molecules and suppress human T cell proliferation, thus serving as a “universal” T cell epitope (271). Parallel efforts in this area in humans and mice offer hopes for developing antigen-specific therapies for SLE. In fact, Teva Pharmaceuticals has already completed a phase I clinical trial in SLE patients using human anti-DNA antibody-derived peptides and a phase II trial is in progress in 2006. It is important to emphasize that a rigorous characterization of the exquisite T cell epitopes that activate regulatory and suppressor T cells versus those that stimulate pathogenic Th cells, in humans is critical to ensure that we do not run into premature disappointment, as seen in some other antigen therapy trials. Complicating the selection of peptides for treatment, our murine studies suggest that suppressor and Th cell epitopes might colocalize or overlap (170), as if nature has done a fine balancing act by putting together the “protective” and “pathogenic” epitopes.

Peptide-Specific Therapy: Lessons from Other Autoimmune Diseases

A large body of work in animal models of organ-specific autoimmune diseases suggests that tolerance-inducing treatments with autoantigenic peptides can be successfully used to suppress autoimmunity in experimental myasthenia gravis, autoimmune neuritis, EAE, and collagen-induced arthritis (285 ,294 ,295 ,296 ,297 ,298 ,299). Such treatments have also been attempted in human diseases such as rheumatoid arthritis with modest success (300). It may be important, however, to remind here that tolerance strategies and mode of peptide delivery that provide beneficial response in organ-specific diseases might not be applicable to SLE. For example, administration of peptides emulsified in IFA that induces peptide-specific immune deviation toward type 2 T cell response prevents subsequent induction of EAE and other organ-specific diseases (301). Similar treatment using an Ig-derived peptide, however, enhanced anti-DNA antibody levels in one study (101). This differential effect might be a result of differences in the nature of autoimmune pathology between the two types of diseases: inflammation in organ-specific autoimmune diseases is mostly mediated by type 1 T cells, whereas both type 1 and type 2 cytokines appear to be important for tissue damage in SLE.

In autoimmune diabetes that results from autoreactive T cell responses directed against multiple pancreatic ß-cell antigens, a phase II clinical trial with glutamic acid decarboxylase (GAD65) antigen in patients having GAD65 autoantibodies was associated with an increase in potentially regulatory $CD4^+CD25^+$ T cells (302). Generally, however, some antigen-specific therapies that readily inhibited autoimmune diabetes in animal models have been problematic or ineffectual when moved to human clinical trials. Studies in mouse models of diabetes indicate that the kinetics and frequency at which ß-cell autoreactive T cell responses are generated against major ß-cell autoantigens varies greatly in individual diabetic mice (303). If ß-cell autoreactive T cells with various specificities also develop in such a stochastic fashion during the course of diabetes development in humans, it would be very difficult to determine what antigen-based immunotherapy would be most efficacious for any given individual. This suggests that the stochastic development of autoreactive T cell responses may indeed be a hurdle that must be overcome in developing autoimmune disease prevention protocols for use in humans. Thus, we must adopt cues from such successes and failures in animal models and clinical studies in other autoimmune diseases to formulate the research agenda for successful antigen-specific therapies for lupus.

Gene Vaccination Approaches for SLE

Peptide “Minigene” Vaccines to Suppress Lupus

We have recently demonstrated that the VH of anti-DNA antibodies contain epitopes that can be processed efficiently owing to their high cleavage probability score to bind MHC class I molecules (172). We hypothesized that $CD8^+$ CTLs reactive with such Ig VH epitope will recognize and lyse B cells that can process and display the relevant VH epitope on their surface class I molecule. We found, however, that it is generally difficult to induce $CD8^+$ CTLs in lupus mice. Since antigen delivery via a plasmid DNA or viral vectors generally elicits strong peptide-specific $CD8^+$ T cell response (295 ,304), we surmised that delivery of Ig VH epitopes via plasmid DNA vectors as minigenes might elicit CTL responses in lupus mice. Indeed, vaccination of (NZB/NZW) F1 mice with plasmid DNA vectors that encode such epitopes activates CTL responses against anti-DNA antibody producing B cells, inhibits anti-DNA antibody production, retards the development of lupus nephritis, and prolongs survival (172). We have been able to induce similar anti-VH

CTL responses in lupus-prone mice by delivering MHC class I-binding VH epitopes conjugated to CpG-oligodeoxynucleotides (305). Thus, minigene mediated induction of anti-VH CTLs that can ablate autoreactive B cells represents a novel approach to treat autoantibody-mediated diseases.

A recent study used autoantigen-specific T cells for the local delivery of therapeutic molecules (306). They engineered nucleosome-specific regulatory T cells by multiple gene transfer (nucleosome-specific TCR-α, TCR-β, and CTLA4Ig). Treatment with these engineered cells suppressed pathogenic autoantibody production and nephritis in (NZB/NZW)F1 mice without impairing the T cell–dependent humoral immune responses. Thus, autoantigen-specific regulatory T cells engineered by multiple gene transfer is a promising strategy for treating autoimmune diseases.

Establishing Immune Tolerance in SLE by Approaches Other Than Peptide-Specific Therapies

Studies from animal models of other autoimmune diseases such as diabetes suggest that some “nonspecific” immunomodulations that inhibit autoimmune disease, and because of their general ability to improve tolerance induction mechanisms, may prove more successful in preventing disease in high risk humans than antigen-based therapies (303). For example, as described above, a recent study has identified one mechanism by which T cells from patients with SLE avoid peripheral tolerance. The study found that lupus T cells selectively use the COX-2/FLIP antiapoptosis program to resist anergy (107). Interestingly, such defect in lupus T cells can be reversed in vitro by some, but not all, COX-2 inhibitors, which cause apoptosis of the anergy-resistant T cells and suppress the production of pathogenic autoantibodies to DNA. Thus, further understanding of the mechanisms of peripheral T cell tolerance in lupus and translating those findings to clinical trials can open new avenues for treatment.

Aberrant expression and regulation of costimulatory signals have been implicated in the breakdown of T and B cell tolerance in SLE. These studies have prompted human SLE trials including soluble CTLA4-Ig fusion protein that blocks T cell–dependent B cell functions (307). Treatment of lupus-prone mice with CTLA4-Ig in combination with TACI-Ig (that blocks BAFF) results in the delayed onset of proteinuria, which is associated with prolonged depletion of B cells past the T1 stage, and a decrease in the absolute number of activated and memory $CD4^+$ T cells (308). Thus, blockade of T cell–mediated costimulation in human SLE might repair tolerance defects in autoreactive cells.

Studies of B cells from SLE patients undergoing B cell depletion therapy using rituximab suggest that apparently nonspecific therapies may repair the specific tolerance defects in SLE (309). Thus, CD20-targeted B cell depletion effectively normalizes the significant disturbances in peripheral B cell homeostasis that typically occur in SLE, including naive lymphopenia, expansion of a novel population of IgD/CD27 double-negative cells, the presence of plasma cell precursors, and expansion of autoreactive memory B cell populations (310). Stem cell transplant could also be another method of resetting normal tolerance in all immune cells. Finally, repairing epigenetic defects, such as by treatment with histone deacetylase inhibitors, such as trichostatin A, which correct these impairments and suppresses lupus in mice (140) holds promise for human SLE.

It is important to mention here that most studies have focused on the prevailing notion that T cell–mediated production of autoantibodies that cause tissue damage underlies the pathogenesis of lupus. Challenging this notion are some recent studies, where lupus-associated organ damage can be “uncoupled” from the production of antinuclear autoantibodies (2 ,185 ,311 ,312). Consistent with this idea, some individuals have high levels of antinuclear autoantibodies but no SLE-associated organ damage, whereas many SLE patients with end organ damage have no antinuclear autoantibodies. In some cases, autoantibodies deposit in tissues, but do not cause any local inflammation and damage. Studies in other autoimmune diseases also provide credence to this idea. For example, the presence of autoantibodies to β-cell antigens is not always related to the clinical onset of hyperglycemia and diabetes (302). These studies, however, do not exclude the possibility that the more relevant pathogenic autoantibodies may differ in antigen specificity, binding affinity and Ig isotype and/or subclass, making their detection more difficult. It is also possible that autoantibodies may contribute to tissue lesions in some individuals, but not in others. Additionally, autoimmunity may play a role in the initiation, but not in perpetuation, of tissue lesions.

Synthesis

Immunologists have been fascinated with the idea of identifying the disease-specific autoantigen(s) and using them in antigen-specific therapies (275 ,285 ,313 ,314 ,315 ,316). This task becomes particularly difficult in SLE, where, in contrast to organ-specific autoimmune diseases, there is no organ-specific autoantigen target. Painstaking efforts by several laboratories have led to identification of peptides that activate potentially pathogenic Th cells. A diverse group of self-antigens appear to be the source of these peptides. It is likely that peptides from several different antigens activate autoreactive Th cells that promote autoantibody production and disease in SLE. Probably, an interconnected circuitry of reciprocal T-B–cell recognition drives the spreading of response from one T cell to another until a massive expansion of diverse arrays of T and B cells has occurred. Such T-B–cell diversification might pose difficulty for designing antigen-specific therapies. The good news, however, is that tolerogenic treatment with one or just a few peptides appear to quell autoimmune responses against a variety of autoantigens. Such peptide treatments appear to retard the progression of nephritis and prolong the survival in lupus-prone mice. While we have

a long way to go to understand these processes in mice and humans with lupus, the initial studies in lupus mice offer new hope for similar treatment approaches in patients with SLE. Remarkably, striking similarities exist between peptides that appear to activate T cells in patients with SLE and peptides that activate Th cells that induce autoantibodies that cause disease in lupus mice. However, experience in other autoimmune diseases such as type 1 diabetes has taught us that rush to clinical trials using autoantigenic peptides must not occur without full realization that the biologic basis by which a tolerogenic therapy may suppress disease in an animal model may not be directly translatable to humans. Further, we must fully understand the mechanisms and pathways of loss of tolerance in self-reactive T cells in both animals and humans. In that regard, different models, including different animal strains and human peripheral blood cells, tonsils, and spleen, and diverse methodologies are being used to uncover tolerance defects in SLE. These studies reveal that whereas breakdown of central tolerance involving positive and negative selection in bone marrow or thymus might explain lupus-like autoimmunity in some instances, impaired peripheral tolerance appears to confer self-reactivity in many cases. In the periphery, these impairments in SLE involve breakdown of anergy or deletion of autoreactive cells or loss of normal censoring at different checkpoints during the development of immune responses. Whereas impairments at the level of APCs, adhesion, constimulation and interactions between different immune cells, and lymphoid organization such as faulty germinal center exclusion of autoreactive B cells might explain the loss of normal censoring in some cases, intrinsic ability of lupus T and B cells to become easily overexcitable might be responsible for lupus-like autoimmunity in other cases. Full understanding of these mechanisms might open new therapeutic avenues that do not depend on rigorous antigen specificity but will be based on repairing the alterations in specific immune mechanisms. Finally, some SLE patients may come to clinic at a late stage when their disease cannot be tackled by repairing faults in immune tolerance. Recent studies have also begun to unravel that faulty immune tolerance might not be the cause of lupus disease development in some cases. For such cases, we must understand the mechanisms of end organ damage.

Section III
Autoantibodies

Chapter 21

The Structure and Derivation of Antibodies and Autoantibodies

Giovanni Franchin

Chaim Putterman

Betty Diamond

The humoral immune response protects an organism from environmental pathogens by producing antibodies (immunoglobulins) that mediate the destruction or inactivation of microbial organisms and their toxins. To perform this function, the immune system generates antibodies to a diverse and changing array of foreign antigens, yet it must do so without generating pathogenic antibodies to self. The production of high-affinity antibodies that bind to self-determinants is a prominent feature of systemic lupus erythematosus (SLE) (1). Some autoantibodies in SLE are considered markers for disease (anti-Sm/ribonucleoprotein [RNP], antinuclear antibody), because they have no established pathogenicity; others play a role in disease pathogenesis and cause tissue damage (anti-DNA, anticardiolipin, anti-Ro) (2 ,3 ,4 ,5 ,6).

There have been extensive investigations of autoantibodies in SLE, which address a number of specific questions:

- Do polymorphisms of immunoglobulin variable region genes contribute to disease susceptibility?
- Do B cells producing autoantibodies arise from an antigen-triggered and -selected response? If so, are these triggering and selecting antigens self or foreign?
- Are particular B cell lineages or differentiation pathways responsible for autoantibody production?
- What are the characteristics of pathogenic autoantibodies, and how do they mediate pathology?
- What defects in immune regulation permit the sustained expression of pathogenic autoantibodies?

This chapter discusses autoantibody structure, assembly, and regulation. Based on new advances in our knowledge of autoantibody structure and regulation, novel potential therapeutic strategies are also briefly addressed.

Structure of the Antibody Molecule

Antibodies are glycoproteins produced by B lymphocytes in both membrane-bound and secreted forms. They are composed of two heavy chains and two light chains. Generally, the two heavy chains are linked by disulfide bonds and each heavy chain is linked to a light chain by a disulfide bond. The intact molecule has two functional regions: a constant region that determines its effector functions, and a variable region that is involved in antigen binding and is unique to a given B cell clone (7) (Fig. 21-1). The light chains appear to contribute solely to antigen binding and are not known to mediate any other antibody function. In contrast, the heavy chains possess a constant region that determines the isotype (i.e., class: immunoglobulin M [IgM], IgD, IgG, IgA, or IgE) of the antibody molecule (Fig. 21-2). Rarely, the same variable region associated with a different constant region may display an altered binding to antigen and the constant region may infrequently help determine the antigenic specificity of the antibody (8 ,9). IgM is the first isotype produced by a B cell and the first to appear in the serum response to a newly encountered antigen. IgM antibodies normally polymerize into pentamers known as macroglobulin, thus conferring higher functional binding strength, or avidity. A 15-kd glycoprotein called the J chain is covalently associated with the pentameric IgM, and mediates the polymerization process (10 ,11). IgM antibodies can activate complement via the classic pathway and therefore cause lysis of cells expressing target antigens. Under the appropriate conditions, B cells producing IgM can switch to the production of the other isotypes. IgG is the predominant isotype of the secondary (also called memory) immune response. In humans, the IgG isotype is divided into four subclasses, IgG1, IgG2, IgG3, and IgG4, all of which possess different functional attributes. IgG1 is the most abundant in the serum. Antinuclear antibodies in SLE are mainly of IgG1 and IgG3 subclasses (12). In addition to activating complement, IgG antibodies can promote Fc-receptor (FcR)-mediated phagocytosis of antigen-antibody complexes. High concentrations of antigen-IgG complexes can downregulate an immune response by cross-linking membrane immunoglobulin and FcRII receptors on antigen-specific B cells. This may be an important mechanism for turning off antibody production after all the available antigen is bound to antibody, and there is some evidence for defective FcRII function in some lupus patients. The IgA constant region allows antibody translocation across epithelial cells into mucosal sites such as saliva, lung, intestine, and the genitourinary tract; IgA antibodies can be found as monomers in serum and as dimers in the mucous secretions. The J chain, implicated in IgM polymerization, is not required for IgA dimerization, but does have a role in

maintaining IgA dimer stability and is essential for transport of IgA by the hepatic polymeric Ig receptor (13). IgE antibodies can trigger mast cells and eosinophils, which are important cellular mediators of the immune response to extracellular parasites and cause allergic reactions.

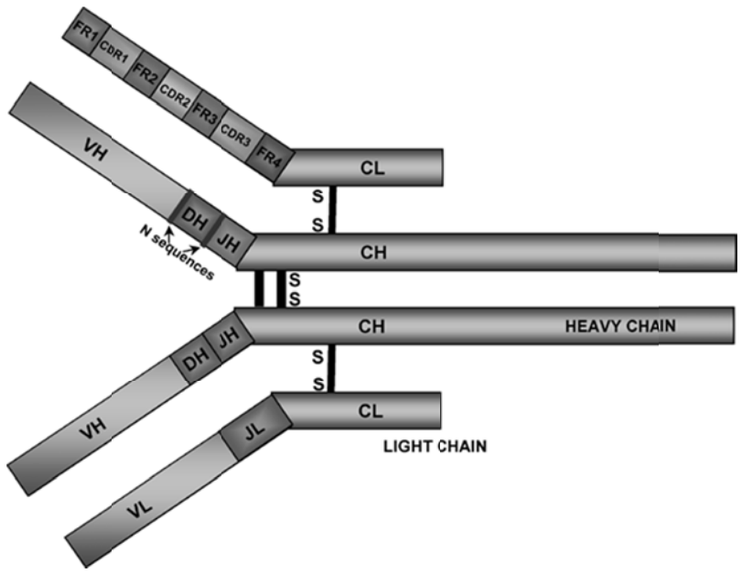

Figure 21-1. A prototypic antibody molecule. C, constant region; CDR, complementarily-determining region; D, diversity region; FW, framework region; J, joining region; V, variable region.

Every complete antibody has two identical antigen-binding sites, each of which is composed of the variable regions of a heavy and a light chain. When the variable regions from the light and heavy chain pair, the hypervariable segments or complementarily-determining regions (CDRs) come together and generate a unique antigen-binding site (Fig. 21-1). The antigen-binding site is divided into the highly polymorphic CDRs, and the more conserved framework regions (FRs). There are three distinct CDRs in both the heavy and light chain, and the most variable portion of the antibody molecule is the CDR3 (14 ,15). There are four FRs. Radiograph crystallographic studies have shown that the amino acids of the CDRs are arranged in flexible loops, while the FRs have more rigid structure that maintains the spatial orientation of the antigen-binding pocket (16), consistent with the fact that CDRs contain the contact amino acids for antigen binding and thus contribute more than the FRs to antigenic specificity.

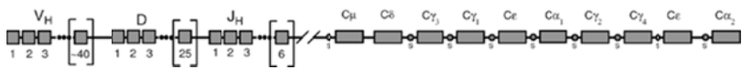

Figure 21-2. The heavy-chain immunoglobulin gene locus on chromosome 14. C, constant region; D, diversity gene locus; J, joining gene locus; S, switch region; V, variable gene locus.

Antibody molecules are Y-shaped structures that can be cleaved into functionally distinct fragments by proteases like papain and pepsin (17 ,18). Limited digestion with papain cleaves the antibody into three fragments: two identical Fab (fragment antigen binding) fragments and an Fc (fragment crystallizable) fragment. The Fab fragment consists of the entire light chain and the heavy chain variable region with the CH1 domain. It contains the antigen-binding site, which is formed by the variable regions of the light and heavy chain at the tip of each Fab fragment. The Fc fragment is composed of the two carboxy-terminal domains from the heavy chains, the hinge region and CH2 and CH3, and interacts with soluble and cell membrane bound effector molecules. The Fc fragment does not have antigen-binding activity. The Fab portions are linked to the Fc fragment at the hinge region, which allows independent movement of the two Fabs (19). Another protease, pepsin, cleaves the antibody molecule on the carboxy-terminal side of the heavy chain disulfide bridges producing several small fragments and an F(ab)2 fragment, that contains both Fabs linked to each other with an intact hinge region. F(ab)2 cannot be obtained from IgG2 by pepsin. However, lysyl endopeptidase digestion will generate F(ab)2

from IgG2 (20). Based on the fact that the F(ab)2 fragment has the same avidity for antigen as the intact antibody, but does not possess any effector functions, this cleavage product may have therapeutic applications.

The variable region of an antibody may itself serve as an antigen, called an idiotype. Anti-idiotypes are antibodies that bind to specific determinants in the CDRs or FRs of other antibodies (21 ,22) (Chapter 15). Antibodies that share the same idiotype presumably have a high degree of structural homology and may be encoded by related variable region genes (23). Idiotypes have been postulated to be important in the regulation of the immune response because they can be recognized by both T and B cells (24 ,25 ,26 ,27) (Chapter 15). Anti-idiotypic antibodies may therefore be useful reagents for tolerizing pathogenic autoantibody-producing B cells (see below).

Antibody Assembly

The immunoglobulin light and heavy chain variable region genes are formed by a process of rearrangement of distinct gene segments, permanently separated in the genome in all cells except B lymphocytes. In B cells these genes are rearranged by a process called somatic recombination. During this process, V (variable), D (diversity), and J (joining) segments are brought together to form a heavy chain variable region gene, and V and J segments to form a light chain variable region gene (28 ,29 ,30 ,31 ,32 ,33).

In humans, heavy chain V, D, and J gene segments each come from gene clusters that are randomly arrayed on chromosome 14 (33 ,34) (Fig. 21-2). The 50 to 100 functional heavy chain V segment genes are divided into seven families, which share 80% homology by DNA sequence primarily in FRs (35 ,36 ,37 ,38). V gene family members are interspersed randomly along the V locus. There are approximately 30 functional D gene segments and six known J gene segments for the human immunoglobulin heavy chain (38).

Each V, D, and J gene segment is flanked by conserved heptamer/nonamer consensus sequences that are crucial for the rearrangement process. The conserved heptamer is always most proximal to the coding sequence, followed by a 12- or 23-base pair (bp) spacer sequence, and then by the conserved nanomer. The length of the spacer corresponds to either one or two turns of the DNA double helix, which allows the heptamer and nanomer to be brought together on one side of the DNA helix and enables them to interact with the proteins that catalyze the recombination process. The heptamer-spacer-nanomer sequence is known as recombination signal sequence (39).

Assembly of the complete heavy chain gene begins with the joining of a D segment from the D cluster to a J segment in the J cluster, mediated by DNA cleavage and deletion of the intervening DNA. In a similar manner, a V gene segment is next rearranged to the DJ unit to form a complete VDJ variable region (28 ,37). This process of variable region recombination is very elaborate and requires a complex of enzymes called V(D)J recombinase (40). Most of these enzymes are also necessary for the maintenance of double-stranded DNA (dsDNA) and are present in all cells. However, for the first cleavage step, specialized enzyme products of the recombination activating-genes RAG-1 and RAG-2 are required (41). The proteins encoded by these genes are active in the early stages of lymphoid development. Signals from both stromal cells and the cytokines interleukin-3 (IL-3), IL-6, and IL-7 are necessary for induction of RAG genes in lymphoid progenitors (42). RAGs bind to the nanomer sequence and initiate VDJ recombination by generating dsDNA breaks at the end of the recombination signal sequence. Joining of the coding segments is mediated by several enzymes involved in repair of dsDNA breaks: Ku 70, Ku 80, DNA-PKs, XRCC4, ligase, and Mre 11 (43). Members of the high-mobility group family of proteins HMGl and HMG2 (44) also play a significant role in the formation and stabilization of the precleavage and postcleavage synaptic complex (45 ,46).

Antibody diversification can be further generated by the addition of P and N nucleotides at the VD and DJ junctions. If the single-stranded DNA (ssDNA) that is present after the break can form a hairpin loop, the resulting double-stranded (palindromic, P) sequences are added at the junction. Alternatively, N-nucleotides or nontemplate-encoded nucleotides, are randomly inserted at the VD and DJ junctions by the enzyme terminal deoxynucleoridyl transferase (TdT) (47). Such N sequences are common in antibodies of the adult immunoglobulin repertoire but are less frequent early in the ontogeny of the B cell repertoire (48). These random modifications create unique junctions and increase the diversity of the antibody repertoire. Because VDJ joining is imprecise and includes P and N sequences, CDRs of variable length and sequence are generated.

After generation of a functional heavy chain, the light chain gene segments can rearrange from either of two loci, κ or λ. The ratio of the two types of light chains varies in different species. For example, in mice the κ/λ ratio is 20:1, whereas in humans it is 2:1. Although the light chain isotype has in general not been found to influence main properties of the antibody molecule, it has been reported that λ light chain can contribute to a faster clearance of some IgG isotypes than the κ chain (49). The reason for this difference is unclear considering that light chain isotype is not expected to alter conformation of heavy chain second and third constant regions which are important for binding to FcR and subsequent clearance. The light chain variable region is composed of only two gene segments: V and J. Genes for the V and J segments of κ light chains are located on chromosome 2. The κ locus contains approximately 40 functional V gene segments, which are grouped into seven families, and five J segments (50 ,51 ,52 ,53 ,54). The λ light chain locus is on chromosome 22, and contains at least seven V gene families, with up to 70 members (55 ,56 ,57 ,58 ,59). As with the heavy chain, V and J elements of the light chain loci also rearrange by recombination at heptamer/nonamer consensus sites. Only rarely are N sequences inserted at the VJ junction of the light chain (60).

RAG gene expression is high in pro-B and pre-B cells. Once a heavy chain rearrangement successfully occurs, the heavy chain associates with a nonpolymorphic light chain,

termed surrogate light chain. The appearance of an Ig heavy chain with surrogate light chain on the cell surface of large pre-B cells coincides with inactivation of the RAG-2 protein. Degradation of both RAG-1 and RAG-2 messenger RNA (mRNA) occurs and there is no further heavy chain rearrangement. Later, RAG-1 and RAG-2 are again expressed and light chain gene rearrangement takes place. When a complete Ig molecule is expressed at the cell surface, RAG expression ceases (61).

The importance of the V(D)J recombination process has been demonstrated in animal studies as well as in some hereditary immune disorders. Mutations that abolish V(D)J recombination cause an early block in lymphoid development resulting in severe combined immune deficiency (SCID) with a complete lack of circulating B and T lymphocytes. Mice missing either RAG-1 or RAG-2 are unable to rearrange immunoglobulin genes or T cell receptor genes (62). In humans, a loss or marked reduction of V(D)J recombination activity can cause a T-B-SCID (63 ,64) or B-SCID phenotype (65). Mutations that impair but do not completely abolish the function of RAG-1 or 2 in humans result in Omenn syndrome, a form of combined immune deficiency characterized by lack of B cells and oligoclonal, activated T lymphocytes with a skewed T-helper-2 (Th2) profile (66). It is clear, however, from studies of immunodeficient mouse strains that additional gene products also are needed for successful rearrangement to occur. Defects in any of the components of the dsDNA break repair machinery such as Ku70, Ku 80, DNA PKs, DNA ligase IV, and XRCC4 lead to an immunodeficient phenotype with increased radiation sensitivity as a common feature (67).

While the rearranged heavy chain VDJ segment is initially associated with an IgM constant region gene, it can undergo a second kind of gene rearrangement during the secondary response to associate with the other downstream constant region genes (68 ,69 ,70) (Fig. 21-2). Switch sequences located upstream of each constant region gene mediate heavy chain class switching (71).

Although all somatic cells are endowed with two of each chromosome, only one rearranged heavy chain gene and one rearranged light chain gene normally are expressed by a B cell. This phenomenon is known as allelic exclusion. A productive rearrangement on one chromosome inhibits assembly of variable region genes on another chromosome. Rearrangement of the first chromosome is often unproductive because of DNA reading frame shifts or because nonfunctional variable region gene segments called pseudogenes are used. If rearrangement on the first chromosome does not lead to the formation of a functional polypeptide chain, then the immunoglobulin genes on the other chromosome will undergo rearrangement. Mono-allelic expression avoids potential expression of immunoglobulins or B cell receptors (BCRs) with two different specificities on the same B cell, which could interfere with normal selection processes (see below). Regulation of allelic exclusion seems to occur at the recombination level suggested by the observation that transgenic mice allow the expression of two pre-arranged alleles at either the heavy or light chain locus (72). Single-cell analysis of germline transcription in pro-B cells have shown transcription of Vk genes on both chromosomes (73); however, the earlier expressed alleles are almost always the first to undergo rearrangement (74). Methylation of DNA mediates gene repression and decreases the probability of recombination when methylation is found in the proximity of recombination signal sequences (75).

While the heavy chain has a single locus of V, D, and J segments on each chromosome, the light chain has two. The κ locus is the first set of light chain gene segments to rearrange. If these rearrangements are nonproductive on both chromosomes, however, then the V and J segments of the λ locus rearrange to produce an intact light chain (76 ,77). Thus, while the heavy chain has two loci from which to form a functional gene, the light chain may rearrange at four loci. Moreover, additional or secondary rearrangements can occur in B cells already expressing an intact antibody molecule if that antibody has a forbidden autospecificity. These additional rearrangements, which are termed receptor editing, are important in allowing B cells to regulate autoreactivity.

Immune tolerance mediated by receptor editing occurs frequently in developing B cells (78). High-affinity receptor binding to self antigen induces a new gene recombination (79) and the replacement of the gene encoding a self-reactive receptor by a gene encoding a nonself-reactive receptor (80 ,81). Receptor editing occurs at both light and heavy chain loci, but at a much lower frequency at the heavy chain locus (82). There is some debate about whether Ig gene rearrangement can occur also in mature B cells or only in immature B cells (83). RAG protein expression in germinal centers, as well as after immunization (84 ,85) has suggested that antibody genes may undergo modification not only in developing but also in mature B cells (85 ,86 ,87). Immunization of BALB/c mice with a multimeric form of a peptide mimetope of dsDNA induces the generation of dsDNA-reactive B cells. Mature B cells that respond to peptide re-express RAG for a short period of time only, suggesting that receptor editing can also participate in peripheral tolerance (88). The regulation and function of secondary rearrangements of Ig genes in mature B cells remains incompletely understood, however as some data suggest rearrangement events can be initiated in germinal center B cells that fail to bind antigen.

Generation of Antibody Diversity

The immune system has several mechanisms to ensure a large antibody repertoire. Before exposure to antigen, B cell diversity results from (a) combinations of V, D, and J gene segments and V and J segments into heavy and light chain genes, respectively; (b) junctional diversity produced by N or P sequence insertion and/or imprecise joining of gene segments; and (c) the random pairing of heavy and light chains. These three mechanisms are consequences of the process of recombination used to create complete Ig variable regions. The fourth mechanism, called somatic hypermutation (SHM), occurs later on rearranged DNA. This mechanism introduces point mutations

into rearranged variable region genes (Table 21-1). These mechanisms are potentially capable of producing a repertoire of 1011 different antibodies (89).

Table 21-1: Mechanisms of Antibody Diversity

Combinatorial diversity of V, D and J gene segments for heavy-chain variable region and V and J gene segments for light-chain variable region
Junctional diversity of rearranged heavy- and light-chain variable regions
N-terminal addition
Imprecise joining
Random association of heavy and light chains
Somatic point mutation

Cross-linking of surface immunoglobulin on the B cell by a multivalent antigen is the first in a series of critical steps that eventually can lead to B cell activation and antibody production. Following cross-linking of membrane immunoglobulin, the antigen-antibody complexes are internalized, and the antigen is cleaved and processed in the cell. Peptide fragments of protein antigen bound to the major histocompatibility complex (MHC) class II molecules are then expressed on the cell surface, where they can be recognized by antigen-specific helper T cells (Fig. 21-3). These T cells provide the co-stimulation and cytokines that are necessary for full B cell activation.

On initial exposure to an antigen, naive B cells recognizing the antigen enter secondary lymphoid organs such as the spleen or lymph nodes, where they proliferate and begin to secrete IgM. The antibodies of this primary immune response generally are polyreactive and display low affinity to a multitude of antigens, even to antigens without obvious structural homology (Table 21-2). The amplification of antigen-specific B cells occurs in specific regions of the lymphoid tissue called germinal centers. SHM (discussed later), leads to the selection of high-avidity B cell clones. Within the germinal center heavy chain isotype switching, and further differentiation to plasma and memory B cells also occur.

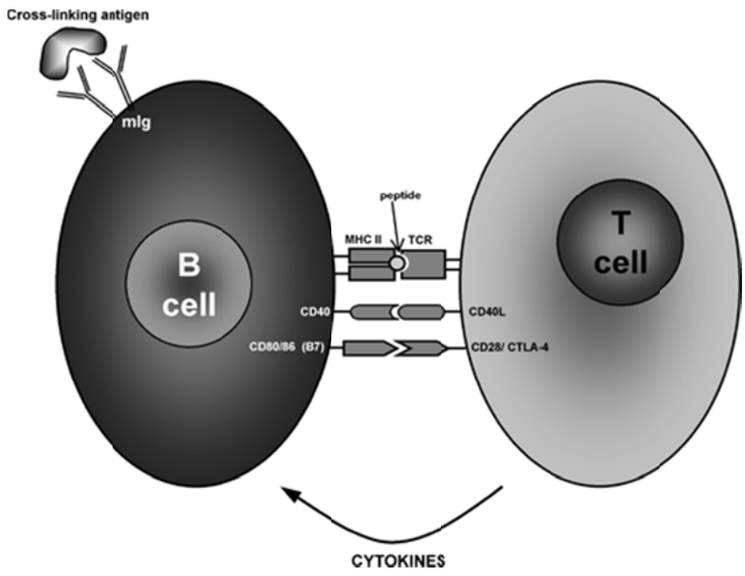

Figure 21-3. B cell-T cell cognate interactions. MHC II, class II major histocompatibility complex; mIg, membrane immunoglobulin; TCR, T cell receptor.

Table 21-2: Distinguishing Features of the Naïve and Antigen-Activated Antibody Repertoire

Feature	Naïve	Antigen Activated
Isotype	Primarily IgM	Primarily IgG
Specificity	Polyreactive	Monospecific
Affinity	Low affinity	High affinity
Sequence	Germline gene encoded	Somatically mutated (high R-to-S ratio)
Titer	Low titer	High titer

Studies using mice with targeted disruptions of particular genes have shown that in addition to a cognate interaction between the T cell receptor and an MHC class II molecule, other pairs of B cell–T cell contacts are also necessary for germinal center formation and function (Fig. 21-3). One important interaction is between the CD40 receptor on the B cell and CD40 ligand (CD40L, gp39) expressed on activated CD4 T cells.

Activation of the CD40 receptor is thought to be necessary for the formation of germinal centers and germinal center reactions (90 ,91). Defective CD40 ligand on T cells in humans and mice causes X-linked hyper-IgM type I syndrome, which is characterized by a defect in isotype switching and severe humoral immunodeficiency, leading to increased susceptibility to infections with extracellular bacteria (92). Since the proliferation of autoreactive B cells in SLE is T cell dependent, current therapeutic approaches include blockade of the co-stimulatory signals important in the activation of T cells by antigen presenting cells (B7-CD28) and in the activation of B cells by antigen-specific T cells.

After the primary immune response is complete, specific antibody secretion decreases. Reexposure to the antigen and activated T cells, however, can activate memory B cells that arose in the germinal center response to initiate the secondary immune response. The secondary serum response is characterized by rapidly produced high titers of IgG antibodies that have greater specificity and increased affinity for antigen (93 ,94 ,95). The increase in both affinity and specificity is a consequence of SHM and selection process within the germinal center. Anti-dsDNA antibodies, which are the most well-characterized pathogenic autoantibodies to date, possess all the features of secondary response antibodies (96 ,97 ,98 ,99) (Table 21-2) (Chapter 23).

Somatic point mutations are single nucleotide substitutions that can occur throughout the heavy and light chain variable region genes (100 ,101 ,102) and represent a site-specific, differentiation stage-specific, and lineage-specific phenomenon (103). Somatic mutation takes place in dividing centroblasts, in which rearranged Ig variable region genes undergo a mutation rate of 1 bp per 10^3 bp/cell divisions compared to 1 bp per 10^{10} bp/cell divisions in all other somatic cells. The DNA mismatch repair system has been implicated in Ig gene mutation because it functions generally to correct point mutations in DNA. A genetic deficiency in a component of the mismatch repair system, PMS2, has been shown to enhance the rate of mutation, suggesting that the DNA mismatch repair system may be altered in hypermutating B cells (104). Similarly, mice deficient in Msh6, a component of the mismatch repair system, have altered nucleotide targeting for mutations (105). Because somatic mutation occurs concurrent with heavy chain class switching, although by a different mechanism, mutation is more common in IgG than in IgM antibodies.

The generation of high affinity antibodies through B cell maturation with SHM and class switch recombination (CSR) critically depends on the action of activation-induced cytidine deaminase (AID) (106). AID is a member of a family of Apobec cytidine deaminases that causes DNA conversions of cytosine to uracil, generating mutations in the immunoglobulin gene that can increase antibody affinity for the antigen (107). AID deficiency in humans causes a disorder called Hyper-IgM type 2 syndrome characterized by elevated serum levels of IgM and undetectable IgG, IgA and IgE (108). Mice with a homozygous deletion of AID display normal B cell maturation but are deficient in SHM and CSR while overexpression of AID is sufficient to induce SHM and CSR in B cell lines or fibroblasts (109 ,110). AID expression is tightly regulated and appears to be restricted to GC, although clearly CSR can occur outside GC. Genomic instability and higher mutation rates are likely to occur in the presence of poorly regulated AID expression, which can lead to malignancies.

Genealogies of B cells with serial mutations in their immunoglobulin gene sequences demonstrate how point mutations can lead to antibodies with altered affinity for antigen (111 ,112 ,113 ,114) (Fig. 21-4). While B cells producing antibodies with decreased affinity appear within the germinal center, progression of these cells to the plasma or memory

cell compartment is rare, as they fail to be amplified further in the immune response. In contrast, B cells producing antibodies of higher affinity continue to be amplified. SHM is an important process in the generation of high-affinity antibodies, and a suboptimal frequency of Ig V gene mutation leads to common variable immunodeficiency (CVID) (115). Mutated antibodies also can acquire novel antigenic specificities. In one in vitro system, a single amino acid change in a protective anti-pneumococcal antibody results in reduced binding to pneumococci and a newly acquired affinity for dsDNA (116). Abundant evidence suggests that antibodies to foreign antigen also can acquire autospecificity in vivo through somatic point mutation (117 ,118).

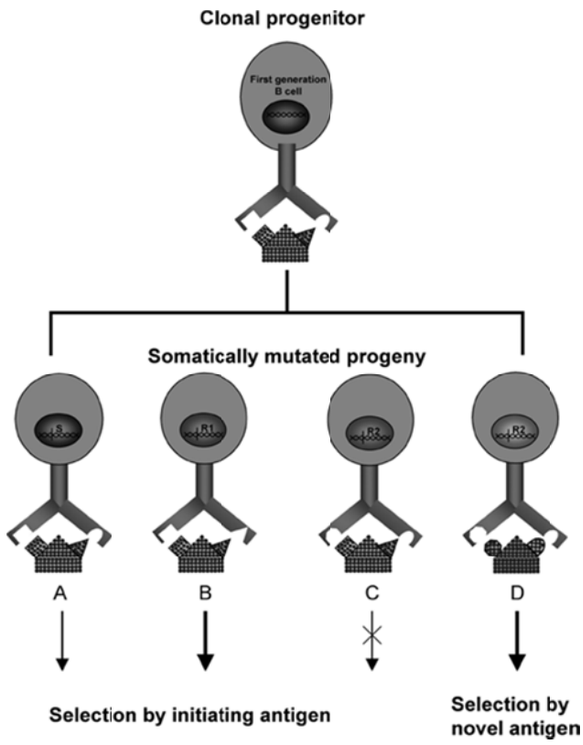

Figure 21-4. B cell genealogy. The progenitor B cell depicted at the top expresses an antibody that is encoded by germline immunoglobulin genes and has a low affinity for antigen. When antigen and T cell factors trigger B cell proliferation, class switching, and somatic mutation, numerous B cell progeny are possible. Three examples are schematized here. A: a B cell with a silent (S) point mutation. This nucleotide substitution does not encode a new amino acid. Therefore, the antibody molecule is unaffected, and affinity for antigen does not change. B: a B cell whose point mutation encodes an amino acid replacement (R), leading to increased affinity for antigen. This mutated antibody exemplifies affinity maturation. C: a B cell with a replacement mutation that alters antigenic specificity. This antibody can no longer bind to the initial triggering antigen. D: the same antibody as in C, despite no longer being able to bind to the initial triggering antigen, can acquire specificity for a novel (perhaps self) antigen.

Because a given amino acid can be encoded by more than one DNA triplet, not every point mutation causes an amino acid substitution that can change antibody affinity for an antigen. It is possible to indirectly analyze antigen selection during the course of the germinal center response by calculating the ratio of replacement (R) to silent (S) mutations in rearranged antibody genes (i.e., mutations that lead to amino acid changes vs. those that do not). Purely random point mutations within a DNA sequence containing equal numbers of each possible codon would result in a predicted random R-to-S ratio of approximately 3:1 (119 ,120). The random R-to-S ratio for a particular DNA sequence, however, might be lower or higher than this depending on the actual codon usage (121 ,122).

In an antigen-selected response, one might expect a higher than random R-to-S ratio, because B cells containing mutations leading to higher affinity for antigen would be favored to proliferate. Further, antigen selection would predict a higher frequency of R mutations in the CDRs, because these regions include the contact amino acids for antigen binding. This type of analysis has been performed to assess whether certain autoantibodies arise from antigen selected responses (96 ,97 ,98). There are two concerns, however, with this analysis. First, the assumption of purely random mutation is incorrect; recent studies have shown that bias for particular kinds of mutations occurs and that hot spots of mutation exist (123). Second, while antibodies with a higher-than-random R-to-S ratio probably are part of an antigen-selected repertoire, the converse clearly is not true: a single amino acid substitution is capable of conferring a tenfold increase in affinity (124 ,125). Thus, antigen selection may occur in the absence of a high R-to-S ratio.

Marginal Zone and B-1 B Cells in SLE: Role of “Natural” Autoantibodies

B-1 cells (also CD5 or Ly-1) represent a distinct population of B cells (126 ,127). B-1 cells are the only subset of B lymphocytes that constitutively express the pan-T cell surface antigen CD 5. The significance of this marker has not yet been elucidated. Data showing that CD5 is implicated in the maintenance of tolerance in anergic B cells (128), along with data demonstrating that CD5 mediates negative regulation of B cell receptor (BCR) signaling in B-1 cells (129), support the hypothesis that the expression of CD5 may help inhibit autoimmune responses.

At present, it is not clear whether the B-1 population is a separate lineage or merely an alternate differentiation pathway of conventional (i.e., B-2) B cells. B-1 cells are unique among mature B lymphocytes in that they appear to be a self-replenishing population that arises in the fetal liver (130). Although rare in the spleen and lymph nodes, B-1 cells comprise approximately 10% to 40% of B cells found in the peritoneum. Being a major source of natural autoantibodies (131 ,132 ,133), the B-1 lineage is of particular interest to those studying autoimmunity. Elevated numbers of B-1 cells are present in the autoimmune New Zealand black (NZB) mouse strain (130), and prevention of the autoimmune symptoms has been reported with their elimination (134). B-1 cell expansion is found in some patients with rheumatoid arthritis and Sjogren's syndrome (135), but an association with SLE is weaker (136 ,137).

B-1 cells generally express germline-encoded, polyreacrive IgM antibodies with limited V gene segment usage (130 ,131 ,132). Much controversy exists over the physiologic function of the B-1 lymphocytes, although there is now growing evidence that many of the low affinity autoantibodies made by this B cell subset are important in the clearance of apoptotic debris. Adoptive transfer experiments have shown that B-1 cells are poor at forming germinal centers (138), which are characteristic of a T-dependent B cell response and are thought to be necessary for antigen selection and class switching; however, class-switched, somatically mutated B-1 antibodies that appear to show evidence of antigen selection have been isolated from humans (139).

MZ B cells share many features with B1 cells. They are phenotypically characterized by cell surface expression of $IgM^{hi}IgD^{lo}CD21^{hi}CD22^{hi}CD23^{lo}CD1^{hi}$ and reside in the marginal zones that girdle the follicles in spleen and tonsils (140). Their hallmark functional characteristic is represented by early activation and rapid immunoglobulin secretion in response to T-independent (TI) antigens that arrive via a hematogenous route in the spleen. Like B1 cells, they are key players of innate immunity as they respond rapidly to antigen and do not generate a memory response. Although it has been generally accepted that this is a self-renewing and mostly non-recirculating population (141 ,142) recent studies suggest that a large population of IgM-positive peripheral B cells correspond to circulating splenic MZ B cells (143 ,144).

Both MZ and B-1 B cells have a high antigen presentation capacity and are strategically located to encounter and process foreign antigens. Both cells secrete polyreactive “natural” antibodies, including self-reactive ones that are generally germline-encoded (145). Low titers of low-affinity autoantibodies are part of the normal B cell repertoire (146 ,147 ,148 ,149). They are not unique to any autoimmune disease, nor is there any evidence that they are pathogenic. These natural autoantibodies resemble the antibodies of a primary immune response in that they are mainly IgM and polyreactive, and bind to a wide variety of both autoantigens

and foreign antigens that often have no apparent structural homology (150 ,151 ,152). “Natural” antibodies have also been shown to bind to altered phospholipids expressed on the surface of cells undergoing apoptosis. The opsonization of apoptotic cells increases their clearance and routes them to nonimmunogenic pathways (153). While sequence analysis shows that the antibodies made by MZ B cells are mainly encoded by germline (i.e., unmutated) genes (154 ,155 ,156 ,157 ,158), numerous exceptions exist (159). Analysis of the variable regions of natural autoantibodies suggests that they may contain more flexible hydrophilic amino acid residues in their CDRs than somatically mutated, affinity-matured antibodies, as well as longer CDRs (159), which may explain their polyreactivity. It is thought that they present a shallow groove for antigen binding that can accommodate more diverse structures.

There are some indications that the B cells producing natural antibodies may be clonally related to pathogenic B cells. Idiotypic analyses of natural anti-DNA antibodies from normal individuals and of potentially pathogenic anti-DNA antibodies from patients with SLE demonstrate that cross-reactive idiotypes are present in both populations (160 ,161). Some investigators have speculated that natural autoantibodies can be the precursors to pathogenic autoantibodies (162 ,163), while other data suggest that the two classes of autoantibodies arise from distinct B cell populations and that the SLE autoantibodies arise by the somatic mutation of genes that encode protective antibodies (99 ,164 ,165 ,166 ,167 ,168 ,169). Adoptive transfer experiments of MZ B cells, unlike B1 cells, have demonstrated T-dependent class-switching and SHM occurring resulting in the production of high-affinity antibodies (170 ,171). Assuming MZ B cells can undergo affinity-maturation, it is conceivable that an enhanced differentiation of MZ B cells along this pathway could contribute to autoimmunity.

Our understanding of innate immune B cells in humans has been further advanced through the study of a population of B cells that can be identified using a monoclonal antibody (9G4) that binds to a unique epitope encoded by the human heavy chain variable region gene V4–34 (172). These 9G4 positive B cells represent 5% to 10% of the mature naïve B cell repertoire and recognize autoantigens and pathogens. Additionally, these cells are present in the MZ B cell compartment and are normally excluded from the T-dependent IgG memory repertoire. However, in SLE patients, 9G4 positive B cells are expanded in the IgG memory population supporting the hypothesis that inappropriate positive selection of innate B cells into an adaptive immune phenotype is a feature of autoimmunity. Although 9G4 positive antibodies have not been demonstrated to have a direct pathogenic effect, they are elevated in up to 75% of patients with active SLE.

Further studies on the role of B cells in innate immunity have revealed the expression of Toll-like receptors (TLR) by these cells that recognize specific molecular determinants common to many pathogens. While in mouse B cells, co-engagement of TLRs and the BCR acts synergistically to induce activation, in humans, TLR9 and TLR10 expression appears to be induced following BCR activation (173). TLRs have been shown to bind exogenous ligands such as lipopolysaccharides (LPS), single- and double-stranded RNA and bacterial DNA (174 ,175 ,176). Potential endogenous ligands include DNA containing CpG motifs released from apoptotic cells (174). Therefore, inducible TLR expression and B cell activation from a wide range of self and foreign ligands could provide the link between innate immune dysregulation and autoimmunity.

Another potential role of MZ B cells in autoimmunity is as antigen presenting cells for self antigens, resulting in the activation of autoreactive CD4 T cells. This interaction can induce T cells to secrete IFN-γ, IL-4 and IL-10 (177). B cells themselves can secrete large amounts of IL-10 and upregulate the expression of cell surface costimulatory molecules that can lead to amplification of the T dependent immune response inducing GC formation and affinity maturation of self reactive B cells. Additionally, CpG binding to TLR9 in B cells from several lupus mouse strains increases the secretion of IL-10 and results in the suppression of IL-12 production (178). IL-10 has been shown to be elevated in patients with SLE and its serum level can correlate with disease activity (179 ,180). In an uncontrolled study, a small number of SLE patients with active disease were given anti-IL-10 antibody and experienced an improvement of disease activity (181). Similarly, anti-IL-10 treatment of NZB/W mice resulted in delay onset of lupus-like disease (182). However, MRL-lpr/lpr IL-10-/- mice showed an increased severity of lupus and higher concentrations of anti-dsDNA antibodies, suggesting that IL-10 can play different regulatory roles in SLE, whether it is a different stage of the disease or a different genetic background (183).

Pathogenic Autoantibodies

Indirect evidence for the pathogenicity of several autoantibodies present in SLE includes their association with clinical manifestations in SLE and their presence in affected tissue. In recent years there is increasing evidence to directly support the pathogenic potential of several lupus-associated autoantibodies. A transgenic mouse expressing the heavy and light chain of the secreted form of an anti-DNA antibody has been shown to develop glomerulonephriris, thereby confirming that anti-DNA antibodies cause renal disease (184). Support for the pathogenic role of anti-DNA antibodies in nephritis can also be found in recent autoimmune disease models displaying high titers of anti-DNA antibodies together with immunoglobulin deposition in the kidney and histologic nephritis (185 ,186 ,187 ,188). Perfusion of monoclonal mouse and polyclonal human IgG anti-DNA antibodies through isolated rat kidney induces significant proteinuria and decreased clearance of inulin (189). Addition of plasma as a source of complement markedly increases proteinuria, while preincubation of the antibodies with DNA can abolish binding to renal tissue (189). It is still unknown, however, whether pathogenic anti-DNA antibodies form immune

complexes with antigen in situ, or if the antibodies bind to a target antigen that is actually some component of glomerular tissue and/or tubular components. A decrease in binding of anti-DNA antibodies to glomerular elements with DNAse treatment in some experimental models (190) but not in others (191) suggests that both models pertain; some anti-DNA antibodies directly cross-react with glomerular antigens, while other anti-DNA antibodies may bind via a DNA-containing bridge. A number of investigators have administered monoclonal anti-DNA antibodies to nonautoimmune mice, either intraperitoneally in the form of ascites-producing hybridomas or intravenously as purified immunoglobulins (192 ,193). In these models, it is possible to demonstrate that anti-DNA antibodies differ with respect to pathogenicity (193 ,194), with some antibodies depositing in the kidney and others not. Moreover, those antibodies that deposit in the kidney may differ with respect to the localization of deposition. Studies performed with the congenic mouse strain NZM2328.C57Lc4 showed that these mice develop chronic glomerulonephritis and severe proteinuria despite the fact that they do not generate autoantibodies to dsDNA or other nuclear antigens (195), consistent with the clinical observation that kidney disease can arise in individuals with no DNA-reactive antibodies.

Recent studies have elegantly demonstrated the arrhythmogenic potential of anti-Ro antibodies. Affinity-purified anti-Ro antibodies from lupus mothers of babies with congenital heart block inhibit calcium currents and induce complete heart block in an ex vivo perfused human fetal heart system (196). Immunization of female BALB/c mice with recombinant La and Ro particles leads to first-degree atrioventricular block in 6% to 20% of pups born to immunized mothers and rarely to more advanced conduction defects (197). Finally, passive transfer of purified human IgG containing anti-Ro and anti-La antibodies to pregnant BALB/c mice results in fetal bradycardia and first-degree atrioventricular block (198).

Experimental evidence also supports the close epidemiologic association between antiphospholipid antibodies and thrombosis. Following experimental induction of vascular injury in mice, injection of affinity-purified immunoglobulin from patients with antiphospholipid syndrome results in a significant increase in thrombus size and a delay in disappearance of the thrombus (199). Injecting human monoclonal anticardiolipin antibodies into pregnant BALB/c mice results in fetal resorption, and a significant decrease in placental and fetal weight (200). Similar results have been obtained with passive transfer of monoclonal murine and polyclonal human anticardiolipin antibodies (201).

Looking at the epidemiologic and experimental data in combination, it seems clear that the importance of several lupus-associated autoantibodies lies not only in their diagnostic significance as markers for the disease, but also in a pathogenic role in tissue damage in affected target organs in SLE. Treating disease with the end point of lowering the titer of specific autoantibodies then becomes a therapeutic goal with a clear pathophysiologic rationale.

Heavy-chain isotype appears to be important in determining the pathogenicity of autoantibodies. For example, marked differences in the severity of induced hemolysis exist among IgG isotype switch variants of an antierythrocytic antibody, related to the capacity of each isotype to bind to Fc receptors (202). In murine lupus, the switch from serum IgM anti-DNA activity to IgG anti-DNA activity heralds the onset of renal disease (203). Similarly, human IgG antibodies present in the immune complex deposits within the kidneys of patients with SLE appear to trigger mesangial cell proliferation and subsequent tissue damage to a greater extent than IgM antibodies, perhaps because mesangial cells or infiltrating mononuclear cells have Fc receptors for IgG (204). The importance of isotype for anticardiolipin antibodies is intriguing (2); several groups have noted that IgG antiphospholipid and ß2-glycoprotein antibodies correlate better with clinical thrombosis than other isotypes do (Chapter 27). Nevertheless, pathogenicity has been shown also for IgM and IgA antibodies (199). IgM and IgA anticardiolipin antibodies also correlate with specific disease phenotypes. For example, IgM antiphospholipid antibodies are associated with hemolytic anemia (205).

It was formerly widely believed that antibodies could not penetrate live cells, and that nuclear staining of sectioned tissues was an artifact of tissue preparation. There is now evidence that some anti-DNA and antiribosomal P autoantibodies bind to the cell surface, traverse the cytoplasm, and reach the nucleus. Furthermore, there are data to demonstrate a pathogenic effect from cellular penetration by autoantibodies (206 ,207 ,208). While antigen translocation to the cell membrane may explain the accessibility of normally intranuclear antigens to interaction with autoantibodies (209 ,210), the capability to penetrate live cells and interact with cytoplasmic or nuclear components may be an additional pathogenic characteristic of some autoantibodies.

This chapter discusses aspects of autoantibody production, but it is increasingly evident that autoantibody–mediated tissue damage requires not just the presence of autoantibodies with particular pathogenic features but also the display of a specific antigen in the target organ (211). Differential display of antigen at the level of the target organ may contribute to genetic susceptibility to autoimmune disease. Evidence for such a hypothesis comes, in part, from a murine model of autoimmune myocarditis, where differential susceptibility to antimyosin antibody-induced disease in different mouse strains is dependent on differences in the composition of cardiac extracellular matrix (212). Similarly, in a rat model for tubular nephritis, antibody-mediated disease depends on genetically determined antigen display in the renal tubules (213).

Genetic and Molecular Analysis of Anti-DNA Antibodies

Genetic analyses of anti-DNA antibodies in both human and murine lupus have provided important information regarding the production of autoantibodies. There is currently no

evidence that a distinct set of disease-associated, autoreactive V region genes is present only in individuals with a familial susceptibility to autoimmunity and is used to encode the autoantibodies of autoimmune disease. It is also clear that no particular immunoglobulin V region genes are absolutely required for the production of autoantibodies (214). Immunoglobulin genes that are present in a nonautoimmune animal clearly are capable of forming pathogenic autoantibodies. The offspring of a nonautoimmune SWR mouse and an NZB mouse (SNF1 mice) spontaneously produce autoantibodies (215), with a large percentage of the anti-DNA antibodies deposited in the kidneys of (NZB × SWR) F1 mice encoded by Ig genes derived from the nonautoimmune SWR parent (215). In fact, both idiotypic and molecular studies show that the V region genes used to produce autoantibodies in lupus are also used in a protective antibody response in nonautoimmune individuals (216 ,217). Autoantibodies bear cross-reactive idiotypes that also are present on the antibodies that are made in response to foreign antigens, and V region genes used to encode autoantibodies also encode antibodies to foreign antigen (218 ,219 ,220 ,221). Indeed, a number of autoantibodies cross-react with foreign antigens, demonstrating that the same V region gene segments can be used in both protective and potentially pathogenic responses (222 ,223 ,224). These cross-reactive antibodies are capable of binding to bacterial antigen with high affinity, but they also possess specificity for a self antigen. Patients with *Klebsiella* infections and individuals vaccinated with pneumococcal polysaccharide develop antibacterial antibodies expressing anti-DNA cross-reactive idiotypes (216 ,225). In vivo, cross-reactive antibodies with specificity to both pneumococcus and dsDNA are protective in mice against an otherwise lethal bacterial infection, yet they also can deposit in the kidney and cause glomerular damage (226). It appears that cross-reactive antibodies are routinely generated during the course of the normal immune response in the nonautoimmune individual. Ordinarily, however, autoreactive B cells expressing a self specificity are actively downregulated and contribute little to the expressed antibody repertoire (117).

Although there is no evidence that specific genes encode only autoantibodies, there are data to suggest that autoantibodies are encoded by a somewhat restricted number of immunoglobulin V region genes (227 ,228 ,229). In murine lupus, extensive analyses of anti-DNA–producing B cells show that 15 to 20 heavy-chain V region genes encode most anti-DNA antibodies (165 ,230 ,231 ,232). There is a dramatic increase in the frequency of use of a particular J558 heavy chain gene in autoimmune as compared to normal mice, while nonautoimmune mice, immunized with an immunogenic DNA/DNA-binding peptide complex displayed intermediate usage (229). This supports the concept that differences in V gene usage that may be seen between autoimmune and nonautoimmune mice are quantitative, rather than reflecting a true qualitative difference. While molecular studies of human antibodies are more limited, idiotypic analyses also suggest restricted V gene usage. This observation is important as it suggests that antiidiotypes can play a role in therapeutic strategies. Furthermore, analysis of restriction fragment length polymorphisms, which is a tool used to identify the similarities and differences among particular genes in a population, has been used to examine whether distinct Ig gene polymorphisms associate with SLE (233 ,234 ,235). A deletion of a specific heavy-chain V gene, hv-3, was reported to be more frequent in individuals with SLE or rheumatoid arthritis (236 ,237). A specific germline VK gene, A30, was found to increase the cationicity (and therefore the pathogenicity) of human anti-DNA antibodies. A defective A30 gene was found in eight of nine lupus patients without nephritis, while this gene was normal in all nine lupus patients with nephritis (238). Polymorphism at the VK gene locus may then contribute to susceptibility to lupus nephritis. While these studies look at small numbers of patients, they suggest that polymorphisms in immunoglobulin genes may make some contribution to the generation of autoantibodies and expression of human lupus. Nevertheless, the anti-DNA response is no more restricted than are many responses to foreign antigen and the restricted V region gene usage does not appear to be skewed toward particular gene families.

SHM is a possible mechanism by which protective, antiforeign antibodies evolve into pathogenic autoantibodies (Fig. 21-4) (239 ,240). The characteristics and mechanics of SHM in SLE are, therefore, of interest. Examining ten human antibodies positive for a specific, lupus-associated idiotype (F4), Manheimer-Lory et al. (241) found no change in the frequency of somatic mutations or the distributions of such mutations in CDRs. While the normal process of somatic mutation is generally random, there is some bias for mutation at specific sequence motifs, termed mutational “hot spots.” Surprisingly, F4 positive antibodies displayed abnormal somatic mutation as shown by a decrease in hot-spot targeting. As mice transgenic for the anti-apoptotic gene bcl-2 also display this same decreased targeting of mutations to hot spots (242), the decreased targeting in F4 positive antibodies derived from lupus patients may reflect an abnormal state of B cell activation rather than defective machinery for somatic mutation. Studies have been performed (243) on the mutational process in the V gene repertoire in individual B cells from a small number of lupus patients. The frequency of mutations was increased in both productive and unproductive VK rearrangements, with evidence of increased targeting to mutational hot spots in framework regions, consistent with altered selection. A single study in mice found essentially no differences in somatic mutation between B cells of an autoreactive and normal strain (244). Abnormal somatic mutation may be due to important alterations in B cell activation in SLE; however, conflicting data prevent drawing firm conclusions as yet.

Autoantibody Induction

For the most part, autoantibodies that are present in SLE do not exist in an unstimulated B cell repertoire. Rather, autoantibodies in SLE usually reflect the process of SHM

and apparently are made by B cells following exposure to antigen and T cell help. For some autoantibodies, mutation of the germline sequences clearly is crucial in generating the autoantigenic specificity (97). These antibodies have a high R-to-S ratio, primarily in CDRs; however, the pitfalls of R-to-S ratio calculations have been discussed and should be considered in the analysis of anti-DNA antibodies (123 ,124). There also are lupus autoantibodies that have a high R-to-S ratio in framework regions (245). As these framework region mutations are less likely to alter antigenic specificity, it is tempting to speculate that they instead may facilitate escape from a putative regulatory mechanism. High-affinity anti-dsDNA antibodies also can be encoded by germline genes (246), but these are rarely found in disease.

There are various hypotheses regarding the nature of the eliciting antigen or antigens in SLE (Table 21-3). Several lines of evidence support the role of foreign, microbial antigens in the generation of autoantibodies (247). Lupus-prone strains of mice carrying the xid mutation, which impairs production of the antipolysaccharide antibodies that are required for antibacterial immunity, develop much lower titers of anti-DNA antibodies and decreased renal disease (248). Similarly, autoimmune–prone NZB mice raised in a germ-free environment produce reduced titers of anti-DNA antibodies and show delayed onset of autoimmune manifestations (249). It has been shown that raising lupus-prone lymphoprolifertive (MRL/lpr/lpr) mice in a germ-free environment and feeding them a filtered, antigen-free diet significantly decreases the severity of renal disease (250). Evidence that an antipneumococcal antibody can spontaneously mutate to become an anti-DNA antibody in an in vitro system (116), as well as in response to immunization with a pneumococcal antigen in vivo (117), also supports a close structural relationship between the autoantibody response and a protective antibacterial response. Finally, to further demonstrate the close relationship between a protective antibacterial and autoantibody response in lupus, Kowal et al. (251) generated a combinatorial immunoglobulin expression library in phage from splenocytes of a lupus patient immunized with pneumococcal polysaccharide. Four of eight (53) of the monovalent Fab fragments selected for expression of a SLE associated idiotype bound both pneumococcal polysaccharide and dsDNA, indicating that a significant portion of the human antipneumococcal response in SLE is cross-reactive with self antigen.

Table 21-3: Antigenic Triggers for Anti-dsDNA Antibodies

Foreing antigen
Molecular mimics
Bacterial DNA
Complexes of DNA and DNA-binding proteins
Self-antigen
RNP auto-epitopes
Histone peptides
Peptides derived from anti-dsDNA antibodies
Cryptic autoepitopes (sequestered autoantigens, altered processing/presentation)
Idiotypic network (antiidiotypic antibody—autoantigen)

dsDNA, double-stranded DNA; RNP, ribonucleoprotein

Molecular mimicry as well as SHM might be important mechanisms by which exposure to foreign, bacterial antigen can elicit autoantibodies. Molecular mimicry refers to a sufficient structural homology between foreign and self antigen that both antigens are recognized by a single, cross-reactive B cell. The best-known example of this mechanism in autoimmunity is rheumatic fever, in which the antibodies arising in the antistreptococcal response cross-react with cardiac myosin, leading to antibody deposition in cardiac muscle and carditis. A molecular mimic induces an autoantibody response by activating cross-reactive B cells specific for both foreign and self antigen. These B cells receive T cell help for autoantibody production from T cells activated by microbial proteins. In support of a possible role of molecular mimicry in inducing anti-DNA antibodies is the rise in autoantibodies seen even in nonautoimmune hosts following infection (252). Furthermore, nonautoimmune individuals vaccinated with pneumococcal polysaccharide generate antipneumococcal antibodies idiotypically related to anti-DNA antibodies (216). Infection does not usually lead to self-perpetuating autoimmunity, as the T cell help available for cross-reactive B cells dissipates following the clearing of the infectious agent. Failure to resolve the autoimmune process induced by a molecular mimic may be a result of a defect in reinduction of tolerance or to the persistence of the foreign antigen. Some possible causes for a lack of return to a tolerant state include activation of T cells specific for antigenic epitopes to which T cell tolerance had never been established (cryptic epitopes) (253), upregulation of costimulatory molecules, the presence of immunomodulatory cytokines, and abnormally enhanced intracellular signaling. It is also possible that regulatory cells are critical in the maintenance of peripheral tolerance following antigen activation and may be dysfunctional in SLE (254 ,255). Finally, it may be that lupus specific immune complexes containing RNA or DNA activate dendritic cells (DC) to create an immunogenic environment (256 ,257).

Peptide antigens that structurally mimic DNA can also elicit an autoantibody response (258 ,259). Screening a phage peptide display library with a pathogenic IgG2b anti-dsDNA antibody, revealed the D/E WD/E Y S/G consensus motif that is recognized by both murine and human anti-DNA antibodies (259). DWEYS inhibits the binding of a high percentage of anti-DNA antibodies to dsDNA in vitro and to glomeruli in vivo. Immunization of nonautoimmune BALB/c mice with a multimeric peptide containing the consensus motif induces significant serum titers of IgG anti-dsDNA antibodies, as well as antihistone, anti-Sm/RNP, and anticardiolipin antibodies. Monoclonal antibodies from peptide-immunized BALB/c mice resemble anti-dsDNA antibodies present in spontaneous murine

lupus, using similar VH and VL gene usage, and exhibiting arginines in heavy chain CDR3 regions (260).

There is some evidence to suggest that nucleic acids can induce anti-dsDNA antibodies (see below). While investigators have long known that mammalian dsDNA is poorly immunogenic, recent studies have focused on bacterial DNA as a potential trigger for induction of anti-dsDNA antibodies. Bacterial DNA contains unmethylated CpG motifs, which can bind to and activate TLR9 and may be an important adjuvant in the immune system (261). Preautoimmune lupus-prone mice immunized with bacterial DNA produce antibodies that not only bind to the immunizing antigen, but are also cross-reactive with mammalian DNA (262). However, the response of nonautoimmune mice to bacterial DNA was noncross-reactive, indicating that bacterial DNA alone is not sufficient to induce anti-dsDNA antibodies in a nonlupus-prone host. While mammalian DNA contains fewer CpG-motifs, these motifs are present and can activate TLR9 and perhaps other TLRs or scavenger receptors that are involved in DC activation. Failure to clear DNA properly and degrade it to nonimmunogenic fragments may contribute to anti-DNA antibody production.

Another possible model for induction of anti-DNA antibodies is by a hapten-carrier–like mechanism, in which T cells recognize epitopes of a protein carrier associated with DNA and provide help for autoreactive B cells specific for hapten (DNA). Novel peptide determinants of the protein component of the complex may then be presented by DNA-specific B cells to recruit autoreactive T cells, and further perpetuate an immune response. Immunization of nonautoimmune animals with DNA together with DNA-binding proteins such as DNAse I (263), Fus 1 (derived from *Trypanosoma cruzi*) (264), and the polyomavirus transcription factor T antigen (265) results in the generation of anti-dsDNA antibodies with structural similarity to anti-dsDNA antibodies present in spontaneous murine lupus.

Because anti-idiotypic antibodies can function like antigen to induce an antibody response, some investigators have emphasized a potential role for antiidiotype in activating autoantibody production. For example, the Ku antigen is a DNA-binding protein (266). Studies of anti-DNA and anti-Ku antibodies suggest that the anti-Ku antibodies are anti-idiotypic to anti-DNA antibodies (267). Several studies have found that mice immunized with an anti-DNA antibody and mice immunized with an anti-idiotypic antibody to an anti-DNA antibody each develop autoantibodies (268 ,269). This has also been shown for other autoantigen–autoantibody systems important in lupus, such as anticardiolipin antibodies (270). Interestingly, immunization with antibodies recognizing a DNA-binding protein (anti-p53 antibodies) can generate anti-DNA antibodies (271). While such studies suggest that the idiotypic network may contribute to the production of autoantibodies, others have suggested that antiidiotypes may function to induce or maintain clinical remissions and that the failure to generate an antiidiotypic response may perpetuate autoantibody production (272).

Autoantibody responses to DNA associated antigens are often simultaneously present in established SLE (Ro/La, Sm/RNP). Longitudinal studies begun early in the disease course, demonstrate that a particular response may be initially limited to a particular peptide epitope, and be followed by intramolecular (other epitopes in the same polypeptide) and intermolecular (epitopes in distinct, but structurally linked molecules) spread of the response (273). This process is termed epitope spreading, and is the result of processing by antigen-presenting cells (including B cells) of the multimolecular complex, and presentation of novel epitopes to nontolerized T cells. The initial target for epitope spreading may be a molecular mimic derived from a microorganism, or a self-antigen. Recent data have suggested that apoptosis can generate novel nuclear autoantigen fragments (274) that may become accessible to interaction with antibody molecules by translocation to the cell surface (210 ,275). Neoepitopes of particular antigens generated by specific forms of apoptosis, for example, granzyme induced rather than caspase involved might also explain defined autoantibody profiles that are associated with SLE.

The potential role for epitope spreading in diversification of the autoantibody response in SLE has been clearly demonstrated for the anti-Sm response. James and Harley (276) identified two B/B' octapeptides that were early targets of an anti-Sm response in lupus patients. Rabbits (277) and some inbred mouse strains (276) immunized with one of these octapeptides, PPPGMRPP, develop over time an immune response against other regions of Sm B/B' and Sm D. Furthermore, in some animals antinuclear antibodies and anti-dsDNA antibodies also arise. B cell epitope spreading has also been demonstrated in the Ro/La autoantigen system (278).

Investigators have (279) identified T cells in SNF1 lupus-prone mice that were pathogenic in vivo, and accelerated the development of an immune complex glomerulonephritis in preautoimmune mice. Many of these pathogenic T cell clones were found to respond to nucleosomal antigens, specifically histone peptides. Stimulating these T cell clones with the histone peptides leads to increased anti-DNA antibody secretion in a B-T cell coculture system, and peptide immunization in vivo induces severe glomerulonephritis (280). Other investigators have focused on the immunogenicity of peptides derived from the VH regions of anti-DNA antibodies themselves (281 ,282). They (281) reported that three VH derived 12-mer peptides induce a class II restricted proliferation of unprimed T cells from preautoimmune NZB × New Zealand white (NZW) Fl mice. Immunization of NZB × NZW F1 mice with one peptide, or transfer of a T cell line reactive with this peptide, increased their titer of anti-dsDNA antibodies and the severity of the nephritis. Further support for a possible role of self peptide in induction of anti-dsDNA antibodies can be found in studies showing that tolerization with self peptides can downregulate anti-dsDNA antibody production and nephritis in murine lupus (282 ,283 ,284). This observation suggests a potential therapeutic strategy in SLE.

B Cell Tolerance

Several transgenic mouse models have been described in which immunoglobulin V regions encoding anti-DNA or other autoantibodies have been introduced into the germline. The importance of these models is multifold: (a) they afford perhaps the best direct evidence that certain anti-DNA antibodies are pathogenic, (b) they have contributed significantly to understanding the tolerizing mechanisms that regulate anti-DNA–producing B cells and the defects that allow the survival and activation of these cells, and (c) they provide models in which to test novel therapies designed to block tissue injury or inactivate pathogenic B cells.

B cells expressing autoreactive immunoglobulin receptors arise in all hosts at times of B cell receptor diversification, both during formation of the naive B cell repertoire and again during the germinal center response. Regulation of these autoreactive receptors occurs through inactivation or deletion (285) (Table 21-4). These mechanisms appear to operate when membrane immunoglobulins are cross-linked by antigen in the absence of T cell help or costimulatory influences. Whether anergy or deletion occurs depends in part on the extent of membrane immunoglobulin cross-linking (286). Normally, the serum of nonautoimmune mice does not contain high-affinity IgG autoantibodies, illustrating that the normal immune system can efficiently regulate autoantibody–producing B cells. Initial studies of anti-DNA transgenic nonautoimmune mice showed that anti-DNA antibodies are eliminated from the immune repertoire through functional inactivation (i.e., anergy) or deletion (287 ,288). In lupus-prone mice, there appears to be a defect in some aspect of regulation, allowing the autoreactive B cells to survive and contribute to the expressed antibody repertoire. A more recent study demonstrated that “ignorance” is an additional possible fate of DNA-binding B cells (289). Bynoe et al. (289) isolated low-affinity, DNA-binding B cells from a nonautoimmune mouse transgenic for an anti-DNA heavy chain. These B cells were in a resting state and produced germline-encoded, nonpathogenic antibodies. These cells may be a potential source of pathogenic autoantibodies; they may be recruited into an ongoing immune response, and then become high-affinity (and pathogenic) antibodies via somatic mutation.

In humans it has been suggested that B cells expressing ANAs and polyreactive antibodies represent 55% to 75% of the repertoire expressed in the bone marrow. The majority of these autoreactive B cells are efficiently removed from the naïve repertoire at an immature stage before exiting the bone marrow (290). Analysis of the B cell repertoire from three patients newly diagnosed with SLE showed that autoreactive B cells comprised 25% to 50% of the total mature naïve B cells compared to the 5% to 20% observed in control subjects (291). While the study showed a deficiency in removal of autoreactive B cells from the immature and transitional stages, implying a defect in negative selection, the autoantibodies that remained were mostly polyreactive against cytoplasmic antigens, insulin or single-stranded DNA and rarely against double-stranded DNA. Hence, they may be precursors of lupus B cells, but they are not themselves pathogenic B cells.

Table 21-4: Mechanisms of B Cell Tolerance

Clonal anergy
Clonal deletion
Clonal ignorance
Receptor editing

Receptor editing (see antibody assembly) is another phenomenon that can be used by B cells to maintain tolerance (292). A second immunoglobulin rearrangement occurs, so that the transgenic heavy chain is paired with an endogenous light chain to generate a VH-VL combination that is no longer autoreactive (293).

Recent transgenic studies have bred anti-DNA transgenes onto autoimmune genetic backgrounds to better understand the differential regulation of the anti-dsDNA specificity in lupus-prone mice (294). An additional innovation has been the application of “knock-in” technology (in which the immunoglobulin transgene is inserted into its proper genetic locus), which provides a more physiologic system in that somatic mutation and isotype switching of the inserted V region may occur (295 ,296 ,297). No one single defect could be identified in tolerance mechanisms (deletion, anergy, receptor editing) to account for the selective expansion of anti-DNA specific B cells in lupus mice. In fact, it has been reported that autoimmune MRL/lpr/lpr mice can efficiently delete B lymphocytes with a transgenic autoreactive receptor (298).

It is important to understand that the various thresholds for tolerance induction in autoreactive B cells (deletion, anergy, indifference) are not static, but rather may be dynamically altered by immune modulators such as cytokines, hormones, or costimulatory molecules. Studies of transgenic and knockout mice, engineered to overexpress or be deficient in molecules of interest, have begun to unravel genes and pathways involved in B cell regulation and in B cell tolerance.

The B cell receptor (BCR) is a complex of surface immunoglobulin with the accessory molecules Igα and Igβ. Following receptor cross-linking by binding of antigen to the BCR, a complex cascade of signaling molecules becomes involved in transducing the signal from the BCR to eventually result in B cell activation and proliferation, or anergy and death. The potential involvement of enhanced signaling or decreases in negative regulatory signals as possible contributors to autoimmunity is discussed below (Table 21-5).

The finding that expression of a lupus-like syndrome in MRL/lpr/lpr and C3H gld/gld mice is due to a single defect in the apoptosis genes Fas and Fas ligand, respectively (299 ,300 ,301), has generated a large amount of interest in examining the role of dysregulated apoptosis in human autoimmunity (Table 21-5). Alterations in Fas and Fas ligand have been described in patients with systemic lupus,

with some studies describing a correlation with manifestations of disease and clinical activity (302 ,303 ,304 ,305 ,306). Interestingly, humans with a variety of defects in the Fas receptor have been described, some of which manifest as significant lymphadenopathy (Canale-Smith syndrome) reminiscent of the lymphoproliferative phenotype of lpr mice with defective Fas (307). While only a single lupus patient has been described with a Fas receptor defect, Fas mutations are clearly associated with dysregulated lymphocytes and even rarely defective apoptosis (308).

Table 21-5: Single Gene Defects Causing Autoimmunity

Molecules involved in apoptosis
lpr deficiency
gld deficiency
bcl-2 overexpression
Serum amyloid protein deficiency
DNAse I deficiency
C1q deficiency
Signaling molecules
CD19 overexpression
CD22 deficiency
Lyn deficiency
SHP-1 deficiency

Other apoptosis genes have also been implicated in the induction of autoimmunity. Transgenic mice overexpressing bcl-2 have long-lived lymphocytes and enhanced immune responses to immunization, and when the transgene is present on certain genetic backgrounds, spontaneously develop antinuclear antigens and immune complex glomerulonephritis (309). Enforced bcl-2 expression allows recovery of cross-reactive anti-dsDNA, antipneumococcal antibodies from the primary response of nonautoimmune hosts immunized with a pneumococcal cell wall antigen (310). Furthermore, normally anergized or deleted autoreactive anti-DNA B cells could be recovered from mice transgenic both for bcl-2 and an anti-dsDNA heavy chain (311). Hormones can also modify the expressed B cell repertoire in mice transgenic for an anti-DNA heavy chain, and facilitate the recovery of high-affinity B cells (312). Estrogen upregulates bcl-2, and may be interfering with tolerance induction by this mechanism as well as by decreasing the strength of BCR signaling. Prolactin also permits the survival and activation of DNA-reactive B cells. It appears to act by increasing costimulatory pathways that can rescue B cells destined for apoptosis.

Another possible link between apoptosis and autoimmunity can be found in studies showing that altered clearance of apoptotic particles and persistence of nuclear material in the circulation may induce anti-DNA antibodies. Immunizing non-autoimmune mice intravenously with syngeneic apoptotic cells induces antinuclear antibodies with specificity for cardiolipin and ssDNA (313). Furthermore, these mice also develop renal immunoglobulin deposition. Recent studies demonstrate a role for complement receptors in clearing of apoptotic cells from the circulation, thus perhaps explaining the apparent paradox that humans with a deficiency in early complement components are more susceptible to SLE. Serum markedly enhances the uptake of apoptotic cells by phagocytes; components of both classic and alternative pathways of complement are responsible for the enhanced uptake (314). Phosphatidylserine on the apoptotic cell surface may activate complement, coating apoptotic cells with C3bi, which facilitates apoptotic cell uptake by complement receptors on macrophages and leading to the degradation of apoptotic material (314). Clearance of apoptotic cells via complement receptors may be important in maintaining self tolerance to nuclear antigens. Deficiency in complement receptors CD21/CD35 or complement protein C4 in Fas-deficient mice (315) and C1q deficiency in normal mice (187) accelerates or induces lupus-like features. C1q binding to apoptotic cells or exposure of anionic proteins on the surface of cells undergoing apoptosis, like annexin V, can lead to a pro-inflammatory cytokine profile of phagocytic macrophages or induce a preferential uptake of these cells by dendritic cells (DC), which can facilitate an autoimmune response (316 ,317).

Serum amyloid P may also play a role in handling of chromatin from apoptotic cells. Serum amyloid P deficient mice spontaneously develop antinuclear antibodies and severe glomerulonephritis, and display increased anti-DNA antibody levels in response to chromatin immunization (318). A similar lupus phenotype occurs in mice with a targeted deletion in DNAse 1, an enzyme that may be important in degrading DNA generated by apoptosis (188). Interestingly, one study has suggested that patients with SLE have significantly lower serum levels of DNAse 1 when compared to controls with nephritis from other causes (319).

In mice, the complete phenotypic expression of autoimmunity caused by the lpr defect (320) or the bcl-2 transgene (321) is highly dependent on the genetic background. It seems reasonable to speculate that Fas, Fas ligand, bcl-2, and other genes and regulators of apoptosis, in combination with additional as yet unidentified genes, may be sufficient to induce many of the phenotypic features of systemic lupus in humans, although it is evident that defects in Fas expression lead to a different human disease.

Abnormalities in signaling pathways can alter thresholds for induction of B cell tolerance. The BCR is associated with several molecules that comprise the B cell coreceptor complex. CD19 is part of the coreceptor complex, and plays a role in regulating signaling thresholds that modulate B cell activation and autoimmunity (322). CD19 overexpression leads to an increased strength of the BCR signal resulting in B cell hyperresponsiveness and breakdown of peripheral tolerance, as manifested by increased levels of anti-DNA antibodies and rheumatoid factor in mice (323). C22 is a B cell surface glycoprotein that becomes rapidly phosphorylated following BCR crosslinking. CD22 is a negative regulator of BCR signaling as shown by hyperresponsiveness to receptor signaling in mice deficient for the molecule (324). CD22 deficient

mice display a heightened immune response, increased numbers of B-1 B cells, and serum autoantibodies (325). Associated with CD22 are Lyn and SHP-1. Targeted deletion of the genes encoding either of these molecules also leads to autoimmune manifestations (326 ,327 ,328). The effects of alterations of these signaling molecules on regulation of tolerance and autoimmunity are evident in mice; however, a definite role for altered signaling in the autoimmune diathesis in patients with lupus remains speculative at this time.

Recent studies have also shown that an overabundance of molecules that rescue B cells from negative selection will lead to the development of a lupus-like serology in mice. BAFF is a B cell survival factor and is critical in the ability of transitional B cells to acquire a mature B cell phenotype and achieve immunocompetence. BAFF overexpression however, leads to the survival of autoreactive B cells that would normally be deleted at an immature stage of development. Presumably, BAFF receptor activation impedes the apoptotic pathway triggered by BCR engagement.

Activation of TLR9 in B cells by DNA-anti-DNA complexes can also rescue B cells from negative selection. Thus, the immune complexes that are characteristic of lupus probably contribute to sustaining the maturation and activation of DNA-reactive B cells that might otherwise undergo tolerance induction.

As mentioned above, increased prolactin can potentiate autoimmunity by upregulating CD40 on B cells and CD40 ligand on T cells. Engagement of CD40 is another mechanism for blocking the completion of an apoptotic program induced by BCR engagement of immature B cells. Not surprisingly, therefore, overexpression of CD40 in mice can also lead to autoantibody production. Several studies have suggested an increased expression of CD40 ligand on both T and B cells in SLE patients that may function to prevent B cell tolerance induction and to enhance activation (329).

Therapeutic Interventions

Classic therapeutic interventions in SLE are characterized by their lack of specificity for B cells making particular pathogenic antibodies. Besides the desired decrease in autoantibody production by B cells, these therapies also cause a more generalized immune suppression, with potentially devastating consequences. In recent years, there have been several new and intriguing developments in the treatment of SLE (Table 21-6). Important advances in the molecular biology of B lymphocytes and their regulation have increased our understanding of the immunologic mechanisms that mediate B cell tolerance and offer new opportunities and novel targets for therapeutic manipulation. While many of these approaches are not selective for autoreactive B cells, they may have the advantage of causing fewer deleterious side effects than conventional cytotoxic therapy. Furthermore, antigen-specific therapies may increase the selectivity of the intervention, offering efficacy while potentially decreasing unwanted side effects.

Table 21-6: Therapeutic Interventions in SLE

Nonantigen-specific therapies
Classic immunosuppressive therapies (corticosteroids, cytotoxics)
Rapamycin
Mycophenolic acid
Inhibition of costimulation (anti-CD40 ligand, CTLA-4-Ig)
BAFF/APRIL blockade
Anti-CD20 antibody (Rituximab)
Stem cell transplantation
Hormonal manipulation
Antigen-specific therapies
LJP 394 (tetrameric oligonucleotides)
Peptide-based
Immunoglobulin V region-derived peptides
Histone peptides
Peptide mimotopes of dsDNA

CTLA, cytotoxic T-lymphocyte antigen; BAFF, B cell-activating factor; APRIL, proliferation-inducing ligand

Nonantigen-Specific Therapies: Interfering with Cognate Interactions

Antiself antibodies in SLE clearly arise from T cell–dependent responses. Among the important accessory molecules in the B cell–T cell interaction, CD40 ligand (gp39) is expressed on activated T cells and binds to antigen-specific B cells to transduce a second signal for B cell proliferation and differentiation (Fig. 21-3) and, as mentioned above, to rescue autoreactive B cells from deletion at an immature stage. A short treatment of young SNF1 lupus-prone mice with a monoclonal antibody to CD40 ligand markedly delays and reduces the incidence of lupus nephritis for long after the antibody had been cleared (330). Furthermore, treatment of older SNF1 mice with established nephritis reduces the severity of nephritis and prolongs survival (331). Similarly, treating NZB × NZW F1 mice with anti-CD40 ligand leads to decreased anti-dsDNA antibody titers, less renal disease, and most importantly improved survival compared to the control group (332). Inhibition of other costimulatory molecules was also found to be beneficial in lupus. Selective inhibition of the interaction of costimulatory molecules B7-CD28 by cytotoxic T-lymphocyte antigen-4 (CTLA-4)-Ig (a recombinant fusion molecule between CTLA-4 and the Fc portion of an immunoglobulin molecule) blocks autoantibody production and prolongs life in NZB × NZW Fl mice, even when given late in the course of disease (333 ,334). This intervention prevents T cell activation, thereby preventing T cell–dependent B cell activation. Simultaneous blockade of B7/CD28 and CD40/CD40 ligand with a short course of CTLA-4-Ig and anti-CD40 ligand was significantly more effective than either intervention

alone (335). Clinical trials with anti-CD40L antibody in lupus were terminated because of a higher incidence of thrombo-embolic events (336). Investigation into the possible mechanisms leading to increased thrombosis revealed that human platelets express CD40L, which interacts with integrins (337 ,338). This interaction apparently is important to maintain stability of a platelet thrombus; in the presence of anti-CD40L antibody preformed platelet clots become unstable and release smaller thrombi. Mechanistic studies performed in a limited number of patients that received this antibody, demonstrated however, a decrease in the number of peripheral anti-dsDNA B cells as well as a decrease in the titers of anti-dsDNA antibodies (339). Clinical studies using CTLA-4-Ig in the treatment of human lupus are underway.

B cell–activating factor (BAFF) of the tumor necrosis factor family plays an important role in B cell survival and excess BAFF is often upregulated in SLE patients. There have also been encouraging results with BAFF blockade in murine SLE and clinical studies in human lupus are in their early stages (340). A vast clinical experience in the treatment of non-Hodgkin lymphoma has accumulated on the use of a humanized chimeric antibody (rituximab) specific for human CD20. This pan-B cell surface marker is expressed on pre- and mature B cells but almost undetectable on plasma cells (341). Recent small clinical trials of rituximab along with cytoxan and steroids in SLE suggest there may be significant benefit for diverse clinical manifestations but a randomized, placebo controlled trial has not yet been performed (342 ,343 ,344).

Nonantigen-Specific Therapies: Interfering with T Cell Proliferation

Mycophenolate mofetil inhibits inosine monophosphate dehydrogenase, an enzyme important in the de novo synthesis of guanine nucleotides. Inhibition of this metabolic pathway inhibits B- and T cell proliferation, and results in immunosuppression (345). While mycophenolate mofetil acts as a cytotoxic agent by inhibiting cell division, this effect is relatively selective, and limited to lymphocytes. In MRL/lpr/lpr (346) and NZB × NZW F1 (347) murine lupus models, mycophenolate mofetil improves renal disease, decreases serum anti-dsDNA antibody levels, and significantly prolongs survival. In a recent study in human lupus, mycophenolate mofetil showed beneficial effects in the treatment of lupus nephritis (348).

Rapamycin is a novel immunosuppressive macrolide drug, which inhibits lymphocyte proliferation. Rapamycin binds to a protein kinase important in regulating cell cycle progression (349). In MRL/lpr/lpr mice, treatment with rapamycin significantly reduces serologic manifestations of lupus as well as tissue damage (350). Treatment of NZB × NZW F1 mice with early nephritis (5 months of age) with a brief course of anti-B7 antibodies in combination with an 8-week course of rapamycin reduced mortality at 10 months from 60% to 0% (abstract FASEB).

Antigen-Based Therapies

There are two theoretical ways by which antigen conjugates might improve the course of disease in lupus. First, antigen conjugates may specifically block pathogenic autoantibodies from binding to their target antigen and initiating a tissue-destructive inflammatory cascade. Second, antigen conjugates may downregulate antigen-specific B cells and induce specific B cell tolerance, which is ordinarily induced by BCR ligation in the absence of costimulation. One such conjugate, polyethylene-glycol with tetrameric oligonucleotides, was administered to BXSB male lupus-prone mice (351). Treatment decreased the number of anti-dsDNA–producing B cells, decreased proteinuria, and significantly increased survival. Several studies in humans have been inconclusive although there does appear to be some decrease in the serum anti-dsDNA titers (352 ,353 ,354). A putative role for peptides in induction of anti-DNA antibodies was discussed above; these small antigens may also be suitable for therapeutic use. Intravenous treatment of preautoimmune SNF1 mice with nucleosomal peptides postpones the onset of nephritis, while chronic treatment of older mice with established disease improves survival (283). Immunization of mice with peptides derived from anti-dsDNA antibodies have been shown to activate autoreactive T cells that provide help for the production of autoantibodies (see above). Treating NZB × NZW Fl mice with several T cell peptide epitopes derived from an anti-dsDNA antibody induces T cell tolerance to these peptides, and results in significantly improved renal disease and prolonged mean survival (284). Similarly, mice treated neonatally with CDR-based peptides acquire resistance to subsequent induction of autoimmunity (282). Clinical trials with tolerogenic peptides are about to commence.

The recent technology of displaying random peptides in phage permits the identification of peptides that function as surrogate antigens to autoantibodies. The selected peptide does not necessarily have to be the actual sequence that is recognized by pathogenic antibody (although it can be). Whether peptide dsDNA mimotopes will be useful in inhibiting polyclonal antibody deposition and/or directly tolerizing pathogenic B cells in lupus mouse models is currently under investigation.

Summary

Sequences of many anti-dsDNA antibodies have been analyzed to see how they differ from the human and murine antibody response to foreign antigens. As expected from idiotypic studies in SLE, certain V region genes or families are used preferentially in the anti-DNA response. However, observations of restricted gene usage do not differ in principle from those made in the response of nonautoimmune animals to foreign antigen, in which a small number of V regions dominate the response to any particular antigen. No particular gene family is absolutely necessary for the production of autoantibodies; nonetheless, investigation is continuing into genetic polymorphisms in the Ig locus that are

associated with human lupus. It appears, however, that all individuals are capable of generating pathogenic autoantibodies; in autoimmune individuals, autoantibodies that have developed high affinity for autoantigen through somatic mutation are present in the expressed B cell repertoire. This appears to primarily reflect a defect in the mechanisms of self tolerance rather than an abnormality in V-gene repertoire, the process of gene rearrangement, or the process of somatic mutation. While a defect in central tolerance permitting exodus of autoreactive B cells from the bone marrow (perhaps through lack of proper receptor editing or through aberrant signaling) seems to occur in lupus, it is equally possible that the defect is in peripheral tolerance (in the regulation of B cells maturing in the germinal centers), where responsible mechanisms are not yet delineated.

The autoantibody response in SLE has the characteristics of an antigen-selected response. Cognate B-T–cell interactions are crucial to the maturation of pathogenic anti-dsDNA antibodies, which are primarily IgG, mono- or oligo-specific, and have high affinity for the antigen (dsDNA). Together with the higher-than-random R-to-S ratio in the CDRs of many anti-dsDNA antibodies, this suggests that the anti-DNA response is both driven and selected by an antigen. Pathogenic, IgG anti-dsDNA antibodies in SLE seem to arise from the conventional B cell lineage, possibly through somatic mutation of genes encoding protective antibodies. There is some speculation that natural autoantibodies, perhaps from the B-1 lineage, also could be precursors for anti-DNA antibodies.

While it is clear that more than one constellation of immunologic defects can result in the clinical syndrome collectively known as SLE, and almost certainly there is heterogeneity in the patient population, advances in understanding aspects of both B cell biology and disease pathogenesis have led to the development of new potential therapeutic modalities. Integration of inhibition of co-stimulation or antigen-specific therapies into the routine management of patients with systemic lupus does not seem to be far into the future.

Chapter 22
Antinuclear Antibodies: An Overview

Ian Giles

David Isenberg

Introduction

The antinuclear antibody test (ANA) is often used as a means to determine whether an individual presenting with joint problems has an autoimmune rheumatic disease (ARD) such as systemic lupus erythematosus (SLE) or a related disorder. A positive ANA is thus a serologic indicator of autoimmune disease although further immunologic investigations coupled with clinical findings are required to make a specific diagnosis. These further investigations may also provide relevant information concerning disease activity, end-organ involvement, and prognosis. Although initially identified on immunofluorescence microscopy (IFM) more than 100 nuclear antigen-antibody specificities have been identified using more sophisticated techniques, e.g., immunoblotting in patients with SLE and various ARD (1) reflecting the heterogeneity of the various nuclear targets. Given however, the vast number of targets available within the cell (around 2000) and the fact that very few specificities are found in more than 30% of patients; the diversity of autoantibodies produced is actually rather restricted. Distinct autoantibody profiles may provide a specific diagnosis.

The LE cell phenomenon, of phagocytosis of leukocytes exposed to lupus patients serum, described by Hargraves in 1948 (2) was the first serologic marker used in the diagnosis of SLE and has now been replaced by ANA testing. For the past 40 years ANA has been detected by IFM initially on rodent tissue sections (3 ,4 ,5) and more recently using human cell lines (6) that are capable of greater pattern recognition because of the larger size of individual cells and more discrete fluorescence of subcellular organelles while displaying species specificity.

Crucial to the interpretation of the ANA test is the recognition that the main patterns of staining on IFM are rarely specific or diagnostic of any individual autoantibody or disease. An exception to this is the centromere pattern seen with antikinetochore antibodies in limited cutaneous scleroderma. The presence and pattern of staining of ANA is indicative of the presence of an autoantibody which should be verified with more specific tests (see later) and considered in the clinical context to deduce if the diagnosis of SLE, another autoimmune or separate disease should be considered.

This chapter summarizes the history of ANA testing, choice of substrate, interpretation of IFM with links to target antigens and their clinical relevance, more specific diagnostic tests and a practical guide to interpretation. The aim is to provide an understanding of the strengths and limitations of ANA determination, its sensitivity and specificity, and above all the importance of a positive ANA result in deciding if the patient has SLE or an autoimmune disease at all.

History

The initial description of the LE cell test (2) constituted one of the first laboratory abnormalities found to be associated with SLE. Haserick in 1950 then demonstrated that the LE factor is a component of the gamma globulin fraction of serum proteins (7), while Miescher in 1954 reported that incubation of sera from lupus patients with a suspension of cell nuclei eliminated the capacity to induce the LE phenomenon (8). Thus the LE test was the first antinuclear antibody reactivity ever described, and has recently been shown to be directed against histone H1 as the major monomeric proteinaceous antigen (9).

Friou et al. in 1957/8 first described and partially characterized the phenomenon by which serum from patients with SLE would bind to nuclear antigens in fresh frozen tissue from humans and a range of vertebrate animals. Using fluorochrome labeled antisera it was shown that the component binding the nucleus was in fact antibody from the patient (3 ,10). These findings were subsequently confirmed by others (4 ,5) and clearly demonstrate that an autoimmune pathology was underlying the disease and heralded a new era of research into SLE and since 1971 has been one of the 11 ACR classification criteria (6 ,11).

Choice of Substrate

In the last 45 years a variety of substrates have been used to identify the presence of a positive ANA. Initially rodent tissues of varying types, e.g., mouse kidney, rat liver were popularized. More recently human cell lines, especially epithelial cells (HEp-2) derived from a human laryngeal carcinoma (12 ,13) have been widely adopted. HEp-2 cells have the advantage that, in addition to the easy visualization of large nuclei and nucleoli, as rapidly dividing cells they present antigens only expressed during certain stages of the cell cycle which enables a wide range of staining patterns to be

recognized on IFM. The cell lines can be cultured in the research laboratory or are available from commercial companies on slides. Analysis of the pattern, intensity, and even presence of immunofluorescence is very time-consuming requiring careful interpretation by a trained technician or pathologist that may still give rise to a wide variability between different laboratories experienced in performing ANA tests (14).

More recently attempts at improved standardization of ANA testing have been introduced using commercially developed enzyme-linked immunoabsorbent assays (ELISA). There are several different assays available some of which coat the ELISA plate with extracts of entire nuclei while others use only specific antigens. However, the results of these different assays vary significantly from each other and in some cases from ANA measured by IFM when tested upon the same serum. Those ELISAs with the highest sensitivity for the detection of SLE (in patients known to have the disease) have the highest false-positive rate, while those tests with a low false positive rate have a low sensitivity for the detection of lupus in the same patients (15).

A further disadvantage of the different ELISA kits that use specific antigens is that they cannot detect as yet unknown cellular antigens. In ELISA kits that utilize whole nuclear extracts to coat the plate it is difficult to monitor the binding of different antigens to the polystyrene plates. Thus IFM is likely to remain the test of choice using HEp2 cells for some time.

Patterns of Immunofluorescence and Links to Target Antigen

Demonstration of a positive ANA is merely the start of the journey. Given that the cell nucleus contains DNA, RNA, proteins, and enzymes together with some special structures such as the nucleolus and nucleosomes—the fundamental unit of chromatin, major attempts have been made in the past 40 years to define more precisely what is/are the antigenic targets of a serum that gives a positive immunofluorescence pattern.

Table 22-1: Patterns of IFM on Tissue Culture Staining

Pattern on IFM	Linked Antigen Specificities	Related Disease
Nuclear		
Homogenous	Chromatin, histone, dsDNA Ku	SLE, DIL PM-Scl-SLE
Rim enhanced	Lamins, nuclear pore complex	SLE
Speckled		
coarse	Sm, U1-RNP	SLE
Fine	Ro, La	SS, SCLE, CHB, NL
Distinct	Anti-p80 coilin, anti-p95	PBC
Nucleolar		
speckles	Scl 70, RNA polymerase 1	Scl
Homogenous	PM-Scl Ku	Scl PM-Scl-SLE
Clumpy	U3RNP	Scl
Centromere	kinetochore	Scl
Different patterns of staining	PCNA	SLE
Cytoplasmic	Ribosomal P protein	SLE

SCLE, subacute cutaneous lupus; CHB, congenital heart block; PBC, primary biliary cirrhosis; DIL, drug-induced lupus; PM-Scl-SLE, polymyositis-scleroderma-SLE overlap.

Six main patterns of IFM on HEp2 cells are recognized, one of which is directed against constituents of the cytoplasm (Table 22-1), not all of these patterns occur commonly in SLE patients. The pattern of staining often reflects the predominant antibody present in the serum. A homogenous pattern corresponds with antibodies binding to dsDNA (16) and/or histones (17 ,18), both of which are described in detail later. The peripheral (rim) pattern has been reported with antibodies to integral glycoproteins of the (1) inner nuclear membrane-lamin B (homogenous rim pattern) in SLE (19) and (2) nuclear pore complex, glycoprotein (gp)210 (punctate rim pattern) in patients with myositis (20), primary biliary cirrhosis (21 ,22), and chronic active hepatitis (23).The antibodies to lamin B found in the sera of patients with lupus may explain the peripheral rim pattern described in previous reports and which was thought to be due to antibodies to DNA (24). A speckled pattern is commonly found in patients with SLE indicating binding to a variety of nonhistone, small ribonucleoprotein (RNP) particles including: Sm (25), Ro, La, and U1RNP (26). The precise function of these particles is unknown but they may play a role in the processing of messenger RNA. In fact, the anti-Sm and anti-Ro reaction consists of multiple antibodies binding to multiple antigens. Anti-Sm antibodies bind to a series of proteins: B, B', D, E, F, and G complexed with small nuclear RNAs: U1, U2, U4–6, and U5 (27). The major antigenic peptides of the Ro RNA protein particle are described by their molecular weight, 52-kD and 60-kD Ro. Antibodies to Sm are virtually diagnostic of SLE and are found in 30% of black lupus patients and 5% of Caucasians, frequently in conjunction with anti-U1RNP antibodies. Anti-La antibodies are particularly

associated with SLE and Sjogren syndrome (SS), frequently in conjunction with anti-Ro antibodies, (16) and lupus patients with anti-La antibodies are less likely to have renal disease (28). Anti-Ro antibodies without anti-La are also detected in subacute cutaneous lupus erythematosus (SCLE), lupus of homozygous C2 and C4 deficiencies and neonatal lupus syndrome (29). Figure 22-1 show some examples of these common patterns of nuclear IFM in lupus patients.

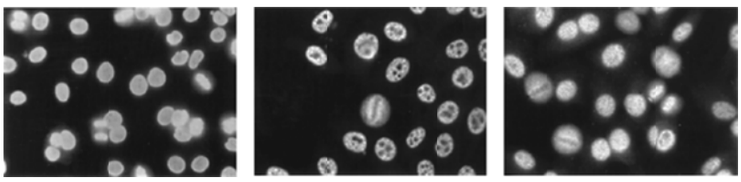

Figure 22-1. Patterns of IFM upon HEp-2 cells commonly seen in patients with SLE. **A,** Homogenous staining characteristic of antibodies to dsDNA. **B,** Coarse speckled staining typical of anti- U1RNP/Sm antibodies. **C,** Fine speckled staining characteristic of antibodies to Ro/La antigens.

Different patterns of cytoplasmic staining exist and are indicative of the distinct target antigens involved. Antibodies directed against components of the cytoskeleton are identified more frequently in ARD but are not specific to lupus (30 ,31). Approximately 15% of SLE sera display a fine speckled pattern on IFM, which has been identified as antibodies to ribosomal P protein. (32 ,33). Interestingly, the presence of an epitope that is antigenically related to the carboxyl terminus of ribosomal P proteins has been found on the surface of a variety of cells including human neuroblastoma cells, endothelial cells, and activated monocytes (34). Recently, antiribosomal antibodies affinity purified from patients with SLE were shown to increase the production of tumour necrosis factor α (TNF-α) and interleukin-6 by activated monocytes in vitro (35).The clinical significance of these findings however are unclear; since although anti-ribosomal P antibodies have been reported to correlate with neuropsychiatric manifestations (36) and severe depression (37) in SLE these associations were not evident in many published series and this proposed link remains controversial (38).

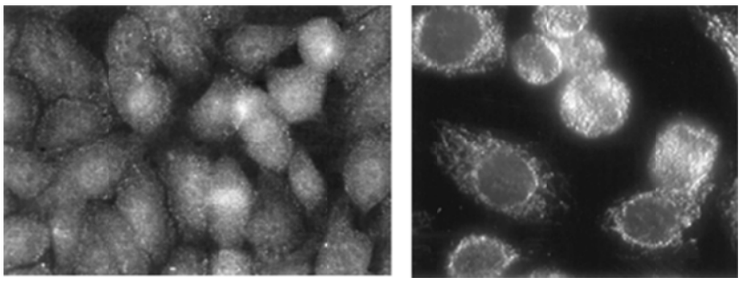

Figure 22-2. A, The fine speckled pattern of cytoplasmic IFM, characteristic of antibodies against ribosomal P and the aminoacyl t-RNA synthetases. **B,** In contrast the reticular, lacy cytoplasmic staining characteristic of antibodies to mitochondria typically seen in patients with primary biliary cirrhosis. The substrate in both cases was HEp-2 cells.

The finely granular cytoplasmic fluorescence seen with antiribosomal P antibodies is also seen with autoantibodies to antigens involved in translation and protein synthesis, the aminoacyl-tRNA synthetases: anti-Jo-1 (39), anti-PL-7 (40), anti-PL-12 (41), anti-EJ (42), anti-OJ (42), anti-KS (43), antibodies to signal recognition particle (44), and anti-KJ (45). Figure 22-2 demonstrate the pattern of staining typical of anti-Jo-1 antibodies. These autoantibodies have not yet been described in lupus being virtually confined to patients with autoimmune myositis especially those with accompanying interstitial lung disease (46).

Centromere and nucleolar patterns of IFM are rarely seen in SLE sera. If detected their presence should alert the physician

to an alternative diagnosis. Nucleolar patterns are mostly displayed in sera from scleroderma (SSc) patients or overlap syndromes. Anti-topoisomerase I antibodies, originally described as anti-Scl-70 (47) are found in approximately 25% of SSc patients and identify the diffuse cutaneous subgroup (DcSSc) with systemic involvement. Anticentromere autoantibodies (ACAs) targeted against the kinetochore are more prevalent, 52% to 82% in SSc patients with limited cutaneous disease (48 ,49). To date, more than six centromere proteins have been identified as bound by sera from patients with SSc, designated CENP-A (centromeric nucleoprotein A) through CENP-F (50). Figure 22-3 illustrates both centromere and nucleolar IFM patterns.

Rarely, a homogenous nuclear and nucleolar IFM pattern is caused by antibodies directed against anti-Ku, which were first described in Japanese PM-SSc overlap patients (51). Initially, there was some confusion with another precipitating antibody system, the anti-Ki, because of the serum used as prototype in the laboratories (16 ,52). The Ku antigen consists of two proteins of 66 and 86 kD, which bind tightly to DNA (53 ,54). Anti-Ku antibodies are found in 55% of Japanese PM-SSc patients (51), and 1% to 19% of SLE-PM-SSc patients and 1% to 14% of SSc patients in North America (46 ,55).

Anti-Ki antibodies described in 1981 (56) are probably identical to the sicca-lupus system (SL) identified in the same year (57) and found in 7% to 10% of unselected SLE sera by immunodiffusion studies (58). The antibodies recognize a 32 kD nonhistone nuclear antigen and display speckled nuclear patterns on IFM. Subsequent detection of anti-Ki antibodies by ELISA using rabbit thymus extract as substrate revealed frequencies of 19% and a fluctuation of the antibodies with disease activity in the sera from lupus patients (59). Further studies with recombinant Ki antigen on ELISA testing found a frequency of 21% of anti-Ki antibodies and an association with central nervous system (CNS) involvement in SLE patients (60). Despite these reported findings anti-Ki antibodies are not specific for SLE being found in sera of many other patients with ARD.

A rare but specific polymorphonuclear pattern corresponding to different phases of the cell cycle is detected in 3% of SLE sera (16) and is caused by antibodies to proliferating cell nuclear antigen (PCNA, previously called cyclin), an antigen involved in cell cycle regulation. Peak expression of PCNA has been shown to occur immediately before full DNA synthesis hence its name (61 ,62). These antibodies are rarely found in other diseases.

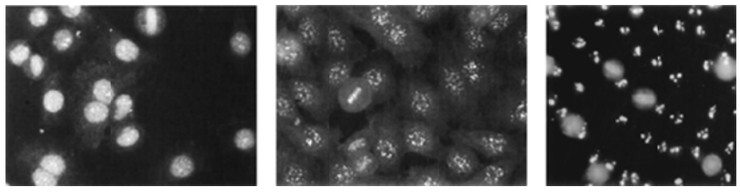

Figure 22-3. Immunofluorescence patterns on HEp-2 cells rarely seen in SLE. **A,** Fine granular nucleolar staining characteristic of anti-Scl-70 antibodies. **B,** The diffuse speckled nuclear pattern typical antibodies against the centromere in metaphase. **C,** Clumpy nucleolar fluorescence characteristic of anti-fibrillarin U3RNP antibodies.

Antibodies to RA-33 an antigen contained in nuclear extracts were initially described in sera from patients with rheumatoid arthritis (RA) but there was no correlation with the presence, absence or pattern of ANA staining on IFM (63). Subsequently RA-33 antibodies have been shown to be identical to the A2 protein of the heterogeneous RNP complex (64). It is now recognized that RA-33 antibodies identify a subset of SLE patients who have an erosive arthropathy (65).

Clinical Interpretation

In high titers, say dilutions exceeding 1:320, in an appropriate clinical setting, e.g., a young woman presenting with a malar rash, polyarthralgia, and leucopenia, the ANA test and interpretation of its significance are straightforward. For every positive ANA result in a case of SLE however, many more will arise because of drug therapy, old age, chronic infection, chronic liver disease, and other ARD. Very rare cases of ANA negative lupus are reported (see later) and a positive ANA may be found

in healthy individuals and asymptomatic first-degree relatives of lupus patients (60 ,61). Furthermore, ANA results vary widely depending on the substrate and immunohistochemical methods used for detection. Currently, the most widely described technique in published studies is IFM on HEp-2 cells. Evidence based guidelines for the use of immunologic laboratory tests in the rheumatic diseases have been published (27 ,50 ,66 ,67 ,68). These guidelines were developed by critical review of all relevant papers using published standards for studies of diagnostic tests, the use of which was then categorized as primarily diagnostic or prognostic. Information extracted from each paper was used to calculate a weighted average for sensitivity and specificity from which likelihood ratios were then derived and used to recommend the usefulness—or otherwise—of a test to practicing physicians (66).

In healthy individuals, age 20 to 60 years, ANA determined by IFM on HEp-2 cells has been shown to be positive at an increasing frequency with decreasing ANA titer. Thus 3.3% of putatively normal individuals are ANA positive at 1:320 dilution and up to 31.7% of the same population at 1:40 dilution (14). There is a steady rise in the prevalence of numerous autoantibodies with increasing age such that 10% to 37% of healthy elderly individuals (older than 70 years of age) have a positive ANA albeit of generally low positive titer (69 ,70). Therefore, ANA results should always include a description of the highest titre for which IFM is detected and ideally a description of the percentage of patients without any ANA-associated disease (controls) who have similar titers (67).

A positive ANA has been found in most patients with a systemic ARD to varying degrees; however it occurs with the highest frequency and titre in SLE (Table 22-2). The absolute level of the titre itself does not carry any prognostic significance, however higher titers are more likely to be significant in making a diagnosis of disease.

In some cases however, the ANA may be positive even before the diagnosis of SLE has been made. An evaluation of a prospectively assembled collection of frozen samples taken from more than 5 million U.S. armed forces personnel found a positive ANA (at a dilution of ≥1:120) in 101 of 130 patients with SLE up to 9.2 years before the diagnosis (71). Furthermore, this study found a progressive accumulation of specific autoantibodies before the onset of SLE; with ANA, anti-DNA, antiphospholipid, anti-Ro, and anti-La antibodies present earlier than anti-Sm and anti-nuclear RNP antibodies (71).

Thus the presence and staining pattern of a positive ANA alone is not sufficient to determine the presence of lupus or any ARD. Detection of specific autoantibodies is required by more specific tests and even then not all autoantibodies can recognise a specific disorder (72). Consideration of autoantibody profiles however increases diagnostic predictive value without loss of specificity or sensitivity. For example, the presence of antibodies to dsDNA and/or Sm are very useful for confirming the diagnosis of SLE, although a negative result does not exclude SLE (27 ,68). Since these autoantibodies are rarely found in other ARD they are very useful in distinguishing patients with SLE from those with other ARD, such as SS (associated with anti-Ro and/or anti-La) or SSc (ACA and/or Scl 70 antibodies) (73). The same autoantibody profiles have been tested in SLE patients and found to identify disease subsets. For example lupus patients with antibodies to dsDNA and/or Sm had a significant increase in malar rash, hypocomplentemia, renal and hematologic involvement while patients with anti-Ro and/or anti-La antibodies had a worse lupus rash and photosensitivity (74). In fact, the strongest autoantibody association with the presence and activity of SLE renal disease occurs with anti-dsDNA antibodies, which also correlate with overall disease activity in many but not all patients with SLE (68). Evidence-based guidelines, described earlier, found that anti-Sm and anti-RNP antibodies add little to the prediction of renal disease in SLE (27). A recent study of a large and consecutive cohort of 285 patients with SLE identified five clusters of autoantibodies with particular clinical associations. The most striking of these associations were of anti-RNP antibodies with Raynaud phenomenon, of anti-Ro and anti-La antibodies with sicca symptoms and of antiribosomal P antibodies with hemolytic anemia (75). Therefore more diagnostic and prognostic power is conferred when autoantibody profiles are considered as a whole in each patient.

Table 22-2: Positive ANA Tests in Various Conditions Using HEp-2 Cells as Substrate

SLE	Other ARD	Other Disease	Normal Population
98%	SSc 98%	Chronic active hepatitis 100%	13.3% at 1:160
	PM 90%	Drug-induced lupus 100%	
	SS 80%	Myasthenia gravis 50%	FDRs of SLE
	pJIA 70%	Waldenstrom macroglobulinemia 20%	patients 20%–30%
	RA 60%	Infectious mononucleosis 15%	
	PAN 18%	Diabetes 25%	

ARD, autoimmune rheumatic diseasel SSc, scleroderma; PM, polymyositis; SS, Sjogren syndrome; pJIA, pauciarticular juvenile idiopathic arthritis; RA, rheumatoid arthritis; PAN, polyarteritis nodosa; FDR, first-degree relative.

A wide variety of drugs can induce a positive ANA and/or symptoms of drug-induced lupus (DIL), most commonly hydralazine, procainamide, isoniazid, minocycline, and chlorpromazine. Of particular interest is the reported induction of ANA and/or anti-DNA antibodies in some patients treated with TNF-α inhibitors (76 ,77), despite which this class of drug has been successfully used to treat a small number of lupus patients in open label trials (78). The homogenous staining pattern seen on IFM with such drugs is caused by antibodies to histones targeted primarily against the H2A-H2B-DNA complex (79 ,80 ,81) or H2A-H2B alone (82). Anti-histone antibodies are also found in 30% to 80% of idiopathic SLE sera directed mainly against H1 and H2B (83), H3 (58), and the H2A-H2B complex (18). The presence of these antibodies is not associated with any particular clinical manifestations in SLE but have been correlated with disease activity (84).

Thus homogenous staining and the presence of antihistone antibodies alone cannot distinguish between idiopathic

lupus and DIL when a patient has appropriate symptoms having been exposed to a potentially lupus inducing drug. If other autoantibodies are present and the symptoms do not abate within a few months of stopping the drug accompanied by a decline in the ANA then DIL is unlikely.

More Specific Diagnostic Tests

Once the presence of autoimmunity is suspected clinically and then reinforced with a positive ANA more specific tests of antibody detection are required. Antibodies to the target antigen of interest are labeled with markers such as enzymes, fluorochromes, or radioisotopes in the tests commonly used notably radioimmunoassay (RIA), ELISA, and Western blotting, which are more sensitive than immunodiffusion techniques.

RIA is similar to IFM in that a labeled antibody, conjugated with a radioisotope in this case, is used to detect a specific antigen. The technique is very sensitive detecting antigen in the picogram range. An inherent drawback of RIA is the use of radioisotopes that require careful handling and expensive equipment to monitor radio-active emissions. Hence the ELISA was devised whereby antibodies against the antigen of interest are attached to an enzyme such as horseradish peroxidase or alkaline phosphatase instead of a radioisotope. Detection of the antibody (and thus antigen) is facilitated by the addition of a substrate and developer that will generate a colour reaction if the enzyme labeled antibody is present. The end point color can be read in a spectrophotometer or ELISA reader to give a quantitative estimation of the bound antibody and hence antigen. Advantages over RIA include the lack of radioisotopes and speed as a 96 well plate can be read in less than 1 minute.

Western (immuno) blotting takes proteins from an extract of cultured cells and separates them by polyacrylamide gel electrophoresis according to their charge. The separated proteins are then transferred electrophoretically to a nitrocellulose (NC) sheet that is a replica of the original gel and a solid support for antigen. The NC sheet can then be probed with either enzyme or radiolabeled antibody (85).

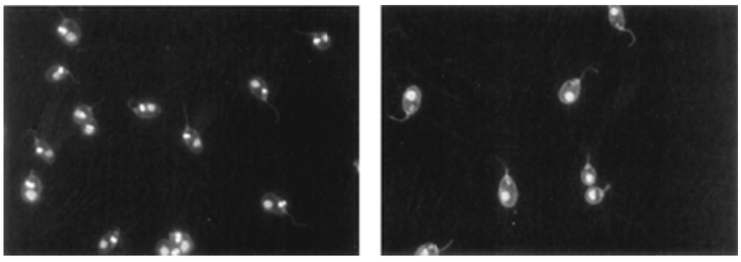

Figure 22-4. A, The Crithidia luciliae assay for antibodies to dsDNA is positive with immunofluorescence of the kinetoplast only. **B,** Fluorescence of the nuclei, in this example, or any structure other than the kinetoplast is not indicative of the presence of anti-dsDNA antibodies.

Identification of Lupus-Related Antibodies

Of the disease specific antibodies found in patients with SLE it is those targeting dsDNA that carry the most diagnostic power and clinical application. The presence of antibodies to dsDNA—especially of the IgG isotype—has been used as a serological marker for the presence of SLE for over 45 years. Between 60% to 83% of lupus patients are found to have anti-dsDNA antibodies when tested by one of the currently available assays and in some patients the titer of these antibodies is an excellent measure of disease activity. Despite some problems with regard to the type of assay used to detect these immunoglobulins and one or two potential challenges to their serological predominance—such as antinucleosome antibodies—on balance the continued inclusion of anti-dsDNA antibodies as a criterion for the diagnosis of lupus remains a reasonable proposition (86). Furthermore, their use as a potential biomarker has been proposed in future clinical trials to study the effects of new therapies for SLE (87).

Amongst the currently available methods of detecting antibodies to dsDNA the Farr (RIA) may be the most specific test for SLE and is the assay most likely to predict occurrence of disease flare especially glomerulonephritis. The Crithidia assay detects anti-dsDNA antibodies by their ability to bind to the kinetoplast of *Crithidia luciliae,* a protozoan organism with a circular dsDNA structure at one pole, and subsequent immunofluorescence. This assay is technically demanding, requiring careful training of technicians to correctly identify the kinetoplast rather than the nucleus or polar body upon IFM, as shown in Figure 22-4 . A major advantage is that it detects antibodies to dsDNA almost exclusively as opposed to the Farr and ELISA that may give positive results with ssDNA. However, the ELISA is widely available and relatively easy to

perform detecting both high- and low-affinity IgG antibodies to dsDNA (88).

Amongst the different ELISA kits available there are marked differences in sensitivity, specificity and predictive values in diagnosing SLE and determining disease activity (89). Hence laboratories may offer more than one test for detection of anti-dsDNA antibodies in certain instances. For example the Crithidia assay may be reserved for diagnosis and ELISA used to monitor antibody titers and thus reflect disease activity.

Recent studies have strengthened the notion that nucleosomes may be in vivo targets of anti-dsDNA antibodies in patients with SLE. Analysis of serum antibody activity against nucleosomes and dsDNA has shown both in human and murine lupus that serum anti-dsDNA reactivity is almost always associated with an antinucleosome activity (90 ,91). In 80% to 90% of patients with SLE the presence of antinucleosome antibodies appear to be a more sensitive marker of SLE than autoantibodies to any other antigen (91 ,92). It has been suggested that antinucleosome antibody titers fluctuate with disease activity (93), although this finding has not been consistently reproduced (94). These discrepancies probably arise because of different methods of nucleosome preparation, insufficient data looking at variations in individual patients over time and variations in the indices of disease activity used. Hence in the future the antinucleosome ELISA is very likely to be an additional immunologic test for diagnosing SLE but its prognostic value is yet to be fully established.

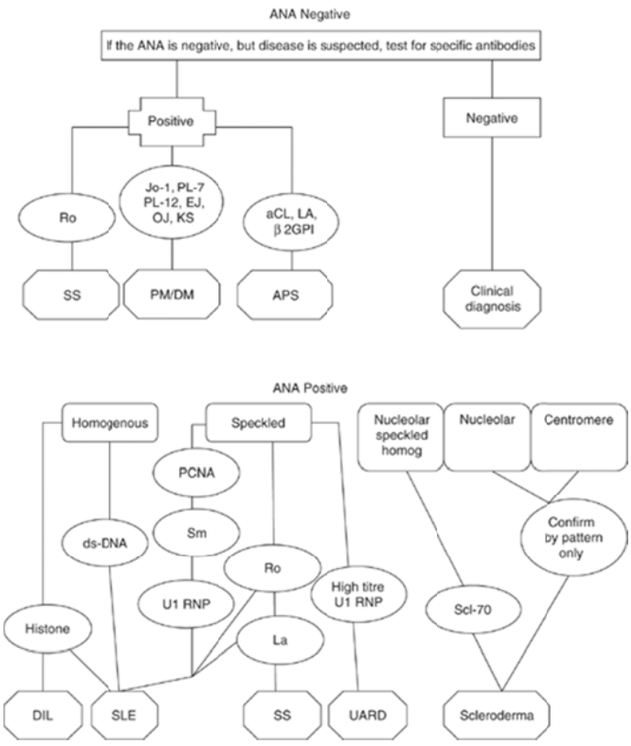

Figure 22-5. A practical guide to interpretation of the ANA test.

ANA Negative Lupus

True negative ANA tests in patients with lupus are now very rare, perhaps 2% of patients at most (95), with the advent of human tissue culture cells as the substrate. Previously more patients were falsely labeled as being ANA negative in up to 5%, using rodent (mainly mouse and rat liver) tissue substrate. Autoantibodies however are detectable by ELISA against Ro and La antigens, originally found in 90% of ANA negative patients sera (96), and now by using a more sensitive

ELISA virtually 100% of the same sera (97). The reason for this apparent dichotomy is the variable distribution of Ro and La antigens in cells of different species with significant quantities of the antigen detected by IFM in cells of humans, monkeys, and guinea pigs but absent to low amounts found in cells of rat, mouse, and chicken (98).

A previously positive ANA test in patients with lupus may become negative with disease remission that occurs either spontaneously or following immunosuppressive treatment. Such ANA negativity can occur in 10% to 20% of cases, especially those lupus patients who experience renal failure.

The disappearance of previously positive ANA does not remove the need for careful vigilance of clinical and laboratory markers of disease as the future course of the disease cannot be assumed to have burnt out. Apart from anti-dsDNA antibodies and possibly antinucleosome antibodies the titre of other autoantibodies and ANA is not a guide to disease activity.

Conclusion

Identification of the presence and pattern of staining of ANA on IFM of HEp2 cells is an essential first step in the immunologic diagnosis of lupus. The subsequent detection of specific autoantibodies and their profile helps to cement the clinical diagnosis of SLE, in the case of anti-dsDNA and/or anti-Sm antibodies, or suggest another ARD such as SSc if ACA or anti-Scl 70 are found. Figure 22-5 offers a practical guide to interpretation of the ANA test, which highlights the diagnostic decision pathway that must be taken each time an ANA test is ordered.

Acknowledgment

We are very grateful to Professor Allan Wiik, Department of Autoimmunity, Statens Serum Institut, 5 Artillerivej, 2300 Copenhagen, Denmark for providing us with the pictures of IFM upon HEp-2 cells.

Chapter 23
Antibodies to DNA

Bevra Hannahs Hahn

Betty P. Tsao

Antibodies to DNA (anti-DNA) are the classic autoantibodies that characterize systemic lupus erythematosus (SLE). High-avidity immunoglobulin G (IgG) antibodies to double-stranded DNA (dsDNA) play a major role in inducing some of the disease manifestations of SLE (especially nephritis), are relatively specific for the disease, and are good markers of disease activity in some patients.

The History of Antibodies to DNA

The lupus erythematosus (LE) cell phenomenon identified the first autoantibody recognized in patients with SLE (1). LE cells result from the action on nuclei of antibodies to DNA protein complexes; the major antigen recognized is the nucleosome, a histone/DNA complex (2). Altered nuclei are then ingested by phagocytic cells. LE cells can be formed by phagocytosis of apoptotic bodies (which contain nucleosomes) induced by antinuclear antibodies (ANAs) (3).

The first reports of anti-DNA in the sera of patients with lupus appeared in 1957, discovered in several different laboratories almost simultaneously (2). The clinical importance of circulating anti-DNA was soon recognized. Certain subsets were found to be specific for SLE and correlated with disease activity and nephritis (4 ,5), and evidence mounted that anti-DNA causes some of the tissue lesions that are characteristic of SLE, especially lupus nephritis. Anti-DNA was eluted from tissue lesions (glomeruli, skin, choroid plexus) of patients and mice with SLE (6 ,7 ,8 ,9). In many murine models of SLE, disease was accelerated by increasing anti-DNA responses and prevented by blocking them (6 ,10 ,11 ,12 ,13 ,14).

The development of monoclonal antibody (mAb) technology permitted expanded studies of DNA antibodies (15), which have providedconsiderable information regarding the characteristics of different antibody subsets, the presence of anti-DNA in unstimulated immune repertoires of healthy individuals, and the features of individual antibodies that contribute to their pathogenicity. The central role of these antibodies in the disease process in some patients seems clear.

Antibodies to DNA as Part of the Normal Immune Repertoire: Natural Autoantibodies

There are many different individual antibodies to DNA. They differ in isotype, complement-fixing capabilities, avidity for DNA, antigenic specificities, charge, idiotypes (Ids), V region sequences, and propensity to deposit in different regions of the kidney (16 ,17 ,18 ,19 ,20) (Table 23-1). Healthy humans and mice make antibodies to DNA as part of their normal resting or natural immune repertoires (10 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28). These natural autoantibodies are largely IgM class, react primarily with single-stranded DNA (ssDNA), have low avidity for DNA and are weakly polyreactive. Analysis of the structure of natural anti-DNA shows that most are IgM encoded by germline DNA, with few or no somatic mutations. However, activation of the resting B cell repertoire in mice and in humans yields not only IgM low-avidity anti-ssDNA but also some IgM and IgG subsets that bind dsDNA (10 ,22 ,23 ,25 ,26 ,27). Therefore, the ability of human and murine B cells to make antibodies to ssDNA and dsDNA is not forbidden but rather is normal. In fact, IgM and IgG antibodies to ssDNA can be found in many healthy individuals and in many disease states other than SLE that are associated with B cell activation, such as infections, chronic inflammatory states, and aging. Administration of certain drugs and biologics (such as tumor necrosis factor alpha (TNF-α) inhibitors can induce IgM anti-dsDNA and in some patients IgG anti-dsDNA as well (28 ,29). In contrast, IgG antibodies to dsDNA are consistently more abundant in the repertoire of individuals with SLE than in healthy persons, and their presence in serum at high titers is indicative of SLE.

Polyreactivity is characteristic of natural autoantibodies. However, both IgM and IgG mAbs directed against ssDNA, dsDNA, or both can be quite specific for these antigens (30) or have multiple reactivities, including cross-reactivity with polynucleotides, Sm, La, the A and D polypeptides of ribonucleoprotein (snRNP), cytoskeletal proteins, histones, nucleosomes, laminin, α-actinin, phospholipids, the Fc of IgG, cell surface structures (on platelets, lymphocytes, and Raji cells), proteoglycans such as heparan sulfate, myelin, neuronal glutamate receptors, gangliosides, and bacterial polysaccharides and proteins (21 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49). Some of these cross-reactivities probably contribute to the pathogenicity of

individual antibodies, while others permit anti-DNA to bind undesirable foreign antigens.

Table 23-1: Different Subsets of Anti-DNA

Probable nonpathogens (the normal repertoire)
IgM
IgG noncomplement fixing
Low avidity for ssDNA
Wide cross-reactivity (low avidity) to
Polynucleotides
Sm/RNP
Cytoskeleton
Histones
Fc of IgG
Laminin
Proteoglycans
Phospholipids
Cell surfaces
Myelin
Gangliosides
Bacteria
Polysaccharides
Phospholipids
Proteins
Probable pathogens (the SLE repertoire)
Complement-fixing Ig isotype (IgG1 and IgG3 in humans, IgG2a and IgG2b in mice, some IgM)
High avidity for dsDNA and ssDNA
Ability to bind directly to glomeruli: α-actinin, planted nucleosomes, heparan sulfate, laminin, phospholipids
Cationic charge
High-avidity binding to
DNA
DNA/histone
Nucleosome
Ability to bind directly to neurons: glutamate/NMDA receptor
Ability to form immune complexes of correct size and charge to avoid clearance and fix to GBM
Enrichment in certain idiotypes
IdGN2
16/6
32/15
3I
O-81
Ability to penetrate cells and fix to cytoplasmic structures or to nucleus

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA; GBM, glomerular basement membrane; Ig, immunoglobulin; RNP, ribonucleoprotein.

Natural autoantibodies to DNA likely serve as a repertoire that, when a foreign antigen arrives, requires minimal somatic mutation to generate high-avidity antibodies against the bacterial or viral invader. Some IgG anti-DNA with pathogenic potential probably derive from a small number of somatic mutations in germline-encoded natural autoantibodies (50 ,51 ,52 ,53 ,54). Conversely, antibodies to bacteria can be precursors of antibodies to DNA, and these two types of antibody can share similar sequences. A single-point mutation changes the ability of an antibody to bind either pneumococcal phosphocholine or DNA (51), and some anti-DNA can bind bacteria directly, possibly via phospholipids (30 ,44). Immunization of a lupus patient with pneumococcal vaccine produced antibodies with the capacity to bind different antigens; some were specific for the bacterial phosphocholine, some for DNA, and some bound both antigens (54). Similarly, immunization of mice with bacteria, bacterial DNA, DNA from activated lymphocytes, or lipopolysaccharide can induce antibodies to DNA (10 ,33 ,34 ,55 ,56 ,57). Thus, the resting natural autoantibody repertoire serves as a sentinel that is designed to provide quick antibody protection against undesirable invaders of the host. Unfortunately, the natural repertoire also has the capacity to generate pathogenic autoantibodies; the difference between recognizing danger and recognizing self can be a matter of a single amino acid change. This was demonstrated in recent work in which single point mutations in two nephritogenic human mAb anti-dsDNA were mutated back to germline configuration; changes in one or two amino acids in either heavy (H) or light (L) chains of the mAbs destroyed ability to bind nucleosomes/DNA (58).

Evidence That Some Subsets of Antibodies to DNA Are Pathogenic

The preceding discussion reviewed the early evidence that anti-DNA play a role in the pathogenesis of SLE. That evidence includes the following: (a) anti-DNA is located in sites of tissue damage in mice and patients with SLE; (b) large quantities of high-avidity IgG antibodies to dsDNA in the serum are associated with active lupus nephritis and active clinical disease in humans and mice; (c) DNA administered as immunogen accelerates murine lupus nephritis; and (d) DNA administered as tolerogen delays the appearance of anti-DNA and nephritis in mice with lupus.

More direct evidence has come from experiments in which anti-DNA are administered to normal mice and cause renal dysfunction or frank clinical nephritis. For example, Dang and Harbeck (59) injected polyclonal antibodies from the serum of nephritic New Zealand black/white (NZB/NZW) F1 mice into young mice of the same strain; cationic populations of serum anti-DNA lodged in glomeruli and induced nephritis earlier than in controls. Raz et al. (60) perfused rat kidneys with various mAb anti-DNA and showed that some bound directly to glomeruli and caused proteinuria. Tsao et al. (61) implanted B cell hybridomas secreting mAb IgG anti-DNA into pristane-primed peritoneal cavities of healthy, young BALB/c mice; several mAbs deposited in glomeruli and induced proteinuria and azotemia. Madaio et al. (62) have identified mAb murine anti-DNA that, when transferred to healthy mice, bind to capillary loops of glomeruli and cause proteinuria. Ehrenstein et al. (63) inoculated severe combined immunodeficiency disease (SCID) mice with human mAb anti-DNA from patients with lupus; one mAb bound to glomeruli and induced proteinuria even though histologic damage was not evident. Later, Ravirajan and colleagues (64) showed that one human IgG anti-dsDNA

mAb grown as a hybridoma in SCID mice caused proteinuria and granular Ig deposition in renal glomerular capillaries. Finally, Tsao et al. (65) made normal mice transgenic for genes encoding both heavy and light chains of a murine IgG anti-dsDNA mAb. B cells in transgenic mice secreted the mAb, IgG anti-dsDNA appeared in the serum, IgG was deposited in glomeruli, and proteinuria appeared. None of these events occurred in nontransgenic littermates. Other laboratories have made mice transgenic for genes encoding heavy or light chains which, when paired with multiple different endogenous light chains, bind DNA; those mice develop glomerular Ig deposits and proteinuria (66).

Several groups have shown that some mAb anti-DNA bind directly to glomeruli, and they have defined some of the components of glomerular basement membrane with which those mAbs cross-react (laminin, heparan sulfate, α-actinin, nucleosomes planted in tissue) (35 ,36 ,37 ,38 ,46 ,47 ,48). Although other antibodies can play a role in inducing the nephritis of SLE, certain subsets of anti-DNA clearly induce nephritis and can be classified as pathogens.

Pathogenic Anti-DNA: Role in Tissue Deposition and Damage

It is generally accepted that antibodies to DNA that can fix to tissue (glomeruli, skin, blood vessels, receptors for glutamate on neurons, platelet membranes, endothelial cells, etc.) are likely to cause damage, although there are examples where deposition occurs but damage does not follow (49). Mechanisms for the deposition in tissue are as follows: (a) antigens and antibodies form circulating immune complexes of the correct size and charge to be trapped in basement membranes of glomeruli, skin, and blood vessels where they activate complement and bind FcγR receptors; (b) antibodies to DNA bind directly to DNA or DNA/histone/nucleosome complexes planted in target tissues (46), following which complement and FcγR are activated; (c) cationic subsets of anti-dsDNA bind to polyanions (e.g., heparan sulfate) in the proteoglycans of basement membranes on the basis of charge, again creating immune complexes in situ (67 ,68 ,69); (d) antibodies to DNA, or antibodies complexed to DNA/histone, can bind to non-DNA antigens that are present in basement membranes, such as alpha-actinin and laminin (36 ,37 ,38 ,47 ,49). A subset of antibodies to dsDNA may cross-react with the NMDA glutamate receptor and can mediate excitotoxic death of neurons, suggesting these antibodies may contribute to memory loss in some SLE patients (48 ,70).

There are several mechanisms by which DNA/anti-DNA complexes and tissue deposition of complexes or anti-DNA cause injury; injury has at least two components, inflammation and sclerosis, which may differ between individuals with lupus (71). Activation of complement causes chemotactic signals for inflammatory cells that release destructive enzymes. Additionally, tissue damage can be mediated through activation of activating FcR (72) that bind Ig (FcγRI and FcγRIII), or prevented by activation of an inhibitory FcR (FcγRII) (73 ,74). Some anti-DNA bind to living cells, mediate antibody-dependent cell-mediated cytoxicity (ADCC), or enter cells by binding to the myosin receptor from which they are transported via caveolin to cytoplasm or nuclei, altering cell functions such as protein synthesis and activation (20 ,75 ,76 ,77 ,78 ,79 ,80 ,81). Anti-DNA can cause release of cytokines by human mononuclear cells, including IL-1ß, IL-6, IL-8, IL-10, and TNF-α (82). Some antibodies to DNA have enzyme activities (83 ,84). Some anti-DNA induce apoptosis of target tissue with creation of apoptotic bodies containing nucleosomal and spliceosomal antigens, further driving autoantibody production and immune complex formation (85 ,86). DNA-reactive B lymphocytes participate directly in tissue damage via antigen presentation to T cells and cytokine release (87). DNA/anti-DNA activate plasmacytoid dendritic cells which release IFN-α and drive the pro-inflammatory pathways associated with innate immunity. DNA/anti-DNA activate B lymphocytes directly via Toll-like receptor 9 (TLR9) (88 ,89). These various abilities are probably related to the structure of each mAb, and to the genetic characteristics of each individual which influence autoantibody persistence, tissue deposition, and the potential inflammation and sclerosis that result.

Importance of Isotype, Complement-Fixing Ability, Avidity for DNA, and Ability to Form Immune Complexes

Several investigators have shown that subsets of anti-DNA that are associated with active disease and with nephritis (in both humans and mice) are predominantly of the IgG isotypes which fix complement well (21 ,59). These are IgG2a and IgG2b in mice, and IgG1 and IgG3 in humans. Such antibodies usually bind both dsDNA and ssDNA; only a small proportion binds dsDNA alone.

Studies of polyclonal anti-DNA eluted from glomeruli of humans or mice with nephritis showed that glomerular populations of Ig are enriched in Ig with high avidity for DNA compared to anti-DNA in sera and urine (8 ,9 ,90). However, studies of mAb anti-DNA have shown less relationship between avidity for DNA and the ability of a transferred mAb to cause glomerulonephritis in normal mice (91 ,92). In fact, mutations introduced in VH regions of mAb that changed avidity for DNA did not correlate with changes in pathogenicity or ability to bind glomeruli in vitro. It is possible that avidity for cross-reacting antigens is more important than avidity for DNA in determining pathogenicity, or that high avidity offers a mAb some pathogenic advantage, but this property alone may not be sufficient to induce disease.

The ability of anti-DNA to form immune complexes of the correct intermediate size favors the ability of that antibody to be pathogenic. Large antigen/antibody complexes are engulfed by the phagocytic system and removed; small complexes are excreted in the urine, so both populations are unlikely to cause disease. In addition to size, conformation of the complex, overall charge, and charge of individual components of the complex, and ability to activate complement

and FcR after being trapped in tissues are all important in pathogenicity, as discussed above.

The Importance of Charge

Many regions of the glomerular basement membrane are polyanionic. Therefore, antigens, antibodies, or immune complexes with cationic charges can bind to glomerular basement membrane via charge (21 ,67 ,68 ,69). If a cationic anti-DNA is trapped by this mechanism and DNA is available, then an immune complex forms in the glomerular basement membrane, complement is activated, and damage occurs. One group has reported that one antibody with a cationic charge in an immune complex is sufficient to permit trapping in the glomerular basement membrane (69). Several investigators have reported enrichment of cationic anti-DNA populations in IgG of glomerular eluates from mice with lupus nephritis (21 ,59 ,67 ,68), although one group disagrees (93). A study of Japanese patients with lupus nephritis showed that cationic clonotypes of anti-DNA (pI 7.0 to 8.5) were found in glomeruli but not in circulating immune complexes (94). Studies of the ability of mAb anti-DNA to induce nephritis in mice have shown that some mAb with neutral pI (7.0 to 7.5) as well as mAb with cationic pI (7.5 to 8.5) can induce nephritis in normal mice (38 ,61). As with high avidity, the presence of cationic charge on a particular anti-DNA probably confers a pathogenic advantage, but some antibodies without cationic charge are perfectly capable of causing disease. Thus, predicting whether a particular mAb anti-DNA is a pathogen or not is difficult and depends on multiple features of that antibody.

The Importance of Idiotypes

The idiotypic characteristics of anti-DNA also may contribute to pathogenicity (21 ,68 ,94 ,95 ,96 ,97 ,98 ,99). Idiotypes are antigenic sequences in the V regions of antibodies; they induce B and T cell antiidiotypic responses that are important in regulating antibody production.

Idiotypes and idiotypic networks are reviewed elsewhere in this volume. Public idiotypes that characterize many antibodies to DNA have been identified in both murine and human lupus. Certain idiotypes have been found in tissue lesions (IdGN2, 16/6, 32/15, 3I, 0-81) of patients with lupus (21 ,68 ,94 ,95 ,96 ,97 ,98 ,99). One human public idiotype or antiidiotype (the 16/6 system), when injected into certain strains of normal mice, can activate an idiotype-antiidiotype network. This results in production of multiple idiotype-positive autoantibodies (including anti-DNA), and the mice develop nephritis (100). Administration of certain peptides from the VH regions of the 16/6 idiotype mAb anti-DNA induce regulatory $CD4^+CD25^+$ T cells and reduce the ability of pro-inflammatory T cells to circulate to target tissue (101). One of these peptides is in clinical trials in human SLE. Experiments in murine models of SLE have shown that anti-DNA and nephritis can be suppressed by administration of antiidiotypes (102 ,103). Therefore, pathogenic anti-DNA subsets are enriched in certain idiotypic markers, and those idiotypes can be targets of regulation that permit the abnormal upregulation of pathogenic subsets of anti-DNA. One study showed that in patients with lupus nephritis, anti-DNA and antiidiotypes leak into the urine (90). The highest avidity anti-DNA and anti-Id were found in glomerular eluates, moderate avidity anti-DNA and anti-Id in serum, and low-avidity anti-DNA and anti-Id in urine.

The Importance of Cross-Reactivity with Tissue

The ability of anti-DNA to cause disease may result from cross-reactivity with structural components of glomeruli or other target tissue rather than (or in addition to) the binding of DNA planted in tissue or passive entrapment of DNA–anti-DNA complexes. For example, several investigators have shown that various mAb anti-DNAs that persist in glomeruli after transfer and cause renal dysfunction can bind laminin, α-actinin and proteoglycans such as heparan sulfate (either alone or complexed with antigen) (36 ,37 ,38 ,43 ,44 ,47 ,48 ,49 ,104).

Subsets of anti-DNA that bind DNA/histone complexes (including nucleosomes [NUCs]) may be particularly enriched in pathogens (35 ,43 ,44 ,104 ,105 ,106 ,107 ,108 ,109). Histones or NUCs are trapped in glomerular basement membrane, particularly in collagen type IV (108), and anti-DNA can fix to those structures via planted histones. Some mAb anti-DNAs can bind to heparan sulfate in glomerular basement membrane only after they bind histone; thus, a complex of anti-DNA/DNA histone is required for pathogenesis (38). Approximately 70% of patients with SLE have antibodies to nucleosomes; the IgG3 subclass of those antibodies correlates with disease activity and nephritis (109). Several studies (110 ,111 ,112) have suggested that IgG antibodies to nucleosomes correlate better with nephritis and active disease than do IgG antibodies to dsDNA, although others disagree (113). Levels of nucleosomes are elevated in sera of patients with SLE but do not correlate with disease activity (113 ,114 ,115). At the time of this writing (2006), testing for anti-dsDNA is still the gold standard for measuring the population of DNA/protein-reactive antibodies found in each SLE patient.

The source of DNA/histone that is planted in glomeruli might be NUC released by apoptotic cells during active SLE. NUC-size DNA is found in the circulation of such patients (113 ,114 ,115). Several investigators have shown that antibodies to NUC appear early in murine lupus; they suggest that NUCs are antigens that induce antibodies that later mature/mutate to anti-dsDNA (106 ,107). This induction would be in addition to that provided by bacterial DNA, DNA from activated lymphocytes (56), mutation of antibodies to bacteria or viruses, and so on.

To study the totality of antibodies that bind to glomeruli, an in vitro method was developed to estimate the pathogenicity of antibodies by incubating polyclonal or mAb Ig with permeabilized rat glomeruli isolated on

filters, or with an extract of those glomerular basement membranes in an enzyme-linked immunosorbent assay (ELISA) (108 ,116 ,117 ,118). This work suggests that some anti-DNAs bind to glomeruli via DNA and/or DNA/histone or NUC combinations fixed to collagen type IV in glomerular basement membrane. Additionally, several non–DNA/NUC-binding antibody populations can play a major role in the nephritis of SLE. Many investigators have reported that non-DNA–binding antibodies to the following antigens can be associated with nephritis in human and murine lupus: ssDNA, laminin, heparan sulfate, Ro (SSA), Sm/RNP, RNA, RNA polymerase I, gp70 (mice only), C1q, and ribosomes (36 ,48 ,49 ,104 ,118 ,119 ,120 ,121 ,122 ,123).

The Potential Importance of Antibodies Penetrating into Living Cells

Several investigators have reported that some anti-DNA (including polyclonal populations isolated from the serum of patients or mAb from mice with SLE) can bind to the surface of living cells, enter those cells, and bind nuclear or cytoplasmic structures (20 ,75 ,76 ,77 ,78 ,79 ,80 ,81). There are probably at least three types of such anti-DNA subsets (79). One binds to cell surfaces and can mediate complement-induced cytotoxicity; the second penetrates cells and binds to cytoplasmic antigens; the third penetrates cells and binds to nuclei. In our library of murine mAb IgG anti-DNA, some pathogenic mAb have these properties, and others do not. F(ab)2 fragments of these anti-DNA also bind and enter cells, so they are not entering via Fc receptors. DNase treatment of cells and antibodies does not impair their ability to access the interior of cells, so DNA as a receptor is not a likely entry point. One receptor that binds anti-dsDNA and permits cell entry is brush-border myosin I (80). Anti-DNA entering via myosin receptors enters the cytoplasm via caveolin (75), interacts with DNase-1, and inhibits endonuclease activity, before moving to the nucleus and attenuating apoptosis. The antibodies can then recycle back to the cell surface. After cell entry, several other abnormalities can occur, including cell activation in an abnormal pattern (81), and decrease of protein synthesis (75 ,79).

All of these interactions between antibodies to dsDNA and living cells are likely to profoundly alter cell functions and to present altered antigens from damaged cells to the immune system to promote autoantibody expansion.

Antibodies to DNA and Nucleosomes

Increases in numbers of apoptotic cells and impairment in their clearance promotes autoantibody production, including anti-DNA and anticardiolipin, and some of these antibodies may deposit in glomeruli (85 ,124 ,125). Antibodies to DNA and to nucleosomes bind NUC released from cells undergoing apoptosis. Since the generation of apoptotic cells in both lymphocytes and neutrophils is increased in patients with SLE, more antibodies to DNA and nucleosomes are induced (86). Additionally, clearance of apoptotic cells is abnormally slow in patients with SLE, permitting persistence of these surface autoantigens (126). Therefore, we have the scenario in which damage to cells caused by lupus autoantibodies drives those cells into apoptosis, and the apoptotic state itself promotes production of more harmful antibodies to DNA, to cardiolipin and to snRNP, thus creating a vicious circle. Furthermore, the combination of nucleosome and IgG antinucleosome acts on normal peripheral blood mononuclear cells (PBMCs) in vitro to induce the release of interferon-α (IFN-α) (127). Since IFN-α is immunostimulatory, it may play an additional role in keeping disease activated. Elevations of IFN-α–inducible genes in peripheral blood cells are a “signature” for SLE in humans (128 ,129). Normal human PBMCs cultured with polyclonal or monoclonal antibodies to DNA from patients with active SLE showed diminished proliferation and enhanced secretion of interleukin-1ß (IL-1ß), IL-8, TNF-α, and IL-10 (82). Polyclonal IgG anti-DNA from SLE patients incubated in vitro with human umbilical vein endothelial cells caused increased expression of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on those cells (130), which could be a mechanism for vascular damage. This is more evidence that additional activities of anti-DNA include influencing tissue damage by altering the release of pro-inflammatory cytokines or of molecules that mediate adhesion of potentially harmful phagocytic cells.

Direct Roles of T and B Lymphocytes in Cell Damage

Although we traditionally think of the role of B cells in lupus as a source of pathogenic autoantibodies, and those antibodies as being necessary for disease, B cells play an additional role. Medical research laboratory (MRL)/Fas lymphoproliferative (lpr) mice expressing a mutant surface Ig but unable to secrete Ig still developed nephritis. The disease was characterized by cellular infiltration within the kidney, indicating that functional B cells produce adverse local effects, either by contributing directly to damage or by presenting peptide antigens that activate cytotoxic T cells (131). The role of B cells as inciters of inflammation via antigen presentation that activates T cells was also suggested by the observation that patients with SLE who improved after treatment with anti-CD20 mAb had not only B cell depletion but also decreased surface markers of activation on circulating $CD4^+$ (helper) T cells, compared to nonresponders (132).

T lymphocytes in the setting of lupus lesions also play a role beyond providing help for local autoantibody production. Multiple T cells and macrophages infiltrate the kidneys of patients and mice with lupus nephritis (133). Chemotactic factors (MCP-1) and adhesion molecules (ICAM-1) facilitate recruitment of these cells into areas of inflammation. Once there, the cells induce increased expression of major histocompatibility complex (MHC,

HLA-D in humans) class II and CD40L on renal tubular epithelial cells, coupled with upregulation of CD40L and IL-2R on infiltrating T cells. Doubtless these properties of infiltrating T cells contribute to the renal damage of SLE.

The Importance of Toll-Like Receptors in Pro-Inflammatory Responses to Anti-DNA.

TLR were first recognized as activating receptors on dendritic cells (DC). Of the several types of TLR (134), TLR9 bind oligodeoxynucleotides (ODN), of which there are also several types. It is now known that B lymphocytes express TLR9. Recently a substantial body of evidence has developed showing that certain DNA/nucleosome/anti-DNA complexes can bind to TLR9, with subsequent activation of plasmacytoid DC and B cells, thus upregulating IFN type 1 and 2 responsive genes, and increasing the pro-inflammatory environment that favors development of clinical lupus (80 ,88 ,89). Interfering with this pathway [by knocking out IFN type 1 receptors (135) or occupying TLR with CpG ODN that are suppressive rather than activating] prevents or suppresses lupus-like disease in genetically susceptible mice (136).

The Structure of Anti-DNA

The structures of many human and murine mAbs to DNA have been determined (38 ,50 ,51 ,52 ,53 ,58 ,61 ,91 ,92 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148) and reviewed (146) (Table 23-2). As reviewed elsewhere in this volume, the heavy chains of Igs are encoded by rearrangements of variable (VH) region gene segments with diversity (D) and joining (JH) segments that combine with constant (CH) regions for the Ig isotype. Light chains are formed by rearrangements of VL and JL with C-κ or C-λ. Joining of the heavy and light chains forms an intact Ig molecule. Diversity in antibody binding is generated by (a) variations of the information contained in germline DNA within different individuals; (b) different rearrangements of V, D, and J segments for heavy chains, and of V and J segments for light chains; (c) addition of nucleic acids by terminal deoxyribonucleotidyl transferase (TdT) at the junctions between variable and constant regions in heavy or light chains; (d) junctional insertion of inverted mono- or dinucleotides that are independent of TdT; and (e) somatic mutations of single nucleic acids in rearranged heavy and light chains. Generally, antigen-driven antibody responses undergo increasing numbers of somatic mutations with each cell division, and such mutations increase the affinity of the antibody for the stimulating antigen. An additional modification, B cell editing, can occur after B cells are mature and “committed” to production of a given antibody. In this process, the B cell shuffles heavy and light chains until a combination that does not bind self with high avidity is found; that combination is then expressed on the cell surface (149 ,150). In a model of lupus nephritis induced by rendering mice transgenic for the H and L chains of a nephritogenic anti-dsDNA, the disease eventually disappeared, as did circulating anti-dsDNA, primarily because of B cell receptor editing (65).

Table 23-2: Structure of Anti-DNA

Genes encoding immunoglobulin
Germline DNA—no unique information
Rearrangement of germline
No unique rearrangements
Many different VH, D, JH, VL, and JL can be used
Enriched in VH J558 in mice, VH3 in humans
Somatic mutations—can be none, a few, or many
Amino acid sequences in heavy and light chains
CDR of heavy and light chains are enriched in Arg, Asp, and Tyr
Ser-Tyr found frequently in CDR1 of VH
Tyr-Tyr-Gly-Gly-Ser-Tyr found frequently in CDR3 of VH
Region gene segments: VH, variable heavy; D, diversity; JH, joining heavy; VL, variable light; JL, joining light.

In the mAb anti-DNA studied to date, no unique germline DNA encoding Ig is used to make anti-DNA. Most DNA-binding mAbs use rearrangements of germline DNA that are similar to those used in antibodies to foreign antigens, especially bacteria (16 ,17 ,51 ,64 ,137 ,138 ,140 ,141 ,142 ,151 ,152). Some mAb anti-DNAs are constructed from germline rearrangements with no or few mutations (153 ,154), but most IgG anti-dsDNA contain somatic mutations (50 ,51 ,61 ,104 ,137 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,150 ,151 ,152 ,153 ,154 ,155 ,156 ,157 ,158). There is one example of a murine MAb directed against phosphocholine (i.e., a dominant response in BALB/c mice to immunization with pneumococcal polysaccharide) that underwent a productive single-point mutation that eradicated the ability to bind phosphocholine but introduced the ability to bind DNA (137 ,142). Conversely, back-mutation experiments of two human nephritogenic anti-dsDNA showed that in one case a single mutation in an Asp residue in a CDR region of the H chain, and in the other case a small number of point mutations in the L chain caused the molecule to lose all capacity to bind dsDNA or nucleosomes (58). It seems likely that the resting IgM anti-DNA repertoire can be used to introduce somatic mutations that drive the immune response toward high-avidity IgG antibacterial or anti-DNA antibodies, and that high-avidity anti-DNA can arise from the mutation of antibacterial antibodies. These observations suggest that pathogenic IgG high-avidity anti-dsDNA can arise from stimulation with foreign antigens, such as bacteria, rather than from antigenic stimulation by mammalian self-DNA. This possibility is supported by the observation that immunization with phosphocholine coupled to protein carrier elicited anti-dsDNA antibodies in a normal mouse (152). Humans without SLE were immunized with pneumococcal vaccine (Pneumovax) and developed an antipneumococcal response that was characterized by a public idiotype found in patients with SLE; however, those

idiotype-positive antibodies did not bind DNA. In contrast, a lupus patient immunized with pneumococcal vaccine developed B cells that secreted antibodies specific for phosphocholine, for DNA, or cross-reactive with both (54).

Certain structural characteristics are common to many mAb anti-DNAs. Although many different V, D, J heavy-chain regions and many different light chains can be used to construct anti-DNA, there is repeated use of certain VH and CDR3 regions (e.g., VH J558 in NZB/NZW and MRL/lpr mice, VH3 in human MAb anti-DNA) (143 ,144 ,155 ,157 ,159 ,160 ,161). In fact, studies in MRL/lpr and NZB/NZW F1 lupus-prone mice suggest that each mouse makes autoantibodies from a small number of clonal B cells, which are then expanded and mutated to form anti-DNA (16 ,143 ,144 ,162).

To summarize, there is limited clonality of anti-DNA, but it is not stringent. Fifteen to 20 heavy-chain regions encode most anti-DNA. The CDR regions of heavy and light chains in anti-DNA often are enriched in arginine, asparagine, and tyrosine (16 ,143 ,162 ,163). These amino acids can form hydrogen bonds with the phosphate backbone of DNA. Studies of computer models and crystals of DNA/anti-DNA complexes have suggested that Arg, Asp, or Tyr project from CDR regions of the Ig molecule into the antigen-binding groove, where they can contribute to high-avidity binding of DNA (64 ,164). However, there are some anti-DNA in which these amino acids play little, if any, role in DNA binding. Although not an absolute requirement, several laboratories have noted that the D regions of anti-DNA antibodies are read in an unusual frame, and CDR3-D regions are long (165). Certain amino acid motifs occur commonly in mAb anti-DNAs, such as Ser-Tyr in CDR1 of VH and other sequences in the D region of the heavy chain. Our observation (38) that the CDR regions of VH in pathogenic anti-DNA compared with nonpathogens is enriched in arginine, lysine, aspartate, and glutamate residues (i.e., positively and negatively charged amino acids) suggests that charge interactions play a role in pathogenicity, possibly by determining tissue structures with which the mAb can cross-react. Arginine residues in CDR and some framework regions of heavy and light chain are important to DNA binding in some anti-DNA, as shown by analysis of mutants in which R residues have been substituted, resulting in loss of binding or changed avidity for DNA (91 ,92 ,166). On the other hand, there are some mAb anti-DNAs that do not have Arg residues in the positions thought to influence DNA binding. For many mAb anti-DNAs, the heavy chain determines the ability to bind DNA, although only certain light chains in combination with that heavy chain permit the binding to occur (166 ,167). Most murine and human IgG high-avidity anti-dsDNAs have undergone numerous somatic mutations, suggesting that specific antigens are driving B cell maturation and secretion (16 ,17 ,19 ,54 ,64 ,168 ,169).

In summary, there are no unique germline DNA sequences, heavy- or light-chain rearrangements, or amino acid motifs that are specific for anti-DNA. Many different heavy- and light-chain rearrangements can encode such antibodies. However, certain V region genes are used more frequently than would be expected, and certain amino acids or motifs are commonly found. The structural differences between pathogens and nonpathogens are not yet understood. Anti-DNA can arise spontaneously from germline DNA without antigenic stimulation; most IgG anti-dsDNAs are mutated and probably arise in response to many different antigenic stimuli as discussed above. Finally, there are experiments in which large quantities of anti-DNA are made and bind to glomeruli, but renal damage with clinical nephritis does not occur (49 ,71). They illustrate that at least some inflammatory pathways must be intact for immune deposition to produce tissue damage and disease.

The Origins of Anti-DNA: Genetic Predisposition, Antigenic, and Environmental Triggers

The ability of an animal or person to make pathogenic, high-titer IgG antibodies to DNA (or DNA/histone) is influenced by genes. Other chapters in this volume detail the genetic predispositions to SLE in humans and in mice; only the summaries will be given here, as they pertain to anti-DNA. In patients with SLE, Tsao et al. (170) showed positive correlation between IgG antibodies to nucleosomes and the 1q41 region on human chromosome 1, a region that also contains a gene or genes that predispose to SLE in mice. Several investigators have shown associations between human leukocyte antigen (HLA) molecules and anti-DNA in patients with SLE, specifically with HLA-DR3 (171), DR2 (172 ,173), and DR7 (174). Their respective linked HLA-DQ alleles may also responsible for the observed associations. In humans, a genome scan stratified for presence or absence of anti-dsDNA in SLE multiplex pedigrees showed linkages at chromosome regions 19p13.2 (in European Americans) and 18q1 (in African Americans) (175). The contributing genes in these regions are not known; candidate genes in or near 19p13.2 include DNase2, DNA methyltransferase 1, and calreticulin.

Studies in murine lupus have identified several candidate genes or loci associated with anti-DNA or antichromatin that occur on several different genes (176 ,177 ,178 ,179).

In mice with a New Zealand background, some of the ability to make anti-DNA depends on genes in the MHC class II region, with combinations such as H-2d/z being particularly susceptible (180). On chromosome 1 in mice with an NZW and NZB background (NZM2410), a gene region designated SLE1ab contains a gene or genes that allow a mouse to break tolerance to nucleosome (150 ,168 ,177) and produce anti-NUC. The gene region dysregulates STAT3 and ras-ERK signaling, resulting in increased IL-6 production by B cells and B cell hyperactivation associated with increased production of ANA (150). SLE1ab seems to be a critical gene; alone it cannot result in clinical immune nephritis, but when combined in a normal mouse with another predisposing gene, such as a gene related to T cell hyperactivity (SLE3) or an autoimmunity accelerating gene on the Y chromosome of another lupus mouse model (BXSB), Yaa, clinical nephritis

occurs in the majority of mice (178 ,179). In contrast, SLE3 plus Yaa do not produce clinical nephritis. The lupus-enhancing capacity of SLE1 is opposed by a gene region from an unaffected mouse (NZW), designated SLEls, located in or near the MHC region (179). The lbw2 gene on chromosome 4 (from NZB mice) in NZB × NZWF1 mice promotes B cell hyperactivity which in a mouse that can make anti-DNA results in more B cells making anti-DNA and more severe disease (181). In conclusion, in mice and humans, antibodies to nucleosome and DNA probably require more than one gene for full expression, as well as additional genes that promote development of clinical disease.

Potential Environmental Inducers of Antibodies to DNA

In addition to the genetic component, it is likely that certain environmental stimuli permit full expression of the gene, probably by initiating an immune reaction that then leads to formation of highly mutated and potentially pathogenic antinucleosome or anti-DNA. Table 23-3 lists the possible antigens that might elicit IgG anti-dsDNA pathogenic antibodies. Possibilities include the following: (a) anti-DNA is induced by DNA of bacteria or viruses and cross-reacts with self-DNA; (b) self-DNA becomes altered (e.g., by viral infection or exposure to ultraviolet light or the process of apoptosis) and therefore becomes immunogenic; (c) an antigen containing DNA plus protein is the initial immunogen, and some of the resultant reactivity happens to be directed toward naked DNA; (d) the initial immunogen is a peptide from another self-antigen, and the immune response spreads to produce multiple autoantibodies, including anti-DNA; and (e) the initial immunogen is not self but has a sequence or conformation similar to that found in self-antigens (such as EBNA1 from EBV virus), including DNA, and the resultant anti-DNA recognizes a similar conformation.

One thinks first of infectious agents, given the examples of single mutations in anti-DNA or in antiphosphochloline antibodies resulting in an antibody of the opposite specificity (137). It is likely that several bacteria and viruses can participate. Although initial antibody after immunization or mice with bacterial DNA is anti-ssDNA, only a few mutations, or recombinations between H and L chains, are required to develop anti-dsDNA (57). Some anti-DNA cross-react with *Klebsiella polysaccharides* (182), with *Escherichia coli* galactosidase (41), and with phospholipids of streptococci and staphylococci (40). Further, the structure of many mAb anti-DNA molecules is similar to that of antibacterial antibodies (137 ,151). Bacteria can supply DNA or lipopolysaccharides that induce anti-DNA (33 ,57 ,183). Pyun et al. (33) showed that immunization of normal mice with *E. coli* DNA induces IgM and IgG anti-DNA. We have mentioned previously that immunization with pneumococcal polysaccharide can induce antibodies to DNA in people who have SLE, and a single point mutation in antibody to pneumococcal polysaccharide can produce DNA-binding (34 ,137). Therefore, it is possible that some bacteria provide antigens that induce anti-DNA responses in humans. Bacterial DNA contains more hypomethylated regions (e.g., CpG) than mammalian DNA; hypomethylation of DNA can trigger autoreactive T cell activation and has been implicated in the pathogenesis of SLE (183 ,184). However, MRL/lpr lupus-prone mice raised in a germ-free environment were not protected from disease, although if they were fed an ultrafiltered antigen-free diet their disease was less (185). It is probably useful to think of certain bacteria as capable of flaring if not inducing SLE, and as inducing anti-DNA in genetically susceptible individuals.

Table 23-3: Possible Antigens

Inducing Anti-DNA
Nucleosomes
May be made available in surface blebs of lymphocytes, neutrophils, or glomerular cells undergoing apoptosis; also released from apoptotic, but not necrotic, cells; there is some evidence that nucleosomal DNA is the initial DNA-containing antigen recognized by the immune system
DNA/histone complexes, or DNA complexed with other proteins
Altered self-DNA (e.g., enriched in CpG motifs); this may occur when lymphocytes are activated
Bacterial DNA (either linked to protein, or forming complexes with Ig which activate plasmacytoid dendritic cells, or complexes which activate B cells directly via TLR9)
Viral infection (especially EBV, producing spreading of initial anti-viral antibody to include DNA-reactive antibody)
Bacterial polysaccharides
Phospholipids
May be made available on surfaces of cells undergoing apoptosis, or in bacteria
Other autoantigens (e.g., Sm, Ro, La or certain peptides associated with these particles)
B- and T-lymphocyte responses initially specific for immunodominant proteins in these Ags undergo degeneration and spreading so that the cell receptors recognize additional self-antigens, such as DNA
Protective immune responses to external antigens (e.g., antibodies to phosphocholine of pneumococcus also bind DNA)
Antibodies to external antigens with anti-Ids that bind DNA
Antibody to virus or bacteria may raise an antiidiotypic antibody that recognizes DNA; thus, protective response to an external antigen also generates autoreactive cells

There has been recent renewed interest in viruses as etiologic agents of SLE and/or its autoantibodies, including anti-DNA. An interesting observation in children with SLE showed that the chance of the patients being infected with Epstein-Barr virus (EBV) is about 50-fold higher than the chance in matched controls of children without lupus attending the same clinics (186). Although this virus is nearly

ubiquitous among adults in the United States, positive serology for EBV and antibodies to EBNA were significantly more frequent in adults with SLE compared to controls (187), and several other investigators confirmed the finding that EBV-infected cells and/or antibodies are more common in SLE patients than in controls (188 ,189). Furthermore, expression of EBNA-1 in normal mice elicits anti-DNA production (190). Another virus that might be involved is polyomavirus, which has been carefully studied in SLE by one group (191 ,192 ,193). Polyoma virus has a transcription factor T antigen that as immunogen induced antibodies to DNA in mice. Activation of that virus, with release of T antigen, is frequent in patients with SLE. T antigen circulates in sera of some patients, complexes with nucleosomes, and stimulates proliferation of $CD4^+$ T lymphocytes from both normals and lupus patients. These $CD4^+$ T cells could help syngeneic B cells produce anti-DNA and anti–T antigen. This interesting work awaits confirmation from other laboratories. In another example of a potential lupus-inducing virus (194), BK virus administered to rabbits induced antibodies against self eukaryotic DNA if the infection became productive, but not if it was contained, again suggesting that activation of a virus is key to providing the antigens required to induce anti-DNA.

Pristane is another external substance that can induce anti-DNA and lupus when injected into genetically susceptible strains (195). BALB/c mice so treated develop IgG anti-DNA and antichromatin, as well as IgG antibodies to nRNP, Sm and Su. Immune complex disease develops in glomeruli. Human exposure to pristane is exclusively by the oral route, and there is as yet little evidence that pristane induces lupus in people.

Antigens from Self Molecules May Induce or Sustain Antibodies to DNA

The interesting observation of Arbuckle et al. (196) that autoantibodies precede the onset of clinical SLE in most patients by as much as 9 years, and that anti-DNA are among the earliest to appear, suggests that people destined to develop clinical SLE either modulate anti-DNA over time to introduce more pathogenic subsets, or fail to regulate autoantibodies normally, or both. Given the recent evidence that EBV infection may be an environmental trigger for SLE (187 ,188 ,189 ,190 ,197), it is possible that EBNA antibodies may easily mutate to anti-DNA, although to our knowledge that has not been demonstrated directly. However, the human Sm B/B' protein contains a highly stimulatory, proline-rich sequence that is nearly identical to an amino acid sequence in EBNA. When used as an immunogen in mice, rabbits, or nonhuman primates the Sm peptide induces T cell activation, then B cell responses to that peptide, then to related peptides, then to unrelated peptides on the same molecule, then to unrelated peptides on different molecules, culminating in IgG anti-dsDNA and proteinuria (198). Under conditions of oxidative damage, e.g. during inflammation, this epitope spreading is even more extensive (199). Similarly, immunization with a peptide from the protein SmD1 complex induced both anti-Sm and anti-DNA in the NZB/NZW F1 lupus model, activated helper T cells and accelerated disease (200 ,201). Similar epitope spreading resulting in production of anti-DNA has been demonstrated after immunization with other external and autoantigens, including pneumococcal polysaccharide and Ro. This topic has been reviewed recently (202).

Another autologous source of antigens that promote development of anti-DNA in individuals predisposed to SLE is the autoantibodies themselves. Several groups (203 ,204 ,205 ,206 ,207) have shown that certain peptides derived from autoantibodies, presented in MHC class II molecules by B cells or other APC, are recognized by $CD4^+$ helper T cells. Those T cells are activated by the peptides, and in turn activate B cells making Ig anti-dsDNA. Thus, an antibody to dsDNA provides its own peptides that activate T cell help for that B cell, resulting in sustained, rather than regulated production of a pathogenic autoantibody. T cell stimulatory peptides have been demonstrated from the VH and VL areas of antibodies to DNA. These T cell determinants occur primarily in autoantibodies, with similar regions at similar locations in the molecule in both murine and human anti-DNA (208). It seems likely that autoantibodies persist and resist downregulation when they contain effective T cell determinants, and B cells with those IgG receptors are thus selected for survival.

Finally, histones associated with DNA also contain peptides that are T cell determinants—determinants that activate T cell help for IgG anti-dsDNA production in both humans and lupus-prone mouse strains. Since many histones have amino acid sequences that are conserved across many species, the T cell determinants that stimulate murine and human cells are similar (209).

In summary, although nucleosomes are effective antigens in initiating antibodies that bind dsDNA, responses to multiple external and self antigens can also lead to T cell help and B cell production of IgG anti-dsDNA–containing populations that are pathogenic, particularly in a permissive genetic environment.

Apoptotic Cells as a Source of Immunizing Autoantigens

It is likely that many of the autoantigens that induce lupus autoantibodies, including pathogenic subsets, arise from apoptosis of autologous cells, particularly T and B lymphocytes. The surfaces of such cells contain blebs, released into tissues as apoptotic bodies, within which lie nucleosomal DNA/histone complexes of the size found in sera of patients with SLE (but not controls) (113 ,114 ,115). In a preceding section we discussed the role of anti-DNA/DNA complexes in activating DC and B cells, which expand inflammation and autoimmunity. Apoptotic blebs also contain the snRNP, Ro and La antigens that stimulate autoantibodies in some patients. In addition, the membranes of cells undergoing apoptosis

change conformation in a way that permits the antigenic “heads” of phospholipid molecules to flip toward the outside of the membrane, where they can be recognized by the immune system. Apoptotic cells administered as immunogens to mice induce antibodies to DNA, RNP, Ro, and cardiolipin (85). Furthermore, patients with SLE have larger numbers of lymphocytes and neutrophils undergoing apoptosis than do matched healthy or diseased controls, and they have significantly less ability to phagocytose apoptotic bodies (86 ,87 ,126). The normal removal of apoptotic bodies requires interactions between the bodies, complement components, serum amyloid P, and phagocytic cells. Genetically engineered normal mice with genes encoding C1q or serum amyloid protein (SAP) “knocked out” develop SLE-like disease with increased numbers of apoptotic bodies in tissues (210 ,211 ,212). It is reasonable to conclude that any condition that permits increases in apoptotic cells or allows them to persist longer than normal predisposes to SLE and to the production of antibodies to nucleosomes and DNA.

Immunoregulatory Abnormalities That Permit Sustained Production of Pathogenic Anti-DNA in SLE

Helper T cells are critical to SLE. They drive the IgM to IgG switch that enhances pathogenesis of autoantibodies, and they sustain autoantibody production and disease. Individuals with SLE have the ability to make pathogenic subsets of anti-DNA and either the ability to continually upregulate antibody production, the inability to downregulate it, or both. Chapter 9 reviews these mechanisms in detail. In the NZB × NZW F1 mouse model of SLE, nephritis does not develop until young mice switch their IgM anti-DNA production to IgG anti-DNA (213). A major role of helper T cells in stimulating the Ig class switch has been shown (214), and, in fact, elimination of helper T cells virtually prevents disease in both the NZB × NZW and BXSB models of lupus (215,216,217). $CD4^+$ and T cells have been cloned from NZB × SWR F1 mice that can make B cells from that animal secrete cationic IgG anti-dsDNA (218). The T cell receptors of those clones are enriched in positively and negatively charged amino acids in both T cell receptor (TCR)-α and TCR-ß chains (219,220), and some of the T cells are activated by nucleosomes (221). Pathogenic anti-DNAs react with DNA/histone and are enriched in charged amino acids in regions that contact antigen; many antigens with which they react are highly charged. Thus, charged amino acids in peptides from anti-DNA molecules are likely to be presented to TCRs containing oppositely charged amino acids. In that way, T cell help is activated for antibodies to DNA. T cell help is provided by many different types of cells in murine and human SLE. Helper T cell phenotypes may be , , or $CD4^-CD8^-$, and TCR may be α/ß or γ/δ. If we understood why these cells are all skewed toward help, without normal regulation, we would be closer to understanding this disease. It is clear that a T cell or B cell initially specific for a single self-antigen soon stimulates other T and B cells that greatly broaden the repertoire of reactivity toward self. This happens by two mechanisms: T- and B cell degeneracy, in which the receptor on one cell can bind many antigens of different sequences; and T- and B cell epitope spreading, in which increasing numbers of cells with different but related specificities are recruited into an active state. As a result, the autoimmune repertoire can become quite diverse and a given patient can have autoantibodies to many apparently unrelated antigens (222,223,224).

Immune tolerance is a mechanism that controls autoreactivity in normal individuals. There are several mechanisms of tolerance. In central tolerance, T cells in the thymus and B cells in the bone marrow are eliminated if they have high avidity for self antigens, expressed within those organs. Some such cells “leak” into the periphery, where they also encounter tolerance mechanisms. Those include (a) deletion (often a consequence of cell activation with strong signals engaging TCR or BCR), (b) anergy, a state in which first signals are received by lymphocyte TCR or BCR but the cells neither activate nor die (this is common when second signals via CD28 and CD40 are not present, which can occur in the presence of tolerized dendritic cells which do not express the CD80, CD86 and CD40L ligands for second signaling), (c) induction of regulatory cells (either NK-T cells, $CD4^+$, or $CD8^+$ T cells), and B cell receptor editing of autoreactive BCR. In normal mice transgenic for various mAb anti-DNAs, B cells expressing these antibodies are subject to all known tolerance mechanisms (225 ,226 ,227). In contrast, B cells are resistant to tolerance in lupus-prone mice (228 ,229 ,230). Induction of regulatory T cells, which are ineffective in lupus-prone mice, can overcome the B cell abnormalities of lupus mice. For example, activation of NK-T cells can prevent murine lupus (231). Regulatory T cells of the $CD4^+CD25^+CTLA4^+$ subsets prevent autoimmunity, including lupus-like disease, in normal mice. Experiments have suggested that all mice are predisposed to autoimmunity, which is only held in check by natural, thymic-educated regulatory $CD4^+CD25^+$ T cells (232 ,233 ,234). $CD4^+CD25^+$ T cells are low in number in patients with SLE (235) and their function is defective in some models of murine lupus (236). These Treg can be stimulated by appropriate peptides, or by in vitro incubation with IL-2 and TGF-ß and thereafter they can suppress autoantibodies and disease (236 ,237 ,238 ,239). Similarly $CD8^+$ T cells are ineffective suppressors of autoantibody-producing B cells in murine and human lupus (231 ,240 ,241). However, several strategies, including immunization with peptides from anti-DNA, can be used to induce/activate $CD8^+$ T suppressor T cells in murine lupus, and these cells are capable of suppressing anti-DNA and nephritis (242 ,243). Work is in progress to adapt these regimens that induce immune regulation to human SLE.

Solving the puzzle of the absence of function in regulatory T cells is an important challenge to lupus investigators.

In summary, APC, B cells, and $CD4^+$ helper T cells are hyperactive in humans and mice with SLE. In contrast, regulatory networks designed to downregulate high antibody

responses (idiotypic networks, NK T cells, $CD4^+CD25^+$ Treg, $CD8^+$ suppressor T cells, and tolerogenic APC) are underactive. As a result pathogenic autoantibodies are made in high titer and persist long enough in time to cause organ damage (205). Each of these abnormalities is discussed in detail in other chapters, and a recent review is available (243).

Structure of DNA

DNA occurs primarily as a B helix in solutions with physiologic tonicity and pH. Figure 23-1 shows the structure. Two polydeoxyribose-phosphate backbones spiral around central base pairs of purines and pyrimidines. The backbone is readily available to react with antibodies; the bases are contained in major and minor grooves. The binding sites of an anti-dsDNA can straddle the backbone and interact with bases in those grooves.

Chapter 22 shows the structure of nucleosomes.

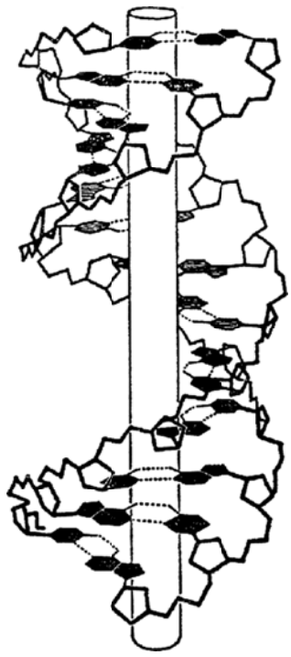

Figure 23-1. The DNA molecule in B helix conformation. Purine and pyrimidine bases in the center of the helix are solid black. Pentose sugars in backbone are open pentagons. Phosphate groups are along the heavy black lines on the outside of the helix. In SLE, anti-DNA may react with nucleosides, oligonucleotides, nucleotide sequences, or the sugar-phosphate backbone. (From Adams ROP, ed. *Davidson's The Biochemistry of the Nucleic Acids.* New York, NY: Academic Press, 1976 , with permission.)

Specificities of Anti-DNA for the DNA Molecule

Anti-dsDNA can react with base pairs, including dG-dC and dA-dT. Anti-dsDNA can recognize the ribosephosphate backbone alone or particular conformations in dsDNA (167 ,182 ,244 ,245 ,246). Multiple different conformations occur: dsDNA may form twisted, supercoiled, closed circular molecules; relaxed circular forms; left-handed Z-DNA segments; and cruciform structures. These polymorphisms are associated with different base-pair sequences and with the physicochemical characteristics of the environment. It is not known which of these reactivities is associated with the most pathogenic antibodies. However, variation in methylation of DNA, particularly with increased numbers of deoxymethylcytosines, increases the immunogenicity of DNA. GC-rich regions can be nuclease resistant, and these combinations increased immunogenicity. Such a combination is found in nucleosomal DNA in apoptotic cells (183 ,247).

When dsDNA is denatured, compact single chains are formed, which can present bases, nucleotide sequences, backbone, short regions of base-paired secondary structures, and short helices. Anti-ssDNA therefore can react with bases, nucleosides, nucleotides, oligonucleotides, and ribosephosphate backbone. Anti-ssDNA react predominantly with individual bases and even better with polynucleotides containing multiples of that base. The largest proportions of anti-ssDNA in sera react with guanosine and thymidine, but others recognize polyA, polyC, polyI, Z-DNA, ssRNA, RNA-DNA hybrids, and poly (adenosine diphosphate (ADP) ribose) (244 ,245).

Anti-DNA induced by immunization with bases, nucleosides, or oligonucleotides usually is highly specific for the immunogen. In contrast, spontaneous anti-DNAs that arise in individuals with SLE usually are polyspecific and react with nucleosomes, multiple oligonucleotides and several forms of DNA. This wide reactivity could result from similar epitopes shared by multiple different molecules (probably conformational) or a single antibody-combining site having multiple contact regions for unrelated epitopes. An example of shared epitopes would be the cross-reactivity of many mAbs for DNA and cardiolipin (44 ,248). There are shared phosphodiester groups in the ribosephosphate backbone of DNA and in phospholipids. The role of bacteria, viruses, apoptotic materials and autoantigens in inducing anti-DNA is discussed above.

When the structure of DNA is altered by cell activation or inflammation, it may become immunogenic. Structural differences might account for bacterial DNA inducing anti-DNA in humans. Krieg et al. (249) showed that unmethylated cytosine phosphyrol guanine (CpG) motifs in bacterial DNA can directly trigger B cells to proliferate and secrete antibodies. Because these motifs are more abundant in bacterial or viral genomes than in mammalian genomes, this property may confer on vertebrates an advantage to fight off microbial infection. These findings also suggest that the increased levels of hypomethylated CpG in DNA of patients

with SLE may play a pathogenic role in inducing a polyclonal B cell activation. Additionally, hypomethylated CpG motifs in T cells promote their activation (183 ,184).

Desai et al. (250) showed that mammalian DNA (usually a weak immunogen) becomes strongly antigenic when combined with a highly charged fusion protein. This might be similar to the association of DNA with histones in nucleosomes, and nucleosomes may initiate a series of dendritic cell, B cell and T cell events that culminate in production of IgG anti-dsDNA, as discussed in an earlier section. DNA found in the circulation of patients with SLE is small in size (100 to 150 base pair [bp]), and units of 200 bp and their multiples (113 ,114 ,115). DNA of these sizes is usually found in nucleosomes. Cell apoptosis releases DNA of this size; cell necrosis does not. Therefore, in SLE, cell apoptosis may be induced by immunologic abnormalities, and the nucleosomes released from those cells provide the antigenic stimulus that results in somatically mutated, high-affinity IgG anti-DNA antibodies.

The last hypothesis—that anti-DNA recognizes a conformation shared with the original, unknown immunogen—has been used to explain the ability of an anti-DNA to recognize molecules with no known structural similarity to DNA (251). This hypothesis will require progress in studies of three-dimensional conformations for verification. To date, one anti-ssDNA has been crystallized (164), but there are no reports of crystals containing anti-dsDNA with antigen.

DNA may be different in individuals with SLE from that in normal individuals. The quantities of DNA released by cultured lymphocytes from humans and mice with SLE are significantly greater than the quantities released by normal cells (252 ,253). The circulating DNA in patients with SLE also is richer in guanosine and cytosine than DNA from healthy controls (254), and in hypomethylated regions (183 ,184). Such changes could increase the immunogenicity and ability to form Z-DNA.

Degradation of DNA

The degradation of DNA may be slower than normal in individuals with lupus, because their nucleases may be impaired. Based on studies in normal mice (253), DNA probably is cleared in two phases. First, large pieces of DNA (more than 15 bp) rapidly bind to various organs (primarily the liver for ssDNA and other soft tissues for dsDNA). Second, DNA is degraded in the circulation and in tissue by nucleases. ssDNA is cleared more rapidly than dsDNA (20 minutes vs. 40 minutes, respectively); the second, digestion phase of clearance is similar for both.

Several conditions may prolong the half-life of DNA. Hepatic uptake of DNA is saturable with excess DNA or excess immune complexes, which results in a prolonged half-life. If DNA is present in small size, organ binding is impaired. In patients with active disease, excess quantities of circulating DNA and of small immune complexes have been detected; therefore, clearance of antigenic DNA is probably impaired (253).

Another factor that allows DNA to persist in patients with SLE is its existence as protected fragments (255). Small DNA fragments (30 to 40 bp), are bound by the two arms of IgG anti-DNA and thus protected from both organ binding and the action of nucleases.

DNA may serve as a target antigen beyond its participation in immune complexes. There is a DNA receptor on a number of cells, including glomeruli (256 ,257), and DNA bound into that receptor might well be a target of pathogenic anti-DNA. Additionally, the ability of DNA or DNA/histone to be implanted in tissues, particularly collagen IV, laminin, and heparan sulfate in basement membranes, may target antibodies to organs that are damaged in patients with SLE (35 ,38 ,42 ,43 ,104 ,105 ,108 ,118 ,257).

In summary, DNA, DNA/histone complex, or small immune complexes containing protected fragments of DNA may persist for abnormally long periods in individuals with SLE for a variety of reasons. Such a situation could result in prolonged antigenic stimulation and in the availability of DNA to bind to target tissues or to circulating anti-DNA, thus perpetuating the disease process.

DNAse-1 is the major nuclease present in serum, urine, and secretions that degrades DNA, particularly at sites of high cell turnover. DNAse-1–deficient mice were generated. They developed ANA and Ig deposition in glomeruli, with clinical glomerulonephritis (258). These observations, coupled with the information that levels of DNAse-1 in plasma of patients with SLE are usually low, led to clinical studies in which recombinant human DNAse-1 was administered to patients with SLE. The trial contained 17 individuals who received a single IV dose of 25 to 125 μg per kg of recombinant human DNAse-1 followed by ten subcutaneous doses or placebo. Serum DNAse-1 concentrations achieving hydrolytic activity of DNA sustained for a few hours after IV, but not subcutaneous administration. Serum antibodies to DNA were unchanged, as were cytokine levels of soluble interleukin-2R (sIL-2R), IL-6, IL-10, and TNF-α (259).

Polymorphisms in genes encoding DNAses that are associated with antibodies to DNA and lupus nephritis in patients have been described by one group (260 ,261).Mutations of DNAse-1 gene resulting in premature termination of mRNA have been reported in two Japanese SLE patients supporting the association between low activity of DNAse-1 and the development of SLE in patients (262).

The Characteristics of Immune Complexes Containing DNA and Anti-DNA and Their Clearance

Immune complexes containing DNA have been found in the circulation of as many as 50% of patients with active SLE, depending on the sensitivity of the method (114 ,263 ,264). The DNA in these immune complexes probably consists primarily of nucleosomes (113 ,115 ,263 ,264). For other immune complexes, small soluble complexes in slight antigen excess that can fix complement are the most pathogenic.

For DNA, complexes in slight antibody excess may be the most stable and therefore most pathogenic (264 ,265 ,266). The complexes should be bound by Fc and CR1 receptors and cleared by the mononuclear phagocyte system. However, during periods of active SLE, clearance of immune complexes is defective. Chapter 12 discusses the complex abnormalities. Abnormalities include a combination of high quantities of complexes, decreased numbers of receptors, saturation of available receptors, and defective phagocytosis of the complexes fixed to receptors (267 ,268). Genetic abnormalities in quantities of CR1 receptors have been reported (268), but the low numbers on cells of patients with SLE also may reflect stripping of occupied receptors. No mutations in CR1 or in Fc receptors have yet been found in patients with SLE. However, polymorphisms in FcγRIIA and RIIIA have been associated with SLE; those polymorphisms probably encode molecules less able to bind Ig strongly compared to other alleles (269 ,270 ,271 ,272). There is also defective FcγRIIB, a receptor which is a downregulator of B cells (273). Therefore, inheritance of inefficient-binding-alleles of these Fcγ receptors could impair the clearance of most immune complexes that cause disease in SLE. IgG1 is usually the most abundant isotype in glomerular Ig deposits. As discussed above, immune complexes containing cationic antigen or antibody, or protected DNA fragments that cannot be bound by cells that clear DNA, are probably important pathogens. These features stabilize the complex and permit its persistence.

Methods of Measuring Antibodies to DNA

Several techniques are available to measure anti-DNA in serum or plasma (274 ,275 ,276 ,277 ,278) (Table 23-4). There is no universal standardized assay used by all service laboratories, in contrast to antibodies to cardiolipin, for example. Therefore, the techniques used by each service or research laboratories are critical to accurate interpretation of test results. Some assays detect only high-avidity subsets of anti-DNA that are enriched in pathogens; these tests have low sensitivity but strong association with nephritis and clinical disease activity. Others detect both low- and high-avidity anti-DNA; these are more sensitive but less likely to be associated with clinical correlations. The following tests measure primarily high-avidity antibodies: precipitation, complement fixation, and the Farr assay. A second group of tests detects both high- and low-avidity antibodies: ELISA, *Crithidia luciliae,* hemagglutination, and radioimmunoassays with precipitation of DNA-containing immune complexes by polyethylene glycol (PEG) assay. In general, the first group is less sensitive than the second, being positive in only 50% to 60% of patients with SLE, but correlates better with disease flares and high risk for glomerulonephritis. The second group is more sensitive, being positive in 70% to 85% of patients with SLE; however, they correlate less well with disease activity and manifestations. These differences account for some of the discrepancy in the literature regarding the clinical utility of anti-DNA testing.

Table 23-4: Methods of Measuring Anti-DNA

Test	Sensitive	Specific	Correlates with Disease Activity and Nephritis	Availability
Precipitation	+	+++	+++	Poor
Hemagglutination	++	+	+	Poor
Complement fixation	++	+++	+++	Poor
Farr assay	++	+++	+++	Fair
PEG assay	++	++	+	Poor
Crithidia luciliae immunofluorescence	++	+++	++	Good
ELISA	+++	++	+	Good
EliA	+++	++	++	New

ELISA, enzyme-linked immunosorbent assay; PEG, polyethylene glycol.

The tests most commonly used in service laboratories are Farr, ELISA, and *C. luciliae*. In the Farr assay, radiolabeled DNA is added to diluted serum or plasma, and Ig is precipitated by ammonium sulfate. Radioactivity in the precipitate indicates binding of DNA by anti-DNA; unbound DNA is not precipitated. DNA can be purified to contain primarily dsDNA, although a few single-strand nicks develop during the assay. This assay has limited availability because of the need to use radiolabeled materials. Both IgG and IgM high-avidity precipitating antibodies are captured in the Farr assay, which probably is the best of the available tests to detect primarily high-avidity antibodies to DNA. In a recent placebo-controlled prospective clinical trial of a oligonucleotide/tetramer tolerogen (LJP394, Riquent, Abetimus) in patients with lupus nephritis, responders were found primarily in the group with anti-DNA that bound the tolerogen with high avidity, and most of the patients who improved were in the groups with falling titers of anti-DNA by Farr assay, whether they received active agent or placebo (279 ,280). This illustrates the important relationship of

high-avidity IgG antibodies to dsDNA in some people with lupus nephritis, and the utility of the Farr assay.

In the ELISA assay, DNA is bound to wells in plastic microtiter plates. In general, ssDNA sticks directly to the wells. The adherence of dsDNA is variable, and some laboratories coat the wells with negatively charged molecules such as protamine sulfate, poly-l-lysine, or methylated bovine serum albumin before dsDNA is added to ensure uniform entrapment of the antigen. However, there are commercial microtiter plates available to which dsDNA adheres well, without requirement for addition of charged lining molecules. Diluted patient plasma or sera are incubated with DNA in the wells. After several hours, the wells are washed and the bound Ig incubated with enzyme-labeled antihuman Ig, IgG, or IgM. The binding of the second antibody is detected by a color change following addition of a substrate on which the enzyme acts, the color being read in a spectrophotometer. This assay allows measurement of both low- and high-avidity antibodies and the detection of total IgG, IgG isotypes, IgM, and total populations of anti-DNA. The substrate fixed to the wells can be highly purified dsDNA (which can be from mammalian or bacterial sources); a few single-strand nicks develop during the incubations. Commercial substrates often contain significant quantities of ssDNA as well as dsDNA; therefore, low quantities of anti-DNA detected in this assay may be primarily directed against ssDNA. Clinical correlations are best if they are confined to the interpretation of high titers of IgG anti-dsDNA detected in this manner. There is considerable variability in the sensitivity and specificity of various manufacturers' ELISA kits for the measurement of anti-DNA and other autoantibodies (274 ,275 ,276). It is therefore most useful to both clinicians and researchers if assays are done repeatedly in the same laboratory using the same procedure or kits from the same sources.

Several groups have analyzed the association between antibodies to nucleosomes (measured in ELISA) and clinical correlations. They have noted strong association between IgG3 anti-DNA, disease activity, and nephritis in their lupus patients (109 ,110), and in general have reported that these antibodies are more sensitive and specific for change in disease activity. However, the test is not widely used. These examples illustrate the importance of every detail of ELISA assays, beginning with the antigen used, in influencing results. International standardization of these assays would be welcome.

The *C. luciliae* test takes advantage of the presence of a kinetoplast containing circular dsDNA in this flagellate. Test sera or plasma are incubated with the organisms on a glass slide. After washing, fluoresceinated antihuman Ig, IgG, or IgM are added. After appropriate incubation, Ig bound to the dsDNA structure is detected by examining the glass slide for fluorescence using an ultraviolet microscope. Although even this circular DNA structure can contain one or two single-strand nicks, this assay is the most specific for detecting antibodies against pure double-stranded DNA. Therefore, positive tests are highly specific for SLE. However, in some laboratories, the sensitivity is not as good as the ELISA assay. The Crithidia assay can be modified to detect complement-fixing antibody subsets, but in the standard test both low- and high-avidity anti-dsDNA are measured. In some comparative studies, antibodies to DNA by Crithidia assay are similar to those detected by ELISA or Farr in terms of specificity, sensitivity, and prediction of disease flares (278). The assay is technician-dependent, because there is an autofluorescent structure in the flagellate that can be confused with the dsDNA-containing kinetoplast.

In summary, several different assays for anti-dsDNA are available commercially; each has advantages and disadvantages. No standardized test is used uniformly in all service laboratories. The ideal anti-DNA assay would detect all IgG high-avidity, complement-fixing anti-dsDNA; however, none of the assays available in most service laboratories does so. Therefore, the physician should determine which assay is used in the laboratory to which the specimens are sent and understand the specificity, sensitivity, and clinical correlations of that method. With methods that detect most populations of anti-dsDNA (and some anti-ssDNA), weakly positive tests can be obtained in patients with chronic liver disease, rheumatoid arthritis, nonlupus connective tissue diseases, drug-induced lupus, infections, and aging.

Measurements of Antibodies to dsDNA: Utility for the Clinician

Detection of anti-dsDNA often is useful in the diagnosis and management of patients with SLE (Table 23-5). Their interpretation is limited by lack of a standardized assay to measure them, inability to equate results of assays with the most pathogenic subsets of anti-DNA, and the fact that antibodies other than anti-DNA participate in the tissue lesions of SLE. Antibodies to ssDNA should not be measured, because they have no specificity for the disease.

Table 23-5: Clinical Utility of Measuring Anti-DNA

High titers of anti-dsDNA
Have approximately 90% specificity for SLE
Often indicate clinically active disease and increased risk for nephritis
Low titers of anti-dsDNA
Can be detecting anti-ssDNA
Can be found in
Drug-induced lupus
Rheumatoid arthritis
Sjögren syndrome
Other CTD
Chronic infections
Chronic liver disease
Aging

CTD, connective tissue disease.

Tests for antibodies to dsDNA are useful in establishing the diagnosis of SLE; 60% to 83% of patients with SLE have

positive tests for these antibodies by the Farr, Crithidia, or ELISA assays at some time during their illness (274 ,275 ,276 ,277 ,278 ,281). The presence of anti-dsDNA fulfills a criterion for the American College of Rheumatology classification of patients as having SLE (282 ,283).

The ability of tests for anti-dsDNA to predict exacerbations of clinical disease, or various organ involvements, is controversial. Some studies suggest strong correlations between increasing levels of these antibodies and subsequent disease activation (281 ,284). Other studies suggest that such correlations are weak (285 ,286). A minority of patients have high titers of IgG anti-dsDNA for prolonged periods of time without developing exacerbations of disease or glomerulonephritis (287). In general, when tests for anti-dsDNA are performed at regular intervals using the same methods and laboratories, rising titers suggest increased risk for disease exacerbation, particularly of nephritis and/or vasculitis (207 ,281 ,284). Sometimes renal flares are preceded by drops in anti-DNA, probably because the antibodies are leaking into the urine. It is likely that combinations of laboratory changes, particularly rising anti-DNA and falling complement levels, are better than either one alone. It comes as no surprise that the clinician must combine results of careful laboratory testing with symptoms and signs to make correct therapeutic decisions. Currently there is an aggressive search for improved biomarkers of active, worsening or improving disease in patients with SLE (207).

In summary, measurement of anti-dsDNA in sera has two useful clinical applications (Table 23-5). First, high titers of these antibodies have a specificity of more than 90% for SLE; therefore, they are useful in making the diagnosis. Second, rising levels should alert the clinician to the possibility of an imminent disease flare, and high levels (especially associated with low levels of serum complement) suggest increased risk for lupus nephritis or vasculitis. We recommend that in each patient with SLE, the physician establish whether the pattern of serum anti-DNA titers correlates with clinical manifestations and disease activity. If such correlations are present, serial measurements of anti-DNA are useful.

Future Directions: Targeting Antibodies to DNA in Therapy of SLE

Many effective, widely immunosuppressive therapies for SLE such as glucocorticoids, mycophenolate and cytotoxic drugs are associated with falls in titers of anti-dsDNA that precede or accompany clinical improvement. There has been considerable interest in developing therapies that specifically target pathogenic autoantibodies and leave the normal immune repertoire intact.

There has been some success in experimental studies with LJP394 (Riquent, Abetimus), which is a DNA tolerogen (279 ,280). LJP394 is a molecule in which four oligonucleotides are held on a tetrameric scaffold. The idea is to cross-link two Ig anti-DNA receptors on B cells; this gives a weak first signal without a second signal, so that the B cells are anergized (not activated) and stop producing anti-dsDNA. Administration as a toleragen was effective in BXSB lupus-prone mice. Recently, in a clinical trial in patients, the number of flares of nephritis was significantly reduced in the patients tolerized with weekly intravenous injections of LJP394 compared to those who received placebo—in the subset of patients with anti-dsDNA that bound the toleragen with high avidity (279). The toleragen was given once a week intravenously. A follow-up study is in progress (2006)p.

Other attempts to reduce anti-DNA antibody as disease treatment have included immunoadsorption of anti-DNA using columns designed to specifically trap anti-DNA and immune complexes (288 ,289 ,290). Passing SLE serum over phenylalanine or human anti-DNA or dextran sulfate columns reduced anti-DNA titers and was associated with clinical improvement in at least half of patients. Administration of DNAse-1 was not effective in initial studies. The future of therapies that target certain autoantibodies is exciting, since many of the autoantibodies of SLE are interconnected, and suppressing one might have beneficial effects on quantities of the others.

Finally, there has been some success in reducing antibodies to DNA by administering peptides from the VH regions of murine or human anti-DNA (207 ,291). These peptides induce regulatory/suppressor T cells which delay the appearance of autoantibodies and nephritis. One of the peptides, Edratide, inhibits anti-DNA production by human SLE cells transferred to SCID mice (291). It is currently in clinical trials.

Chapter 24

Antibodies to Histones and Nucleosome-Related Antigens

Robert L. Rubin

Marvin J. Fritzler

Discovery of Histone-Reactive Antibodies

Histone-reactive antibodies played a major role in the demonstration almost six decades ago that systemic lupus erythematosus (SLE) is an autoimmune disease. The initial recognition that autoimmunity underlies diseases such as SLE is generally attributed to the observations of Hargraves et al. (1) on the lupus erythematosus (LE) cell phenomenon in which nuclear material derived from dead cells is phagocytosed by neutrophils in vivo. This phenomenon was reproduced in vitro by Hamburger (2) and Miescher and Fauconnet (3) by mixing normal neutrophils with SLE plasma, and Holman and Deicher (4) showed that the responsible factor in SLE plasma was an antinuclear antibody (ANA). Absorption of SLE sera with calf thymus nucleohistone and histone-DNA complexes but not with pure DNA greatly reduced the LE-cell phenomenon (5), suggesting that the specificity of this ANA was related to histone-reactive antibodies. Several groups showed that histones were necessary for maintaining the antigenicity of nuclei for the LE cell factor (4 ,6 ,7), and direct demonstration of the antigenicity of free histones was obtained by Holman et al. (8) and Kunkel et al. (9) using a complement-depletion assay. Thus, histone-reactive antibodies hold a preeminent position in the recognition of the autoimmune nature of SLE and lead to the discovery of many other ANA.

Much of the subsequent, older work on histone-reactive antibodies in SLE was limited to histone-containing nucleoproteins. Histones complexed with sonicated DNA were shown to form immunoprecipitins with SLE sera using classic Ouchterlony analysis (10). Many SLE patients had complement-fixing anti-DNA and anti-(histone-DNA), which tended to increase along with clinical disease (11). Various nuclear immunofluorescence patterns (rim, fibrillar, homogeneous) were attributed to antibodies to nucleoprotein (10 ,11). Over 50% of SLE sera had antibodies to soluble nucleoprotein that were not removed by absorption of sera with DNA (12), but the fine specificity of these autoantibodies was not determined until years later (13). It was generally inferred from these early studies that antibodies that bind nucleoprotein are antibodies to histone-DNA complexes, and this specificity is equivalent to the LE-cell factor. Studies by Hannestad et al. (14 ,15) suggested that a complex of histones in the absence of DNA possessed antigenic activity for the LE factor. More recently it has been shown that antibodies to histone H1 are primarily responsible for LE cells (16 ,17).

Histone Organization in the Cell

Histones are normally found in eukaryotic cells associated with DNA and organized in a huge macromolecular structure called chromatin, which is the native form of nucleohistone in the cell. In addition to DNA and histone which constitute 80% of its mass, chromatin contains non-histone proteins, RNA and other macromolecules. Many constituents of chromatin are targets for autoantibodies in SLE—histones, DNA, RNA, and proteins such as the centromere proteins, nucleolin and high-mobility group proteins (18). Histones and DNA constitute the repeat subunit of chromatin called the nucleosome (19 ,20), and the linear array of nucleosomes held together by a continuous strand of approximately 2×10^7 base pairs of DNA forms the polynucleosome, the primary chromatin fiber of approximately 100ö in diameter. This thin filament has a tendency to supercoil into higher-order solenoid-like structures of increasing diameter (21), compacting the DNA 5,000- to 10,000-fold as depicted in Figure 24-1 . In a typical chromosome approximately 7 millimeters of DNA is condensed to 1 micron by the organizing capacity of about 100,000 nucleosomes.

The nucleosome consists of two molecules of each of the “core” histones, H2A, H2B, H3, and H4, along with one H1 molecule and approximately 200 base pairs of DNA. Acid-solubilized histones are monomeric; the five major polypeptides can be distinguished by polyacrylamide gel electrophoresis and can be separated by gel permeation chromatography (Fig. 24-2). DNA of 146 base pairs wraps with 1.75 superhelical turns around an octamer of histones H2A, H2B, H3, and H4, and this core particle is connected to the adjacent core particle by a segment of the continuous stand of DNA designated as the linker. All the histones participate in limited contacts with DNA at 10 base pair

intervals wherever the minor grove of the DNA double helix faces the histone core (22 ,23 ,24), resulting in 14 regions on the twisting DNA anchored to arginine side chains of the histones (25). These multiple interactions account for the stability of the nucleosome and constrain the DNA to curve tightly around the octamer. Histones H1 or H5 appear to bind close to the exposed face of one of the two H2A molecules, creating asymmetry in the nucleosome that provides a ramp where DNA exits and is directed to the adjacent nucleosome (26). The amount of linker DNA shows wide interspecies and even inter-tissue variation so that nucleosomes may contain from 166 to 231 base pairs of DNA.

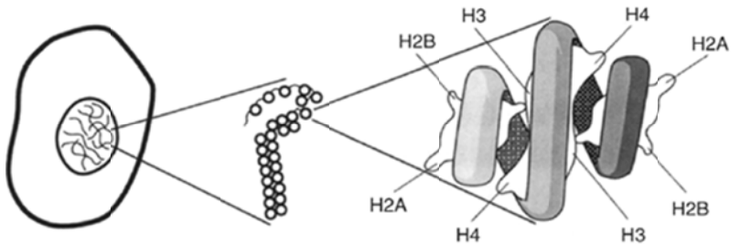

Figure 24-1. Higher ordered structure of histones in chromatin. On the right is a diagrammatic representation of the core particle of the nucleosome in which two turns of DNA wrap around an octamer of histones consisting of two H2A-H2B dimers flanking an H3-H4 tetramer. Separation of dimers from the tetramer is exaggerated for clarity—the native core particle is a compact structure stabilized by non-covalent bonds (25,27). Association with H1 completes the nucleosome (not shown), and an array of polynucleosomes supercoil into a solenoid-like structure depicted in the middle diagram. Additional supercoiling into even higher ordered structures is presumed to take place until chromatin fibers are eventually visible in the light microscope as mitotic chromosomes.

Digestion of chromatin with micrococcal nuclease preferentially cuts the less protected internucleosomal, linker DNA; H1 tends to dissociate and is removed by treatment with 0.5 M NaCl (Fig. 24-3). Unlike native chromatin, H1-stripped chromatin is soluble in physiological solutions. Partial digestion of chromatin with micrococcal nuclease produces a mixture of core particles, nucleosomes and oligonucleosomes, resulting in a “ladder” representing DNA of various sizes. The natural tendency of histones to interact with each other is of fundamental importance in the stability of the core particle, and dissociation of DNA by 2.0 M salt releases the histone octamer. Decreasing salt concentration causes dissociation of the component H3-H4 tetramer from the two H2A-H2B dimers (28). An artificial complex between the H2A-H2B dimer and DNA can be formed in vitro at physiological conditions; this complex is an important antigenic target in patients with SLE and drug-induced lupus.

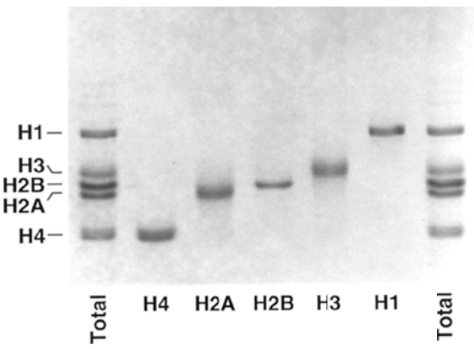

Figure 24-2. The five major histone classes. Total histones were derived by acid extraction of calf thymus chromatin and subjected to SDS polyacrylamide gel electrophoresis (29). The individual histone classes can be purified on a preparative scale by gel exclusion chromatography (30).

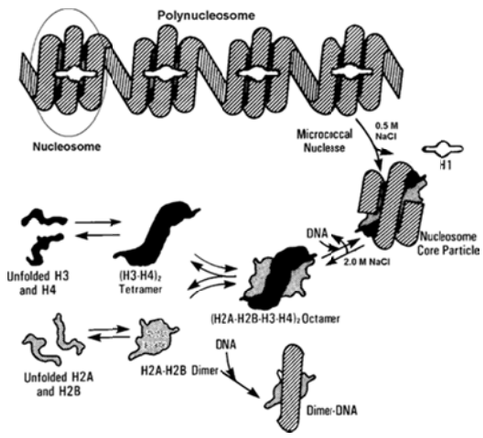

Figure 24-3. Dissociation of the polynucleosome. The nucleosome core particle is released by digestion of chromatin with micrococcal nuclease and treatment with 0.5 M NaCl. DNA can be reversibly released from the core particle in 2.0 M NaCl, producing the core histone (H2A-H2B-H3-H4)2 octamer. Decreasing the salt concentration causes dissociation of the component H3-H4 tetramer from the two H2A-H2B dimers; at very low salt concentration or low pH the individual, monomeric histones are produced. The (H2A-H2B)-DNA complex is stable in physiological conditions.

Structure of the Histones and Their Variants

The amino acid sequences of all five histones and numerous variants from many animals and plants have been determined (31 ,32). Histones H3 and H4 are two of the most conserved proteins (33)—bovine H3 and H3 from the pea plant differ by only 4 of 135 amino acids, and bovine and pea H4 are identical except for two conservative amino acid substitutions. Human and calf H4 are identical including the presence of three posttranslationally modified residues (34). The primary structure of human spleen H3 is identical to calf thymus H3 except for serine in place of cysteine at position 96 and for the presence of two minor variants in human H3 (35). The primary structure of H2B also displays remarkable similarity in the C-terminal half of the molecule among a wide variety of animals, but considerable variation in the amino acid sequence of the N-terminal half of H2B has been detected within the animal kingdom (32). However, human spleen H2B is identical with calf thymus H2B except for two minor variants in human H2B, each of which has a single amino acid substitution (36). The entire molecule of H2A appears to be more highly conserved than H2B. Calf thymus H2A is identical with human spleen H2A except for a minor variant having a histidine deletion at residue 123 or 124 (37). The vast majority of histone variants are identical among mammalian species, suggesting their importance in the biology of the cell. Because of this near identity between human core histones and their counterpart from calf thymus (the material of choice for chromatin extraction), bovine histones can generally be considered as valid autoantigens for analyzing human autoantibodies.

The H1 class of histones is considerably more complex and heterogeneous. An internal segment of approximately 70 amino acids displays extensive homology among the animal H1 histones sequenced, but the N-terminal 40 residues and C-terminal half of the protein show substantial primary structure divergence (32). H1 includes at least eight variants which differ in primary structure, and many of these, especially human, have only recently been sequenced or identified only by deduction from the nucleotide sequence of cloned genes. Mammalian H1° is present mainly in terminally differentiated, quiescent cells and shows extensive homology with histone H5, which is found in phylogenetically lower organisms and is generally isolated from avian nucleated erythrocytes. Human H1° and chicken H5 share eight essentially identical segments of 6–21 amino acids if only one amino acid deletion, addition or substitution is allowed per segment (38). However, these histones show less than 10% homology with the main H1 class (39). The nomenclature for the H1 family of histones has not been formally standardized, so structural comparisons between species are presently ambiguous. However, all the H1 histones including H1° and H5 share a nearly identical 16 amino acid long region in the globular domain (human H1.1 94–108, human H1.2 91–105, human H1° 79–94, bovine H1.1 91–106, chicken H5 80–95) as well as a highly conserved octapeptide in the C-terminal domain (human H1.1 151–158, H1.2 153–160, and H1° 152–159, chicken H5 148–155) (40). The significance of the H1 variants has been the subject of intensive study for years and appears to be related to the role of H1 in affecting the higher order structure of chromatin and, consequently, the overall transcriptional activity of the genome. Although extensive antigenic cross-reactivity can be expected among the H1 variants, the complexity of this histone class and the difficulty in physically separating and identifying these variants presently confounds the interpretation of studies involving autoantibodies to the H1 family of histones.

The different histone classes have very limited amino acid sequence similarities (41 ,42), but these similarities may account for some cross-reactions among antihistone antibodies. H2A shows homologies with H4, H2B, and H3, each in different parts of the H2A molecule, an octapeptide in H3 is similar to a decapeptide in H4, and H3 and H2B share an identical tetrapeptide (see (43) for sequence). Although all the histones are rich in basic amino acids, especially in their amino terminal regions, extensive, uninterrupted strings of such residues are generally not observed. There is a pentapeptide in H2B and H4 consisting of all basic amino acids, but tandem arrays of greater than three lysine, arginine or histidine residues do not occur in any histone, including H1. This may explain why naturally occurring antihistone antibodies display only weak or negligible cross-reactivity with basic homopolypeptides.

Within each class of histones, numerous subtypes or variants have been identified (44). Variants occur among different biological species as well as within a species, such as between stages of development, among different tissues and even within a homogeneous cell type. This heterogeneity in primary structure can be the result of transcription from multiple genes for a histone class with slightly different coding sequences or because of postsynthetic modifications. Posttranslational modifications occur on only a portion of the total histone pool of a cell or tissue, resulting in a variety of subtypes being present simultaneously.

Phosphorylation

Phosphorylation occurs in the N-terminal region on certain serine residues of all histones, threonine on H3 and H1, histidine on H4 and lysine on H1. H1 is extensively phosphorylated on both the N- and C-termini, especially during the S phase of cell division (45). Phosphorylation reduces the net positive charge and is thought to alter histone-DNA interaction (46), but whether this disruption of DNA-histone interactions contributes to the enhanced template activity of chromatin is unknown.

Acetylation

From two to four lysine residues may be acetylated in histones H3, H4, H2A, and H2B, as is the amino terminus of H2A, H4 and H1 (45). Unacetylated protruding amino terminal tails may make contact with DNA and/or histone of the adjacent nucleosome (25), thereby “locking” the polynucleosome into a higher order structure (Fig. 24-2) that suppresses transcriptional activity. Transcription factors associated with histone acetyltransferase activity resulting in added acetyl groups to the protruding histone tails neutralize the positive charge of the reacting residues, thereby disrupt this compact structure, allowing access to the transcriptional machinery (47).

Methylation

A portion of all the histones is methylated at certain lysine residues and probably at the guanidine nitrogen of arginine. Methylation is a relatively stable modification and occurs after DNA synthesis in the late S or G2 phase after chromatin biosynthesis, suggesting that this modification is not essential for the assembly of chromatin. On the other hand, methylation has been suggested to be important in chromatin condensation, other mitotic events, and gene transcription.

Poly(ADP-Ribosylation)

The covalent addition of an ADP-ribose moiety of nicotinamide adenine dinucleotide (NAD) to proteins is catalyzed by poly(ADP-ribose) polymerase (48). The major acceptor proteins for poly-(ADP-ribose) are H1 and H2B although ribosylation of H2A, H3and H4 also have been reported. This modification has been postulated to play a role in DNA replication and repair, cell differentiation and apoptosis (49). An increase in the activity of poly-(ADP-ribose) polymerase has also been correlated with the appearance of DNA strand breaks produced by nucleases and other agents (50). This is interesting in light of observations that metabolites of drugs that are associated with drug-induced lupus induce extensive DNA strand breakage (51) and increase poly(ADP-ribose) polymerase activity in certain cells (52).

Table 24-1: Structural Domains within the Histones*

Histone	Number of Residues in Parent Molecule	Major Trypsin Resistant Domain	
		Residue Number	Designation
H3	135	27–129	P1
H2A	129	12–118	P2
H2B	125	21–125	P2
		24–125	P3
H4	102	18–102	P4
		20–102	P5
H1	212–222	36–121	P0 (G-H1)

*Compilation is based on (62) and refers to calf thymus histones. Histones are arranged in order of increasing electrophoretic mobility of the trypsin-resistant domain.

Ubiquitination

Approximately 10% of calf thymus H2A is covalently associated at lysine 119 with ubiquitin, a protein of 76 amino acids, resulting in a variant of H2A possessing an electrophoretic mobility equivalent to approximately twice the size of the parent molecule (53 ,54). Approximately 1% of H2B is ubiquitinated at lysine 120 (55). Poly-ubiquitinated H2A is a chain of at least four ubiquitin molecules bound to the amino group of H2A lysine 119 (56). Although ubiquitination in the cytoplasm tags proteins for degradation by the proteasome (57), ubiquitin in histones appears to be important in docking transcription factors or maintaining the structure of transcriptionally active chromatin (58).

Significance of Primary Structure Variation

Clearly, both very subtle variants as well as highly altered forms of histones have been identified among higher organisms. Even single amino-acid differences in histone variants could potentially be recognized immunologically (59), and side-chain modifications such as ribosylation and ubiquitination are profound. Autoantibodies to poly-(ADP-ribose) (60) and to ubiquitin (61) have been reported in SLE, but since these modifications are found on many other proteins, their relationship to antihistone antibodies is unclear. The significance of posttranslationally modified histones as well as of the histone variants with different amino acid sequences in the elicitation of antihistone antibodies or the antigenicity of the targeted histones is unknown.

Domain Structure of Histones

Histones in chromatin (but not the individual proteins) show a remarkable resistance to trypsin digestion considering their high content of lysine and arginine, the amino acids immediately N-terminal of the specific cleavage site of trypsin. Table 24-1 shows the trypsin-resistant “limit digest” products can be separated by sodium dodecyl sulfate (SDS) gel electrophoresis and their compositions. Since similar polypeptide products are observed after trypsin digestion of

nuclei, chromatin or core particles but not of histones in low ionic strength environments, resistance is attributed to protection of potential cleavage sites by the tertiary or quaternary conformation of the histones in the nucleosome. DNA does not afford principle protection of histones from trypsin because the DNA-free octamer in 2 M NaCl displays a similar resistance to trypsin digestion. In fact, the trypsin-sensitive sites are the highly positively charged regions previously (incorrectly) believed to be stably bound to the DNA phosphates: the 11–30 amino acid residues of the N-terminal ends of the four core histones and the C-terminal 11 residues of H2A and six residues of H3.

Biophysical studies on trypsinized core particles indicate that they are largely indistinguishable from their native counterparts (63). The trypsin-sensitive tails are highly mobile with no stable conformation or binding sites on DNA, although they have been suggested to provide relatively non-specific electrostatic shielding of DNA phosphates, stabilizing higher order chromatin structure (64). Apparently, these domains are accessible to the enzymes involved in histone posttranslational modification because almost all the sites for phosphorylation, acetylation, methylation and ubiquitination are at the trypsin sensitive regions. It has also been claimed that these domains comprise the predominant epitope for antihistone antibodies in SLE, but as discussed in later section, significance of antihistone fine specificity is an oversimplification.

All the H1 variants including H5 and H1° bear a similar three-domain structure as previously described. The highly conserved central globular domain is involved in the critical function of redirecting the DNA as it exits the core particle, and the flanking regions which are rich in the basic amino acids arginine and lysine presumably play a role in internucleosomal interactions involved in chromatin condensation into higher order structure (26). Histone H5 possesses an unusually large arginine-rich C-terminal domain believed to condense chromatin to the transcriptionally inactive form present in avian erythrocytes. The otherwise closely related H1° retains the lysines in the C-terminal domain characteristic of the main H1 family, but is associated with chromatin in terminally differentiated cells that have only selected genes that are transcriptionally active. The highly conserved 16-mer in the globular domain and octamer in the C-terminal region of all members of the H1 family are presumably involved in critical structural/functional roles. Although autoantibodies to H1 have been reported frequently (see the later section on H1), the domain structure and the complexity of the H1 family complicate interpretation of these data.

Assays for Antihistone Antibodies

To appreciate data on the clinical and pathologic significance of histone autoantibodies, an understanding of the methods that are used to demonstrate them is important. In most clinical laboratories, an indirect immunofluorescence (IIF) assay is used as a screening test to identify ANA (65). In SLE most histone autoantibodies can be detected by this test and are commonly correlated with a homogeneous or diffuse IIF staining pattern (Fig. 24-4). However, this technique commonly produces misleading information regarding antihistone antibodies. The homogeneous or diffuse pattern also is seen with other autoantibodies, notably those directed against dsDNA (66). Additionally, sera that have antibodies to certain histone classes (e.g., H1, H3, H4) or hidden determinants (cryptotopes) on native or on denatured histones may show only weak or negative ANAs (67 ,68 ,69 ,70). Therefore, the identification of histone antibodies must rely on more specific assays.

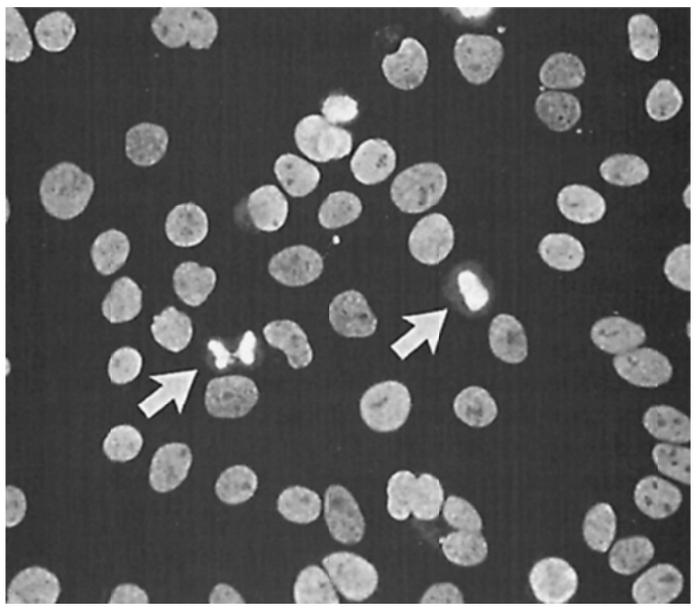

Figure 24-4. Indirect immunofluorescence of autoantibodies from a patient with SLE produces a homogeneous pattern of nuclear staining on human epithelial (HEp-2) cells. Note that staining is particularly intense over chromosomes of dividing cells (arrows) and that the cytoplasm displays no detectable staining.

Historical Perspective

The first assay for antihistone antibodies was an adaptation of the microcomplement fixation method using lysis of sensitized red blood cells as the indicator (9 ,71). Antihistone antibodies were reported to be infrequent in SLE using this assay (72) and reactive predominantly with histone H1, although a few sera displayed binding to all histones (71). It was also inferred from these and other studies (10 ,11 ,12 ,73) that a complex of histones with DNA was required to generate antigenicity. The stringent requirements of this assay (74), the procomplementary nature of histones (75) and its apparent insensitivity (76) have led to abandoning the complement-fixation assay for detecting antihistone antibodies and a general disinterest in antihistone antibodies.

Renewed interest in antihistone antibodies followed the modification of the IIF assay by Tan et al. (77) to render

it specific for histone-binding antibodies. Histones were extracted from mouse kidney tubule nuclei by 0.1 N HCl, preventing the binding of antihistone antibodies. The histone content of such nuclei can be partially "reconstituted" by incubation with a pure histone solution. Sera with antihistone activity display binding to histone-reconstituted nuclei and to untreated mouse kidney but not to acid-extracted sections. This assay was used to demonstrate that high titers of histone antibodies are found in patients with SLE (78 ,79) and procainamide-induced lupus (79). While this assay is highly specific for antihistone antibodies, it cannot be used with sera that contain anti-DNA antibodies, which display background binding to acid-extracted nuclei. It later became clear that the assay had limitations in that sera with antihistone activity predominantly to H3 and H4 displayed negligible reaction in the immunofluorescence assay (70 ,80), presumably because of the failure of these histones to bind to DNA with this technique. Thus, the immunofluorescence assay is largely selective for antibodies reactive with H1, H2A, H2B, and may preferentially detect epitopes requiring a histone-DNA complex.

Current Assays for Antihistone Antibodies

Solid-phase assays have largely replaced older assays for antihistone antibodies. Histones, histone complexes, and chromatin readily adsorb to polystyrene, and antibody binding can be quantified with a class-specific enzyme-, fluorescent-, or radio-labeled anti-immunoglobulin. The first solid phase assays detected antibodies to histones raised in rabbits (81 ,82), in human SLE (80 ,83 ,84) and in murine lupus (85). Most studies on antihistone antibody in the past two decades have relied on purified histones in solid phase enzyme-linked immunosorbent assays (ELISA). Subnucleosome structures have also been adapted to ELISA formats (86), which allow measurement of autoantibodies requiring these higher-ordered structures. Antihistone antibodies can also be measured by immunoblots (Western blots) of histones separated by SDS polyacrylamide gel electrophoresis. However, this technique may not detect autoantibodies reacting with native epitopes on histones and cannot detect antibodies to epitopes generated by histone-histone or histone-DNA complexes. More recently addressable laser bead immuno-assays have been used to detect chromatin antibodies.

Problems and Discrepancies in Measuring Antihistone Antibodies

Discrepancies in the literature on the prevalence and fine specificity of antihistone antibodies are common (see next section). The quality of histones used as antigens is highly variable, and commercial sources were often degraded or contaminated with nonhistone proteins. Inhibition of endogenous proteolysis during histone isolation is necessary to obtain intact histones, as shown in Figure 24-2 . It is difficult to remove all traces of DNA, a serious problem when assessing sera that may also contain anti-DNA antibodies. Additionally, the propensity for histones to bind DNA in biological fluids can result in artifacts such as false-positive reactions with anti-DNA antibodies (see below). Commercial sources of chromatin (nucleosome-related antigens) are not currently available, so assays for antibodies to the higher ordered structures in nucleohistone which are common in SLE are more difficult to develop in the laboratory. Other technical concerns common to many immunoassays such as differences in procedures to determine the cutoff between normal and pathologic sera, diagnostic criteria, ethnic or regional variation in patients, prescribed therapeutic agents (especially the use of corticosteroids which may suppress immune responses), and secondary antibodies as detecting reagents contribute to interobserver variation. A collection of normal human sera generally establishes the cut-off value used to assign an experimental sample to a positive category, but borderline values are always difficult to interpret in quantitative immunoassays, and these low level reactivities may sometimes be a result of increased nonspecific binding as a result of elevated gamma globulins commonly observed in sera from patients with rheumatic diseases. Finally, most studies use histones or chromatin prepared from calf thymus or chicken erythrocytes; ideally, human histones should be used for studies of true histone autoantibodies although, as discussed above, there is near identity between human core histones and their counterpart from calf thymus. As with many other areas in clinical laboratory medicine, attempts to standardize these variables through inter-institutional collaboration are a mandate of the Serology Subcommittee of the International Union of Immunological Societies.

Artifactual Antihistone Antibodies

Special problems arise when measuring antihistone antibodies in complex biologic fluids. Three features of this antigen-antibody system contribute to ambiguous results: (1) histones have a net positive charge and readily bind soluble polyanions such as DNA in physiologic medium or sulfated macromolecules on membranes, (2) DNA and/or histones are not uncommon contaminants of antibody-containing fluids or of other components of the assay, and (3) anti-DNA and antihistone activities commonly co-exist in SLE sera. Soluble DNA in human serum can be responsible for false-positive antihistone antibody signals by forming a macromolecular bridge between anti-DNA antibodies and histone bound to the solid phase. These interactions result in anti-DNA antibody binding to histones, indistinguishable from bona fide antihistone antibody activity (see Antilymphocyte Antibodies). This phenomenon can be clearly seen when harvesting tissue culture supernatants from a hybridoma secreting anti-DNA antibodies (87). DNase treatment of the antibody preparation removes the antihistone activity, consistent with the involvement of DNA in generation of artifactual antihistone activity.

Similar artifacts can occur in serum. Subiza et al. (88) demonstrated that DNase pretreatment of SLE sera resulted

in a significant decrease in antihistone antibody activity in 7/11 sera. Affected sera invariably had anti-DNA antibodies (whose activity increased after DNase digestion) and the histone binding activity could be regenerated by addition of DNA. These results would suggest that a significant portion of the antihistone activity in SLE may actually be a result of DNA-anti-DNA immune complexes. However, Suzuki et al. (89) observed a DNase effect on the antihistone activity in only 27% of SLE sera; this decrease was relatively small and uniform across all histone classes. Therefore, it appears that measurement of antihistone activity in carefully prepared samples of SLE sera gives largely valid results even in the presence of anti-DNA antibodies.

Nucleohistone in bovine milk (a common blocking medium) or serum can bind to histone bands transferred to nitrocellulose, introducing artifacts (90). Histones were isolated from bovine serum and milk by affinity chromatography on DNA-cellulose (91), and this material mediated the binding of antihistone antibodies to solid phase DNA (87). This type of artifact was recently confirmed with nucleosome-reactive autoantibodies obtained from a peptide phage display library due to DNA and histones in the milk blocking agent (92). Indirect evidence strongly suggests that DNA exists in serum in the form of mono- and oligonucleosomes (93 ,94), which can be immunoprecipitated with antihistone antibodies (94). Therefore, blocking media from these natural biological fluids should be avoided when measuring antihistone antibodies. This type of phenomenon may also have pathologic significance as suggested by the report of Schmiedke et al. (95) that circulating nucleohistone binding to the negatively charged residues on heparin sulfate in the glomerular basement membrane (GBM) may mediate the binding of DNA and anti-DNA antibodies to the glomerulus.

Recently, Teodorescu and associates have explored the basis for binding of immunoglobulin from SLE and rheumatoid arthritis (RA) sera to solid phase histone in ELISA formats. Surprisingly, much of the histone binding of IgG from SLE sera was eliminated by digestion with pepsin (96), which removes the Fc region of IgG, inconsistent with the manner by which bona fide antibodies bind to antigen. Immune complexes, common in SLE and the Felty syndrome variant of RA, also displayed a propensity for binding solid phase histone (97 ,98), and immune complexes are also affected by pepsin digestion. While the histone binding of immunoglobulins from RA sera correlated with immune complex and rheumatoid factor activity (98), the bulk of the histone-binding activity in SLE sera resided in the monomeric IgG fraction (99). This suggested that IgG with anomalous features was responsible for much of the antihistone activity in SLE sera. While these observations raise serious concerns about the nature and significance of antihistone antibodies, autoantibodies reacting with chromatin/nucleosomes bound strictly through the classical antigen combining site (99). Further studies will be required to gauge how widespread this anomalous antibody reactivity is and to evaluate its impact on the measurements and characteristics of antihistone antibody activity, including the reports described below.

Terminology

There is considerable confusion in the literature regarding terminology for histone-reactive antibodies. The term “antihistone antibody” should be reserved for assays that employ purified, monomeric histones such as Western blot and some solid phase assays; it can be assumed that the bulk of the “auto-epitopes” in purified histones are expressed in denatured regions of histones because DNA-free histone does not exist in vivo. As discussed below, antibodies to denatured purified histones detected by most assays are common and have little diagnostic value. Other assays which use histone-DNA complexes, including LE cells, fixed cells, deoxyribonucleoprotein, chromatin, soluble (H1-stripped) chromatin, (poly)nucleosomes, and (H2A-H2B)-DNA complexes would more likely be measuring auto-epitopes in native regions. It is possible that there is overlap of epitope content between denatured histones and native (DNA-bound) histones especially in some assays (77). However, for the most part antibodies to histones and antibodies to nucleosome-related antigens should be considered distinct. In the context of autoimmunity the terms chromatin, nucleosome, and polynucleosome can be used interchangeably (100).

Prevalence and Disease Association of Antihistone and Anti-Nucleosome Antibodies

Overall Disease Association

Table 24-2 lists reports of antihistone antibodies in various diseases. Although antihistone antibodies have been observed in a variety of (generally rheumatologic) diseases, most studies have focused on SLE or DIL. Reported prevalences ranged from 17% to 95% in SLE (average = 51%) and 67% to 100% in DIL (average = 92%). Antihistone antibodies have also been consistently observed in RA (average prevalence = 11%) and juvenile chronic arthritis (JCA) (average prevalence = 51%). RA patients with ANA were 2 to 7 times more likely to have antihistone antibodies than ANA-negative RA patients (137 ,138 ,169). Other than SLE in which other ANA commonly co-exist, the bulk of the ANA in sera with antihistone activity is probably due to these antibodies, although this relationship has been formally demonstrated only in DIL and DIA (170). There have been several recent reports on histone-reactive antibodies in a substantial proportion of patients with scleroderma-related disorders especially localized scleroderma with generalized morphea (124 ,153 ,154).

Limited studies on antihistone antibodies in various other syndromes have appeared. In some cases a remarkably high occurrence of antihistone antibodies was observed, especially in primary biliary cirrhosis (159 ,160), autoimmune hepatitis (162), ANA-positive neoplastic diseases (136) and Felty syndrome. Patients with undifferentiated connective tissue disease displayed predominately IgM anti-H3 producing a variable large speckled ANA pattern (69 ,171). There have been isolated case reports of unusual

antihistone antibodies such as anti-H1° in patients with sensory neuropathy (172 ,173) and antibody to chymotrypsin digested H2B in a patient with vasculitis (68). While antihistone antibodies have been observed in rheumatic diseases such as Sjögren syndrome, mixed connective tissue disease, and vasculitis, these tend to be of low titer and represented by few reports. Antihistone antibodies in polymyositis/dermatomyositis have been reported in 17% of 46 patients (158), predominantly reacting with H1. Anti-H2B antibodies were reported in over half of HIV+ patients with persistent lymphadenopathy (167) or patients with squamous cell carcinoma (166), but these results have not been reported elsewhere. In a study of 249 patients with monoclonal gammopathies, Shoenfeld et al. (165) found that 34 (14%) were positive for histone antibodies, and 11/12 purified monoclonal antibodies demonstrated antihistone activity.

Table 24-2: Reported Prevalence of Antihistone/Anti-Nucleosome Antibody in Human Disease

Disease/Syndrome	Prevalence*	References
Rheumatic diseases		
SLE	24%-95%	(13,13,84,89,89,89,89,101,101,102,103,104,104,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,118,119,120,121,122,123,123,124,125,126,127,128)
DIL	50%-100%	(70,79,106,118,129,130,131,132,133,134,135,134)
DIA	22%-95%	(106,130,131,132,134,135,136)

*Prevalence of elevated IgG and/or IgM antibody to total histone or to at least one histone class.

In addition to the occurrence of antibodies reactive with isolated histones, patients with lupus-like disorders commonly have autoantibodies to chromatin (nucleosomes) (Table 24-3). The first report found that approximately three fourths of untreated SLE patients from Singapore had anti-nucleosomal antibodies (13); somewhat lower prevalence and titer were observed in (American) SLE patients under medication treatment (13). Anti-nucleosome (and anti-nDNA) appear to be particularly sensitive to corticosteroid therapy (186). The bulk of this reactivity was a result of binding to the (H2A-H2B)-DNA complex in the higher-ordered structure of chromatin. Other studies from various locations throughout the world reported 38% to 86% sensitivity of antinucleosome antibodies in SLE (Table 24-3). Most patients with lupus induced by procainamide, penicillamine, isoniazid, acebutolol, methyldopa, timolol, and sulfasalazine also have anti-nucleosome antibodies, predominately reactive with the (H2A-H2B)-DNA complex, although a substantial number of patients have only been examined with lupus induced by procainamide. Approximately half the patients with drug-induced lupus related to quinidine and hydralazine had anti-([H2A-H2B]-DNA). Several groups reported anti-nucleosome antibodies in almost half the patients with autoimmune hepatitis (187 ,188). Antinucleosome antibodies have also been reported in 25% (124) to almost 50% (122 ,189) of patients with PSS (scleroderma), but the specificity of these antibodies may be different from bona fide antichromatin

antibodies as discussed below. Antinucleosome antibodies have generally not been seen to any significant extent in other rheumatic disease patients and are remarkably low in the normal population, resulting in an overall sensitivity for SLE of 63% and specificity for SLE compared to other rheumatic diseases of 95% (100).

Table 24-3: Prevalence of IgG Anti-nucleosome antibodies in Idiopathic and Drug-Induced Lupus

Disease	Antinucleosome Antibody Prevalence	Reference
SLE, oriental, untreated	78%	(13)
SLE, American, treated	59%	(13)
SLE, Spanish	69%	(151)
SLE, Mexican	100%	(128)

Hydralazine-induced lupus	43%	(132)

N.D., not determined

Systemic Lupus Erythematosus

Studies on the association of antihistone antibodies with disease activity or severity, with the predominant organ system affected or with specific clinical features have been inconsistent. Some reports showed no association between presence or amount of antihistone antibodies and any measure of disease activity (78 ,103 ,106 ,139 ,140 ,186) with the exception of a history of photosensitivity in one report (140) and joint disease in another (78). On the other hand, in one of the earliest reports on histone-reactive antibodies, Rothfield and Stollar (11) observed that 14 out of 15 patients with active lupus contained antibodies to histone-DNA complexes, whereas only 4 of 26 patients in remission had these antibodies. Subsequently, associations of antihistone antibodies with active disease were observed with solid-phase (110) and histone-reconstituted immunofluorescence assays (136). Population correlations of the presence of antihistone antibodies with neuropsychiatric involvement (190), skin and joint symptoms (84 ,109) or overall disease severity have been reported (104). However, no quantitative association has been observed between the level of antihistone antibodies and any specific array of clinical symptoms or the overall disease activity. Perhaps variants of SLE characterized by increased disease severity commonly display antihistone antibody because of the general linkage between symptoms and signs in SLE. This view is supported by the association of anti-histone or nucleohistone antibodies with antibodies to native DNA (103 ,112 ,114 ,191), a well established correlate of disease activity. Part of the confusion about this issue is that some studies excluded patients with anti-DNA antibodies and others used assays that favored detection of antibodies to (denatured) histones which display low disease specificity and other assays primarily detected nucleosome-specific autoantibodies.

In recent years studies that deliberately used nucleosomal antigens have shown strong symptom correlation in SLE and a clinical specificity as high as 95% to 99% (126 ,127 ,128). Antichromatin and anti-([H2A-H2B]-DNA) antibodies was significantly correlated with glomerulonephritis (13 ,174 ,192) and were more specific for this feature than anti-DNA. Antinucleosome antibody of the IgG3 subclass were present at high levels in patients with active SLE, associated with flares and significantly correlated with lupus nephritis (122) or Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) score (191). Other groups also observed a higher prevalence and/or amount of antichromatin antibodies in SLE patients with kidney disease (125 ,151 ,175) or overall disease activity score (128 ,151 ,176 ,177 ,178 ,179), although association with disease activity was not seen in all studies (126). Clearly, however, screening antigens using native nucleosomal materials are a substantially better tool for monitoring

SLE than assays using DNA-free histones, and most studies concluded that it is a better marker for SLE than anti-DNA.

Drug-Induced Lupus and Drug-Induced Autoimmunity

Histone-reactive antibodies have been reported in 50% to 100% of patients with DIL (Tables 24-2 and 24-3), depending on the drug and the assay employed. The drugs most commonly implicated in DIL include procainamide, hydralazine, quinidine, and isoniazid, although a variety of other drugs have been implicated as well (see Chapter 42). However, most patients who are treated with procainamide and other lupus-inducing drugs eventually develop antihistone antibodies even though symptomatic disease occurs in only 10 to 20 percent of patients (131 ,134 ,193). Thus, most antihistone antibodies are apparently benign, consistent with the occurrence of histone-reactive antibodies in many rheumatic and non–rheumatic diseases (Table 24-2). However, examination of their class and fine specificity has revealed that antihistone antibodies in asymptomatic patients are predominantly IgM and display broad reactivity with all the individual histones (130 ,194), or are inhibited in binding histones by DNA (132 ,135). In contrast, patients with symptomatic DIL induced by procainamide and many other drugs including penicillamine, isoniazid, acebutolol, methyldopa, timolol, sulfasalazine, and quinidine develop predominantly IgG anti-histone antibodies that display pronounced reactivity with a H2A-H2B complex (131), especially when bound to DNA (132) (Table 24-3). In fact, anti-(H2A-H2B) has been observed to precede overt clinical symptoms and therefore may have predictive as well as diagnostic value (133 ,195). Anti-(H2A-H2B) has a sensitivity of close to 100% and specificity of >90% for symptomatic procainamide-induced lupus compared to asymptomatic procainamide-treated patients (131) and an even higher specificity when an (H2A-H2B)-DNA complex is used as the screening antigen (132). As mentioned above, antibodies to the ([H2A-H2B]-DNA) complex are remarkable because they are also an important feature of the immune response in SLE as well as several murine models of SLE (196 ,197 ,198 ,199 ,200) but not in canine lupus (201).

Rheumatoid Arthritis

The frequency of histone antibodies in rheumatoid arthritis (RA) has been reported to be as high as 80% (Table 24-2). Aitcheson et al. (169) found that 14% of unselected patients with RA and 24% of patients with RA and a positive ANA had histone antibodies as demonstrated by the histone extraction-reconstitution assay. Other studies have reported similar frequencies in unselected patients with RA and higher frequencies in patients with RA and a positive ANA (138 ,202). Unlike patients with SLE and DIL, the titer of histone antibodies tends to be low in RA, and RA patients with antihistone antibodies did not display more active disease than antihistone antibody negative RA patients (138). Antinucleosome antibodies are generally not detected in RA (127).

Felty Syndrome

In Felty syndrome antihistone levels were considerably higher than in non-Felty's RA, especially of the IgG isotype (137). Campion et al. (143) reported histone antibodies in the sera of 20 of 32 patients (68%) with Felty syndrome compared to 12% prevalence in RA and the 54% in SLE. The antibodies in this syndrome appear to be directed against conformational histone determinants, because reactivity was lost when the histones were denatured in detergent. The high frequency of histone antibodies in Felty syndrome is of interest because these patients commonly have high levels of rheumatoid factor, an autoantibody believed to cross-react with histones (169 ,203), especially H3 (169 ,202)

Juvenile Chronic (Rheumatoid) Arthritis

Antihistone antibodies have been extensively studied in juvenile chronic arthritis, and most studies agree that histone antibodies are found in at least 40% of JCA sera (Table 24-2). In early studies when the acid extraction-reconstitution technique was used JCA sera were found to bind histones infrequently (144). Using immunoblot techniques the predominant reactivity of JCA sera was with a 33-kd doublet thought to be H1 (150). Antihistone antibodies in JCA are predominantly IgM, are commonly directed against H1 and H3, and tend to react with DNA-free histones.

The studies of histone antibodies in JCA were of interest because of their potential to aid in the subclassification of this disease. Antihistone antibodies were reported in 93% (145) and 67% (67) of JCA patients with uveitis compared to 33% of patients without uveitis (145). However, associations with uveitis were not observed in other studies (141 ,150 ,204), although patients with uveitis (active or inactive) tended to have higher levels or antihistone antibody compared to those JCA patients with no history of uveitis (149). When other clinical subsets were compared, antihistone antibodies tended to be more common in pauci- or polyarticular types of JCA compared to systemic onset JCA (67 ,150 ,205). These antibodies react preferentially with DNA-free histones (146 ,204), similar to those in asymptomatic drug-induced autoimmunity, and may not substantially contribute to the ANA commonly occurring in these children. Although the association of anti-histone antibodies with HLA-A2 (205) created optimism that histone antibodies might identify a subset of patients with JCA, the evidence of earlier studies as well as a thorough subsequent study (147) do not favor an association of histone antibodies with patterns of disease onset or the course of disease.

Vasculitides

Antibodies to histones have been reported in 75% of patients with RA and vasculitis (140), and antibodies to H2B have been reported in a man with vasculitis (68). These reports are of interest because both vasculitis (206) and SLE (207) have been associated with the presence of myeloperoxidase antibodies (perinuclear antineutrophil cytoplasmic antibody [pANCA]). Because both histones

and myeloperoxidase are highly basic proteins, the possibility of crossreactivity between them may occur. In fact antibodies to neutrophil myeloperoxidase are found in patients with hydralazine-induced lupus (207 ,208), and these patients also commonly have antihistone antibodies (Table 24-2). However, procainamide-induced lupus is not associated with anti-myeloperoxidase antibodies. More recently, it was reported that antihistone antibodies in pANCA positive ulcerative colitis patients react with two nonoverlapping segments in the COOH-terminal of histone H1 associated with a recurring PKKAK amino acid sequence motif (164). However, this specificity was not significantly correlated with pANCA titer or disease status, indicating that this epitope is not a predominant specificity of serum pANCA.

Scleroderma Spectrum of Diseases

Antibodies to histones have been reported in 1/3 to 2/3 of patients from the scleroderma spectrum of diseases (Table 24-2). It was claimed that this reactivity is relatively restricted to (H2A-H2B)-DNA complex (164 ,189). This is surprising because sera from these patients generally do not have the typical homogenous ANA pattern of antinucleosome antibody (Fig. 24-4). It has been suggested that these antibodies are of low titer and/or are primarily reactive with denatured regions on histones or contaminating autoantigens (100), and several groups have failed to detect antibodies to native epitopes on nucleosomes in scleroderma-related disorders (123 ,209) or they have been of low titer in a minority of patients (126). On the other hand, patients with localized scleroderma appear to have a particularly high frequency of antihistone reactivity (152 ,154), especially against H1 and H3 (154 ,156). Reports suggesting that patients with scleroderma that have concomitant histone antibodies have a higher frequency of pulmonary fibrosis (152), a more severe form of the disease and a poor clinical outcome (157), have not been substantiated in another study (154). As in studies of SLE and JCA, part of the reason for these differences is related to patient selection and technical aspects of the antihistone assays. In particular it was recently shown that contamination with the autoantigen Scl-70 in chromatin preparations could account for essentially all the binding of scleroderma sera to nucleosomes (123).

Summary

Because of the numerous reports of antihistone antibodies in many diseases, antihistone antibodies cannot be considered a specific marker for any disease. Additionally, the presence of histone antibodies does not necessarily correlate with disease activity. It is unclear how much assay differences and the artifactual reactivities discussed previously contribute to the discrepancies within the literature and the poor disease specificity. However, autoantibody reactivity to higher ordered structures involving histones such as chromatin or nucleosomes has been consistently reported to be a highly sensitive and remarkably specific marker for lupus-like diseases. The common occurrence of antinucleosome antibodies in drug-induced and idiopathic lupus suggests that loss of immune tolerance to chromatin and its conformationally native constituents such as the (H2A-H2B)-DNA complex and, less commonly, native DNA is a sensitive and perhaps early indication of the immune dysregulation that characterizes these conditions.

Characteristics of Histone-Reactive Antibodies

Isotype

Antihistone antibodies can be found in all the major immunoglobulin classes in patients with SLE, but, as discussed in detail (43), there is little agreement as to the predominant isotype. There appears to be a significant correlation between the amount or at least presence of IgG (but not IgM) antihistone antibody and overall clinical disease activity (101 ,104), although there was no correlation between isotype and predominant organ system involvement (104). The isotype profile tended to remain constant over time (210) and for IgG antibodies consisted mainly of IgG1 and IgG3 with notably negligible amounts of IgG2 antihistone antibody (210 ,211). IgG1 and IgG3 are strong complement fixing subclasses, implicating these antihistone antibodies in pathogenic processes. A broader distribution of the IgG subclasses was observed in drug-induced autoimmunity in which antihistone activity commonly occurred in all four IgG subclasses (211). These patients as well as patients with frank drug-induced lupus are more likely than SLE patients to have IgG, IgA and IgM antihistone and anti-([H2A-H2B]-DNA) antibodies. These autoantibody isotypes often appear to arise simultaneously during procainamide treatment, although patients who remain asymptomatic fail to develop IgG anti-([H2A-H2B]-DNA) (133). Interestingly, as treatment with the lupus-inducing drug continued, a gradual shift to predominantly IgG1 antihistone antibodies occurred (211), similar to the isotype profile in idiopathic SLE. The substantial IgA autoantibody levels in procainamide- (133) and isoniazid- (135) treated patients is remarkable, suggesting induction of autoantibody synthesis within the gastrointestinal mucosal immune system where drug concentration is presumably highest. The rather slow development of autoantibodies, the apparent concordance of IgG, IgA and IgM isotypes and the perpetuation of IgM autoantibodies for many years in asymptomatic, procainamide-treated patients suggest that the mechanism underlying drug induction of autoantibodies is unlike a classical immune phenomenon.

Fine Specificities of Autoantibodies to Individual Histones

Histone heterogeneity and chromatin structure (see the previous sections) raise the possibility that useful information may be derived from examining antibody activity to individual

histone classes and variants, domain regions within individual histones (Table 24-1) or to subnucleosome particles. Most studies have focused on the five major histone classes, although antibody activity to histone variants such as H1° (172), H5 (67) and ubiquitinated-H2A (212) have been reported. The methods employed have been either analytical separation of total histones by gel electrophoresis followed by Western blot or ELISA using biochemically purified histones or histone complexes.

In general SLE patients with antihistone antibodies tended to have antibody to all histones, with pronounced reactivity to H1 and/or H2B (107 ,108 ,109 ,114 ,118 ,120 ,140 ,194). However, there has been only modest agreement within these studies in that anti-H1 (107 ,194) or anti-H2B (139) was sometimes observed to be a minor antibody, or other histones, especially H3 (101 ,107 ,140), were major antigenic targets for antihistone antibodies in SLE sera. Biases in assays, differences in patient population and small sample size contribute to these discrepancies. Furthermore, patient-to-patient variability is obscured by this type of analysis.

Table 24-4 summarizes the reported average profiles in individual patients of antibody activities to a panel of histones. The aforementioned predominance of anti-H1 and anti-H2B in SLE can be observed in the patient profiles of only half the reports; the other studies showed no particular profile because of substantial patient-to-patient variability. Many of these studies used non-class specific immunoglobulin detecting reagents, adding additional ambiguity because the specificity of antihistone antibodies may depend upon the immunoglobulin class being examined. Considerable disagreement on the characteristic antihistone antibody profile in DIL is also apparent (43). With procainamide-induced lupus, a discrete profile of reactivity was only discernible when the dimer of histones H2A and H2B was included as a test antigen, although reactivity with the H2A-H2B complex may also be because of antibody binding to the individual, constituent histones (134 ,193).

Table 24-4: Antibodies to Histone Classes in Individual Patients

Disease	Method	Ig Class	Histone Class Reactivity	Reference
SLE	ELISA	G,M	Variable	(83,89,116,213)
	ELISA	G	H2B ≥ H2A > H3 = H4	(108)
	WB	Undefined	H1 = H2B > H4 > H3 > H2A	(120,121)
	FIA	Undefined	Variable; H1 = H2B = H3 > H2A = H4	(140)
	WB	G,M	Variable	(89,214)
	ELISA & WB	G	H1 = H2B > H2A > H3 > H4	(109)
DIL-PA	RIA/ELISA	G	H2A-H2B complex >>H2A = H2B	(70,130,131)
	WB	Undefined	H2B > H3 = H1 > H4 = H2A	(215)
	WB & ELISA	Undefined	H2A-H2B complex > H2A = H2B > H4	(214)
DIL-HY	FIA	Undefined	Variable	(194)
	WB	Undefined	H3 > H2B = H2A = H1 > H4	(215)
	WB & ELISA	Undefined	H3 > H4 >> H2B > H2A	(214)
DIA-PA	ELISA	M	Relatively uniform	(130,213)

ELISA, enzyme-linked immunosorbent assay; FIA, solid phase fluorescence immunoassay; G, IgG antibodies; M, IgM antibodies; RIA, solid phase radioimmunoassay; WB, Western (immuno-)blot; DIL-HY, hydralazine-induced lupus; DIL-PA, procainamide-induced lupus; DIA-PA, procainamide-induced ANA in asymptomatic patients.

H2A and H2B

There is good agreement that antibody to H2A and/or H2B in most SLE sera does not bind in Western blot to the large trypsin-resistant domain of these histones (Table 24-1). Thus, only 15% (214), 8% (118) and 0% (216) of SLE sera with anti-H2B retained activity on the C-terminal H2B polypeptide (21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125), i.e., when the N-terminal 20 amino acids were removed. Direct evidence that the N-terminal region of H2B contained a predominant epitope was obtained by Hardin and Thomas (120) who showed that 63% of sera with anti-H2B reacted with the N-terminal cyanogen bromide polypeptide (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59), while there was no reactivity with the C-terminal (63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125) polypeptide. Similarly, removal of the N-terminal 11 and C-terminal 11 amino acids from H2A dramatically reduced its antigenicity, so only 20% (118) 15% (214) and 11% (216) of anti-H2A in SLE retained activity on H2A polypeptide (12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118). These studies would suggest that the major epitope on H2B contains peptide (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20) and on H2A peptide (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11) and/or (119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129). In fact in ELISA H2B (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25) was antigenic for 38% of SLE sera (113). Gohill et al. (118) reported that the H2A 38-mer (91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129) retained good antigenicity for SLE sera having anti-H2A activity, but Muller et al. (113) found that the smaller C-terminal H2A peptide (116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129) and N-terminal H2A peptide (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15) displayed only weak antibody binding for 13% and 29%, respectively, of SLE sera. There are considerable discrepancies in DIL as to the predominant epitopes within the trypsin-resistant domains, as discussed (43). However, the trypsin-resistant domains of H2A and H2B are clearly important because these regions contain the amino acid residues responsible for H2A complex

formation with H2B (62 ,217) creating the highly antigenic H2A-H2B dimer (70 ,130 ,131 ,214).

H3 and H4

The effect of trypsin digestion on the antigenicity of both H3 and H4 is similar. In Western blot, the H3-derived P1 domain (“A” band) (118 ,215 ,216) and the H4-derived P4/P5 domain (“C” band) (118 ,215 ,216) (Table 24-1) retained antigenicity for fewer than 10% of SLE and procainamide-induced lupus sera having anti-H3 and/or H4 activity (118 ,214 ,215 ,216). This would suggest that the major epitope for SLE anti-H3 and anti-H4 antibodies resides in the N-terminal 26 amino acid and/or C-terminal six amino acids of H3 and the N-terminal 17 amino acids of H4, assuming no tertiary interaction between these and other regions of the molecules, as would be expected (62 ,217). In fact in ELISA, H3 peptide (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21) and (130 ,131 ,132 ,133 ,134 ,135) bound 76% and 39% of SLE sera, respectively, and 54% of SLE sera bound H4 (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29) (113). However, H3 peptide (40 ,41 ,42 ,43 ,44 ,45) was also antigenic (113), and absorption experiments to show that these activities were related to antibody to the parent molecule were not reported.

In contrast to SLE and procainamide-induced lupus, 80% (215) or 100% (214) of hydralazine-induced lupus sera reacted with the trypsin-resistant domains of H3 and H4 to an extent similar to that of the parent histones. The dichotomy between the reactivity of antibodies in hydralazine-induced lupus with those in procainamide-induced lupus and SLE is also manifested on subnucleosome particles (see Prevalence and Disease Association) and would suggest a difference in the immunogenic stimulus driving the autoimmune responses in these disease groups.

H1

Chymotrypsin cleaves accessible peptide bonds on the C-terminal side of aromatic amino acids, and brief digestion splits H1 approximately in the middle of the central, globular domain at phenylalanine 106. In Western blot the C-terminal polypeptide (107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129 ,130 ,131 ,132 ,133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,150 ,151 ,152 ,153 ,154 ,155 ,156 ,157 ,158 ,159 ,160 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 ,201 ,202 ,203 ,204 ,205 ,206 ,207 ,208 ,209 ,210 ,211 ,212 ,213 ,214 ,215 ,216 ,217 ,218 ,219 ,220) retained full antigenicity for 100% (109 ,115 ,218) or 86% (120) of SLE and 100% of procainamide-induced lupus sera (218) having anti-H1 antibodies (both IgM (218) and IgG (115 ,215 ,218)). In contrast, the N-terminal half (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106) displayed lower antigenicity in most (but not all (109)) studies in showing reaction with only 28% (115), 16% (218) and 14% (120) of SLE sera with anti-H1 activity. When Gohill et al. (218) tested the antigenicity of the globular domain (36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121) (generated by trypsin digestion of H1) using ELISA, no SLE or procainamide-induced lupus serum reacted. These results suggested that the bulk of H1 antigenicity lies in the C-terminal hydrophilic domain. In a study using synthetic 15-mer peptides, Stemmer et al. (219) observed definite skewing of reactivity of SLE sera with C-terminal peptides of human H1b, although N-terminal and globular domain peptides were occasionally antigenic as well. Nevertheless, these data suggest that the apparent lower antigenicity of the N-terminal domain reported using bovine (109 ,115 ,218) or chicken (120) H1 fragments applies to human H1 as well, presumably the bona fide immunogen driving the autoimmune response. The highly conserved octapeptide in the C-terminal region (see preceding section) might be a candidate epitopic region which would cross species barriers and is included in the second most antigenic peptide in H1b (219). It is unlikely, however, that there is an immunodominant epitope in H1, consistent with the heterogeneity of anti-H1 antibodies in murine lupus (220). Additionally, SLE sera appear to have substantial antibody heterogeneity within the H1 variants; of 9 SLE sera examined, H1.5 was recognized by all 9 patients, but from none to all of the five other H1 variants showed antigenicity by Western blot (221).

Antibodies to H1 from JCA sera have also received considerable attention. Of particular interest was the report by Pauls et al. (67) that a small proportion (5 of 51) of JCA patients had antibody activity to chicken histone H5 without concomitant reactivity with the major H1 class. A similar preferential reactivity with H5 compared to H1 with SLE sera was observed by Stemmer et al. (219). Since H5 is not present in human tissues, it was suggested that the anti-H5 immune response was driven by an unknown nonhistone cross-reacting antigen. However, as previously discussed, H5 has extensive homology with H1°, the variant found in terminally differentiated cells. In fact, Monestier et al. (149) showed that JCA sera with anti-H5 had even higher reactivity with human brain H1° Antibody binding to H1° from human brain without binding to the major H1 fraction was also detected in a patient with sensory neuropathy (172). There are seven sequences in human H1° not present in H1 which are nearly identical to sequences in chicken H5, and these are distributed mainly in the globular and N-terminal region (38), possibly accounting for cross-reaction between H1° and H5. In fact epitope mapping demonstrated that peptides within the globular domain of H5 had the highest antigenicity in SLE and procainamide-induced lupus (222). Antibodies in JCA displayed poor binding to the central globular domain of H1 whether or not the amino terminal segment (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32) was also present, while highest reactivity was observed on the C-terminal segment containing the globular domain (33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129 ,130 ,131 ,132 ,133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,150 ,151 ,152 ,153 ,154 ,155 ,156 ,157 ,158 ,159 ,160 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 ,201 ,202 ,203 ,204 ,205 ,206 ,207 ,208 ,209 ,210 ,211 ,212 ,213 ,214 ,215 ,216 ,217 ,218 ,219 ,220) (149). This reactivity appears to be similar to that of SLE sera, but coblocking studies between IgM antibodies in JCA and IgG antibodies in SLE have not been performed. The C-terminal region of H1 also contained the epitopes for antihistone antibodies in patients with ulcerative colitis (164).

Significance of Antihistone Antibody Fine Specificity

The specificity of histone-reactive antibodies in SLE and in lupus induced by most drugs is consistent with some form of chromatin being the predominant in vivo immunogen driving these B cell responses. Antibodies in SLE and DIL

which react with intact histones but not with histones from trypsinized chromatin can be most readily explained as having been elicited by chromatin rather than by free histones because the trypsin-resistant domain structure of histones is preserved in the form of chromatin and nucleosomes but not in individual histones. However, subnucleosome particles and histones in the form of the DNA-free H2A-H2B dimer and the H3-H4 tetramer are also resistant to trypsin digestion. Furthermore, the argument that chromatin drives the autoantibody response is weakened by the observations that antibodies reacting with the trypsin-resistant, and largely inaccessible cores of H2A and/or H2B also occur in some SLE sera and were the predominant activity in procainamide-induced lupus (132 ,214). This discrepancy is especially pronounced with antibodies in hydralazine-induced lupus, which retain reactivity with histones after trypsinization of chromatin (214 ,215). IgM antibodies from patients taking hydralazine or chlorpromazine (132) as well as IgG antihistone antibodies from patients with JCA (146) bound strongest to DNA-free histones, less to subnucleosome structures, and very little or not at all with chromatin. Thus, immune tolerance to more native forms of nucleohistone is largely preserved in JCA and with antibodies induced by chlorpromazine, isoniazid and IgM antihistone antibodies in hydralazine-induced lupus. This is the same pattern of antibody binding found when normal mice were immunized with histones (223) and is more consistent with some unknown form of DNA-free histone driving the immune response to histones in these patients.

A more convincing argument that chromatin drives the bulk of the histone-reactive antibody response in SLE and most DIL can be made from the data that compares the antigenicity of various forms of histones. As previously discussed, antibodies from patients with SLE and lupus induced by 10 drugs (Table 24-3) as well as antibodies from murine lupus bound prominently to a structural epitope in the (H2A-H2B)-DNA complex. Some patients with SLE also bound native DNA and the $(H3\text{-}H4)_2$-DNA subnucleosome, but reactivity with individual histones was much lower (13 ,174 ,186). In murine lupus, antibodies to (H2A-H2B)-DNA were found early in disease, before antibodies to native DNA and $(H3\text{-}H4)_2$-DNA arose (196). Absorption with chromatin removed most of the antibody reactivity to subnucleosome structures, indicating that regions buried in chromatin were not antigenic in SLE, DIL or murine lupus. Thus, histone-reactive antibodies in SLE can be most readily explained by auto-immunization with chromatin accompanied by sequential loss of tolerance first to the (H2A-H2B)-DNA region and then to $(H3\text{-}H4)_2$-DNA and native DNA. Loss of immune tolerance to epitopes on DNA-free histones, which can be considered “denatured histones,” and to “denatured DNA” (and to other nuclear antigens) may accompany the immune disregulation associated with lupus-related disorders, but, because of the complexity of these epitopes and the heterogeneity of this immune response, only with nucleosome-reactive antibodies can a strong case be made for the putative in vivo existence of a chromatin-like immunogen.

Histone Antibody Genes

Studies on the sequences of autoantibody variable (V) region genes provide insight into the origin of autoantibodies. One study showed that the nucleotide sequences of anti-histone monoclonal antibodies from MRL-*lpr/lpr* mice were not clonally related and that diverse V, D, and J genes were represented (224). However, other studies demonstrated that monoclonal antibodies to (H2A-H2B)-DNA obtained from $MRL^{+}/+$ mice were clonally related and possessed numerous charged residues in the heavy chain as a result of somatic mutations and various V_HDJ_H rearrangement processes (200 ,225), indicating antigen selection rather than polyclonal activation. However, the replacement/silent mutation ratios even in the complementarity-determining regions (CDR) were much lower than the ratio expected for random mutations (200), suggesting that once B cells with sufficient avidity for chromatin arise, something else, presumably T cell help, causes their expansion. This view is supported by the detailed sequence comparisons of anti-(H2A-H2B) antibodies derived from an (SWR × NZB)F1 (198) and an (NZB × NZW)F1 (199) mouse; these antibodies showed very few somatic mutations, suggesting that chromatin-reactive T cells selected a single precursor of these B cells for expansion at an early stage in their development and limited further V-region mutations to an extent corresponding to only one week of antigen-driven auto-immunization.

The physicochemical properties of some histone antibodies have at least a superficial resemblance to anti-DNA antibodies in immunochemistry, suggesting an analogous, antigen-mediated selection process. For example the antihistone antibody MRA12 has five negatively charged amino acid residues in its CDR2 and an isoelectric of 6.0–6.3 (224). This anionic region presumably is responsible for binding to H1, reminiscent of the observations that cationic anti-DNA antibodies react with the anionic phosphate groups on DNA (226 ,227). Similar physicochemical features in human monoclonal antihistone antibodies were noted (228). A simplistic view of the role of these negatively charged residues is that they are responsible for binding to the basic region of histones. However, because the monoclonal MRA12 bound specifically to H1 and not other histones, factors other than charge-charge interactions likely are important for antibody specificity and binding.

T Cell Epitopes and Histone-Reactive T Cells

Production of IgG antibodies including autoantibodies usually requires that B cells are stimulated not only by antigen but also by proximal T cells that produce the requisite co-stimulation and cytokines. Lymphocytes from 54% of SLE patients showed a proliferative response to nucleosomes in vitro (125). Chromatin-specific T cells were isolated from mouse (229) and human (230) SLE, and histone-reactive T cell lines were obtained from SLE and normal individuals

(231 ,232). T cell clones derived from lupus-prone (SWR × NZB)F1 (SNF1) mice displayed proliferative and cytokine responses to nucleosomes but not their component macromolecules. Of the clones that could be mapped, five reacted with peptides corresponding to H4 (13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39) and/or H4 (73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90) and one with H2B (10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33) (233), and their specificity seemed to be conferred primarily by the α-chain of the T cell receptor (234). Interestingly, these T cell epitopes were similar to those commonly recognized by T cells from SLE patients; human lupus T cells also recognized H3 (91–105 or 100–114), H2A (34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48), and H4 (49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63) (235). However, when peptides were extracted from the class II MHC of lymph node cells from lupus-prone MRL-*lpr/lpr* mice, the only detected histone-derived peptide was H2A (84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103) bound to I-E^k (236) which induced a significant T cell response in young MRL-*lpr/lpr* mice (237). However, this response was weak, and H2A (84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103) was not related to the dominant T cell epitopes reported in SNF1 mice (233) or human SLE (235). The basis for this discrepancy is not clear.

Nucleosome-reactive clones provided helper activity to primary B cells for secretion of IgG “anti-histone/DNA” in vitro (233). A controlling role for such chromatin-specific T cells in the humoral response of BXSB mice was the demonstration that injection of chromatin in vivo directly into thymic lobes delayed the appearance of anti-chromatin and anti-DNA antibodies, presumably due to the enhanced deletion or other form of central T cell tolerance of spontaneously arising autoreactive T cells (238). Histone-reactive T cell lines have been developed from normal individuals after stimulation with nucleosome-polyomavirus T antigen complexes (232 ,239), demonstrating that quiescent histone-reactive T cells may be part of the normal T cell repertoire.

The notion that the antichromatin response is limited by the availability of T helper cells is supported by immunization studies. Normal mouse strains generally fail to produce autoantibodies reactive with native self-antigens using various immunization protocols (240). Thus, host B cells from (C57BL/6 × DBA/2)F1 mice produced anti-[(H2A-H2B)-DNA] antibodies after in vivo transfer of DBA/2 T cells because of the graft-versus-host (GVH) reaction (241), but only antibodies to nonnative regions in chromatin can be detected after immunization of this strain with various chromatin-related antigens (223). These results are consistent with the findings that immunoglobulin receptors for (H2A-H2B)-DNA are derived by limited somatic mutations of the normal B cell repertoire (198 ,200 ,225), but these cells or their precursors remain quiescent until appropriate T cell help becomes available. Apparently, DBA/2 T cells provide this help in the GVH model, but direct immunization does not break T cell tolerance to chromatin. However, when a reactive metabolite of the lupus-inducing drug procainamide was injected into the thymus of (C57BL/6 × DBA/2)F1 mice, anti-([H2A-H2B]-DNA) antibodies arose (242), consistent with the view that chromatin-reactive T cells, created by disruption of central T cell tolerance, have sufficient helper capacity to drive precursors of ([H2A-H2B]-DNA)-specific B cells to somatically mutate, expand, and secrete autoantibodies. Recently Kang, et al (243) showed that injection of remarkably low amounts of a dominant T cell epitope, H4 (71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94), reduced development of autoantibodies and prolonged the life of SNF1 mice, apparently because of production of regulatory T cells. Taken together a strong case can be made for the view that histone-reactive T cells are a necessary and probably sufficient force in the development of lupus-like autoimmunity.

Cross-Reactions of Antihistone and Antinucleosome Antibodies

Rheumatoid Factors

Polyclonal IgG RF with ANA activity were first clearly demonstrated by Hannestad and Johanessen (244), and an IgM RF with capacity to bind nucleosomes containing the core histones was isolated from another RA patient (245). Several subsequent studies verified and extended these findings (169 ,246 ,247 ,248 ,249 ,250), suggesting that RF with histone binding activity was quite common. Trivial explanations such as contaminating immune complexes were ruled out by the discovery of monoclonal RF produced in tissue culture with similar properties (251). Although the structural basis for these cross-reactions is unclear, it is possible that the combining site of an antibody is considerably larger than that needed to accommodate a single epitope, permitting distinct regions within the Fab part of an antibody molecule to react with unrelated epitopes. It may also be relevant the IgM RF+ B cells can be co-activated (with anti-IgM) by nucleosome/anti-nucleosome complexes, apparently involving TLR9 (252), although it is not clear if these B cells produced cross-reacting RF.

Antilymphocyte Antibodies and Nucleosome/Membrane Interactions

Of 27 LE-factor-positive sera, 26 contained ANA that bound to and could be eluted from viable leukocytes (253). These “X-ANA” reacted with nucleosomes (254), and absorption experiments indicated that ANA, LE factor and antilymphocyte activities were properties of the same antibody population (15). In addition to human leukocytes, LE factor also bound to mouse and rabbit splenocytes, rat hepatocytes and human endothelial cells but not human or chicken erythrocytes (255 ,256). X-ANA behaved as a subset of the cold reactive antilymphocyte antibody repertoire (255). The related capacity of anti-DNA antibodies to bind a “lupus-associated membrane protein” (LAMP) has been shown to be mediated by DNA or nucleohistone debris contaminating the anti-DNA preparations (257 ,258), although apparently DNA-independent anti-DNA antibody binding to cell membranes has been described (259). The capacity of mononuclear cells or granulocytes to bind X-ANA was not mediated by the Fc region of IgG or by the Fc or C3 receptors on leukocytes, and, in contrast to anti-LAMP

antibodies, nuclei derived from dead cells appeared not to be responsible for the capacity of leukocytes to immuno-adsorb X-ANA (254 ,260 ,261). The cell membrane antigen is similar to an epitope in the core histone octamer (in the presence or absence of DNA) but not in nucleosomes depleted of H2A and H2B (253), and solid-phase H2B or H2B peptide (6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18) reacted with antibody affinity purified on leukocytes (262). A peptide derived from H2B also appears to be present on murine B cells (263). However, studies with a panel of histones as well as antihistone and anti-DNA antibodies failed to detect other chromatin-related antigens on cell membranes (264).

Activation of monocytes by endotoxin in the medium can apparently induce expression of a receptor (265) which binds chromatin debris released into the medium (266). Additionally, nucleosomes were observed to interact with bone marrow derived dendritic cells (DC) independent of endotoxin contamination, resulting in DC maturation and inflammatory cytokine secretion (267). Various receptors are candidates for these effects including a 94 kDa protein in a cell membrane extract which bound DNA and nucleohistone (257), a 30 kDa protein which is a component of a DNA receptor on mononuclear cells (268 ,269), or a 50 kDa protein that acts as a nucleosome receptor on a fibroblast cell line (270). However, there is no evidence that SLE patients, in which anti-H2B and/or anti-DNA antibodies are commonly observed, display membrane-associated antibody on circulating mononuclear cells in vivo. It is possible that receptor association is transient, and nucleosomal material is engulfed by macro- or micro-pinocytosis (267 ,270). Regardless of its pathogenic implications, it is possible that membrane-associated chromatin could be involved in driving the autoimmune response. This view is supported by findings in NZB/NZW mice that endogenous retroviruses carry chromatin-like material apparently derived from host cell membranes during virion budding, and these viruses can induce antichromatin antibodies by immunization with adjuvant (271).

Murine Strains with Antihistone and Antinucleosome Antibodies

Strains of mice in which serum antihistone antibodies spontaneously appear during their natural life history include (NZB × NZW)F1 (85 ,220 ,272 ,272 ,273 ,274 ,275), MRL-*lpr/lpr* (105 ,196 ,220 ,273 ,274 ,275 ,276 ,277), MRL$^{+/+}$ (225 ,274 ,275 ,276), BXSB (196), (SWR × NZB)F1 (198 ,229) Palmerston North (105), Swan (105), NZB (220 ,276 ,277), ddY (278), Yaa (275), NZM2410 congenic lines (279) and (C57Bl/6 × DBA/2)F1 mice undergoing chronic GVH disease after injection of DBA/2 T cells (223 ,241 ,273 ,280 ,281 ,282 ,283). As with most human SLE and some DIL, predominant reactivity with linear epitopes in the trypsin sensitive region of the core histones was also observed with spontaneously arising antibodies in murine lupus (272 ,281).

Murine lupus has provided the opportunity to examine the kinetics, pathogenic potential, and origin of nucleosome-reactive antibodies in considerable detail. In a genetic dissection of murine lupus it was shown that a region on chromosome 1 (Sle1) consisting of several loci is responsible for the development of anti-([H2A-H2B]-DNA) antibodies in NZM2410 mice (284). The presence of anti-chromatin was also strongly linked to early death in the progeny of (NZB × NZW)F2 intercross mice (285). When the kinetics of autoantibody appearance in the lupus prone MRL-*lpr/lpr* and BXSB mice were examined over short time intervals, the earliest autoantibodies detected reacted with native chromatin rather than its constituents such as histones and DNA (196 ,197). Similar early appearance of antinucleosome antibodies were seen in MRL$^{+/+}$ mice along with anti-U1A-RNP antibodies; anti-DNA antibodies appeared much later (275). Anti-([H2A-H2B]-DNA) accounted for the bulk of the early anti-chromatin activity in MRL-*lpr/lpr* and BXSB mice (196). This serology was similar to that observed in 14 out of 40 newly diagnosed SLE patients, and the mouse and human sera efficiently coblocked, indicating a similar target epitope (13). Another 14 SLE sera had elevated reactivity to multiple antigens in chromatin including (H2A-H2B)-DNA, native DNA, H3-H4 tetramer, and various individual histones (13). This serology, in turn, was very much like that in older lupus mice which had rapidly developed antibodies to multiple epitopes on chromatin (196). These data suggests that, as in DIL, the autoimmune response in human and murine SLE is initially directed to the (H2A-H2B)-DNA component of chromatin, but unlike DIL, spreads to other regions in chromatin (and to other nuclear antigens).

Pathogenic Potential of Antihistone Antibodies

The pathogenic mechanisms in SLE and DIL have not been clearly elucidated, but there is a general consensus that complexes between autoantibodies and their cognate antigens play at least a contributing role. A pathogenic role for chromatin-reactive antibodies in lupus nephritis, but not antibodies to histones (286), is suggested by studies in experimental animal models of nephritis and in vitro assays of glomerular-binding immunoglobulin. Antinucleosome-nucleosome immune complexes bound to glomeruli in vivo and to the glomerular basement membrane (GBM) in vitro (287). However, in SLE such preformed immune complexes appear to be of minor importance (288). Although serum from 81% of SLE patients with nephritis showed elevated IgG binding to a preparation of basement membranes isolated from human glomeruli in an ELISA format (288), GBM binding activity was substantially decreased by DNase treatment of the GBM (but not the sera), and nucleosome preparations were especially potent in restoring antibody binding to GBM. These and other data (95 ,287 ,289 ,290 ,291 ,292 ,293) demonstrated that chromatin or nucleosome core particles bind through ionic interactions to type IV collagen and/or heparin sulfate in the GBM and to skin basement membranes (294), providing an in situ surface for binding chromatin-reactive antibodies. Approximately 20% of SLE

patients were reported to have increased levels of circulating nucleosomal material, although plasma chromatin did not correlate with disease activity or SLEDAI score (191).

Other studies, however, suggest that binding of anti-nucleosome (including anti-DNA) antibodies to chromatin deposits in the kidney does not by itself initiate glomerulonephritis. Sera from a substantial proportion of SLE patients without nephritis also showed capacity to bind glomerular structures (295) or GBM (288) in vitro. Furthermore, sera from patients with DIL displayed a range of in vitro GBM binding capacity similar to that of SLE sera (288). Since SLE but not DIL patients develop glomerulonephritis, antichromatin antibodies alone are unlikely to be sufficient to cause this pathology. A compromised capacity to clear immune complexes either from the circulation or following their deposition in the kidney has been described as a feature of SLE patients (296) and murine lupus (297), but it is difficult to distinguish cause from effect in this phenomenon.

SLE patients with active nephritis typically have substantial GBM-associated immunoglobulin, more severe clinical disease and poorer prognosis than SLE patients with low GBM-binding antibody (295). These patients usually have hypocomplementemia, suggesting that activation of the classical complement pathway by autoantibodies deposited in the kidney contribute to disease. While antihistone antibodies from SLE sera did not fix complement in the histone-reconstituted IIF assay (78), SLE sera showed strong capacity to deposit complement proteins C3, (298 ,299) C4 and properdin on nuclei of HEp-2 cells (298). SLE sera with antiribonucleoprotein autoantibodies had particularly good capacity to fix complement (78 ,298 ,299). These data along with the finding that IgG1 and IgG3 are the predominant isotypes of autoantibodies antibodies in SLE (122 ,211) suggest that the frequent heterogeneity of autoantibodies in SLE sera make for a particularly strong cocktail of complement-fixing ANA. In contrast sera from patients with DIL, which contain predominately antichromatin antibodies, did not show strong capacity to fix complement in IIF assays (299 ,300). However, depressed complement levels have been detected in patients with lupus induced by procainamide (301) and hydralazine (302), and a prospective study of a patient with procainamide-induced lupus demonstrated elevated C4d/C4 ratios during symptomatic disease (195), indicating activation of the classical pathway in vivo. It is likely, therefore, that while nucleosome-reactive antibodies are not well tolerated and contribute to in vivo complement activation and its accompanying inflammatory sequelae in SLE and DIL, the more global immune disregulation and complicated abnormal serology in SLE is necessary for tissue destruction involving autoantibodies.

Chapter 25
Antibodies to Ro/SSA and La/SSB

Morris Reichlin

John B. Harley

Anti-Ro and anti-La are important autoantibodies in systemic lupus erythematosus (SLE). Respectively, they are found in just less than one half and nearly one fifth of these patients in concentrations sufficient for precipitin formation. These autoantibodies also are closely allied with particular clinical findings. They are such an intrinsic component of disease expression that one is led to the conclusion that an understanding of the immune response to these (or to any one of the other major autoantigens) would reveal the mechanism of the autoimmune dysregulation of lupus, if not the etiology of the disease as well.

History and Development

A precipitin, likely to have been anti-Ro or anti-La, was first described over 40 years ago in a patient with Sjögren syndrome (1). This observation was expanded on by Anderson et al. (2), who defined both antigens, which they called SjT and SjD. In addition, they observed a "lupus" precipitin that in retrospect is likely to have been an antinuclear ribonucleoprotein (nRNP) or anti-Sm specificity. Unfortunately, these observations lay fallow until the anti-Ro and anti-La specificities were independently described by Reichlin et al. (3 ,4). Anti-Ro and anti-La autoantibodies, as well as the autoantigens they bind, have been under continuous investigation since then. They also have been described as Sjögren syndrome A (SS-A) and Sjögren syndrome B (SS-B) antigens (5 ,6). Figure 25-1 present an Ouchterlony immunodiffusion showing an example of the anti-Ro and anti-La responses. Beyond this discovery, the most fundamental contribution has been the marriage of autoimmune serology with molecular biologic approaches for the analysis of these antigens (7).

Clinical Relationships

The clinical relevance of anti-Ro has been particularly well established. The data are less compelling for anti-La, although clearly this autoantibody also is important. Table 25-1 presents the associations of clinical findings with anti-Ro and anti-La, which do not in themselves constitute direct evidence of an immunopathogenic role of the autoantibody for any aspect of the disease. Nevertheless, and at the very least, these associations are important as aids in diagnosis and prognosis.

Photosensitive skin rash in lupus as an association with anti-Ro was first appreciated by Maddison et al. (8) and has been confirmed by Mond et al. (9). Lee and David (10) as well as Lee and Weston (11) also have established that anti-Ro is specifically deposited in human skin, and therefore is likely to be directly involved in the cutaneous injury of these patients.

Chest radiographs showing the changes of interstitial pneumonitis have been repeatedly found to be associated with anti-Ro (12 ,13). There is no evidence directly implicating anti-Ro in the pulmonary disease of lupus, however.

Idiopathic thrombocytopenic purpura (ITP) is well known to present before lupus can be diagnosed in some patients. These patients tend to have anti-Ro precipitins (14 ,15 ,16). Both anti-Ro and a positive antinuclear antibody test may be found at presentation with immune thrombocytopenia and precede fulfilling the classification criteria for lupus by at least as much as 14 years (14). How long before presentation with immune thrombocytopenic purpura these patients develop anti-Ro is not known.

Indeed, the temporal relationship of the appearance of anti-Ro or anti-La to the clinical presentation with lupus or Sjögren syndrome is not known. Anti-Ro or anti-La appears after diagnosis only in the rare patient. In addition, most mothers with anti-Ro and anti-La who have infants with congenital heart block or neonatal lupus dermatitis have never had clinical manifestations of any of the disorders associated with these autoantibodies (17 ,18). Many mothers, however, develop Sjögren syndrome or lupus in the years following birth of the affected infant (19 ,20). This leads one to suspect that anti-Ro and anti-La autoantibodies may arise years before the clinical illness appears, which has been convincingly established (21).

In addition to thrombocytopenia, other hematologic cytopenias have been associated with anti-Ro. Patients with lupus who in any way satisfy the hematologic criterion for classification of SLE (22), but particularly those with lymphopenia, tend to have anti-Ro (23). In Sjögren syndrome, thrombocytopenia, anemia, and lymphopenia are associated with anti-Ro (24). In rheumatoid arthritis, although anti-Ro is uncommon (i.e., approximately 5% of patients) (25), this autoantibody is associated with leukopenia when it is present (26). One study shows that anti-Ro binds directly to the granulocyte surface and is closely associated with granulocytopenia (27).

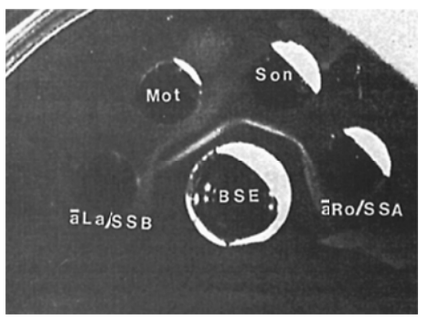

Figure 25-1. Anti-Ro and anti-La precipitins. The mother (Mot) has both anti-Ro and anti-La autoantibodies, while the affected son (Son) has only a faint anti-Ro precipitin. Precipitins from reference anti-La (aLa/SSB) and anti-Ro (aRo/SSA) sera also are presented against a bovine spleen extract (BSE). The anti-La precipitin is light and diffused in this example. This pedigree is described in Reichlin M, Friday K, Harley JB. Complete congenital heart block followed by anti-Ro/SSA in adult life: studies of an informative family. *Am J Med* 1988;84:339–344.

Table 25-1: Associations with Anti-Ro and Anti-La Autoantibodies in Systemic Lupus Erythematosus and Related Disorders*

Specificity	Clinical or Genetic Association
Anti-Ro	Photosensitive skin rash (lupus) Interstitial pneumonitis (lupus) Thrombocytopenia (lupus, Sjögren syndrome) Lymphopenia (lupus, Sjögren syndrome) Nephritis (lupus) C2 complement deficiency (lupus) HLA-DQ1/2 T cell receptor ß gene (lupus) Vasculitis (Sjögren syndrome) Thrombocytopenic purpura (Sjögren syndrome, subacute cutaneous lupus) Primary biliary cirrhosis
Anti-Ro and anti-La	Absence of nephritis (lupus) HLA-B8, DR3 (lupus) HLA-DQ1/2 (Sjögren syndrome) Rheumatoid factor (lupus, Sjögren syndrome) Sjögren syndrome Subacute cutaneous lupus erythematosus Neonatal lupus dermatitis Complete congenital heart block

*Associations are presented for systemic lupus erythematosus (lupus) unless the data are derived from patients with another diagnosis, such as Sjogren syndrome. While rheumatoid factor, Sjögren syndrome, subacute cutaneous lupus erythematosus, neonatal lupus dermatitis, and complete congenital heart block are frequently associated with both anti-Ro and anti-La precipitins, they also all occur in association with anti-Ro without anti-La. HLA, human leukocyte antigen.

There are data supporting a role for anti-Ro in nephritis as well. In a series of patients with anti-Ro precipitin, only those who had anti-Ro without an anti-La precipitin developed renal disease (28). Subsequent work has confirmed that patients with anti-La tend to be spared renal disease (23). Acid-eluted immunoglobulin from the renal tissue of two patients with anti-Ro precipitin contained anti-Ro that had been concentrated in the antibody deposited in the kidney (29). More recent data have shown that anti-Ro, anti-La, and anti-DNA all are concentrated in renal tissue (30). This is prima facie evidence to support a direct role for anti-Ro and other autoantibodies in the nephritis of some patients. Anti-Ro deposited in the tissue either as an immune complex or by virtue of binding to a specific antigen has the potential to be phlogistic and to mediate the inflammatory response that follows antibody binding.

Complete Congenital Heart Block

Over the past two decades, a compelling association has been demonstrated between complete congenital heart block and both anti-Ro and anti-La precipitating autoantibodies (17 ,31 ,32). The anti-Ro immunoglobulin G (IgG) clearly originates with the mother, who may be asymptomatic for an autoimmune rheumatic disorder. In a few cases, normal fetal cardiac conduction has been demonstrated before the third trimester (33 ,34). Heart block often appears late in the second trimester or early in the third trimester, coincident with the active transport of maternal IgG across the placenta.

Complete congenital heart block is found in approximately one of every 20,000 births (35). In the largest series of congenital heart block cases, anti-Ro and/or anti-La was found in 83% (17). Survey studies estimate that an anti-Ro precipitin may be present in as many as 1% of pregnant women (36 ,37). An expectant mother with an anti-Ro precipitin has an increased risk of bearing a child with complete congenital heart block, but even so, this risk remains small.

The mechanism of heart block is unclear. Cardiac conduction tissue is bound by anti-Ro more avidly than other cardiac cell types (38). Data from a set of fraternal twins who were discordant for heart block have shown depletion of anti-Ro in the serum of the affected twin, which is consistent with the possibility that anti-Ro is being specifically deposited in cardiac tissue (39). This observation strongly suggests that critical contributions are made toward the generation of heart block by the fetus in a way that varies among potentially affected pregnancies. Specific concentration of anti-Ro (both anti–60-kd Ro and anti–52-kd Ro) in cardiac tissue, but not in other tissues, has been demonstrated (40).

One theory of pathogenesis holds that the basic process is a nonspecific endomyocarditis that involves the atrioventricular node by extension at a time when the node is anatomically vulnerable (39). If true, then many fetuses of mothers with anti-Ro autoantibodies may have the endomyocarditis, while only a fraction of these involve the atrioventricular node and develop heart block. The association of anti-Ro and

anti-La antibody with endocardial fibroelastosis has been recently reported in 13 instances (41).

Much progress has been made in understanding the pathogenesis of complete heart block related to anti-Ro/SSA antibodies. Boutjdir et al. (40) showed that anti–52-kd Ro/SSA antibodies induce complete atrioventricular (AV) block in the human fetal heart perfused by the Langendorff technique and inhibit L-type $Ca2^{+}$ currents at the whole-cell and single-channel level. In addition, these workers immunized female BALB/c mice with recombinant 52-kd Ro/SSA protein and these antibodies crossed the placenta during pregnancy and were associated with varying degrees of AV conduction abnormalities, including complete AV block, in the pups (42). Similar results were reported by Viana et al. (43), in which affinity purified anti-52-kd Ro/SSA antibodies could induce complete AV block in isolated whole rabbit hearts. Finally, Miranda-Carus et al. (44) showed in mice that complete AV block was only seen in offspring from mothers immunized with 52-kd Ro/SSA, but not La/SSB or 60-kd Ro/SSA, although lesser AV conduction abnormalities were noted with the latter two antigens.

There are at least three ways that complete congenital heart block is relevant to lupus. First, pregnant female patients with lupus and anti-Ro, by virtue of having this autoantibody, have a one in 20 risk of having a child with complete congenital heart block (45). Second, the mothers of children with heart block are at an increased risk of developing a systemic autoimmune rheumatic disorder, even if the mother is asymptomatic when the child is born (19). Indeed, we have seen a patient whose lupus developed 26 years after the delivery of an infant with congenital heart block and that coincided with her retiring from Ohio to bask in the sunshine of Florida (46). Third, a study of adult patients with lupus has revealed an increased prevalence of conduction abnormalities among patients with anti-Ro precipitins (47).

Neonatal Lupus Dermatitis

Infants of mothers with anti-Ro also may develop neonatal dermatitis. This rash most often appears after birth. Areas that are exposed to sunlight predominate but are not exclusively involved. Skin lesions often are similar to those found in subacute cutaneous lupus with arcuate erythematous macules or papulosquamous lesions. Occasionally, they may leave hypopigmented skin, but the lesions generally resolve without sequelae. In infants, all lesions that appear usually develop and resolve together. As the maternal IgG is cleared from the infant's circulation, the rash also resolves. Additionally, in those infants who are not affected at or very soon after birth, the likelihood of developing the rash diminishes as maternal IgG is metabolized. Maternal IgG is almost undetectable in the infant by 6 months of age, and the onset of neonatal lupus dermatitis is unheard of at this stage. A few cases of neonatal dermatitis have been reportedly associated with an anti-nRNP precipitin in the absence of an anti-Ro precipitin (48).

Figure 25-2. The rash of subacute cutaneous lupus erythematosus, showing erythematous macules and papulosquamous lesions. The typical arcuate lesions can be appreciated on the back of this middle-aged woman at presentation.

Subacute Cutaneous Lupus Erythematosus

The diagnosis of subacute cutaneous lupus erythematosus is established by the presence of one of the two typical and usually photosensitive rashes, annular or papulosquamous (Fig. 25-2), along with consistent histology. Approximately 75% of patients with subacute cutaneous lupus have anti-Ro precipitins (49). It has now been reported that anti-Ro precipitin negative patients with SCLE have elevated anti-Ro antibodies detectable with a sensitive and specific enzyme-linked immunoabsorbent assay (ELISA) (50). These patients may or may not satisfy the classification criteria for systemic lupus (22). The lesions are erythematous and may or may not be raised. In some patients, the lesions have central clearing. Lesions at all the different stages of maturity may be present simultaneously. Some of these patients develop petechiae or purpura, particularly of the lower extremities, biopsy specimens of which often reveal small vessel vasculitis. Those with vasculitis seem to be a subgroup with greater hypergammaglobulinemia who are more likely than the remaining patients to have Sjögren syndrome.

Sjögren Syndrome

Of the disorders that are associated with anti-Ro and anti-La, perhaps none is more intriguing than Sjögren syndrome. Depending on the assay performed and the population selected, from 40% to over 95% of these patients have anti-Ro, and from 15% to over 85% have anti-La (51). Dry eyes and dry mouth associated with a lymphocytic infiltrate of the salivary or lacrimal glands are not uncommon in a number of autoimmune rheumatic disorders, including SLE, rheumatoid arthritis, progressive systemic sclerosis, primary biliary cirrhosis, and autoimmune myositis. Hence, Sjögren syndrome is a feature shared by a minor proportion of the patients with each of these diseases, which suggests that they also must have fundamental aspects in common.

Primary Sjögren syndrome is considered to be present when the diagnostic criteria for Sjögren syndrome are satisfied (52) in the absence of another rheumatic disease with autoimmune features. Because the etiology and pathogenesis of all these diseases are unknown, and because there is great latitude in applying the diagnostic standards, the relative composition of patient groups is likely to vary greatly between investigators. This situation does not seem to have been improved by the current criteria for classification of rheumatoid arthritis (53), which are more broadly inclusive than the previous criteria (54).

There are a number of patients whose predominant disease process over time is Sjögren syndrome but who then develop features that are consistent with SLE (55 ,56 ,57). As a group, they are highly enriched for human leukocyte antigen (HLA)-DR3 and commonly have both anti-Ro and anti-La. The distinction between primary and secondary Sjögren syndrome is lost in this situation. Indeed, these patients are commonly referred to as having lupus-Sjögren overlap disease. The important point is that these and other patients with lupus or Sjögren syndrome form a continuous spectrum of disease expression, from classic primary Sjögren syndrome through the overlap with shared features to a more typical lupus process. The failure of existing nosology to distinctly separate patients demonstrates the inadequacy of present diagnostic practices, and it provides some of the impetus to understand etiology and pathogenesis.

Complement Deficiency Status

SLE also is associated with hereditary deficiencies of the early components of the classic complement cascade (58 ,59). Patients with complement component C2 deficiency tend to have an anti-Ro precipitin but not an anti-La precipitin. Anti-Ro may be more common in homozygous patients with C2 deficiency than in the remainder of patients with lupus (60). Patients with lupus and C2 complement component deficiency also tend to have a mild form of lupus with cutaneous manifestations, but with neither anti-double-stranded DNA (anti-dsDNA) autoantibody nor nephritis. Patients with lupus and the other early complement component deficiencies also have anti-Ro without an anti-La precipitin, but this has not been evaluated in a sample large enough to be conclusive (59).

Tissue Concentration of Anti-Ro and Anti-La

Anti-Ro and anti-La clearly are related to autoimmune rheumatic disease expression. In only a few situations has strong evidence been obtained for their phlogistic potential. In individual tissues, anti-Ro has been shown to be concentrated in the kidney, heart, and parotid gland (29 ,30 ,40 ,61). Affinity-enriched anti-Ro has been shown to deposit specifically in human skin transplanted onto nude and severe combined immunodeficiency disease (SCID) mice (10 ,11) as presented above.

Immunogenetics of Anti-Ro and Anti-La

Immunogenetic associations with individual autoantibodies have led to model building in an effort to understand the possible molecular events in the context of what has been learned about the immune response. The first relationship to be appreciated has been the association of anti-Ro with HLA-DR3 (62 ,63). Subsequently, it has been appreciated that anti-Ro also is related to HLA-DR2 in both lupus and Sjögren syndrome (64 ,65).

These multiple associations have been reconciled in two ways. First, a gene interaction effect has been defined between HLA-DQw1 and HLA-DQw2 such that patients with lupus or Sjögren syndrome who have both of these alleles tend to have anti-Ro. This has been extended in lupus to show that particular subsets of the DQA1 and DQB2 genes mediate this effect, which therefore is consistent with a gene complementation mechanism (66). One of the attractive possibilities that could explain these results is a DQ molecule composed of the predicted DQA1 and DQB2 genes and encoded by different chromosomes. There is no direct evidence for or against such a molecule in lupus or Sjögren patients. Others have performed experiments in cell lines and have obtained data suggesting that the predicted molecule is not favored (67).

Reveille et al. (68) have taken a more inclusive approach by attempting to define the primary sequence of HLA-DQ that is common to all patients with anti-Ro relative to that of a control population. They also have mapped the most powerful associations to the DQ locus. Nearly all patients with an anti-Ro response had a glutamine at amino acid position 34 of at least one of their DQ α-chains and a leucine at amino acid position 26 of at least one of their DQ ß-chains.

The HLA associations with the anti-La response are a little different. In primary Sjögren's syndrome, anti-La is related to HLA-B8, DR3, and DR2 (51 ,69 ,70), much as for anti-Ro. Indeed, the association of anti-La with the HLA-DQ1/w2 heterozygous state was as powerful as it was for anti-Ro (71). In lupus, however, the strongest association is with the B8, DR3 haplotype (23). The basis for this discrepancy is not known.

Models of Pathogenesis

Humoral autoimmunity is revealed by the presence of autoantibodies. It is much more difficult to be confident that human diseases with lymphocytic infiltrates but without autoantibodies also are autoimmune, but work in animal models has provided convincing and overwhelming evidence that this mechanism of disease pathogenesis is a practical possibility. Here, the prevailing suspicion is that T lymphocytes are mediating autoimmunity without stimulating B lymphocytes to differentiate and produce autoantibodies.

T lymphocytes appear to determine not only whether a cellular, as opposed to an antibody, response results from immunogen exposure, but also in many circumstances whether tolerance is maintained or broken. For these and other reasons, most investigators suspect that T lymphocytes have an obligate role in the immunoregulatory decision to synthesize autoantibody against protein autoantigens. Defining this role in human lupus has been difficult, as it has been in other inflammatory, and possibly autoimmune, disorders of unknown etiology. For example, in lupus, there is no evidence to suspect the linkage of lupus with α, ß, or γ T-lymphocyte receptor genes in multiplex families (72).

On the other hand, just as the histocompatibility associations are different for risk of disease than they are for production of individual autoantibodies, there may be analogous differences at the level of the T cell receptor. Recent work has shown that alleles of the T cell receptor ß-chain gene are related to the presence of anti-Ro in lupus (73). Interestingly, the association is most significant for those patients who have an anti-Ro precipitin without an anti-La precipitin, and it does not exist for those who have both anti-Ro and anti-La precipitins. Preliminary analysis is consistent with synergy between the T cell receptor association and the HLA-DQ alleles that are associated with anti-Ro (74). Other work with the 70-kd U1 ribonucleoprotein has shown that lymphocytes proliferate after exposure to this peptide when it is presented as a fusion protein, and that a region from the carboxyl terminus is more stimulatory than other regions of the molecule (75).

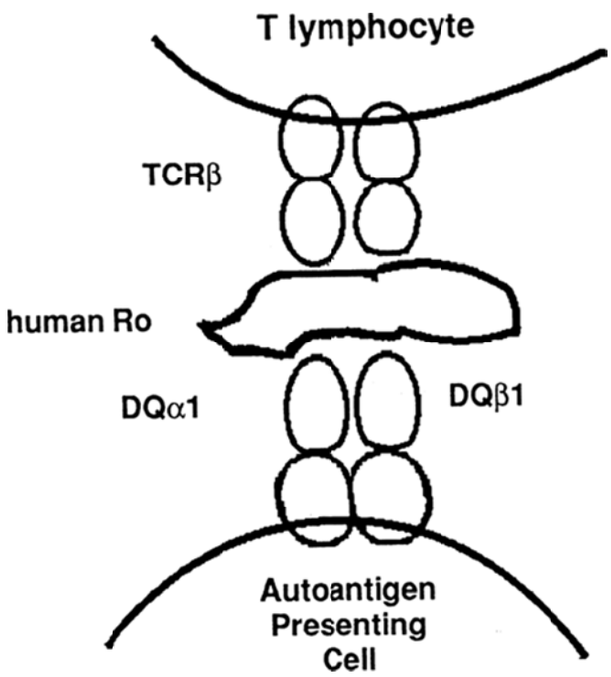

Figure 25-3. The trimolecular complex model for autoantigen presentation of the human Ro autoantigen based on associations of anti-Ro with alleles at human leukocyte antigen (HLA)-DQ and the ß peptide of the T-lymphocyte receptor.

These data are consistent with a model of the generation of lupus autoantibodies in general, and of anti-Ro in particular, that requires the participation of HLA-DQ and T cell receptor alleles along with the autoantigen to form a trimolecular complex (Fig. 25-3). Human Ro is suspected to be directly involved, because Ro from other species is less antigenic with human autoantibodies (76). From these data the conclusion that the anti-Ro autoimmune response is Ro autoantigen—driven in lupus is compelling. Similar conclusions have been reached using other experimental strategies for the anti-Sm and anti-DNA responses in lupus (77 ,78). Accordingly, autoantigen—driven autoimmune responses appear to be the general rule in lupus.

Some of the genetic risk factors for the generation of individual autoantibodies have been defined. Associations with clinical manifestations also are known. The question that remains to be determined, however, is how the clinical features, immunogenetics, and autoantibodies are interrelated in lupus, although one would suspect that relationships should flow from the genetic features to the autoantibodies and from autoantibodies to the disease manifestations. This concept of the disease predicts, for example, that HLA alleles generally are related to clinical manifestations through the autoantibodies, and that the relationships of autoantibodies with HLA alleles and of autoantibodies with clinical manifestations will be stronger than those of HLA alleles with clinical manifestations.

This hypothesis was confirmed in a group of 40 patients with lupus in whom the anti-La, anti-Ro, anti-Sm, anti-nRNP, anti-single-stranded DNA (anti-ssDNA), and anti-dsDNA were measured (23). The first four specificities were detected by gel diffusion. Antibodies to ssDNA were detected by radio-immunoassay and anti-dsDNA antibodies were detected by the Crithidia assay. Primary relationships were found between HLA-DQw1/w2 and anti-Ro, and between HLA-B8, DR3, and anti-La. Primary associations were found between anti-Ro and lymphopenia, and between anti-La and the absence of nephritis. Nephritis was present if either proteinuria exceeded 0.5 g per 24 hours or cellular casts were present in the urine. No statistically relevant relationships were present between any of the HLA antigens that were determined and any criterion for the classification of lupus (22). Logistic regression analysis established that the presence of lymphopenia was best explained by considering the combined contributions of anti-Ro and anti-ssDNA (23).

The relationship of anti-La with the absence of nephritis was analyzed by an analogous approach (23). The literature inconsistently shows an association of anti-dsDNA with nephritis, although there is convincing evidence that some anti-dsDNA antibodies are deposited in the kidney (79 ,80 ,81 ,82 ,83). On the other hand, both anti-La and anti-nRNP have been associated with a decreased incidence of nephritis in lupus (28 ,84 ,85). In this group of 40 patients with lupus, there was no simple association between anti-dsDNA and nephritis (23). Logistic regression analysis, however, produces an interesting result (Table 25-2). The association of anti-La with the absence of nephritis is powerful; however, once this effect is incorporated into the logistic model, then anti-dsDNA makes an important contribution. Here, anti-La and anti-dsDNA have opposing effects, which is demonstrated in the resulting logistic equation presented in Figure 25-4 . These data support a mechanism

of disease expression in which the clinical manifestations result from complicated interactions of various kinds of autoantibodies. The autoantibodies in turn are strongly influenced by the particular HLA and T cell receptor alleles that are present. One mechanism to explain these relationships is the recent demonstration that subsets of anti-La antibodies are in fact anti-idiotypes to anti-dsDNA (86).

Table 25-2: Logistic Regression Model of Renal Disease*

		Improvement		Goodness of Fit			Standard
Step	Term	x^2	*p*	x^2	*p*	Coefficient	Error
1	Anti-La(SS-B)	8.7	.003	33	.50	-1.22	0.52
2	Anti-dsDNA	6.9	.008	26	.79	2.75	1.19

*Anti-La (SS-B) is presented as the log10 of the ELISA units of the La (SS-B) solid-phase binding activity (range 2–7.03). Anti-double-stranded DNA (anti-dsDNA) is a dichotomous variable (1 = positive and 0 = negative). From Harley JB, Sestak AL, Willis LG, et al. A model for disease heterogeneity in systemic lupus erythematosus. Relationships between histocompatibility antigens, autoantibodies, and lymphopenia or renal disease. *Arthritis Rheum* 1989;32:826–836, with permission.

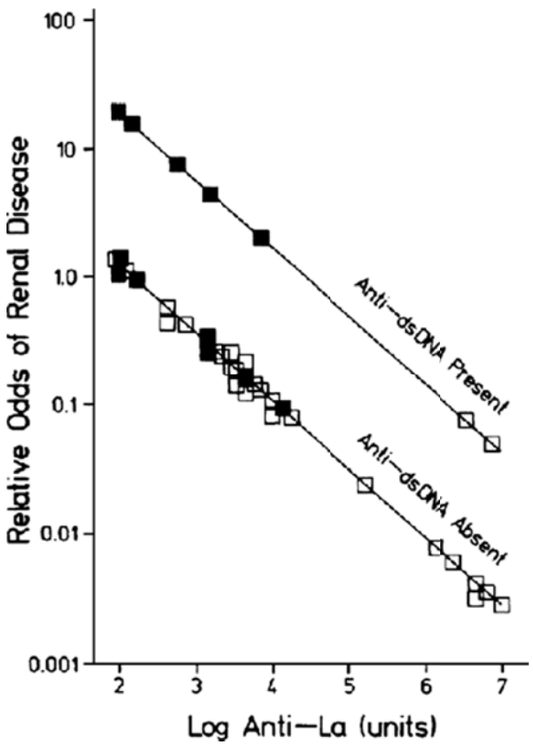

Figure 25-4. Relative odds of lupus nephritis in 40 patients with lupus as modeled from the anti-La and anti-double-stranded DNA (anti-dsDNA) antibody levels. Anti-La titer is expressed as the log10 of the relative binding in a solid-phase assay using purified bovine La. The presence or absence of anti-dsDNA is indicated. The presence (closed squares) or absence (open squares) of renal disease is indicated as well. The relative odds of renal disease are calculated from the logistic regression model presented in Table 25.2 (*n* = 40): ln (relative odds of renal disease) = -1.22 (anti-La) + 2.75 (anti-dsDNA) + 2.67. (From

Assays for Detecting Anti-Ro and Anti-La

In clinical practice, Ouchterlony double immunodiffusion is the traditional method of determining whether anti-Ro or anti-La is present (Fig. 25-1). Most data relating these serologies to clinical manifestations have been developed using either this technique or the closely related procedure of counterimmuno-electrophoresis. Double immunodiffusion is specific and sufficiently sensitive for nearly all clinical applications. Unfortunately, the procedure usually requires 2 days to complete, and its performance requires specialized training. Not infrequently, an anti-Ro precipitin is missed, either because poor-quality reagents have been used or because an inexperienced person is performing the test.

These difficulties and inefficiencies have provided an incentive for the development and marketing of alternative methodologies. Immunoprecipitation, immunoblotting, and solid-phase ELISAs are available in research laboratories. Anti-Ro and anti-La ELISAs have been marketed to clinicians and clinical laboratories and these assays have largely supplanted the more traditional methodologies for clinical assessment. These assays appear to provide as much as a 10- to 100-fold increase in sensitivity over double immunodiffusion. There is greater potential for interfering and artifactual binding in ELISA, and consequently the specificity of these assays is reduced relative to double immunodiffusion. The increased sensitivity means that half or more of patients with lupus, and perhaps over three quarters of patients with Sjögren syndrome, are positive for anti-Ro in these assays. The proportion of patients who are positive for anti-La often is doubled, from 10% to 20% in lupus and from 15% to 40% in Sjögren syndrome, by the application of the routinely available assays.

The antigenicity of the Ro antigen is adversely affected by denaturation and often is not detected whether the antigen is fixed in situ (e.g., in a cell line for the antinuclear antibody test) or by another method (e.g., by boiling in sodium dodecyl sulfate for the Western blot test). Indeed, the Ro antigen, as expressed by bacterial systems, produces an antigen that has a similarly profound reduction in antigenicity. Thus, Western blotting or reliance on Ro antigen in Western blots or on expression in a bacterial system from a recombinant complementary DNA (cDNA) will provide misleading results unless special precautions or adjustments are made.

Another ingenious assay is available for the detection of anti-Ro. Three groups have transfected cell lines with the coding sequence of the 60-kd Ro protein behind a promoter that increases the production of Ro protein in the cell (87 ,88 ,89). With the increased Ro antigen available, the problems that are associated with fixation may be overcome (87). Indeed, HEp-2 slides with overexpressed human Ro are now commercially available (HEp-2 2000).

The importance of identifying patients who have anti-Ro or anti-La by an ELISA is problematic for those who do not form precipitins. A significant proportion of normal individuals may fall into this category. At present, this level of anti-Ro does not assist in formulating diagnosis or prognosis. The ready availability and relative ease of performing these solid-phase assays dictates their increasing use. Nevertheless, whatever assay the clinician chooses, he or she should fully understand the meaning of the results and the limitations on their interpretation.

The levels of anti-Ro and anti-La vary over time by as much as 10- to 20-fold during the course of the disease, but the relevance of this to disease expression is not known. Mildly affected patients have been known, or inferred, to have had anti-Ro or anti-La precipitins for decades. It is rare to observe the disappearance of an anti-Ro or anti-La precipitin after disease onset unless the patient has had aggressive cytotoxic therapy, corticosteroids at high doses for an extended period, heavy proteinuria, or renal failure.

Molecular Considerations

Important progress also has been made in defining the molecular properties of the Ro and La antigens. All four human Ro-associated RNAs, known as hY RNAs, have been sequenced (Fig. 25-5). Each is a product of RNA polymerase III and is from 84 to 112 bases in length. The hY RNAs have a triphosphate 5′ terminus and a polyuridine 3′ terminus (90 ,91). Two highly conserved regions of 24 bases, one half from the 3′ end and one half from the 5′ end, are found in each hY RNA sequence (92). Part of this conserved region is thought to bind to the Ro protein by virtue of its being protected from RNAse digestion of the intact ribonuclear particle (91). From two to four Y RNAs have been isolated from every other vertebrate species evaluated (93), leading to the impression of substantial heterogeneity in Y RNAs between species. The Y3 RNA appears to be the most conserved among vertebrate species (94).

The peptide with a molecular weight of approximately 60 kd is the major antigenic peptide in the Ro RNA protein particle (95). Two sequences of this peptide have been obtained, which are essentially identical except for a small region of sequence divergence at the amino terminus (96 ,97). The 60-kd Ro peptide has a putative ribonucleoprotein binding domain and a zinc finger. Itoh et al. (98) have presented evidence for two antigenically related forms of 60-kd Ro. Of the Y RNAs, only hY5 is antigenic (99).

A number of other polypeptides have been related to anti-Ro autoantibodies, including 54-kd Ro and 60-kd Ro, which are both found in red cells; 52-kd Ro, a 57-kd polypeptide; and calreticulin. With La, these constitute a family of autoantigens. Except for calreticulin (100 ,101 ,102), antibodies that bind these autoantigens are found virtually only in sera that contain precipitating levels of anti-Ro autoantibodies.

A 52-kd peptide has been identified from lymphocytes by immunoblot (103), and its cDNA has been cloned and sequenced (104 ,105). Although one study detected a molecular association of the 52-kd Ro with the 60-kd Ro protein (106), this has not been confirmed, and most existing data support there being no stable molecular association between 52-kd Ro and the 60-kd Ro (107 ,108 ,109 ,110). The Ro hY RNAs are immunoprecipitated in association with 60-kd Ro (110 ,111). While some anti-Ro and anti-La sera immunoprecipitate the 52-kd protein, most appear to contain antibodies against the denatured form of 52-kd Ro found in Western blot (110 ,111). The 52-kd Ro gene may be important beyond its being a target of autoimmunity, because an allele of the 52-kd Ro gene is associated with lupus in blacks (112 ,113).

In erythrocytes, 60-kd and 54-kd peptides are variably identified in immunoblot by different sera containing anti-Ro (114). The 54-kd erythrocyte Ro peptide appears to be antigenically related to the 52-kd lymphocyte Ro (104). Interestingly, only hY1 and hY4 RNAs are immunoprecipitated from human erythrocytes, where they are slightly smaller than in other human cell types (92). This difference probably results from the shorter polyuridine 3′ end on the Y RNAs found in erythrocytes. The Y RNAs in human platelets are demonstrated to be restricted to hY3 and hY4 (115).

A 46-kd protein has been identified and sequenced using patient sera that contain anti-Ro activity. This sequence appears to be the human form of calreticulin, which is a calcium-binding protein (116). No clinical associations with this autoantibody have been established.

Maddison et al. (117) defined another specificity found in sera with anti-Ro autoantibodies: anti-p57. These antibodies are found in approximately 10% of patients with lupus and in nearly 40% of mothers of infants with complete congenital heart block or neonatal lupus dermatitis.

Ro particles also have been studied without exposure to denaturing conditions to allow an evaluation of in vivo Ro particle composition. In gel filtration, these particles range from 230 to 350 kd, thus supporting the position that there may be more than one peptide in a Ro particle (118). One of these particles appears to contain the hY5 RNA and not the other hY RNAs (99 ,118).

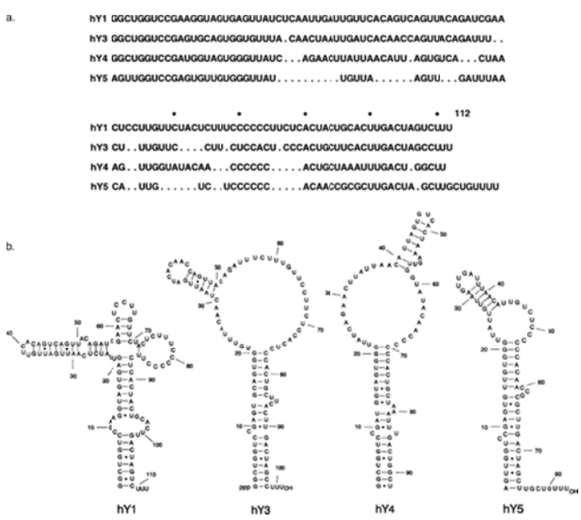

Figure 25-5. hY RNAs: **A,** Sequence comparison of the four Y RNAs. Periods indicate gaps in the sequence arranged to maximize sequence alignment. **B,** Proposed secondary structures of the hY RNAs. (Adapted from Farris AD. *Phylogenetic analysis of Ro ribonucleoprotein associated small RNAs [dissertation].* Oklahoma City, OK; University of Oklahoma Health Sciences Center, 1995:119, for hy1; Farris AD, O'Brien CA, Harley JB. Y3 is the most conserved small RNA component of Ro ribonucleoprotein complexes in vertebrate species. *Gene* 1995;154:193–198, for hY3 and hY4; and O'Brien CA, Margelot K, Wolin SL. Xenopus Ro ribonucleoproteins: members of an evolutionarily conserved class of cytoplasmic ribonucleoproteins. *Proc Natl Aca Sci USA* 1993;90:7250–7254, for hY5.)

At least one of these isolated Ro particles also contains the La peptide, thereby providing a structural basis for the association of anti-Ro and anti-La autoantibodies in patient serum. The La peptide contains 408 amino acids and has a predicted molecular weight of 46.7 kd (119 ,120 ,121). La also has an 80 amino acid conserved element referred to as the RNA recognition motif (122). The carboxyl end of the protein is methionine free and phosphorylated, while the amino end is methionine rich (123). The La peptide appears to bind any RNA with a polyuridine 3′ end (124 ,125). In addition to the Y RNAs, these include the precursors of 7S, 5S, U6, and precursors of transfer RNAs. The bound RNAs generally are the immature transcription products of RNA polymerase III, except for U1-RNA, which is an RNA polymerase II product that binds La (126).

Some virus-encoded RNAs also bind La from adenovirus, Epstein-Barr virus, and vesicular stomatitis virus (127 ,128 ,129). Additionally, La appears to play important roles in the expression of genes from poliovirus and human immunodeficiency virus (130 ,131).

There is evidence for La playing multiple roles in the molecular economy of the cell, while Ro has been implicated in only the discard pathway for 5S RNA (132) and with telomerase (133). La may function as a shuttle protein to carry RNA transcripts from the nucleus to the cytoplasm (134 ,135), and other investigators have obtained evidence that La is a termination factor for RNA polymerase III (136 ,137). La has been shown to melt an RNA-DNA hybrid in a reaction that requires adenosine triphosphate (ATP) hydrolysis (138) and to bind double-stranded RNA, thereby

influencing interferon-inducible protein kinase (139). The most intriguing data show that La increases the efficiency and fidelity of internal translation (131 ,140 ,141).

La proteins are found in widely divergent species, from humans to yeast. In all known instances, the La protein binds polyuridine termini of RNA (142). Despite all the activities found for La and the evolutionary implications of its presence throughout eukaryotic life, yeast are viable despite the destruction of the La protein gene (142 ,143).

Fine Specificity of Anti-Ro and Anti-La

With more detailed structural information now available, attention has turned to the fine specificity of anti-Ro and anti-La autoantibodies. By expressing fragments of the recombinant La cDNA clone, a number of groups have shown multiple epitopes on the La peptide that are distributed throughout the primary structure (119 ,144 ,145 ,146 ,147 ,148 ,149).

The 60-kd Ro peptide also appears to have multiple linear epitopes (150 ,151). In addition, there is evidence of multiple epitopes throughout the 52-kd Ro molecule (149 ,152), suggesting this is a general finding in lupus autoimmunity.

In both anti-Ro and anti-La autoantibodies, IgG1 predominates, with the other subclasses of IgG being variably represented (153 ,154 ,155). Anti-La is composed predominantly of IgG1 antibodies, while anti-Sm is not subclass restricted (153).

Unexpectedly, the antigenic peptides of 60-kd Ro tend to share short sequence homology with the nucleocapsid protein of vesicular stomatitis virus (151 ,150). Humans infected with vesicular stomatitis virus tend to have low levels of anti-Ro (156), and animals immunized with the cross-reactive nucleocapsid from vesicular stomatitis produce antibodies that bind 60-kd Ro (157).

There are many other hints about the origin of anti-Ro and anti-La autoantibodies. Sera with these antibodies and anti-dsDNA cross-react with the denatured Sm D and nRNP A polypeptides (158 ,159), thereby providing some unity for lupus autoimmunity across the major known protein autoantigen specificities. Antibodies that bind to hY5 RNA, but not the other hY RNAs, have been detected (99). Because Ro ribonuclear particles containing hY5 RNA can be isolated as distinct particles, some suspect that this may be the original autoantigen (99).

Very recently, a potentially important relationship has been discovered between anti-Ro and Epstein-Barr nuclear antigen-1 (EBNA-1) (163). The detailed sequence of events was revealed by serial sera from donors who had progressed from no anti-Ro to an anti-Ro precipitin over a few years of observation. (Only the anti-Ro sera alone were studied; none of these developed both anti-Ro and anti-La.)

In all informative sera the first anti-Ro activity detectable bound peptides from the amino acid sequence positions 169 to 180, TKYKQRNGWSHKD (using the single letter code for amino acids). Virtually all of the anti-Ro activity binds this single epitope at this point in anti-Ro development. Astonishingly, the affinity purified anti-TKYQRNGWSHKD from the sera where this is the only detectable anti-Ro activity also bind EBNA-1 at GGSGSGPRHRDGVRR (EBNA-1 amino acids 58 to 72). This presumed cross-reaction assumes a level of structural similarity between the Ro and EBNA-1 peptides, though it is formally possible that the anti-Ro sequence bound (TKYKQRNGWSHKD) and the anti-EBNA-1 sequence bound (GGSGSGPRHRDGVRR) are actually binding different variable parts of the IgG molecule.

In any case, these results provide a second example of a cross reaction between EBNA-1 and the first autoimmune epitope from a lupus autoantigen (162), reinforcing the potential etiologic relevance of EBV infection and SLE (164).

Mechanisms explaining maturation of the autoimmune response are under intensive inquiry. Epitope spreading has been shown for anti-La antibodies (163 ,164) and for the Sm B/B', where this maturation can be induced by immunization with a single peptide. Such a situation is also found in the restricted autoimmune response of the few patients with sera available from early in the disease process (167). Perhaps, defining the initial autoimmune response will provide important clues to etiology and pathogenesis.

Summary

Anti-Ro occurs in nearly half, and anti-La occurs in about one-fifth of patients with SLE. Anti-La always occurs in association with anti-Ro. Anti-Ro is specifically deposited in skin in lupus and is likely involved in the pathogenesis of cutaneous injury. Thrombocytopenia, when it occurs before other clinical signs of lupus, is usually accompanied by anti-Ro. Anti-Ro and anti-La can occur many years before clinical disease of lupus or Sjögren syndrome as evidenced by its association with neonatal lupus. Patients with both anti-Ro and anti-La very infrequently have renal disease. Lupus patients with the clinical findings of subacute cutaneous lupus erythematosus (SCLE) invariably have anti-Ro autoantibodies detected by a sensitive ELISA. There is substantial evidence for the participation of anti-Ro in lupus nephritis.

Chapter 26

Antibodies to Spliceosomal Components

Carol S. Lutz

Judith A. James

Antispliceosomal autoantibodies are commonly found in systemic lupus erythematosus (SLE) and related systemic autoimmune rheumatic diseases (1 ,2). Anti-Sm and anti-nRNP, which target these spliceosomal proteins, are useful in the diagnosis of SLE and other rheumatic diseases and in spliceosomal characterization. This chapter briefly reviews the structure and function of the targets of these autoantibodies, the methods of detection for these autoimmune specificities, the clinical associations with these autoantibodies and provides a summary of evolving information regarding the epitopes, origins, and potential pathogenic features of spliceosomal autoimmunity.

Structure of the Spliceosome

An important functional component in eukaryotic cells is a variety of discrete complexes consisting of proteins and RNA molecules. Complexes of this theme exist in every compartment of the cell: cytoplasm, mitochondria, nucleolus, and nucleus. Small nuclear ribonucleoprotein complexes (snRNPs) are protein-RNA complexes that are localized to the nucleus and are intimately involved in RNA processing as essential components of the multiprotein splicing machinery known as the spliceosome. Historically, they were identified as autoantigens of patients with autoimmune disorders, particularly SLE (3 ,4 ,5 ,6 ,7 ,8). The U1, U2, U4, U5, and U6 snRNPs are so named after their highly structured RNA counterparts (i.e., U1 snRNA, U2 snRNA, and so forth), and are quite abundant, ranging from thirty thousand to one million copies per cell (9). Each snRNP is composed of a small (i.e., less than 190 nucleotide) RNA molecule that is made by RNA polymerase II and has an unusual trimethylated cap (with U6 an exception on both counts; reviewed in (10)). U1, U2, U4, and U5 snRNPs contain a set of proteins common to all snRNPs; these proteins are called the Sm proteins (B, B', D1, D2, D3, E, F, and G) and range in molecular weight from 29 to 9 kD (reviewed in (11)). The crystal structure of the Sm protein complexes has recently been revealed (12). U1, U2, U4/U6, and U5 snRNPs also contain proteins uniquely associated to each particular complex (reviewed in (13)).

The U1, U2, U4/U6 and U5 snRNPs represent the so-called “major” spliceosome components which are involved in the splicing of approximately 99% of all introns. However, another class of spliceosomes exists in human cells, the “minor” spliceosome, which consists of U11, U12, U4atac, and U6atac (reviewed in (14)). The U5 snRNP is found in both classes. U11, U12, and U4atac snRNPs contain Sm proteins along with other specific protein components and are the U1, U2, and U4 counterparts, respectively (14). Cellular assembly and biogenesis of U snRNPs has been a matter of much investigation recently (reviewed in (15 ,16)). The snRNP assembly pathway is complex, involving export of snRNA from the cell nucleus to the cytoplasm, assembly of the Sm proteins onto the snRNA in the cytoplasm, and re-import of the mature snRNP into the nucleus. Assembly of the Sm complex onto the snRNA is accomplished by the survival of motor neurons (SMN) complex (15 ,16 ,17 ,18). The final steps of snRNP maturation take place in discrete sub-nuclear domains called Cajal bodies (19 ,20). Recently a rare specificity of SLE patient sera with reactivity against Cajal body proteins was noted in a study in Mexico (21).

SnRNPs and Associated SnRNP Factors

SnRNPs, as defined originally, have a set composition of RNA and protein components distinct to that particular snRNP in addition to the Sm, or “core”, complex (11 ,22). The U1snRNP has three unique proteins, called U1 70K, U1A, and U1C. The U2snRNP has eleven unique proteins (23), including two proteins called U2A' and U2B”. This nomenclature is somewhat confusing but historical in nature based on relative size and not actual similarity. The U4/U6 snRNP is formed by extensive base-pairing via intermolecular helices between the two RNA molecules, and has two proteins of 60 and 90 kD uniquely associated (24). The U5 snRNP has at least 9 proteins associated with it uniquely: these are proteins of 220, 200, 116, 110, 102, 100, 52, 40, and 15 kD (25). However, these snRNPs have additional, non-snRNP factors associated with them; these associations will be highlighted here.

The U4/U6 and U5 snRNPs interact with each other in the nucleus, and this association helps to form the mature spliceosome (reviewed in 26). The tri-snRNP complex has

five additional proteins (63, 61, 27, 20, 15.5 kD) that are not part of either the U4/U6 snRNP or the U5 snRNP (25). One of these proteins (20 kD) has been recently identified as a novel cyclophilin, and has been shown to exhibit the cis/trans isomerization of peptidyl-prolyl bonds characteristic of cyclophilins (27). This interaction may possibly reflect a role in the assembly of the tri-snRNP complex or may be involved in conformational changes of proteins required during spliceosome assembly. Another of these proteins, the tri-snRNP-specific 27K protein, has been identified as a member of the SR protein family (see below) (28).

Another notable interaction with snRNPs is a 69kD protein (known as 69KD) that shares structural homologies with human translocated in liposarcoma (TLS) and Ewing sarcoma (EWS) proteins (29 ,30). This protein copurified with snRNPs, particularly U1snRNPs, and associated with the Sm complex of proteins in Xenopus micro-injection experiments as well as in in vitro binding studies. Since TLS and EWS share domains with 69KD that act as transcriptional activators, it is interesting to speculate what role 69KD might also play in mRNA transcription.

SnRNPs and Splicing Factors

Splicing of pre-mRNA is an intricate process involving more than 100 proteins and at least 5 RNA factors (reviewed in (26 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39)). Splicing is a two-step process in which the coding regions (exons) are retained and the noncoding regions (introns) are removed (Fig. 26-1). Catalytic step I results in cleavage of the 5′ splice site, yielding a “free” 5′ exon and a lariat intermediate. Step II involves ligation of the 5′exon to the 3′ exon with displacement of the intron as a lariat product. Cis acting signals present within the mRNA are also involved, such as splice donor and acceptor sites at the 5′ and 3′ ends of the introns, respectively. Recently, exonic sequences have also been identified that promote (exonic splicing enhancer, ESE) or repress (exonic splicing silencer, ESS) utilization of alternative splice sites (reviewed in (40 ,41 ,42 ,43)). These may become more important in the future as alternative splicing is becoming linked to many diseases.

Assembly of the mammalian spliceosome begins with the association of the U1snRNP at the 5′ splice site by base-pairing of U1 RNA with the 5′ splice site, followed by association of the U2 snRNP at the branch site. The U4/U6-U5 tri-snRNP complex then binds, U1 and U4 are destabilized and released, and the spliceosome is activated for catalysis (Fig. 26-1). Changes in intermolecular basepairing between the snRNAs also occur. Recently, cryo-electron microscopy has helped to reveal the three-dimensional structure of individual snRNPs as well as the structure of the native spliceosome (44 ,45 ,46).

Additional, non-snRNP proteins are also required for efficient splicing. In an early step, pre-mRNAs are committed to the splicing pathway not only through association with the U1snRNP, but also with non-snRNP factors, including the U2 auxiliary factors U2AF65 and U2AF35 as well as members of the SR protein family (47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56). SAPs, or spliceosome-associated proteins, are additional non-snRNP proteins that are involved in splicing of pre-mRNA, and include such proteins as polypyrimidine tract binding protein associated splicing factor (PSF) (50 ,57 ,58 ,59). HnRNP proteins are yet another group of highly conserved, non-snRNP RNA binding proteins that participate in pre-mRNA processing (reviewed in (60 ,61)). Interactions of SR proteins and hnRNP proteins with target sequences in the pre-mRNA appear to play important roles in directing alternative splicing, perhaps with additional protein factors in some cases (reviewed in (62)).

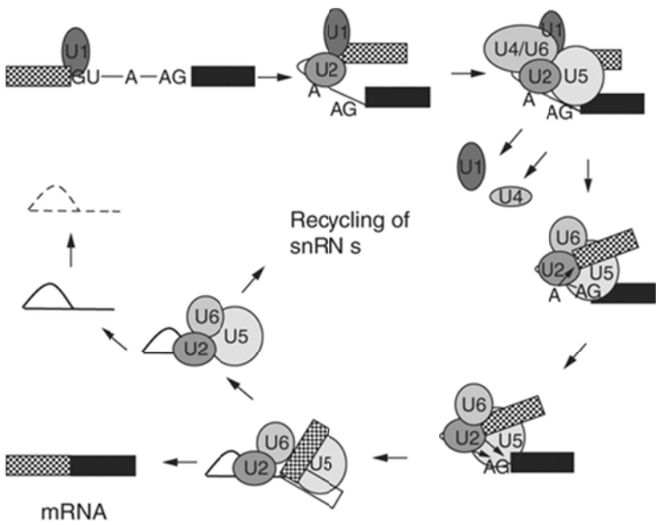

Figure 26-1. Schematic of the splicing cycle. Black and black/white checked boxes represent exons 1 and 2, respectively. The line indicates the intron. Pre-mRNA enters splicing complexes with snRNPs and leaves the cycle as ligated, mature mRNA. Highly conserved GU (5′ splice site), AG (3′ splice site) and A (branch point) residues are noted. Individual snRNPs are depicted as U1, U2 U4, U5, and U6. Other, non-snRNP splicing factors have been omitted for simplicity. The excised intron lariat is degraded after splicing is complete. (Adapted from Moore MJ, Query CC, Sharp PA. Splicing of precursors to messenger RNA by the spliceosome. In: Gesteland RF, Atkins JF, eds. *The RNA World.* Cold Spring Harbor, NY: Cold Spring Harbor Laboraotry Press, 1993:303–358 and Jurica MS, Moore MJ. Pre-mRNA splicing: awash in a sea of proteins. *Mol Cell* 2003;12:5–14.)

Despite all these potential protein-protein interactions of snRNP proteins with the myriad of splicing factors, only a few direct interactions have been characterized. For example, Wu and Maniatis described the interaction between U1 70K and U2AF65 (51).

SnRNPs and Non-SnRNP Complexes

SnRNP-free U1A complexes (SF-A) were discovered using a mouse monoclonal antibody (12E12) (63 ,64). This antibody is specific for U1A as shown by immunoprecipitation followed by Western blotting, but does not immunoprecipitate U1A that is complexed with U1 RNA as shown by Northern blotting. This suggests that SF-A is not complexed with U1 RNA. Additional anti-U1A monoclonal antibodies

that we prepared (1E1, 10E3, and 20F8) precipitated the U1snRNP. These data suggest that monoclonal antibody 12E12 is unable to recognize U1A when it is bound to U1 RNA because the epitope is “masked” (63).

Immunoprecipitation of ^{35}S labeled cell extracts using monoclonal antibody 12E12 revealed additional, non-snRNP proteins associated with U1A. In contrast, monoclonal antibody 10E3 primarily immunoprecipitated the U1snRNP and associated proteins. To demonstrate that the association of U1A with non-snRNP proteins is genuine and not a result of antibody cross-reactivity, 5% to 30% sucrose gradient fractionation of ^{35}S labeled cell extracts was performed, followed by immunoprecipitation (63). The SF-A fraction coprecipitates with at least five other non-snRNP proteins (p105, p65, p63, p59, and p58), and migrates with these proteins during sucrose gradient centrifugation as a novel complex of proteins. The gradient analysis of the SF-A complexes indicates a core complex consisting of U1A, p58, p65, and p105 and suggests that p59 and p63 dynamically associate with the core complex. No RNA species have been detected with the SF-A complex as determined by immunoprecipitation of ^{32}P-orthophosphate labeled cell extracts. Thus, these data establish that U1A protein is not an exclusive component of the U1snRNP. A significant fraction is found in a snRNP-free form in a complex with other cellular proteins (63 ,64) and some SLE patients appear to recognize this novel complex (65).

One of the proteins in the SF-A complex has now been identified as the splicing factor PSF the polypyrimidine-tract binding protein associated splicing factor (57 ,66). Additionally, p68 helicase and p54nrb have been found to be part of the SF-A complex using epitope-tagged U1A (66). Another report has shown that p53 and human MDM2 can be found in association with U1A in the absence of the Sm proteins in leptomycin-treated human primary fibroblasts (67).

SnRNPs and Viral Proteins

Generally, viruses accomplish transcription of their own genes over those of the host cell in a variety of creative ways. Some of these ways include shut-off of host cell splicing by redistribution of splicing factors, strong promoter recruitment of transcription factors, and commandeering the RNA processing machinery. Therefore, opportunities abound for direct interaction with snRNP proteins. Yet these interactions have just begun to be understood. A recent report reveals that human papillomavirus type 5 (HPV-5) E2 transcriptional activator has a hinge region that resembles the SR proteins, and this region interacts in vitro with U1 70K, U5 100 kD, ASF/SF2, and SC35 (68). A two hybrid screen in the same report shows much weaker interaction in vivo of HPV-5 E2 protein with U1 70K and U5 100 kD than that with ASF/SF2 and SC35, but the authors state that this could be due to reduced amounts of the proteins produced in yeast. This report suggests that HPV-5 E2 protein may assist in coupling viral transcription and splicing.

Herpes simplex virus type 1 (HSV-1) accomplishes host cell shut-off by reorganization of snRNPs and inhibition of host cell splicing (reviewed in (69)). Recent studies have shown that the HSV-1 regulatory protein ICP27 is responsible for this effect, and that ICP27 is co-immunoprecipitable with anti-Sm antiserum (70). This suggests that ICP27 interacts with snRNPs during HSV-1 infection but does not demonstrate whether the interaction is direct or indirect.

Protein Targets of Anti-Spliceosomal Autoimmunity

Anti-Sm autoantibodies are directed predominantly against the Sm B, B' (71) and Sm D1 proteins (72) and immunoprecipitate the U1, U2, U4/U6, and U5 RNAs (73). Minor responses are also detected against Sm D2, Sm D3, E, F, and G. As much as 40% of the entire immunoglobulin repertoire of lupus patient sera may bind Sm proteins (74). Nearly all of the SLE patients who have anti-Sm antibodies also have anti-nRNP antibodies. Those who begin with anti-Sm alone nearly universally develop anti-nRNP reactivity over the course of their disease (75). Anti-nRNP autoantibodies immunoprecipitate only U1 RNA and bind the nRNP 70K, nRNP A, and nRNP C proteins (76). Additionally, anti-U2 RNP antibodies recognize A' and B” proteins of the U2 snRNP (77 ,78 ,79) and rare responses specific to U4/U6 (80 ,81), U5 (82), U7 (83), and U11 snRNPs (84) have been reported.

Assays for Measuring Anti-Sm and Anti-U1 RNP Antibodies

The methods for detection of anti-Sm and anti-nRNP autoantibodies have expanded greatly over the past two decades, now to include at a minimum immunofluorescence, immunodiffusion, immunoblotting, immunoprecipitation of proteins or RNAs, and enzyme-linked immunoabsorbent assays (ELISAs) (85 ,86 ,87 ,88 ,89 ,90 ,91 ,92) (Fig. 26-2). Great strides have also been made in the development of detection methods for these autoantibodies by protein microarrays, bead assays and peptide-based methods (93 ,94 ,95 ,96 ,97).

Immunofluorescence remains a dominant screening method for detection of spliceosomal autoantibodies. Anti-Sm and anti-nRNP autoantibodies bind to proteins in the cell nucleus in a nuclear speckled pattern, as do the remaining spliceosomal autoantibodies (2). However, this staining pattern is not specifically unique for spliceosomal antibodies. For many years immunodiffusion has served, and in some locations continues to serve, as the primary method of detection for anti-Sm and anti-nRNP. Indeed, formation of precipitin lines with patient sera against calf thymus extract serves as the basis for many of the clinical diagnostic criteria and clinical association afforded these autoimmune responses (85 ,86). Additional sensitivity may be increased by counterimmunoelectrophoresis (87). Many clinical laboratories, however, are moving to testing by ELISA or perhaps Western blot analysis.

ELISAs for spliceosomal autoantibody detection (Fig. 26-2) have been developed and commercialized (88 ,89). These assays require the binding of a purified or recombinant

antigen to the bottom of a 96-well plate, blocking of nonspecific antibodies and then incubation with various dilutions of patient or control sera. A secondary antibody with an enzymatic tag is developed with substrate to induce a colorimetric change, which is quantified by reading the optical density at given wavelengths. These optical densities (ODs) may be reported directly, or oftentimes are converted to international standardized ratios (ISRs) based upon normalization with positive, negative, and calibrator controls. The major benefits of the ELISA methods are ease of operation, minimized time for results, and increased sensitivity. The primary limitation is the potential for false-positive results.

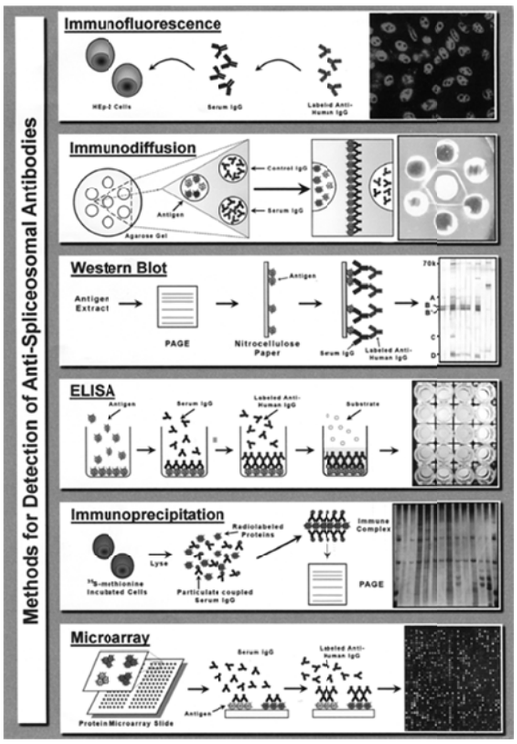

Figure 26-2. (See color plate.) Methods of anti-Sm and anti-nRNP detection. Several of the most common forms of autoantibody detection are presented in this figure with schematic diagrams followed by examples of data produced from each method. Additional detail regarding each method with references is presented within the body of the chapter. The initial approach is still considered the gold-standard screening approach for autoantibody detection, immunofluorescence. However, immunodiffusion is still considered the gold-standard for confirmation of the specific anti-Sm and anti-nRNP immune responses. Western Blot analysis is an immunoblotting technique which allows the determination of antibody binding to specific protein targets. Enzyme-linked immunosorbent assays (ELISAs) are becoming more widely used and have increased sensitivity (with some loss of specificity). Finally, new approaches are being developed to test hundreds of proteins at a time with micro-array analysis.

Additional approaches are available to detect specific protein targets of these autoantibody responses. Two of the most common are immunoprecipitation and immunoblotting. Immunoprecipitation requires the radioactive labeling of cellular proteins that are mixed with patient sera coupled to a particulate carrier, such as protein A-sepharose (90).

Once binding of the antigen to the antibody has occurred, the complexes can be immunoprecipitated with the particulate carrier, run on polyacrylamide gel electrophoresis and identified by autoradiography (Fig. 26-2). The benefits of this approach are the high sensitivity, high specificity and ability to detect U snRNAs. The limitations include use of radioactivity, length of time for results and the highly specialized training required of lab personnel to perform this approach.

Immunoblotting can also identify antibody reactivity with a specific protein of the anti-Sm or anti-nRNP responses (91 ,92). Cellular extracts or purified antigens are separated by gel electrophoresis, transferred to a membrane and then probed with dilutions of patient sera (Fig. 26-2). Using a secondary antibody with enzymatic substrate, color development demonstrates the binding of patient antibodies to specific spliceosomal proteins. Pre-run blots containing spliceosomal proteins are now commercially available. The benefits of this approach include specific protein detection, good sensitivity, and specificity. The potential drawbacks include the preference of this method to detect antibodies directed against denatured proteins and specialized training of personnel.

Several new approaches are emerging to detect spliceosomal autoantibodies. Protein micro-array experiments allow the coupling of recombinant or highly purified spliceosomal autoantigens to glass slides. These protein microarrays are incubated with patient sera and then incubated with a secondary antibody coupled to a fluorescent dye (93 ,94). The intensity of these spots can be measured and compared to standards to determine patient serum reactivity with spliceosomal antigens. Similar approaches using proteins coupled to beads as the antigen source are also becoming available (95). An automated multiparameter line immuno-assay system is a commercialized, standardized, modified immunoblot for which nine individual recombinant or purified antigens are coated as discrete lines on nylon strips, incubated with patient sera followed by a substrate secondary antihuman IgG conjugate and developed colorimetrically (96). Bands are compared to standards run in parallel. This approach appears to have similar sensitivity and specificity to anti-Sm and anti-nRNP but has decreased cost and decreased serum use (96). A modified radioactive method has also been recently reported. Radioligand assays were performed following in vitro transcription and translation from the appropriate labeled cDNA of spliceosomal autoantigens. Patient sera autoantibodies react with this radiolabeled protein and were captured by protein-A Sepharose and quantified by radioactivity counting. This assay showed good specificity and sensitivity and even demonstrated a strong correlation between Sm B' antibody levels and the severity of SLE (measured by <Systemic Lupus Erythematosus Disease Activity Index [SLEDAI]) and showed a correlation between anti-U1A and nephritis (97). These approaches are still primarily used in research settings.

Table 26-1: Prevalence and Association with Anti-Sm and Anti-nRNP in Systemic Lupus Erythematosus and Related Disorders

Specificity	Clinical Association	Prevalence
Anti-Sm	SLE	10%–30%
Anti-nRNP (U1)	Mixed connective tissue disease	100%
	SLE	30%–40%
	Raynaud's phenomenon	60% (SLE)
		<20% (others)
	Myositis	10%
	Scleroderma	10%
	Sjogren syndrome	Rare
Anti-U2 snRNP	MCTD, SLE, scleroderma/myositis	Rare
Anti-U4/U6 snRNP	Sjogren syndrome	Very Rare
	Scleroderma	Very Rare
Anti-U5	SLE (with anti-nRNP)	Very Rare
	MCTD (with anti-nRNP)	Very Rare
	Scleroderma/Polymyostis (alone)	Very Rare
Anti-U7	Scleroderma	Very Rare
Anti-U11	Scleroderma	Very Rare
Anti-U1 RNA	SLE (with anti-nRNP)	15%
	MCTD (with anti-nRNP)	30%
	Scleroderma (pulmonary fibrosis)	5%–10%

Clinical Features Associated with Anti-Sm Antibodies

Sm antibodies are so specific for SLE that they are considered as one of the diagnostic criteria (98). Anti-Sm is detected in approximately 10% to 25% of European-American SLE patients and in higher frequencies in African-American patients (2 ,99 ,100 ,101 ,102) (Table 26-1). Estimates of anti-Sm

prevalence may be even higher with use of the ELISA method of detection without losing the sensitivity for SLE (103 ,104 ,105). SLE, or a disorder closely resembling SLE, is closely associated with anti-Sm in human lupus, inbred mice (lpr/lpr MRL) (106), induced models in mice and rabbits (107 ,108 ,109), two different studies of collections of canine lupus (110 ,111) and macaques fed alfalfa (112). The same disease phenotype found associated with the same autoantibody across these enormous species barriers suggest the fundamental contribution that this autoantibody system may make to SLE.

Patients with both anti-Sm and anti-nRNP precipitating autoantibodies appear to be a distinct subset of SLE patients. These patients have higher morbidity and mortality and more severe renal disease (113 ,114 ,115 ,116 ,117) in some studies. No clear association of SLE disease damage from two lupus clinics in Birmingham, UK with anti-Sm or anti-nRNP reactivity was found (118). Interestingly, patients initially diagnosed with SLE at or older than the age of 50 are less likely to have antibodies to Sm or nRNP proteins and may have a milder form of the disease (119), while childhood-onset SLE may be associated with increased prevalence of anti-Sm and anti-nRNP (120).

Other studies have sought to evaluate the association of anti-Sm specificity with various clinical manifestations. Recent work suggests an enrichment of anti-Sm and anti-nRNP in nephritis; however, only anti-Sm was associated in a multivariate analysis (121). A Japanese study showed that anti-Sm detected by ELISA was associated with a low frequency of progression to end-stage renal disease, but an increased prevalence of late-onset proteinuria and poorer prognosis than patients without anti-Sm (96). In older literature, however, anti-Sm was found less commonly in lupus nephritis (122). In a single center cohort study from Spain of over 600 SLE patients, Sm autoantibodies were associated with cutaneous lupus involvement (123). Sm antibodies are substantially more frequent in patients of African-American heritage (113) and controlling for association based upon ethnic heritage may impact some of the previous studies.

Although quite specific for SLE, anti-Sm reactivity has been reported (especially as detected by ELISA) in several other disorders. These include rheumatoid arthritis after infliximab treatment (124), parvoviral infection presenting as a lupus-like illness (125), pediatric HIV infection (126), monoclonal gammopathies (127), schizophrenia (128), and uveitis (129).

Recently, the American College of Rheumatology Ad Hoc Committee on Immunologic Testing Guidelines published a guidance document summarizing the current literature regarding clinical usefulness of testing for anti-Sm and anti-nRNP reactivity (130). A positive anti-Sm response by a number of methods was found to be very sensitive for SLE; however, based upon the low number of all SLE patients with anti-Sm the specificity was relatively low. Although one study shows that rising anti-Sm titers are predictive of disease flares (131) and another associates anti-Sm with more active disease (132), insufficient data was available in category A publications (based upon a standard Evidence Based literature review approach) (133 ,134) to determine the use of anti-Sm titers to predict disease severity or disease flares (130).

Clinical Features Associated with Anti-U1RNP Antibodies

Anti-nRNP antibodies are found in approximately 30% to 40% of SLE patient sera by immunodiffusion (99 ,100 ,127 ,135 ,136) (Table 26-1). Although sometimes found in combination with anti-Sm as outlined above, oftentimes anti-nRNP will be detected as the sole specificity. The primary clinical association with anti-nRNP antibodies is a clinical entity, mixed connective-tissue disease (MCTD), which is characterized by overlapping symptoms of lupus, scleroderma and myositis. High titers of anti-nRNP antibodies are a hallmark of this disorder and are considered a key feature for diagnosis (103 ,136 ,137). Anti-nRNP antibodies may also be found in other systemic rheumatic diseases such as scleroderma, polymyositis, rheumatoid arthritis, and Sjögren syndrome (103 ,135 ,136) or in patients with Raynaud phenomenon (138) (Table 26-1).

Some studies have focused on the clinical features associated with specific anti-nRNP responses directed specifically against the 70K or U1A proteins. The anti-70K response is found in 75% to 95% of anti-nRNP positive MCTD patient sera (117 ,139 ,140) but may be only found in 20% to 50% of anti-nRNP positive SLE patient sera (117 ,139 ,140). These associations may be significantly influenced by testing methodology used (115 ,127 ,136 ,141 ,142). When anti-nRNP positive individuals are evaluated together (both SLE and MCTD) then anti-nRNP is associated with Raynaud's phenomenon, myositis, esophageal hypomotility, lack of nephritis, and HLA-DR4 (117 ,141 ,143).

Anti-U1A antibodies are also commonly found in individuals with anti-nRNP by immunodiffusion. Overall, the frequency of anti-70K and anti-U1A responses are nearly equivalent in nRNP antibody positive individuals (144), yet this specificity may be present in 75% of anti-nRNP SLE patients and only 23% of all individuals with anti-nRNP (139). Cross-reactive regions between a common lupus U1A epitope have been shown with nRNP C and Sm B' (145 ,146) and this cross-reactive specificity is much more common in lupus than MCTD. Little clinical information regarding the anti-nRNP C response is available.

Again, the American College of Rheumatology Ad Hoc Committee on Immunologic Testing Guidelines has recently published a guidance document summarizing the current literature regarding clinical usefulness of testing anti-nRNP (130). Although with good sensitivity and modest specificity, a positive anti-nRNP response by several different methods was not a strong predictor of SLE over other autoimmune rheumatic diseases. Anti-nRNP did serve as the best clinical surrogate for mixed connective tissue disease (130). Category A publications evaluating the association of this autoimmune response and SLE disease severity or disease flares were not available for assessment (130).

Other Anti-SnRNP and U1RNA Antibodies

Antibodies against the U2, U4/U6, U5, U7, U11 snRNPs, and the U RNAs themselves have been detected infrequently. Significantly less information is available than with the anti-Sm and anti-nRNP response described above; however, all of these specificities appear to be associated with some forms of clinical overlap between SLE and other rheumatic disorders. Anti-U2 snRNP antibodies are found in up to 15% of SLE or MCTD patient sera and are often associated with clinical overlap syndromes, such as scleroderma with myositis, psoriasis, or Raynaud syndrome (2). Anti-U4/U6 snRNP antibodies have been described in a few patients with Sjögren syndrome and scleroderma (80 ,81). Anti-U5 snRNP antibodies are found in anti-nRNP or anti-Sm positive SLE or MCTD patients (2), but as a sole specificity anti-U5 snRNP reactivity has been reported in a single scleroderma/polymyositis overlap patient by two separate groups (91 ,147). Anti-U7 snRNP antibodies have been described in a few SLE patients (83) and anti-U11 snRNP antibodies have been found in a few scleroderma patient sera (84 ,148). Most of these autoantibodies also produce a nuclear speckled immunodiffusion pattern and immunoprecipitation remains the most common method of detection for these specificities.

Anti-U1RNA antibodies have been found in up to 38% of anti-snRNP positive patient sera and again are quite specific for SLE and MCTD based upon an early study by van Venrooij et al. (149). These antibodies were found in anti-nRNP positive but not in anti-Sm positive patient sera. These anti-U1RNA antibodies can bind to the various portions of the U1RNA, including the cap structure and two different hairpin loops (149). Recent work has confirmed the presence of these anti-U1RNA antibodies in SLE and MCTD patients, as well as described their presence in 61% of anti-nRNP positive systemic sclerosis patient sera (150). These anti-U1RNA antibodies were associated with pulmonary fibrosis in this study (150). Interestingly, U1RNA itself has been shown to induce innate immune signaling and may contribute to the immunogenicity of the 70K nRNP autoantigen (151).

Origins and Pathogenic Features of Spliceosomal Autoimmunity

Autoantibodies are a hallmark of SLE and serve as the only classification criterion present in over 98% of patients (99). Therefore, significant investigation has focused on understanding the initiation, perpetuation, evolution, and potential pathogenic roles of these autoimmune responses in SLE. Specific interest has focused on understanding potential genetic risk factors for these responses and considerable work in understanding the fine specificity of the humoral and T cell responses has occurred. This section will briefly summarize some of the areas of current investigation.

Genetics

Familial aggregation of anti-Sm antibodies by ELISA suggest that the anti-Sm response may be governed at least in part by genetic susceptibility (152 ,153). HLA associations have been previously reported between anti-Sm or anti-nRNP and HLA-DR2 and HLA-DR4, as well as with weaker associations with members of the DP, DQ and DR families (3 ,154 ,155). However, these weak associations do not appear to confer all of the risk. The IL-10 high responder haplotype has also been associated with anti-Sm positive SLE in a small cohort of Caucasian German patients (156). The genetic susceptibility to this abnormal immune response is likely multigenic and further information is needed.

Occurrence of Autoantibodies

Autoantibodies are often found years if not decades before clinical onset of SLE (157). Interestingly, the anti-nRNP and anti-Sm responses occur closer to the time of diagnosis than do other common lupus autoantibodies, such as anti-Ro and anti-La (157). nRNP 70K appears to be the initial target of the anti-nRNP response and Sm B/B' appears to be the initial target of the anti-Sm response as detected by immunoblotting of serial patient samples referred for clinical testing (91).

Humoral Responses and Epitope Mapping

Extensive work describing the key humoral antigenic targets of the spliceosomal proteins by SLE patient sera have been performed by recombinant protein mapping, deletion clone mapping, large synthetic peptide mapping, and solid phase overlapping octapeptide mapping
(158 ,159 ,160 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199). This large body of work is summarized in several reviews (158 ,159 ,160). Briefly, the work in the Sm B', Sm D1, 70K, and U1A systems will be outlined here.

Over the past 10 years, our laboratory has been involved in characterizing the fine specificity of the human lupus autoimmune response against the spliceosome. Mapping the fine specificity by describing the small peptide epitopes of these systems led to identification of the initial anti-Sm B' humoral epitope (107 ,161), descriptions of common epitopes of human SLE (107 ,145 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170), establishment of a new peptide-induced model of lupus autoimmunity (107 ,108 ,200), and identification of a potential etiological trigger for human lupus (201 ,202 ,203 ,204 ,205 ,206 ,207 ,208). We will first briefly discuss the B cell epitopes of anti-Sm and anti-nRNP in naturally arising SLE autoimmune sera. Next, we will briefly present the data from rabbits and mice, which support the theory that peptide immunization results in anti-spliceosome autoimmunity and the association data of human lupus and Epstein-Barr virus (EBV), the candidate etiologic agent identified by our immunochemical approach (145 ,161 ,163).

Characterization of the sequential antigenic regions of the autoantigens Sm B/B', Sm D1, D2, D3, nRNP 70K, nRNP A, and nRNP C have been published by our laboratory (107 ,145 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170) and other groups (158 ,159 ,160 ,161 ,162 ,163 ,164 ,165 ,166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199). At least

40 common antigenic targets of these responses have been described (158 ,159 ,160).

The anti-Sm B/B' response was the first antispliceosomal autoantigen evaluated extensively for common humoral targets (Fig. 26-3). SLE patient sera, which contain both anti-Sm and anti-nRNP autoantibodies, have a very homogeneous pattern of binding to the overlapping octapeptides of Sm B/B'. All anti-Sm B/B' patient sera bind five very similar regions of B/B'. Four of these epitopes are proline-rich, very similar regions: PPPGMRPP (which is repeated three times in the carboxyl region of the protein) and PPPGMRGP (145).

These antipeptide responses have proven interesting in several ways. First, specific reactivity with these peptides have been confirmed in a large number of patients (compared to controls) using a different peptide methodology, as well as in other research laboratories (145 ,172 ,173 ,174 ,175 ,176 ,177 ,178). Only SLE patient sera with anti-Sm autoantibodies bind these specific proline-rich sequences. Second, these sequences are the targets of two unique anti-Sm monoclonal antibodies developed from MRL lpr/lpr mice suggesting that these are primary targets not only in human but murine lupus (167). Third, this PPPGMRP(G)P structure is the target of human monoclonal antibodies derived from a SLE patient (171). Fourth, these proline-rich, carboxyl terminal regions of Sm B/B' are the first targets of the anti-Sm response in all of the several serial lupus patient sera tested to date (107 ,161). Fifth, some animals immunized with this initial epitope constructed on a branching poly-lysine backbone develop a lupus-like illness (107 ,108 ,200). Finally, antibodies to this repeated antigenic sequence of Sm B' cross-react with a similar sequence of EBV nuclear antigen-1 (EBNA-1) (145). Immunization with this EBNA-1 sequence, PPPGRRP, also can lead to lupus like autoimmunity and features of clinical disease (208). Immunization of inbred strains of mice with EBNA-1 by DNA immunization can lead to anti-Sm and anti-dsDNA antibody production (209). Association studies have shown an increased prevalence of seroconversion to EBV in pediatric and adult SLE patients compared to matched controls (201 ,202 ,203 ,204 ,205 ,206 ,207 ,210 ,211). Additional work has shown intrinsic defects in the control of EBV infection attributable to an abnormal, immune response to EBV in SLE patients compared to matched controls (212 ,213 ,214 ,215). Additional extensive work has mapped the common antigenic regions of the Sm D1, D2, and D3 humoral immune responses in human SLE (163 ,166 ,179 ,180 ,181 ,182 ,183 ,184 ,185). Figure 26-3 partially summarizes the collective work evaluating D1 epitopes. The carboxyl region of Sm D1 contains a common antigenic humoral target, spanning amino acids 83–119 and containing a long glycine-arginine repeat (163 ,166 ,179 ,180 ,181 ,182 ,183 ,184 ,185). This epitope has been found to be a major target of reactivity in nearly all studies completed. This epitope is also bound by the Y12 monoclonal antibody which is derived from MRL lpr/lpr mice (163 ,181). The additional major targets of the Sm D2 and Sm D3 proteins are also quite basic and contain similar glycine-arginine rich regions (166). One study has shown that dimethylarginines in both D1 and D3 are found in these common

antigenic regions and are preferentially bound by patient antibodies (190). SLE patient sera also contain antibodies that cross-react with these antigenic targets of Sm D1 and glycine-arginine regions of EBNA-1 (163 ,186). This common carboxyl-terminal humoral antigenic region of Sm D1 has also been shown to provide T cell help for the production of anti-dsDNA antibodies in an animal model of lupus (216). Recent work has shown that intravenous injection of the parent D1 protein can postpone murine lupus and induce regulatory T cells (217).

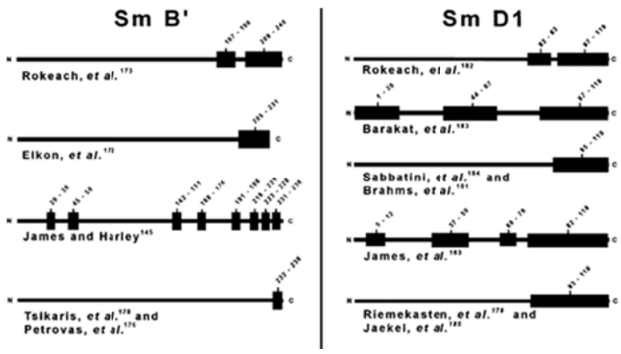

Figure 26-3. Summary of epitope mapping. Multiple groups have used various approaches to identify common humoral antigenic targets of Sm B' (74,172,173,174,175,176,177,178) and Sm D1 proteins (163,179,180,181,182,183,184,185). Antigenic regions of Sm B' identified by each individual study are presented in Panel A and common humoral epitopes of Sm D1 are presented in Panel B. These data are summarized in the following reviews (158,159).

The common humoral antigenic targets of the 70K and U1A responses have been reviewed in more detail in (158 ,159). Briefly, the 70K humoral epitopes have been evaluated by several different methods; however, nearly all studies have found key patient binding to the RNP-80 motif which is essential for binding of U1 snRNA (158 ,162 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196). Fine mapping of this RNP-80 region to key residues and additional 70K epitopes have also been described (158 ,162 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196). The humoral antigenic regions of the U1A response have been somewhat more diverse. Our group has described at least seven different sequential humoral epitopes, two of which are solely recognized by a subset of patient sera (164). One common area of antigenicity recognized by nearly all groups includes the RNP-80 region of U1A (158 ,164 ,197 ,198 ,199). Rabbits immunized with this RNP-80 common antigenic region develop antibodies to multiple different regions of U1A, develop other anti-Sm, anti-Ro, anti-nRNP, and anti-dsDNA antibodies, and develop renal insufficiency and thrombocytopenia (218). Rabbits immunized with another peptide epitope of U1A, which is recognized by various SLE patient sera and the monoclonal antibody which is "masked" by U1 RNA only make antibodies to the peptide of immunization (218). Less work has been performed with the nRNP C system to date.

T Cell Responses

Significant work has been done to characterize the common T cell responses and epitopes of the Sm and nRNP proteins in human SLE. Autoreactive T cells to Sm B', Sm D1, 70K, and U1A have been isolated from SLE patient peripheral blood (219 ,220 ,221 ,222 ,223 ,224 ,225 ,226 ,227 ,228 ,229). These are primarily $CD4^+$, TCR α/β^+ cells that produce substantial amounts of interferon-γ, moderate IL-2, and variable amounts of IL-4 and IL-10 (224). 70KsnRNP specific T cell clones can provide ex vitro help for anti-70K antibody production (228). Limited T cell epitopes have been mapped for these proteins and nearly all are located either in the Sm binding motifs of Sm B' and Sm D1 or the RNA binding domains of 70K. The TCR usage of these clones is quite restricted (226 ,227 ,228 ,229 ,230). Interestingly, recent work has suggested a novel mechanism for autoantigen cross-reactivity. Significant plasticity of TCR usage by autoreactive T cells in SLE showed that a single TCR can recognize two distinct snRNP autoantigen peptides with no primary sequence homology that are located on 70K and Sm B' specifically (223). These findings are nicely reviewed by Robert Hoffman (231).

Pathogenic Mechanisms

Evidence for direct pathogenicity of anti-Sm or anti-nRNP antibodies within SLE has not been clearly demonstrated. However, several evolving areas of investigation suggest pathogenic potential. Animal models that have shown the development of anti-Sm antibodies before clinical onset of disease support a potential pathogenic role for anti-Sm (107 ,108 ,109 ,179 ,200 ,217). Monoclonal anti-Sm antibodies have also been shown to penetrate live cells and localize to the nucleus (232). Finally, anti-Sm antibodies have been associated with the complement-fixing properties of antinuclear antibodies in SLE, which are not found in drug induced lupus antibodies (233). Additional investigation into potential pathogenic mechanisms of these responses is underway.

Acknowledgments

We would like to thank Ben Bruner for his technical assistance and our colleagues who have supported this research. This work is supported in part by grants from the National Institutes of Health (AR45451, AR48940, AR49084, AI47575, RR15577, AI062629, RR020143, AR48204, AR053734) and the Oklahoma Medical Research Foundation Lou Kerr Chair in Biomedical Research to JAJ and National Science Foundation award MCB-0426195 and National Institutes of Health AR052038 to CSL.

Chapter 27
The Lupus Anticoagulant and Antiphospholipid Antibodies

Gale A. McCarty

The antiphospholipid antibody syndrome (APS) is characterized by an ever-widening spectrum of clinical correlates, screening and confirmatory tests detecting diverse antigenic specificities, and both established and evolving models of in vivo pathogenesis (1 ,2 ,3). Chapter 65 considers clinical features of antiphospholipid antibodies (aPLs), specificities detected by enzyme immunoassays (EIAs), and primary/secondary treatment and management. For that set of aPLs that are classically, but ironically, called “lupus anticoagulants” (LACs) defined by coagulation-based tests, their historical development, techniques, new antigenic targets, and novel roles in pathogenesis are considered here.

Historical Perspectives

Circulating anticoagulants (CACs) are ubiquitous inhibitors of coagulation that are detected by abrogation of in vitro coagulation tests and in vivo coagulation. Specific CACs are most often but not always naturally occurring or acquired immunoglobulins (Igs) that either recognize epitopes on various coagulation factors at active sites and thus inhibit functional activity (e.g., an antibody to factor VIII), or do not recognize epitopes associated with the active site and are not always associated with pathology, e.g., the subset of LAC patients who have antibodies to prothrombin (anti-PT), which can be clinically silent, associated with bleeding, or rarely thrombosis. Nonspecific CACs include various LACs, paraproteins, or fibrin split products. LAC is defined here as a mixture of immunoglobulins (most commonly IgG/M/A) that interfere with one or more phospholipid-dependent coagulation tests, originally identified in patients with systemic lupus erythematosus (SLE). The multidisciplinary work on LACs that burgeoned from 1948 to 1983 (Table 27-1) served to explain and interrelate three prior discoveries: (1) reaginic antibodies reactive to ethanol tissue extracts of syphilitic sera in 1906 (i.e., the first aPL recognizing the mixture of the neutral phospholipids choline, cholesterol, and cardiolipin); (2) biologic false-positive serologic tests for syphilis (BFP-STS) in 1938; and (3) cardiolipin (i.e., a negatively charged phospholipid (PL) as its major antigenic component in 1941 (4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20).

From the initial description by Conley et al. (7) in 1948, the chronology of LAC reflects confusion because of limitations of available technology, as well as a lack of recognition of the complex symptomatology that eventually came to be associated with APS. Clinical associations such as bleeding (7), thrombosis (12 ,18 ,20), the BFP-STS (8), and fetal loss (9 ,20) were recognized but incompletely interrelated, even before Laurell and Nilsson (10) demonstrated that the factor responsible for LAC activity was an immunoglobulin, an observation extended to both IgG and IgM isotypes by Yin and Gaston (13). That these clinical features and laboratory components (Table 27-1) occurred in patients with SLE and with non-SLE diseases was shown by Bowie et al. (12) and Schleider et al. (16), and they encompass most major elements of what now is considered to be the spectrum of primary and secondary APS (12 ,16 ,20). Even before the naming of this CAC as “LAC” by Feinstein and Rapaport (14), several major areas reflecting pathophysiology and test variability were known; these include prothrombin-like cofactor activity (11), phospholipid dependence (7 ,11 ,15 ,17 ,18 ,19), and the common occurrence of paradoxic findings in LAC tests (17). Since the 1980s, consensus recommendations in nomenclature and technology have been sought for all LAC tests by the International Society for Thrombosis and Haemostasis, and analogously for aPLs as detected by EIAs by the aPL Standardization Committees and Workshops. Ironically, this chronology foreshadowed controversies about the interrelationships of LAC and aPL (8 ,10 ,13 ,14), necessary and sufficient plasma proteins or cofactors (11), and how understanding the importance of phospholipid-protein interactions, β_2 glycoprotein I(β_2GPI), and prothrombin (PT) has proffered new solutions to old paradoxes (8 ,15 ,19).

That LAC is a misnomer and attempts should be made to simply rename the entity as “a positive coagulation-based test” is supported by several tenets: (a) the majority of “LAC”-associated conditions are not associated with lupus, and represent the primary syndrome, or “lupus-like disease” in patients who do not meet criteria for the diagnosis of SLE, but may be evolving APS patients who will develop thromboses; (b) thrombosis is more common than bleeding, and (c) the number of patients who are being identified as having aPL by LAC or other aPL tests may alert the clinician

to consider special circumstances such as combined clinical conditions.

BFP-STS, biologic false-positive serologic tests for syphilis; CAC, circulating anticoagulant; Ig, immunoglobulin; LAC, lupus anticoagulant; PNP, platelet neutralization procedure.

Clinical Situations for Testing

Clinical presentations prompting coagulation testing primarily involve patients with unexplained bleeding or thrombosis, asymptomatic or symptomatic prolonged screening tests, or acquired coagulation abnormalities (dysproteinemias, lymphomas, other neoplasia, infections [chronic bacterial], human immunodeficiency virus [HIV], parvovirus, or drugs). The goal of testing is to differentiate the presence of a true phospholipid-dependent LAC from that of primary coagulation factor deficiencies (most commonly, factors VIII, IX, or XI, acquired immunoglobulin inhibitor[s] of these factors, or apparent coagulopathies due to binding of “LAC” to various plasma proteins that bind to phospholipid surfaces) (21). The important differential here is the risk of thrombosis in the LAC group versus that of bleeding, which more commonly is seen with the factor-deficient or factor-inhibited patients (4 ,5 ,6). The astute clinician will already have ruled out historical or age-related comorbidities suggesting causes of venous thrombosis that may exist independently of LAC or aPL positivity (e.g., protein S/C/antithrombin III deficiencies, activated protein C resistance because of the factor V Leiden mutation and activated protein C resistance, paroxysmal nocturnal hemoglobinuria, oral contraceptive use, nephrotic syndrome) or vasoocclusive disease states where vascular damage exteriorizes altered self components that might function as an “antigen driven state” and resultant procoagulant phenotype (e.g., hypertension, diabetes, smoking, intracardiac thrombi, Buerger's disease, hyperhomocysteinemia, or sepsis).

While the presence of LAC in health individuals ranges from 0% to 3.6%, anticardiolipin (aCL) positivity occurs in 1% to 9% of normals. Most studies analyzing LAC positivity show that approximately 45% occur in established or evolving SLE (22 ,23). LAC positivity approximates 15% in the peripartum state (24), and 12% in drug exposures, primarily procainamide (25 ,26), phenothiazines (27 ,28), chlorpromazine (29), and, rarely, procainamide and hydralazine (30 ,31). The remainder occurs in adults and children with viral infections (often transient), HIV or hepatitis C disease (sustained or intermittent), hematogenous or solid malignancies (32 ,33), or they are discovered in normal individuals undergoing preoperative assessment.

An important clinical subset are patients with hemophilia who acquired HIV via blood products and develop aPL or LAC that is uncommonly associated with thrombosis but risk bleeding caused by specific factor deficiencies (34). Rarely, immunoglobulins directed at von Willebrand factor (35), factor VIII (36), factor IX (37), factor XI (38), and fibrin polymerization (39), and protein S/C (40) occur in SLE, and characterization of factor inhibitors that can mimic these states is progressing. Increasing reports of LAC and/or aPL positivity with concurrent antibodies to specific coagulation factors should alert rheumatologists, hematologists, and both hospital and reference laboratory directors, to the importance of multidisciplinary management in these patients (40 ,41 ,42 ,46).

The prevalence of LAC activity in normal individuals as well as in patient populations varies widely because of several factors: (a) the vagaries of methodology and lack of adherence to standardization for performance of the most

commonly used test worldwide, the activated partial thromboplastin time (aPTT), and other screening and confirmatory CAC tests (43 ,44); and (b) the sparseness of studies in which both normal and patient plasma and sera were co-investigated for LAC and aPL, respectively, with sensitive and specific screening as well as confirmatory tests that demonstrated PL-dependency or where a platelet neutralization procedure (PNP) was performed (45 ,46) (Table 27-2). In SLE, the prevalence of LAC varies from less than 10% to approximately 40% relative to the sensitivity and specificity of the individual screening and/or confirmatory test procedures used (21 ,22 ,23 ,44 ,45 ,46) Other studies cumulatively show higher percentages for aCL (69%) versus LAC (48%) positivity in SLE sera analyzed concurrently by multiple methods; when populations are examined based on investigation at the time of a thrombotic event, the percentages are proportionally higher in some studies and in others they are lower, due to aPLs being involved in tissue deposition and/or immune complexes (47 ,48). Of note is that when patients are retested within 2 months of an index event, there is a demonstrable, incremental benefit in diagnosis, especially for LAC testing; performance of a repeat test and a second, different test increases the chance of demonstrating an aPL or a LAC (49) (see Chapter 65 for detailed epidemiology of LAC). That LAC and aPL are heterogeneous antibodies recognizing related but different antigenic determinants is indisputable, and there is a wide range of concordance (0% to 60%) between the functional (e.g., LAC) and the immunologically (e.g., BFP-STS, aPL) derived test procedures.

Table 27-2: Comparative Aspects of Major LAC Tests

	aPTT	KCT	dRVVT	TTI (dPT)	Textarin Time
Test choice	1st	2nd	2nd	2nd	2nd
Sensitivity for LAC	Very	Intermediate	High	Intermediate	High
Screen and confirm LAC	Y/N	Y/N	Y/Y	Y	Y/Y
Phospholipid source	Cephalin	None	Thrombofax	TF/thromoplastin	None/platelets
Initiator	Silica/kaolin	Kaolin	Russell's viper venom	(See text)	Pseudonaja textilis and Ecarin venoms
Normal (secs)	25–35	60–100	25–30	Ratio, <1.3	20–40
Use in pregnancy	N	Y	Y	Y	Y
Resistance to factor deficiency/inhibition	Variable	Variable	Most resistant (except low X, V)	(See text)	Except V
Sensitivity to heparin	Y	Y	N	N	(See text)
Mechanized test	Y	Y	Y	Potential	Potential
Specificity	Low	High	High	High	(See text)

aPTT, activated partial thromboplastin time; KCT, kaolin clot time; dRVVT, dilute Russell's viper venom test; TTI (dPT), tissue thromboplastin inhibition test (dilute prothrombin time), TF tissue factor, Y, yes; N, no.

Laboratory Diagnosis of LAC

Figure 27-1 shows the classic coagulation scheme, which involves dynamic interactions among cellular, protein, phospholipid, and calcium ions that are localized and controlled in space and time. That procoagulant reactions occur faster than fibrinolytic reactions is an important concept to recall as the molecular basis for thrombosis evolves.

Since 1964, coagulation has been thought to be initiated by the intrinsic pathway (i.e., contact factor components)

or the extrinsic pathway (i.e., cell membrane proteins and tissue factor [TF]), with either pathway resulting in factor Xa generation and eventual thrombin formation (50). Testing for the intrinsic pathway involved the aPTT, and for the extrinsic pathway the prothrombin time (PT) (51). In 1996, the accepted scheme involved TF VIIa complexes initiating coagulation via factor X, sustaining the process via factor IXa activation of factor VII, and completing the process by activation of factor XI. Figure 27-2 shows the two classic tenase complexes and the prothrombinase complex; these represent three of the four major phospholipid-dependent coagulation processes.

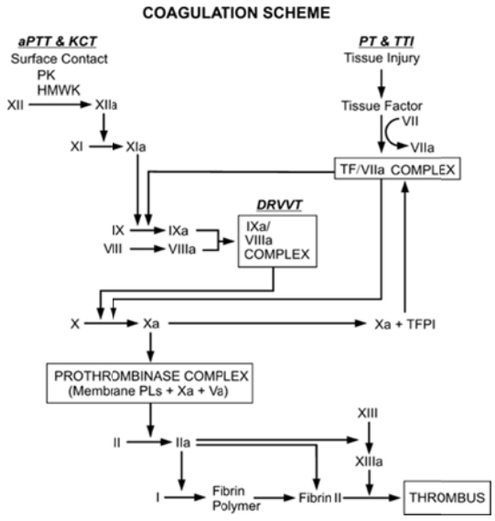

Figure 27-1. The coagulation scheme updated from 1964 to the present, with the three main phospholipid-dependent complexes highlighted in closed boxes (the two classic tenase complexes, tissue factor/factor VIIa and factor IXa/factor VIIIa, and the prothrombinase complex; membrane phospholipids, factor Xa, and factor Va). Relevant coagulation tests are listed in italics for respective sections of the cascade. The end result is thrombosis.

Endothelial cell or platelet damage or activation exposes negatively charged inner membrane leaflets or reorganizes phospholipid arrays. The vitamin K-dependent clotting factors bind to these charged phospholipid surfaces, and platelet receptors allow adherence to subendothelial connective tissue and other sites (Fig. 27-2A-D). The endothelial cell surface itself modulates its procoagulant versus anticoagulant properties via thrombomodulin and the activated protein C/protein S complex (i.e., the fourth phospholipiddependent complex [Fig. 27-2E]). Coagulation therefore is localized to sites of vessel injury and restricted there by binding to negatively charged phospholipid/membrane components that are not normally accessible. Recently, the elucidation of the thrombomodulatory role of annexin V as a regulatory “shield” that clusters on exposed PL-rich surfaces and abrogates the binding of aPL or LAC to PLs in the maternal-fetal unit will likely be shown to be operative at other endothelial cell sites.

Thus, several phospholipid-dependent complexes have the capacity to be influenced by LACs or different aPLs. Additionally, the natural anticoagulant $ß_2$-glycoprotein I, or apolipoprotein H) has affinity for anionic phospholipid as well as other coagulation components; phospholipid flip-flop or loss of membrane asymmetry that exteriorizes or exposes phosphatidylserine (PS), or other phospholipids, via the translocase reaction after membrane perturbation or injury might contribute to immunogenicity by revelation and/or creation of neoepitopes ($ß_2$GPI dimerization, CL/plate irradiation) which might drive LAC/aPL production (52).Thus, there are multifactorial ways in which these antibodies might interact in vivo to generate a procoagulant surface, which might then continue to drive phospholipid-dependent coagulation reactions. Recent vascular injury models in the presence of aPLs or LACs have shown augmentation of cell functions and thrombosis size or frequency (see Chapter 52).

Rationale for Screening Tests

The minimal laboratory assessment for all coagulation abnormalities includes an aPTT, a PT, and a platelet count as a first step (53). The second step is the determination of LAC by demonstrating that the prolongation of the screening test results from an antibody and not a quantitative or qualitative coagulation factor deficit or inhibition. Mixing normal plasma with patient plasma does not correct the aPTT prolongation to normal with most LACs, whereas mixing with normal plasma usually does partially or completely correct aPTT prolongation by the provision of normal clotting factors. This is not infallible, as some aPLs act at multiple levels or on multiple factors in the coagulation scheme.

The definition of a screening test is an assay that is based on a single concentration of phospholipid (54). The major tests compared are the aPTT, the kaolin clot time (KCT), the dilute Russell's viper venom test (dRVVT), the tissue thromboplastin inhibition (TTI) test (otherwise known as the dilute PT), and the Textarin time test (Table 27-3). Other tests include the plasma clotting time (PCT), and new integrated systems where multiple reagents are incorporated in reaction mixtures (PLs or chromogenic substances) (46 ,54).

A source of confusion for nonhematologists interpreting the literature is use of the descriptive phrase that a test component is “sensitive to the presence of the LAC”; often, this is misinterpreted as the test has high sensitivity. When referring to aPTT reagents, reagent sensitivity means that the abnormal aPTT results from the presence of a LAC, while reagent responsiveness means the degree of test prolongation (46 ,53). Thus, reagents often are classified in terms of paired sensitivity/responsiveness, and as laboratories strive to improve tests in different size study populations, inconsistencies in comparative results occur. This is the basis for both past (46) as well as current (55 ,56 ,57) recommendations that even if the screening aPTT is normal, an additional screening test is recommended.

Because LACs are heterogeneous, no single test detects all LAC, and no one test approximates 100% sensitivity or 100% specificity. Caveats and special circumstances are clarified in this text to reflect these methodologic considerations as an evolving area; while a majority of experts now agree that two tests need to be performed (one screening test and a confirmatory test), there are some who espouse that perhaps a third test be added, but they remain in the minority at this time. Figure 27-3 provides an overview of some comparative aspects of LAC screening and confirmatory testing and represents a consensus from clinical experience and the current literature (46 ,54 ,55 ,56 ,57 ,58).

The laboratory criteria for LAC testing, as established by the Scientific and Standardization Committee Subcommittee for the Standardization of Lupus Anticoagulants in 1991 (57), have been simplified by Exner et al. (57) to represent the minimally acceptable criteria to define LAC: (a) an in vitro, phospholipid-dependent coagulation test must be prolonged; (b) an inhibitor (or LAC) must be demonstrable as the cause by mixing studies using appropriate ratios of patient-to-normal plasma; and (c) the inhibitor (or LAC) must be differentiated as being directed at a phospholipid, preferably a hexagonal phase II PL, not at a specific coagulation factor (46 ,54 ,55 ,56 ,58). However, recent data reviewed by Exner (5) show that correction of test abnormality by PL is more specific for LACs than the platelet neutralization procedure that has been “recommended” since 1984. The most recent recommendations from the Subcommittee, summarized by Brandt et al. (21) in late 1995, are similar and state appropriately that despite excellent and careful research, both the ordering physician and the patient must be aware that aPLs are very heterogeneous, and that even well-standardized

LAC assays may have a range of sensitivity for the detection of certain subgroups of LACs.

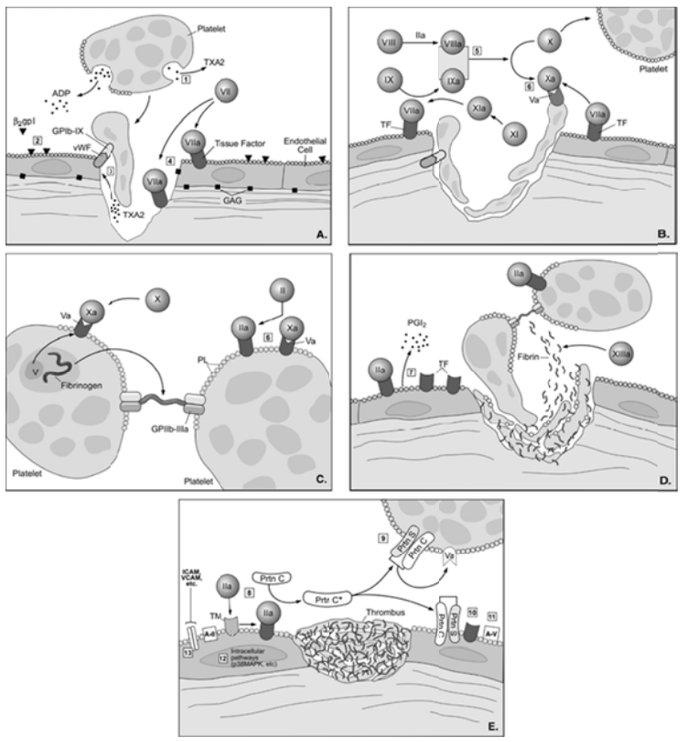

Figure 27-2. The coagulation scheme occurring at a localized site of vascular injury or altered self. The luminal side is up; the basement membrane side is down. For this series, phospholipids (PLs) on cell membranes are designated by open circles on the luminal side; ß glycoprotein I (2GPI) by a black triangle; glycosaminoglycans (GAGs) in subendothelial areas by a black square; coagulation factors by shaded and numbered circles, often bound to tissue factor (TF), with activated coagulation factor fragments as specified and shown by stippled receptors. The boxed numbers 1 to 13 refer to areas where lupus anticoagulants (LACs) and antiphospholipid antibodies (aPLs) have either been proven or suspected to interact with cell surfaces, coagulation components, or PL-dependent binding reactions. *A–D*, The steps in Fig. 27-1 culminate in the formation of a thrombus at the site of a vessel injury or altered self. *E:* The fourth main PL-dependent complex is added, that of protein S/C and thrombomodulin (TM, cross hatch) The annexin V shield has been added (A-V). Thus, LACs and aPLs also may work in effecting the return to an anticoagulant surface after procoagulant effector molecules have resulted in thrombosis. TF, tissue factor; TXA2, thromboxane A2; vWF, von Willebrand factor.

Table 27-3: Antigenic Targets of LAC/aPL

Antigen:	Autoantibody Type:	Test:
$ß_2$GPI	LAC Type 1	Coagulation
	aCL Type 1	aCL ELISA
	anti-$ß_2$GPI	a$ß_2$GPI ELISA
Prothrombin	LAC Type 2	Coagulation
	(Low Affinity)	aPT ELISA
	LAC Type 3	Coagulation
	(High Affinity)	aPT ELISA
Anionic PL	aCL Type 2	aCL ELISA

Additionally, the Subcommittee recommends the following: (a) two or more different screening tests should be performed for LAC, one of which should be a low phospholipid concentration test (KCT, dRVVT, dilute aPTT, daPPT, dPT); (b) the presence of inhibitor activity should be determined by incorporation of a mixing step (i.e., patient plasma's effect on pooled normal plasma) in the initial screening test, using a well-characterized pooled normal plasma; (c) documentation of multiple abnormal screening tests is not presumptive evidence of a LAC until phospholipid dependence is established; (d) confirmatory tests should be based on methodology similar to screening tests (Fig. 27-3); (e) a PT and an aPTT should be performed before screening LAC tests to rule out other coagulation factor disorders that might affect LAC determination, and they should be based on clinical history; (f) heparin presence should be determined by a thrombin time before screening or confirmatory LAC tests if the tests used are sensitive to heparin; (g) concurrent positivity of patient sera for aPL enzyme-linked immunosorbent assay (ELISA) is not considered to be a confirmatory test for the presence of LAC by one method; and (h) the current LAC nomenclature should be retained until a more definitive understanding is available regarding its pathophysiology, although there is universal awareness of the need to consider shedding the

“LAC” designation (58). Lastly, the Subcommittee has not re-addressed the need to consider that some LAC are time dependent, such as factor VIII inhibitors because of the time it takes for factor VIII antigen to dissociate from von Willebrand factor.

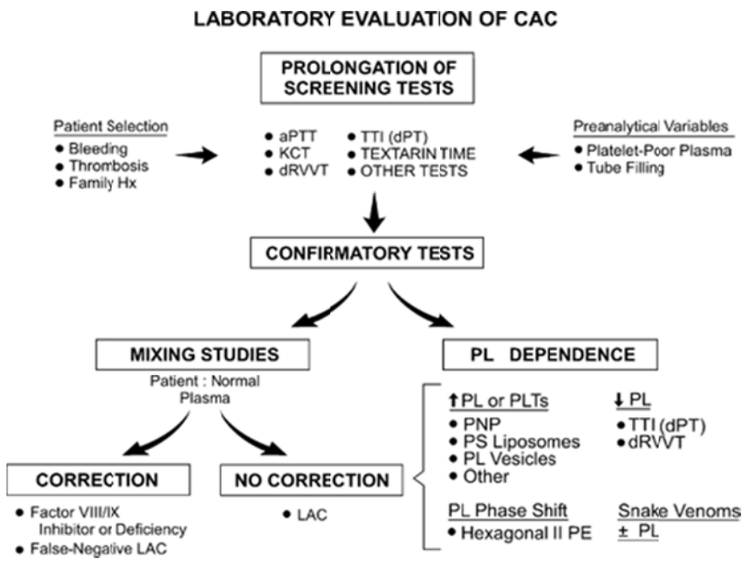

Figure 27-3. The laboratory evaluation of circulating anticoagulants, with the main procedures highlighted in closed boxes (demonstration of a prolonged screening test, performance of a confirmatory test, usually not the same test as the screen, with mixing studies of patient and normal plasma, and demonstration of phospholipid dependence by one of a variety of means). The presence of a LAC often is determined when the mixing study does not correct to normal, thus separating LAC from coagulation factor inhibitors or deficiencies. Phospholipid dependence is now favored over platelet neutralization procedures.

Thus, there are many bases from both past (46) and current (57 ,58) recommendations supporting the premise that even if the screening aPTT is normal, an additional screening test is recommended. Both aPL and aPTT tests appear to be warranted.

Pre-Analytic Variables

Preparation and handling of patient and normal plasma used for both screening and confirmatory studies (e.g., mixing studies or phospholipid dependence) may be affected by the following: (a) less than 50% filling of the anticoagulated tube with patient blood does not afford the proper dilutionary effect; (b) the type of anticoagulant that is used in the tube may be a source of variation; (c) temperature during processing and handling, as membrane microvesicles might be created during a freeze-thaw cycle, gives an in situ PNP and thus a false-negative test result; (d) the pH of the mixture as it changes over incubation time may range from physiologic to 8.2, at which level factor V is likely to be selectively destroyed; and (e) the presence of platelets or platelet fragments (which provide a source of factor V, other procoagulants, and platelet factor 4) that decrease the sensitivity of tests using low phospholipid concentrations because they bind aPLs. Gentle centrifugation (10 minutes, 5,000 to 10,000 g) and/or filtration (pore size 0.22 μm) is recommended to avoid platelet fragmentation and release of platelet factors via activation that can augment coagulation or affect von Willebrand factor assays (5 ,58).

A recent study comparing commercial re-agents for the detection of LA using a photo-optical array versus a mechanical coagulometer showed that considerable variation in sensitivity and specificity was noted for the same reagent used on the different analyzers, as well as between reagents. Thus, there remains a need to address optimization of reagents for specific analyzer types.

aPTT Test

The sensitivity of the aPTT varies proportionally with the nature of the commercial reagents, including the activator, and the source, amount, composition, and physical state of the phospholipid. That excess phospholipid shortens the prolonged aPTT because of LAC is the basis for the development of tests on this model, and the aPTT is more sensitive than the PT to the

presence of LAC. PS concentration and lipid phase (either bilayer or hexagonal phase II conformation) (59), either in the phospholipid in aPTT reagents or the phospholipid in tissue factor reagents, may be operative here. Modifications to increase sensitivity have included using a dilute phospholipid or increasing the dilution of the aPTT reagents (daPTT) (5), but studies have shown that increasing the incubation time rather than the phospholipid concentration may be more important (i.e., dual-incubation aPTT) (58).

That LAC may show time dependency, a feature that previously was relegated to factor deficiency or inhibitor states, has been recently recognized, and extended to include effects related to the pH of the mixture, which varies with time. Addition of 0.05 M HEPES buffer in one study looking at the aPTT over time showed that a stable pH using platelin as the re-agent was achieved (57). Comparative assessments have shown that several reagents (i.e., actin FSL, automated aPTT, and ThromboSol) are sensitive to LAC (60 ,61 ,62). Recent advances such as the Staclot-LA reagent have incorporated a heparin blocker and hexagonal phase II lipids in the incubation mixture for increased specificity, but mechanically this test is more difficult. Some IgM LAC may be missed with this test as well. While rising factor VIII levels have often limited the usefulness of aPTT during pregnancy in prior studies (46 ,53), Blanco et al. (60) showed that the standard aPTT was more useful during pregnancy than the daPTT. False-positive aPTTs occur with contact factor deficiencies, heparin, factor VII inhibitors, and factor IIX/VIII deficiencies (4).

KCT Test

The KCT test is an aPTT without a platelet lipid source, and the activator is provided by kaolin (clay). Current recommendations state that a 2% suspension in water is a more sensitive text mixture, as sodium chloride hastens the precipitation of kaolin out of suspension. Platelet poor plasma is most critical for the KCT (46 ,53 ,58). Its sensitivity is intermediate between that of a sensitive aPTT and the dRVVT, and it is considered to be a test with high specificity. The modified KCT is considered to be useful in the detection of low-titer LACs. Like the aPTT, KCT can have false-positive results under the same conditions as noted earlier. Exner (5) has improved its performance with 4:1 dilutions of plasma, and the test now has been automated because of the ability to decrease the kaolin concentration from 12 to less than 1, thus permitting photoelectric quantification. Additionally, in paired samples with KCT and DRVVT (LA Screen, Gradipore, Sydney, Australia), a platelet count of 1×10^9/L will obviate a positive KCT but will not affect the dRVVT results.

dRVVT Test

Developed by Thiagarajan et al., this test is increasingly used worldwide investigationally and clinically, and it is unique in being a screening as well as a confirmatory test (46 ,53 ,58). Sources of both phospholipid and venom may affect the test, and it now can be performed in a single vial. It requires low phospholipid concentrations. The venom activates factor X, bypasses factors VIII, IX, and contact factors, and eliminates some of the poorly understood effects in LAC testing that can either lengthen or shorten the tests. Polybrene or other heparin inhibitors may be added, which will not give false-positive results, but without these additives the dRVVT may yield false positives with patients who have been on heparin. Sensitive reagents include the LA-Confirm and the DRVV-Confirm.

Like the previous two tests, the dRVVT is sensitive to factor VII inhibitors or factor IX/VII deficiencies, but it is prolonged only in very high-titer factor VIII inhibitors. Therefore, in reality, it is the most resistant (6). The dRVVT is useful during pregnancy as it is independent of the naturally occurring increase in some clotting factors, and does not give false-positive results with contact deficiencies. In the most recent recommendations, it is considered to be the next test after an aPTT (58). In our experience with 392 APS patients followed between 2 and 4 months longitudinally from 1996 to mid-2000, two caveats have emerged: (1) 20% of all patients will only be positive by an LAC test; (2) in paired simultaneously drawn sera/plasma samples, the DRVVT was 3 to 5 times more likely to identify an aPL than the standardized aPTT (McCarty, Indiana APS Database Project, 1996–2000; Univ of Va Database 2000–2003).

TTI (dPT) Test

This test is a dilute PT performed with varying dilutions of tissue factor (TF) or thromboplastin and expressed as a ratio of patient-to-normal PT. A major source of variation is the lack of a standardized normal plasma, which is a common complaint with many of these tests. Because the TTI assesses all three critical phospholipid-dependent coagulation reactions, it seems ideal for a LAC screening test. Like some aPTT variations, however, IgM LAC may be missed. Like the dRVVT, it does not give false-positive results with contact deficiencies, and heparin inhibitors have been added to the reagents to increase the utility of this test. Direct data on use in pregnancy have not been reported, but the test is likely to be useful in pregnancy. Recombinant human TF modifications by Zanon et al. (63) and Arnout et al. (64) are attempts to provide a uniform reagent for the TTI. The TTI because of its use of TF as a reagent may be optimized to more selectively identify anti-β_2-glycoprotein I antibodies, as recent studies have shown that this specific aPL may enhance tissue factor activity on monocytes.

Textarin Time Tests

Venom from *Pseudonaja textilis* and *Echis carinatus* snakes is used in these tests, popularized by Triplett et al. (65), which were developed as a confirmatory test but actually violate the definition of a confirmatory test in that phospholipid is not augmented to demonstrate correction (58). The basis for this test is the difference in the phospholipid requirements of the two venoms. Currently, it is considered to be the

most specific test available for LAC, and interest in its development is based on a high specificity for phospholipid effects on the prothrombinase complex. The Textarin time is compared with the Ecarin time here. These tests are resistant to factor inhibitors or deficiencies, except for factor V.

Other LAC Tests

In contrast to the above functional tests, an ELISA using partial thromboplastin derived from human brain as the antigen was developed for detection of LACs (64). This assay circumvents some of the disadvantages of coagulation assays and is highly sensitive and specific. A synthetic reagent called Synthesil in preliminary tests compared well to rabbit thromboplastin. Additionally, Schjetlein and Wisloff (66) have developed an integrated test system, adapted for computer analysis, that uses aPTT and dRVVT comparison between normal plasma and a mixing test with high PL. Finally, the PCT requires fresh plasma and is unaffected by the presence of platelet membrane fragments in re-agent preparations, but is not generally performed. A new silica clot test appears to be more sensitive, specific, and predictive of thrombosis in APS patients when compared to parallel determinations of DRVVT but remain to be confirmed by others (67).

Rationale for Confirmatory Tests

The observation that excess phospholipid substantially shortens the prolonged aPTT because of LAC has been exploited to distinguish LAC from other CACs. As shown in Fig. 27-3 , the PNP by PS liposomes, and rabbit brain phospholipid are common ways to demonstrate phospholipid dependence. The PNP has been particularly recommended since its inception in the early 1980s as a confirmatory test for aPTT-based tests and the dRVVT. Platelet vesicles are particularly suited for the dRVVT and KCT. Phospholipid dilutions are best matched with the TTI (dPT) and the dRVVT. Hexagonal phase II phospholipid also is used to confirm aPTT results.

Special Cases

Despite appropriate precautions, discrepancies often occur with these tests, and paradoxic results are sometimes the legacy of LAC testing. Several clinical situations may arise to challenge the clinician and the consulting hematologist or laboratory director.

Specific factor inhibitors may cause false-positive results with confirmatory LAC tests. The performance of factor assays using two or more dilutions of patient plasma may be helpful if the clinical history and screening aPTT and PT results are not. LACs often have a dilutional effect on several specific factor activities, whereas specific factor inhibitors are associated with a low level of one factor that does not change with dilution. The LAC can artifactually decrease the values by impairing the reactivity of the PL reagents. One approach is to perform several of the specific, one-stage clotting factor assays based on the aPTT technique (e.g., factors VIII, IX, and XI) (46 ,57 ,58).

Strong factor inhibitors may cause dilutional effects on levels of other factors to which they are not directed specifically. Thus, the absence of a dilutional effect is not presumptive evidence that LAC is not present.

High-titer LACs may artifactually appear as a factor deficiency when a sensitive aPTT is used, without the dilutional effect mentioned earlier. In this setting, specific factor antigenic assays should be performed.

The hypoprothrombinemia-LAC syndrome is an important clinical entity because the prothrombin deficiency resulting from this LAC-like antibody that binds to prothrombin in vivo may result in significant bleeding. Hypoprothrombinemia might also result from direct-acting anti-PT antibodies. Additionally, binding in immune complexes if active aPL antibodies are proximal is possible. This is the modern correlate of the classic LAC misnomer, although its existence was reported in 1959 by Loeliger (11). Prothrombin-LAC immune complexes cause an artifactual hypoprothrombinemia by their normal removal from the circulation, but prothrombin function in the in vitro assays is normal. The clinical clue here is the finding of a substantially prolonged PT, beyond the range that is noted for LAC (e.g., 18 to 20 seconds). Prothrombin antigenic activity is present but the level is decreased and abnormal mobility may be electrophoretically present (68). SLE, viral infections, drugs, and idiopathic etiologies have been associated with this syndrome (69). Prothrombin antibodies have all reacted with epitopes on the carboxy terminal segment of the prothrombin molecule (67). Whether these are distinctive antiprothrombin antibodies or represent part of the antigenic target spectrum of LAC/aPL reactivity with epitopes on prothrombin and anionic phospholipids, however, remains unclear (70).

Caveats on Testing

The innate heterogeneity of aPLs and the features of APS are mirrored by the necessity to perform several levels of screening and confirmatory testing, and the vagaries of LAC screening and confirmatory tests remain protean despite significant new knowledge regarding multifactorial mechanisms by which aPLs interfere with coagulation. Large meta-analyses are difficult because of the rare performance of simultaneous or longitudinal standardized studies, so summary statements regarding overall sensitivity and specificity remain incorrect and misleading if taken out of the context of the individual test. As has been noted for the EIA-based aPL tests since the publication of the Sapporo criteria, the trend is toward the performance of two tests for LAC (aPTT and DRVVT), coupled with the caveats for addressing pre-analytical variables such as sample obtainment and reagent matching for type of analyzer. Appropriate studies regarding the positive predictive values of individual as well as panels of tests are needed. A synthesis of current laboratory approaches to diagnosis LACs has been used to generate Fig. 27-3 . Table 27-2 addresses specific caveats regarding individual tests.

The 1995 update from the Scientific and Standardization Subcommittee (21) supports performing two screening tests (i.e., an aPTT plus another test, such as dRVVT) and further evaluating those tests results either sequentially or concurrently. If both an aPTT and dRVVT are abnormal, a mixing study of patient and normal plasma is done. If the mixing study is abnormal, then progression to demonstration of phospholipid dependence is performed, and if positive, LAC is confirmed. If the initial mixing study corrects to normal, then an incubated mixing study is performed. If the incubated mixing study fails to correct to normal, then the demonstration of phospholipid dependence is next. If it corrects to normal, then specific factor assays are done. Although no specific protocols are as yet agreed on for mixing studies, these tests are relatively easy to perform in most laboratories and may be helpful cost-savers as standards and methods for LAC indices or calibrations evolve.

Mechanisms of LAC Action

A consideration of proven and putative mechanisms of action for LAC supports the contention that they are separable activities from other aPLs in some ways (13) (see Chapter 52). The reader is referred to Fig. 27-3 , in which both proven and putative mechanisms of action that are relevant to coagulation components and vascular injury models are indicated by numbered squares. Although there exist murine induction and vascular injury models that produce with some fidelity the major features of APS and a fulfillment (to some extent) of Koch's postulates for their contributions to pathogenicity, the full in vivo correlates of these likely mechanisms are still not fully understood. Recent reviews examined the hypotheses that concepts regarding the relevant antigens should be extended beyond phospholipids only (i.e., the antiphospholipid antibody protein syndromes) (71 ,72 ,73 ,74).

Phospholipid Binding

Anionic phospholipid binding initially was demonstrated for an IgM monoclonal LAC (75) and, since then, for sera and plasma samples using affinity purification (76 ,77 ,78 ,79). Studies using affinity-purified patient IgGs and improvements in column chromatography of LAC plasma have fostered the reexamination of anionic phospholipid binding. The discovery of $ß_2$GPI as a major antigenic target of aPLs has prompted this re-evaluation. The presumed form of the phospholipid was a lamellar array but subsequently was shown to be a different phase form changed by calcium and PS. When critically examined, the data for direct cardiolipin binding in the absence of $ß_2$GPI or other lipid-protein interactions have been based primarily on the initial IgM monoclonal LAC (75 ,78 ,79). Perhaps other anionic phospholipids such as PS will prove to be more important or that the true epitopes represent phospholipid–protein-lipid combinations that are recognized differentially by LAC and aPLs (Fig. 27-2A).

$ß_2$GPI, Prothrombin Interactions

LACs were shown to be chromatographically separable into two different populations using phospholipid liposome preparations (79 ,80 ,81 ,82 ,83). The identification of $ß_2$GPI, a natural anticoagulant as the cofactor responsible for a prolonged PTT or KCT of patient plasma lengthening further with the addition of normal plasma (i.e., the source of ßGPI) has allowed the profiling of aPLs into different sets (Table 27-2) (many aPLs and some LACs also have been shown to require ßGPI for binding (82 ,83). These (Table 27-3) enhance the inhibition of prothrombin conversion by $ß_2$GPI; thus, the LAC effect in plasma results from enhancement of $ß_2$GPI binding (80 ,81 ,82 ,83). Although this research has opened several new areas of mechanistic consideration, there are still some areas of controversy (71 ,72 ,73 ,74 ,80 ,84). However, the irony that is intrinsically associated with LACs continues in that although $ß_2$GPI is a natural anticoagulant, patients who are genetically deficient in $ß_2$GPI paradoxically do not appear to be at risk for thrombosis (71 ,72). Recent studies by Hwang et al. have shown multiple patient-derived monoclonal antibodies react to prothrombin and/or thrombin, and thus inhibit feedback regulation of thrombin (84).

Prothrombinase Complex and Other Phospholipid-Dependent Coagulation Reactions

LACs have been shown to interfere with phospholipid-dependent coagulation reactions in the presence of human plasma (79 ,80 ,81 ,82 ,83). Three potential sites exist where LAC might bind and shift the balance from an anticoagulant to a procoagulant surface on endothelial cells or platelets (Fig. 27-2B). Because LAC affects all phospholipid-dependent reactions, its site of action is at least at the level of the prothrombinase complex. The inhibition is specific for human, but not for bovine, prothrombin and required phospholipid vesicles (83). Thus, this population of LAC is different from the antiprothrombin LAC described later. The anticoagulant effect of LAC likely results from binding to the phospholipid-bound human prothrombin complex once calcium has also bound. That this reaction could occur on platelet surfaces was shown by the substitution of activated platelets or platelet-derived vesicles as phospholipid sources (79 ,84 ,85). An IgM monoclonal LAC was shown to inhibit factor X activation by the intrinsic tenase complex, thus confirming previous direct LAC binding to anionic phospholipids.

Endothelial Cell/Platelet-Protein S/Protein C and Thrombomodulin Interactions

Prostaglandins are major products of endothelial cells and platelets, and their production is important in maintaining the neutrality of a coagulant surface. LACs (and aPLs) have

been shown to stimulate prostacyclin release from endothelial cells in both patients with and without thrombosis (71 ,72 ,79). Thromboxane A2 has been shown to inhibit endothelial cell production of procoagulant molecules and thus plays a role via its balance with prostacyclin (PGI_2) (Fig. 27-2A). Once tissue injury occurs, TF on the cell surface, and glycosaminoglycans (GAGs) from the subendothelium may become exposed, and GAGs are important in determining the anticoagulant properties of the endothelial cell surface (Fig. 27-2A,E). Platelets are thought to bind LAC (as well as aPL), but most LACs may require only platelet activation to bind, independently of $ß_2$GPI, although some LAC may be dependent (84 ,85). It currently is unclear whether this binding generates procoagulant effects. When thrombin binds to thrombomodulin on the surface of endothelial cells, an anticoagulant milieu is generated, protein C is activated, and, once complexed with protein S, is capable of inhibiting factors Va and VIIIa. Currently, LACs are thought by some investigators to inhibit thrombomodulin-mediated activation of protein C, although this has been questioned (71 ,72 ,79 ,84 ,86 ,87) (Fig. 27-2E).

Other Antiphospholipid Antibody ELISA Tests and Their Phospholipid Targets

A consensus statement on the preliminary classification criteria for definite antiphospholipid antibody syndrome in 1999 now referred to as the Sapporo Criteria represented the extensive work of an international panel of physician-investigators and laboratory researchers to put forth general guidelines based on the most widely used tests (the IgG/M aCL enzyme-linked immunoabsorbent assay [ELISAs] as described in Chapter 55 , and one or more LAC tests as detailed in this chapter and meeting specifications (55 ,56 ,57 ,58 ,88). There are some caveats: (1) as with most clinical guidelines, the criteria may not be applicable in an individual patient, who may not make these particular antibodies or have only these manifestations of APS; (2) that proven thrombotic events were required to be temporally relevant to positive tests, and (3) strict exclusions were refined for the diagnosis of APS-related fetal loss (88). Despite the widely known studies since 1990 showing that $ß_2$GPI binding to CL and dimerizing molecules forming a neoepitope that is the most frequent antigenic target of aPLs, anti-$ß_2$GPI tests were not considered in the Sapporo Criteria, because very low percentages of APS patients exhibit solely this antibody. The updated International Consensus Statement by Miyakis et al. now includes this test (89). Despite use of the Harris standards for IgG/M ELISAs in second- and third-generation kits, various commercial and hospital labs use different criteria for the definition of aPL positivity. Some of the variability in aPL assays has been shown to be related to the provision of adequate $ß_2$GPI in the diluents in the ELISA tests, which initially used fetal or newborn bovine serum as blocking agents or patient sera diluents (88 ,89 ,90 ,91 ,92). Most of the negatively charged PLs (CL and PS) require $ß_2$GPI as a cofactor. Buffers containing only $ß_2$GPI do not detect aPL that are dependent on other PL-binding proteins such as prothrombin or protein C, or those such as aPE that require the low or high molecular weight kininogens (LMWK-HMWK), and are clinically relevant to patients, being associated with the same APS clinical criteria as cited above. Recent characterization of patient-derived monoclonals show that additional targets of aPLs include tissue plasminogen activator (91). The incremental value of adding IgA aPS and IgA aPE testing to IgG and IgM aCL ELISA testing in 5632 patients with APS-associated events has been well demonstrated to additionally identify patients who would otherwise be considered “seronegative” and therefore not be identified for treatment by McIntyre et al. (92). IgA isotype testing and anti-$ß_2$GPI testing has been suggested by Harris as the next steps to consider in IgG/M aCL/LAC negative patients with APS symptoms in a recent review; the prevalence of IgA aCL responses may also be related to ethnicity rather than methodology (90).

Animal Models

Most work on APS has involved the passive or active immunization of purified human IgG aCL or purified PL antigens into nonautoimmune prone or naive mice. aPLs are not exclusively produced by autoimmune mice such as the MRL/lpr and the (NZW × BXSB)F1 strains, but develop in the nonobese diabetic (NOD) mice; several recent reviews address this subject in detail (93 ,94). Demonstration of thrombocytopenia, autoimmune hemolytic anemia, decreased fertility due to involution of murine pregnancies, and placental thrombotic micro-angiopathy have been found for CL and PS antibodies by active induction (93 ,94). Active induction studies with $ß_2$GPI show decreased fecundity, elevated APTTs, and hemolytic anemia, but no clinical thromboses: some mouse models develop aCL, aPS, aPI (phosphatidylinositol) in response. In most experiments, CL alone is not immunogenic by itself in most of the early studies but the response is enhanced by its cofactor. The spontaneously developing aPL mice produce functional antibodies but may not faithfully reproduce human pathology-only male NZB/W F1 mice develop arterial thrombosis, and aCL have been detected in mouse strains without clinical APS features. Another approach has been to induce an endothelial cell pinch injury by clamping femoral or cremasteric veins, infuse aCL or other aPLs, and evaluate the kinetics of thrombus formation, size, and platelet content, showing aPLs do induce thrombosis at sites of vascular injury in vivo (95).

When immunized with $ß_2$GPI, mice made antibodies to this antigen and to aCL; when immunized with human IgG, murine aCL and anti-human IgG were produced, and mean thrombus area was significantly greater in these groups than controls immunized with human serum albumin. These murine aCLs were thrombogenic analogously to the passively immunized mice in other models, showing thrombogenicity is related to aCL specificity rather than to the source of the aCL. Recently, this group has shown that some human IgG monoclonal aCL and aPS antibodies

recognize 15 amino acid sequence GDKV binding site epitope of $ß_2$GPI in the pinch model activates endothelium as measured by the upregulation of vascular endothelial cell adhesion molecule 1 (VCAM-1) on cultured endothelia (96). A recent analysis of hybridomas from a (NZW × BXSB) F1 male showed binding to three supramolecular complexes of anionic PLs and protein: CL-$ß_2$GPI, PS-annexin V, and nucleosomes, and H and L chain analyses showed recurrent H and/or L chain rearrangements (97). That aCL monoclonal antibodies cross react with nucleosomes may explain the frequent coincidence of APS and SLE (secondary APS) and primary APS patients with antinuclear antibodies. In a rat mesenteric model, platelet aggregate and thrombus formation induced by anti-$ß_2$GPI was related to pro-inflammatory events involving terminal complement components (98). These models are important in both pathogenesis and evaluation of treatment modalities for APS.

Summary

Lupus anticoagulants are a heterogeneous set of aPLs with the potential to reflect in vitro actions with in vivo consequences. Endothelial cell or platelet membrane injury or activation could result in an enhanced procoagulant surface that is permissive for the binding of prothrombin, $ß_2$GPI, or protein S and activated protein C to exposed anionic phospholipids. In a manner analogous to the creation of a neoepitope or altered reactivity of other domains of $ß_2$GPI, these components then might be recognized as immunogenic and continue to drive the production of LACs/aPLs, which likely are part of the natural repertoire already. This scenario would explain the protean nature of LAC effects, in that the shift to the procoagulant state would then drive phospholipid-dependent coagulation reactions and cause thrombosis. That qualitative and quantitative differences in regional vascular beds may explain why thrombosis (while sometimes mimetic in site) can range in scope from trivial and localized to catastrophic and generalized remains under investigation. A proposed sequential evaluation flow diagram for LAC/aPL that represents opinion synthesized from extensive academic practice and recent literature comprises Fig. 27-4 (2 ,4 ,21 ,23 ,71 ,88 ,90 ,92). Although cost containment is important, consideration of the cost of morbidity, and possibly mortality, is balanced only by that which might be prevented by appropriate therapy (see Chapter 65). The emerging knowledge that $ß_2$GPI is a control protein in fibrinolysis (99) may offer new therapeutic options, address positive predictive values that will help to identify at-risk patients for prophylactic treatment. Further elucidation of surface-based LAC binding to cell surfaces such as the monocyte with subsequent activation of p38 MAPK resulting in the upregulation of tissue factor (100) and other surface proteins in endothelial cells may open pathways for specific targeted therapies for patients.

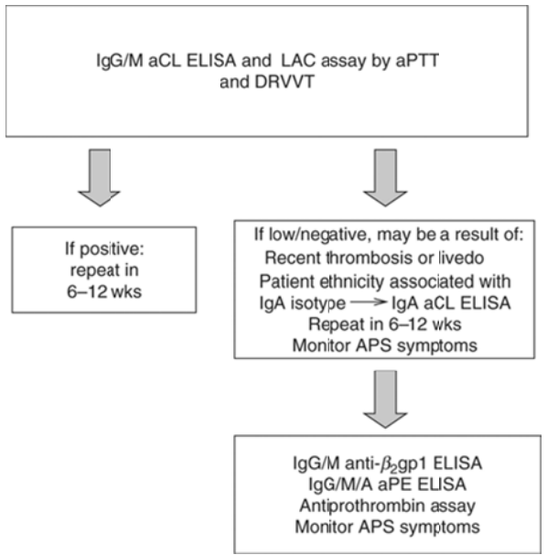

Figure 27-4. A proposal for the sequential evaluation of LAC/aPL is presented.

Acknowledgments

I gratefully acknowledge many colleagues in antiphospholipid antibody research worldwide who again provided critical but thoughtful discussion. The devotion of Drs. Bevra H. Hahn and Daniel J. Wallace to the success of this book is gratefully appreciated. Dana Clerkin (Georgetown University), Rose H. Davis (University of Virginia), and Mary Veal (Washington Hospital Center) assisted in online searches. David Klemm (Georgetown University Educational Media) is again thanked for graphic artistry. Nancy Winter's editorial expertise is appreciated.

Chapter 28

Other Serologic Abnormalities in Systemic Lupus Erythematosus

Francisco P. Quismorio Jr.

Antierythrocyte Antibodies

Antibodies to red blood cells (RBCs) are detected by the antiglobulin (i.e., Coombs) test, of which there are two variations. The direct Coombs test, also known as direct antiglobulin test (DAT), measures the presence of antibodies that are bound to the surface of circulating RBCs. The antiglobulin reagent, usually rabbit or goat antibody to human gamma globulin, is added to a saline suspension of washed erythrocytes of the patient, and if the erythrocytes are coated with antibodies, cell agglutination ensues. The indirect Coombs test measures for free anti-RBC antibody in the serum of the patient. Test serum is incubated with suspension of a mixture of washed normal group O red cells that express most of the known RBC antigens; thereafter, the cells are allowed to react with antihuman gamma globulin. Cell agglutination indicates the presence of free anti-RBC antibodies in the patient's serum.

Antiwhole human gamma globulin usually is employed as the antiglobulin reagent, but monospecific antisera to human IgG and other Ig classes, IgG subclasses, C3, and C4 also are being used. In certain situations, immune complexes that are unrelated to RBC antigens may bind to erythrocytes, giving rise to a positive direct Coombs test.

Washed RBC from healthy nonanemic subjects has less than 14 fg IgG per 10,000 cells. Hypergammaglobulinemia of various etiology results in an increase in surface IgG, causing a positive direct Coombs test, but with no evidence of significant hemolysis. Immunoglobulin eluted from the RBCs of patients with hypergammaglobulinemia and the corresponding serum is negative for specific anti-RBC antibody activity (1). On the other hand, RBC eluates of patients with SLE and polyclonal hypergammaglobulinemia and a positive direct Coombs test contain anti-RBC autoantibodies. This has been interpreted to mean that the net effect of hypergammaglobulinemia on the Coombs test is obscured by the bound anti-RBC antibodies (2).

The limited sensitivity of the antiglobulin test has led to the development of other methods with improved sensitivity, such as the enzyme-linked immunosorbent assay (ELISA) and radioassay (3 ,4 ,5); however, in most clinical laboratories, the Coombs test remains the standard test for anti-RBC antibodies.

Characteristics of Anti-Red Blood Cell Antibodies in SLE

Autoantibodies to RBCs are classified into two major types (5) according to their thermal requirements: warm antibodies react optimally with surface membrane antigens at 37°C (6 ,7), and cold-type autoantibodies react more avidly with RBC antigens at 0°C to 5°C than at higher temperatures (8 ,9).

Autoantibodies to RBC in SLE as well as in idiopathic autoimmune hemolytic anemia (AIHA) are predominantly warm antibodies. Warm antibodies most commonly belong to the IgG class (8). All four subclasses of IgG are represented, although IgG1 is the predominant IgG subclass, and IgG2 and IgG3 are found less frequently. Warm anti-RBC antibodies belonging to IgG4 subclass are uncommon. Cold-reacting antibodies to RBCs are mostly IgM antibodies and rarely of the IgG class. A few cases of patients with SLE and hemolytic anemia associated with cold agglutinins have been reported (9 ,10). The cold agglutinin has specificity for “I” antigens.

Specificity of Anti-RBC Antibodies

Warm antibodies that are bound to the surface of RBCs in vivo can be eluted and examined for biologic properties.

In patients with idiopathic AIHA, the warm antibodies react with antigenic determinants of the Rh complex (11 ,12). The specificity of warm antibodies in SLE is not completely known; however, it has been noted that warm antibodies eluted from erythrocytes containing both IgG and complement on their surface (including that from patients with idiopathic AIHA) react with Rh null cells (13 ,14).

Investigations employing more sensitive immunochemical techniques have shown that warm antibodies (including those seen in SLE) are heterogeneous, reacting with a variety of antigens on the RBC membrane. Two minor RBC proteins that appear to be members of the Rh family as well as two major integral membrane glycoproteins (band 3, an anion transporter and glycophorin A) have been identified as target antigens of warm anti-RBC antibodies (15 ,16).

Several studies have demonstrated a significant association between anticardiolipin (aCL) antibodies and AIHA

in SLE (17 ,18). Sthoeger et al. (19) reported that immunoglobulin eluted from the RBCs of patients with lupus contained aCL antibody activity, suggesting that in some patients, aCL antibodies may act as anti-RBC autoantibodies, causing hemolysis. IgG aCL antibodies may bind to phospholipids of the Rh system or to the phosphatidylcholine moiety of RBC membranes.

Prevalence of Anti-RBC Antibodies in SLE

Mongan et al. (20) examined the frequency of a positive direct Coombs test in patients with various types of systemic rheumatic diseases. Five of 103 (5%) patients with rheumatoid arthritis (RA) and 15 (65%) of 23 patients with SLE had a positive test. None of six patients with systemic sclerosis and two with polyarteritis nodosa were positive. Additionally, two of three cases of thrombotic thrombocytopenic purpura and only one of 103 subjects with nonrheumatic conditions were positive. Worlledge (21) found positive antiglobulin tests in 16 (44%) of 35 patients with SLE. Among normal blood donors, the frequency of a positive Coombs test was estimated to be 1 in 14,000 (22).

Despite the high frequency of positive direct antiglobulin tests among patients with SLE and RA, Mongan et al. (20) found no clinical evidence of active hemolysis. This observation illustrates the frequent dissociation between abnormal serologic findings and the occurrence of tissue injury. A positive direct Coombs test in the absence of hemolysis should be regarded as one of the multiple serologic abnormalities that frequently are seen in SLE.

Pattern of Reaction with Antiglobulin Serum

With the use of antisera of different specificities, three patterns of reactivity are commonly identified in the direct Coombs test: (a) type I: IgG, IgM, IgA, either singly or in combination is present on the RBC surface; (b) type II: both immunoglobulin and complement components are bound on the RBC surface; and (c) type III: RBCs are coated with complement components (C3, C4) alone. Type I is the pattern most commonly found in patients with idiopathic AIHA, whereas types II and III are the patterns generally associated with SLE (21 ,23 ,24).

Of 180 patients with warm-type AIHA, Worlledge (25) found that 83 patients (46%) had IgG coating alone on their RBCs, 64 (36%) had both IgG and complement, and 33 (18%) had complement coating alone. Of the 17 patients with SLE who were included in her series, none had bound IgG alone, 12 showed bound IgG and complement, and the remaining 5 had complement reactivity alone. Chaplin and Avioli (8) suggested that a diagnosis of SLE is unlikely in a patient with immune hemolytic anemia if complement components are not detectable on the RBC surface.

Among patients with SLE who have a positive direct Coombs test but no evidence of overt hemolysis, 12 of 13 showed complement reactivity alone, 3 had both IgG and complement, and none showed IgG alone (25). Of 103 patients with RA tested, 5 had a positive direct Coombs test, and all showed complement reactivity alone (20). The pattern of red-cell autosensitization in RA was confirmed by Gilliland and Turner (26), who found that 12 of 75 consecutive patients with RA who were tested reacted with anti-C antiserum exclusively. Two independent investigations established that RBCs coated with complement components alone, as determined by the standard direct Coombs test, contain IgG antibody as well, suggesting that complement deposition is in fact antibody mediated (27 ,28). Gilliland et al. (27) devised a sensitive, complement-fixing antibody consumption test, based on the principle of the antiglobulin test that detected as few as 20 IgG molecules on the red-cell surface. On the other hand, MacKenzie and Creevy (28) detected IgG antibody on the surface of complement-coated RBCs when the standard Coombs test was performed at 4°C, but not at 37°C. The IgG antibody was not eluted from RBCs at 37°C; however, it apparently underwent a thermal-dependent conformational change so that agglutination with the Coombs antiglobulin reagent did not occur. Patients with SLE and combined warm-reacting IgG and cold-reacting IgM anti-RBC antibodies have been reported (29 ,30).

Pathophysiology of Immune Hemolytic Anemia

The pathogenesis of RBC damage by anti-RBC autoantibodies has been extensively investigated (31 ,32). Erythrocytes that are sensitized with warm-reactive IgG antibodies are cleared from the circulation by macrophages in the splenic sinusoids. Macrophages express surface receptors for the Fc portion of the IgG molecule and C3b fragment of complement. The macrophage Fc receptors bind erythrocytes with bound IgG anti-RBC antibody, causing membrane damage, spherocytosis, and phagocytosis of some RBCs. Microspherocytes have a shortened life span, because of their increased rigidity and increased osmotic fragility. As the amount of surface-bound antibody increases, splenic trapping becomes more efficient, and red-cell survival shortens significantly. When the density of bound IgG antibody is substantial, complement activation occurs. RBCs coated with IgG and complement are cleared by two distinct macrophage receptors, the C3b and Fc receptors, causing an accelerated clearance of RBCs from the circulation that results in extravascular hemolysis. Sequestration of sensitized RBCs by hepatic macrophages with complement, but no Fc receptors also may occur at this stage.

The IgG subclass of the anti-RBC antibody is an important determinant in RBC destruction, because splenic macrophages have IgG Fc receptors for IgG1 and IgG3 subclasses. The macrophage FcR avidity for IgG3 is greater than that for IgG2 antibodies. RBCs with critical quantities

of IgG1 and/or IgG3 antibodies on their surface are destroyed. It has been calculated that RBCs coated with IgG1 antibody alone or with additional IgG2 and IgG4 antibodies require at least 2,000 molecules per each RBC to initiate phagocytosis or rosette formation with monocytes in vitro. In contrast, as few as 230 molecules of IgG3 anti-RBC antibodies per each RBC are required for binding to monocytes (33). Moreover, the clearance of RBCs that are sensitized with IgG antibody and complement is accelerated, and IgG1 and IgG3 antibodies fix complement efficiently, whereas IgG2 antibodies are less efficient and IgG4 antibodies do not activate complement.

Table 28-1: Antierythrocyte Antibodies in Systemic Lupus Erythematosus (SLE)

1. A positive direct Coombs test (direct antiglobulin test) in the absence of active hemolysis is a frequent serologic finding.
2. The direct Coombs test frequently shows reactivity with complement alone or with immunoglobulin plus complement.
3. Antierythrocyte antibodies in SLE are IgG antibodies, warm type, and react with a variety of antigens on the RBC surface.
4. These antibodies can be associated with significant hemolysis in some patients.

Erythrocytes coated with increased amounts of IgM and IgA in addition to warm IgG anti-RBC antibodies are more predisposed to hemolysis than are RBCs coated with IgG antibodies alone (34). Erythrocytes coated with IgM anti-RBC antibody, as in the case of cold hemagglutinin disease, are cleared by a mechanism that is dependent on complement activation. IgM-coated RBCs bind to C3b receptors of macrophages and are cleared rapidly in the liver (35 ,36). When the amount of IgM antibody on the RBC surface is high, complement activation is rapid and extensive so that the terminal components of complement become activated, resulting in intravascular hemolysis (Table 28-1).

Platelet Antibodies

A special relationship exists between SLE and chronic immune thrombocytopenic purpura (ITP), both of which primarily afflict young women. Some patients with thrombocytopenic purpura that is labeled as idiopathic at the onset later develop classic SLE (37 ,38), suggesting that ITP may be an early manifestation of the disease. Further, a thrombocytopenic purpura that is indistinguishable from chronic ITP may develop during the course of SLE. Thrombocytopenia in SLE, as in chronic ITP, is caused by increased peripheral destruction of platelets brought about by autoimmune mechanisms. Platelet survival studies in SLE with 51Cr-labeled platelets have demonstrated shortened life span (39).

In 1953, Harrington et al. (40) transfused normal human volunteers with plasma from patients with chronic ITP and noted a significant and prompt drop in platelet counts. Autologous plasma from chronic ITP subjects, obtained during disease exacerbations and then stored, produced thrombocytopenia when reinfused into the same patients during periods of disease remission (41). The humoral antibody nature of the antiplatelet factor in this disorder has been established, and Shulman et al. (41) showed that the factor was a 7S gamma globulin, reactive to autologous as well as to allogeneic platelets, and produced in vivo effects both quantitatively and qualitatively similar to those exhibited by known antiplatelet antibodies. These findings indicate that the platelet-depressing factor in the plasma is an antiplatelet antibody.

Similar plasma transfusion experiments have not been performed in patients with SLE and thrombocytopenia. However, Nathan and Snapper (42) reported an analogous situation in a premature infant born of a mother with SLE who at the time of delivery had thrombocytopenia. At birth, the infant had low platelet counts, which persisted until 3 weeks of age. Both mother and infant had platelet agglutinins and positive lupus erythematosus (LE)-cell tests. It was suggested that transplacental transfer of both platelet antibody and antinuclear antibody (ANA) had occurred from the mother to the baby.

Tests for Antiplatelet Antibodies in SLE

Although the transfusion experiments provided a strong argument for the autoimmune nature of chronic ITP, some investigators remain unconvinced, because reliable in vitro tests for the detection of antiplatelet antibodies are not available. Over the years, many in vitro tests have been introduced, indicating that a test of reasonable specificity, reproducibility, and sensitivity has yet to become widely accepted. Of the many in vitro tests for antiplatelet antibodies, the following few have been employed in SLE: platelet agglutination (43 ,44), direct antiglobulin consumption test (45 ,46), dextran agglutination test (47), platelet factor III method (48), the indirect immunofluorescence method (49 ,50 ,51), direct platelet immunofluorescence test, immunobead (52), and more recently the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) (53 ,54).

Karpatkin and Siskind (55) introduced the platelet factor III immunoinjury technique to detect antiplatelet antibodies in SLE and chronic ITP. The method is based on the property of antiplatelet antibodies to damage normal platelets, releasing factor III. In turn, this factor is made available to the coagulation cascade, and its effect is measured as a shortening of the clotting time. The gamma globulin fraction of serum isolated by ammonium sulfate precipitation rather than whole serum was tested for antiplatelet antibodies, and with this sensitive method, they found platelet antibodies in 65% of patients with chronic

ITP (of whom 96% were thrombocytopenic at the time of testing). The antiplatelet antibody was removed with prior incubation of the serum using rabbit antihuman IgG or absorption with normal human platelets. Further, the antiplatelet activity can be eluted from normal platelets after prior incubation with positive, but not with negative, serum (48). Karpatkin and Lackner (56) suggested that patients with SLE who test positive for antiplatelet antibodies, but have normal platelet counts represent a subset of patients with a compensated thrombocytolytic state, in which an increased turnover of platelets is compensated for by increased platelet production. On the other hand, Kutti et al. (57) showed that the abnormal values of platelet factor III assay in nonthrombopenic patients with SLE correlated with the amount of circulating immune complexes, suggesting that the assay measured not only antiplatelet antibodies, but also immune complexes that presumably bind to surface Fc receptors.

The direct antiglobulin consumption test detects the presence of gamma globulin that is fixed onto the surface of platelets. Used extensively by early workers, this test appears to be sensitive, but it is technically complex and may yield false-positive results (58). Van de Wiel et al. (46) found that 13 of 23 patients with chronic ITP and all of 6 patients with SLE and thrombocytopenia were positive by this test. Dausett et al. (45) reported that 46 of 93 patients with chronic ITP and 23 of 24 patients with SLE were positive.

Pujol et al. (50) found a high prevalence (62%) of antiplatelet antibodies in 90 consecutive patients with SLE, especially in those with active disease, using a platelet immunofluorescence method. The antibodies were predominantly IgG, although IgM and IgA isotypes also were detected in some patients. Except for thrombocytopenia, the presence of platelet antibodies was not associated with other disease manifestations.

Platelet-Bound IgG in SLE

In 1975, Dixon et al. (59) introduced a quantitative method of measuring the IgG bound on the surface of platelets that is based on the inhibition of complement lysis. All of 17 patients with chronic ITP showed an elevated level of platelet-associated IgG when compared with that of healthy controls. Moreover, an inverse relationship between platelet count and the concentration of platelet-associated IgG was observed both before and during drug therapy. These observations were soon confirmed by several investigators using other methods of measuring platelet-bound IgG (60 ,61).

Platelet-associated IgG has been shown to be increased in practically all patients with SLE and thrombocytopenia (62 ,63 ,64 ,65). Kelton et al. (64) reported an inverse correlation between platelet count and platelet-associated IgG in 10 thrombocytopenic patients with SLE. Mulshine et al. (65) confirmed this inverse relationship and further observed that patients with SLE and normal platelet counts had platelet-associated IgG levels even lower than those seen in normal controls. Conversely, Bonacossa et al. (66) found an elevated level of platelet-bound IgG in patients with SLE and normal platelet counts. Subjects with high amounts of platelet-associated IgG had significantly more anti-DNA antibodies than those with normal or slightly elevated levels of platelet-bound IgG. However, they found no correlation between disease activity and platelet-bound IgG.

The IgG antiplatelet antibodies in the sera of patients with chronic ITP appear to be restricted to the IgG3 subclass (67), whereas in SLE sera, all four IgG subclasses are represented (68). Conversely, all four IgG subclasses are bound in vivo to platelets of patients with chronic ITP, suggesting that circulating antiplatelet IgG and platelet-associated IgG may represent different populations of platelet antibodies (69 ,70). The nature of the platelet-associated IgG is not completely known. It may represent IgG antibody bound to platelet-specific surface antigens (i.e., autoantigens), IgG antibody bound to HLA or blood group antigens or to exogenous antigens absorbed on the surface of platelets, IgG nonspecifically fixed to damaged platelets, or circulating immune complexes attached to platelet surface Fc receptors (60 ,71).

McMillan (72) showed that IgG platelet antibodies that are synthesized by splenic lymphocyte cultures of patients with chronic ITP bind to platelets through their Fab terminus, indicating a specific antibody reaction. Moreover, eluates from platelets of the same patients contain IgG that bind to normal allogeneic platelets. Kelton et al. (73) reported that the increased amounts of platelet-associated IgG in malaria were partly caused by the binding of IgG-specific antibody to malarial antigens absorbed on the surface of platelets. Thrombocytopenic purpura in patients infected with human immunodeficiency virus is associated with increased platelet-associated IgG. Walsh et al. (74) presented evidence to show that the platelet-associated IgG in these patients does not result from bound antiplatelet antibodies, but rather from the deposition of complement and immune complexes onto the surface of platelets. Samuel et al. (75) reported higher amounts of platelet-associated IgG, C3 and C4 in thrombocytopenia-associated immune complex disease including SLE, human immunodeficiency virus (HIV) infection, and chronic liver disease than in classic ITP.

The nature of platelet-associated IgG in SLE has not been fully studied, but it may in part represent bound immune complexes (60). This is supported by the observation that the antiplatelet antibody found in SLE sera fixes complement, unlike that found in the sera of patients with chronic ITP, which is noncomplement fixing (68). Moreover, preformed complexes of DNAanti-DNA antibodies bind to the surface of platelets (76). Puram et al. (77) noted a positive relationship between platelet counts in SLE with immune complex-like material in serum, as measured by polyethylene glycol precipitation, but not with platelet-associated IgG. On the other hand, no correlation was evident between the level of circulating immune complexes as measured by C1q binding (66) or Raji-cell assay (56) and the amount of platelet-bound IgG in SLE, indicating

that platelet-bound IgG is not entirely caused by antigenantibody complexes. Kurata et al. (78) reported an ether elution method of differentiating between platelet-specific antibodies and bound immune complexes, and they showed that eluates from platelets of patients with SLE contain specific antiplatelet antibodies.

Elevated levels of platelet-associated IgG are not necessarily diagnostic of chronic ITP or thrombocytopenia as a result of SLE. High levels can be seen in patients with thrombocytopenia that is considered to be nonimmune in origin (60) as well as in some patients with normal platelet counts (66). Conversely, a diagnosis of ITP is unlikely in a patient with thrombocytopenia if the platelet-associated IgG level is low or normal.

Specificity of Antiplatelet Antibodies in SLE

A limited number of studies have examined the antigenic specificity of autoantibodies to platelets in SLE (79 ,80 ,81). Platelet autoantibodies are directed mainly to GpIIb/IIIa complex, although multiple platelet antigens, including surface membrane and cytoplasmic proteins, have been identified, implying heterogeneity of these antibodies in SLE.

Howe and Lynch (80) examined the binding specificities of circulating antiplatelet antibodies in SLE by Western blotting. All patients with SLE who were thrombocytopenic and had increased amounts of platelet-bound IgG had serum antibodies that reacted with platelet protein fractions having molecular weights of 120 and 80 kd. Patients with SLE and normal platelet counts but with elevated platelet-associated IgG also were positive for serum antiplatelet antibodies. Absorption of sera with whole platelets or platelet lysates removed the antibody activity. The binding pattern was found to be relatively specific for SLE and was not seen in healthy controls. Sera from patients with chronic ITP reacted with multiple platelet fractions, but with no consistent pattern, unlike that seen in SLE, suggesting that the specificities of platelet antibodies in the two conditions are different.

Using a similar methodology, Kaplan et al. (81) confirmed the presence of serum antibodies to platelets in three of ten thrombocytopenic patients with SLE. The antigens involved were cytoplasmic proteins from normal platelets with molecular weights of 108 and 66 kd, respectively. Tomiyama et al. (82) identified the 120-kd antigen to be vinculin, a cytoplasmic platelet protein. Antivinculin antibodies were found to be prevalent not only in patients with immune thrombocytopenia (67%), but also in healthy subjects (40%), suggesting that these are naturally occurring antibodies. The pathogenetic role of these antibodies remains to be determined.

In chronic ITP, target antigens of circulating antiplatelet antibodies as well as platelet-bound IgG have been identified by immunoblotting and by using monoclonal antibodies. Antigenic epitopes on the GPIIb-IIIa complex (CD41/CD61) have been the most frequently observed, whereas GP Ib/IX and GPIa/IIa antigens also have been reported (83 ,84 ,85). These glycoproteins belong to a complex of membrane proteins on the surface of platelets, termed integrins, which function as receptors for fibrinogen, fibronectin, collagen, and other extracellular matrix components that are important in hemostasis.

Berchtold et al. (79) examined the specificity of antiplatelet antibodies in patients with disease-related immune thrombocytopenia, including SLE, other connective tissue diseases, and lymphomas. Autoantibodies against platelet GPIIb-IIIa complex were found in patients with SLE and in mixed connective tissue disease and Sjögren syndrome, showing that the specificity of the antiplatelet antibodies in some patients with systemic rheumatic diseases is similar to that seen in patients with chronic ITP (Table 28-2). The presence of specific antibodies against GP IIb-IIIa and to other platelet glycoproteins in SLE has been confirmed by other investigators (52 ,53 ,86). Serum antibodies to platelet membrane antigens (GP IIb-IIa, GP Ib-ICX, GP Ia-IIa, and GP IV) were found to more prevalent in thrombocytopenic SLE patients than in those patients with normal platelet counts (86), however, other investigators have failed to confirm this association (53).

In a more detailed study, Michel et al. (87) confirmed that the specificity of antiplatelet antibodies in SLE is directed mainly against GpIIb/IIIa complex. Using an indirect MAIPA assay, they found these serum antibodies in 36% of thrombocytopenic SLE patients and in only 5% of SLE patients with normal platelet counts. Antibodies to other platelet antigens including GpIbIX, GpIaIIa, CD9, and others were also found in smaller number of patients, implying the wide heterogeneity of antiplatelet antibodies. More importantly, when platelet-bound immunoglobulin and platelet eluates from thrombocytopenic patients were tested, 69% showed the presence of specific antiplatelet antibodies.

Table 28-2: Platelet Antibodies in Systemic Lupus Erythematosus (SLE)

1. In vitro tests for platelet antibodies, such as immunofluorescence, direct antiglobulin consumption test, and monoclonal antibody-specific immobilization of platelet antigens frequently are positive in SLE. These tests are of limited clinical application.
2. Tests that measure platelet-associated IgG show elevated values in practically all patients with SLE and thrombocytopenia as well as in some patients with normal platelet count.
3. The nature of platelet-associated IgG is not completely known, but it probably represents specific antiplatelet antibodies and bound immune complexes.
4. Platelet antibodies in SLE react mainly with platelet membrane glycoproteins GpIIb/IIIa complex that function as receptors.

Antigen-Specific Platelet Autoantibody Assays

The clinical application for antigen-specific platelet autoantibody assay for the laboratory diagnosis of immune thrombocytopenia in SLE remains to be established. McMillan (88) opines that a positive antigen-specific platelet autoantibody assay provides strong evidence of immune thrombocytopenia in chronic adult ITP and SLE. However, in prospective studies a significant number of patients have tested negative, so that a negative result does not exclude the presence of immune thrombocytopenia (89).

Antiphospholipid Antibodies and Antiplatelet Antibodies

The presence of antiphospholipid antibodies, including aCL, and lupus anticoagulant in SLE is strongly associated with thrombocytopenia (see Chapter 29 , “Pathomechanisms of Cutaneous Lupus Erythematosus”). For this reason, it has been hypothesized that aCL may cross-react with platelet phospholipids, resulting in inactivation and/or subsequent sequestration in the reticuloendothelial system. Rupin et al. (90) examined the significance of specific platelet antibodies and aCL in patients with SLE and thrombocytopenia, and although one half of their patients with low platelet counts tested positive for aCL, the thrombocytopenia correlated better with the presence of serum IgG antibody to an 80-kd platelet antigen. Moreover, absorption of the serum with platelets removed the aCL activity in only one half of the sera with antiplatelet antibodies. Jouhikainen et al. (91) examined 71 consecutive patients with SLE for platelet antibodies by immunoblotting. The most common antibody found reacted with a 65-kd platelet antigen, and its presence was significantly associated with lupus anticoagulant, a history of thrombocytopenia, and thrombosis, especially arterial occlusions. Out et al. (92) observed that IgG eluted from the platelets of patients with SLE had antibody activity against negatively charged phospholipids. Nevertheless, there was no evidence of the in vivo activation of platelets, and platelet aggregation was not impaired. By adsorption experiments, Lipp et al. (52) have shown that antiphospholipid antibodies and antiglycoprotein antibodies (GPIIb-IIA and GPIb-IX) in chronic ITP and in SLE with thrombocytopenia have distinct specificities and do not cross-react. Moreover, in patients with primary antiphospholipid antibody syndrome and associated immune thrombocytopenia, Godeau et al. (93) reported that specific antiplatelet glycoprotein antibodies, but not anticardiolipin antibodies were found in the platelet eluates. This finding suggests that the absence of cross-reactivity between anticardiolipin and antigen-specific platlet autoantibodies.

These data indicate a heterogeneity of platelet antibodies in SLE, some of which cross-react with phospholipids and some with specific platelet glycoproteins, as well as other membrane and cytoplasmic antigens. Further studies to characterize the antigens and to clarify the relative importance of the different antibodies in the pathogenesis of the thrombocytopenia are needed.

Antineutrophil Antibodies in SLE

The frequent occurrence of leukopenia in SLE, possibly mediated by immunologic processes similar to those described in autoimmune hemolytic anemia or autoimmune thrombocytopenia, led to investigations on the presence of antileukocyte antibodies. Various conventional serologic methods, such as agglutination, complement fixation, antiglobulin consumption test, and cytotoxicity, have been used (94). Early studies employed whole leukocyte preparations rather than purified fractions (e.g., lymphocyte subsets) as substrate, and differences in their specificity and sensitivity make it difficult to compare results of the various tests. Further, the presence of isoantibodies against leukocytes, which may be a consequence of multiple pregnancies and/or blood transfusions, must be differentiated from genuine leukocyte antibodies when interpreting the results.

Technical improvements in the fractionation of peripheral blood leukocytes led to the development of new procedures to detect antibodies to lymphocytes. In 1970, Mittal et al. (95) employed the lymphocyte microcytotoxicity test, which was developed for histocompatibility testing, for the detection of cytotoxic antibodies to lymphocytes in SLE. They found a high prevalence of specific lymphocytotoxic antibodies in SLE, and this observation soon was confirmed independently by other workers (96 ,97 ,98) (see Chapter 65 , “Clinical and Management Aspects of the Antiphospholipid Antibody Syndrome”). In contrast, techniques to detect specific immune reactions to granulocytes have been more difficult to standardize (99).

Tests for antineutrophil antibodies fall into two major types: immunochemical and functional (99). The former detects immunoglobulins that are bound to the surface of the patient's neutrophils (i.e., direct test) or free antibodies in the serum (i.e., indirect test) using normal allogeneic neutrophils as substrate. When interpreting the results of these tests, immune complexes binding via Fc and complement receptors on leukocytes should be excluded from the binding of specific antineutrophil antibodies. The latter type measures in vitro sequelae of granulocyte antibodies such as lysis of sensitized cells, phagocytosis, and so on. Flourescence flow cytometry has been adapted for measuring IgG antineutrophil antibodies, and a study using this method found that sera from nonneutropenic patients with SLE as well as patients with other connective tissue diseases show significant binding (100).

Both IgM- and IgG-specific antineutrophil autoantibodies have been found in SLE. Drew and Terasaki (101) described cytotoxic granulocyte-specific antibodies in 53% of 57 patients with SLE using a panel of 70 granulocytes from random normal persons. The antibodies were of IgM class, complement fixing, exhibited optimum activity at 4°C, and were present in 10% healthy, nonimmunized individuals. The clinical significance of these antibodies in

SLE was not examined. Starkebaum et al. (102) studied the mechanism of neutropenia in a patient with SLE and found increased amounts of IgG bound on the surface of polymorphonuclear neutrophils (PMNs). The patient's serum caused opsonization of normal neutrophils for ingestion by other neutrophils. Additionally, fractionation of the serum showed that both immune complexes and monomeric IgG antineutrophil bound to PMNs; however, only the latter caused opsonization of neutrophils. The F(ab)2 fragment of the IgG reacted to the PMNs, confirming the true antibody activity (103). Although IgG neutrophil-binding activity of serum was found to be common in SLE, there was no association between the level and neutropenia (103). Two independent groups of investigators confirmed the absence of correlation between neutrophil count in SLE and the titer of PMN-binding IgG in the serum (104 ,105). In contrast, there is some correlation between antilymphocyte antibody titers and lymphopenia (see Chapter 29 , Cutaneous Manifestations of Lupus Erythematosus). However, the ability of SLE sera to opsonize normal PMNs to be phagocytosed by monocytes (104), as well as the capacity of serum antineutrophil antibodies to fix C3 on allogeneic normal PMNs, were both found to be correlated inversely with neutrophil count in SLE.

Specificity of Antineutrophil Antibodies

Studies on the specificity of antineutrophil antibodies in SLE have revealed multiple antigens, however the molecular structure and biological functions of these antigens remain to be elucidated. Ro(SSA) and La(SSB) antigens have been reported to be target antigens of antineutrophil antibodies in some SLE patients.

Using Western immunoblots, Sipos et al. (106) found antineutrophil antibodies in SLE reacted with two membrane antigens with molecular weights of 50 to 60 kd and of 30 kd, respectively. Moreover, the antineutrophil antibodies inhibited the binding of mouse monoclonal antibodies to CD15 (granulocyte antigen) and CD16 (FcR) to normal neutrophils. Whether the antigens seen in the immunoblots are identical to CD15 or CD16, however, remains to be clarified. Chen et al. (107) described two antigens in mature neutrophils and five antigens in precursor neutrophils as target antigens of antineutrophil antibodies in SLE. The structure and identity of these antigens are presently unknown.

Kurien et al. (108) found a correlation between neutropenia and the presence of anti-Ro antibodies in SLE. Anti-Ro antibodies were shown to bind to neutrophils and thus, can potentially induce cell injury via complement activation. However, they found that the antigen bound on the surface of neutrophils was not the 60-kd Ro but instead a 64-kd membrane protein called “D1,” an antigen associated with autoimmune thyroid disease. Inhibition studies showed serologic cross-reactivity between the two antigens, implying that anti-Ro antibodies may be important in the pathogenesis of granulocytopenia.

Table 28-3: Antineutrophil Antibodies in Systemic Lupus Erythematosus (SLE)

1. Circulating antineutrophil antibodies are prevalent in SLE; however, the antibody titer does not correlate with the neutrophil count.
2. Ability of SLE sera to opsonize as well as to fix C3 on normal allogeneic PMNs is inversely correlated with the neutrophil count.
3. Most antineutrophil antibodies are directed to surface antigens on polymorphonuclear cells; however, some react with cytoplasm of PMNs. P-ANCAs may be found, but not C-ANCAs.

ANCA, antigen(s) of human neutrophils and monocytes; PMN, polymorphonuclear neutrophils.

Hsieh et al. (109) reported that 20% of SLE sera contain antineutrophil antibodies that reacted with a 50 kDa membrane protein. Further analysis revealed that the antigen was surface-expressed La(SSB) autoantigen on neutrophils. Functional studies revealed that purified anti-La(SSB) antbodies bind and penetrate neutrophils and impair phagocytosis, accelerate apoptosis and enhance interleukin-8 production in vitrol.

The lack of correlation between titer of antineutrophil antibodies and neutrophil count suggests that factors other than antineutrophil antibodies are important in the pathogenesis of neutropenia in SLE. Antibody-coated PMNs may remain in the circulation longer because of the defective reticuloendothelial function in SLE. The role of antibody avidity, specificity, and the density of membrane antigens may be important. A study of neutrophil kinetics is needed to determine whether peripheral destruction of neutrophils in SLE is compensated for by increased production, such that the net result is a normal peripheral neutrophil count (Table 28-3).

Antineutrophil Cytoplasmic Antibodies

Autoantibodies directed against cytoplasmic antigen(s) of human neutrophils and monocytes (ANCA) are associated with Wegener granulomatosis, microscopic polyangiitis, and other primary systemic small-vessel vasculitides (110 ,111). These antibodies are detected by the indirect immunofluorescent test using ethanol-fixed normal neutrophils as substrate. Four fluorescent patterns are seen: a classic cytoplasmic (C-ANCA), atypical C-ANCA, a perinuclear with or without nuclear extension (P-ANCA), and atypical ANCA (112). C-ANCA is detected in most patients with Wegener granulomatosis and reacts with proteinase 3, although other antigens also are involved. P-ANCAs are found in patients with idiopathic, necrotizing, crescentic glomerulonephritis, and polyarteritis nodosa and react predominantly with myeloperoxidase, a lysosomal enzyme,

although other antigens such as elastase, cathepsin G, lactoferrin, and azurocidin are involved as well (111 ,113).

ANA may interfere with interpretation of the immunofluorescent test for P-ANCA (114). All serum samples containing ANCA should be tested for specific antibodies to proteinase-3 and myeloperoxidase by ELISA. Antimyeloperoxidase antibodies may be overestimated in SLE serum containing anti-DNA-DNA immune complexes. The DNA antigen in the complex binds to the cationic myeloperoxidase used in the ELISA test giving rise to a false-positive result (115).

None of 96 patients with SLE studied by Nassberger et al. (116) using the immunofluorescent test had C-ANCA, whereas 93 had ANA. Antimyeloperoxidase antibodies were found in 21% of the patients by a specific ELISA test. Serum titers generally were low, and presence of the antibody did not correlate with any particular disease feature. Other investigators have reported serum titer of antimyeloperoxidase antibodies in 9% of patients with lupus (117 ,118). Both antibodies to elastase and to myeloperoxidase were found to be prevalent in hydralazine-induced LE (116).

Lactoferrin is a single-chain glycoprotein that is present in many body secretions and derived primarily from neutrophils; it is located in the secondary granules of these cells. IgG antilactoferrin antibodies are reported in five to 39 of patients with SLE (119 ,120), and IgM antilactoferrin antibodies are present in 10% of these patients (120). IgG antilactoferrin antibodies are more prevalent in patients with active disease and appear to be associated with adenopathy and crescentic glomerulonephritis (119).

Schnabel et al. (121) found ANCA in 40 of 157 (25%) patients with SLE. Only P-ANCA was found. The specificities of the SLE antibodies were directed to lactoferrin, elastase, and lyzozyme. No reactivity to myeloperoxidase or to proteinase 3 was detected. More importantly, there was no correlation between P-ANCA with organ system involvement, including lupus vasculitis. Other investigators confirmed the lack of correlation between ANCA, disease activity, and clinical features of SLE (114 ,122). In contrast, a study of a large cohort of European patients with SLE showed correlation of ANCA and antilactoferrin with certain clinical manifestations including serositis, livedo reticualris, thrombosis, and arthritis. However, anticardiolipin and anti-Ro antibodies were more closely correlated than ANCA with these features (123). Antibodies to lysozyme were found in one third of 44 patients with SLE in another study (124).

A 5-year prospective controlled study of ANCA in a large number of patients with various connective-tissue diseases including SLE and healthy controls showed a high prevalence of P-ANCA and atypical ANCA. P-ANCA was associated with the presence of antinuclear antibodies. None had C-ANCA and specific antibodies to proteinase-3 rarely were found (125).

A recent analysis of 13 published studies on ANCA in SLE concluded that 15% to 20% of SLE patients have pANCA and in some patients there may be an association with lupus disease activity (126).

Thus, the presence of C-ANCA and antibodies to proteinase-3 suggests a systemic vasculitic disease other than SLE. P-ANCA, however, can be found in patients with SLE as well as in patients with other conditions.

Rheumatoid Factors

Rheumatoid factors (RFs) comprise a heterogenous group of antibodies that are reactive with antigenic determinants on the Fc portion of human or animal IgG. Although RFs belonging to the IgM class are the most commonly measured isotype by clinical tests, RFs belonging to the IgA, IgG, IgD, and IgE classes have been identified (127 ,128). RFs can react with autologous and isologous as well as homologous IgG.

Serum RFs are measured by a variety of serologic methods, including agglutination, ELISA, radioimmunoassay, and nephelometry. Agglutination tests such as the latex fixation test preferentially measure IgM RFs that are reactive with human IgG. The sheep-cell agglutination test (SCAT) measures IgM RFs using rabbit IgG as an antigen. Clinical laboratories prefer nephelometry over the latex fixation test, because the former is automated and less labor intensive.

Prevalence of RFs in SLE

The prevalence of RFs in large series of patients with SLE as measured by the latex fixation test varies from 20 to 60% (mean, 33%). Singer (129) reviewed several earlier reports and found that 20.5 of tested patients with SLE were positive. Estes and Christian (130) found a positive latex fixation test in 21% of their 150 patients. The serum antibody titer was relatively low, and unlike RA, in which the titer persists, most of their patients did not have a sustained titer. Lee et al. (131) reported positive tests for RFs in 36.7% of 110 patients with SLE. In 31.2% of their patients, the titer was equal to or greater than 1:160, and in 28.8%, the serum titer was greater than 1:320. On the other hand, Feinglass et al. (132) described a higher frequency of RFs among their patients with SLE; 61% of their 122 patients had a positive latex fixation test. In agreement with other studies, the RF titers were modest, with a titer of 1:80 seen in one half of the patients. Further, the serum titer fluctuated intermittently in patients in whom serial determinations were performed.

The SCAT for RFs is less sensitive than the latex fixation test, but a positive SCAT is considered to be more characteristic of RA (128). None of 25 patients with SLE studied by Cathcart et al. (133) had a positive SCAT, and only three patients had borderline titers of less than 1:32.

RFs belonging to isotypes other than IgM are not commonly seen in SLE. If present, they tend to have lower serum titers than those observed in patients with RA. IgG RFs, which are implicated in the pathogenesis of synovitis and extraarticular lesions of RA such as vasculitis, generally are absent in SLE (134 ,135). IgE RFs that also are associated with the extraarticular manifestations of RA are not seen in SLE (136 ,137). Dunne et al. (138) found elevated levels of

IgA RFs in the sera of patients with RA, Sjögren syndrome, and SLE. The serum level of IgA RFs in SLE was lower than that in RA.

The major RF cross-reactive idiotype (RF-CRI) is a public idiotype defined by human IgM RF paraproteins. RF-CRI is expressed in adult and juvenile RA. In SLE, Bonagura et al. (139) found RF-CRI to correlate with the presence of anti-double-stranded DNA (anti-dsDNA) antibodies and disease activity.

Potential Significance of Rheumatoid Factors in SLE

In vitro experiments as well as studies in experimental animal models point to a dual effect of RFs on immune-mediated tissue injury. On one hand, RFs have been shown to exert protective effects by competing with complement for binding to immune complexes (140 ,141). RFs binding to antigenantibody complexes may result in more efficient removal from the circulation by the reticuloendothelial system (142 ,143). Bolton et al. (144) showed that RFs blocked the attachment of C3 to aggregated IgG and the formation of C3b capable of reacting with the C3b receptors of glomeruli in vitro. This phenomenon potentially can shield the glomerulus from deposition of pathogenic immune complexes.

Conversely, others have found RFs to enhance immune-mediated tissue injury in different experimental animal models (145). Floyd and Tesar (145) showed that the administration of IgM RFs aggravated cutaneous Arthus reaction in animals. RFs and immune complexes injected into the mesenteric arteries of rats induced thrombosis and hemorrhage (146). Another series of experiments (147 ,148 ,149) showed that RFs bind in situ to immune complexes that are bound to renal glomeruli in experimental glomerulonephritis. These investigators postulated that bound RFs subsequently act as an immunosorbent, trapping circulating antigenantibody complexes that may be unrelated to the initial renal insult and, by fixing complement, contribute to the chronicity of the renal disease. Birchmore et al. (150) noted that RFs enhanced the binding of DNAanti-DNA immune complexes to C3b receptors on RBCs in vitro by fixing complement by way of its own Fc region. Their finding suggests that RFs may potentiate renal injury in SLE.

Miyazaki et al. (151) found IgM, IgA, and IgG RFs in the serum of five patients with diffuse lupus nephritis, but not in two patients with membranous lupus nephritis. More importantly, they observed the binding of fluorescein-labeled normal human IgG and Fc fragment, but not F(ab)2 fragment, to the renal glomeruli in diffuse lupus glomerulonephritis. No binding was observed in membranous lupus nephritis or in IgA nephropathy. They interpreted this to mean RF activity was present in the glomerular deposits that bind the labeled IgG, suggesting that RFs may be important in the development of diffuse lupus nephritis. This study confirms earlier observations by Agnello et al. (152), who showed glomerular deposits of IgM RFs in lupus nephritis by reacting fluorescein-labeled aggregated human IgG and antidiotypic antibody to RFs with renal biopsy specimens.

Clinical Correlates of Rheumatoid Factors in Systemic Lupus Erythematosus

Which of the many and varied biologic effects of RFs in vitro or in experimental models are important in the pathogenesis of lesions in SLE remains to be seen. Nevertheless, several investigators have examined clinical correlates of RFs in SLE. In 1966, Davis and Bollet (153) noted that nephritis was less prevalent in a group of patients with SLE who were RF positive by the latex fixation test. They suggested that RFs exerted a protective role in vivo in SLE and other diseases of immune complex deposition. A retrospective analysis of their patients confirmed their initial observation, and additionally, they found that patients with SLE who are RF negative and cryoglobulin positive are likely to develop renal disease, whereas those who are RF positive and cryoglobulin negative are unlikely to do so (154). Hill et al. (155) found that patients with SLE and nephritis who were RF positive (by latex fixation test) had milder morphologic renal lesions compared with RF-negative patients with SLE and nephritis. This protective effect of RFs on lupus nephritis was likewise observed in a study using the SCAT for measuring RFs (156), and Corke (157) found that in patients with SLE, proteinuria was less frequent in RF-positive than in RF-negative patients. Mustakallio et al. (158) described a negative correlation between RFs and anemia, skin disease, and the LE-cell test. Moreover, the RF-positive patients with SLE tended to have a more benign and chronic clinical course. A multicenter European study of 1,000 patients with SLE found RF in 180 patients (16) and was associated with higher prevalence of discoid skin rash, sicca syndrome, and a lower prevalence of nephropathy (28 vs. 41) (159).

In the foregoing studies, the tests used for detecting RFs preferentially measured IgM RFs. Tarkowski and Westerberg (160) used an ELISA assay to measure the different isotypes of RFs in SLE and found that the presence and serum level of IgG RFs, IgA RFs, and IgM RFs correlated significantly with the absence of renal disease.

Witte et al. (161) confirmed this negative association and in addition found that the presence of IgA RF defined a clinical subset characterized by sicca syndrome, anti-Ro and anti-La antibodies, and HLA DR3.

Other investigators, however, have failed to confirm a protective role of RFs in SLE nephritis or in other organ involvement (162). Kantor et al. (163) measured RFs in 51 consecutive patients with SLE and found that the frequency as well as the antibody titer of RFs in those with nephritis did not differ from those without clinical renal disease. Baldwin et al. (164) confirmed these observations and found that the presence of RFs was not associated with histologic type of nephritis. Estes and Christian (130)

reported that the frequency of renal disease as well as the 5-year survival rate of RF-positive patients with SLE did not differ from those of the general SLE population. Two other studies using the SCAT for RFs (165) and radioimmunoassay for IgM, IgA, and IgG RF isotypes (166) failed to find a protective effect from RFs on the development of nephritis.

Certain observations not only refute the protective role of RFs but in fact point to their participation in the pathogenesis of tissue lesions in SLE. Cryoglobulins, which represent a subset of circulating immune complexes in SLE, often contain RF activity. Agnello et al. (152) identified RFs in the glomerular immune deposits of patients with SLE and nephritis, hypocomplementemia, and cryoglobulinemia. Deposition of antiglobulins (including RFs) in the renal glomeruli was observed in lupus nephritis and in other types of glomerulonephritis, and their presence appeared to be associated with a relatively severe renal injury (167 ,168). My own group has found that immune deposits in the walls of pulmonary arteries in patients with SLE and pulmonary hypertension were eluted when incubated with aggregated human IgG, suggesting the presence of RFs in the vascular immune deposits (169).

In addition to renal disease, a correlation between RFs and other clinical features of SLE has been examined. RFs were more prevalent in late-onset SLE, defined as onset in individuals above 50 years of age, than in younger patients (170) Moutsopoulos et al. (171) described a high frequency of RFs in patients with SLE and histologic evidence of sicca syndrome on lip biopsy. The prevalence of RFs in 35 patients with SLE positive for anti-Ro/SSA antibody (63%) was significantly higher than that in 77 such patients negative for anti-Ro/SSA antibody (7%). Zizic et al. (172) reported a high frequency of RFs among patients with SLE presenting with acute abdomen secondary to vasculitis and/or serositis. My own group, as well as other investigators have found a high prevalence of RFs in patients with SLE presenting with pulmonary hypertension (169 ,173).

Conversely, Feinglass et al. (132) observed no correlation between RFs and neuropsychiatric involvement in SLE. Patients with SLE and a persistently positive latex fixation test for RFs tended to have less severe clinical manifestations of the disease, were less likely to have received high-dose steroids or cytotoxic drugs for treatment, and were less likely to have had an episode of herpes zoster than patients with SLE who had persistently negative or inconsistently positive tests for RFs (174).

The discrepancy in the results of various investigations on the relationship between RFs and lupus nephritis or SLE in general probably is caused by several factors such as differences in the methods used to measure RFs, selection of patients, ascertainment of activity of the renal disease, and the retrospective design of most of the studies. In addition, the titer of the RFs may fluctuate or even disappear along the course of the illness, thus the timing of the test will affect the result of the study. Moreover, it now is well recognized that RFs are heterogenous with respect to the immunoglobulin class, reactivity with IgG of different species, complement-fixing property, avidity, and other characteristics. Conceivably, varying types of RFs may differ in their effects on renal disease and other tissue lesions. My own group's observations, showing that IgM RFs specific for rabbit IgG correlate positively with arthritis and negatively with other clinical manifestations, suggest a dual effect of RF (175).

Rheumatoid Factors Cross-Reactive with Nuclear Antigens

In 1963, McCormick and Day (176) observed that exhaustive absorption of certain sera containing both RF and ANA activities with aggregated gamma globulin removed the RF activity and was accompanied by a substantial loss of ANA titer. They suspected that the phenomenon was caused by the presence of IgG ANAs associated with the IgM RFs as an immune complex. Subsequently, Hannestad (177) and Hannestad and Johannessen (178) established that this was not caused by complexed IgG ANAs, but rather by the dual reactivity of certain polyclonal IgM RFs with both IgG and nuclear antigens. Other investigators have confirmed these findings (179) and showed that isolated IgM RFs reacts with DNAhistone complex (180 ,181), with histones (182), and/or with nonhistone nuclear polypeptides (183). Cross-reactive IgM RFs have been found most frequently in patients with RA and in some cases of overlap syndromes and mixed connective-tissue disease (180). Kinoshita et al. (184) found IgM RFs that are cross-reactive with single-stranded DNA to be prevalent in a variety of rheumatic diseases, including SLE; however, the serum titer was highest among patients with RA and extraarticular features. Johnson (179) suggested that the cross-reactive IgM RFs are of limited immunopathogenic significance, because such antibodies are noncomplement fixing, react optimally at pH 8 or 9, and fail to bind at pH 6.5. The explanation for the reactivity of human RF with histones is not entirely clear, but recent evidence suggests multifunctional combining regions on RF for human IgG and histones with distinct binding sites located in the variable regions (185) (Table 28-4).

Table 28-4: Rheumatoid Factors (RFs) and Anti-CCP Antibodies in SLE

1. The latex fixation test for IgM RFs is positive in 33% of patients with SLE. Serum titers generally are lower than those seen in patients with RA, tend to fluctuate, and may become negative.
2. RFs have been identified in serum cryoglobulins and glomerular deposits of some patients with SLE.
3. The hypothesis that renal disease tends to be less frequent and less severe in RF-positive than in RF-negative patients with SLE has not been confirmed consistently by other investigators and remains controversial.
4. Anti-CCP antibodies may be seen in a small number of SLE patients. The presence of anti-CCP antibodies alone does not exclude a diagnosis of SLE.

Anticitrullinated Protein Antibodies in SLE

Anticitrullinated protein antibodies are found in RA and are considered diagnostic marker for the disease with high sensitivity and specificity. Commonly measured by an ELISA using fillagrin epitopes and most recently citrullinated cyclic peptides (anti-CCP) as antigens, the test is now widely available as a surrogate marker for the diagnosis and prognosis of RA. However, a few patients with other diagnoses including SLE, psoriatic arthritis, Sjogren syndrome, and juvenile idiopathic arthritis may test positive for anti-CCP antibodies (186).

Anti-CCP antibodies are uncommon in SLE (187) but may be useful in differentiating rheumatoid arthritis from SLE patients with erosive arthritis. Mediwake et al. (188) found erosive arthritis in 10 of 231 SLE patients. Rheumatoid factor was positive in 6 of the 10, whereas only 1 patient had anti-CCP antibodies. Eleven of 201 (5.5%) SLE patients studied by Hoffman et al. (189) tested positive for anti-CCP antibodies. Six fulfilled classification criteria for both RA and SLE and 3 had erosive arthritis. Sauerland et al. (190) found anti-CCP antibodies in 9 of 71 (12.7%) SLE patients tested in a cross-sectional study. Thus, the presence of anti-CCP antibodies alone does not necessarily exclude a diagnosis of SLE. Whether the presence of anti-CCP antibodies in SLE patients predisposes to the development of erosive arthritis is not known.

Cryoglobulins in Systemic Lupus Erythematosus

It has long been recognized that serum specimens from certain groups of patients develop a precipitate spontaneously when they are allowed to incubate in a test tube at low temperatures. Lerner et al. (191) described this phenomenon in patients with leukemia, pneumonia, bacterial endocarditis, and other diagnoses. Having identified gamma globulin as the serum protein fraction that reversibly precipitates at 5°C, the term cryoglobulin was introduced to refer to the cold-insoluble precipitates.

Frequency of Cryoglobulins in SLE

Barr et al. (192) examined sera from patients with various diagnoses as well as from normal subjects for cryoprecipitation. Sera from 8 of 121 patients, but none from 57 healthy controls, had significant amounts of cryoglobulins. Three of the 6 patients with SLE in this early series had cryoglobulins. Christian et al. (193) reported the presence of cryoglobulins in 10 of 12 patients with SLE, with protein concentrations ranging from 7 to 38 mg/dL. In a larger series, Stastny and Ziff (194) studied 137 sera from 31 patients with SLE; 37 sera from 11 patients had cryoglobulins. Lee and Rivero (195) observed cryoglobulinemia in 9 of 57 SLE sera, whereas Garcia-Carrasco et al. (196) reported cryoglobulins in 31 of 122 (26%) consecutive SLE patients.

Components of Cryoglobulins

Immunochemical analysis of the cryoprecipitate (197) has revealed three major types of cryoglobulins. Type I cryoglobulins consist of a single monoclonal immunoglobulin: IgG, IgM, IgA, or Bence Jones protein. Type I cryoglobulins are associated with lymphoproliferative disorders. Type II cryoglobulins are mixed cryoglobulins with one of the components being a monoclonal immunoglobulin. Monoclonal IgM with polyclonal IgG is the most common combination, and frequently, the monoclonal component has antiimmunoglobulin (i.e., RF) activity. Type II cryoglobulins are found in patients with chronic hepatitis C infection, lymphoproliferative diseases, Sjogren syndrome, and autoimmune disorders. Type III cryoglobulins are mixed cryoglobulins with polyclonal components. This type is the most common and is associated with infections and autoimmune disorders such as SLE, RA, and systemic sclerosis. Types II and III may contain RF, other autoantibodies, and complement components C1q, C3, and C4.

Hanauer and Christian (198) analyzed isolated serum cryoprecipitates from six subjects with SLE and observed that these consisted largely of IgG, IgM, and C1q. When the washed cryoglobulins were used as immunogens in rabbits, the resulting antiserum reacted with IgG, IgM, C1q, and 2-macroglobulin. Some of the antisera also reacted with C4, C3, and IgA.

Barnett et al. (199) found IgG and IgM in all 156 SLE cryoprecipitates they studied. Eleven contained IgA and C3. Stastny and Ziff (194) reported that IgM was not a prominent component in SLE cryoprecipitates and that the complex consisted mainly of IgG and C1q. Although IgG was the predominant immunoglobulin, relatively more IgM than IgG was concentrated when compared with the corresponding immunoglobulin levels (200).

The formation of cryoprecipitates in SLE sera requires the presence of C1q (193). Prior incubation of SLE serum at 56°C for 30 minutes to inactivate complement resulted in the loss of cryoprecipitability, which was restored when either fresh human serum or purified C1q was added to the test serum.

Fibronectin, which is a normal plasma protein and a major cell surface membrane protein of fibroblasts, is a component of cryoglobulins from patients with connective tissue diseases and other illnesses (201 ,202 ,203). Plasma fibronectin can bind to other molecules, such as collagen, fibrin, and heparin, and the binding may result in formation of a precipitate at low temperatures. Kono et al. (204) showed that fibronectin is capable of binding to C1q, including C1q that is fixed to immune complexes. Because fibronectin and C1q frequently coprecipitate in SLE cryoglobulins, this reaction and/or binding of fibronectin to other serum proteins may be important in the formation of cryoglobulins.

Clinical Correlates of Cryoglobulinemia in SLE

Cryoglobulinemia is associated with clinical disease activity. Eight of 11 patients with cryoglobulins reported by Stastny and Ziff (194) had active nephritis, and the remaining

3 had evidence of extrarenal involvement. Nine of the 12 patients with cryoglobulins studied by Christian et al. (193) had active nephritis. Cryoglobulinemia in SLE also has been associated with reduced serum levels of C3 and C1q (205). Cryoglobulins and RF have independent and opposite association with lupus myelitis (154).

Cryoglobulinemia is a common finding in hepatitis C infection. Garcia-Carrasco (196) reported correlation between cryoglobulinemia in SLE and cutaneous vasculitis, rheumatoid factor, hypocomplementemia and evidence of hepatitis C infection. Other investigators have confirmed the high prevalence of cryoglobulinemia in SLE patients with concomitant hepatitis C infection (206 ,207).

Cryoglobulins as Circulating Immune Complexes

The association between cryoglobulinemia, disease activity, and hypocomplementemia in SLE led to investigations on the potential pathogenicity of the cryoprecipitates. Mixed cryoglobulins are considered to represent circulating immune complexes for several reasons. In certain conditions, such as essential mixed cryoglobulinemia, the property of cryoprecipitability does not reside on either moiety of the cryoglobulin; it requires combination of the separated components (208). Complement components are required for cryoprecipitability, and further, isolated cryoglobulins have the property of activating the complement system (209 ,210). Cryoglobulins isolated from the sera of patients with lupus nephritis activate the complement system in vitro either through the classic or alternative pathway (211).

Despite similarities in immunoglobulin content, SLE cryoglobulins differ from RA cryoglobulins in their complement-binding property. Although SLE cryoglobulins frequently bind C1q in vitro, isolated RA cryoglobulins do not (200). This difference may reflect varying properties of the antigen-antibody systems that involved in cryoglobulin formation in the two conditions.

Antibody Activity of SLE Cryoglobulins

The deposition of ANAs and their corresponding antigens in target organs has been implicated in the pathogenesis of organ injury in SLE. Cryoprecipitates in patients with SLE during periods of disease activity may represent circulating immune complexes of ANAs and nuclear antigens. Lee and Rivero (195) found no ANA activity in the cryoprecipitates of nine SLE sera that contained high titers of ANAs. Stastny and Ziff (194) reported ANA IgG component in two out of three SLE cryoglobulins tested; however, they failed to find a preferential concentration of ANAs in the cryoglobulins. Conversely, Winfield et al. (205) found that SLE cryoglobulins were highly enriched with antibodies to single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA) and, less frequently, with antiribonucleoprotein antibodies relative to the concentration of these autoantibodies in the corresponding sera. Erhart et al. (200) confirmed these findings and reported that 95 of isolated SLE cryoglobulins studied contained antibodies to dsDNA.

Hanauer and Christian (198) found anti-IgG antibody (i.e., RF) in SLE cryoglobulins, and this finding has been confirmed by several investigators (152 ,212 ,213 ,214). In addition, RF activity was found to be preferentially enriched in the cryoprecipitates when compared with the antibody activity of the matching serum specimen (212 ,213). Similarly, cold-reactive IgM antilymphocyte antibodies were found to be selectively concentrated in SLE cryoglobulins (212 ,213). Lymphocytotoxic activity of SLE cryoglobulins did not correlate with clinical severity of the disease, serum complement level, or serum titer of anti-DNA antibody (214).

Specific Antigens in SLE Cryoglobuinns

To identify specific antigens that may be complexed with corresponding antibody in the cryoprecipitate, experimental animals were immunized with cryoprecipitates isolated from patients with SLE (198). After absorption with pooled normal human serum, anti-SLE cryoglobulin antisera did not recognize any unique antigens, except for two antisera that contained antibody activity against intrinsic determinants in IgM molecules. Using a similar approach, Klippel et al. (215) detected reactivity of anti-SLE cryoglobulin antiserum against lymphocytes, suggesting that lymphocyte membrane antigens or antigens that cross-react with cell surface determinants were present in SLE cryoprecipitates. McPhaul and Montgomery (216) found that anti-SLE cryoglobulin antisera reacted not only against nuclear antigens but also with reticulin and idiotypic determinants of immunoglobulin deposits in the renal glomeruli. These observations indicate the multiplicity of antigenantibody systems that are involved in the formation of cryoglobulins in SLE.

Lee and Rivero (195) reported the presence of DNA in SLE cryoprecipitates in only one of nine specimens using ultraviolet light absorption, diphenylamine reaction, and immunoprecipitation. Davis et al. (217) identified DNA in most SLE cryoglobulins they tested, but only after digestion of the precipitate with pronase, suggesting the DNA was bound to anti-DNA antibodies and thus was inaccessible to biochemical or immunologic detection. The major portion of the DNAanti-DNA antibody system in cryoglobulin from patients with lupus nephritis consists predominantly of low molecular weight complexes (218).

The presence of DNA in cryoprecipitates is not specific for SLE. DNA also has been identified in cryoglobulins isolated from patients with bacterial endocarditis, Sjogren syndrome, and non-SLE glomerulonephritis (219 ,220). Free DNA has been demonstrated in the sera of normal individuals (219), patients receiving high doses of corticosteroids

for a variety of medical conditions, and patients undergoing cardiac surgery (221 ,222). Not only was DNA found in non-SLE cryoglobulins, but Roberts and Lewis (223) identified anti-DNA activity in cryoglobulins isolated from patients with nonlupus glomerulonephritis, bacterial infections, and essential cryoglobulinemia. IgG anti-DNA antibody was demonstrable in cryoglobulins after preincubation of the precipitate in acid buffer or after digestion with deoxyribonuclease, suggesting that anti-DNA antibody in the cryoglobulin was bound to antigen.

It now is recognized that the syndrome of mixed cryoglobulinemia is strongly associated with chronic hepatitis C infection (225 ,226). Hepatitis C virus, polyclonal IgG, and monoclonal RF have been identified in isolated cryoprecipitates, and these represent pathogenic immune complexes that become deposited in the blood vessels of target organs. Studies have shown no association between hepatitis C infection and SLE, and hepatitis C infection is not the primary etiology of cryoglobulinemia in lupus patients (227).

Pathogenetic Significance of Cryoglobulins

In addition to complement activation, mixed cryoglobulins possess other biologic properties that suggest a potential pathogenic role. Intradermal injection of redissolved cryoglobulins in unsensitized animals caused localized skin edema, erythema, and hemorrhage within 24 hours, and intravenous administration caused either anaphylaxis or a glomerulitis (228). Whitsed and Penny (229) described the development of a cutaneous vasculitis following intradermal injection of autologous cryoglobulin into the clinically normal skin of a patient with mixed cryoglobulinemia. Deposition of cryoglobulin in target organs in vivo is supported by the demonstration of a distinctive crystalline fibrillar structure in renal glomeruli that was identical to that found in the serum cryoglobulins of the same patient with essential mixed cryoglobulinemia. Using an anti-idiotypic antibody, Agnello et al. (152) demonstrated the deposition of IgM RF moiety of cryoglobulin in the renal glomeruli of a patient with SLE nephritis. Su et al. (230) described an identical “fingerprint” morphology between glomerular deposits and serum cryoglobulins by electron microscopy in diffuse proliferative lupus nephritis.

Cryoglobulins may contribute to the susceptibility of patients with SLE to bacterial infections. Nivend et al. (231) found that the impairment of opsonization of *Staphylococcus aureus* by SLE serum was associated with cryoglobulinemia. When the cryoglobulin fraction of the immune complexes was removed from the SLE serum, normal opsonic capacity was observed. Moreover, reduction of opsonic property was transferred with SLE cryoglobulins to normal serum. The binding of cryoglobulins to protein A of *Staphylococcus* species probably blocked contact between surface receptors of phagocytic cells and opsonized organisms, resulting in defective phagocytosis and killing (Table 28-5).

Table 28-5: Cryoglobulins in Systemic Lupus Erythematosus (SLE)

1. Serum cryoglobulins in SLE usually are type III (mixed polyclonal) consisting of immunoglobulins, complement components, and fibronectin.
2. Elevated levels of serum cryoglobulins are associated with hypocomplementemia and clinical disease activity, especially active nephritis.
3. Cryoglobulins represent cold-precipitable, circulating immune complexes. ANAs (including anti-DNA), antilymphocyte antibodies, RFs, as well as DNA and lymphocyte antigens have been identified in SLE cryoglobulins.

ANA, antinuclear antibody; RF, rheumatoid factor.

The Lupus Erythematosus Cell

In February 1946, Dr. Malcolm M. Hargraves, a hematologist at the Mayo Clinic, examined bone marrow aspirate from a boy with an obscure medical problem. Part of his report (136) read: “The outstanding thing in this bone marrow is the phagocytic reticuloendothelial cells which contain a blue-staining material which we have not previously observed. Some cells are markedly filled with this material gathered together in round vacuoles or droplets. An occasional cell has been ruptured, with the material in discrete globules scattered out among the other cells. This material stains from a light blue to a very dark, almost indigo blue. There is an occasional reticuloendothelial cell that has other phagocytized material as well as that noted above, but most of the reticuloendothelial cells involved seem to be specifically concerned with this material and do not show other phagocytic activities.”

On learning that the patient probably had SLE, Dr. Hargraves went on to examine bone-marrow specimens in the next 4 days from two other patients with definite SLE. He observed that the striking feature is the marked phagocytic activity of neutrophils containing a muddy purple homogenous material. Some of the cells are so filled with the material that the nucleus is crowded to the periphery.

This is the initial description of the LE cell, and 2 years later, Hargraves et al. (232) reported their experience in 25 patients with SLE and noted the frequent appearance of the LE cell in acute cases. The inclusion body of the LE cells as well as the extracellular material stained with Feulgen stain showed that both contained DNA and were presumed to be nuclear in origin. Hargraves et al. postulated that phagocytosis of the material resulted in the formation of LE cells.

The LE-cell phenomenon occurs in vitro during the incubation of peripheral blood or bone marrow aspirate. It is completed in two distinct stages (Fig. 28-1), with the initial phase involving the immunologic reaction of the LE-cell factor that is present in the serum of patients with the nuclear material of damaged or traumatized leukocytes.

Trauma allows the nuclear penetration of the LE-cell factor, and the reaction leads to nuclear swelling accompanied by the disintegration of the normal chromatin pattern and basophilia. The altered nucleus then detaches itself from the cytoplasm and appears as a free extracellular LE body. In the second stage, the LE body is engulfed by a neutrophil (or occasionally a monocyte) in the presence of complement. The cytoplasm remains outside and is not taken up by the phagocyte (233). When stained with Wright's stain, the globular inclusion body appears as a homogenous, pale blue to deep purplish material, pushing the nucleus of the phagocyte to one side of the cell (Fig. 28-2).

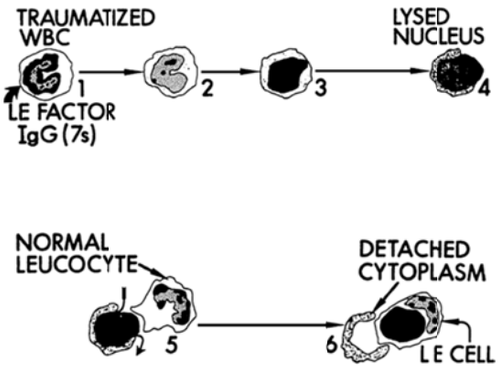

Figure 28-1. Scheme of the lupus erythematosus cell formation.

In 1951, Lee et al. (234) observed a striking morphologic resemblance of the LE-cell inclusion body to the hematoxylin bodies found in the tissues of patients with SLE at autopsy. The latter, described earlier by Klemperer et al. (235), consisted of altered nuclear material containing DNA in a depolymerized state. The LE-cell inclusion body and the tissue-bound hematoxylin body were found to have diminished affinity for methyl green, which is a dye that binds stoichiometrically with DNA. Studies by Godman and Deitch (236) have established that the diminished affinity is not a result of DNA polymerization but rather of interference by proteins that are bound to the DNA moiety of the inclusion body.

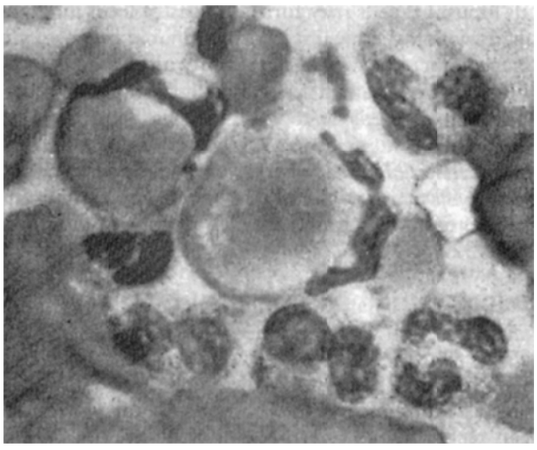

Figure 28-2. Two typical lupus erythematosus cells (× 1,700).

Lupus Erythematosus-Cell Factor

Haserick et al. (237) fractionated SLE plasma by electrophoresis and identified the serum factor that participated in the LE-cell phenomenon as gamma globulin, implying that it is an antibody. Other investigators, using ultracentrifugation and chromatography separation methods, confirmed the LE factor to be a serum 7S gamma globulin (238 ,239), whereas the 19S was inactive. Subsequent studies established that IgG but not IgM antibody to deoxyribonucleoprotein induces LE-cell formation in vitro (240).

Lupus Erythematosus-Cell Antigen

In 1960, Miescher and Fauconnet (241) noted that the capacity of SLE serum to induce LE cells in vitro diminished when the serum was preabsorbed with nuclei isolated from human leukocytes. This observation as well as the information that the LE-cell factor is a gamma globulin led to definitive investigations that established the ANA activity of the LE-cell factor. Application of the fluorescent antibody technique by Friou et al. (242) contributed significantly to our understanding the nature of the LE-cell factor and other ANAs. In a series of elegant studies, Holman et al. (243 ,244 ,245) established that the LE-cell factor is an antibody to deoxyribonucleoprotein of cell nuclei, requiring both DNA and histone for the reaction.

More than 50 years after its description, Schett et al. (246), using highly purified antigens and a series of immunoprecipitation and immunoblotting and blocking experiments, recently has identified histone H1 as the major antigen involved in the LE-cell phenomenon. In addition, they have shown that a positive LE-cell prep correlated not only with antihistone 1 antibody measured by ELISA test, but also with active disease with major organ involvement (246 ,247).

Apoptotic Bodies

An alternative mechanism in the formation of LE cells in vitro proposed by Schmidt-Acevedo et al. (248) involves the phagocytosis of apoptotic bodies induced by antinuclear antibodies that can penetrate cells. They found that the nuclear material engulfed by LE cells contains DNA strand breaks that corresponds to apoptotic bodies. Lee et al.

(249) described in vivo LE cells in the biopsy of the skin lesions of a patient with an overlap syndrome. The material engulfed by the LE cells seen in the papillary dermis appeared to be apoptotic bodies rather than opsonized bare nuclei released from dying cells.

Role of Complement in Lupus Erythematosus-Cell Formation

In 1959, Aisenberg (250) reported that the incubation of SLE serum at 56°C for 30 minutes diminished its capacity to induce LE-cell formation in an indirect LE-cell test. Instead of classical LE cells, the preparation instead showed homogenous, globular, purplish extracellular material. Addition of fresh human serum to isolated cell nuclei complexed with LE-cell factor caused formation of LE cells in the presence of viable phagocytes. This observation suggested that a heat-labile factor in normal serum is required for completion of the LE cell. It remained for Golden and McDuffie (240) and MacDuffie et al. (251) to establish the importance of complement in the LE-cell phenomenon. Frozen and thawed human leukocytes were incubated with gamma-globulin fraction of SLE serum containing antideoxyribonucleoprotein antibody. Viable leukocytes then were added to the system to complete the second, or phagocytic, stage of the LE-cell phenomenon. Typical LE cells formed even after thorough washing of the phagocytes and the leukocyte nuclei with saline. These investigators assumed that small amounts of complement remained adherent to the viable phagocytes. Nevertheless, when antiserum to human C3 was added to the system, there was inhibition of LE-cell formation; addition of excess fresh human serum abrogated the inhibitory effect of anti-C3 antiserum. Thus, complement clearly is required for the second stage of the LE-cell phenomenon, and the amount that is required probably is relatively small.

Extracellular Nuclear Material

Extracellular basophilic aggregates of amorphous or ovoid shape sometimes are seen in LE-cell preparations. This extracellular material (ECM), sometimes referred to as a hematoxylin body, may occur either alone or accompanied by typical LE cells. It has been assumed that ECMs represent products of the initial stage of the LE-cell phenomenon (i.e., complex of the LE-cell factor and nucleoprotein) left unphagocytosed. Arterberry et al. (252) found hematoxylin bodies without typical LE cells in 358 out of 3,000 patients with various diagnoses who underwent an LE-cell test. Three morphologic types were identified: (a) homogenous round hematoxylin body, (b) a lacy type, and (c) an amorphous variety. The homogenous round body was the most common, being found in 259 patients. Forty-five percent of patients in this group had definite SLE, and another 46% had RA or some disease variant.

By block titration of serum, Golden and McDuffie (240) have shown that the number of LE cells produced by lupus serum decreases as the number of ECMs increases, whereas the amount of complement and number of viable phagocytes stay constant in the indirect LE-cell test. IgG and IgM antideoxyribonucleoprotein antibodies were purified, and both antibody preparations produced ECMs. In contrast, only IgG antibody had the property to induce the classic LE cell. McDuffie et al. (251) suggest that the inability to induce typical LE cells may be related to the lack of complement-fixing property of IgM antideoxyribonucleoprotein antibody.

In Vivo Occurrence of Lupus Erythematosus Cells

The LE-cell factor and most other ANAs are not capable of penetrating intact and viable cells to react with their corresponding antigens in the nuclei. Lachmann (253) observed no morphologic changes in actively dividing HeLa cells when grown in tissue culture medium containing lupus serum. Rapp (254) showed that ANAs reacted with the nuclei of air-dried, but not viable, HeLa cells. Direct smears of the peripheral blood of patients with SLE showed absence of in vivo binding of immunoglobulin with the nuclei of leukocytes (255). However, in vivo LE cells occasionally have been described in direct smears of pericardial fluid (256), pleural fluid (257), joint fluid (258), ascitic fluid (259), and cerebrospinal fluid (260) of patients with lupus. LE cells may form in areas of local inflammation, as within the pleural cavity, probably because of the presence of leukocytes that are subtly altered or damaged to allow nuclear penetration by the IgG antideoxyribonucleoprotein antibody to form LE bodies. These damaged leukocytes may appear to be active and viable by morphologic criteria (261). Phagocytosis of the LE bodies by polymorphonuclear leukocytes or by macrophages will complete the reaction to form classic, and sometimes atypical, LE cells (262).

Clinical Significance of the Lupus Erythematosus Cell

The LE-cell test has largely been abandoned as a routine clinical test and supplanted by the fluorescent test for ANAs. The LE-cell test is labor intensive, and it requires a skilled technician to interpret the cytology. Atypical LE cells are seen not infrequently in clot preparations, and some observers may report this as a positive test while others will not unless classic LE cells also are present. Among the many modifications that were developed to increase the yield and/or to improve the cytology, the heparinized rotary glass bead method, the 2-hour clot test, and the combined rotated and washed clot technique were the major procedures used for several years. The American Society of Clinical Pathologists recently has endorsed that the LE-cell

test (CPT No. 85544) be abandoned in favor of more definitive, quantitative immunologic tests for SLE (263).

The frequency of a positive LE-cell test in SLE varies with the method of testing used, the frequency of performing the test, and the duration of time that the patient is studied. At some point during the course of the illness, the rotary glass bead LE-cell test was positive in 75.7 of 520 patients with SLE who were studied by Dubois and Tuffanelli (264). With combined rotary glass-bead and washed-clot methods, LE cells were found in approximately 90 of the patients.

Despite the high frequency in SLE, it now is well recognized that a positive LE-cell test is not entirely specific for the disease. Positive LE-cell tests have been reported in five to ten of adult patients with RA and in a smaller percentage of patients with systemic sclerosis, polymyositis, polyarteritis nodosa, and mixed connective-tissue disease (94 ,265 ,266 ,267 ,268). LE cells have been described in drug reactions secondary to penicillin (269 ,270 ,271 ,272), tetracycline (273), chlorpromazine (274), anticonvulsants (268), hydralazine (268), and procainamide (275) (see Chapter 47 , The Mother in Systemic Lupus Erythematosus). LE cells have been found in a case of intermittent hydrarthrosis with positive ANAs (276), in lupoid hepatitis (263 ,264), in two cases of lymphoma with no autopsy evidence of SLE (277), and in DiGuglielmo disease (acute erythroleukemia) (278).

Positive Lupus Erythematosus-Cell Test with Negative ANAS

There have been occasional reports of cases in which the LE-cell test is positive, despite a negative fluorescent test for ANAs (278). Koller et al. (279) found 20 cases among a large group of patients tested for LE cells. Five met the criteria for SLE, seven had RA, and three had drug reactions. Wallace and Metzger (280) described two patients with biopsy-proven, cutaneous mild SLE with major organ involvement who had positive LE-cell and negative ANA tests using both rat liver and Hep-2 cells.

The explanation for this discrepancy in most of the cases that have been studied is not entirely clear (278). Nevertheless, when the clinical picture of a patient is compatible with or highly suspicious for SLE and the standard fluorescent test for ANA (FANA) is negative (after using multiple substrates), an LE-cell test should be ordered to corroborate the diagnosis (281). In addition, other tests that may be of value in this situation include the lupus band test on nonlesional skin and serologic tests for anti-Ro/SSA antibody and ELISA test for antihistone 1 antibody.

Table 28-6 summarizes information about the LE cells. Because positive LE cell tests are rare in patients without rheumatic disease, its presence in a patient with a low-titer, positive ANA may be confirmatory of lupus. (The reader is referred to pages 211 to 226 of the third edition of this textbook for a detailed description of LE-cell methodologies.)

Table 28-6: The Lupus Erythematosus (LE) Cell

1. The LE cell is induced in vitro by an IgG antibody to deoxyribonucleoprotein (LE-cell factor) and has specificity for histone H1.
2. The LE-cell factor reacts with the nuclear material of traumatized white blood cells to form a hematoxylin body. Phagocytosis of the hematoxylin body by a viable phagocyte in the presence of complement leads to the formation of classic LE cells.
3. In vivo LE cells may be seen in pleural, pericardial, synovial, ascitic, blister fluid, and the cerebrospinal fluid of patients with systemic lupus erythematosus.
4. The LE-cell test is positive in 90% of all patients with SLE at some time during the disease course. A positive LE-cell test may be seen in other conditions, including rheumatoid arthritis, scleroderma, mixed connective-tissue disease, lupoid hepatitis, and drug-induced LE.

Antiendothelial Cell Antibodies

Antiendothelial cell antibodies (AECAs) were first reported in 1971 by Linqvist and Osterland (282) using an indirect immunofluorescent test with mouse kidney sections as substrate. Since then, AECAs have been reported in SLE, systemic vasculitis, other connective tissue diseases and inflammatory conditions (283). Several different techniques are used to measure AECAs, including cellular ELISA, cytofluorometry, microcytotoxicity, Western blot analysis using cell extracts, and immunoprecipitation of radiolabelled endothelial proteins. Human umbilical vein endothelial cells commonly are used as substrate.

AECAs are a heterogenous group of antibodies that bind to a number of vascular endothelium cell antigens including surface-membrane proteins, nuclear and cytoplasmic antigens. However, nuclear and cytoplasmic components may represent contaminants released or exposed when endothelial cells are disrupted or fixed to prepare the antigen preparation in certain test systems for AECAs. Westphal et al. (284) showed that an ELISA test using fixed cultured endothelial cells detected antibodies not only to cell surface antigens but to intracellular components including DNA, histones, and cytoskeletelal proteins. On the other hand, flow cytometry analysis using unfixed endothelial cells detected antibodies to endothelial cell surface antigens.

AECAs bind to endothelial cells from arteries, veins, and human and murine endothelial cell lines, and cross-react with fibroblasts and peripheral blood mononuclear cells (285 ,286). The specific target antigens in endothelial cells recognized by AECAs are not known. Del Papa et al. (287) found AECAs in SLE sera reacted with a heterogenous series of endothelial-cell surface antigens including four proteins with molecular weights of 200, 180, 155, and 25 kd. Other candidate autoantigens that have been identified

include heat shock protein 60, ribosomal P protein P0, endothelial-specific plasminogen activator inhibitor, $ß_2$-glycoprotein I and proteins that have not previously been identified as autoantigens including ribosomal protein L6, elongation factor, profilin II, heparin sulfate, and other novel proteins (288 ,289 ,290). The target antigen(s) recognized by SLE AECAs may differ from one patient to another.

Clinical Association of AECAs in Systemic Lupus Erythematosus

AECAs are prevalent in SLE and have been reported by various investigators in 39% to 93% of patients (291). The wide range of prevalence rate is in part a result of the difference in the test method used and in the selection of patients. D'Cruz et al. (292) showed that AECAs were associated with active lupus nephritis and the highest serum antibody titers were found in patients with both nephritis and vasculitis. There was no correlation between AECAs levels and anti-dsDNA, antineutrophil cytoplasmic antibodies, and other antinuclear antibodies. The association of AECAs and lupus nephritis has been confirmed by other investigators (286). Conti et al. (293) reported a high prevalence and elevated serum titers of AECAs in SLE patients with psychosis and mood disorders.

Arterial and venous thrombosis and anticardiolipin antibodies also have been reported to be associated with AECAs in SLE (283), however, other investigators have failed to observe correlation with anticardiolipin antibodies (292). Yoshio et al. (294) found elevated titers of AECAs in SLE patients with pulmonary hypertension, Raynaud phenomenon, and digital vasculitis.

A prospective study in a small group of SLE patients for 25 months showed that the serum level of AECAs can serve as a marker of disease activity. In some patients, a rise in the serum titer of AECAs was the only serologic marker of disease exacerbation when the serum C3 and anti-dsDNA levels remained unchanged (295).

Pathogenic Signficance of AECAs in SLE

The clinical association between AECAs, active nephritis, and vasculitis led investigators to propose a role of AECAs in the pathogenesis of vascular damage in SLE. Carvalho et al. (296) have shown that purified IgG isolated from SLE sera containing AECAs upregulated the expression of adhesion molecules and leukocyte adhesion to endothelial cells. AECAs induced the release of interleukin-1 and another mediator that stimulates endothelial cells in an autocrine manner. AECAs in patients with Wegener granulomatosis also have been shown to exhibit similar in vitro activity and in addition induced the secretion of IL-1ß, IL-6, IL-8, and MCP-1 (297).

AECAs that recognize heat shock protein 60 can induce apoptosis of endothelial cells providing a target for antiphospholipid antibodies leading to vascular thrombosis (288). A monoclonal IgG AECA derived from SLE was shown to bind and activate endothelial cells in vitro through the NF-κB pathway (298).

Based on these observations, it is proposed that AECAs induce vascular damage in SLE and other systemic vasculitides by activating endothelial cells, inducing the secretion of cytokines and chemokines, and facilitating leukocyte recruitment and adhesion and local production of tissue actor leading to thrombosis.

Section IV
The Skin in Lupus

Chapter 29
Pathomechanisms of Cutaneous Lupus Erythematosus

Jan P. Dutz

Richard D. Sontheimer

Victoria P. Werth

Abnormal cutaneous reactivity to sunlight is such a seminal clinical feature of lupus erythematosus (LE) that it is one of the 11 classification criteria proposed by the American Rheumatism Association in 1982 for a case definition of systemic lupus erythematosus (SLE) (1). Photosensitivity also is a cardinal feature of the cutaneous and neonatal forms of lupus erythematosus. This strong clinical association has led to the postulate that abnormal photoreactivity participates in the pathogenesis of cutaneous lesions in lupus erythematosus. In this review we will discuss the evidence for abnormal photoreactivity in lupus erythematosus and speculate on the cellular, molecular, and genetic factors that may underlie this abnormality. Most of our current understanding of cutaneous photoreactivity is derived from animal studies. As there is yet no convincing animal model of cutaneous lupus erythematosus, many studies remain descriptive in nature. To arrive at an understanding of the potential mechanisms underlying the development of cutaneous lupus, we will discuss the possible interrelated roles of ultraviolet light-mediated induction of apoptosis and inflammation as well as immunomodulation. Additionally, we will consider the role and importance of humoral and cellular factors and also discuss the roles of blood vessels as targets and participants in the disease process. Finally, we will comment on the participation of soluble cytokines and cofactors of inflammation in lesion induction. An incorporation of recent advances in the fields of photobiology, immunology, cell biology, and genetics then will allow the construction of a current model of the pathophysiology of cutaneous lupus.

Clinical Photosensitivity in Lupus

Skin lesions are common in SLE and are found in up to 90% of patients (2). Lupus-specific cutaneous findings such as malar rash (acute cutaneous lupus erythematosus [ACLE]) and discoid lupus (chronic cutaneous lupus erythematosus [CCLE]) were found in 64% and 31% of patients in a large cohort (2), respectively. Skin disease is the first symptom of disease in 23% to 28% of patients with SLE (3). There is a clear relationship between sunlight exposure and the manifestations of cutaneous LE and cutaneous lesions tend to occur in sun-exposed skin. Cazenave, in the original 1851 description of LE stated that outdoor workers were predisposed (4). Isolated case reports suggested that lesions could be induced by light (5). In 1965, Epstein used a repeated light exposure technique to demonstrate that ultraviolet (UV) radiation could induce skin lesions in patients with LE (6). This observation was confirmed quickly by two other groups (7 ,8). Lesion induction was often delayed by up to 2 weeks, and patients with either systemic lupus or cutaneous lupus were shown to develop more prolonged skin redness than normal controls (9 ,10). Recent studies have confirmed that clinical aberrant photosensitivity manifested as prolonged and delayed erythema is present in almost all patients with cutaneous or systemic disease; however, the minimal doses of UV light required to induce erythema in standard testing protocols appears to be within the normal range of the general population (336).

Action Spectrum of Cutaneous Lupus Erythematosus

Ultraviolet light is commonly divided into germicidal UV light (UVC), midrange UV light or sunburn UV light (UVB) and long-wave UV light (UVA) also termed near UV or black light (Fig. 29-1). This separation is important as the differing wavelengths have varying biologic effects (vide infra). Although UVC has been used in many in vitro studies of the cellular response to UV irradiation, this spectrum of UV light is completely blocked by the earth's atmosphere and is of dubious pathophysiologic relevance. Early investigators (6 ,7 ,8 ,11 ,12), defined an action spectrum in the UVB range (290 to 320 nm) for the cutaneous forms of LE. More recent studies have demonstrated that UVA (320 to 400 nm) also can contribute to the induction of skin lesions. Lehmann et al. performed extensive photoprovocation studies (13). They were able to induce lesions in 63% of patients with subacute cutaneous lupus erythematosus (SCLE), in 72% of tumid LE cases, in 60% of SLE cases and 45% of CCLE cases (14). Of those with UV-induced lesions, 53% were induced by a combination of UVB and UVA, 34% by UVA alone and 42% by UVB alone. Abnormally prolonged erythema was also noted in SLE patients after exposure to

UVA (15). Although UVA-induced erythema in normal skin requires 1,000 times more energy than from UVB (12), daily exposure to UVA is much greater than UVB, and at the level of the dermal capillaries, the UVA effect, as a result of greater penetrance, is much stronger that UVB (Fig. 29-2). Thus UV light of varying wavelengths can induce abnormal skin responses in lupus patients and can induce cutaneous lesions.

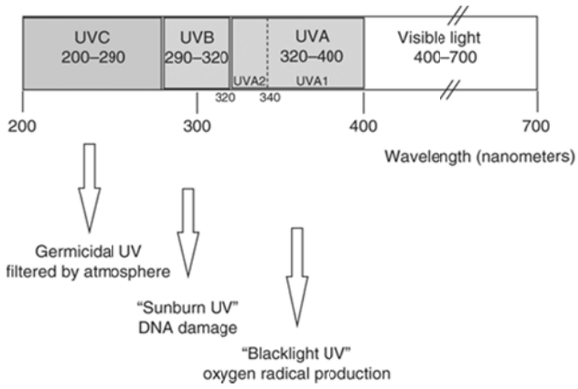

Figure 29-1. The spectrum of ultraviolet light irradiation by wavelength. Ultraviolet light is commonly divided into germicidal UV light (UVC), midrange UV light or sunburn light (UVB) and long-wave UV light (UVA) also termed near UV or black light. Both UVB and UVA can induce skin lesions in photosensitive lupus erythematosus. UVA-1 is light limited to the longer wavelength spectrum of UVA and has been used therapeutically in systemic lupus erythematosus.

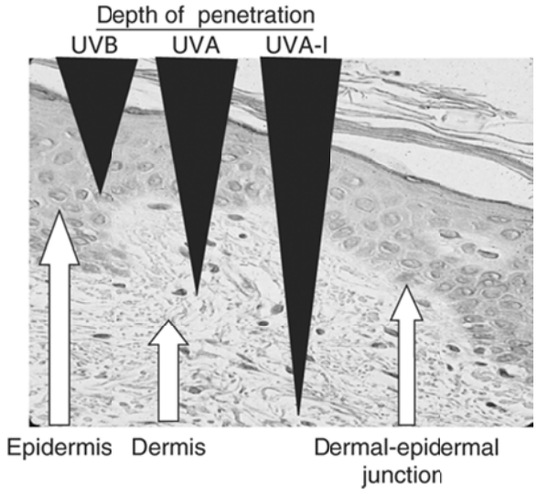

Figure 29-2. Photomicrograph of normal skin depicting the depth of penetration of the various forms of ultraviolet radiation (UVR). The skin is formed by an epidermal compartment that includes the stratum corneum (horny layer), the epidermis proper, and a basement membrane zone. Keratinocytes (skin cells), melanocytes (pigment cells), and Langerhans cells (dendritic cells) are found in this compartment. The dermal compartment includes the vasculature of the skin and connective tissue. Penetration of UVR is directly proportional to the wavelength of the radiation. UVB is absorbed primarily in the epidermis. UVA penetrates the dermis and can affect the skin vasculature. UVA-1 has the potential to penetrate the skin more deeply that UVA of shorter wavelength.

Role of Ultraviolet in Exacerbation of SLE

It often is stated that sunlight cannot only aggravate cutaneous LE but can potentiate systemic features of disease. Up to 73% of patients with SLE report photosensitivity (16). However, phototesting with standardized protocols correlates poorly with patient-reported photosensitivity (17). This may be because of the delayed nature of the phenomena observed on phototesting (14). Although patients report that several disease symptoms (including weakness, fatigue, and joint pain) are increased by sun exposure (16), variation in disease activity related to sun exposure using objective variables has not been shown in large cohort studies. The available evidence is largely anecdotal. Repeated single-patient observations indicate that sunlight may precipitate disease de novo or aggravate existing disease. Phototherapy for incorrectly presumed psoriasis (using UVB) has led to aggravation of the lupus lesions (18). Tanning bed use (a source of predominant UVA) also has been reported to either induce (19) or exacerbate SLE (20). Two recent studies show that although cutaneous manifestations are more common in the summer months, systemic disease activity is increased in the 3 to 6 months following maximal potential sun exposure. This has led these authors to suggest that summer UV light exposure may lead to systemic flares several months later (21 ,22). Interestingly, a pale, sun-reactive skin type was independently associated with increased risk (OR = 2.3) of developing SLE in a Swedish case-control study (23).

Polymorphous Light Eruption as a Predisposing Feature of LE Photosensitivity

Is there direct clinical evidence of a predisposing sensitivity to UV irradiation in patients with LE? Polymorphous light eruption (PLE) is a common photodermatosis affecting up to 10% of the population (24). There is a lag time of 2 hours to 5 days between sun exposure and the development of a pruritic, erythematous eruption on the skin. Selected patients with PLE have been noted to have severe photosensitivity as defined by the persistence of photo-induced lesions. These patients were noted to have positive antinuclear antibodies in significant titers and have been proposed to be a “forme fruste” of photosensitive LE (25). Nyberg recently assessed 337 consecutive lupus patients (with either cutaneous or systemic LE) recruited from dermatology departments in Finland and Sweden and found that almost 50% gave a history of photosensitivity consistent with PLE (26) and this predated the clinical onset of LE by many years. In a separate study, they went on to photoprovoke lesions in their photosensitive LE patients and produced lesions of clinical PLE with histology consistent with PLE in

about half of these patients (27). Immunohistochemical analysis shows upregulated intercellular adhesion molecule-1 (ICAM-1) staining on basilar keratinocytes in both PLE (28) and cutaneous LE (29). This molecule can enhance inflammatory cell infiltration. It is thus possible that there is a mechanistic link between abnormal photosensitivity (as manifest by a PLE-like eruption) and susceptibility to LE. A similar association was subsequently noted in British families of patients with photosensitive cutaneous lupus where first-degree relatives had a significantly higher risk of PLE (30). It should, however, be pointed out that studies of long-term cohorts of patients with PLE have not documented an increased risk of LE in these populations (31 ,32). Thus a less common disease (LE) may be preceded by an increased incidence of a more common photosensitive condition (PLE) but the presence of PLE-like photosensitivity alone does not predict lupus.

A Selective Sensitivity to UV Light in LE?

Clinical observations suggestive of a role for UV light in the pathogenesis of systemic lupus erythematosus and lupus skin disease have been supported by mechanistic studies. Autoantibodies to DNA and DNA-associated proteins characterize systemic LE. In early studies, UV-irradiated DNA but not native DNA was shown to induce a humoral immune response in animals. Repeated injections of UV-irradiated DNA (UV-DNA) into rabbits resulted in renal disease characterized by proteinuria and renal immunoglobulin deposition (33). Similar results were obtained in mice and some of the immunopathologic and histopathologic changes associated with cutaneous LE were then reproduced by exposing the skin of UV-DNA immunized mice to UV radiation (34). One of the changes induced in DNA by UV is the formation of thymidine dimers. Thymidine dimers were found in the skin of UV-irradiated mice and UV-DNA antibodies reacted to these thymidine dimers (35 ,36). Such immune responses to UV-altered DNA have also been found in LE patients (37). From this concept of an immune response to UV-DNA evolved the idea that patients with LE may have an impaired ability to repair UV-damaged DNA with subsequent persistence of potentially immunogenic UV-damaged DNA. Studies using fibroblasts from patients with LE showed that these cells were more susceptible to the cytotoxic activity of UVB (38) as well as UVA (39) than fibroblasts from controls. This susceptibility was manifested as an increase in cellular lethality following UV exposure. This enhanced cellular toxicity to UV was not from defects in DNA repair and has not yet been adequately explained (40).

Table 29-1: Biologic Effects of Ultraviolet Radiation

Characteristic	UVB	UVA
Absorption by molecules	DNA, amino acids, melanin, urocanic acid	Melanin
Direct DNA damage	Increased	Minimal
Free-radical production	Minimal	Increased
Depth of penetration	Epidermal	Dermal
Epidermal effects	Stratum corneum thickening, intermediate and delayed apoptosis, keratinocyte cytokine transcription and release	Immediate apoptosis
Langerhans cell effects	Inactivation, emigration	Minimal

UVA, ultraviolet A; UVB, ultraviolet B.

UV-altered DNA can induce lupus-like disease in animals and LE patients may exhibit increased levels of UV-altered DNA. Does UV light also accelerate disease in animal models? Repeated exposure to UV light can accelerate the spontaneous systemic lupus of certain murine strains. Exposure of BXSB autoimmune lupus mice to UVB has been shown to induce the release of autoantigens, to promote antibody production and to promote early death (41). This could not be reproduced in other lupus strains such as the NZB/NZW model (42), the MRL/lpr mouse (41), or a C1q-deficient mouse (43), suggesting that UV light may have a variable role in the genesis and acceleration of lupus depending on the genetic background (44). Nevertheless, these observations, both clinical and mechanistic, have been used to justify continued photo-protection for patients with systemic lupus (45 ,46).

Biologic Responses to Ultraviolet Light

Ultraviolet light has multiple effects on living tissue. Potential molecular targets of ultraviolet light include not only DNA, but RNA, proteins, and lipids. Table 29-1 summarizes the biologic effects of UV light on the skin. In addition to alteration of DNA, cytoskeletal reorganization was noted in keratinocytes (skin cells) after UV irradiation (47). An early study by LeFeber revealed that UV light can induce the binding of antibodies to selected nuclear antigens on cultured human keratinocytes (48). The specificity

of these antibodies was not defined, but it is now known that they are commonly directed against Ro/SSA, La/SSB, ribonucleoprotein, and Smith (Sm) antigens, and are the antibodies associated with LE and photosensitivity. Norris later noted increased antibody binding to keratinocytes following in vivo UV irradiation of human skin (49). This was confirmed independently by Golan, who observed binding of anti-Ro/SSA–positive sera to cultured keratinocytes (50). These results could be explained by UV-induced translocation of antigens to the cell surface with or without the death of the cell, or by other alterations in the antigens allowing the binding of autoantibodies taken up by the living cell (51). In 1994, Casciola-Rosen et al. demonstrated that when keratinocytes grown in cell cultures are irradiated with UVB, they actively cleave their DNA and die by a process termed apoptosis (52). During this process, the antigens recognized by autoantibodies such as Ro/SSA, and calreticulin are concentrated in structures termed blebs or apoptotic bodies found at the cell surface. Larger blebs arise from the nucleus and harbor Ro/SSA, La/SSB, and other nuclear material. These investigators (53) and others (54) have proposed that these bleb-associated antigens may then be phagocytosed, packaged, and presented to lymphocytes, thereby stimulating autoimmune responses.

Ultraviolet Light, Apoptosis, and the Skin

Apoptosis and necrosis are the two major mechanisms of cell death. Apoptosis is an ordered means of noninflammatory cell removal in which a central biochemical program initiates the dismantling of cells by nuclear fragmentation, formation of an apoptotic envelope, and shrinking of the cell into fragments leading to phagocytosis by parenchymal cells as well as phagocytes (55 ,56 ,57). In necrosis, cells are passive targets of extensive membrane damage leading to cell lysis and release of contents. Apoptosis can be further categorized into “immediate” apoptosis or preprogrammed cell death, and “intermediate” and “delayed” apoptosis or programmed cell death (reviewed in (58)). Immediate apoptosis is protein synthesis–independent, occurs rapidly after triggering (59), and is the result of singlet-oxygen damage to mitochondrial membranes. Intermediate apoptosis is commonly the result of activation of a membrane receptor with a death domain such as Fas (reviewed in (60)). Delayed apoptosis requires several hours for execution and is protein synthesis–dependent. This can be the result of DNA damage (61) or from lack of essential survival signals (62).

Keratinocyte Apoptosis and Ultraviolet Light

Keratinocytes die by programmed cell death as part of their normal program of differentiation (63 ,64 ,65). This occurs normally in the granular cell layer of the epidermis, at the interface with the stratum corneum. The molecular machinery controlling this programmed cell death in keratinocytes is complex and still poorly understood (66). Basilar keratinocytes have been found to be relatively resistant to apoptosis induced by a variety of stimuli (67). This may be as a result of the expression of proteins that specifically inhibit apoptosis such as bcl-2, survivin (68), and other inhibitors of apoptosis (IAPs) (reviewed in (69)). Ultraviolet light has long been known to induce apoptotic death in suprabasilar keratinocytes; such cells were called “sunburn cells” by morphologists (70). UV light now is known to induce apoptosis by multiple mechanisms. Long-wave ultraviolet light (UVA1; 380 to 400 nm) can induce “immediate” apoptotic death through singlet-oxygen damage to mitochondrial membranes (71). UVB can induce direct, ligand-independent activation of membrane death receptors such as Fas (72) as well as FasL (Fas ligand) upregulation and subsequent Fas-FasL binding (73). UVB also sensitizes keratinocytes to TNF-related apoptosis inducing ligand (CD253) (TRAIL)-induced apoptosis by downregulating the level of TRAIL decoy receptors (74). Tumor necrosis factor-α (TNF-α) release and consequent ligation of the TNF receptor p55 (TNFR1) also has been shown to be an important mediator of UVB-induced keratinocyte apoptosis (75 ,76). Finally, UVB can induce keratinocyte apoptosis secondary to DNA damage (77). Once the signal for apoptosis is triggered, specific enzymes within the cell begin the dismantling process. These enzymes now are collectively called caspases, an acronym for cysteine asparate proteinases (78). These enzymes are known to be important in UV-induced cell death because specific inhibitors of these enzymes prevent the UV-induced death of keratinocytes (79).

Apoptosis in Cutaneous Lupus Erythematosus

The potential importance of apoptosis in the pathogenesis of cutaneous lupus is underscored by a number of recent observations. Using terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) staining to detect nuclei with DNA damage, Norris demonstrated the presence of an increased number of apoptotic keratinocytes in the basal zone of CCLE lesions and in the suprabasal zone of SCLE lesions (67). An increase in the number of apoptotic cells in lesional skin from patients with cutaneous LE since then has been confirmed and has been associated with increased p53 protein expression as determined by immunohistochemistry (80 ,81). The nuclear phosphoprotein p53 is a tumor suppressor that is upregulated in response to UV-induced DNA damage (82) and in response to the cytokines TNF-α (68) and interferon-γ (IFN-γ) (83). Upregulation of p53 in suprabasilar keratinocytes can initiate cell death by apoptosis (84). Therefore, the increased number of apoptotic cells could be a result of an increased rate of apoptosis induction mediated directly by UV light or as a consequence of UV-induced cytokine release. Apoptosis also can be induced by cellular cytotoxic mechanisms. Cytotoxic T lymphocytes (CTL) and natural killer (NK) cells can induce apoptosis through multiple mechanisms (reviewed in (85)),

including the release of perforin and granzymes (83); cytokine release (IFN-γ, TNF-α, TNF-α, interleukin (IL)-1) (86); and triggering of Fas by FasL (87). The presence of leukocytes in proximity to the apoptotic cells (67) and the presence of FasL-positive macrophages in proximity to apoptotic cells in lesional hair follicles (88) suggest a role for such cellular apoptotic mechanisms in established lesions.

An increased number of apoptotic cells are noted in lesional LE skin. Can this have systemic as well as local consequences? There is evidence that the biochemical processes of apoptosis generate novel antigens that are uniquely targeted by autoantibodies. Casciola-Rosen et al. have shown that the caspases activated during apoptosis cleave intracellular proteins into fragments that are bound by autoantibodies from some patients with LE (89). Further, proteins specifically phosphorylated by stress-induced apoptosis are targeted by antibodies from LE patient sera (90 ,91). From these observations, it has been inferred that the process of apoptosis is important in the initiation of autoimmune responses. Recently, it has been shown that patients with LE skin disease have autoantibodies that preferentially recognize apoptotic-modified U1–70-kd RNP antigen when compared to patients without skin disease (92). This provides further in vivo evidence that immune recognition of modified forms of self-antigen occurs in cutaneous LE and suggests that this immune recognition and the processing of apoptotic-derived antigens may participate in the pathogenesis of the disease.

Granzyme B, a serine protease found principally in the cytotoxic granules of CTL and NK cells, also can induce cell death by apoptosis in susceptible target cells. Granzyme B can cleave cellular proteins into unique fragments not detected in other forms of apoptosis. Such cleavage products, specific for cytotoxic-granule–induced death, also are bound by antibodies present in LE sera (93). Interestingly, expression of granzyme B has been detected in keratinocytes, suggesting that these molecules may participate in cutaneous defense mechanisms (94) and perhaps in keratinocyte death. In this case, specific correlation of autoantibodies to granzyme B–generated epitopes with cutaneous LE has not yet been made. Novel autoantigens can be generated by apoptosis that is either stress-induced (UV light, viral infection, or other trigger) or secondary to cellular immune mechanisms. The generation and concentration of such neo-antigens could pose a challenge to self-tolerance (95). Whether the increased keratinocyte apoptosis noted in cutaneous LE leads directly to the formation of autoantibodies specific to apoptosis-derived byproducts is still speculation.

Abnormalities of Ultraviolet-Induced Keratinocyte Apoptosis as a Predisposing Factor in Cutaneous Lupus Erythematosus

Although detection of an increased number of apoptotic cells in LE epidermis may underlie an increase in apoptosis, either an increase in the rate of apoptotic death or a decrease in the rate of clearance of apoptotic debris could lead to the observed increase in apoptotic cell numbers. Phagocytosis by macrophages or parenchymal cells is the final event in the clearing of cells undergoing apoptosis (56 ,57). A number of observations suggest that clearance of apoptotic debris may be impaired in LE. Systemic autoimmunity has been noted in mice deficient for molecules potentially involved in the clearance of apoptotic cells including serum amyloid P (SAP), c-Mer, C4, IgM or C1q (reviewed in (96)). SAP is a member of a family of proteins termed pentraxins that bind to apoptotic cells and then interact directly with phagocyte receptors or with C1q. C1q and a related protein, mannose binding lectin (MBL) are collectins or proteins with globular lectin–like heads and collagen-like tails that also flag late-apoptotic cells for disposal by phagocytosis. Interestingly, the surface blebs of apoptotic keratinocytes bind C1q, an early component of the complement cascade (97). The major C1q-binding protein that has been identified in apoptotic blebs to date is calreticulin (52), and autoantibodies to calreticulin can interfere with this binding (98). The binding of C1q to apoptotic cells has been postulated to facilitate the clearance of these cells by macrophages that express a C1q cell surface receptor (99). A potential role for C1q in the clearance of apoptotic debris and in the genesis of cutaneous LE is suggested by two observations. First, patients with C1q deficiency develop LE-like photosensitive eruptions (100). Second, mice with C1q deficiency develop an SLE-like disease associated with an accumulation of apoptotic cells in the kidney (101). Moreover, a recent study in humans has demonstrated that the clearance of apoptotic lymphocytes by macrophages is indeed impaired in some patients with SLE (102) and impaired uptake of apoptotic cells by macrophages has been noted in germinal centers of patients (103). While a number of cellular signals and receptors for the phagocytosis of apoptotic debris has been identified, the magnitude of a clearance defect in patients with cutaneous lupus remains unclear. Further it is unknown if impaired clearance is secondary to a defect in the recognition and the binding of apoptotic particles or in macrophage phagocytosis. It is also unknown if this defect extends to the phagocytosis of other cell types such as keratinocytes. Sunburn cells normally are cleared rapidly and disappear within 24 to 48 hours in murine skin (104 ,105). Whether this is the result of shedding or of phagocytosis by either neighboring keratinocytes or macrophages has not yet been clarified.

Macrophages are the organism's primary remover of cellular debris. Macrophages that have ingested apoptotic cells in vitro secrete factors such as transforming growth factor-β and prostaglandin E-2 (PGE2). These factors can inhibit the release of pro-inflammatory cytokines such as TNF-α by neighboring cells. In addition to removal of cellular debris, macrophages may therefore actively promote tolerance and inhibit pro-inflammatory cytokine production (106). Acquisition of apoptotic cells material by immature dendritic cells (DC), similar to macrophages, is

enhanced by C1q and MBL, and promotes the production of immunomodulatory cytokines such as IL-10 (107). Mature DC, in contrast, are professional antigen-presenting cells present in the skin that have been shown both to acquire antigen from apoptotic cells and then to prime naive T cells in an antigen-specific fashion (108). Thus, depending on the nature of the phagocytic cell (macrophage and immature DC versus mature DC) with which the apoptotic cell interacts, autoimmunity or tolerance may ensue. High numbers of apoptotic cells have been shown to act as a trigger for local DC maturation and to promote antigen presentation to class I and class II MHC-restricted T cells in a murine system (109). Necrosis is a cell-death process characterized by the rapid depletion of ATP stores and subsequent loss of cell membrane integrity that can also result from UV light injury. For example, high doses on UVB preferentially induce keratinocyte necrosis (110). Necrotic cells release potent pro-inflammatory mediators such as high mobility group 1 protein (111) and uric acid (112). The incidence of necrotic cells following UV insult has not been accurately determined. An abundance of apoptotic cells and possibly necrotic cells, either from excessive amount of death induction by UV or other mechanisms or from a defect in clearance could permit tolerance to self antigens to be broken. Figure 29-3 summarizes the potential role of apoptotic mechanisms in the initiation and perpetuation of photosensitive LE.

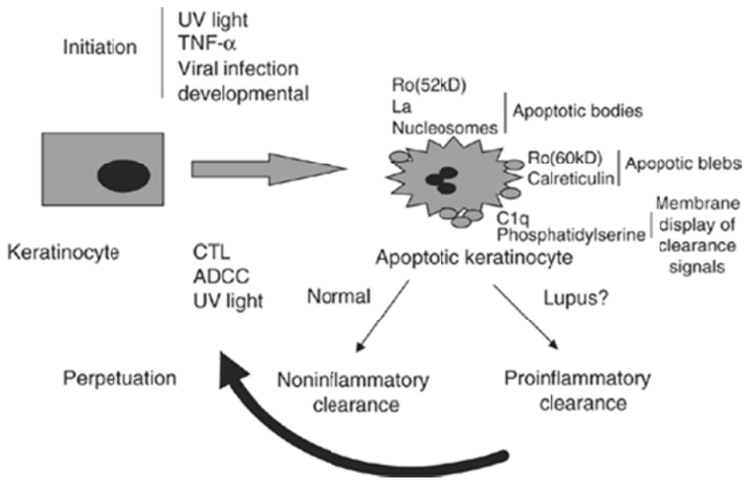

Figure 29-3. Potential role of keratinocyte apoptosis in the pathogenesis of photosensitive lupus erythematosus. Apoptosis is an ordered means of cell death. Apoptosis can be initiated in keratinocytes by ultraviolet (UV) radiation (UVB as well as UVA), by viruses, by cytokines (TNF-α), by growth-factor withdrawal, by differentiation, and by cytotoxic cellular assault. Apoptosis leads to small bleb formation in which Ro antigen and calreticulin are concentrated. Larger apoptotic bodies contain other potential autoantigens including Ro antigen (60 kd), La, nucleosomes, and 70-kd RNP antigen. Apoptosis leads to the exposure of phosphtidylserine on the cell surface and to the binding of C1q. The presence of apoptotic cell in a proinflammatory environment may lead to uptake and processing by antigen-presenting cells leading the priming and boosting of T cells and B cells to self-antigen.

Ultraviolet Light as Inflammatory Stimulus

Erythema (redness) is a normal response to UV light and is mediated by multiple eicosanoids, vasoactive mediators, neuropeptides, and cytokines released from keratinocytes, mast cells, endothelial cells, and fibroblasts (113 ,114). Table 29-2 lists the wide range of mediators released by UV light in the skin. As discussed, UV light can induce prolonged erythema and cutaneous lesions in patients with LE. UV light is not only an executioner, killing keratinocytes by apoptosis, it also is a generator of neo-antigens (such as UV-DNA).

Cytokine Release

UV light can induce cutaneous inflammation by promoting the release of inflammatory mediators and cytokines by inducing adhesion molecule display and by releasing chemokines to attract inflammatory cells into the skin (reviewed in (115)). Both UVB and UVA can participate in lesion induction and act by differing mechanisms. UVB induces the release of the primary cytokines IL-1α and TNF-α from the epidermis, initiating a cascade of inflammatory events. UVB induces IL-1α gene transcription in keratinocytes (116) and elevates circulating levels of IL-1α

bioactivity (117). Likewise, UVB induces the release of TNF-α from keratinocytes (118). This may be partly dependent on the photo-isomerisation of trans- to cis-urocanic acid in the differentiated epidermis (119). TNF-α release has been noted to be greatest in terminally differentiated keratinocytes in culture (120) and is thus proposed to be maximal in the superior layers of the epidermis. IL-1α and TNF-α are “primary cytokines” that induce the release of a number of other pro-inflammatory cytokines from the epidermis (reviewed in (121)). For example, IL-1α and TNF-α induce the secondary release of IL-6, PGE2, IL-8, and granulocyte-monocyte colony-stimulating factor (GM-CSF) by keratinocytes (122 ,123). These molecules are costimulatory factors for lymphocyte activation by antigens or superantigens, stimulate Langerhans cell function (the Langerhans cell is the resident DC of the skin), stimulate collagenase production, and act as pyrogens and stimulators of acute-phase reactants. Additionally, IL-8 and GM-CSF are chemotactic and induce inflammatory cell migration into the skin (124). Both IL-1α and TNF-α also induce adhesion molecule expression such as ICAM-1. Importantly, TNF-α can induce activation of Langerhans cells, the professional antigen-presenting cells of the epidermis, via binding of the TNF p75 receptor (TNFR2) on these cells (125). This results in migration of these cells to the regional lymph nodes where they can participate in immune responses (126). In addition to IL-1α and TNF-α release, UVB can stimulate the release of IL-10 (127 ,128 ,129 ,130), and IL-6 directly (131). IL-10 has been shown to mediate local (132) as well as systemic UV-induced immunosuppression (133). Chemokines are chemo-attractive proteins that are associated with inflammatory cell recruitment. UVB irradiation of primary human keratinocytes, in the presence of pro-inflammatory cytokines such as IL-1 and TNF-α or IFN-γ significantly enhances the expression of the inflammatory chemokines CCL5, CCL20, CCL22, and CXCL8 (134). This is of relevance in cutaneous lupus as CCL5 and CXCL8 are highly upregulated in lesional skin (134). Following photo-testing, elevated levels of CCL27, a novel skin-specific chemokine known to recruit memory T cells into the skin was also found in the dermis of LE patients (134).

Table 29-2: Mediator Release by Ultraviolet Radiation

Source of Mediator	UVB	UVA
Keratinocyte	IL-1α, TNF-α	
	GM-CSF, IL-6, IL-8	IL-8
	IL-10	IL-10, IL-12
	TGF-ß	PGE2, PGF2α
	PGE2, PGF2α	
Mast cell	TNF-α LTC4, LTD4, PGD Histamine	
Endothelial cell	TNF-α, PCI2	PCI2
Langerhans cell		IL-12

Ultraviolet radiation results in the release of interleukins (IL), prostaglandins (PG), prostacyclin (PC), leukotrienes (LT), and other mediators.
UVA, ultraviolet A; UVB, ultraviolet B.

Transgenic overexpression of IL-6 in murine keratinocytes has been associated with an increase in the thickness of the stratum corneum but not with significant cutaneous inflammation when expressed alone (135). Both IL-10 and IL-6 have further been shown to induce local heat-shock protein synthesis (136 ,137). UVB induced primary cytokine production and release is likely the result of UVB-induced DNA damage: UV-damaged DNA, specifically UV thymidine dimer formation, induces DNA repair enzymes that also regulate cytokine transcriptional activity (138).

In contrast to UVB, UVA upregulates ICAM-1 in keratinocytes directly by producing oxygen-free radicals that affect gene transcription (139). UVA also upregulates IL-8 and IL-10 production in keratinocytes and FasL expression in dermal mononuclear cells (140 ,141). The longer wavelength of UVA allows it to penetrate into the dermis and to upregulate vascular endothelial ICAM-1 and E selectin thereby increasing leukocyte-vascular adhesion (142). Acute low-dose UVA administration, but not UVB, also results in IL-12 production by keratinocytes in vivo (143 ,144). UVA results in a rapid increase in interferon-γ (IFN-γ) levels in the skin, the source of which may be resident epidermal T cells (144). This IFN-γ has been postulated to potentiate IL-12 release (144). IL-12 is a potent immunostimulant that can abrogate tolerance induced by low-dose UVB (145) by enhancing DNA repair (146). IL-12 also decreases UV-induced serum TNF-α in mice and UV-induced keratinocyte TNF-α (147 ,148), possibly through the effects on DNA repair. Interestingly, UVA inhibits chemokine CCL17 production by keratinocytes (149). The chemokine CCL17 or thymus and activation-regulated chemokine (TARC) is one of the major chemokines that attract T cells into inflamed skin.

Ultraviolet Light and Th-1/Th-2 Cytokine Balance

Overall, exposure to UVB radiation correlates with a predominance in cytokines that promote T helper 2 (Th2) immune responses at the expense of T helper 1 (Th1) immune responses and that may result in photo-immunosuppression (150). While potentially suppressing cellular immune responses, Th2 responses generally promote antibody production (151). Exposure to physiologic levels of UVA radiation alone, or together with UVB (like natural sunlight), results in the local predominance of cytokines that promote Th1 immune responses. These Th1 responses are “immunopotentiating” and result in strong cellular immune responses including $CD8^+$ cytotoxic T cell responses (151). Whether patients with cutaneous LE have a

unique primary or secondary sensitivity to UV light-induced cytokine changes is not yet clear. Significant interindividual variability in UV light-induced ICAM-1 expression and TNF-α release has been noted in keratinocyte cell lines (120) and this suggests that there may be genetic variability in the human skin response to UV. Indeed, the presence of the TNF-α promoter -308A allele, increased in patients with SCLE, has been associated with enhanced TNF-α production following UV exposure of keratinocytes (152). An increased frequency of this TNF-α promoter allele has also recently been noted in neonates with cutaneous manifestations of neonatal LE. Lesional skin, but not skin from normal neonates, demonstrated TNF-α on immunostaining (153).

Possible Benefit of Ultraviolet in Lupus Erythematosus Patients

Although the above discussion has focused on the potential inflammatory effects of UV light, recent work has suggested that selective UV radiation may have salutatory effects in LE. UVA irradiation of NZB/NZW mice has resulted in increased survival and decreased levels of circulating anti-DNA antibodies (154). Subsequently, a randomized, double-blind, cross-over study of low-dose UVA1 light (light limited to the longer wavelength spectrum of UVA, 340 to 400 nm) compared to visible light showed significant clinical and serologic improvements in SLE patients treated with UVA1 light (155). Recently, treatment of patients with moderately active SLE was shown to significantly decrease disease activity scores (156) and to improve skin disease and this correlated with a decrease in the proportion of circulating IFN-γ–producing T cells, particularly of the $CD8^+$ T cell subset (157).

Humoral Factors in Cutaneous Lupus Erythematosus

Autoantibody production is a sine qua non of SLE and the autoantibodies can be pathogenic. Extracutaneous lupus-like disease can be induced in animals by the introduction of anti-DNA antibodies either transgenically (158) or by intravenous injection (159). Autoantibodies can initiate cellular cytotoxicity and activate the complement cascade and also can promote the recognition of epitopes related to the original autoantigen through a process termed epitope spreading.

Immunopathology of Cutaneous LE

Immunofluorescence studies of cutaneous LE lesions show lesional deposition of immunoglobulins (Fig. 29-4). In 80% to 90% of CCLE or ACLE, and in 50% to 60% of SCLE, a thick band of immunoglobulins and complement components is deposited along the dermo-epidermal junction (160). These complexes have been localized on the upper dermal collagen fibers and along the lamina densa of the epidermal basement membrane zone (161). As these deposits also are found in clinically normal skin of patients with SLE, their role in the local induction of cutaneous tissue injury is still unclear (162). Further, the specificities of these skin basement membrane-deposited antibodies has not been defined although colocalization of the lupus band deposits with collagen VII has been determined using confocal laser scanning microscopy (163).

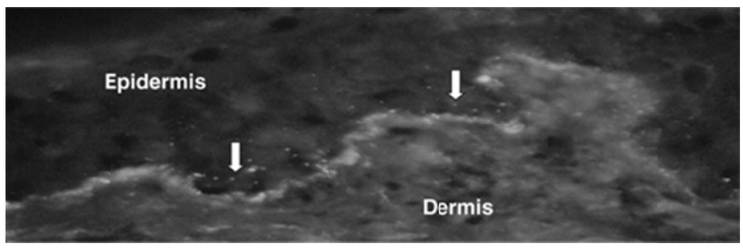

Figure 29-4. (See color plate.) Immunopathology of subacute cutaneous lupus. Direct immunofluorescence analysis for the presence of IgG reveals a “dustlike” distribution of IgG deposits in the suprabasilar keratinocytes (arrowheads mark specific IgG “dust” deposits). There is also IgG deposition in the basement membrane zone.

Ro/SS-A and La/SS-B Autoantibodies and LE Photosensitivity

Several specific autoantibodies have a special relationship to cutaneous LE. SCLE was recognized as a distinct and uniquely photosensitive subset of cutaneous LE by Sontheimer et al. (164). This form of cutaneous disease is strongly associated with a particular autoantibody specificity, anti-Ro/SSA (165); Ro/SSA antibodies have been observed in frequencies ranging from 40% to 100% of SCLE patients by immunodiffusion techniques (166). Neonatal LE also is strongly associated with an anti-Ro response (167). In this disorder, infants have maternally acquired IgG Ro/SSA antibodies and develop SCLE-like skin lesions. As the maternally derived Ro/SSA antibodies are cleared from the infant's circulation several months after birth, the skin lesions resolve (168). The anti-Ro antibody specificity has been implicated in animals as a direct cause of heart block, another manifestation of neonatal LE (169 ,170 ,171 ,172). It has been proposed that Ro/SSA and La/SSB antibodies bind human cardiocytes only after appropriate developmental apoptosis and that in vivo opsonized apoptotic cardiocytes then promote an inflammatory response damaging surrounding tissue (173). Anti-Ro/SSA antibody infusion can lead to the deposition of anti-Ro/SSA antibodies onto human skin grafts in severe combined immunodeficient (SCID) mice (174). The deposition pattern is identical to “dustlike particles” of immunoglobulin deposition over the cytoplasm and nuclei of cells in the lower epidermis and upper dermis seen in adults with SCLE and babies

with NLE and first described by Nieboer (175) (see also Fig. 29-3). The cellular pathology of SCLE however, is not reproduced in the SCID mouse model arguing that autoantibodies may be participatory, but other factors must be present as well. In favor of this, no difference has been noted in the frequency of Ro/SSA autoantibodies among lupus patients with positive or negative phototest reactions (9 ,15). Additionally, titers of antibodies to Ro/SSA do not always correlate with skin activity (176). The presence of levels of Ro/SSA antibodies similar to SCLE in disorders such as Sjogren syndrome (not typically associated with cutaneous lesions) also argues that factors other than the serologic presence and local Ro/SSA antibody deposition must participate in the genesis of LE skin disease.

The Ro/SS-A Autoantigen System

The originally described Ro antigen is a protein of 60 kd that may be bound in vivo to four small RNA molecules called “Y RNA” or “hY RNA” (177). Subsequent studies have indicated that the hY RNA molecules also can be targets of autoantibody production in SLE patients (178). The term “Ro” derives from the first two letters of the last name of the index patient from whom the antibody was characterized. It is identical to an antigen characterized from patients with Sjögren syndrome and given the name “SSA” (179). It is now known that Ro/SSA autoantibodies can variably bind to at least four antigenically distinct polypeptide components of the Ro/SSA ribonucleoprotein (180) in addition to the hY RNA molecules themselves. The function of the 60-kd antigen still is unknown but it has been proposed that it may be involved in ribosome synthesis, assembly, or transport (181) or that it may be part of a salvage pathway for mutant rRNA precursors (182). In this way, it may be a quality-control mechanism for ribosome biogenesis. A recent study has linked a bacterial homologue of Ro/SSA to a UV-resistant phenotype in bacteria (183). Based on these observations, Ro/SSA may bind to UV-damaged RNA and protect the cell from UV damage. Mice lacking Ro protein develop an autoimmune syndrome characterized by antiribosome antibodies, antichromosome antibodies, and glomerulonephritis (184). Further, mice lacking Ro demonstrate increased sensitivity to irradiation with UV light re-enforcing the role of this protein as a UV survival factor. It was proposed that Ro functions to sequester defective ribonucleoproteins and thereby protects against autoantibody development (185).

Reactivity against a 52-kd polypeptide is another antibody specificity commonly found in anti-Ro/SSA positive sera (186). The expression of 52 kd Ro/SSA is upregulated in keratinocytes by TNF-α (187). The function of the 52 kd Ro/SSA antigen is likewise still unknown but the protein recently has been shown to interact with the de-ubiquinating enzyme UNP, suggesting an involvement in the ubiquitin pathway (188). A physical association between the 52-kd and 60-kd proteins has been demonstrated by immunoprecipitation assays (189). A protein-protein interaction between these two polypeptides recently has been confirmed (190). Calreticulin, a 46-kd calcium-binding protein also has been reported to bind both hY RNA and 52-kd Ro (191) and may play a role in facilitating the binding of 60 kd Ro/SSA to hY RNA. Calreticulin binds calcium in the endoplasmic reticulum and has been found to have multiple functions including the inhibition of C1q-mediated immune functions (192 ,193). Calreticulin also has been shown to have in vivo peptide-binding activity and to facilitate the priming of CTL against such bound peptides (194).

The La/SS-B Autoantigen System

The La/SSB antigen is a 48-kd protein that participates in the control of RNA polymerase III transcription termination (195). Recently, La/SSB has been shown to control the synthesis of the x-linked inhibitor of apoptosis protein (XIAP), a key inhibitor of apoptosis upregulated in cells under physical stress (196). La/SSB also is associated with 60 kd Ro, likely through mutual binding to hY RNA (197). The functions and cellular redistribution of calreticulin (198), the 52-kd and 60-kd Ro/SSA polypeptides (199 ,200 ,201), and the La antigen (200) all have been associated with the heat-shock response. The heat-shock response is characterized by the production and activation of ubiquitous cellular proteins that detect and bind proteins damaged by heat or other physiologically stressful stimuli (202). The potential involvement of the variable cutaneous LE-associated autoantibody antigens with the heat-shock response may relate to the general importance of this response to cellular stresses or may be a function of a potentially unique relationship of this response to the abrogation of self-tolerance. Heat shock proteins (HSPs), which are induced in heat-shock responses, have been shown to promote cellular immune responses by both chaperoning peptides into cellular antigen-processing compartments and by directly activating antigen-presenting cells (203 ,204). HSP induction by UV light has been correlated to the increased binding of Ro/SSA and La/SSB antibodies in keratinocytes in vitro (200). Finally, increased HSP70 expression is increased in both sun-exposed and sun-protected skin of SLE patients (205).

Epitope Spreading

Epitope spreading is the process by which specific immune responses that arise to particular determinants on a macromolecule diversify over time (206). B cells, by virtue of their immunoglobulin receptors, can process and concentrate antigen prior to T cell presentation and are central to this process. This spread of immune responses can occur to epitopes within the primary macromolecule (intramolecular epitope spreading) or to physically associated molecules (intermolecular epitope spreading). Both inter- and

intramolecular epitope spreading have been reported in cases of murine immunization with peptides of 60 kd Ro/SSA, 52 kd Ro/SSA, and La (207 ,208 ,209). This is consistent with a physical linking of these antigens (210). Spreading of the immune response for 52 kd Ro/SSA and 60 kd Ro/SSA (but not La/SSB) to calreticulin is consistent with the notion that calreticulin may associate with a subpopulation of Ro/SSA particles from which La/SSB already has dissociated (209). The observation that human anti-Ro/SSA immune responses segregate with either anticalreticulin responses or anti-La/SSB responses (211) also is consistent with a differential compartmentalization of Ro/SSA and La/SSB antigens at the time of initiation of the immune response. The secondary recruitment of antibodies to the inducible heat shock proteins Grp78 and HSP70, following immunization of mice with either 52-kd Ro/SSA, 60-kd Ro/SSA, but not La/SSB, suggests physical association and colocalization of these proteins with the Ro/SSA polypeptides under conditions such as apoptosis, that may promote autoimmunization (199). In addition to providing evidence for the physical association of autoantigens, the phenomenon of epitope spreading to specific antigens associated with cutaneous LE in these animal models suggests that such epitope spreading may occur in human disease. These autoantibodies thereby may enhance and perpetuate cell-mediated autoimmune inflammation.

Interaction of Ro/SS-A and La/SS-B Autoantibodies and Human Skin

There is compelling evidence that antibodies to Ro/SSA and La /SSB bind to human epidermis in vivo (174). The binding of these antibodies to keratinocytes in vitro can be enhanced by UV radiation in the presence (52) or absence (212) of apoptosis. Estrogens (213), heat shock (200), and viral-induced apoptosis (214) also can enhance binding. What are the potential consequences of this binding? The predominant IgG subclass that is deposited in lesions is IgG1, a form that is known to activate complement and initiate antibody-dependent cellular cytotoxicity (ADCC) (215). The presence of complement membrane attack complex at the dermal-epidermal junction (DEJ) of cutaneous LE lesions further suggests an antibody-mediated pathogenesis for the cell damage seen in cutaneous LE (216). The presence of the complement membrane attack complex (C5b-9) in only the lesional skin of patients with SLE, SCLE, or CCLE (217 ,218) suggests that this complex may then play a role in the pathogenesis of the lesions. MRL/lpr mice deficient in decay accelerating factor, an inhibitor of both the classical and alternative complement pathways, develop more severe skin findings associated with C3 deposition (219). Furukawa et al. have shown that keratinocytes from patients with lupus are more susceptible to binding of anti-Ro/SSA antibodies following UV exposure than controls and that these keratinocytes can be lysed by ADCC when sera and peripheral blood leukocytes from patients are added to the keratinocytes (220 ,221). This increased binding may be from an increased susceptibility to UV-induced apoptosis or from other causes of increased Ro/SSA antigen availability (50). Considerable interindividual variation in levels of keratinocyte Ro/SSA and La/SSB epitope expression has been noted (222) and expression is higher in lupus patients with documented photosensitivity (223). Despite this evidence, anti-Ro/SSA, La/SSB, and other autoantibodies may not have an initiating role in the clinical lesions of cutaneous lupus because the deposition of immunoglobulin and complement components as detected by fluorescence microscopy generally follows the appearance of perivascular inflammation in photo-provoked lesions (8 ,13). Keratinocytes generally are susceptible to ADCC but are able to resist cytotoxic damage by the complement membrane attack complex (224). Although anti-Ro/SSA antibodies can potentiate ADCC in vitro (225), NK cells are the most common mediators of ADCC and these are seen rarely in cutaneous lupus infiltrates (226 ,227). It remains possible that other cell types, including monocytes or lymphocytes, are participating in ADCC, but this has not been confirmed in vivo.

While the anti Ro/SSA response is clearly associated with SCLE, another clinical type of cutaneous lupus, CCLE is not exquisitely photosensitive. The majority of CCLE patients do not have anti-Ro/SSA responses as detected by standard immunodiffusion techniques. Additionally, epidermal IgG deposits are found rarely, and immunoglobulin deposition is limited to the DEJ (166). When sensitive ELISA techniques were used, 11 out of 15 CCLE patients were found to have low-level IgG anti-Ro/SSA antibodies. Other, as yet undefined, antibody sensitivities or cell-mediated responses may be paramount in CCLE.

Cellular Factors

Immunogenetics

Anti-Ro/SSA antibody responses have been linked to susceptibility loci associated with Class II MHC alleles. There is a strong association between SCLE, anti-Ro/SSA antibodies, and the HLA-B8, DR-3, DRw52 phenotypes (228). Associations between Ro antibody responses and DQA1 alleles, DQ2 alleles, and HLA-DR3 in different populations suggest that specific MHC class II molecules participate in the anti-Ro response (229 ,230 ,231). Diversification of the Ro/SSA and LA/SSB antibody response also has been linked to specific HLA class II phenotypes (232). This would imply the participation of Ro/SSA antigen-specific T cells in the generation of the Ro/SSA antibody response. Although 52 kd Ro/SSA-specific T cells have been described in the salivary glands of Sjögren patients (233), no antigen-specific T cells have been described in cutaneous LE. Murine T cell epitopes have been defined in a number of lupus autoantigen systems including the La/SSB autoantigen (234) and the Ro/SSA antigen (235). The specificity

and role of similar autoantigen–specific T cells in humans is an obvious area of ongoing investigation.

T Cells and Murine Models of Cutaneous LE

As in the examples above, there is growing evidence that the highly specific humoral immune response to autoantigens in SLE is T cell dependent (236). Murine models of cutaneous LE include the spontaneously occurring and UV accelerated forms of disease in MRL/lpr mice, graft-versus-host disease, and NZB/NZW mice (reviewed in (237)). None of these accurately recapitulate the cutaneous pathology seen in human disease. They nevertheless have been useful in a dissection of the potential cellular mechanisms of autoimmune inflammation.

The NZB/NZW mouse offers a model of immune globulin deposition at the DEJ, but these animals do not develop clinical cutaneous inflammation (238). The acute phase of graft-versus-host disease generated by minor histocompatibility disparity simulates the histopathology of cutaneous lupus (239) but immunoglobulin deposition at DEJ is uncommon.

MRL/lpr mice develop alopecia and scab formation associated with histopathologic changes similar to cutaneous lupus including DEJ immunoglobulin deposition (240 ,241). These lesions are characterized by a T cell inflammatory infiltrate. The important accelerator role of the lpr mutation on the MRL background has been documented in backcross experiments. The lpr mutation results in deficient Fas expression and this interferes with the apoptotic death of potentially self-reactive B and T cells (242). Both conventional (αß) and nonclassical (γδ) T cells have been shown to participate in the MRL/lpr disease phenotype including the skin disease (243 ,244) and autoantigen–specific αß T cells are absolutely required for full penetrance of disease (245). The spontaneous activation of T cells in MRL/lpr mice is highly B cell dependent (246) but is dissociated from antibody production (247) suggesting that antigen processing and presentation to T cells by B cells is important (248). A protective role for nonclassical MHC restricted NKT cells is suggested by the fact that CD1d-deficient MRL/lpr mice have exacerbated skin disease (249) and treatment with α-galactosylceramide, which results in the expansion and activation of CD1d-reactive NKT cells, improves dermatitis in MRL/lpr mice (250). Humans with active systemic LE also have diminished numbers of NKT cells (251).

Recently, the critical role of the costimulatory molecules B7–1 (CD80) and B7–2 (CD86) in this model has been shown. MRL/lpr mice deficient in both of these molecules have diminished skin lesions and do not develop renal pathology (223). These molecules provide essential signals for T cell activation and immunoglobulin class switching, again establishing a crucial role for B and T cells in this disease. Another costimulatory molecule that may have a primordial role is CD40, expressed on DC. Transgenic expression of CD40 ligand in the skin using a keratin promoter resulted in constitutive activation of cutaneous DC and a $CD8^+$ T cell–mediated autoimmune disease characterized by dermatitis, myositis, pneumonitis, nephritis, and autoantibody formation (252). This model recapitulates a number of features of SLE and places the skin dendritic cell at the center of disease initiation.

Role of Activated T Cells in Human Cutaneous Lupus Erythematosus

The pathology of cutaneous lupus is one of a lichenoid tissue reaction in which the basal keratinocytes are the primary focus of injury (253) (Fig. 29-5). This injury is associated with keratinocyte hyperproliferation, with normal early differentiation and premature terminal differentiation (254). The inflammatory-cell infiltrate is characterized by mononuclear cells at the DEJ as well as around blood vessels and dermal appendages. Inflammatory cells in the infiltrate of established cutaneous LE lesions are predominantly CD3 positive cells with CD4 positive cells present in higher numbers than CD8 cells (reviewed in (160)). The study of photo-induced lesions has allowed an analysis of early histologic changes and their evolution. In early lesions, this analysis has demonstrated $CD4^+$ T cells predominantly at the DEJ associated with rare HLA class II expression by keratinocytes. In spontaneous lesions and late photo-induced lesions, an increased number of $CD8^+$ T cells was observed, epidermal class II MHC expression was increased and the number of Langerhans cells was reduced (255 ,256 ,257 ,258). The decrease in Langerhans cell number may reflect DC activation and migration into the regional lymph nodes. The predominant type of T cell in established inflammatory infiltrates remains controversial. Volc-Platzer et al. have suggested that T cells of a specific γδ T cell receptor phenotype are preferentially expanded within the infiltrates (259). They proposed that these cells may recognize heat shock proteins induced or translocated in keratinocytes by UV or stress. Fivenson et al., however, reported that γδ T cells are virtually absent in the infiltrates (260). The Vß usage of infiltrating T cells in lesions of cutaneous LE recently was compared to that in

peripheral blood and in other inflammatory skin conditions (261). The percentage of Vß 8.1 $CD3^+$ cells was elevated in skin lesion from both CCLE and ACLE when compared to patients with other inflammatory skin disease. There was a significant skew to this Vß type when compared to peripheral blood. This selective expansion is consistent with an antigen-driven response. Sequencing of TCR clonotypes derived from the inflammatory infiltrates further suggests antigen-induced clonal accumulation (262). The expression of class II MHC molecules and CD28 by infiltrating T cells and expression of B7–1 (CD80) and B7–2 (CD86) costimulatory molecules by antigen-presenting cells in the lesional but not nonlesional skin suggests ongoing active and productive antigen presentation to T cells in cutaneous LE (263). Recently, a primary role for $CD8^+$ T cells in SLE has been suggested by the observation that activated $CD8^+$ T lymphocytes expressing perforin and granzyme B correlate with disease activity (264). Scarring CCLE has now been associated with the presence of lesional and circulating $CD8^+$ T cells that express CCR4, the receptor for CCL17/TARC, implicating cytotoxic $CD8^+$ T cells in the scarring subtype of CCLE (265).

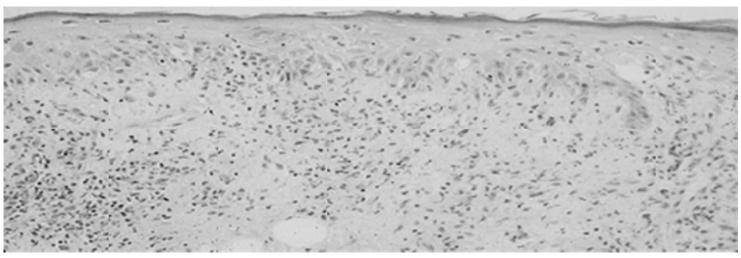

Figure 29-5. (See color plate.) Photomicrograph of a biopsy of subacute cutaneous lupus. There is disarray in the maturation pattern of the keratinocytes. There is evidence of hyperkeratosis (increase the thickness of the horny-cell layer). The basement membrane zone is disorganized with a mononuclear cell infiltrate and thickening of the basement membrane zone. There is a dermal mononuclear cell infiltrate that is predominantly perivascular. The mononuclear cells are predominantly CD4 T cells, many showing an activation phenotype, and macrophages.

Cofactors in Cutaneous Lupus Erythematosus

Ultraviolet Effects on Cutaneous Vasculature

Observational studies in humans and animal models have furthered our understanding of the roles of autoantibodies and cellular mechanisms in cutaneous lupus. Dermal blood vessels are involved in all forms of cutaneous lupus as targets for the cytokines and other mediators released from keratinocytes. These vessels also are affected directly by UV light. The potential importance of UV light in contributing to dermal and perivascular inflammation is underscored by the exquisite photosensitivity of lupus tumidus, a dermal variant of cutaneous LE without epidermal or interface changes (255 ,266). In a model of UV-induced erythema in the guinea pig, infusion of sera from patients with SCLE greatly enhanced UV-induced blood flow and this was greatest with sera containing high titers of anti-Ro/SSA (267). This observation highlights the potential interactions of the various soluble factors present in circulation of patients with cutaneous LE with the vasculature. Passive transfer of serum from patients with vesiculobullous LE into guinea pigs followed by UV irradiation also results in lesion induction (268) providing further evidence that circulating factors contribute to LE photosensitivity.

Vascular Activation

Enhanced expression of adhesion molecules on the surface of endothelial cells is an essential point of control for leukocyte attachment and migration through the endothelial barrier into cutaneous tissues (reviewed in (269 ,270)). A subpopulation of human memory T cells preferentially recirculates to the skin. These cells interact via cutaneous lymphocyte antigen (CLA) molecules on their surface with E-selectin molecules on dermal microvascular endothelial cells. In addition to CCR4, the $CD8^+$ T cells in the peripheral blood of patients with CCLE express elevated levels of CLA (265). E-selectin can be upregulated by UVB (271) and its expression is increased in CCLE and SLE photo-induced lesions (272). Elevated levels of soluble E-selectin in LE patients with widespread and active cutaneous disease further suggests an important role for endothelial-cell activation in the pathogenesis of disease (273). Intracellular adhesion molecule 1 (ICAM-1) expression by endothelial cells is a crucial step in the initiation of endothelial T cell binding, which occurs via LFA-1. ICAM-1 expression also facilitates T cell adhesion to keratinocytes (274). Endothelial ICAM-1 also is upregulated following UV irradiation, and this is stimulated by TNF-α and IFN-γ (275). In the MRL/lpr mouse model of SLE, TNF-α and IL-1 sequentially induce endothelial ICAM-1 in vivo with disease evolution (276). Vascular cell adhesion molecule (VCAM)-1 is necessary for leukocyte emigration from the microvasculature and is the ligand for VLA-4 on leukocytes. Immunohistochemical studies have confirmed that the endothelium underlying cutaneous lupus lesions is activated: VCAM-1 is expressed both in lesional and nonlesional cutaneous endothelium in active systemic lupus (277) and levels of VCAM-1 are increased in lesional skin (272 ,278). ICAM-1 is expressed by the endothelial cells in lesional skin of most patients with CCLE or SCLE (279). Figure 29-6 summarizes the role of these molecular interactions in facilitating leukocyte migration into the skin. Chemokines are induced by UV light and are upregulated in lesional lupus skin. The TH1 associated CXCR3 ligands CXCL10 and, to a lesser amount CXCR9 and CXCL11, are expressed at the dermo-epidermal junction in CCLE (280) and are the most abundantly expressed chemokine family members in cutaneous LE (134). A functional role for these ligands is suggested by the expression of CXCR3 by infiltrating dermal T cells. The CXCR3 ligands cooperate with the homeostatic chemokine CXCL12 to recruit CLA^+ memory T cells into the skin (134). The functional relevance of lymphocyte CCR4 expression and tissue expression of CCL17 in patients with scarring CCLE was likewise confirmed by in vitro migration assays (265).

Nitric Oxide

The clinically normal appearing skin of patients with active SLE demonstrates elevated levels of inducible nitric oxide synthase (iNOS) in both the epidermis and adjacent vascular endothelium (281). Aberrant regulation of iNOS expression also has been noted in photo-induced lesion of cutaneous lupus (282). Healthy controls were shown to have short-term expression (days 1 to 2) of iNOS after either UVA or UVB irradiation. Patients with cutaneous LE were noted to have significantly delayed, but prolonged expression (days 3 to 24) of iNOS. Both IL-1 and TNF-α promote the expression of iNOS (283) and this abnormal expression

in cutaneous LE may be secondary to a genetic dysregulation of these cytokines (see below). Synthesis of iNOS leads to nitric oxide (NO) production, which is known to promote apoptosis and have multiple pro-inflammatory effects. When applied to normal human skin, NO induced accumulation of $CD4^+$ and $CD8^+$ T cells, expression of ICAM-1 and VCAM-1, and accumulation of p53, followed by apoptosis (284). Altered expression of this molecule, if confirmed, may link dysregulated apoptosis and inflammation.

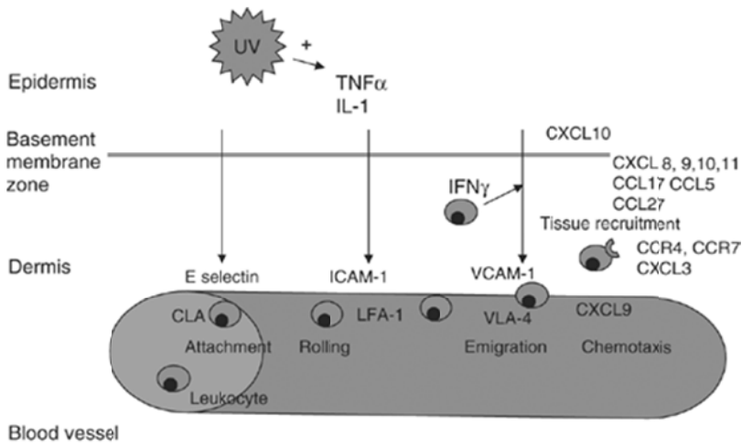

Figure 29-6. Ultraviolet (UV)-induced leukocyte migration into the skin. UV radiation induces cytokine release in cutaneous tissues. These cytokines then induce adhesion molecule expression on endothelial cells and leukocytes promoting inflammatory cell recruitment to the skin. Likewise, cytokines released by the inflammatory cells can enhance and perpetuate this recruitment. Specific chemokines promoting local inflammation are then expressed in lesional skin and promote chemotaxis of inflammatory cells. The selectins, chemokines, chemokine receptors and adhesion molecules depicted all have been shown to be upregulated in cutaneous lupus erythematosus.

Cytokines

An appropriate cytokine milieu can facilitate and modulate immune responses. Abnormalities in the production and function of cytokines could underlie the abnormal photoreactivity noted in cutaneous LE. Analysis of interleukin-2, -4, -5, and -10 and IFN-γ mRNA levels in lesions of cutaneous LE has revealed increased local levels of IL-5 and significant levels of IL-10 and IFN-γ (285). These results indicate a mixed cytokine pattern favoring cell adhesion and cellular inflammation via IFN-γ–induced ICAM-1 expression and a T-helper 2 response, favoring antibody production, with IL-5 and IL-10.

TNF-α

TNF-α is a primary cytokine that can be induced in keratinocytes (118) and in dermal fibroblasts by UVB (286 ,287 ,288). TNF-α has numerous effector functions and has been termed a master regulator of leukocyte movement (289). Abnormal TNF-α expression can promote autoimmunity. Prolonged overexpression of TNF-α in the pancreas of mice has been shown to initiate organ-specific autoimmune disease (290). In the skin, TNF-α can induce rapid Ro/SSA and La/SSB antigen translocation and surface expression in keratinocytes (291). In mice, transgenic overproduction of TNF-α by the epidermis, results in: (a) epidermal basal-cell degeneration; (b) a pleomorphic dermal leukocyte infiltrate with macrophage engulfment of degenerating cells; (c) hyperkeratosis, and ultimately (d), a graft-versus-hostlike histology (292). Some of these features are reminiscent of cutaneous lupus. Unfortunately, these mice also have high levels of TNF-α in the serum and soon die of cachexia, which has presumably prevented further analysis for features of autoimmunity. In the MRL/lpr mouse model of lupus, systemic TNF-α (and IL-1) levels are elevated and induce endothelial adhesion molecule expression (276). Raised circulating levels of TNF-α may correlate with disease activity in human systemic lupus (293). A polymorphic variant in the TNF-α promoter in humans (TNF-α 308A) is associated with increased production of TNF-α (261). The presence of this promoter is associated with an increased risk of SLE in African Americans (294). It is an independent susceptibility factor for systemic lupus in Dutch Caucasians (295). TNF-α production in keratinocytes shows interindividual variability and it has been proposed that this variability may underlie a predisposition to cutaneous lupus (29 ,120). Recently, this concept has found support in that the TNF-α –308A promoter

polymorphism associated with increased TNF-α production has been shown to be highly associated with photosensitive subacute cutaneous LE (152), and confirmed in a separate population (296), as well as the related cutaneous neonatal LE (153). Direct involvement of TNF-α in the pathogenesis of cutaneous LE inflammation could explain the clinical benefit of thalidomide in this setting (297 ,298 ,299). Thalidomide decreases TNF-α production in monocytes, DC, and keratinocytes (300 ,301 ,302 ,303), possibly via an increase in the rate of TNF-α mRNA degradation (300 ,304) although it may also inhibit TNF-α–independent keratinocyte apoptosis (302).

IL-1

Another early response to UV light is the production of and release of IL-1 by keratinocytes. Like TNF-α, IL-1 has broad pro-inflammatory activities (305). IL-1α predominates in keratinocytes while IL-1ß is the predominant form in monocytes, macrophages, and DC. Transgenic overexpression of IL-1α by basal keratinocytes in mice results in hair loss, scaling, and focal inflammatory lesions (306). Keratinocytes also contain an excess of IL-1 receptor antagonist, which binds to the IL-1 receptor and inhibits IL-1–induced activation (307). This molecule is particularly polymorphic and a significant increase of a null allele has been reported in SLE patients (308), especially those with photosensitivity (309). A correlation with CCLE also has been published as an abstract (310).

Interleukin-10

IL-10 is a key mediator of UV-induced immune suppression (133). Skin disease in MRL/lpr mice is exacerbated by IL-10 deficiency in association with increased IFN-γ production by T cells (311). IL-10 also can promote B cell activation (312). Polymorphisms within the IL-10 gene promoter associated with high levels of expression of this cytokine have been associated with anti-Ro/SSA sero-positivity (313). Abnormalities in either constitutive or UV-induced cytokine expression or the genes governing these factors thus may be central to the cutaneous-lupus phenotype. The associations of gene polymorphisms with disease described so far remain preliminary in nature and will need to be confirmed in multiple populations.

Interferon-γ

Interferon-γ is detected in normal skin after low-dose UVA exposure (144) and elevated IFN-γ mRNA levels are noted in lesions of cutaneous LE (285). This cytokine recently has been shown to be pivotal in the induction of keratinocyte apoptosis in two skin inflammatory conditions: allergic contact dermatitis and atopic dermatitis (314). In these conditions, T cell derived IFN-γ promotes keratinocyte apoptosis by enhancing the expression of the Fas death-inducing molecule on the keratinocytes (314). Overexpression of IFN-γ alone in the suprabasal skin of transgenic mice by the use of the involucrin promoter (a protein restricted to suprabasal keratinizing epithelium) results in a model of systemic lupus with the production of antinuclear antibodies and immune-complex glomerulonephritis (315 ,316). The mice also develop scaly skin, alopecia, and cutaneous inflammation—suggestive but not characteristic of cutaneous LE. This murine model demonstrates increased keratinocyte apoptosis and requires the presence of αß T cells (317). This is currently the most provocative experimental evidence that the upregulation of cutaneous immune responses through cytokine overexpression can promote T cell–mediated local and systemic lupus-like disease.

Interferon-α

Recent gene array studies have demonstrated that type I interferons (IFN-α/ß) play an important role in the pathophysiology of SLE. Interferon-inducible protein transcripts were found to be upregulated in pediatric and adult SLE patients and the levels of these transcripts correlated with disease activity (318 ,319). Curiously, natural IFN-α–producing cells, also termed plasmacytoid DC, are found in the skin (but not the peripheral blood) of LE patients and in the cutaneous lesions of LE (320 ,321 ,322) and are found in association with the presence of type I interferon inducible proteins such as Mx (323). This suggests that local IFN-α production by these cells promotes Th1-biased inflammation. In favor of this, the number of infiltrating $CXCR3^+$ lymphocytes correlated closely with the expression of Mx and the type 1 interferon–inducible chemokine CXCL10 (323) and IFN-α was shown to potently induce CXCR3 ligands expression by keratinocytes, endothelial cells, and dermal fibroblasts in vitro (134). IFN-α has also been shown to confer a pro-inflammatory function to IL-10, resulting in the enhanced production of CXCL10 and CXCL9 (324). The potential central role of plasmacytoid DC-derived IFN-α production in cutaneous LE is underscored by the further observations that immune complexes containing nucleic acid released by necrotic or late apoptotic cells and opsonized by lupus IgG potently induce IFN-α production by plasmacytoid DC, thereby, potentially promoting ongoing disease activity (325).

Complement

Homozygous deficiencies of the complement components C2 and C4 have been associated with both SCLE and systemic LE (326 ,327), and most patients with homozygous C2 or C4 complement deficiency possess anti-Ro/SSA antibodies. Likewise, most individuals with a complete deficiency of C1q or C1r/C1s develop systemic LE (reviewed by (328)). These patients also have prominent photosensitive cutaneous involvement. Such deficiencies may enhance

the lupus phenotype by decreasing the clearance of apoptotic cells, thereby allowing immune-cell activation. Such abnormalities thus may both initiate and potentiate cutaneous lupus. In this regard, a silent C1q A chain mutation (C1QA single nucleotide polymorphism Gly70 [GGG.GGA]) in exon 2 has been associated with SCLE and with decreased expression levels of C1q (329). This mutation has also been found in virtually all C1q-deficient patients (330). Such a “silent” mutation may affect gene product function through effects on pre-mRNA splicing.

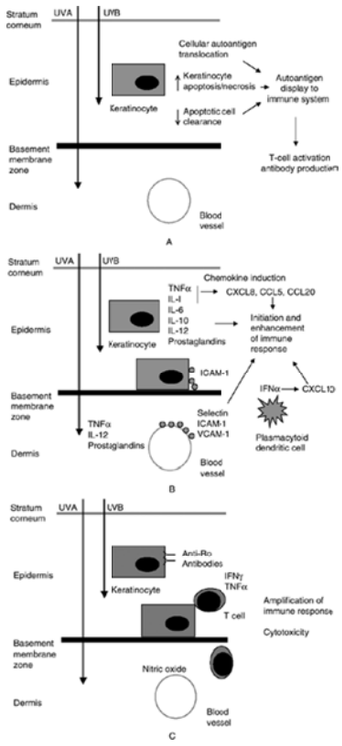

Figure 29-7. A, A model of the pathogenesis of photosensitive cutaneous lupus erythematosus. Recent studies of photosensitive lupus patients have demonstrated and increased number of apoptotic keratinocytes in both established lesions and following photoprovocation. Either increased apoptosis/necrosis or a delay in the clearance of apoptotic cells could result in an increase in autoantigen packaging and processing in a form accessible to the immune system. **B,** Ultraviolet radiation can induce keratinocyte apoptosis and/or necrosis and can also stimulate local cytokine release. This cytokine release can then lead to the observed increase in local mediateor of inflammation including selectins, adhesion molecules, chemokines and prostanoids. These molecules serve to recruit and activate dendritic cells and T cells. Plasmacytoid dendritic cells release IFN-α locally resulting in further chemokine release. **C,** The end result is a stimulation of the immune system to produce antibodies and to activate dendritic cells to prime T cells directed against stress-induced or stress-altered molecules (Ro antigen, La antigen, calreticulin). These agents of the immune system then act to promote further inflammation and tissue damage by processes such as epitope spreading mediated by antibodies and B cells, and cellular cytotoxic mechanisms mediated by T cells, natural-killer cells, and monocyte-macrophages.

A Model of Pathogenesis of Cutaneous Lupus Erythematosus

David Norris has proposed a four-step model for the pathogenesis of cutaneous lupus (49): (a) exposure to UV light induces the release of proinflammatory epidermal and dermal mediators such as IL-1 and TNF-α; (b) these mediators induce changes in the dermal and epidermal cells including the induction of adhesion molecules and the promotion of translocation of normally intracellular autoantigens such as Ro/SSA to the surface of epidermal cells; (c) autoantibodies then bind to the translocated autoantigens; and (d) keratinocyte cytotoxicity ensues as the result of lymphoid cells that are recruited from the circulation via an antibody-dependent cellular cytotoxicity mechanism. According to this model, several factors are required concurrently for the development of cutaneous LE, including: (a) abnormal susceptibility to UV light, resulting in altered cytokine expression and possibly increased keratinocyte apoptosis induction; (b) the presence of antibodies with appropriate specificities, targeting keratinocyte components upregulated by stress; and (c) the presence of activated lymphocytes, specific for autodeterminants.

Since this model was first proposed, a great deal of new data has accumulated (also reviewed in (331 ,332 ,333 ,334 ,335)). Clinical and experimental data now suggest that apoptosis may be an important mechanism leading to autoantigen display in cutaneous LE and that UV light may be an important initiator of apoptosis and possibly necrosis. Abnormalities may exist in either apoptosis induction or in apoptotic cell clearance that result in an increased load of apoptotic and necrotic cells. In addition to promoting cell death and neo-antigen generation (such as UV-DNA), UV light induces and modulates inflammatory mediator release. Genetic abnormalities in TNF-α, IL1 receptor antagonist, and IL-10 have been linked tentatively to cutaneous lupus. The dysregulation of such cytokines may allow the upregulation of adhesion molecules, chemokines, and costimulatory molecules to allow self-antigen recognition and the initiation of an immune response in genetically predisposed individuals. The autoantibodies linked with cutaneous LE are directed at antigens involved in cellular-stress responses and in the heat-shock response. Autoantibody production and directed T cell responses may perpetuate and amplify autoantigen recognition as well as keratinocyte toxicity leading to the clinical hallmarks of cutaneous LE disease. A central role for skin resident DC such as plasmacytoid DC and for dysregulated IFN-α production in the initiation and perpetuation of skin disease is emerging. Figure 29-7 shows the salient points of this revised model. Ongoing research will no doubt shed light on the in vivo role of cellular apoptosis in disease induction and perpetuation, the primary or secondary pathophysiologic role of specific autoantibodies, and the nature of the underlying genetic makeup that predisposes to disease.

Chapter 30

Lupus-Specific Skin Disease (Cutaneous LE)

Richard D. Sontheimer

Daniel P. McCauliffe

Realizing that the classification of cutaneous lupus erythematosus (LE) remains somewhat controversial, the authors have chosen to use the Gilliam classification system for LE skin disease (1) to organize the material in this chapter (Table 30-1). See Table 30-2 for an overview of the organization of this chapter. LE-nonspecific skin disease and pathomechanisms of cutaneous LE and photosensitivity are discussed in Chapters 31 and 29 , respectively

Historical Perspective

In his review of the history of LE, Thomas Benedek (see Chapter 1) points out that this disease initially was recognized by its visible cutaneous manifestations long before its systemic manifestations were known to exist (2 ,3 ,4). In this section, we will attempt only to highlight the people and events that relate primarily to the evolution of thought concerning the cutaneous manifestations of this protean disease process.

In 1851, Cazenave first used the term “lupus érythÜmateaux” in referring to Biett's earlier description of what appears to have been discoid LE (DLE) skin lesions (5). The term “lupus érythÜmateaux” helped to further distinguish this entity as a cutaneous malady that was distinct from cutaneous tuberculosis (lupus vulgaris) with which it had been earlier confused. Cazenave stated that LE preferentially occurred in outdoor workers and that exacerbations were related to cold, heat, fire, and the action of air.

In 1875, Kaposi further expanded Hebra's earlier description of what is now recognized as the systemic manifestations of LE and employed the “butterfly” simile first used by Hebra to describe the facial skin lesions of LE (6). He also commented upon the relationship between DLE skin lesions and the systemic manifestations of this disease, noting that DLE can, on occasion, progress to SLE. Payne reported the treatment of DLE with the natural antimalarial, quinine, in 1893 (11). Hutchinson (7), and later Osler, at the turn of the century (8), emphasized the multisystem nature of LE and the patient-to-patient variation with which its cutaneous and systemic manifestations are expressed. Lehmann and Ruzicka (9) have pointed out that Osler went on to say that LE patients did not tolerate sun well (10). Lehmann and Ruzicka also note that in 1913, Pussey commented on the exacerbating effects of sunlight on cutaneous LE in a young woman (12). Brocq's initial description of “symmetrical erythema centrifugum” (13), probably representing the earliest delineation of what Gilliam later referred to as “subacute cutaneous LE” (SCLE), the bridging form of LE-specific skin disease in his revised classification of cutaneous LE (14).

Lehmann and Ruzicka point out that in 1929, Fuhs reported the exacerbating effect of an artificial light source on a patient with “lupus erythematosus subacutus,” a term that appears to be referring to what we recognize today as SCLE (15).

In 1934, O'Leary's introduction of the term “disseminated DLE” as part of his new classification scheme included both its cutaneous and systemic manifestations (16). The term “disseminated” in his classification scheme was used somewhat ambiguously in referring both to a widespread distribution of LE skin lesions and the transition from disease limited to skin to the systemic illness that we now recognize as SLE. Thus, several forms of widespread LE-specific skin disease (i.e., generalized DLE and SCLE) were thereafter often lumped together under the designation “disseminated DLE” or “subacute-disseminated LE,” thereby obscuring the clinical and laboratory correlates of each of these clinically distinctive types of cutaneous LE. As a result, when the large LE population studies were later presented in which the clinical features of LE patients were correlated with the newly identified autoimmune serologic manifestations of the disease, the distinction between patients having generalized DLE and SCLE was often blurred.

In 1936, Freidberg presented the heretical idea that the systemic manifestations of LE could occur in the absence of any type of skin lesion (17). In 1951, the synthetic antimalarial, quinacrine (18), and corticosteroids (19) were introduced for the treatment of LE. In 1948, Hargrave's description of the LE-cell factor (20) and Friou's subsequent description of the antinuclear antibody assay in 1957 (21) ushered in the era of serologic-clinical correlation in LE. In 1963, Neville Rowell described EM-like lesions that

occurred in LE patients in the context of autoantibodies to the Sjögren syndrome antigen, Sj-T, which are now thought to represent the La/SS-B specificity (22). Dr. Rowell's other work has contributed significantly to our current understanding of various aspects of cutaneous LE including chilblains lupus (perniotic LE) and classical DLE.

Table 30-1: The Gilliam Classification of Lupus Erythematosus (LE)-Associated Skin Lesions

I. Histopathologically Specific (LE-Specific)
A. Acute cutaneous LE

b. Generalized
2. Hypertrophic (verrucous) DLE
3. Lupus profundus (LE panniculitis)
4. Mucosal LE
5. LE tumidus
6. Chilblains LE (perniotic LE)

DLE, discoid lupus erythematosus; LE, lupus erythematosus.

In 1963, Burnham et al. identified the “lupus band” (23) and Edmund Dubois and Denny Tuffanelli presented their landmark description of 520 consecutive SLE patients, 29% of whom had DLE skin lesions (24). Dubois was among the first to use the “spectrum” analogy for LE, emphasizing that this illness represented a disease continuum extending from localized DLE at the more benign pole to fully expressed SLE at the more severely affected pole. He also emphasized the fact that various transitional forms commonly occurred within this spectrum, including the appearance of SLE in patients who had initially presented with DLE lesions alone and the development of DLE lesions in patients with pre-existing SLE. These concepts were emphasized in the first edition of his classic book (25 ,26). Dubois' spectrum concept influenced Jim Gilliam's thinking concerning the classification of cutaneous LE.

LE, lupus erythematosus; SLE, systemic lupus erythematosus.

In 1969, Reichlin et al. described anti-Ro/SS-A antibodies (27), which were later identified as the serologic markers for SCLE and neonatal LE, and in 1975, James N. Gilliam extended Dubois' spectrum analogy, which focused on the relationships between the various cutaneous and systemic manifestations of LE (28). He also stressed the value of the various forms of cutaneous LE as markers for subsetting LE (the exercise of identifying more homogeneous subgroups of LE patients based upon the sharing of common clinical, pathologic, and laboratory features) that had become popular by the 1970s (29).

In 1976, Marian Ropes published a comprehensive monograph (30) that detailed the experience gained from a large number of SLE patients followed over several decades in the inpatient and outpatient settings at Massachusetts General Hospital. Careful observations concerning the mucocutaneous manifestations of this disease were reported.

In 1977, Barba and Gonzalez presented one of the earliest reports on the beneficial effects of thalidomide on cutaneous LE (31). The tremendous impact of thalidomide on cutaneous LE inflammation subsequently was documented by a number of other workers (reviewed in (32)). Thalidomide subsequently has been shown to inhibit tumor necrosis factor-α (TNF-α) gene expression. These observations taken together with the modern work indicating abnormal TNF-α expression in photosensitive cutaneous LE such as SCLE could lead to new therapeutic approaches.

Gilliam et al. characterized the immunogenetically homogeneous LE subset in 1979, which was marked by the presence of SCLE skin lesions (33 ,34 ,35). These were virtually the same group of patients being described concurrently by Provost et al. under the designation of “ANA-negative SLE” (36). The concept of SCLE originally was introduced by Gilliam as a component of a new classification of cutaneous LE that emphasized the clinical differences existing between different types of histopathologically specific LE skin lesions (29). Gilliam's earlier work at Stanford with the dermatopathologist, Alvin Cox, and later at University of Texas Southwestern with Robert Freeman greatly influenced his thinking in this area.

In 1981, Weston and Provost described the anti-Ro/SS-A autoantibody as the serologic marker for neonatal LE (37) and in 1990, Lehmann et al. redefined LE photosensitivity in modern photobiological terms by documenting that SCLE is among the most photosensitive subsets of cutaneous LE and that ultraviolet A (UVA) and ultraviolet B (UVB)-play significant roles in SCLE photosensitivity (38 ,39).

In 1984, Norris et al. showed that ultraviolet B (UVB) radiation modulates Ro/SS-A autoantigens to the surface of

human epidermal keratinocytes and proposed a model for the pathogenesis of Ro/SS-A autoantibody–associated photosensitive cutaneous LE involving antibody-dependent, cell-mediated cytotoxicity (40 ,41). In 1992 and 1993, Beutner et al. attempted to systematically classify the clinical forms of cutaneous LE (42 ,43).

In 1994, Casciola-Rosen et al. first demonstrated that autoantigens (e.g., Ro/SS-A, calreticulin) that are targeted in SLE are clustered in two populations of surface structures on UVB-induced apoptotic keratinocytes (44). In 1995, a systematic characterization of cutaneous LE subsets in a relatively homogenous ethnic population (45) was described by Watanabe and Tsuchida. In 1996 these two authors further characterized LE profundus/panniculitis (46).

In 2000, the most modern characterizations of the subsets of LE tumidus (47) was reported. Werth et al. initially reported a specific genetic marker for SCLE, the presence of the -308A TNF-α promoter polymorphism (48).

Definition and Classification

LE is a systemic autoimmune disorder associated with polyclonal B cell activation that is thought to result from an interplay of genetic, environmental, and hormonal elements. It is convenient to consider the heterogenous clinical expression of this disorder as constituting a disease continuum or spectrum extending from a limited cutaneous disorder to a life-threatening systemic disease process.

The term “discoid LE” (DLE) often was used in the past to generically designate the subgroup of LE patients whose disease was expressed only in the skin (49). The use of the term “DLE” in this sense can create confusion because this same term also is commonly used to identify one of several clinically distinctive forms of LE-specific skin disease. In the following discussion, the term “DLE” will be used in the latter, more restricted sense to refer only to a certain clinical form of chronic cutaneous LE. The term “cutaneous LE” will be used in an umbrella fashion in this chapter to refer to all skin lesions that have some form of association with LE.

The term “SLE” has been used in the past synonymously with the term “LE” to generically designate all patients suffering from this autoimmune disease process (unfortunately, many in the present continue to use the term in this manner). However, in this sense, the term “SLE” unfairly stigmatizes those LE patients whose disease is expressed clinically only in their skin throughout their entire disease course. The term “SLE” will be used in this discussion to refer only to the systemic manifestations of the fundamental underlying disease process, LE. It must be remembered that the large majority of patients with SLE will express some form of cutaneous LE during the course of their disease.

The American College of Rheumatology (ACR) has formulated a set of revised clinical and laboratory criteria for the classification of SLE primarily for the purpose of providing some degree of uniformity to the patient populations of clinical studies (50). This classification system is used commonly by clinicians to establish a diagnosis of SLE in a given patient. However, this system is not perfect. For example, based on the devised criteria, a patient can be classified as SLE based on mucocutaneous findings only (i.e., the four criteria being photosensitivity, oral ulcers, discoid rash, and malar rash). It also is unfortunate that this classification did not include histopathologic evidence of cutaneous LE as a diagnostic criterion (e.g., evidence of vacuolar degeneration in the basal layer of the epidermis). Dr. Victoria Werth led an effort, which included the two authors of this chapter, to develop recommendations on revising the clinical and laboratory criteria for the classification of LE (51).

The LE disease spectrum can be subdivided in a number of ways—clinically, serologically, or pathologically. Using this approach, various patterns (or subsets) of illness can be identified, i.e., some patients will share common patterns of clinical, immunologic, and pathologic abnormalities. One example would be SCLE. Patients who present with SCLE skin lesions have a clinically and pathologically distinctive form of cutaneous LE, frequently produce anti-Ro/SS-A autoantibodies, and share a common HLA phenotype (HLA-B8, DR3, DRw52, DQ 1/2) (52). The clinical expression of skin involvement in LE is very common and extremely heterogenous (Table 30-3). Because the type of skin involvement in LE can be reflective of the underlying pattern of SLE activity, it is important to have a common language when referring to LE skin lesions. Much attention has been paid to the issue of classifying LE from the dermatologic perspective in the past and there continues to be considerable debate in this area (53). For the purpose of this discussion, we will use the classification system developed by Jim Gilliam, which divides the skin lesions that can be encountered in LE patients into those that are histologically specific for LE (i.e., LE-specific skin disease) and those that are not histologically specific for this disease (i.e., LE-nonspecific skin disease) (29). The histologically specific skin lesions share the following elements of a lichenoid tissue reaction (54): hyperkeratosis; epidermal atrophy; liquefactive (vacuolar, hydropic) degeneration of the epidermal basal-cell layer; a mononuclear cell infiltrate focused at the dermal-epidermal junction (DEJ), perivascular areas, and perifollicular areas; thickening of the epidermal-basement membrane; and melanin-pigment incontinence. There are three broad categories of LE-specific skin disease: acute cutaneous LE (ACLE), subacute cutaneous LE (SCLE), and chronic cutaneous LE (CCLE). LE-nonspecific skin lesions such as cutaneous vasculitis have histopathologic changes that are seen in conditions other than LE and thus are not specific for this disorder (see Chapter 31).

It is important to note, however, that other cutaneous disorders can have LE-like histopathology. These disorders include dermatomyositis, graft-versus-host disease, erythema

multiforme, drug eruptions, and polymorphous light eruption, which sometimes can clinically mimic the gross morphologic features of cutaneous LE. An experienced dermatologist usually can differentiate between these various disorders by analyzing additional information from the patient's history, physical examination, and laboratory evaluation.

Table 30-3: Clinical Feature Comparisons between the LE-Specific Skin Diseases

	ACLE	SCLE	Classical	DLE
Clinical Features:				
Induration		0	0	+++
Scarring		0	0	+++
Pigment changes		+	++	+++
Follicular plugging		0	0	+++

Antinuclear antibodies		+++	++	+
Ro/SS-A antibodies:				
By immunodiffusion		+	+++	0
By ELISA		++	+++	+
Antinative DNA antibodies		+++	+	0
Hypocomplementemia		+++	+	+
Prognosis				
Risk for developing SLE		+++	++	+

+++Strongly associated.
++Moderately associated.
+Weakly associated.
0 Negative, or no association;
ACLE, acute cutaneous lupus erythematosus; DLE, discoid lupus erythematosus; ELISA, enzyme-linked immunosorbent assay; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus.

With any arbitrary subdivision of a disease continuum such as LE, overlapping features can occur. For example, patients who have predominately SCLE lesions also can develop scarring DLE or ACLE lesions at some point in their course. However, in most patients, one form of LE-specific skin involvement will predominate.

An occasional patient will be encountered who has skin lesions that demonstrate LE-specific histopathology but whose cutaneous disease does not conform fully to one of the categories of LE-specific skin disease under the Gilliam classification scheme. The few such patients that have been encountered have been considered to have a clinically generic variety of LE-specific skin disease. It has been the impression of one of the authors (RDS) that this situation arises more commonly in African American patients.

It also should be remembered that LE patients not infrequently develop unrelated common dermatologic disorders that are not the direct result of LE activity in the skin. Harm to patients can result when skin disorders are misdiagnosed as cutaneous LE causing patients to be subjected to unnecessary tests and/or potentially toxic therapies. In their study of 84 consecutive SLE patients, Weinstein et al. found that (42%) had dermatoses attributable to SLE while 58 (69%) had dermatoses that were not directly attributable to SLE (55). Some conditions can simulate the clinical appearance of different forms of cutaneous LE. One example would be acne rosacea simulating the clinical appearance of ACLE on the face (56). Additionally, cutaneous complications of treatment of SLE, such as corticosteroid-induced acne vulgaris, might be attributed to the underlying systemic autoimmune process by observers less familiar with the cutaneous manifestations of this disorder.

Lupus Erythematosus-Specific Skin Disease

Epidemiology

There is very little population-based data concerning the epidemiology of LE—cutaneous or systemic. Most studies are reported by rheumatologists or dermatologists working separately, and as a result, selection bias often is present in the data that are commonly reported. In most large clinical studies of selected LE patients, the skin is second only to joints as the most frequently affected organ system, and skin disease is the second most common way that LE initially presents clinically (57). This also was true for a population-based cohort of 80 patients (58). In some study populations, cutaneous disease has been the most common disease manifestation (59).

Together, all forms of cutaneous LE have a significant socioeconomic impact within the United States. It has been suggested that cutaneous LE is the third most common cause of industrial disability from dermatologic disease, with 45% of cutaneous LE patients experiencing some degree of vocational handicap (60). It is most informative to discuss the epidemiology of the three major types of LE-specific skin disease in more detail.

Acute Cutaneous Lupus Erythematosus

In most large clinical studies carried out by rheumatologists or internists, ACLE is reported under the designations “malar rash” or “butterfly rash” (i.e., presumably localized ACLE) and “rash,” “maculopapular rash,” or “photosensitive lupus dermatitis” (presumably generalized ACLE). In such studies, the skin lesions usually are not biopsied and thus it is difficult to know whether they in fact represent LE-specific skin disease. Because dermatologists usually do not primarily mange such patients because of the strong association between ACLE and systemic LE activity, little data concerning this form of LE-specific skin disease is available in the dermatologic literature. Because of its strong association with SLE, the epidemiology of ACLE might be expected to closely parallel that of unselected SLE patients, which have been comprehensively reviewed (61).

Demographics

Malar rash or butterfly rash has been reported in 20% to 60% of large LE patient cohorts (59). Limited data suggest that the “maculopapular rash” of SLE is present in about 35% of SLE patients (57). Malar rash is more common in women than men (57). Because photosensitivity is seen more frequently in whites than African Americans (62), one might infer that the same could be true for ACLE. Malar rash has been suggested to be associated with a younger age of disease onset (57). A clinically nonspecific maculopapular rash resembling a drug eruption but felt to be related to SLE was present in 59% of the 81 patients studied by Wysenbeek et al. (63); however, because biopsy data were not presented, it cannot be certain whether this “rash” was related to generalized ACLE.

Genetic Associations

Curiously, little effort has been made to determine whether ACLE has any specific HLA associations. ACLE lesions usually occur in the context of SLE and SLE has been associated with HLA-DR2 and -DR3 (64). Familial associations and concordance in twins suggest that SLE has an important genetic component (64).

Environmental Factors

Exposure to natural or UV irradiation is a frequent precipitating factor for SLE patients (65). Although photosensitivity was more common in patients with anti-Ro/SS-A autoantibody in one study (66), this association has not been confirmed in a more recent phototest study (67). Chemicals such as L-canavanine present in alfalfa sprouts can induce a SLE-like illness (61). Numerous drugs have been implicated in inducing various features of SLE (68), although the skin often is spared in classical drug-induced SLE. Infections, especially with subtle types of viruses, have long been suspected to be capable of precipitating and/or exacerbating SLE (69).

Subacute Cutaneous Lupus Erythematosus

Demographics

SCLE patients comprised 9% of the total LE patient population examined by Sontheimer et al. (33). Others have found SCLE lesions in 7% to 27% of their LE patient populations (70). SCLE is primarily a disease of white females of all ages. Seventy percent of the original cohort of SCLE patients were female and 85% were white (33). The mean age of this group of patients was 43.3 years with a range from 17 to 67 years. Others have reported similar racial and sexual demographic data (70). There have been at least five case reports of children affected by SCLE, ranging in age from 18 months to 9 years (71 ,72 ,73 ,74 ,75).

Genetic Associations

The majority of studies have found that at least one half of their SCLE patients have the HLA-DR3 phenotype (76), although some groups have found a lower frequency of HLA-DR3 (77). HLA-DR3 normally is found in only 25% of the U.S. white population (78). One group has suggested that the HLA-DR3 phenotype is most strongly associated with the annular form of SCLE (79) and that annular SCLE lesions denote the most homogeneous subgroup of SCLE patients immunogenetically (79). HLA-DR2 also has been associated

with SCLE (80). SCLE patients with overlapping features of SCLE and Sjögren syndrome are more likely have the HLA-B8, DR3, DRW6, DQ2, and DRW52 extended haplotype (81). It has been suggested that the HLA-DR antigen associations of SCLE relate more to the anti-Ro/SS-A antibody response in these patients than to the SCLE skin lesions (80). Patients with the extended haplotype HLA-B8, DR3, DRW6, DQ2, and DRW52 produce very high levels of Ro/SS-A autoantibodies (82). High Ro/SS-A antibody titers also have been associated in individuals with HLA-DQw1/DQw2 (82).

There is a growing body of evidence that genetic factors may influence the putative role TNF-α plays in the pathogenesis of the Ro/SS-A associated LE-specific skin diseases—SCLE and neonatal LE skin disease (83). Werth et al. have demonstrated that SCLE patients often have a TNF-α gene promoter polymorphism (–308A) that appears to be associated with higher levels of TNF-α expression in cells exposed to UVB radiation (84). There is linkage disequilibrium between the –308A allele and HLA-DRB1*03, the latter being found more frequently in patients producing Ro/SS-A antibodies. Of interest, Werth et al. found that the proportion of Caucasians with a –308A allele and the HLA-DRB*3 allele was 100% in SCLE patients (85). Sixty-four percent of 22 patients with neonatal LE skin disease have the TNF-α –308A allele (86). In this same study, TNF-α staining was observed in lesional skin from three neonatal LE patients but not in skin from a normal infant. Another study has found that TNF-α expression is increased in epidermal cells within SCLE skin lesions compared to cells from uninvolved skin from SCLE patients and cells from other inflammatory or neoplastic skin diseases (87).

Genetically based deficiencies in various complement components including C2, C3, C4, and C5 have been associated with SCLE and/or DLE (88 ,89). Additionally, genetic deficiency of C1q is a very strong risk factor for photosensitive SLE (90 ,91). There is preliminary evidence that a synonymous single nucleotide polymorphism in the Gly70 codon in the second exon of the C1QA gene (C1QA-Gly70GGG/A) is associated with the SCLE phenotype (92). The C1QA-Gly70GGG/A single nucleotide polymorphism also curiously appears to be linked to other DNA sequence variations that result in complete congenital deficiency of C1q (93).

Table 30-4: Drugs That May Precipitate or Exacerbate LE-Specific Skin Disease

SCLE	acebutolol, angiotensin-converting enzyme inhibitors (captopril, cilazapril), antihistamines (cinnarizine, ranitidine, thiethylperazine), calcium channel blockers* (diltiazem, nifedipine, nitrendipine, verapamil), carbamazepine, etanercept, griseofulvin, hydrochlorothiazide*, interferon-alpha and beta, leflunomide, naproxen, oxprenolol, d-penicillamine, phenytoin, piroxicam, procainamide, proton pump inhibitors (lansoprazole, omeprazole), spironolactone, statins (pravastatin, simvastatin), sulfonylureas (glyburide), tamoxifen, terbinafine*, taxotere, tiotropium
DLE	etanercept, infliximab, uracil-tegafur, voriconazole
Chilblain LE	infliximab, terbinafine
LE Tumidus	angiotensin-converting enzyme inhibitors, bupropion, antiretroviral therapy, hydrochlorothiazide

*bold text = many reports

Environmental Factors

Earlier studies (data reviewed in (94 ,95)) have indicated that a large majority of SCLE patients are highly sensitive to ultraviolet irradiation. One recent phototesting study demonstrated photosensitivity in 100% of SCLE patients and that the majority of the photosensitivity reactions occurred more than a week after exposure (67). SCLE has also has developed following radiation therapy (96), UVA therapy in combination with oral psoralen (97), and from fluorescent light exposure (98) and photocopier light (99). A single case of SCLE has been associated with pesticide exposure (100). A number of drugs, many of which are photosensitizers, have been implicated in inducing SCLE (Table 30-4). Ro/SS-A autoantibodies have been found in most reported cases of drug-induced SCLE (101). The skin lesions began between 4 and 20 months after the medication was started, and the lesions improved 6 to 12 weeks after the offending agent was withdrawn (101). These drugs include spironolactone (102), angiotensin-converting enzyme inhibitors (captopril, cilazapril) (103 ,104), calcium-channel blockers (verapamil, diltiazem, nifedipine) (105), hydrochlorothiazide (106), interferon-α and -ß (101 ,107), procainamide (108), beta blockers (acebutolol (109) and oxprenolol) (110), d-penicillamine (94), sulfonylureas (94), terbinafine (111 ,112), griseofulvin (113), piroxicam (114), naproxen (115), phenytoin (116), carbamazepine, (117), tamoxifen (118), docetaxel (119), pravastatin and simvastatin (101), leflunomide (120 ,121 ,122), etanercept (123) and PUVA (97). One patient developed annular SCLE after taking the combination of cinnarizine and thiethylperazine (124). The implication that the antihistamine cinnarizine might induce SCLE is of additional interest in light of the recent report of antihistamine-induced SCLE-like dermatitis (125). One of the authors (DPM) has witnessed a patient who developed SCLE shortly after

starting the gastric acid/proton-pump inhibitor omeprazole that resolved after discontinuing this medicine. The patient noted a recurrence of her lesions 1 to 2 years later after starting the proton-pump inhibitor lansoprazole (unpublished observation). The other author (RDS) has observed ranitidine associated SCLE and is also aware of a case of omeprazole (Prilosec, Astra Merck)-induced annular SCLE in a male (A personal communication, Dr. Mark DeMay, Sioux City, Iowa; April, 2000). Inhalation of the bronchodilator tiotropium has also been demonstrated to induce SCLE in a patient with Ro/SS-A autoantibodies (126).

It is difficult to envision a mechanism by which so many different classes of drugs might trigger the appearance of SCLE lesions. However, it is interesting that the majority of drugs that have been observed to be capable of triggering SCLE skin lesions are also known to be capable of triggering photosensitive skin reactions in individuals who have no evidence of LE autoimmunity. It is tempting to speculate that drug-induced SCLE lesions might result when an individual who is immunogenetically predisposed to SCLE develops what might otherwise be viewed as an innocent drug-induced photoallergic or phototoxic reaction that results in the induction of a secondary SCLE skin reaction via the Köebner or isomorphic response (i.e., the well-documented cutaneous phenomena of LE specific skin inflammation being triggered by different types of nonspecific skin injury).

Smoking may be a risk factor for contributing to the development of SCLE and DLE (89 ,127).

Chronic Cutaneous Lupus Erythematosus

No reliable population-based data exist pertaining to the true prevalence or incidence of classical DLE (the most common form of CCLE) presenting in the absence of systemic LE activity. Such patients tend to be underrepresented in studies reported by rheumatologists and internists and over represented by those reported by dermatologists. Additionally, the epidemiologic data that is available pertaining to DLE is hard to interpret. Studies prior to 1970 did not stratify patients according to the American Rheumatism Association's (now known as the American College of Rheumatology ACR) classification criteria for SLE. Additionally, these workers did not have access to the various laboratory parameters that gauge the presence and degree of activity of systemic autoimmunity. Also, prior to 1979, investigators did not distinguish between DLE and SCLE, usually lumping these two varieties of cutaneous LE together under the generic designations of “DLE” or “disseminated DLE.” Thus, it can be difficult to gain an accurate view of the prevalence of or incidence of DLE from the data presented in studies prior to that time.

Demographics

Based upon data from the available studies, the following points can be made concerning the epidemiology of DLE, as distinguished from SCLE. DLE skin lesions are present in 15% to 30% of variously selected study populations of SLE (59). Approximately 5% to 10% of SLE populations have DLE skin lesions as their presenting disease manifestation (24). It has been suggested that for every patient affected primarily with DLE, seven will be affected primarily by SLE (128). The most common age of onset of DLE is between 20 and 40 years in both males and females (129). DLE lesions, however, can appear in infancy as well as the elderly. The female:male ratio for DLE has been reported to be between 3:2 to 3:1 (130 ,131), which is much lower than that of SLE. In a review of 27 children with DLE, the ratio of females to males was 5:1 (132). Another study of 16 cases of childhood DLE from Tunisia found and equal sex ratio (133). DLE patients in any race can be affected and most of the classical studies have found DLE to be more frequent in whites (134). Some earlier studies suggested that African Americans were relatively protected from DLE; however, Hochberg et al. have presented data that argue that DLE might actually be more prevalent in African Americans (62). There are few reports in the medical literature of children with chilblain LE, LE tumidus, and LE profundus.

Genetic Associations

Knop et al. found significant increases of HLA-B7, B8, Cw7, DR2, DR3, DQW1, and a significant decrease in HLA-A2 in a large group of German DLE patients (135). The combinations of HLA-Cw7, DR3, DQW1, and HLA-B7, Cw7, DR3 conferred the maximum relative risk (7.4) for DLE. Partial C2 and C4 complement deficiencies have been reported in chronic cutaneous LE including DLE and LE panniculitis (89 ,136 ,137 ,138).

Environmental Factors

Skin lesions are precipitated or aggravated by ultraviolet irradiation, especially UVB, in approximately half of patients with DLE. A phototesting study found 41 of 46 (89%) of DLE patients to develop an abnormal reaction to UV light and visible light exposure (67). The skin lesions often took 1 to 4 weeks after irradiation to develop. The validity of the irradiation protocol and the significance of these finding might have been better appreciated if a control group had been included. However, histopathology of the photo-provoked skin lesions did show characteristic findings of LE (including vacuolar degeneration and necrotic basal cell keratinocytes).

Several reports have suggested that smoking may predispose patients to develop DLE (89 ,139 ,140 ,141 ,142). We have observed several patients whose previously refractory DLE lesions improved spontaneously in a dramatic fashion following the cessation of cigarette smoking. It is possible that smoking may predispose patients to develop other forms of chronic cutaneous LE, and/or make them more resistant to antimalarial treatment. This might be ascertained if authors of future reports include the smoking history of their patients.

Nonspecific injury to the skin can precipitate the development of DLE activity within the areas of trauma (i.e., the Köebner/isomorphic phenomenon) (143 ,144 ,145).

In contrast to many drug-induced SCLE reports, there are only a few drug-induced chronic cutaneous LE reports in the literature (Table 30-4). There has been one case report of DLE-like lesions developing after a rheumatoid arthritis (RA) patient was treated with infliximab (146) and three cases apparently induced by etanercept (123 ,147). A patient developed DLE-like lesions on her neck after being treated with the azole antifungal drug voriconazole (148) and another on her cheek after receiving uracil and tegafur for lung cancer (149). Infliximab appeared to induce chilblain LE in a RA patient (150). Terbinafine induced both SCLE and chilblain LE in one patient (151). There has been one case report of possible hydrochlorothiazide-induced (152), and angiotensin-converting enzyme inhibitor–induced tumid LE (153). There has also been one case report of lupus erythematous tumidus being worsened by bupropion therapy for smoking cessation. (154). This later report is disconcerting as bupropion is sometimes prescribed to help cutaneous LE smokers quit so that they might become more antimalarial responsive. LE tumidus has also occurred following antiretroviral therapy in an HIV patient (155).

Cutaneous Manifestations

Acute Cutaneous Lupus Erythematosus

ACLE can present in either a localized or generalized distribution. Localized ACLE (the classic “butterfly rash” or “malar rash” of SLE) is the most common pattern (Fig. 30-1). Localized ACLE typically is characterized by confluent, symmetrical erythema and edema centered over the malar eminences (unilateral involvement with ACLE has been described (30)). Inflammation extending over the bridge of the nose completes the body of the classic butterfly. However, the nasolabial folds typically are spared. The forehead and V area of the neck can be similarly involved. Facial swelling may be severe in some patients with ACLE (156). Occasionally, ACLE begins on the face as small, discrete macular and/or papular lesions that later become confluent and hyperkeratotic (157) (Fig. 30-2).

Figure 30-1. (See color plate.) Localized acute cutaneous lupus erythematosus (ACLE). ACLE confined to the face and neck is classified under the Gilliam scheme as localized ACLE. The most typical presentation, as seen in this case, is that of a confluent erythema that can be associated with some degree of induration because of edema formation. As the inflammation subsides, postinflammatory hyper- or hypopigmentation can remain; however, atrophic dermal scarring is not seen.

Generalized ACLE is less common than DLE. It presents as a more widespread morbilliform or exanthematous eruption (Fig. 30-3). This presentation has been referred to in the past as the “maculopapular rash” or “photosensitive lupus dermatitis.” Some patients experience an extremely acute form of ACLE that can simulate toxic epidermal necrolysis. This form of bullous LE results from dissolution of the epidermal basal-cell layer as a result of intense lichenoid inflammation (158) (Fig. 30-4). Su and Alegre present a framework for considering how this form of bullous LE skin change relates to the other clinical patterns of bullous cutaneous injury that can be seen in LE patients (159).
ACLE is very photosensitive and can be quite transient, lasting only several days or weeks. Occasionally, lesions will wax and wane over a period of several hours and some patients will experience more prolonged disease activity. Postinflammatory pigmentary change is most prominent in LE patients with darkly pigmented skin (Fig. 30-5). ACLE lesions do not result in scarring. Patients with localized ACLE occasionally will have SCLE lesions elsewhere on their body, however, the simultaneous occurrence of ACLE and active DLE is very unusual.

Figure 30-2. (See color plate.) Macular/papular acute cutaneous lupus erythematosus (ACLE). ACLE less commonly presents as a macular and/or papular erythema, as demonstrated in this young woman who ultimately died from systemic lupus erythematosus.

Figure 30-3. Generalized acute cutaneous lupus erythematosus (ACLE). ACLE that presents both above and below the neck is classified as generalized ACLE. Note the macular erythema over the extensor aspect of the wrists that becomes confluent over the dorsal aspect of the hand and interphalangeal areas.

Figure 30-4. Acute cutaneous lupus erythematosus (ACLE) simulating the appearance of toxic epidermal necrolysis. Note the hemorrhagic crusting of the lips and the erosions over the V-area of the neck and upper chest. These skin changes developed during an acute flare of this patient's systemic lupus erythematosus that followed her decision to abruptly discontinue all medications. Therefore, there was no possibility that her toxic epidermal necrolysis-like skin changes resulted from a drug hypersensitivity reaction.

Figure 30-5. Hyperpigmented acute cutaneous lupus erythematosus (ACLE). Hyperpigmentation often can soon follow the onset of ACLE inflammation in darkly pigmented individuals. This rather stoic patient's only presenting complaint was darkening of the skin of her face. However, her evaluation revealed the presence of active systemic lupus erythematosus, including renal involvement. Soon after starting prednisone and hydroxychloroquine, she developed an acute abdominal crisis, resulting in an unrevealing exploratory laparotomy. The source of her abdominal pain subsequently was realized to have been antimalarial-induced hepatotoxicity in the setting of clinically silent porphyria cutanea tarda.

Subacute Cutaneous Lupus Erythematosus

SCLE was first discussed as a distinct disease entity by Gilliam in 1977 (14) and expanded further in 1981 (29). SCLE skin lesions have been referred to in the past under a number of other designations including symmetric erythema centrifugum, disseminated DLE, autoimmune annular erythema, subacute-disseminated LE, superficial-disseminated LE, psoriasiform LE, pityriasiform LE, and maculopapular-photosensitive LE (original data reviewed in (33)). The entity “LE gyratum repens” now is also considered to be synonymous with annular SCLE (159). The original cohort of SCLE patients presented in 1979 (33) and the others that have followed indicate that SCLE is a distinct subset of cutaneous LE having characteristic clinical, serologic, and genetic features (76).

SCLE consists of nonscarring papulosquamous or annular skin lesions having an LE-specific histopathology (161) that occurs in a characteristic photodistribution (33). Approximately 85% of all SCLE patients report photosensitivity (162), although some ethnic groups report this less frequently. While circulating autoantibodies to the Ro/SS-A ribonucleoprotein particle supports this diagnosis (35), their presence is not required to make a diagnosis of SCLE according to its original definition (33).

SCLE lesions present initially as erythematous macules or papules that evolve into scaly, papulosquamous or annular/polycyclic plaques (Figs. 30-6 and 30-7). Approximately 50% of patients have predominately papulosquamous- or psoriasis-form lesions (Fig. 30-6), whereas the other half

have the annular/polycyclic form (Fig. 30-7). A few patients may develop both types of lesions. Some workers have observed a predominance of papulosquamous lesions (77), whereas others have noted an abundance of the annular/polycyclic form (163). SCLE lesions characteristically occur in sun-exposed areas (i.e., upper back, shoulders, extensor aspects of the arms, V area of the neck, and less commonly, on the face) (Figs. 30-8 and 30-9).

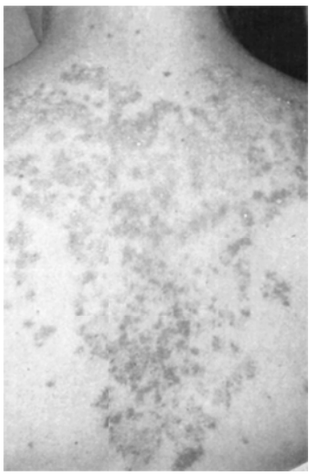

Figure 30-6. Papulosquamous subacute cutaneous lupus erythematosus on the mid- and upper back of a patient with no extracutaneous manifestations of systemic lupus erythematosus. Note the superficial scale and tendency for the individual lesions to merge into a retiform pattern.

Figure 30-7. (See color plate.) Annular subacute cutaneous lupus erythematosus. Note the polycyclic array resulting from the confluence of the individual annular lesions. This young woman ultimately died from complications of chronic active hepatitis.

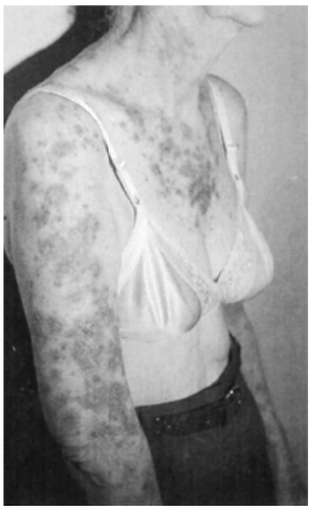

Figure 30-8. (See color plate.) Characteristic photodistribution of subacute cutaneous lupus erythematosus (SCLE). Curiously, the face of this patient with hydrochlorothiazide-induced SCLE was not affected. In the experience of one of the authors (RDS), sparing of the central face in patients with SCLE has been the rule rather than the exception.

Infrequently, SCLE lesions present initially looking like erythema multiforme (Fig. 30-10) (164). Occasionally, arcuate lesions are seen resembling erythema annulare centrifugum (Fig. 30-11). Such cases can simulate the appearance of

Rowell syndrome (erythema multiforme–like lesions occurring in SLE patients in the presence of La/SS-B autoantibodies (22). As a result of hyperacute basal-cell-layer injury, the active edge of annular SCLE lesions on rare occasion undergoes a vesicular change that breaks down to produce a striking crusted appearance (Fig. 30-12) (165). On at least one occasion, such lesions have progressed to mimic toxic epidermal necrolysis (166). One SCLE patient was reported to initially present with exfoliative erythroderma (167), whereas another presented with a curious acral distribution of annular lesions (168). Pityriasiform (94) (Fig. 30-13), poikilodermatous (169), and exanthematous (164) variants of SCLE have been mentioned anecdotally on rare occasion.

Figure 30-9. Annular subacute cutaneous lupus erythematosus (SCLE) with central hypopigmentation. As opposed to other types of annular skin lesions, the central portions of annular SCLE lesions characteristically display hypopigmentation in areas where the inflammation has subsided, reflecting the pigment-compartment injury pattern commonly seen on biopsy specimens. Although not visible in this photograph, telangiectasia also frequently can be observed in the inactive central areas of annular SCLE lesions.

Figure 30-10. Annular subacute cutaneous lupus erythematosus (SCLE) presenting with an appearance highly similar to that of erythema multiforme. Note the targetoid appearance of the small primary lesions surrounding the more established annular SCLE lesion in the center.

Lesions typically heal without scarring but can sometimes leave long-lasting or permanent vitiligo like leukoderma and telangiectasias (Figs. 30-9 and 30-14). In one case, annular SCLE lesions were observed over time to progress to plaques of morphea (170).

Figure 30-11. An arcuate lesion of biopsy-confirmed subacute cutaneous lupus erythematosus (SCLE) simulating the appearance of erythema annulare centrifugum. Although the fine scale at the trailing edge of the actively inflamed border is characteristic of erythema annulare centrifugum, it also can be seen in arcuate and annular lesions of SCLE.

Patients with SCLE lesions also may develop ACLE (Fig. 30-15) or classical DLE (Fig. 30-16). Localized facial ACLE lesions have been seen in 20% of the SCLE patients examined by one of the authors (RDS). Others have reported ACLE lesions in 7% to 100% of SCLE patients (163). Figure 30-17 illustrates the patterns of overlap that can occur between the three forms of LE-specific skin disease. ACLE skin lesions tend to be more transient than SCLE and heal with less pigmentary change. They tend to be more edematous and less scaly than SCLE lesions. ACLE more commonly affects the malar areas of the face. The experience of one of the authors (RDS) and others (95) suggests that SCLE affects the central face much less often.

Various reports have noted that 0% to 29% of SCLE patients manifest DLE lesions sometime during their clinical course (171). Nineteen percent of the original cohort of SCLE patients had classical DLE lesions (33). DLE lesions can predate the onset of SCLE lesions. DLE lesions in patients with SCLE usually are confined to the head and neck but may be more widely distributed (Fig. 30-16). DLE lesions in this setting generally are associated with a greater degree of hyper- and hypopigmentation, may display atrophic dermal scarring, and are more characteristically associated with follicular plugging and adherent scale. DLE lesions are characteristically indurated whereas SCLE lesions are not (95). Calcifying lupus panniculitis has occurred in a patient with SCLE (172).

A number of other skin lesions that are not histopathologically specific for LE can be found in SCLE patients (data reviewed in (94)). The most frequently encountered of these include alopecia, painless mucous-membrane lesions, livedo reticularis, periungual telangiectasias, vasculitis, and Raynaud phenomenon (173). Cutaneous sclerosis (174) and calcinosis (175) may be seen rarely in SCLE patients. Multiple HPV-11-associated squamous-cell carcinomas of the skin were noted in one SCLE patient (176). Polymorphic light eruption, DLE, and SCLE may sometimes occur together and may share a common genetic predisposition (177).

Chronic Cutaneous Lupus Erythematosus

Classical DLE

The most common form of chronic cutaneous LE is classical DLE (hereafter, the unqualified term “DLE” will be used to refer to this form of DLE lesion). DLE lesions of this type begin as flat or slightly elevated, well-demarcated, red-purple macules or papules with a scaly surface. Early DLE lesions most commonly evolve into larger, coin-shaped (i.e., “discoid”) erythematous plaques covered by a prominent, adherent scale that extends into dilated hair follicles (Fig. 30-18). These discoid plaques can enlarge and merge to form even larger, confluent, disfiguring plaques (Fig. 30-19).

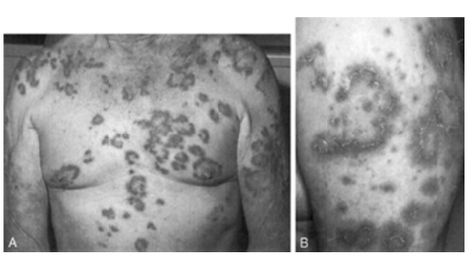

Figure 30-12. (See color plate.) Vesicobullous annular subacute cutaneous lupus erythematosus **(**SCLE). On rare occasions, the active advancing border of annular SCLE lesions undergoes a vesiculobullous change because of extensive liquefactive degeneration of the epidermal basal cell layer **(A)**. As these vesicular elements break down, crusts can form (more evident on the closer view shown in **(B)**. At times, such eroded areas can become secondarily infected with gram-positive bacteria. Intact pustules occasionally can be seen intermixed with vesicles at the border of annular SCLE lesions such as this.

Involvement of hair follicles is a prominent clinical feature of DLE lesions. Scales accumulate in dilated follicular openings, which soon become devoid of hair (Fig. 30-20). When the adherent scale is peeled back from more advanced lesions, follicle-sized keratotic spikes similar in appearance to carpet tacks can be seen to project from the undersurface of the scale (i.e., the carpet-tack sign) (Fig. 30-20).

Erythema and hyperpigmentation are present during the initial phase of DLE lesions. The lesions slowly expand with active inflammation and hyperpigmentation at the periphery leaving depressed central scarring, telangiectasia, and depigmentation. The central atrophic scarring is highly characteristic (Figs. 30-18 and 30-19). Pigment changes alone do not constitute scarring when referring to cutaneous LE lesions. In some ethnic backgrounds such as Asian Indians, the DLE histopathology can present clinically as isolated areas of macular hyperpigmentation (178).

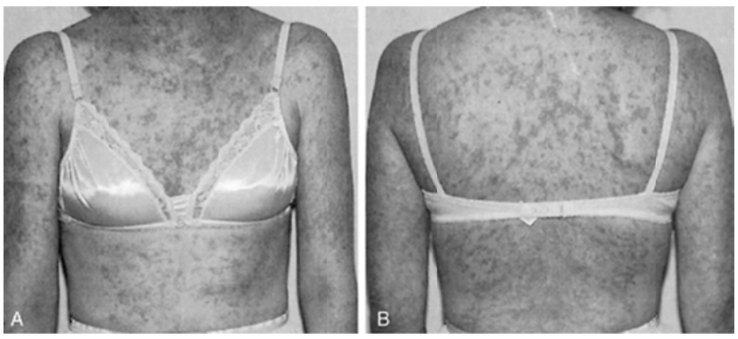

Figure 30-13. (See color plate.) Pityriasiform subacute lupus erythematosus. This anti-Ro(SS-A) antibody-positive patient had a generalized eruption of local, minimally scaling, nonscarring lesions demonstrating lupus erythematosus-specific skin disease on biopsy.

Typical DLE lesions occur most often on the face, scalp, ears, V-area of the neck, and extensor aspects of the arms. Any area of the face can be affected, including the nose (Figs. 30-18 an 30-19), lips (Figs. 30-19 and 30-22), eyebrows (Fig. 30-19), and eyelids (Fig. 30-21). There have been multiple cases of DLE occurring in and around the eyes, which are often initially misdiagnosed (179 ,180 ,181).

DLE can masquerade as blepharitis and chronic blepharoconjunctivitis (182) and has presented as periorbital edema and erythema (183), madarosis (loss of eyelashes) (184), and cicatrizing conjunctivitis (185).

Figure 30-14. Subacute lupus erythematosus of the neck and face resolving with permanent vitiligo-like depigmentation.

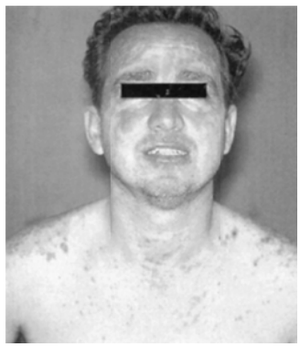

Figure 30-15. (See color plate.) Facial acute cutaneous lupus erythematosus (ACLE) occurring in a patient with subacute cutaneous lupus erythematosus (SCLE). This man had experienced uncomplicated papulosquamous SCLE for several years before developing confluent malar erythema at a point in his illness where he experienced clear evidence of extracutaneous SLE activity, including nephritis. It has been the experience of one of the authors (RDS) that the superimposition of ACLE on SCLE is a worrisome prognostic sign regarding the risk for developing extracutaneous manifestations of SLE.

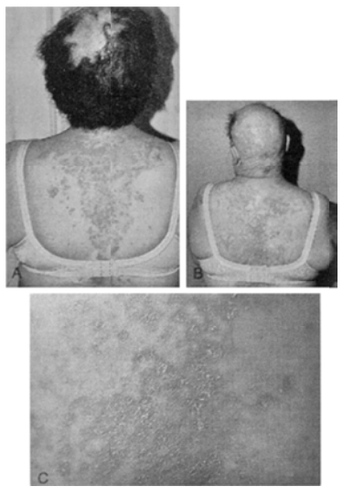

Figure 30-16. (See color plate.) Coexistence of subacute cutaneous lupus erythematosus (SCLE) and discoid lupus erythematosus (DLE). Approximately 20% of patients with SCLE will develop classical scarring DLE skin lesions at some point. This patient presented initially with DLE of her scalp and, several years later, developed typical nonscarring papulosquamous SCLE lesions on her back **(A)**. Her cutaneous disease was extremely resistant to therapy, and over the ensuing 5 years, she experienced progression of her DLE scalp involvement, resulting in extensive scarring alopecia **(B)**. The SLCE activity on her back smoldered throughout this period, resulting in the development of superficial atrophy **(C)**. This is one of two such cases observed by one of the authors (RDS) in which dermal atrophy developed within long-smoldering papulosquamous SCLE lesions. Such a progression has not been observed in annular SCLE lesions.

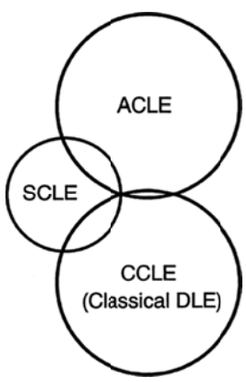

Figure 30-17. Potential for overlap between the three major forms of lupus erythematosus-specific skin disease.

Figure 30-18. Classical discoid lupus erythematosus lesion. Note the erythema (indicating disease activity), keratin-plugged follicles, and dermal atrophy. This is a relatively early lesion that lacks the typical adherent scale usually accompanying more established lesions.

Figure 30-19. More extensive examples of therapeutically refractory facial discoid lupus erythematosus lesions that produce large areas of disfigurement on confluence. The characteristic pattern of hyperpigmentation at the active border and hypopigmentation at the inactive center is especially evident in African American patients **(B)**. Facial involvement of this sort can produce extreme psychosocial disability. The proper application of corrective camouflage cosmetics can be of great psychologic benefit to such patients.

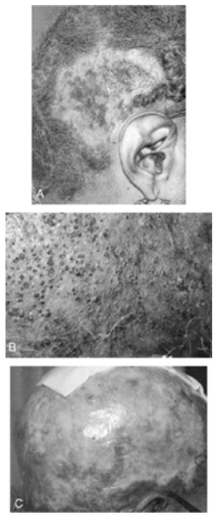

Figure 30-20. Discoid lupus erythematosus (DLE) of the scalp. **A,** A relatively early lesion. At this stage, the alopecia might be reversible to some degree with effective treatment. **B,** Close-up of the pattern of keratin-plugged follicles that can be observed in such lesions. **C,** A patient in whom the DLE disease process has progressed to the point of total, irreversible scarring alopecia. The areas of crusting represent a superimposed secondary bacterial infection.

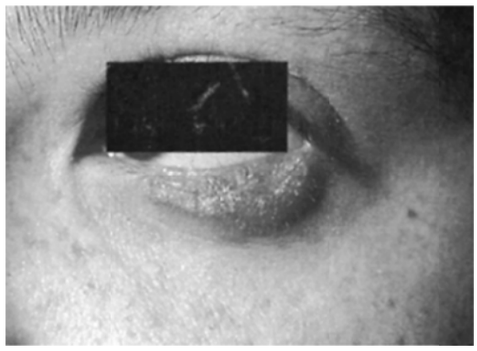

Figure 30-21. Discoid lupus erythematosus of the lower eyelid resulting in loss of the eyelashes.

A symmetrical, butterfly shaped DLE plaque occasionally will be found over the malar areas and bridge of the nose. Such DLE lesions are not to be confused with the more transient, edematous-erythema reactions that occur over the same distribution in ACLE lesions. As with ACLE, DLE usually spares the nasolabial folds. Perioral DLE lesions can occur and often resolve with a striking acneiform pattern of pitted scarring (Fig. 30-23). DLE often involves the external ear, including the outer portion of the external auditory canal. The earliest lesions in this area present as dilated, hyperpigmented follicles (Fig. 30-24).
Scalp involvement occurs in 60% of DLE patients, and is the only area involved in approximately 10% (186) (Fig. 30-20). Irreversible scarring alopecia from permanent follicular destruction occurred in 34% of patients in one recent series (187). The irreversible, scarring alopecia that occurs as the result of persistent DLE activity in a localized area differs from the more widespread, reversible, nonscarring alopecia that SLE patients often develop during periods of disease activity.

Figure 30-22. Discoid lupus erythematosus of the vermillion border of the upper lip. Although the lower lip is more exposed to sunlight, the upper lip for some reason more often is affected with lupus erythematosus-specific skin disease.

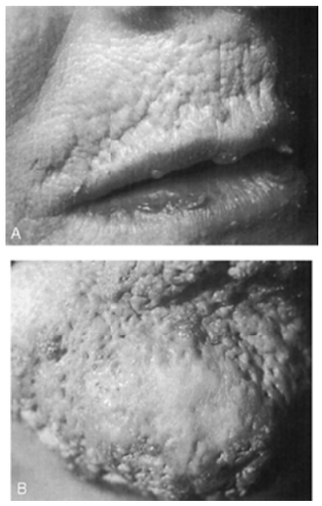

Figure 30-23. (See color plate.) **A,** Perioral pitted scarring resulting from prior discoid lupus erythematosus involvement. **B,** This pattern of scarring over the chin of a different patient was improved by dermabrasion. Note that smoother surface and appearance of the central part of the photograph that was treated as a test area. This patient was on antimalarial treatment at the time of the dermabrasion to minimize the chance for Köebnerization.

Figure 30-24. Discoid lupus erythematosus (DLE) involvement of the ear. Note the patulous, keratin-plugged follicles within areas of hyperpigmentation in the conchae. This pattern of clinical involvement is highly specific for DLE.

Figure 30-25. Discoid lupus erythematosus (DLE) lesions of the dorsal hands indicating generalized DLE. There is a somewhat higher risk of developing systemic lupus erythematosus in patients with generalized DLE compared to those patients with localized DLE (i.e., head and neck involvement only).

DLE lesions that occur only on the head or neck are referred to as “localized DLE.” DLE lesions occurring both above and below the neck are referred to as “generalized DLE.” The presence of DLE lesions below the neck only is extremely uncommon. DLE lesions occurring below the neck are most commonly found on the extensor aspects of the arms, forearms, and hands (Fig. 30-25), although DLE lesions can occur at virtually any site on the body, including completely sun-protected sites such as the perineal area (188) (Fig. 30-26). Unusual locations can reflect the fact that DLE, as well as other forms of LE skin disease activity, can follow in the wake of any form of trauma to the skin (i.e., the Köebner or isomorphic response) (Fig. 30-27). Painful, erosive palmar-plantar DLE involvement can predominate in some cases producing significant disability and presenting an especially difficult management problem (189) (Fig. 30-28). On occasion, DLE lesions can remain as small, discrete, follicule-based papules having a diameter of less than 1 centimeter or less. Such “follicular DLE” lesions often are seen around the elbow (Fig. 30-29), but can occur elsewhere as well.

Figure 30-26. Biopsy-confirmed discoid lupus erythematosus lesion of the inguinal fold.

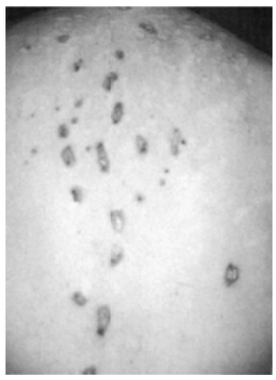

Figure 30-27. Köebnerized discoid lupus erythematosus (DLE). DLE lesions occurring in areas of neurotic excoriation. Note the linear shape of some of these lesions.

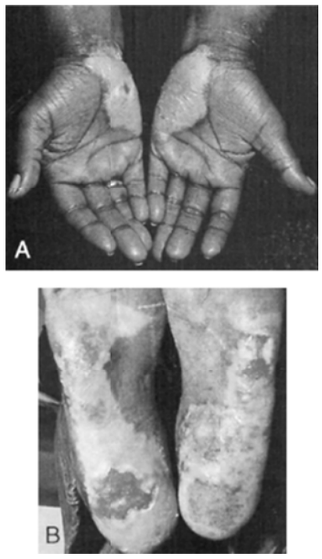

Figure 30-28. (See color plate.) Palmar-plantar discoid lupus erythematosus (DLE). DLE involvement of the palms of the hands **(A)** and soles of the feet **(B)** can present a very difficult management problem. Erosions that can develop in such areas can cause extreme pain and result in occupational disability **(B)**.

Figure 30-29. Discoid lupus erythematosus presenting as discrete follicular lesions around the elbow, the most common site for this pattern of involvement.

Linear DLE lesions rarely have been reported and may be more common in children (190 ,191), usually following the lines of Blaschko (192).

DLE lesions can be potentiated by sunlight exposure however, this occurs less frequently than with ACLE and SCLE. Patients often are unaware that UV irradiation exacerbates or precipitates their skin disease, perhaps from the fact that there may be a 1- to 4-week lag time from the time of light exposure until the skin lesions develop (38) (67). It is predominately UVB that aggravates DLE lesions, although increasing evidence suggests that the longer UVA wavelengths also can be deleterious in some LE patients (193). However, in as many as 50% of patients, sun exposure does not appear to be related to the cause of their DLE lesions. DLE lesions in the hair-bearing scalp, external auditory canal, or perineal areas are examples where this form of cutaneous LE is not related to light exposure.

DLE also can localize to the nail unit (194). Focal lesions of DLE occurring over the nailfold can produce nail-plate dystrophy (Fig. 30-30). The nail unit can be impacted by other forms of cutaneous LE as well as SLE-producing nail-fold erythema and telangiectasia, red lunulae, clubbing, paronychia, pitting, leukonychia striata, and onycholysis (primary data reviewed in (3)).

Figure 30-30. Symmetric discoid lupus erythematosus lesions of the nailfold producing medial nailplate dystrophy. None of the other fingernails were affected.

Hypertrophic Discoid Lupus Erythematosus

Hypertrophic DLE (i.e., hyperkeratotic DLE, verrucous DLE) is a rare variant of chronic cutaneous LE in which the hyperkeratosis that normally is present in classical DLE lesions is greatly exaggerated (Fig. 30-31). These lesions can occur at any site that classical DLE lesions develop, although the extensor aspects of the extremities, the upper back, and the face are the areas most frequently affected. The histopathology sometimes reveals features of squamous-cell carcinoma or keratoacanthoma, which can lead clinicians to make the wrong diagnosis (195 ,196). However, it is important to realize that squamous-cell carcinoma sometimes can develop in DLE lesions and can metastasize (197 ,198). When multiple widespread lesions with histopathologic features of squamous-cell carcinoma or keratoacanthoma are present, one should consider a diagnosis of hypertrophic LE. Overlapping features of hypertrophic LE and lichen planus also have been described (199). Fortunately, patients with hypertrophic DLE lesions often have classical DLE lesions elsewhere on their body that helps clinicians make the correct diagnosis.

The entity “LE hypertrophicus et profundus,” that was described originally by Bechet in 1942 (200) appears to represent a very rare form of hypertrophic DLE affecting the face associated with the additional features of violaceous (or dull red), indurated, rolled borders, and striking central, crateriform atrophy. The name of this entity is somewhat ambiguous because its pathology does not include a significant degree of LE panniculitis.

LE Profundus/LE Panniculitis

Historically referred to as Kaposi-Irgang disease (201), this rare form of chronic cutaneous LE is characterized by inflammatory lesions in the lower dermis and subcutaneous tissue. Approximately 70% of the patients with this type of chronic cutaneous LE also have typical DLE lesions often overlying the panniculitis lesions (202 ,203). The term “LE profundus” has been used by some (including one of the authors [RDS]) to arbitrarily designate those patients who have both LE panniculitis and DLE lesions. However, traditionalists might considered this to be an artificial distinction.

The lesions present as deep, firm, 1- to 3-cm diameter nodules often with normal-appearing overlying skin (204). The skin ultimately becomes attached to the firm, subcutaneous nodular lesions and is drawn inward to produce deep, saucerized depressions as the lesions mature (Fig. 30-32). The head, proximal upper arms, chest, buttocks, and thighs are the sites of predominant involvement. Confluent involvement

of the face can simulate the appearance of lipoatrophy (Fig. 30-33). LE profundus also can present as periorbital edema (205 ,206).

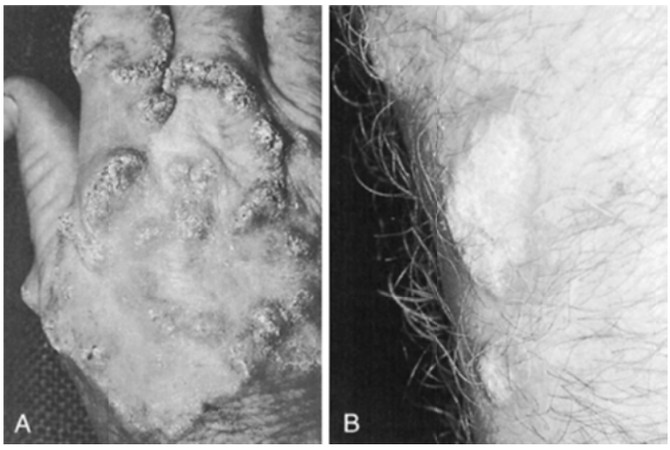

Figure 30-31. Two clinical patterns of hypertrophic (verrucous) discoid lupus erythematosus (DLE). **A,** A pattern where warty hyperkeratosis occurs at the active edge of an active DLE lesion. **B,** A DLE lesion that is entirely covered by a thickened shield of hyperkeratosis, presenting a clinical appearance that could be mistaken for other common dermatoses such as keratoacanthoma, squamous-cell carcinoma, or prurigo nodularis.

Linear involvement of the extremities also has been observed (207). Dystrophic calcification within older lesions of LE profundus is common and at times can be a prominent clinical feature of the disease requiring surgical excision. Additionally, LE panniculitis may produce breast nodules that can mimic carcinoma clinically and radiologically (208). Rarely anetoderma, a peculiar form of skin atrophy that is often associated with antiphospholipid antibodies, and is a LE-nonspecific skin disorder, has been found in patients with LE panniculitis (209). Cases of subcutaneous panniculitis-like T cell lymphoma may mimic LE panniculitis (210 ,211).

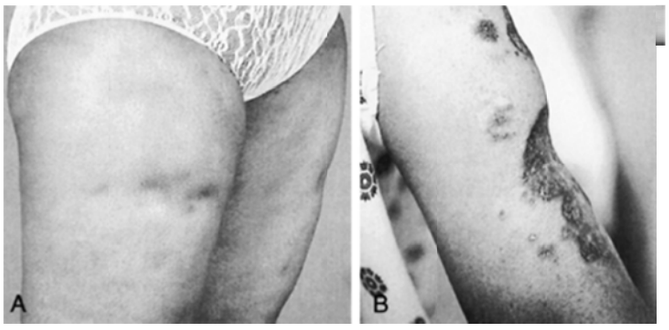

Figure 30-32. Lupus erythematosus (LE) panniculitis/profundus. **A,** An example of LE panniculitis without overlying discoid lupus erythematosus (DLE). The primary lesion is a firm subcutaneous nodule that is associated with saucerized areas of atrophy at the surface of the skin. **B,** The combination of LE panniculitis with overlying DLE involvement, referred to as LE profundus.

Figure 30-33. Lipoatrophy of the face resulting from lupus erythematosus profundus.

Mucosal DLE

It long has been recognized that mucosal-membrane involvement can occur in chronic cutaneous LE patients (212). Studies by Burge et al. have confirmed that the prevalence of mucous-membrane involvement in chronic, cutaneous LE is about 25% (213). While the oral mucosa is most frequently involved, nasal, conjunctival, and genital mucosal surfaces also can be affected.

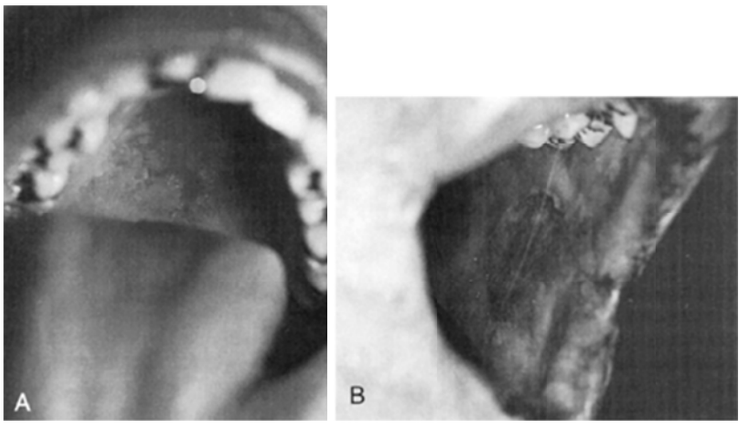

Figure 30-34. (See color plate.) Discoid lupus erythematosus (DLE) of the oral mucosa. **A,** Typical appearance of a lesion on the hard palate. Note the honeycomb appearance. These lesions show a typical lupus erythematosus-specific histopathology and usually are painless. **B,** Margins of a DLE lesion on the buccal mucosa of another patient are demarcated by staining with a toluidine blue mouthwash. This patient ultimately developed a squamous-cell carcinoma within a different area of chronic DLE involvement on his buccal mucosa.

Within the mouth, the buccal mucosal surfaces are most commonly involved, with the palate, alveolar processes, and tongue being sites of less-frequent involvement. Individual lesions begin as painless, erythematous patches later maturing to a chronic plaque that can present an appearance quite similar to that of lichen planus (Fig. 30-34). The chronic buccal-mucosal plaques have a sharply marginated, irregularly scalloped white border with radiating white striae and telangiectasia (213). The surface of these plaques overlying the palatal mucosa often has a well-defined meshwork of raised hyperkeratotic white strands that encircle zones of punctate erythema, which gives a “honeycomb” appearance (213). The center of older lesions can become depressed and occasionally undergoes painful ulceration. Well-defined chronic DLE plaques also can appear on the vermillion border of the lips (Fig. 30-22). At times, DLE involvement of the lips can present as a diffuse cheilitis, especially on the more sun-exposed lower lip. Although lesions can appear on the tongue, this location is quite rare (213).

Chronic oral-mucosal DLE lesions occasionally can degenerate into squamous-cell carcinoma (214), similar to cutaneous DLE lesions. Any area of asymmetrical nodular induration within a mucosal DLE lesion should be carefully evaluated for the possibility of malignant degeneration.

Discrete DLE plaques also can develop on the nasal, conjunctival, and genital mucosa (213). Nasal septum perforation is relatively rare and is more often associated with SLE

than DLE (215). However, nasal-mucosal involvement has been suggested to be relatively common in LE patients (216). Conjunctival DLE lesions begin as small areas of nondescript inflammation most commonly affecting the palpebral conjunctivae or the margin of the eyelid. The lower lid is affected more often than the upper lid. As the early lesions progress, scarring becomes more evident and can produce permanent loss of eyelashes and ectropion (Fig. 30-21). DLE involvement of the eyelid can produce considerable disability (217). It has been suggested that corneal, stromal keratitis also can occur as a result of DLE ocular involvement (218). Although quite rare, anogenital mucosal DLE lesions also have been observed (213).

Chilblains Lupus/Lupus Pernio

Some LE patients develop red-purple patches and plaques on their toes, fingers, and face that are precipitated by cold, damp climates. Such lesions are highly reminiscent of simple chilblains or pernio lesions (219). As these lesions evolve, however, they take on the typical appearance of DLE lesions clinically and histopathologically. The terms “chilblains lupus” and “perniotic LE” have been used to describe such lesions (Fig. 30-35). Unfortunately, the term “lupus pernio” also has been used for such lesions; however, this term is more properly used to designate a form of cutaneous sarcoidosis (220). Chilblains lupus patients often have typical DLE lesions on the face and head (219).

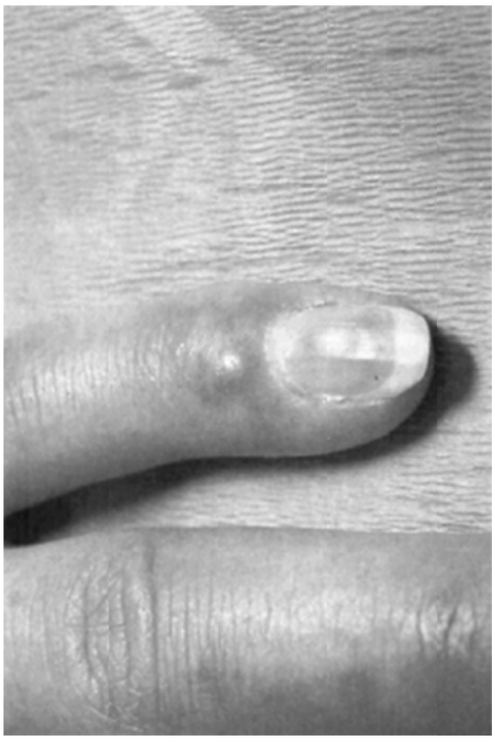

Figure 30-35. Chilblains lupus erythematosus (LE) (perniotic LE). Note the rather nondescript appearance of this early lesion. At this stage, the pathology might be nonspecific; however, with time, such lesions can present a typical discoid lupus erythematosus histopathology.

Lupus Erythematosus Tumidus

The accumulation of excessive dermal mucin early in the course of a cutaneous LE lesion can result in the succulent, edematous, urticaria-appearing plaques of LE tumidus (Fig. 30-36). The characteristic liquefactive degeneration and basement membrane thickening seen microscopically in lesions of SCLE and DLE are usually absent in lupus tumidus lesions (221). The lack of these histologic features, and absence of an associated serologic marker, make it more difficult to diagnose LE tumidus, compared to diagnosing other forms of LE-specific skin disease.

Kuhn et al. have reported a series of 40 LE tumidus patients and have traced the line of thought relating to this clinical entity from its apparent original description by Gougerot and Bournier in France in 1930 (222). Three other smaller patient cohorts of LE tumidus also have appeared recently (222 ,223 ,224). It now is clear that terms such as the “urticarial plaque” form of LE (225), “lupus tumidus” (223 ,226), and “tumid LE” (222) in the modern

English literature have been functionally equivalent to the classical term “LE tumidus” described by Gougerot and Bournier in 1930 and others since. LE tumidus patients accounted for 16% of their total population of cutaneous LE patients examined by Kuhn et al. LE tumidus has accounted for a much lower percentage of the total number of cutaneous LE lesions seen by the workers outside Germany including the United States (204 ,223 ,227 ,228). Additionally, in epidemiologic studies of large series of SLE patients in which cutaneous lesions have been recorded, lesions consistent with LE tumidus are mentioned rarely (4 ,24 ,55 ,229). This plus the dearth of specific published experience on LE tumidus from the United States suggests the possibility that the epidemiology of LE tumidus might differ somewhat between Western Europe and the United States. Alternatively, some of these latter workers might not have recognized LE tumidus as a distinct form of cutaneous LE or have included patients with LE tumidus under other designations such as “urticaria” in the context of SLE.

Figure 30-36. Lupus tumidus. This form of chronic cutaneous lupus erythematosus (CCLE), which is very rare in the authors' experience, presents succulent, elevated plaques occurring in a sun-exposed distribution. In this case, which is not typical of all cases of lupus tumidus, there was a pattern of surface-color change reminiscent of Wickham striae. However, the biopsy specimen did not show changes of lichen planus, nor were LE-specific skin disease changes clearly present at the DEJ. The predominant pathologic change was mononuclear cell infiltration around the superficial and deep dermal blood vessels. It is quite likely that lupus tumidus lesions and lesions described by other investigators under different designations such as urticarial plaque lupus erythematosus represent the same disease process (personal communication, Irwin M. Braverman, MD).

Other intriguing aspects of the large LE tumidus case series presented by Kuhn et al. include male predominance, negative lesional direct immunofluorescence, and virtual absence of associated SLE disease activity. However, the other three recently published cases series of LE tumidus, although much smaller in patient number, did not find a male predominance and some of their patients had LE tumidus occurring in the context of discoid LE and systemic LE (224 ,230).

The systematic phototesting studies performed by Kuhn et al. revealed a rather strong presence of UVA in the action spectrum of LE tumidus. This is in agreement with earlier such work (231). The extreme photosensitivity noted in their patients occurred in the virtual absence of epidermal changes and Ro/SS-A antibody production. These findings suggest the possibility that there is a fundamentally different mechanism of photosensitivity in LE tumidus compared to SCLE. However, it is interesting to note that when Lehmann et al. (38) challenged the nonlesional skin of SCLE patients with UVA alone, only dermal changes of LE-specific skin disease were noted.

Table 30-3 presents a comparison of the selected clinical and laboratory features of patients presenting with ACLE, SCLE, and classical DLE skin lesions.

Relationship between Cutaneous and Systemic Disease

Figure 30-37 illustrates the different relationships that exist between the three major forms of LE-specific skin disease and the systemic autoimmune manifestations of LE.

Acute Cutaneous Lupus Erythematosus

Because the “malar rash” or “butterfly rash” is so common in patients with SLE and because such lesions are considered to be a fundamental component of the clinical expression of SLE disease activity, few workers have directly examined the relationship that exists between ACLE and SLE disease activity.

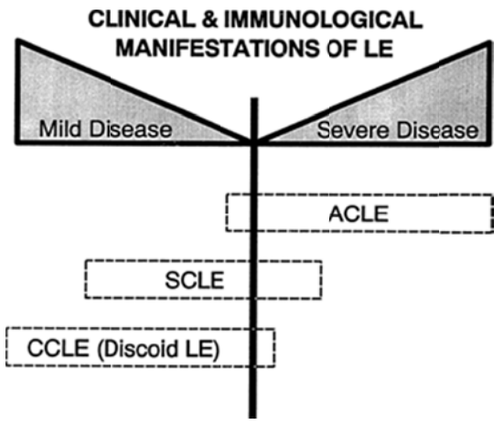

Figure 30-37. Relative risks for systemic lupus erythematosus disease activity that are associated with the three major forms of lupus erythematosus-specific skin disease.

Ropes noted that the “butterfly rash” of SLE often waxed and waned in parallel with underlying SLE disease activity (30). However, Dr. Ropes was unable to demonstrate a positive correlation between skin disease activity and evidence of LE nephritis. Curiously, a significant negative correlation was noted with psychosis and serum protein electrophoresis abnormalities (30). Vlachoyiannopoulos et al. found that flaring of the “rash” of SLE frequently accompanies flares of SLE activity (59). Wysenbeek et al. also have demonstrated that the generalized “nonspecific rash” of SLE (presumably generalized ACLE) correlated positively with lymphadenopathy, antinative DNA antibody, low-complement levels, and higher prednisone doses (63). However, these workers found no such correlation with renal disease, central nervous system (CNS) disease, or SLE disease activity index.

It has always been our impression that either localized or generalized ACLE is associated with a high risk for aggressive SLE activity, including the risk of LE nephritis.

Subacute Cutaneous Lupus Erythematosus

Approximately one half of SCLE patients meet the ACR's revised criteria for the classification of SLE (50) (data reviewed in (94)). However, it has been the experience of most observers that severe SLE (i.e., LE nephritis, CNS disease) develops in only ~10% of SCLE patients (data reviewed in (94 ,232)). While most SCLE patients who develop four or more SLE classification criteria tend to have a relatively mild disease course overall, there are reports of such patients who have had severe and sometimes fatal outcomes, usually from renal and CNS involvement (233).

There is some indication that patients with the papulosquamous variety of SCLE might be at more risk of developing renal involvement (70). Sontheimer et al. identified

five patients in a cohort of 47 individuals with SCLE that had evidence of lupus nephritis (234). All five of these patients had the papulosquamous type of SCLE, leukopenia, high-titer antinuclear antibody (ANA) (>1:640) and anti-double–stranded (ds) DNA antibodies. All five also developed ACLE lesions at some point during their disease course and all had been refractory to antimalarial treatment. Another report noted that SCLE patients with renal disease were more likely to have the papulosquamous type of lesions (235). Men with papulosquamous SCLE may have higher risk of severe SLE (70).

SCLE can overlap with other autoimmune disorders. Some patients with SCLE will later manifest clear evidence of Sjögren syndrome, whereas some patients whose illness begins as Sjögren syndrome will later develop SCLE lesions. Three to 12% of patients who present with SCLE skin lesions will later developed Sjögren syndrome (34). It is interesting to note in this regard that both SCLE and Sjögren syndrome have been associated with circulating Ro/SS-A and La/SS-B autoantibodies and the presence of the HLA-B8, DR3, DRW6, DQ2, and DRW52 extended haplotype.

A number of Japanese patients having Sjögren syndrome and Ro/SS-A and La/SS-B autoantibodies have been reported to have an annular erythema reaction that appears somewhat similar clinically to annular SCLE, although biopsies of the lesions have revealed histopathologic findings somewhat distinct from SCLE (236). While some consider this to be a distinct entity (i.e., annular erythema of Sjögren syndrome), it is possible that genetic differences between occidentals and whites could account for this difference in disease expression. For example, the HLA-DR3 allele is distinctly unusual in the citizens of Japan.

Roughly one third of SCLE patients produce rheumatoid factor (94). It is therefore not surprising that SCLE patients have been noted to subsequently develop RA on occasion (237). Additionally, patients presenting with RA can subsequently developed SCLE lesions. One group reported that of 12 RA patients who produced Ro/SS-A autoantibodies, two had SCLE skin lesions (238). An association between SCLE and antithyroid autoantibodies and Hashimoto thyroiditis also has been reported (239).

There have been case reports of malignancies occurring in patients with SCLE (breast, lung, gastric, uterine, lymphoma, hepatic, and melanoma) (240 ,241 ,242 ,243 ,244). In some of these reports, the SCLE lesions have been suggested to represent a paraneoplastic manifestation of the underlying malignancy. Other disorders that have been anecdotally related to SCLE have been Sweet syndrome (245), porphyria cutanea tarda (246), gluten-sensitive enteropathy (247), X-linked chronic granulomatous disease (248), hereditary angioedema (249), and autoimmune polyglandular syndrome type II (Schmidt syndrome) (250) and Crohn disease (251). The infrequency of these associated conditions mitigates against anything more than a casual association. However, it should be kept in mind that the usual dose of aminoquinoline antimalarial agents used in the management of SCLE (or DLE) can cause significant hepatotoxicity in patients who might have underlying subclinical porphyria cutanea tarda.

Chronic Cutaneous Lupus Erythematosus

The relationship that exists between classical DLE and SLE has been the subject of debate throughout the 20th century. Daniel Wallace has presented a comprehensive overview of this subject, which systematically and thoughtfully addresses the following issues (134).

What is the Risk for Patients Presenting with Classical DLE Subsequently Developing SLE?

Five percent to 10% of patients presenting with classical DLE lesions subsequently will develop unequivocal evidence of the extracutaneous manifestations SLE (134). Considerable effort has been made to identify clinical or laboratory features that might correlate with such a pattern of disease progression. One clinical feature that can be useful in this regard is the extent and distribution of the DLE lesions. Generalized DLE patients (i.e., lesions both above and below the neck) have a higher rate of immunologic abnormalities and risk for progressing to SLE compared to localized DLE patients (228). Additionally, generalized DLE patients are at higher risk for developing the more severe manifestations of SLE (228). In some instances, SLE patients may develop DLE skin lesions late in the course of their disease when their SLE disease activity has fully remitted (252). A 36-month follow-up of 27 children who initially presented with DLE (15 localized and 12 with disseminated disease) revealed that 7 (26%) had developed SLE (132).

Other physical findings that should alert one to the possibility of underlying systemic disease are diffuse, nonscarring alopecia, generalized lymphadenopathy, periungual nailfold telangiectasia, Raynaud phenomenon, SCLE, and LE-nonspecific skin lesions such as vasculitis (186).

The following laboratory findings have been reported to be risk factors for the development of SLE in DLE patients: unexplained anemia, marked leukopenia, false-positive tests for syphilis, persistently positive high-titer antinuclear antibody assay, anti-single–stranded DNA antibody, hypergammaglobulinemia, an elevated erythrocyte sedimentation rate (especially of greater than 50 mm/hour), and immune deposits at the dermal-epidermal junction of nonlesional skin (i.e., a positive lupus band test) (228).

A recent multivariate study of 51 SLE patients and 245 patients with SCLE and/or DLE revealed that those patients with evidence of nephropathy (e.g., proteinuria, hematuria), arthralgias, or an ANA titer 1:320 were at significantly greater risk of having systemic disease (253). This analysis found that the erythrocyte sedimentation rate, anti-dsDNA antibodies, photosensitivity, and recurrent headaches

were not useful in distinguishing between patients with or without systemic disease. Recent work also has suggested that elevated soluble interleukin 2 (IL-2) receptor levels might also be a risk factor for SLE in patients with DLE (254).

What Are the Clinical Implications of Classical DLE Lesions Occurring in SLE Patients?

Roughly one fourth of SLE patients will develop DLE lesions at some point in the course of their disease. Some work has suggested that such patients tend to have less severe forms of SLE with life-threatening complications such as diffuse proliferative glomerulonephritis are being uncommon in these patients and survival is increased when compared to SLE patients without DLE lesions (255).

What Are the Risks for Developing Systemic Disease Associated with Other Forms of Chronic Cutaneous LE?

Hypertrophic DLE patients do not appear to have a greater risk for developing SLE than do patients with classical DLE lesions (256). Several reports have indicated that approximately 50% of the patients with LE profundus/panniculitis have a relatively mild form of SLE (200). In a recent retrospective review of 40 LE panniculitis patients, only 10% met the ACR criteria for SLE (257). In an earlier study, only 25% of 16 LE panniculitis patients that were followed over a decade on average ever developed SLE (258). A more recent review of 12 LE panniculitis cases from Singapore reported 3 of the 12 cases with evidence of SLE. (203). The systemic features of patients with LE panniculitis/profundus tend to be less severe, similar to those in SLE patients who have DLE skin lesions (200). Severe nephritis is an uncommon complication in SLE patients with LE panniculitis. In one study, 3 of 15 (20%) patients presenting with chilblain LE later developed SLE (219).

Figure 30-38. Oral mucosal ulceration in systemic lupus erythematosus (SLE). As seen in this case, superficial ulcers often occur in the junctional area of the hard and soft palates; however, ulceration of the gingival, buccal, and lingual mucosa also occur. In the early stages of such lesions, the histopathology often is nonspecific. While difficult to see in this photograph, this young woman with active SLE, including nephritis, also had ulceration of the nasal mucosa. Oral and nasal mucosa ulceration in this setting can be associated with severe pain, or it can be painless.

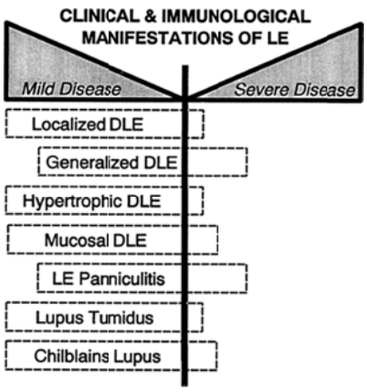

Figure 30-39. Relative risks for systemic lupus erythematosus disease activity that are associated with the various clinical varieties of chronic cutaneous lupus erythematosus (CCLE).

The risk for systemic disease activity in LE patients having mucosal involvement is a function of the type of mucosal lesion that is present. Superficial, transient oral or nasal mucosal ulcerations having a relatively nonspecific histopathology are commonly seen in patients with active SLE (Fig. 30-38) (such mucosal lesions represent one of the 11 ACR's revised classification criteria for SLE). Chronic mucosal LE plaques, the mucosal equivalent of DLE lesions are seen most commonly in LE patients who do not have life-threatening SLE. The more severe manifestations of SLE such as renal disease appear to be quite uncommon in SLE patients who develop chronic mucosal plaques (213).

Figure 30-39 illustrates the relative risks for systemic disease activity that are associated with the various clinical varieties of chronic cutaneous LE.

The Lupus Band Test

No discussion of the relationship between the cutaneous and systemic manifestations of LE would be complete without addressing the lupus band test. Burnham et al. first identified the presence of immunoglobulins and complement components in a continuous bandlike array at the DEJ of lesional skin biopsies from LE patients using direct immunofluorescence microscopy (23). This phenomenon, subsequently referred to as the “lupus band” (259), initially was felt to be quite specific for LE; however, subsequent work has documented

that the lupus band can be found in a number of skin disorders other than those caused by LE (260).

Cormane (261) later described similar findings in biopsies from clinically normal skin of SLE patients in the complete absence of any signs of cutaneous inflammation. Because DLE patients lacked this finding in their nonlesional skin, it was suggested that such results might have diagnostic specificity for SLE. The search for immunoreactant deposition in nonlesional skin of LE patients subsequently has been referred to by many as the lupus band test (LBT).

Controversies concerning terminology have clouded this field from the beginning. Although some workers use the term “LBT” to refer to LE lesional as well as nonlesional immunopathologic findings (262), others reserve this designation for reference to the results of immunopathologic examination of nonlesional skin (263). Less confusion might exist in this area if the terms “lesional LBT” and “nonlesional LBT” were uniformly adopted by those working in this area.

The immunopathologic findings in nonlesional skin of LE patients must be distinguished from those present in LE lesional skin biopsies. Issues related to immunopathologic findings in LE-specific skin lesions (i.e., the lesional LBT) will be discussed later in this chapter (see Pathology/Immunopathology). The remainder of this discussion will be limited to the presence or absence of immunoreactants at the DEJ of nonlesional skin (i.e., the nonlesional LBT).

All three major immunoglobulin classes (IgG, IgM, and IgA) and a variety of complement components including constituents of the membrane attack complex have been identified in these DEJ deposits (260). Studies have suggested that the presence of membrane attack complex at the dermal-epidermal junction of lesional skin is relatively sensitive and specific for LE (264). The immunoglobulin-staining pattern of immunoreactants in nonlesional LE skin under low power generally is described as being granular. Upon high-power magnification, the pattern of fluorescence has been variously described as appearing homogeneous, stippled, fibrillar, shaggy, lumpy-bumpy, linear, or thready (details related to the appearance and significance of these various patterns have been reviewed (265)). Ultrastructurally, these immunoreactants are seen to be deposited on and below the lamina densa of the DEJ (266). The intensity of the staining and the number of immunoreactants present in these deposits can vary considerably (262). Most authorities require a continuous pattern of immunoreactant deposition along the DEJ for a

positive nonlesional LBT. Numerous studies have suggested that a discontinuous or interrupted nonlesional LBT can be seen in a number of other disorders and thus is much less specific for SLE (260). Additionally, the presence of IgM alone appears to be very nonspecific (260). The diagnostic and prognostic significance of the nonlesional LBT has been the subject of much controversy over the past two decades. In-depth analyses of these issues are available elsewhere (262). The following summary points can serve to acquaint the reader with the clinically relevant issues pertaining to the nonlesional LBT:

- Standardization. It is quite curious that a test such as this that has been used clinically for well over four decades has been so poorly standardized. Clinically normal individuals have been studied to determine the incidence of a false-positive nonlesional LBT in both sun-exposed and nonexposed skin regions. Such studies have suggested that as many as 20% of healthy young adults have a positive LBT in sun-exposed nonlesional skin regions such as the lateral aspect of the neck whereas virtually none are positive in sun-protected nonlesional sites such as the buttocks (267). Thus, considerable caution must be taken when interpreting the results of immunopathologic findings in both lesional and nonlesional biopsies taken from sun-exposed skin sites (e.g., face, neck, extensor aspect of forearm and hand) or partially sun-exposed skin sites (flexor aspect of the forearm, deltoid region) with respect to the diagnosis of cutaneous or systemic LE.

  Autofluorescence of dermal collagen and elastin fibers at low power can give the appearance of a positive nonlesional LBT (i.e., the “fibrillar pseudoband” (259)). At higher power, the artifactual nature of this false-positive finding becomes apparent. A false-negative, nonlesional LBT can occur when high levels of extravascular dermal IgG is present. This finding, which correlates with hypergammaglobulinemia, can obscure the distinctness of the lupus band at the DEJ (268).

  It also is important to understand that considerable anatomic regional variation exists with respect to the nonlesional LBT. It has been suggested that there is a cephalocaudal gradient in the frequency of a positive lesional LBT in DLE lesions, with lesions on the head more often being positive than those on the trunk (262). There are indications that a similar phenomenon might exist with the LBT in nonlesional skin of NZB/W mice, a murine model of SLE (33). Firm data addressing this issue in human LE patients have not yet been presented.

- Diagnostic specificity. Because the strongest clinical association of the nonlesional LBT has been with SLE, it is not surprising that classical DLE patients without clinical or laboratory evidence of extracutaneous disease have been uniformly nonlesional LBT negative (186). Only about 25% of SLE patients who have DLE lesions have a positive, nonlesional LBT (186). Approximately 25% of SCLE patients (an LE subset that frequently has mild symptoms of SLE) are nonlesional LBT positive in relatively sun-protected flexor forearm skin (33). As noted earlier, the diagnostic specificity of the nonlesional LBT for SLE has become a point of controversy. Factoring in the profile of individual immunoreactants present in a positive nonlesional LBT has been suggested to be one approach to enhancing the specificity of this test. Several studies have suggested that when three or more immunoreactants are present in the nonlesional LBT, the diagnostic specificity for SLE is very high (269). These observations taken together with the fact that actinically damaged skin can yield false-positive results (267) would suggest that a positive nonlesional LBT (confirmed under high-power observation to exclude the artifacts such as the fibrillar pseudoband) in fully sun-protected skin from the buttock or inner aspect of the upper arm that consists of three or more immunoglobulin or complement components might have the greatest specificity for SLE. Under these conditions, a positive nonlesional LBT can serve as a very useful piece of additional diagnostic information in those difficult cases of SLE where the clinical and laboratory manifestations of this disorder are being expressed atypically.
- Prognostic significance. Although the nonlesional LBT was initially adopted because of its perceived diagnostic specificity for SLE, subsequent work suggested that it also correlated positively with a more aggressive course of systemic disease including the development of lupus nephritis (270). The presence of IgG in the nonlesional LBT was suggested to be more indicative of severe SLE than the presence of IgM alone (271). The idea that the nonlesional LBT had prognostic value also became a point of contention. However, a prospective follow-up study has confirmed the predictive value of a positive nonlesional LBT (272). Whether the nonlesional LBT provides incremental value over more generally available and less invasive tests such as circulating dsDNA antibody levels in prognosis assessment is not clear; however, there are those who continue to feel that this is the case (269). It is the authors' opinion that a properly interpreted nonlesional LBT has its greatest utility as an additional diagnostic maneuver in patients with atypical clinical and laboratory presentations of SLE.

Pathology and Immunopathology

Acute Cutaneous Lupus Erythematosus

Histopathology

The histologic picture in ACLE is generally less impressive than that seen in SCLE and DLE lesions. The dermal cellular infiltrate is often relatively sparse. The most prominent changes are edema of the upper dermis and focal liquefactive degeneration of the epidermal basal-cell layer. In the most severe forms of ACLE, epidermal necrosis may occur, producing a histopathologic pattern strongly resembling toxic-epidermal necrolysis.

Immunopathology

Curiously, there is very little published data concerning direct immunofluorescence findings in ACLE. In one study, five of five (100%) skin biopsies from ACLE (i.e., “diffuse erythema”) lesions were reported to be lesional LBT positive (273). More recent work has indicated that the lesional lupus band test is positive in 60% of patient having the “malar rash” of SLE (55).

Subacute Cutaneous Lupus Erythematosus

Histopathology

While the histopathology of SCLE is clearly that of LE-specific skin disease, it may be impossible to clearly differentiate SCLE from ACLE and DLE. Characteristically, ACLE, SCLE, and DLE have variable degrees of hyperkeratosis, basal-cell degeneration, dermal edema, and mononuclear cell infiltration around the DEJ extending into the dermis. In SCLE, there is focal basal-cell injury and disorientation with liquefaction degeneration, sparse upper-dermal mononuclear-cell infiltrate that may partially obscure the DEJ, dermal edema, and rarely epidermal necrosis (161). The mononuclear infiltrate usually is limited to perivascular and adnexal structures in the upper third of the dermis and the epidermis may be mildly atrophic. Vesicular changes can occur in SCLE lesions, particularly at the active border of annular SCLE lesions (274). It has been suggested that such patients are more likely be HLA-DR3 and have Ro/SS-A autoantibodies (274).

SCLE lesions generally have less hyperkeratosis, follicular plugging, mononuclear cell infiltration of adnexal structures, and dermal melanophages compared to DLE lesions. Qualitative differences in the histopathology of SCLE versus DLE have been noted (275); however, not all agree on this point (276). Bangert et al. were unable to differentiate papulosquamous from annular SCLE by blinded histopathologic examination (161).

Immunopathology

As in other LE-specific lesions, immune deposits can be detected frequently by immunofluorescence staining in SCLE skin lesions. The initial studies indicated that these deposits consist of immunoglobulin (IgM, IgG, and/or IgA) and complement components arranged in a granular bandlike pattern along the DEJ (33). Approximately 60% of SCLE lesions from the original cohort of SCLE patients had such deposits, compared to somewhat higher percentages for ACLE and DLE lesions. Others have found similar results in SCLE skin lesions (274), whereas some workers have found even higher frequencies (178). A more recent study revealed IgM +/- C3 was the predominant immunoreactant in perilesional biopsies from patients with LE, being found in 75% of 199 patients. Of 13 SCLE patient biopsies in this study, 62% had IgM, 46% had IgG, 23% had IgA, 62% had C3, and 31% had fibrin, alone or in various combinations (277). Thus, the presence of immune deposits at the DEJ can help confirm a diagnosis of SCLE, but its absence does not necessarily rule it out. These immune deposits are not specific for LE as similar deposits can be found in normal or sun-damaged skin (267) and in other non-LE dermatologic conditions (260).

Nonlesional deltoid and flexor forearm skin biopsies from the original group of SCLE patients contained junctional immune deposits in 46% and 26%, respectively (33). The prognostic significance of such deposits has not yet been determined.

Nieboer et al. reported finding a “dust-like particle” pattern of IgG deposition deposited in and around the epidermal basal keratinocytes and subepidermal regions in 30% of SCLE lesional skin biopsies (278). This group suggested that this pattern of immunoglobulin deposition is specific for SCLE although its presence did not correlate with the presence of circulating Ro/SS-A autoantibodies. Others have noted this same immunofluorescence pattern in SCLE patients (279). A recent review of 4,374 skin-biopsy specimens submitted for direct immunofluorescence exam revealed 66 samples from 60 patients with “dust-like particles.” Fifty-three percent of these patients had SCLE, but only 36% of these 60 patients had Ro/SS-A autoantibodies (280).

It is curious, however, that one of the authors (RDS), as well as a number of other observers (269), have not been impressed by this pattern of immunofluorescence in SCLE lesional biopsies, suggesting that it might be somewhat technique dependent. This dust-like pattern of IgG is similar to that found in human skin explants grafted onto nude mice that resulted from intravenous infusion of human Ro/SS-A autoimmune sera (281). One of the authors (RDS) has noted a similar pattern of IgG and IgM deposition in guinea-pig skin following intradermal injections of human Ro/SS-A autoimmune sera.

Chronic Cutaneous Lupus Erythematosus

Classical Discoid Lupus Erythematosus

The epidermal basal cell layer is the principal site of injury in all three forms of LE-specific skin disease (161). In classical DLE, there is also prominent hyperkeratosis and follicular plugging. The nucleated layer of the epidermis generally is not thickened and may be somewhat atrophic. Epidermal basal-layer changes include: loss of the normal organization and orientation of basal cells, edema with vacuole formation between and sometimes within basal cells (i.e., liquefaction or vacuolar degeneration), partial obliteration of the DEJ by a mononuclear-cell infiltrate, thickening of the epidermal-basement membrane, increased melanin-pigment formation, and interruption of pigment transfer between melanocytes and keratinocytes leading to the accumulation of melanin by phagocytosis in dermal macrophages.

The dermal histopathologic changes are less specific. A mononuclear-cell infiltrate composed predominantly of T lymphocytes and macrophages is present most predominately in the periappendageal and perivascular areas. Plasma cells occasionally are seen in the more chronic lesions and dermal mucin deposition can at times be quite prominent. The chronic scarring DLE lesions more often have a denser inflammatory cell infiltrate that extends well into the deeper reticular dermis and/or subcutis. In contrast, ACLE and SCLE lesions contain a less dense inflammatory infiltrate that is confined to the upper dermis but still shows the distinctive pattern of injury along the DEJ (161). The periappendageal inflammation that is characteristic of DLE is less prominent in SCLE and ACLE.

Direct immunofluorescence examination of biopsy specimens taken from DLE lesions often reveals a thick, continuous band of immunoreactants along the DEJ (262). This band also extends along the basement membrane of the hair follicle, a finding that is not often seen in those other disorders that have been reported to have similar DEJ immunoreactants deposited in a bandlike pattern. Multiple immunoglobulin classes (IgG, IgA, IgM) usually are present within this band and various complement components (C3, C4, Clq, properdin, factor B, and the membrane attack complex, C5b–C9) also can present in many of these lesions (264).

Early reports suggested that over 90% of DLE lesions had lesional immunoreactants at the DEJ (273), however, subsequent studies have reported somewhat lower frequencies (262). A more recent study of 50 DLE patient biopsies found 78% had IgM, 58% had IgG, 38% had IgA, 72% had C3, and 66% had fibrin, alone or in various combinations (277).

The frequency with which immunoreactants are found in DLE lesions also appears to vary with the anatomic region from which the biopsy is taken. In one study, lesions on the head, neck, and arms were more often positive (80%) than those on the trunk (20%) (282). The frequency of bandlike immunoreactant deposition at the DEJ appears also to be a function of the age of the lesion being examined with older lesions (i.e., greater than 3 months) being more often positive than younger ones (i.e., less than 1 month) (283). Ultrastructural localization of immunoglobulin at the DEJ has confirmed that these proteins are deposited on the upper dermal collagen fibers and along the lamina densa of the epidermal basement membrane zone (266).

Hypertrophic Discoid Lupus Erythematosus

The histopathology and immunopathology is similar to that of classical DLE lesions except for a much greater degree of epidermal acanthosis and hyperkeratosis. The histopathology sometimes reveals features of squamous-cell carcinoma or keratoacanthoma, which can lead clinicians to make the wrong diagnosis (23 ,24). Overlap between the histologic features of hypertrophic LE and lichen planus have been described (199). A more recent clinicopathologic study of 14 hypertrophic LE patients found they all had concomitant classical DLE lesions (284). Histopathology of the hypertrophic LE lesions often showed hydropic degeneration of the basal cell layer, thickening of the basement membrane, a lichenoid reaction at the dermoepidermal junction and a perivascular and periadnexial lymphocytic infiltrate. Pseudoepitheliomatous hyperplasia engulfing elastotic material was also frequently encountered.

Lupus Erythematosus Panniculitis/Profundus

LE panniculitis is the only LE-specific skin lesion that spares the epidermis; however, Dr. James Gilliam felt that the pathologic changes within the subcutaneous tissue were characteristic enough to classify this entity as a form

of LE-specific skin disease. Absence of the characteristic epidermal and dermal changes of LE can make the histologic diagnosis difficult and controversy has existed in the past as to the specificity of the histopathologic changes of LE panniculitis when overlying changes of DLE are not present at the DEJ. The histologic features are that of a lobular lymphocytic panniculitis: perivascular infiltration with lymphocytes, plasma cells, and histiocytes in the deep dermis and subcutaneous fat (including lymphoid nodule formation); vessel-wall thickening and invasion by mononuclear cells (“lymphocytic vasculitis”); absence of polymorphonuclear leukocytes; hyaline-fat necrosis, prominent fibrinoid degeneration of collagen; as well as mucinous degeneration and calcification in old, established lesions (285). Immunoglobulin and complement deposits usually are found in blood-vessel walls of the deep dermis and subcutis by direct immunofluorescence staining of biopsy specimens (202). Immunoglobulin deposits at the DEJ may or may not be present depending on the site biopsied, the presence or absence of accompanying SLE, and the presence or absence of overlying changes of DLE at the DEJ.

A retrospective clinicopathologic study on 12 patients from Singapore found fat necrosis in all cases, and hyaline necrosis in 8 (203). The majority of cases showed lobular and paraseptal lymphocytic inflammation. One third of the cases had evidence of lymphocytic vasculitis and 75% had mucin deposition. Sixty-seven percent had histologic features diagnostic of DLE in the overlying skin, although only a third had overt evidence of DLE. Direct immunofluorescence was positive in only a third of cases compared to 70% in a previous study (284). A more recent retrospective study of 11 biopsy specimens from 9 patients with LE panniculitis found lobular panniculitis in all specimens and co-existent septal involvement in 82% of cases. Epidermal involvement occurred in 73% of cases. Superficial and deep dermal infiltrates were found in 82% of cases, mucin deposition in 73%, and reactive germinal centers in 45%. The subcutaneous infiltrate was composed of lymphocytes in all cases, and contained plasma cells in 91% of the specimens. Immunohistochemistry studies revealed a predominance of α/ß T-helper cells and cytotoxic lymphocytes admixed with B cells in 80% of the cases (211).

Mucosal Discoid Lupus Erythematosus

Except for the differences related to the absence of hair follicles and stratum corneum in mucous membranes, the microscopic changes are highly reminiscent of those seen in cutaneous DLE lesions (286).

Chilblain Lupus Erythematosus

Several studies have addressed the histopathologic findings in chilblain LE lesions in an attempt to differentiate these lesions from idiopathic chilblain lesions (287 ,288). One study found spongiosis, dermal edema and deep perieccrine inflammation may be more common to idiopathic chilblains, although vacuolar change in the basal keratinocytes is more common in chilblain LE (287). However, another study only found deep perieccrine inflammation as a distinguishing characteristic more common to idiopathic chilblains (288). A verrucous form of chilblain LE has recently been reported with prominent hyperkeratosis (289).

Lupus Erythematosus Tumidus

A recent histopathologic study of 80 LE tumidus patients including 53 primary lesions and 38 UVA- and/or UVB-induced lesions showed a characteristic and diagnostic pattern of periadnexal and perivascular lymphocytic infiltrate that in some cases included a few scattered neutrophils. (221). All specimens demonstrated interstitial mucin deposition. Epidermal atrophy or alteration of the dermoepidermal junction was absent. Direct immunofluorescence of LE tumidus lesions have been negative in most cases.

Laboratory Findings

Acute Cutaneous Lupus Erythematosus

Little data are available concerning specific laboratory associations of ACLE. Wysenbeek et al. reported that anti-dsDNA antibodies and low complement levels were more common in patients who had the nonspecific “rash” of SLE (presumably generalized ACLE) (63).

Subacute Cutaneous Lupus Erythematosus

Autoantibodies

ANAs have been detected in 60% to 81% of SCLE patients when human-tissue substrate was used (171), but only in 49% to 55% of patients when mouse or rat substrates were used (274). Ro/SS-A antibodies have been observed in frequencies ranging from 40% to 100% of patients by immunodiffusion techniques (290) (earlier data reviewed in (94)). Higher percentages of patients are anti-Ro/SS-A positive by the more sensitive enzyme-linked immunosorbent assay (ELISA) (290). Some have suggested that anti-Ro/SS-A precipitins more often are associated with annular SCLE patients (79), although this has not been the experience of the authors. Most SCLE patient series report finding La/SS-B antibodies by immunodiffusion in 12% to 42% of their SCLE patients (291), however, two series outside of the United States found that considerably higher percentages of their patients had these antibodies (163). Table 30-3 presents a comparison of the frequency of lab abnormalities seen in SCLE to those seen in ACLE and DLE.

False-positive Venereal Disease Research Laboratory (VDRL) reactions, indicative of antiphospholipid antibodies, have been detected in anywhere from 7% to 33% of SCLE patients (94). Anticardiolipin antibodies have been detected by ELISA in approximately 10% to 16% of patients (292). Rheumatoid factor has been present in approximately one

third of SCLE patients (94); however, relatively few SCLE patients have developed RA (237). Sm, dsDNA, and U1RNP antibodies have been reported to occur in approximately 10% of SCLE patients (data reviewed in (94)). One report has found anti-U1RNP antibodies in eight of 15 SCLE patients (53%) (293), though others have noted a much lower frequency (35). Antilymphocyte antibodies were found in 33% of patients in one study (35). Antithyroid antibodies have been reported in 18% (235) and 44% (294) of SCLE patients.

Other Laboratory Findings

Patients with SCLE, particularly those with systemic involvement, may have a number of laboratory abnormalities. Various studies have found the following: anemia, leukopenia, thrombocytopenia, an elevated erythrocyte sedimentation rate, hypergammaglobulinemia, proteinuria, hematuria, urine casts, elevated serum creatine and blood urea nitrogen, and depressed complement levels (data reviewed in (94)). Levels of complement components such as C2 or C4 can be depressed as a result of genetic deficiencies that have been associated with SCLE (295). One small study suggests that SCLE patients with normal lymphocyte counts are unlikely to have SLE (296).

Chronic Cutaneous Lupus Erythematosus

Autoantibodies

Only a small percentage of patients with classical DLE who have no evidence of systemic disease by history or physical examination will have detectable immunologic abnormalities (186). Antinuclear antibodies may be detected in low titer in as many as 30% to 40% of DLE patients; however, less than 5% will have the higher levels that are characteristically seen in severe SLE. While antibodies to single-stranded DNA are not uncommon in DLE, antibodies to dsDNA are distinctly uncommon (297). Precipitating antibodies to U1RNP sometimes are found in patients whose disease course is dominated by DLE lesions, however, such patients usually have evidence of mild SLE or overlapping connective-tissue disease (228). Ro/SS-A precipitins also can be seen occasionally in DLE patients (290). The presence of precipitating Sm and La/SS-B antibodies are, however, distinctly unusual in patients with isolated DLE lesions (298). Fewer than 10% of DLE patients have IgG anticardiolipin antibodies (299).

Antinuclear antibodies are present in 70% to 75% of patients with LE profundus/panniculitis, but anti-dsDNA antibodies are uncommon (200).

The frequency that autoantibodies have been detected in chilblain LE patients has varied. A recent study has reported ANA in 9 of 14 patients, anti-DNA antibodies in 4 of 14 and Ro/SS-A and /or La/SS-B antibodies in 2 of 14. It is likely that the true frequency of autoantibodies in chilblain LE may be lower, as some patients without antibodies may have been deemed idiopathic chilblains, from selection bias (288). Another study found Ro/SS-A antibodies in the sera of eight out of nine chilblain lupus patients, suggesting that these antibodies might be a useful clinical marker of this disorder (300). The majority of these patients also complained of photosensitivity and Raynaud phenomenon.

Other Laboratory Abnormalities

A small percentage of DLE patients will have a biologic false-positive serologic test for syphilis (VDRL), positive rheumatoid factor tests, slight depressions in serum-complement levels, modest elevations in gamma globulin, and modest leukopenia. The significance of such findings will be discussed below. One study found that 10 of 14 patients with severe chilblains had leukocytopenia and/or lymphopenia, 8/14 had hypergammaglobulinemia, and 5/14 had hypocomplementemia (288).

Differential Diagnosis

Acute Cutaneous Lupus Erythematosus

There are a number of dermatoses unrelated to LE that can produce a red face (56 ,301 ,302). Among those more commonly confused with ACLE are acne rosacea, dermatomyositis, and seborrheic dermatitis. Facial swelling may be severe in patients with ACLE and SLE, sometimes simulating the facial skin changes that are characteristic of dermatomyositis (156). Generalized ACLE can be confused with other causes of widespread exanthematous reactions such as drug hypersensitivity reactions as well as erythema multiforme.

Subacute Cutaneous Lupus Erythematosus

The cutaneous lesions of papulosquamous SCLE can be most closely mimicked by psoriasis (particularly photosensitive psoriasis). Psoriasis has been reported in SLE patients (303). Psoriasis and SCLE have occurred concurrently in the same patient (304 ,305). Histopathology can usually easily distinguish between the two disorders.

Occasionally, SCLE lesions can be confused with pityriasis rubra pilaris (306) and crusted scabies (307). Seborrheic dermatitis, polymorphous-light eruption, dermatophyte infections, nummular eczema, contact dermatitis, dermatomyositis, and cutaneous T cell lymphoma/mycosis fungoides also can be confused with SCLE on occasion. Annular SCLE lesions are more apt to be misdiagnosed as granuloma annulare (308), erythema multiforme, or types of figurate erythemas such as erythema annulare centrifugum and erythema gyratum repens. The photodistribution of SCLE lesions and the LE-specific histopathology often are crucial in helping the clinician differentiate SCLE from these other skin diseases. The presence of circulating Ro/SS-A autoantibodies can serve to further support a diagnosis of SCLE.

Chronic Cutaneous Lupus Erythematosus

Classical Discoid Lupus Erythematosus

With respect to diagnosis, discoid-shaped skin lesions that have erythema and hyperpigmentation at their active borders and depigmentation, telangiectasia, and atrophy at the centers are very unlikely to result from dermatological disorders other than cutaneous LE. However, there are other dermatoses that can produce persistent red plaques on the face that at times can be confused with DLE.

Polymorphous light eruption (PLE), as the name implies, is an exclusively photo-triggered dermatosis that can be expressed in several clinical forms, including succulent red plaques that occasionally can mimic the earlier phases of evolving DLE lesions. PLE lesions, however, clinically lack the keratinaceous follicular plugging, telangiectasia, and atrophy that are characteristic of DLE lesions. Histopathologically, PLE usually lacks the prominent liquefaction degeneration of the epidermal basal-cell layer and basement membrane thickening that is characteristic of DLE lesions. In the dermis, the lymphoid-cell infiltrate is predominately perivascular in PLE and does not involve the cutaneous appendages as in DLE.

Immunoglobulins and complement components are not deposited at the DEJ in PLE as in DLE. Ro/SS-A autoantibodies have been detected in 3.5% to 14% of PLE sera (309 ,310 ,311). ANA titers 1:80 were found in 14% (28 of 198) of PLE patient sera (310), six of whom were Ro positive. Three of the 198 patients met the ACR criteria for SLE, one of whom was Ro positive. Some of these patients may have had cutaneous LE rather than PLE, as histopathologic examination of lesions from six of these patients revealed vacuolar changes of the basal keratinocytes. However, none of these patients developed typical SCLE lesions, and PLE lesions can show LE-like histopathology (312 ,313). At times, it can be difficult to differentiate cutaneous LE from PLE. The history of a recurrent photodistributed eruption that begins in spring and improves or resolves during the summer months supports the diagnosis of PLE over cutaneous LE.

Granuloma faciale also can present as indolent, red-brown, to purple facial plaques that can be very resistant to all forms of treatment. Hyperkeratosis, follicular plugging, and atrophy are not seen in this disorder. The epidermis is spared by the histopathologic process seen in granuloma faciale and the pattern of dermal inflammation is quite distinct from that seen in DLE lesions.

Sarcoidosis, Jessner benign-lymphocytic infiltration of the skin, pseudolymphoma of Spiegler-Fendt (syn., Spiegler-Fendt sarcoid), lymphocytoma cutis, angiolymphoid hyperplasia with eosinophilia, lymphoma cutis, lupus vulgaris (314), and tertiary syphilis (315) are other disorders that can clinically simulate some phases of DLE lesions and at times present diagnostic confusion. The histopathologies of these conditions are quite distinct from DLE and each is usually negative for immunoglobulin and complement components at the DEJ upon direct immunofluorescence examination.

Hypertrophic Discoid Lupus Erythematosus

The hyperkeratotic and pseudoepitheliomatous character of hypertrophic DLE lesions can easily be mistaken for keratoacanthoma, squamous-cell carcinoma, prurigo nodularis, or hypertrophic lichen planus (195 ,284).

Lupus Erythematosus Profundus/Panniculitis

The differential diagnosis of patients with lupus panniculitis includes Weber-Christian panniculitis, factitial panniculitis, Talwin-induced panniculitis, pancreatic panniculitis, traumatic panniculitis, morphea profundus, eosinophilic fascitis, sarcoidosis, subcutaneous granuloma annulare, subcutaneous T cell lymphoma, and rheumatoid nodules. Deep excisional biopsy often is required to distinguish LE panniculitis from these other disorders, particularly when classical DLE lesions are not present. One report suggests that the most useful histologic criteria for differentiating LE panniculitis from subcutaneous panniculitis-like T cell lymphoma are the presence of epidermal involvement, lymphoid follicles with reactive germinal centers, clusters of B lymphocytes, mixed cell infiltrate with plasma cells and polyclonal T cell receptor γ gene rearrangement (211).

Mucosal Discoid Lupus Erythematosus

Oral lichen planus presents the closest clinical appearance to that of oral mucosal DLE. A biopsy can be useful to differentiate between these two disorders, but often is not necessary.

Chilblain Lupus Erythematosus

Chilblain LE patients must be distinguished from idiopathic chilblains and the presence of cryoglobulins or cold agglutinins should be ruled out. Chilblain LE patients are more apt to have other evidence of LE (e.g., autoantibodies, DLE, neutropenia), Raynaud phenomenon and their chilblain lesions are more likely to persist into warmer weather months, compared to idiopathic chilblains (288).

Lupus Erythematosus Tumidus

Lesions of LE tumidus can mimic Jessner benign lymphocytic infiltration of the skin, polymorphic light eruption, pseudolymphoma, reticular erythematous mucinosis, DLE, SCLE, scleredema, and erythema figuratum. Microscopically the lesions can look like cutaneous mucinosis.

Management

Acute Cutaneous Lupus Erythematosus

ACLE lesions respond to the more aggressive regimens of systemic corticosteroids and other immunosuppressive agents (e.g., azathioprine, cyclophosphamide) that often are

required to manage the more severe systemic manifestations of LE that often accompany this form of LE-specific skin disease. Increasing evidence suggests that drugs such as hydroxychloroquine can have a steroid-sparing effect on SLE (316). This is likely to be true for ACLE as well. Table 30-5 outlines the treatment of nonacute LE-specific skin disease, which is very similar for subacute cutaneous LE and the various subsets of chronic cutaneous LE.

Subacute Cutaneous Lupus Erythematosus

The management of patients with SCLE should include evaluation to rule out underlying systemic disease at the time of diagnosis, then again at 6- to 12-month intervals, unless the patient develops symptoms that dictate an earlier reassessment (317). The initial evaluation should include a history, review of systems, and physical examination to elicit symptoms and signs of underlying systemic disease (i.e., arthritis, serositis, CNS disease, renal disease). Initial laboratory evaluation should include, at minimum, a complete blood count, platelet count, erythrocyte sedimentation rate, urinalysis, and blood-chemistry profile. Additional determinations that can be of help include C3, C4, and CH_{50}.

Table 30-5: General Treatment Approach to Subacute and Chronic Cutaneous LE

1. Photo-protective measures
a. Physical protection
   Schedule discretionary outdoor activities before 10 am and after 4 pm even on cloudy days since as much as 80% of UV rays penetrate the cloud cover. Limit exposure to reflected UV rays from surfaces such as water, concrete, sand, snow, tile, and reflective window glass in buildings. The window glass in homes blocks some UV rays, especially the sunburning UV rays (UVB). However, considerable amounts of long wavelength UV rays (UVA) may still pass through such glass. Plastic adherent films that can easily be applied to home window glass are available that block all UVB and UVA rays. Clothing can be an excellent form of sun protection. Cover-up with loose fitting and lightweight clothing (long pants and long-sleeved shirt when possible), sunglasses and 4-inch wide brimmed hats. Tightly woven fabric blocks UV rays best. UV protection drops significantly when the fabric becomes wet. Dark colors protecting better than light colors. The average white t-shirt provides a SPF (sun protective factor) of only 6 to 8. Sun protective clothing lines with a rating of SPF 30 or greater are available.
b. Sunscreens
   Sunscreen products (syn. “sunblocks”) should be applied 15 to 30 minutes prior to sun exposure to be most protective. Sunscreen should be reapplied after prolonged swimming or vigorous activity. Water-resistant sunscreens protect skin for 40 minutes of water exposure and waterproof sunscreens protect for 80 minutes. Sunscreen needs to be applied liberally. As much as 1 oz may be needed to cover the entire body. Particular attention needs to be paid to the back of the neck, the ears, and the areas of the scalp with thin hair. Use sunscreens with at least a 30 SPF (sun protection factor). Select a broad-spectrum sunscreen that contains ingredients that effectively block both UVB and UVA rays. Such ingredients include photostabilized forms of avobenzone (Parsol 1789), titanium dioxide, zinc oxide and Mexoryl-conventional. Sunscreen lotions help dry skin and sunscreen sprays work best on the body. Stick type sunscreens can be used on the lips or around the eyes to avoid eye irritation or for maximal protection of the ears. UV light from sunlight exposure causes the skin to produce an important precursor of vitamin D. Adults who use sunscreens daily should consider taking a daily oral supplement of 400 to 800 units of vitamin D. Sunscreen should not be applied to broken skin or rash (allergies to sunscreen ingredients can develop in some people). Keep in mind, sunscreens are not meant to allow individuals to spend more time in the sun than they would otherwise. They are meant to protect the skin while you must be in the sun.
2. Topical or intralesional corticosteroids, tacrolimus and/or pimecrolimus
3. Begin hydroxychloroquine up to 6.5 mg/kg lean body weight/day
a. If smoker, encourage methods for smoking cessation
b. If no response by eight weeks add 100 mg quinacrine/day
c. If no response in 4 weeks switch hydroxychloroquine to chloroquine up to 0.3–2.5 mg/kg lean body weight/day while continuing quinacrine 100 mg/day; if responsive, consider discontinuance of quinacrine to see if needed.
4. If no response after several weeks, try dapsone, a retinoid, clofazimine or gold. (Dapsone might be tried before antimalarials in bullous LE).
5. If the above treatments fail, or could not be tolerated, consider thalidomide or immunosuppressive agents including short-term systemic steroids, methotrexate, azathioprine, mycophenolate mofetil or cyclosporin.
6. Patients with more severe disease may initially be treated more aggressively with immunosuppressive agents, in combination with the antimalarial agents that often take weeks to months before providing beneficial effects 7) Biologics (see text).

The initial management of all SCLE patients should include education regarding protection from sun and artificial sources of UV light, and the elimination of potentially provocative photosensitiving drugs such as hydrochlorothiazide, griseofulvin, and piroxicam if at all possible.

With regards to specific medical therapy, local measures should be maximized first, then systemic agents employed if significant disease activity continues (Table 30-5).

Sun Protection

Patients should be advised to avoid direct sun exposure, particularly during the midday hours and during the summer months when the UV component of sunlight is least attenuated by the atmosphere. A useful rule of thumb is that if one's shadow is longer than one is tall, there is relatively less danger from UV radiation exposure. Tightly woven clothing with vented panels for comfort in hot environments and hats should be worn in conjunction with broad-spectrum sunscreens to achieve maximal shielding from sunlight. Several clothing lines offering maximized UV protection currently are being marketed and are easily accessed through the internet (e.g., Solumbra Ultra Sun Protective Clothing (http://www.sunprecautions.com/); MasqueRays (http://www.sunproof.com/); Sun Protective Clothing (http://www.sunprotectiveclothing.com/)). Such specialty clothing also is marketed for fishermen and those going on safaris.

Patients should select broad-spectrum sunscreens that contain agents that block UVB with a sun protective factor (SPF) of 30 or greater. It has been found that much lower amounts of sunscreens actually are used in real-life situations compared to the amounts employed under lab conditions for determining the SPF rating of a specific sunscreen product. Therefore, when a photosensitive patient uses a SPF 30 sunscreen in real life, they often get a real-life SPF of about 15 or less, the minimum necessary for adequate protection for a LE patient. Sunscreen products containing photostabilized Parsol 1789 (avobenzone), Mexoryl, zinc oxide, or titanium dioxide provide the broadest degree of UVA protection (318) and such products may have added value in SCLE patients (319). Products also should be selected that are most resistant to being washed off by sweating or bathing. Sunscreens should be applied at least 30 minutes before sun exposure and reapplied after bathing or appreciable perspiration. Stick-type sunscreens that are formulated for use on the lips also can be applied around the eyes to avoid the eye irritation that often occurs when other products are applied to this area.

Several reviews addressing comparative sunscreen efficacy have been published (318). A more recent comparison of three different sunscreen combinations showed that some were more effective than others (320). The sunscreen that contained the UVA blockers Mexoryl SX, Mexoryl XL, avobenzone (Parsol 1789), and titanium dioxide in combination with the UVB blocker octocrylene was most effective in protecting 11 of 11 patients. A second sunscreen protected 5 of the 11 patients, and a third protected only 3 of the 11 patients. (The latter two sunscreens did not contain Mexoryl and contained alternative UVB blocking agents other than octocrylene). These results indicate that sun protection may be beneficial to LE patients, and that protection may vary considerably between different sunscreens.

A number of companies offer UV light-blocking films can be applied to home and automobile windows. More information on these products can be obtained through the internet (e.g., Southwall Technologies [http://www.southwall.com/]; North Solar Screen [http://www.northsolarscreen.com/]; UVShield [http://www.uv-shield.com/]). Several of these companies offer films or plastic shields that can be placed over fluorescent light bulbs to block the small but finite amount of UV irradiation that can leak from such sources (321).

Corrective camouflage cosmetics such as Dermablend (Johnson Products [http://www.dermablend.com/]) and Covermark (Covermark Cosmetics [http://www.covermark.com/]) offer the dual benefit of being highly effective physical sunscreens as well as aesthetically pleasing cosmetic masking agents for patients suffering psychologically from therapeutically refractory, chronic, disfiguring skin disease as can result from cutaneous LE.

Local Corticosteroids

Initial treatment usually includes the use of a potent topical corticosteroid like clobetasol propionate 0.05% (Temovate, Glaxo Wellcome), betamethasone dipropionate 0.05% (Diprolene, Schering), halobetasol proprionate 0.05% (Ultravate, Westwood-Squibb), or diflorosone diacetate 0.05% (Psorcon, Dermik). Twice-daily application of these products to lesional skin for 2 weeks followed by a 2-week rest period can minimize the risk of local complications such as steroid atrophy and telangiectasia. Cutaneous LE represents one of the very few clinical situations where such potent topical fluorinated corticosteroids can be recommended for use on atrophy-prone areas such as the face, because the alternatives are unchecked, disfiguring skin disease, or the potential side for effects from systemic therapy. Unfortunately, topical corticosteroids alone do not provide adequate improvement for the large majority of SCLE patients. Most SCLE patients' lesions are too numerous to be managed by intralesional corticosteroid injections and oral corticosteroids should be avoided as long as possible when treating this chronic cutaneous condition.

Topical Pimecrolimus and Tacrolimus

There have been several reports demonstrating benefits of topical tacrolimus (322 ,323 ,324 ,325 ,326 ,327) and pimecrolimus (328) in treating ACLE, SCLE, and DLE. It has been one of the authors' experience (RDS) that these agents tend to be more effective for cutaneous LE that is expressed on facial skin compared to non facial skin, perhaps because of greater ease of percutaneous penetration in facial skin.

Antimalarials

While a number of systemic medications have been reported to be of benefit to SCLE patients, by far the most useful are the aminoquinoline antimalarial agents. The authors as well as

others (329 ,330) have found that approximately 80% of SCLE patients will respond to single-agent or combined antimalarial therapy. The three agents most frequently prescribed for SCLE patients are hydroxychloroquine sulfate (Plaquenil-Sanofi Pharmaceuticals), chloroquine phosphate (Aralen-Sanofi Pharmaceuticals), and quinacrine hydrochloride (Compounding Labs of America) (quinacrine was previously available in the United States under the brand name, Atabrine [Winthrop Labs]). Generally, hydroxychloroquine is best tolerated with the least side effects. The generic form of quinacrine dihydrochloride that has been available from compounding pharmacies in the United States over the past decade appears to be functionally equivalent to Atabrine in the treatment of LE-specific skin disease. A recent article reviewed the use of antimalarial agents in treating cutaneous lupus erythematosus patients (331).

When using either hydroxychloroquine or chloroquine, ophthalmologic examination is required to minimize the risk of retinal toxicity (quinacrine has not been confirmed to be retinopathic). It has been controversial how often ophthalmologic screening exams should be performed. The Physicians' Desk Reference (Physicians Desk Reference. 59th ed. Thompson PDR, 2005; Montvale, NJ.(332) has recommended quarterly examinations, though most clinicians have felt this to be too frequent. Recently the American Academy of Ophthalmology formed a task force to study this issue. The task force recommended that all patients treated with hydroxychloroquine or chloroquine have an exam that includes a funduscopic exam and central visual field testing, during the first year of therapy. Patients at low risk of developing retinal toxicity (patients taking the antimalarials less than 5 years at recommended doses (<6.5mg/kg/day hydroxychloroquine or <3 mg/kg/day of chloroquine) whose initial examination is normal, should have no further special testing for the next 5 years. Patients in the high-risk group (patients who: are older than 60 years, have a high body fat level, are taking higher than recommended doses, or have kidney, liver or retinal disease, or have taken the drug for over 5 years) should have an annual examination (333 ,334). Use of the self-administered Amsler Grid test at home is a useful ancillary measure to help patients detect the earliest evidence of visual-field defects. Retinal changes can become irreversible if not detected early.

Although there have been descriptions in the medical literature of hematological and hepatic toxic effects during HCQ or CQ treatment, some authors stress that pretreatment and follow-up laboratory testing are not necessary, particularly for hydroxychloroquine (335). However, it seems prudent to obtain baseline and periodic blood counts and hepatic function tests, particularly in patients that have pre-existing hepatic or hematologic disease, or in patients at increase risk of developing hematologic or hepatic diseases.

Quinacrine hydrochloride is more likely to induce hemolysis in glucose-6-phosphate dehydrogenase-deficient patients than is hydroxychloroquine or chloroquine (336). Neurotoxicity and muscular toxicity can occur but was much more of a problem in the past when higher daily doses of these drugs were used.

Antimalarial agents can induce a number of dermatologic changes. All can cause a blue-black pigmentation of the skin (particularly in the sun-exposed areas), the palatal mucosa, and the nails. Antimalarials have also been reported to cause lichenoid eruptions that can exacerbate or mimic cutaneous LE lesions (337). Litt's Drug Eruption Reference Manual lists skin conditions (with references) that have been associated with chloroquine and hydroxychloroquine treatment (338). These associations include acute generalized pustulosis, angioedema, bullous eruption, erythema annulare centrifugum, erythema multiforme, erythroderma, exanthems (1% to 5%), exfoliative dermatitis, fixed eruptions, lichenoid eruption, photosensitivity, pigmentation, pruritus, psoriasis and pustular psoriasis, purpura, pustules, Stevens-Johnson syndrome, toxic epidermal necrosis, urticaria, vasculitis, hair bleaching/pigmentation, nail discoloration/pigmentation, gingival/oral pigmentation, and stomatitis. Quinacrine-associated skin conditions have included exfoliative dermatitis, lichenoid eruption, ochronosis, photosensitivity, pigmentation, urticaria, alopecia, and nail/oral pigmentation. Quinacrine frequently causes diffuse yellowing of the skin, sclera, and bodily secretions that are fully reversible on discontinuation of the drug. On occasion, quinacrine and other antimalarials can produce a lichenoid drug reaction that can be the harbinger of severe bone-marrow toxicity (339).

In an average-sized adult, therapy with hydroxychloroquine alone at 400 mg/day initially should be tried. If there is no significant improvement by 2 months, quinacrine, 100 mg/day, can be added to the hydroxychloroquine (340). If the response is inadequate after 4 to 6 weeks of hydroxychloroquine plus quinacrine, chloroquine 250 mg/day can be substituted for the hydroxychloroquine while continuing the quinacrine (an occasional cutaneous LE patient will respond better to chloroquine than hydroxychloroquine). Once disease activity is controlled, the hydroxychloroquine can be decreased to 200 mg/day for maintenance. The mechanisms by which antimalarials might provide therapeutic benefit have been reviewed elsewhere (341).

Two studies have confirmed earlier suspicions that smoking may interfere with the efficacy of antimalarials in treating DLE and SCLE (140 ,141). Both authors have witnessed dramatic improvement in DLE skin lesions in antimalarial-resistant patients soon after they have quit smoking. Therefore, one has additional reasons to encourage cutaneous LE patients to quit this dangerous habit.

Dapsone

Diaminodiphenylsulfone (Dapsone, Jacobus Pharmaceutical Co.) is best for treating the occasional patient having LE-nonspecific vesiculobullous skin lesions that can occur in SLE patients (“bullous SLE”) (342). Within days, 100 mg/day of this drug can provide significant improvement. Hematologic, renal, and hepatic toxicity can occur with this drug and

requires frequent monitoring. The authors have had relatively little positive experience in treating SCLE patients with this agent, although others have reported benefit in isolated cases within a few weeks after starting therapy (296). A topical version of Dapsone (Aczone, 5% gel, QLT USA, Inc, Fort Collins, CO) has recently been approved by the Food and Drug Administration (FDA) for treating acne. It will be interesting to see if it provides benefit when used “off-label” to treat cutaneous LE.

Retinoids

The synthetic retinoids isotretinoin (Accutane, Roche Laboratories), etretinate (Tegison, Roche Laboratories), and acitretin (Soriatane, Roche Laboratories) at approximately one half to 1 mg/kg/day have been shown to significantly improve SCLE lesions (343 ,344). (Please note that etretinate is no longer available, and has been replaced by acitretin.) These agents also have been advocated for hypertrophic DLE (345). The great potential for teratogenic effects with the retinoids make it imperative that fertile females are using contraceptive techniques according to guidelines set forth specifically for patients on retinoids. The new IPLEDGE program has recently been instituted to more closely monitor patients, and help prevent pregnancies (http://www.ipledgeprogram.com/). A common dose-related side effect is mucocutaneous dryness. It is advisable to have patients use sunscreens judiciously while being treated with these agents to minimize their tendency to aggravate photosensitivity. Drug-induced hepatitis and hypertriglyceridemia can occur with these agents and require periodic laboratory evaluation. On occasion, these drugs also can induce bony changes consistent with the diffuse idiopathic skeletal hyperostosis (DISH) syndrome.

Clofazimine

Crovoto reported the successful use of clofazamine (Lamprene, Geigy Pharmaceuticals) in a patient with annular SCLE in 1981 (346). He used a dose of 100 mg/day and noted clearing of the lesions within a few weeks. At this dosage, clofazimine generally is well tolerated, though gastrointestinal intolerance can be a problem. At higher doses, clofazamine rarely has been reported to precipitate in mesenteric arteries resulting in major abdominal catastrophes such as splenic infarction (347). A pink to brownish-black skin pigmentation develops in most patients on long-term clofazimine therapy. This pigmentation resolves over months to years after discontinuing the drug. Similar discoloration of bodily secretions also frequently occurs.

Thalidomide

Thalidomide, 50 to 200 mg/day, can be very effective in otherwise-refractory SCLE and DLE (32 ,348 ,349 ,350 ,351 ,352 ,353 ,354). Generally, about 75% of cutaneous LE patients will respond to antimalarial monotherapy or combination therapy. It now appears that thalidomide can produce good-to-excellent results in 75% of antimalarial-refractory cutaneous LE. Thalidomide is thought to be beneficial from its TNF-α antagonistic effects, although there is also indirect evidence that it might impede UVB-related mechanisms (355).

Because of its notorious teratogenicity (356), special precautions should be taken when prescribing thalidomide. It is available in the United States under the brand name Thalomid (Celgene Corporation). Prescribing physicians and dispensing pharmacies first must register with Celgene Corporation. Once this has been accomplished, Celgene Corporation will send the physician specially developed materials (System for Thalidomide Education and Prescribing Safety [STEPS]) to educate patients to help them avoid birth defects.

Thalidomide can produce irreversible sensory neuropathies in treated patients (356 ,357). A recent study found that cutaneous LE patients receiving a higher dosage of thalidomide had no greater therapeutic response or increased risk of developing neurotoxicity, compared to patients receiving lower doses (358). Another recent study found peripheral neuropathy developed in 50% of 14 cutaneous LE, after a median time of 14 months. No correlation between the occurrence of peripheral neuropathy and cumulative thalidomide dose could be made (359). Baseline and periodic peripheral nerve conduction studies (i.e., measurements of sensory nerve-action potential amplitudes) have been recommended in hopes of detecting neuropathy early so that the thalidomide can be discontinued before more severe, irreversible neuropathy develops. The role of nerve conduction studies in monitoring thalidomide-treated patients still is not well defined.

Recently, there have been a number of cases of thromboembolic disease developing in patients within days to months of starting thalidomide, including patients with SLE, SCLE, and DLE (360 ,361). Some have advised checking antiphospholipid antibodies and plasma homocysteine levels in LE in patients before starting thalidomide as the presence of these antibodies or high homocysteine levels might put thalidomide-treated LE patients at increased risk of thrombotic events, including pulmonary embolism (360 ,362). It is advisable to avoid using thalidomide in patients at increased risk for developing thrombosis until more is learned. The role for prophylactic anticoagulation therapy in patients treated with thalidomide has not yet been well defined. Other thalidomide side effects include a transient myoclonic jerking reactions of the extremities, neutropenia, and secondary amenorrhea as a result of ovarian failure (363).

Gold

Oral gold (auranofin [Ridaura, Connetics Corporation]) or parenteral gold (aurothioglucose [Solganal, Schering]) therapy has been successfully used in those cutaneous LE patients whose disease is resistant to the less toxic forms of therapy (364). Gold frequently has mucocutaneous toxicity and less commonly has hematologic, renal, and pulmonary toxicity that may require its discontinuance.

Interferon-a

Earlier clinical observations had suggested that endogenously produced interferon might be of benefit in SCLE (365). Recombinant interferon (IFN)-α 2A (Roferon-A, Roche) has been used to treat four SCLE patients (366). The dosage ranged from 18 to 120 × 10^6 units injected weekly for 4 to 13 weeks. Two patients had a complete response, one had a partial response, and one patient had no response to treatment. All three patients that responded to treatment later relapsed 4 to 12 weeks after treatment was stopped. Others have noted similar effects (367). Intralesional IFN-α has been reported to be of value in DLE (368). However, the risk of inducing or exacerbating systemic autoimmune reactions, including SCLE, probably outweighs any benefits of IFN-α in this setting (101).

Systemic Corticosteroids and Other Immunosuppressive Agents

Systemic corticosteroids and cytotoxic agents are reserved for patients with more severe disease who have failed the less toxic forms of therapy discussed above. A patient occasionally may be encountered whose disease is so severe that these more potent agents may be used earlier in the disease course, even before the patient is given a complete trial of the less toxic agents.

Methylprednisolone given in “pulse doses” (1 g intravenously for three consecutive days) has been reported to provide improvement in SCLE patients with systemic LE (369). Anecdotally, cyclophosphamide and methotrexate (329 ,370 ,371) as well as azathioprine (372) have been suggested to be of benefit in refractory SCLE. Because of the potential for severe immunosuppression, risk of cancer induction, bone marrow, and mucous-membrane toxicity, these agents should be reserved for patients with severe disease and used only as a last resort in patients with severe cutaneous LE alone. More recently several case reports have indicated that mycophenolate mofetil can be beneficial in treating SCLE (373 ,374 ,375). However, a more recent study found that seven SLE patients with refractory cutaneous lesions, including ACLE, SCLE, DLE, and chilblain LE, were not very responsive to mycophenolate mofetil (376). Dosages ranged between 2 and 3 g and were generally well tolerated.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) treatment has been successful in treating cutaneous LE, however, the high cost of this treatment, and its potential side effects should make this treatment reserved for more severe cases unresponsive to more conventional agents (377 ,378).

UVA-I Phototherapy

Preliminary animal work has suggested that UVA might dampen the autoimmune abnormalities in experimental SLE (379). Additionally, work from two centers has suggested that SCLE patients might actually benefit from very low doses of whole-body UVA-I (340 to 400 nm) irradiation (380). However, the true value that this somewhat controversial form of treatment will ultimately play remains to be confirmed by controlled studies in larger groups of patients. Caution should be taken in interpreting these data in view of the increasing evidence that UVA (381), including long-wave UVA (193), can play an exacerbating role in the cutaneous manifestations of SLE. Recent experimental evidence in a murine model of SLE argues for further caution in this area (382).

Other Treatments

A number of other therapies have been reported to be beneficial in treating cutaneous LE including extracorporeal photochemotherapy (383), cefuroxime axetil (384), CD4 monoclonal antibody (385) and hormonal treatment, though these reports have been mostly anecdotal and have not been well corroborated. Although there has been a case report of a RA patient with SCLE clearing the skin lesions after etanercept (386), as mentioned earlier, this agent may also induce SCLE. The more recently developed biologic agent rituximab (Rituxan), a recombinant monoclonal antibody that inhibits CD20 expressing B cells, has shown to be beneficial in some patients with SLE and cutaneous LE (387 ,388). Although there is reason to suspect that new biologic agents involved in blocking antigen presentation (alefacept [Amevive] and efalizumab [Raptiva]) may provide benefit in treating cutaneous LE, the high cost these medications make them less than attractive for this purpose.

Table 30-5 presents a suggested treatment approach for subacute and chronic cutaneous LE. These recommendations are based upon the authors' personal experience pertaining to the relative efficacy and safety of this group of drugs.

Chronic Cutaneous LE

The initial approach to the medical management of CCLE is basically the same as that described above for SCLE lesions (Table 30-5). For the most part, both forms of cutaneous LE respond similarly to medical therapy. Local therapy, especially intralesional corticosteroids (e.g., triamcinolone acetonide suspension, 3 to 5 mg/mL for the face with higher concentrations allowable elsewhere), often is more useful in the management of DLE compared to SCLE because one often is treating fewer and smaller lesions in a DLE patient compared to a SCLE patient. Additionally, we, and others (342), have been particularly impressed that combination antimalarial treatment (hydroxychloroquine or chloroquine plus quinacrine) has been more effective in a number of our DLE patients who did not respond to hydroxychloroquine alone. As stated earlier, two studies have indicated that smoking may interfere with the efficacy of antimalarials in treating DLE and SCLE (140 ,141). These findings, and the fact that both authors have witnessed dramatic improvement in DLE skin lesions in antimalarial-resistant patients soon after they have stopped smoking, make it advisable for

all cutaneous LE smokers to quit smoking. It is possible that the dramatic effects that cigarette smoking can have on hepatic microsomal enzyme induction (389) could alter the metabolism of the aminoquinoline antimalarials so as to blunt their effect on cutaneous LE. Alternatively, compounds present in cigarette smoke might be capable of directly exacerbating LE-specific cutaneous inflammation.

As with SCLE, drugs such as dapsone (390), retinoids (390), clofazimine (391), thalidomide (353 ,354 ,392), gold (365), methotrexate (393 ,394 ,395), and azathioprine (390), can be of value in DLE, and other forms of CCLE, when antimalarials have failed. Azathioprine has been advocated for those patients having antimalarial-resistant palmar/plantar DLE (372). One report has demonstrated improvement in DLE from topical tazarotene (396). More recently several case reports have indicated that mycophenolate mofetil can be beneficial in treating DLE, LE profundus, LE tumidus, and (397 ,398) and chilblain LE (397 ,399).

Several other treatments have been reported to be beneficial in treating DLE including imiquimod (400), phenytoin (401), sulfasalazine (402), extracorporeal photochemotherapy (403), vitamin E (reviewed in 404), and cyclosporin A (405) though most have not been well substantiated.

Additional reports have demonstrated improvement in DLE lesion erythema and telangiectasias with pulsed dye (406 ,407) and argon lasers (408).

Once scarring develops within a DLE lesion, little can be done to reverse this process. Although plastic surgery repair of disfiguring lesions of DLE has produced disappointing results, probably a result of the resultant trauma inducing the Köebner or isomorphic phenomenon (409), resurfacing measures by dermabrasion (410), CO_2 laser (411) and erbium:YAG lasers (412) have provided benefit in some patients. It will be of interest to learn if the newly developed nitrogen plasma skin resurfacing technique (Rhytec, Inc., Waltham, MA) offers similar benefit. Hair transplantation, and autologous fat transplantation might occasionally be safely carried out in areas of scarring that are devoid of active inflammation (413). There is some evidence to suggest that the risk of disease reactivation is lessened if the patient is concurrently on medical therapy (e.g., antimalarials) to blunt the Köebner response. The best overall strategy for the management of DLE, however, is always one of early, aggressive, medical management to suppress the inflammatory disease process before scarring and alopecia have developed.

Once DLE lesions have progressed to the point of irreversible dystrophic scarring, the use of properly personalized and applied corrective camouflage cosmetics (e.g., Covermark [http://www.covermark.com/], Dermablend [http://www.dermablend.com/]) and properly fitted hair pieces can offer temporary refuge from the devastating emotional impact that this disfiguring disease process can produce. One study found significant improvement in the quality of life in patients using corrective cosmetics to improve the appearance of their disfiguring disease (414).

Hypertrophic DLE lesions that do not respond to single-agent or combined antimalarial therapy have been reported to respond to treatment with systemic retinoids such as isotretinoin (Accutane) (345) and acitretin (415). Cryotherapy has also provided benefit for hypertrophic DLE lesions (416), as has thalidomide (417).

Untreated, LE panniculitis/profundus is indolently progressive with ulceration often eventually supervening. Intralesional corticosteroid therapy should be approached with great caution because even this minimal form of trauma can cause LE panniculitis lesions to break down and ulcerate. Even a carefully executed diagnostic skin biopsy can, at times, produce chronic ulceration in these lesions. Most cases of LE panniculitis/profundus can be managed successfully with single-agent or combined antimalarial therapy, however, some will require more aggressive treatment with systemic corticosteroids (200). Thalidomide (418) gold (419), methotrexate (395), and cyclosporin A (420) also have been used in refractory LE panniculitis/profundus.

Chilblain LE lesions are often improved by keeping the affected area warm and dry. Antimalarial therapy is often beneficial, and some patients have benefited from dapsone, prednisone and pentoxifylline (421). Methotrexate (395) and mycophenolate mofetil (422) have been helpful in some cases.

LE tumidus lesions are often responsive to photoprotective measures and oral antimalarial therapy. Topical and systemic corticosteroids and methotrexate have also proven beneficial (224 ,395). There is one case report of successful use of topical tacrolimus in a LE tumidus patient, published in the German language (423).

Prognosis

The risks of developing systemic manifestations of LE have already been discussed under the sections dealing with the relationship between the cutaneous and systemic manifestations of the various types of LE-specific skin disease. In this section, we will deal with the outcome of the skin lesions themselves as well as the available morbidity and mortality data concerning these forms of cutaneous LE.

Acute Cutaneous Lupus Erythematosus

Localized ACLE lesions can wax and wane in parallel with the underlying SLE activity (30), often leaving pigment changes in their wake but not producing atrophic dermal scarring.

The authors are unaware of mortality data associated specifically with ACLE. As previously discussed, ACLE often is considered to be an integral expression of underlying SLE and as such, little effort has been made to determine if such patients fare better or worse than those who do not develop ACLE.

Subacute Cutaneous Lupus Erythematosus

Having been recognized as a distinct disease entity for only 25 years, the long-term outcome associated with SCLE lesions has yet to be determined. In the authors' experience, most patients appear to have intermittent recurrences over long periods of time. Some have unremitting lesions that smolder in the same location for years. A superficial form of atrophy has been noted to develop in the lesions of several such patients (personal observation) (Fig. 30-16). Other patients appear to enjoy long-term, if not permanent, remissions of their skin disease.

In short-term follow-up studies, approximately 15% of the SCLE patients studied by one of the authors (RDS) developed ACLE lesions and evidence of active SLE including lupus nephritis (164). This subgroup of patients was marked by the presence of high-titer ANA, leukopenia, and/or anti-dsDNA (234). An interim report from a long-term follow-up study involving the original cohort of SCLE patients at University of Texas Southwestern Medical Center in Dallas, Texas, indicates that the relatively mild disease course that these patients enjoy over the short term appears to hold for longer periods of time (up to 20 years) (424). One of the authors (RDS) is aware of only one death directly attributable to SLE in over 130 SCLE patients that he examined personally (personal unpubl. observation).

More recent reports of the epidemiology of additional SCLE cohorts from different parts of the world have supported the view that this is a subset of LE patients with relatively low risk of developing life-threatening forms of SLE (232 ,425). Additional long-term follow-up studies will be required to determine the true risk of severe systemic disease in patients presenting with SCLE skin lesions.

Chronic Cutaneous Lupus Erythematosus

Left untreated, the majority of patients with classical DLE lesions tend to suffer an indolently progressive disease that can spread to produce large areas of dystrophic cutaneous scarring and scarring alopecia that can be disabling emotionally if not physically. In one recent series of 86 chronic cutaneous LE patients having a mean disease duration of 15.1 years, 57% had some form of destructive or deforming scarring, whereas 35% had pigmentary disturbances (426). Spontaneous remission is observed occasionally (228) and the disease activity can recrudesce within the site of older inactive lesions. Squamous-cell carcinoma occasionally develops in chronic smoldering DLE lesions (Fig. 30-40) (427).

Death from SLE disease activity is distinctly uncommon in patients who present initially with localized DLE. As previously discussed, generalized DLE does carry a higher risk of associated SLE activity.

Figure 30-40. Squamous-cell carcinoma developing in the discoid lupus erythematosus lesions of the lower lip.

Chapter 31
Lupus-Nonspecific Skin Disease

Melissa I. Costner

Richard D. Sontheimer

The cutaneous manifestations of lupus erythematosus have significant diagnostic and prognostic potential. Lupus-specific skin diseases such as acute cutaneous lupus erythematosus (ACLE) and discoid lupus erythematosus (DLE) are seen exclusively in patients with a lupus diathesis, and share specific histopathologic features. When present, such lesions provide important clues about visceral manifestations of systemic lupus erythematosus (SLE). For example, an exacerbation of ACLE almost always suggests potentially aggressive organ-threatening visceral disease. Additionally, generalized DLE (DLE lesions both above and below the neck) indicates a patient who typically meets ACR criteria for SLE although the specific clinical features of the systemic illness can be mild.

A large number of cutaneous lesions that are found in LE patients are not specific for LE, that is, they also occur in patients that don't have or never develop LE (Table 31-1) and do not share the histologic features of LE-specific skin disease. Such skin lesions are usually found in the context of SLE or a significant risk thereof. Nonspecific skin findings in LE include vasculitis, photosensitivity reactions, alopecia, Raynaud phenomenon, livedo reticularis, soft-tissue calcification, bullous lesions, urticaria, cutaneous mucinosis, skin necrosis, ulcerations, and nail changes.

As with some forms of LE-specific skin disease (e.g., ACLE), the presence of nonspecific skin lesions may be an indicator of underlying SLE activity. Parodi et al. applied the Systemic Lupus Activity Measure (SLAM), which is used to evaluate systemic disease activity, to 176 patients with skin manifestations of LE. The most frequent skin lesions found in patients who had higher activity scores were photosensitivity, Raynaud phenomenon, oral ulcers (all lupus nonspecific lesions) in addition to cicatricial alopecia (1). Similarly, a Yugoslavian group of investigators led by Zecevic evaluated 66 patients with the SLE Disease Activity Index (SLEDAI) and found that patients with LE-nonspecific skin lesions had significantly increased disease activity compared to those with LE-specific lesions (2). Additionally, Vila et al. studied patients with incomplete lupus and discovered that patients who had photosensitivity, oral ulcers, Raynaud phenomenon, as well as serologic abnormalities and a malar rash, were more likely to evolve into complete SLE (3). Herein we review this important group of cutaneous manifestations of LE, which may have equal if not more importance than LE-specific skin lesions in regards to correlation with systemic disease activity.

LE-Nonspecific Lesions as Classification Criteria for SLE

Some LE-nonspecific conditions have high prevalence rates in SLE (i.e., photosensitivity, oral ulcerations, alopecia, Raynaud phenomenon) and have previously been or are currently included in the ACR criteria for classification of SLE.

Photosensitivity

Patients with SLE often have photosensitivity reactions. Indeed, the presence of sensitivity to ultraviolet radiation (UVR) is one of 11 American College of Rheumatology (ACR) criteria for the diagnosis and treatment of lupus erythematosus (4).

Photosensitivity is defined clinically as an abnormal response to UV (5). These responses include exaggerated sunburn reactions that do not necessarily show the characteristic LE-specific histopathology, although LE-specific skin lesions can often be induced after UVA and/or UVB light exposure (6 ,7). Some patients with SLE merely exhibit burning, stinging, and/or redness after exposure to low levels of UVR (i.e., decreased minimal erythema dose). Such photosensitivity may be induced by UVA and/or UVB radiation, or possibly even fluorescent lights under special circumstances (8). Some patients even report that systemic disease symptoms, including weakness, fatigue, and joint pain, are increased by sun exposure (9). However, for ethical reasons this has not been examined experimentally in humans and reliable animal models of the systemic component of lupus photosensitivity are not available. The clinician should be wary of diagnosing photosensitivity based on history alone, and other causes and/or mimics of photosensitivity such as medication-induced photosensitivity and rosacea should be excluded.

Photosensitivity seems to correlate strongly with the presence of Ro/SSA antibody. In one study, patients with photosensitivity had higher titers of anti-Ro antibody than those without photosensitivity (10). Ioannides et al. found that Ro and La antigen expression in skin biopsy specimens was 4- to 10-fold higher in patients with LE with photosensitivity than in those patients with LE without photosensitivity (11), however this work has not been independently confirmed. Chapter 29 presents a complete review of the pathogenetic basis of lupus photosensitivity.

Table 31-1: Classification of LE Nonspecific Skin Disease (Modified from the Gilliam Classification Scheme)

I. LE NONSPECIFIC CUTANEOUS LESIONS THAT SERVE AS CLASSIFICATION CRITERIA FOR SLE
- a. Photosensitivity
- b. Mucosal ulceration
- c. Alopecia
- d. Raynaud phenomenon

II. LE NONSPECIFIC CUTANEOUS VASCULAR REACTIONS
- a. Vasculitis
  - i. Small vessels
    1. Dependent palpable purpura
    2. Urticarial vasculitis
  - ii. Medium and large vessels
    1. Purpuric plaques with stellate or retiform borders with or without cutaneous necrosis and ulceration
    2. Subcutaneous nodules that with or without ulceration
- b. Vasculopathies
  - i. Ischemic
    1. Raynaud phenomenon
  - ii. Thromboembolic
    1. Associated with antiphospholipid antibodies
       - A. Livedo reticularis
       - B. Superficial thrombophlebitis
       - C. Cutaneous ulcers
       - D. Purpura/ecchymoses
       - E. Subungual splinter hemorrhages
    2. Not associated with antiphospholipid antibodies
       - A. Resulting from monoclonal cryoglobulins
         - i. Purpura/ecchymoses
         - ii. Hemorrhagic skin necrosis
         - iii. Ulceration
       - B. Resulting from cholesterol embolization
         - i. Livedo reticularis
         - ii. Purpuric infarction of toe tips and/or fingertips
       - C. Resulting from calciphylaxis
- c. Other cutaneous vascular reactions
  - i. Urticaria
  - ii. Periungual telangiectasia
  - iii. Palmar erythema
  - iv. Erythromelalgia

III. OTHER LE NONSPECIFIC CUTANEOUS LESIONS
- a. More common
  - i. Cutaneous mucinosis
  - ii. Calcinosis cutis
  - iii. Nail changes
  - iv. Cutaneous manifestations of overlapping autoimmune disorders
  - v. Acquired SLE-associated bullous dermatoses
    1. EBA-like bullous dermatosis of LE
    2. Dermatitis herpetiformis-like bullous dermatosis of LE
    3. Pemphigus erythematosus
    4. Bullous pemphigoid
    5. Porphyria cutanea tarda
- b. Less common
  - i. Lichen planus
  - ii. *Acanthosis* nigricans
  - iii. Erythema multiforme
  - iv. Cutis Laxa
  - v. Eruptive dermatofibromas
  - vi. Acquired ichthyosis
  - vii. Interstitial granulomatous dermatitis/palisaded neutrophilic granulomatous dermatitis

Photosensitivity appears to be a relatively sensitive indicator of SLE. Chien et al. found photosensitivity in 90% of 80 Taiwanese children with SLE (10). Sanders et al. found an abnormal reaction to UVR and visible light in 93 of 100 patients with cutaneous lupus and/or SLE (12). Other studies cite between 50% and 79.5% incidence rates of photosensitivity in patients with SLE (13 ,14). In a large epidemiologic study, Cooper et al. found that photosensitivity occurs less often in African-American patients (15). Nonetheless, because of the frequency of photosensitivity in SLE, all patients should be taught the importance of protecting skin from UVR. See Chapter 30 for recommendations regarding UV protection.

Mucosal Ulceration

Oral ulceration is commonly found in patients with LE, and represents one of the 1982 revised ACR criteria for the classification of SLE (4). Oral ulcers are present in roughly 25% to 45% of SLE patients (14 ,16) and up to 25% of DLE patients (17). Although these lesions can show LE-specific histopathologic changes on biopsy, particularly in DLE patients, they often are nonspecific. Available incidence/prevalence data does not separate between LE-specific and LE-nonspecific oral ulceration. Nonetheless, oral ulcerations are likely an indicator of disease activity, and in one study they were only seen in patients with active SLE (16). Yell et al. assessed mucocutaneous findings in 73 patients with SLE, and found that 31.5% had a history of mouth ulceration. Of these, 15% noted ulcers at the onset of their disease. Four percent had ulceration of the palate, and 4% had buccal ulceration, whereas an additional 4% had lip lesions (14). Another study noted 6% of SLE patients with lip lesions (17).

The location and asymptomatic nature of LE-related oral ulcers can help differentiate them from other types of oral ulcers such as aphthous stomatitis, lichen planus, herpes simplex, or drug-induced ulcers (e.g., methotrexate or gold). LE-related ulcerations are more apt to be on the hard palate (Fig. 31-1). One study, conducted by Urman et al., found them on the hard palate in 89% of 182 SLE patients. These authors also observed that oral ulcers were asymptomatic in 82% of patients (18). By contrast, non-LE-related oral ulcers are usually quite painful. LE-related oral ulcers often improve with treatment of other systemic or cutaneous manifestations of LE. Symptomatic lesions may also be treated topically with various agents alone or in combination, including topical corticosteroids, tetracycline, diphenhydramine, and lidocaine hydrochloride (Xylocaine Viscous).

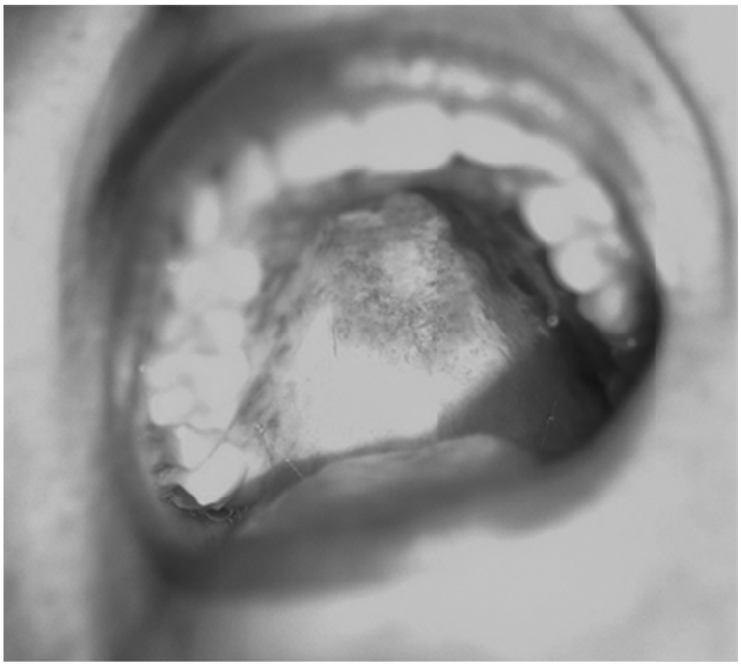

Figure 31-1. (See color plate.) Ulceration on hard palate in a patient with SLE.

Nasal and genital ulcerations are also seen in SLE and appear to occur during periods of disease activity. Burge et al. looked at mucosal involvement in 121 patients with either SLE or CCLE, and found that nasal ulcerations were present in 7 (6%). Vulvar lesions were present in 2/121 patients (17). Nasal ulcerations are often painful, and may even progress to ulceration of the nasal septum. Nasal ulceration and perforation have been reported in association with flaring systemic disease (19).

Alopecia

Alopecia is a common finding in lupus patients, as is suggested by its inclusion in the original 1971 preliminary criteria for the classification of SLE. Because of low sensitivity and specificity, it was not incorporated into the 1982 revised criteria. Alopecia in lupus can have a considerable psychosocial impact (20).

There are several different types of hair loss in patients with SLE. Some are associated with scarring of the scalp's skin, whereas others are not.

Scarring alopecia frequently occurs in DLE lesions (see Chapter 30). This should be distinguished from the diffuse nonscarring alopecia that characterizes LE-nonspecific hair loss. LE-nonspecific alopecia has been referred to as “lupus hair” and presents as course, dry hair that has increased fragility. It often results in broken hairs and may be more prominent over the frontal hairline (Fig. 31-2). Dubois noted

such “lupus hair” in 6% of 520 SLE patient (21). This likely has considerable overlap with a diffuse nonscarring alopecia caused by telogen effluvium, which involves a synchronization of hair into the telogen (resting) phase with subsequent hair shedding, and typically follows by 2 to 3 months of an acute illness, such as a systemic lupus flare, delivery of a pregnancy, or other types of physical stress. Alopecia areata is another cause of nonscarring alopecia and is seen in increased frequency in patients with lupus and other autoimmune illnesses (22). Its pathogenesis, histology, and course are distinct from LE nonspecific alopecia (“lupus hair”). Lastly, medication-induced hair loss, as may be seen with medications commonly used in lupus patients such as cyclophosphamide and methotrexate, should also be considered in the differential diagnosis of LE-nonspecific alopecia.

Figure 31-2. (See color plate.) Lupus hair in a patient with active lupus nephritis and low complements.

As with photosensitivity and oral ulceration, assessing prevalence and incidence of LE-nonspecific alopecia is difficult, since most studies do not clearly delineate between scarring alopecia as a result of chronic DLE and LE-nonspecific hair loss. Saurit et al. found that alopecia was the most prevalent nonspecific mucocutaneous manifestation in 77 patients with SLE, affecting nearly 60% of patients. Similar to photosensitivity, diffuse alopecia was more frequent among patients with active SLE (23). Another study performed by Wysenbeek found alopecia in 54% of 74 SLE patients (24,24a). The two studies that specifically separate nonscarring alopecia cite slightly lower incidence rates. Cardinali et al. found that 18 of 58 patients with SLE (31%) had nonscarring alopecia, and confirmed the finding of occurrence in the active phase of SLE (25), whereas another group of investigators in the United Kingdom reported LE-nonspecific nonscarring alopecia in 40% of 73 SLE patients (14).

LE-nonspecific alopecia is typically self limited. The hair usually returns to normal after the underlying SLE activity diminishes. There may be some shortening of the time to regrowth of hair with use of topical minoxidil 2% (26).

Additionally, lupus patients can develop common forms of nonscarring alopecia that are experienced by individuals not having lupus. For example, a male lupus patient can develop typical male pattern balding (androgenetic alopecia) that is unrelated to his lupus. Additionally, a female lupus patient is also at risk for developing a closely related pattern of androgenetic alopecia.

Raynaud Phenomenon

Raynaud phenomenon was included in the original American Rheumatism Association classification criteria set for SLE but was removed when this criterial set was revised in 1982. Raynaud phenomenon will be discussed below as a type of cutaneous vascular reaction pattern.

Cutaneous Vascular Reactions

Reactions that involve the cutaneous vasculature are important to recognize in patients with SLE as they can frequently indicate underlying systemic vascular pathology. In a discussion of cutaneous vascular reactions that can be seen in lupus patients, it is crucial to differentiate between vasculitis (inflammatory vascular wall injury) and several types of vasculopathy. In this context, the term “vasculopathy” is defined as vascular wall narrowing resulting in ischemia or noninflammatory vascular lumen occlusion resulting from thromboembolic disease. Vasculitis is caused by primary inflammation (usually immune-complex-mediated) of vessel walls with secondary occlusion of lumina with fibrin. Vasculopathic processes are multifactorial with some being caused by vascular lumen narrowing (e.g., Raynaud phenomenon/systemic sclerosis) and others being caused by occlusion with bland thrombi in the absence of primary vascular wall inflammation (e.g., hypercoagulable state resulting from antiphospholipid antibody production) (27). There are many causes of vasculopathy (Table 31-2) in patients with lupus. LE-nonspecific vasculopathy is most commonly the result of antiphospholipid antibodies. The cutaneous vasculitides and vasculopathies may present with similar clinical findings, but are important to distinguish from one another, since they have different treatments (i.e., anticoagulation in thromboembolic disease and immunosuppressives/glucocorticoids in vasculitis).

Vasculitis

Vasculitis is typically classified based on the size of the affected vessel (28). In SLE, all sizes of vessels may be affected (29). Leukocytoclastic vasculitis (LCV) (syn. hypersensitivity vasculitis, cutaneous small vessel vasculitis) affects postcapillary venules and presents as palpable petechial lesions on dependant areas (Fig. 31-3). When LCV presents in patients with SLE, other causes of LCV such as medications and infections should be excluded before a diagnosis of primary lupus-associated LCV is assigned. Involvement of medium and/or large vessels may present as purpuric plaques with stellate or retiform borders with or without cutaneous necrosis and ulceration, or subcutaneous nodules (Fig. 31-4). Occasionally lesions may not be purpuric, but rather may resemble urticaria.

So-called urticarial vasculitis is not uncommon in SLE and may be distinguished from urticaria by presence of individual lesions greater than 24 hours, tenderness, and possibly the presence of residual pigment or bruising upon resolution of the urticarial component, and histologic changes of vasculitis (Fig. 31-5). Cutaneous vasculitis may be treated with colchicine, diaminodiphenylsulfone (Dapsone), glucocorticoids, or immunosuppressive medications. Compression stockings play a vital role in preventing recurrences. Vasculitis is discussed in further detail in Chapter 36 .

Table 31-2: Potential Causes of Vasculopathy in SLE

1. Lupus anticoagulant/antiphospholipid antibodies
2. Cholesterol emboli
3. Infectious emboli (endocarditis, etc.)
4. Calciphylaxis
5. Protein C, protein S deficiency
6. Antithrombin III deficiency
7. Heparin/warfarin necrosis
8. Prothrombin 2021A mutation
9. Homocystinemia
10. Cryoglobulinemia
11. Cryofibrinogenemia
12. Disseminated intravascular coagulation
13. Purpura fulminans (meningococcemia)

Figure 31-3. (See color plate.) Palpable purpura on the lower extremities in a patient with leukocytoclastic vasculitis and SLE.

Vasculopathy—Ischemic

Raynaud Phenomenon

Rheumatic disease–associated Raynaud phenomenon is associated with intimal hyperplasia of digital arterioles resulting from poorly understood nonvasculitic immunologic processes. With progression of the intimal hyperplasia, the vascular lumen is narrowed resulting in decreased blood flow and distal ischemia. This ischemia is accentuated to the point of clinical symptoms by cold and stress-induced reflexes that induce peripheral vasospasm.

Like photosensitivity, oral ulcers, and alopecia, Raynaud phenomenon has been clearly documented as a cutaneous finding that strongly correlates with underlying systemic lupus erythematosus. Cardinali et al. found that Raynaud phenomenon was found in 39.6% of patients with SLE (25). Additionally it has been shown that Raynaud phenomenon seems to herald a worse prognosis and is associated with higher disease activity scores (1 ,3). The presence of Raynaud phenomenon in patients with SLE may correlate with an increase in DLE lesions on the hands (Fig. 31-6). Skin changes that can be seen in association with chronic severe Raynaud phenomenon include focal ulcerations on the fingertips and periungual areas that result in pitted scarring upon resolution, prominent nailfold capillary ectasia and drop out, punctate cuticular hemorrhage due to incompetent nailfold capillaries, fingertip tuft atrophy, digital calcinosis, and pterygium inversus unguium, A more complete discussion of Raynaud phenomenon can be found in Chapter 36 .

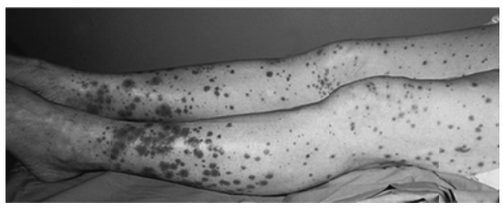

Figure 31-4. (See color plate.) Medium-sized vessel vasculitis with large retiform purpura and smaller ulcerations in an SLE patient.

Figure 31-5. (See color plate.) Urticarial vasculitis in a patient with SLE and flaring lupus nephritis.

Vasculopathy—Thromboembolic

Associated with Antiphospholipid Antibodies

Patients with SLE and antiphospholipid antibodies frequently present with cutaneous symptoms. These include livedo reticularis, thrombophlebitis, retiform purpuric plaques, which may later become necrotic and ulcerate, lower extremity ulcers, purpura, ecchymoses, painful skin nodules, and subungual splinter hemorrhages (25 ,30 ,31). Lesions are often present in acral locations, since smaller vessels are more likely to become occluded. Both venous and arterial vessels may be involved, and may result in digital infarcts and even gangrene. Other rarer skin changes associated with antiphospholipid antibodies include atrophie blanche-like lesions (painful, ivory colored stellate scars on the lower extremities), Degos-like lesions (small, porcelain-white circular atrophic lesions with peripheral erythema and telangiectases) and lesions of primary anetoderma (focal loss of dermal elastic tissue, resulting in localized areas of flaccid

or herniated saclike skin (32 ,33). Scheinfeld et al. describe a patient with reticulate and stellate acral pigmentation who had high titers of circulating anticardiolipin antibodies (34).

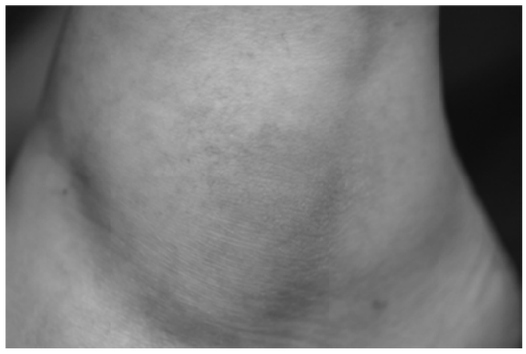

Figure 31-6. (See color plate.) Patient with Raynaud's phenomenon, tapered fingers, and LE-specific skin lesions on the fingers.

Livedo reticularis is clinically manifested as net-like, blanchable, complete or incomplete, red-purple rings on the extremities and less commonly on the trunk resulting from impeded flow of blood through vessels. Some data argue that the incomplete or broken form of livedo reticularis (i.e., livedo racemosa) has a stronger association with the thromboembolic clinical manifestations of the antiphospholipid antibody syndrome than the complete ring variety. The presence of livedo reticularis may be an indication of risk for pregnancy loss.

Sneddon syndrome is characterized by widespread livedo reticularis and ischemic cerebrovascular disease often accompanied by labile hypertension. Antiphospholipid antibodies are seen in at least 41% of Sneddon syndrome patients, and some consider it to be a variant of SLE with antiphospholipid antibodies (35). Livedo reticularis frequently accompanies purpuric skin lesions in vasculopathic conditions (Fig. 31-7).

Not Associated with Antiphospholipid Antibodies

Skin lesions resulting form cutaneous vascular occlusion can be seen in lupus patients for reasons other than phospholipids antiphospholipid antibody-induced thrombosis. An example would be the presence of cryoglobulins. Cryoglobulins have been observed in approximate 25% of various SLE cohorts. Monoclonal cryoglobulins tend to precipitate in cutaneous vessels producing overlying purpura/ecchymosis, hemorrhagic skin necrosis, and ulceration. Mixed cryoglobulins, especially in the context of concurrent hepatitis C virus infection, produce a small vessel cutaneous vasculitis, typically dependent palpable purpura, rather than primary vessel lumen occlusion.

SLE patients are at risk for premature, severe atherosclerosis. Cholesterol crystals can release from atherosclerotic plaques spontaneously or after intravascular procedural manipulation and embolize to smaller vessels producing livedo reticularis as a result of the impedance of blood flow to the overlying skin. (Livedo reticularis is a cutaneous vascular pattern resulting from slowed blood flow that can be seen in a number of clinical settings other than SLE.) When cholesterol crystals embolize to terminal arteries in the digits, purpuric infarction of the tips of toes and/or fingertips can result. This can be confused with SLE vasculitis or antiphospholipid antibody-associated vasculopathy affecting digital vessels.

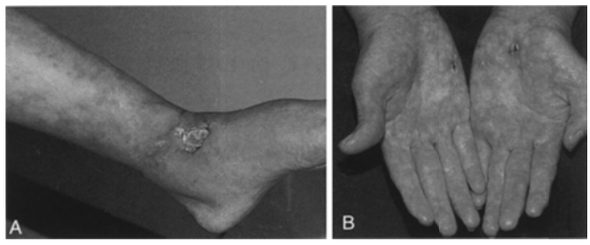

Figure 31-7. (See color plate.) **A**, Livedo reticularis and ulceration of the leg in a patient with systemic lupus erythematosus and high-titer IgG anticardiolipin antibodies. **B,** Similar changes on the hands of the same patient.

Skin necrosis also can result from calciphylaxis in SLE patients with renal failure. These lesions typically present with painful indurated areas of cutaneous hemorrhage that rapidly become necrotic and ulcerate. Radiographic or histopathologic evidence of cutaneous calcification can help diagnose this disorder. It is important to remember that cutaneous necrosis, and ulcerations also can be induced by certain medications (e.g., propylthiouracil, warfarin, hydroxyurea).

Other Cutaneous Vascular Reactions

Urticaria

Urticaria is sometimes associated with LE, and is thought to be a manifestation of the disease process' immune dysregulation. One study found chronic urticaria in 44% of 73 SLE patients (14). This study also reported that some patients noted worsening urticaria with sun exposure. Urticaria typically presents with an acute onset of edematous erythematous papules and plaques (wheels) that itch. It must be differentiated from urticarial vasculitis (see above). Urticarial vasculitic lesions are more likely to be painful, nonblanching (e.g., purpuric), and remain in the same location for at least several days, whereas urticarial lesions tend to be pruritic, blanching, and more evanescent (typically less than 24 hours). A skin biopsy can be helpful in differentiating between the two.

Urticaria is commonly caused by medications, and LE-nonspecific urticaria that occurs merely as part of the patient's lupus diathesis should be considered a diagnosis of exclusion. Additionally, chronic infections and even underlying malignancies may induce urticaria, particularly in treatment resistant cases. Urticaria is often associated with thyroid autoimmunity, which is seen frequently in patients with SLE. Verneuil and colleagues reported that the frequency of antithyroid antibodies was 26.7% in patients with urticaria, as opposed to only 3.3% in normal controls (39). Thus, laboratory studies for antithyroid peroxidase and antithyroid microsomal antibodies may be helpful in evaluating the cause of urticaria in lupus patients.

Treatment of urticaria includes discontinuing any suspected triggering drugs or foods, in addition to the use of antihistamines and other antipruritics. A recent study documented efficacy of hydroxychloroquine in ameliorating symptoms of urticaria (40).

Palmar Erythema

Macular erythema over the hyper- and hypothenar eminences has been reported in lupus patients. One study documented that 4% of a group of 73 patients with SLE had chronic palmar erythema (14). Reticulated palmar

erythema can also be a sign of vasculopathy associated with antiphospholipid antibodies (Fig. 31.7-B).

Periungual Telangiectasia

Dilated capillaries of the nailfolds have been found in LE patients but less frequently than in patients with dermatomyositis (including clinically amyopathic dermatomyositis) or systemic sclerosis. Dilated capillary loops (megacapillaries), and capillary loop dropout are the hallmarks of “scleroderma-pattern” capillaroscopic changes, however, when seen in SLE patients, this pattern of nailfold changes appears to correlate strongly with Raynaud phenomenon. Furtado et al. found that such nailfold telangiectasias in SLE patients were associated with anti-U1RNP antibodies (36). They found no correlation with anticardiolipin antibodies. In another study, telangiectasia and erythema of the proximal nailfold were found in 76% of patients who had both DLE and SLE, but none in patients with DLE in the absence of SLE, suggesting that this is a rather sensitive indicator for systemic disease activity (25).

Erythromelalgia

Erythromelalgia (erythermalgia) is characterized by intense burning pain in the feet and hands, accompanied by local macular erythema and warmth. It differs from Raynaud phenomenon in that it worsens with exposure to heat instead of cold. It may be seen as an isolated clinical entity or in association with several different underlying illnesses, including SLE. It appears to be caused by microvascular arteriovenous shunting. Erythromelalgia that occurs in association with SLE is well documented, and should be included in the list of nonspecific vascular cutaneous reactions in SLE (37 ,38).

Other LE-Nonspecific Skin Lesions

Cutaneous Mucinosis

Small amounts of mucin deposition are sometimes found in LE-specific skin lesions, particularly in biopsies from chronic cutaneous LE lesions. However, some LE patients will manifest papulonodular cutaneous lesions with abundant amounts of mucin in the absence of the classic vacuolar changes in the basal layer of the epidermis or perivascular and perifollicular inflammation seen in LE-specific skin disease (41 ,42 ,43 ,44). Such lesions may be differentiated from the tumid subtype of chronic cutaneous lupus, and appear as indurated erythematous papules, nodules, or plaques, typically on the trunk and/or arms (Fig. 31-8). Histopathologic examination of these lesions reveals diffuse dermal mucin deposits. Some of these patients have LE-specific lesions elsewhere.

The pathogenesis of these lesions remains uncertain, although one report found that fibroblasts isolated from an LE patient with cutaneous mucinosis produced larger amounts of glycosaminoglycan than normal fibroblasts, and the production of this glycosaminoglycan was stimulated by the patient's serum (45). Similar lesions also have been reported in patients with dermatomyositis and scleroderma (46). There have been anecdotal reports of massive cutaneous (46) and periorbital (47) mucinosis in LE. One LE patient presented with nodular cutaneous mucinosis that 3 years later developed into atrophie blanche-like skin lesions (48), with evidence of an underlying vasculopathy, as has been found in other cases (42). Cutaneous mucinoses are often responsive to antimalarial or prednisone therapy (41).

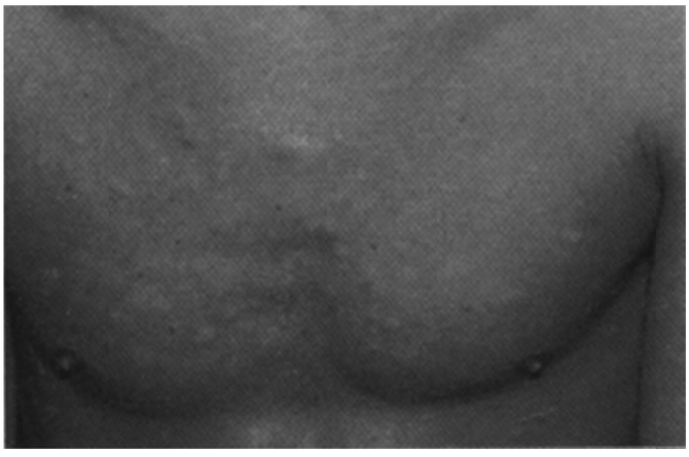

Figure 31-8. (See color plate.) Papular and nodular dermal mucinosis in a patient with systemic lupus erythematosus, including pleural effusions and glomerulonephritis.

Calcinosis Cutis

Calcinosis cutis is less common in SLE than it is in juvenile dermatomyositis and systemic sclerosis, with prevalence rates of 17% according to one study (49 ,50). Calcinosis in SLE has occurred in the setting of normal calcium metabolism and renal function. Calcinosis cutis because of secondary dystrophic calcification also has been reported in SCLE (51), DLE, and especially in lupus panniculitis (52 ,53). Calcification is commonly found on the extremities and buttocks, is often asymptomatic, and is sometimes found as an incidental radiologic finding (49). Calcification in SLE may be periarticular, within joints or muscles, or in the subcutis. Sometimes the overlying skin can ulcerate and the calcified material can be extruded as a white toothpaste-like or pebble-like material. Patients with superficial lesions should protect these areas from trauma with padded bandages. Some improvement of calcinosis cutis has been noted anecdotally in patients treated with aluminum hydroxide (54), calcium-channel blockers (55), colchicine (49), probenecid (56), low-dose warfarin (57), and bisphosphonates (49), although no controlled trials have been performed. Surgical treatment has been reported to provide additional benefit in some cases (58 ,59).

Calciphylaxis presents in patients with chronic renal failure as painful, indurated plaques, ecchymoses, ulceration, and eschar formation. Calcium is deposited in the walls of blood vessels and fibrosis and thrombosis occurs consequently, with secondary ischemia and necrosis of tissues.

Prognosis is poor, with mortality rates between 60% and 80%. Although the cause is unknown, altered calcium-phosphorous metabolism has been implicated. Patients have been treated with parathyroidectomy with variable results (58). Calciphylaxis has been reported in patients with lupus and end-stage renal disease (60 ,61). It has recently been reported that chelation therapy with intravenous sodium thiosulfate has been of benefit to several calciphylaxis patients (62 ,63). If this form of treatment is confirmed to be of value in calciphylaxis, it would be interesting to know whether it might be of therapeutic benefit in cutaneous calcinosis resulting from SLE and related entities such as dermatomyositis and systemic sclerosis.

Nail Changes

A number of nail changes have been noted in LE patients. One study reported nail changes in 31% of 165 SLE patients, the most common change being onycholysis (64). Tosti has noted that patients with SLE may have many nonspecific nail changes including altered keratinization of the nail matrix leading to leukonychia, nail pitting or ridging, and onycholysis or onychomadesis (65). One study reported finding diffuse, dark blue-black nail dyschromia in 52% of 33 African-American SLE patients, apparently from increased melanin deposition (66). Red lunulae have been reported in LE (67 ,68). One study found red lunulae in 11 of 56 (20%) patients with SLE or cutaneous LE, usually in association with periungual erythema or chilblains lupus lesions (68). DLE may affect the nail bed and nailfold and produce marked subungual hyperkeratosis or longitudinal melanonychia (69).

Cutaneous Manifestations of Overlapping Autoimmune Disorders

LE patients often may present with clinical features that overlap with other autoimmune disorders such as Sjögren syndrome and systemic sclerosis. It is therefore not surprising that LE patients sometimes exhibit cutaneous manifestations of other autoimmune disorders, including sicca signs and sclerodermatous skin changes, such as sclerodactyly or morphea (70 ,71). Anti-U1RNP antibodies have been found frequently in sera from patients with SLE-systemic sclerosis overlap syndrome. A recently described disorder called nephrogenic fibrosing dermopathy may mimic scleroderma and should be considered in lupus patients with renal disease who develop rapidly progressive sclerotic skin lesions (Fig. 31-9) (72 ,73). Rheumatoid nodules have been reported in patients with lupus and may or may not be associated with concomitant rheumatoid arthritis (74 ,75).

Acquired SLE-Associated Bullous Dermatoses

Confusion persists concerning the nosology and classification of the bullous skin changes that can occur in LE (76). LE-specific skin diseases (ACLE, SCLE, and DLE) may all manifest with secondary bullae as a consequence of intense injury at the dermoepidermal junction (77) (see Chapter 30). A second group of blistering skin lesions in SLE comprises disorders in which autoantibodies directed at skin antigens lead to blister formation. Since these do not have the specific LE histology, they have been referred to as LE nonspecific bullous lesion (78). The entity commonly described as “bullous SLE” represents an example of such lesions. Active SLE patients occasionally will develop a severe, generalized vesiculobullous eruption that resembles dermatitis herpetiformis (DH) or epidermolysis bullosa acquisita (EBA) (79) (Fig. 31-10). The histology of these lesions shows marked neutrophilic infiltration with papillary microabscess formation similar to DH and the inflammatory variant of EBA. The direct immunofluorescence findings, however, are more consistent with those seen in SLE, which is the primary argument in classifying these lesions as a unique entity, rather than an overlap between EBA or DH and SLE. Autoantibodies against type VII collagen (the EBA antigen), a normal constituent of anchoring fibrils of the sublamina densa zone, are present in some such patients (79). This type of lesion occasionally can represent the initial manifestation of SLE in adults and children and often occurs in the context of very

active SLE including lupus nephritis. The rather vague term “bullous SLE” often has been used to describe such lesions (79), however, we feel that the more descriptive terms “DH-like bullous dermatosis of LE” or “EBA-like bullous dermatosis of LE” are more appropriate, because other forms of bullous skin lesions can occur in SLE patients. Dapsone is a very effective treatment for this subset of disorders. Methotrexate and other immunosuppressives have been utilized as well (80 ,81).

Figure 31-9. (See color plate.) Nephrogenic fibrosing dermopathy in a patient on renal dialysis for SLE-induced end stage renal disease.

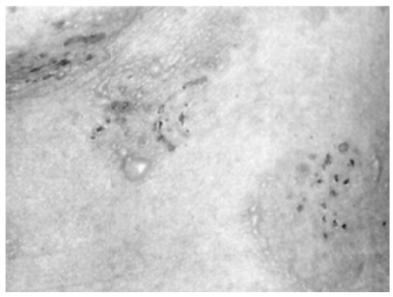

Figure 31-10. EBA-like bullous dermatoses of LE in patient with active membranoproliferative glomerulonephritis.

Examples of bullous skin diseases that have been linked anecdotally to cutaneous LE and SLE include bullous pemphigoid (82), dermatitis herpetiformis (83), porphyria cutanea tarda (84), and pemphigus vulgaris (85). In many of these reports, it is not clear whether the bullous skin changes are the result of the LE autoimmune process or develop as a mere chance occurrence in patients who also have LE. Pemphigus erythematosus also has been linked to LE. Patients with pemphigus erythematosus whose skin lesions are typically accentuated in sun exposed areas often have immunological evidence of LE-like autoimmunity, circulating antinuclear antibodies and immunoglobulin/complement deposition at the dermal-epidermal junction (DEJ) (i.e., the Senear-Usher syndrome) (86). However, such patients rarely develop significant clinical manifestations of SLE.

Less Common LE-Nonspecific Skin Diseases

There is some controversy over whether lichen planus occurs simultaneously in some cutaneous LE patients or whether some cutaneous LE lesions are mimicking lichen planus (87). In one case, lesions of SCLE appeared to evolve into those of lichen planus (88). One study concluded that some LE patients do, in fact, have both skin disorders, based on clinical, histopathologic, and immunopathologic findings (89). The histopathology of lichen planus can sometimes mimic that of LE-specific skin lesions so that it may not always be easy to differentiate between the two when the clinical appearance of the skin lesions is not classic for either.

Acanthosis nigricans has been reported in SLE in the absence of glucose intolerance (90), as well as in the presence of anti-insulin receptor antibodies (Type B insulin resistance). Acanthosis nigricans also has been associated with lupoid hepatitis (91).

LE patients may develop erythema multiforme from drugs or other causes. It is important to remember that sometimes SCLE can mimic erythema multiforme and one can question if the initial report of Rowell syndrome (e.g., erythema multiforme along with chilblains and DLE plus anti-Ro/La autoantibody production) might have been SCLE rather than erythema multiforme (92).

Cutis laxa (acquired loose skin due to destruction of elastic fibers) and anetoderma (focal loss of dermal elastic tissue, resulting in localized areas of flaccid or herniated saclike skin) can occur in lupus patients. Both have been reported to occur as a consequence of previous inflammation with LE-specific skin lesions, and in the absence of such lesions (Fig. 31-11). There has been speculation that loss of elastic fibers may be the result of infiltrating lymphocytes and/or circulating antibodies in patients with SLE (93). Anetoderma has also been associated with the antiphospholipid antibody syndrome.

Figure 31-11. (See color plate.) Anetoderma in a patient who had typical discoid lupus erythematosus lesions on other parts of her body.

Multiple eruptive dermatofibromas (small, firm, benign fibrohistiocytic cutaneous neoplasms) have been described to occur in patients with SLE (94).

Acquired ichthyosis, which is characterized by symmetric fish-like scaling of the skin, may present in patients with SLE. A case reported by Tlacuilo-Parra et al. resolved with treatment for SLE (95).

Over the past decade, a spectrum of aseptic dermal granulomatous histopathologic changes referred to as interstitial granulomatous dermatitis/palisaded neutrophilic granulomatous dermatitis has been increasingly described in the skin of patients having autoimmune connective tissue diseases including lupus erythematosus (96 ,97), rheumatoid arthritis (98), antiphospholipid syndrome (99), and nonspecific arthritis (100). Additionally, this histopathologic reaction pattern has been described in other dermatologic settings as well, including drug reactions (angiotensin-converting enzyme [ACE] inhibitors, calcium channel blockers [CCBs], beta-blockers, lipid-lowering agents, antihistamines, anticonvulsants, antidepressants) (101), other hypersensitivity reactions (soy) (102), and paraneoplastic syndromes (lymphoma) (103). Also, a reaction that was first thought to represent interstitial granulomatous dermatitis/palisaded neutrophilic granulomatous dermatitis was subsequently shown to be a reaction to occult cutaneous infections (atypical mycobacteria, histoplasmosis, and HIV) (104 ,105 ,106). This histopathologic reaction pattern has been described in the context of a number of different syndromic designations

(arthritis and interstitial granulomatous dermatitis [Ackerman syndrome], interstitial granulomatous dermatitis with cords, interstitial granulomatous dermatitis with arthritis, interstitial granulomatous dermatitis with plaques and arthritis, rheumatoid papules, Churg-Strauss granuloma, cutaneous extravascular necrotizing granuloma, superficial ulcerating rheumatoid necrobiosis, and palisaded neutrophilic and granulomatous dermatitis of immune complex disease). The pathophysiology of this reaction pattern has been speculated to relate to immune complex deposition.

The interstitial granulomatous dermatitis/palisaded neutrophilic granulomatous dermatitis histopathologic pattern has been associated with a number of different types of cutaneous lesions including red to violaceous papules, plaques, subcutaneous nodules, and rope-like cords. The papules, plaques, and subcutaneous nodules have typically been described in a bilaterally symmetrical distribution on the trunk and/or extremities favoring the skin folds. The rope-like cords that occur in this setting are typically unilateral and have a predilection for the lateral chest wall and axilla. Such lesions can simulate a superficial thrombophlebitis, however, veins are not affected. This histopathologic pattern has also been associated with generalized pruritic scaly eruptions and pigmented purpura (97 ,98 ,99 ,100).

There has been limited success in treating interstitial granulomatous dermatitis/palisaded neutrophilic granulomatous dermatitis lesions with hydroxychloroquine, dapsone, systemic corticosteroids (107).

Dermatoses in SLE not Related to Lupus

Greenwald's law of lupus states that SLE is often falsely accused of causing anything and everything that might happen to a patient subsequent to the diagnosis of SLE (108). Therefore, one must keep in mind that not everything that appears in the skin of a patient having a diagnosis of LE is necessarily a direct cause of LE.

A patient with SLE who presents with skin lesions may have (1) LE-specific skin disease (e.g., ACLE); (2) LE-nonspecific skin disease (e.g., urticarial vasculitis); (3) lesions resulting from SLE-induced internal organ damage (e.g., calciphylaxis); or (4) lesions that occur as a consequence of medical therapy required for SLE (e.g., adverse drug reactions, cutaneous infections). Additionally, patients may present with common dermatoses that are not at all connected to LE or its treatment (e.g., androgenetic alopecia, seborrheic dermatitis, seborrheic keratoses, acne rosacea, allergic contact dermatitis from poison ivy exposure). One study of skin disease in SLE patients found that rashes unrelated to LE autoimmunity were more common (69%) than rashes were related to LE autoimmunity (42%). Nonlupus rashes included rosacea, seborrheic dermatitis, acne, xerosis, facial telangiectasia, and eczema, among others (109). This highlights the need for accurate diagnosis of skin lesions in patients with SLE.

Drug-Related Skin Disorders

Drugs that are administered to LE patients not infrequently induce skin lesions. In a study of 84 consecutive patients with SLE, 6 were noted to have a drug eruption (109). A wide variety of skin lesions can be induced by medications, including SCLE, which is discussed in detail in the previous chapter. Many nonspecific skin lesions that are associated with LE can also be caused by medications, including photosensitivity reactions, alopecia, vasculitis, urticaria, bullous skin lesions, and erythema multiforme. *The Drug Eruption Reference Manual,* which is updated annually by Jerome Z. Litt, is a useful resource that lists the cutaneous side effects of numerous medications that have been cited in the literature (111).

Drug reactions may mimic lupus-specific skin disease, as is seen with medications that induce a photodistributed rash. These include antihypertensives (thiazide diuretics, ACE inhibitors, and CCBs), sulfa-drugs, and nonsteroidal anti-inflammatory drugs (NSAIDS). Toxic epidermolytic necrolysis (TEN) is often very difficult to distinguish from generalized blistering ACLE. TEN more often results from exposure to a number of medications including anticonvulsants, antibiotics, allopurinol, and sulfonamides, among others.

Antibiotic allergy, especially to sulfonamides has been reported as both a predisposing factor and as an exacerbating agent in SLE. Petri and Allbritton compared 221 patients with SLE to age-and sex-matched controls. Allergy to penicillin/cephalosporin, sulfonamides, and erythromycin was significantly more common in exposed patients with SLE than in exposed controls (110). Antibiotic rashes most commonly produce a morbilliform or measles-like eruption that typically occur 3 to 7 days after initiation of the antibiotic therapy. Indeed, this type of skin reaction is the most common presentation of drug hypersensitivity in general (112).

NSAIDs frequently are associated with pruritus, urticaria, and/or edema. Photosensitivity reactions, oral ulcerations, alopecia, purpura, erythema multiforme, TEN, vasculitis, exacerbation of psoriasis, and fixed drug eruptions also have been associated with the use of these agents.

Systemic corticosteroids are commonly associated with acneiform lesions, ecchymoses, and stria formation. Facial erythema, acanthosis nigricans, hypertrichosis, black hairy tongue, and steroid-withdrawal panniculitis are less frequently associated with the use of these agents. Depigmentation, atrophy, and skin necrosis have occurred at corticosteroid injection sites. The immunosuppressive effects of these medications can result in bacterial, viral, and fungal skin infections.

Antimalarials can cause ecchymotic blue-black pigmentary changes in the skin, particularly on photo-exposed areas, oral mucosa, nails, and anterior shins (Fig. 31-12). Bleaching of body hair also can be seen. Quinacrine can cause a yellow discoloration of the skin, sclera, and body secretions and might be misdiagnosed as jaundice. Quinacrine also can cause lichenoid reactions (thickening of the skin often with increased pigmentation and

accentuated skin markings typically associated with pruritus) (Fig. 31-13). The pigmentary changes usually will resolve within several months after stopping the antimalarial agent; however the pigmentation of the oral mucosa may be irreversible.

Figure 31-12. (See color plate.) Hydroxychloroquine hyperpigmentation involving the nails and oral mucosa.

Immunosuppressive drugs may cause adverse drug reactions as well. Cyclophosphamide has been reported to induce neutrophilic eccrine hidradenitis, a self-limited skin condition causing painful cutaneous nodules, characterized by an inflammatory cell infiltrate involving the eccrine sweat glands (113). Methotrexate can induce oral ulcerations, TEN, and acral erythema (114).

Both parenteral and oral-gold preparations can cause pruritus, stomatitis, exfoliative dermatitis, lichen planus-like, and pityriasis rosea-like skin reactions. Chrysiasis is the term that refers to the slate-gray pigmentary skin change that occurs in gold-treated patients. The dose-dependent color change is most marked in sun-exposed areas and may be permanent. Gold compounds also may cause drug-induced cutaneous LE, alopecia, purpura, vasculitis, erythema nodosum, and brown-nail discoloration.

Physicians should always consider the possibility that a drug might be inducing cutaneous disease in patients that present with skin problems. A history that a drug was recently started a few weeks before a skin change was noted might implicate an offending medication. However, it is important to realize that some drug-induced skin conditions do not become apparent until after months, and sometimes years of treatment with a particular medication. Delayed cutaneous hypersensitivity reactions to phenytoin sodium (Dilantin) and a number of other drugs characteristically appear at 3 to 6 weeks following initiation of the drug. Delayed drug-induced multiorgan hypersensitivity syndrome (DIDMOHS) (115) and drug rash with eosinophilia and systemic symptoms (DRESS) (116) are synonymous terms that have been used to refer to this characteristic pattern of drug hypersensitivity. Additionally, hydroxyurea-induced dermatomyositis-like skin disease might become apparent only after the patient has been treated with hydroxyurea for several years (117 ,118).

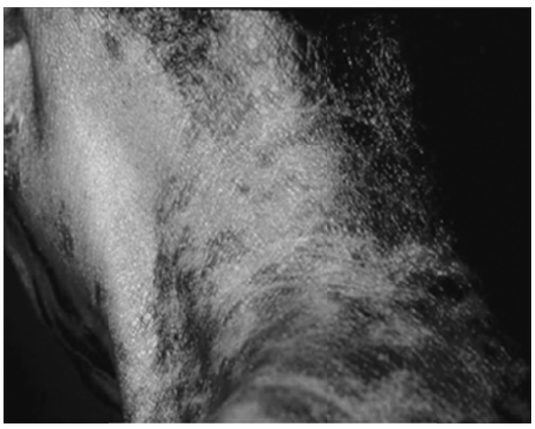

Figure 31-13. (See color plate.) Lichenoid drug eruption from hydroxychloro-quine.

Cutaneous Infections

Infections cause 25% to 50% of morbidity in SLE patients, and major infections are important causes of hospitalization (119 ,120). Patients with SLE develop cutaneous infections as the result of immune dysregulation and/or treatment with immunosuppressive medications. Skin infections were found to be one of the most common types of infection in SLE patients in a review by Juarez et al. (120).

Not only is cutaneous infection with *Staphylococcus aureus* common, but it may eventuate in staphylococcal bacteremia and even death in immunocompromised SLE patients (121). Staphylococcal skin infections include impetigo, folliculitis, furunculosis, pyoderma, and cellulitis. Cutaneous streptococcal infections, including cellulitis from streptococcus pyogenes and *Streptococcus pneumoniae*, have been described in lupus patients (122 ,123). Mortality from bacterial infections was found to correlate with hypocomplementemia (121). One group of authors concluded that seemingly minor bacterial infections of the skin in patients with SLE should warrant aggressive antimicrobial treatment, especially when there is complement deficiency (122).

Atypical mycobacterial infections are a frequent cause of morbidity in SLE patients. Cutaneous infections with *Mycobacterium kansasii*, *M. marinum*, *M. haemophilum*, *M. chelonae*, and *M. fortuitum* have been reported. Presentations varied, and included erythematous papules, plaques, cellulitis, panniculitis mimicking lupus profundus, ulcerative subcutaneous nodules, abscesses, and vasculitis (Fig. 31-14). In a few cases hematogenous dissemination occurred (124 ,125 ,126 ,127 ,128 ,129).

Herpes zoster is the most frequent viral infection in lupus patients and occurs mainly in those with previous histories of nephritis, hemolytic anemia, thrombocytopenia, and previous use of cyclophosphamide (119). Localized herpes zoster is the most common clinical presentation, and is typically seen in patients with inactive disease, who take less

than 20 mg/day of prednisone. Disseminated herpes zoster (affecting two or more noncontiguous dermatomes) and bacterial superinfection may occur and are related to the use of high doses of corticosteroids or immunosuppressants, especially mycophenolate mofetil and cyclophosphamide (119). Recurrent and disseminated herpes simplex infection may be a problem for patients with SLE, again especially those treated with medications like mycophenolate mofetil (130 ,131). Disseminated viral infections are classically characterized by painful or pruritic vesicles on erythematous bases, often with central umbilication. Any lupus patient with blisters should have a Tzanck preparation or direct fluorescent antibody exam from a representative lesion. Patients with herpes zoster who are immunosuppressed may require treatment with intravenous acyclovir in addition to holding immunosuppressive medications.

Figure 31-14. (See color plate.) Mycobacterium chelonae infection in a male with SLE on immunosuppressive medication.

Norwegian (crusted) scabies is a severe skin infestation which has been described in patients who are immunosuppressed, including those with SLE (132). Patients typically present with intensely pruritic, widespread crusted erythematous plaques, which may mimic hypertrophic DLE, psoriasis, or even impetigo. Mite counts are very high and the diagnosis is easily confirmed with a skin scraping. Treatment with both topical and oral antiparasitic agents (i.e., permethrin and ivermectin) is usually required.

Cutaneous fungal infections can occur frequently in SLE patients, especially in those receiving high doses of corticosteroids (Fig. 31-15). Oral candidiasis is the most common infection (119). Onychomycosis from candida species, as well as from dermatophytes, has a higher prevalence in SLE than in controls (133 ,134). Cutaneous deep fungal infections such as coccidioidomycosis, histoplasmosis, cryptococcosis, and chromoblastomycosis have presented in patients with SLE particularly those on immunosuppressive medications (135 ,136 ,137 ,138). Such infections typically present as erythematosus papules, nodules, plaques, or cellulitis-like changes. Rarer infections, which include those caused by *Penicillium marneffei,* subcutaneous phaeohyphomycotic cyst as a result of *Exophiala jeanselmei,* and primary cutaneous mucormycosis may present significant morbidity in lupus patients (139 ,140 ,141). Patients with SLE, a fever and new skin lesion(s) should have a biopsy, including tissue sent for both routine histologic evaluation with special stains for organisms, and culture directed at detecting common bacterial as well as mycobacterial and fungal infections.

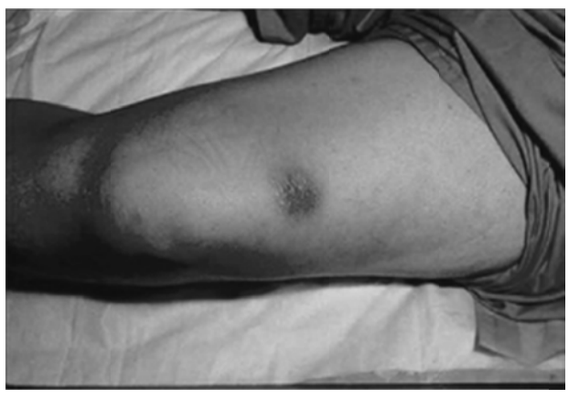

Figure 31-15. (See color plate.) Dermatophyte infection in an SLE patient mimicking DLE.

The Skin Biopsy

As this and the previous chapter have emphasized, the skin biopsy plays a central role in the diagnosis, classification, and management of lupus skin disease. In the ideal world, a fully trained dermatologist would be available to help evaluate, biopsy, and comanage any lupus skin lesion about which a rheumatologist or primary care physician might have questions. However, in the United States there is a growing dermatology manpower problem and American dermatology is drifting away from a focus on clinical issues relating to complex medical dermatology problems such as cutaneous LE. Therefore, for the rheumatologists and primary care physicians who do not have ready access to a dermatologist, we offer the following comments pertaining to skin biopsy techniques.

There are three types of skin biopsy techniques commonly used in dermatology: punch excision, shave excision, and scalpel excision. The shave excision technique is used predominately for suspected cutaneous malignancies in which only a superficial biopsy specimen containing predominately epidermal and superficial dermal tissue is required for diagnosis. This technique is not adequate for obtaining the deeper tissue necessary for an appropriate evaluation of cutaneous LE lesions. When one is interested in the subcutaneous pathology such as in suspected lupus profundus/panniculitis, a full-thickness wedge excision obtained by scalpel followed by suturing is the best way to ensure an adequately deep sample of subcutaneous tissue plus overlying dermis and epidermis. However, since the epidermis and dermis are the most frequently affected components of the skin in most types of LE skin lesions, a punch type excisional biopsy is the technique most commonly used in LE patients.

The punch biopsy technique itself is a very straightforward and can be performed by any physician or a physician assistant (142). It can be relatively painless when performed under local anesthesia accomplished by using lidocaine (Xylocaine) buffered with sodium bicarbonate delivered with a 30- or 32-gauge needle. The small linear scar left behind after a 3- or 4-mm punch biopsy defect has been sutured can be virtually invisible after healing. Facial skin heals exceedingly well in this regard. On less cosmetically sensitive areas of skin, the biopsy defect can be left open to heal by secondary intention with little risk. Thus, there should be no hesitation in obtaining biopsy specimens from facial skin lesions if this information might be of help in the diagnosis or management of an LE patient.

More important than the technical aspects of a skin biopsy is the skill and experience that the pathologist who examines the biopsy specimen has in evaluating inflammatory skin disease. Just as muscle pathology is a highly specialized area of pathology, so is dermatopathology. Every effort should be made to ensure that a biopsy from an inflammatory skin lesion is reviewed by a board-certified dermatopathologist. The value of the dermatopathologic evaluation can be enhanced by providing the dermatopathologist relevant clinical and laboratory information concerning the patient when submitting the biopsy specimen.

Take Home Points

- Patients with SLE may present with the more common lupus nonspecific skin lesions: photosensitivity, mucosal ulceration, alopecia, and Raynaud phenomenon. These correlate with SLE disease activity and may be used as a type of biomarker in most patients.
- Patients with SLE often have lupus-nonspecific cutaneous vascular reactions. These include true vasculitis of any sized vessel, and thrombotic vasculopathies, of which there are several different causes, including thrombosis related to antiphospholipid antibody syndromes. Disease presentations range from palpable purpuric lesions, urticarial lesions, eschar formation, and ulceration, to gangrene. Activity of the cutaneous vascular lesions often correlates with SLE disease activity.
- Patients with SLE have other less commonly encountered lupus nonspecific skin diseases which may cause significant morbidity. These include, cutaneous mucinosis, nail changes, bullous dermatoses, lichen planus, acanthosis nigricans, erythema multiforme, cutis laxa, eruptive dermatofibromas, and acquired ichthyosis.
- The clinician should exclude drug-induced dermatoses when a patient with SLE presents with skin lesions that are atypical or are discordant to the clinical context. Drug-induced skin lesions can simulate both LE specific skin disease (e.g., subacute cutaneous LE) and lupus non-specific skin disease (e.g., palpable purpura because of small-vessel cutaneous leukocytoclastic vasculitis).
- The clinician should exclude cutaneous infections when a patient with SLE presents with skin lesions. Such lesions might represent primary cutaneous infections or be a reflection of systemic infection with opportunistic organisms.
- Many patients with skin lesions and SLE may benefit from dermatologic referral and possibly skin biopsy.

Section V
Clinical Aspects of Lupus

Chapter 32

The Clinical Presentation of Systemic Lupus Erythematosus

Daniel J. Wallace

Before the description of the lupus erythematosus (LE) cell by Hargraves et al. (1) in 1948, systemic lupus erythematosus (SLE) was considered to be a rare, fulminant disease occurring in young women, with classic rash and a fatal termination in months. The illness now is conceptualized as a chronic disorder of a pleomorphic nature. No classic pattern exists, and the diagnosis must be based on an overall view of the clinical picture with the aid of serologic and laboratory studies and, if required, biopsies or other diagnostic procedures. This chapter presents an overview of the clinical presentation of SLE; the following chapters detail its involvement in various organ systems.

History

The author commences the interview by asking the patient how they feel, and a social, occupational, and emotional history and listing of current medications precedes the review of systems along with eliciting prior therapeutic interventions and workups. All of the items in Tables 32-1 and 32-2 should be covered. The physician should inquire specifically about the effects of sun exposure on the patient's skin, as well as probe for constitutional symptoms of fatigue, fever, weight loss and aching. Queries include what time of day is associated with stiffness (e.g., morning stiffness for lupus, afternoon for fibromyalgia) and aching, and which joints hurt the most. Early symptoms and signs can be subtle. Up to 10% of healthy individuals have a positive antinuclear antibody, and two thirds who are told by a doctor they have lupus do not fulfill established criteria for the disease (2). It is often useful to have patients fill out a detailed medical history questionnaire at the time of their first visit, which should take less than 30 minutes to complete. This allows detection of subtle psychosocial or sensitive issues that otherwise would not be found. Having patients write down what bothers them, in their own words, can be revealing. Filling out a questionnaire also decreases the possibility that important information might be inadvertently omitted.

Chief Complaint

Many variations are seen in the presenting complaint that brings a patient to the physician. Diagnosis is rendered difficult by the protean manifestations of the disease. The classic presentation of butterfly rash and arthritis in a young woman occurs in a minority of patients. Initially, any system may be affected and heal; months or years later, the same or another system may become involved. Table 32-3 lists the chief complaints noted at the initial diagnosis of SLE in several large studies. The two major areas of involvement are joint and cutaneous systems, followed by the nonspecific complaints of fatigue, fever, and malaise. The presentation of 101 children who were followed at the Mayo Clinic was similar to that of adults (4). Additionally, Ropes (5) found that joints were the first system to be involved in 27% of 142 patients, followed by fever, weight loss, and malaise (25%), and then skin rash (20%). Grigor et al. (6) followed 50 patients with lupus; the initial manifestations were arthritis or arthralgia (62%), cutaneous (20%), fever and malaise, thrombocytopenia, hemolytic anemia, and neuropsychiatric symptoms (4% each), and recurrent thrombophlebitis (2%). If present, organ-system damage evolves early. Rivest et al. followed 200 lupus patients and showed evidence for organ-system damage a mean 3.8 years after disease onset (7). In the <LUpus in MInority populations: NAture vs. nurture (LUMINA) cohort of 471 patients, the first American College of Rheumatology (ACR) criteria fulfilled were arthritis (34.5%), photosensitivity (18.2%), and positive antinuclear antibody (14.2%) (8).

Variations in Clinical Presentation

The presentation and clinical characteristics of SLE are presented in detail in the following chapters. Age and sex may cause variations in the appearance of the disease; these distinctions are summarized here. Chapter 49 covers features of incomplete lupus, other rheumatic diseases, and undifferentiated connective-tissue disease.

Table 32-1: Cumulative Percentage Incidence of SLE Manifestations

Manifestations	Harvey et al. (54) 1954(105 cases)	Dubols and Tuffanelli (55) 1964 (520 cases)	Estes and Christian (79) 1971 (140 cases)	Fries and Holman (42) 1977 (193 cases)	Hochberg et al. (14) 1985(150 cases)	Pistiner et al. (3) 1991 (464 cases)	Eurolupus (69) 1992 (704 cases)	GLADEL Cohort (67) 2003 (1214 cases)
I. Systemic Sx

Table 32-2: Cumulative Percentage Prevalence of 16 Clinical and Laboratory Manifestations in 2,000 Lupus Patients

(Attributable to lupus during the course of their disease; in published studies since 1975 collected by the author)

Positive ANA	97%
Arthritis, arthralgia, or myalgia	80%
Skin changes	71%
Low complement	51%
Cognitive dysfunction	50%
Fever	48%
Elevated anti-dsDNA	46%
Leukopenia	46%
Pleuritis	44%
Proteinuria	42%
Anemia	42%
Antiphospholipid antibodies	35%
Elevated gamma globulin	32%
Pleural or pericardial effusion	12%
Central nervous system vasculitis	12%
Adenopathy	10%

Table 32-3: First System Involved as Determined by History (%)

Manifestation	Dubois and Tuffanelli (50) (520 cases)	Harvey et al. (49) (105 cases)	Haserick (69) (275 cases)	Larsen et al. (70) (200 cases)	Norris et al. (5) (101 cases)

STS, biologic false positive for syphllis.

Proto or Latent Lupus

When does lupus begin? Sixteen healthy Finnish women who stored sera in connection with a maternity welfare program developed SLE years later. Ten (62.5%) were ANA positive at the time of collection, compared with 6% of controls (9). 130 individuals diagnosed with SLE while serving in the U.S. military had previously donated blood to the Army/Navy Serum Repository. ANAs, as well as other autoantibodies, were positive an average of 3.3 years prior to diagnosis (10).

A 1981 survey of our 609 private patients who were diagnosed between 1950 and 1980 revealed a 4.1-year interval between the onset of symptoms and the diagnosis of SLE (11). Our survey of 464 patients with idiopathic SLE who were seen between 1980 and 1989 documented a 2.1-year interval (3). Is the disease changing, or have increased physician awareness and newer diagnostic and serologic testing made it possible to diagnose SLE earlier? In the 0- to 19-year age group, it took only a mean of 3 months to make the diagnosis; in patients older than 60 years, the more subtle presentation of idiopathic SLE took 3.2 years to detect, on average. One third of 44 patients

who were referred to our group with a positive ANA to rule out lupus but who did not fulfill ACR criteria for the disease at the time of the visit had clear-cut SLE 6 months later (12). Urowitz et al. identified 22 patients with a constellation of features that were suggestive of SLE but who did not fulfill ACR criteria (13). Over a 5-year observation period, seven patients (32%) evolved into SLE. Few had organ-threatening disease, and no predictive factors distinguished the 7 who developed SLE from the 15 who did not. Hochberg et al. reported a 1-year interval among 150 patients who were seen between 1980 and 1984 (14). The Eurolupus cohort of 1,000 patients reported a mean 2-year period between the onset of symptoms and diagnosis in 1993 (15). Improved diagnostic techniques have allowed for more rapid diagnosis. In Limerick, Ireland, the mean time from symptoms to diagnosis has decreased from 102.8 months to 11.5 months between the 1970s and 1990s (18). By 2004, the interval had dropped among the LUMINA group to a mere 9 months (8).

In summary, nonorgan-threatening lupus, especially in older patients, can be difficult to diagnose initially; additionally, it may be difficult to determine when SLE started.

Lupus in Children

See Chapter 53 , Systemic Lupus Erythematosus in Childhood and Adolescence.

Late-Onset Lupus

Defined as disease with onset in patients over the age of 50 years, late-onset lupus often is insidious (19), with a polymyalgia-like or rheumatoid arthritis-like pattern (20), and it may be difficult to distinguish from autoimmune thyroiditis (4) or primary Sjögren syndrome (21). It comprises 6% to 20% of all cases (22) and includes more men than any other group, except young children (Table 32-4). The clinical course generally is benign, and the disease is more easily controlled with medication. One of our patients had active disease at age 90 (23), and onset has been reported at age 92 (24). The relatively small number of patients with late-onset lupus in large, published series led Ward and Pollison (25) to perform a meta-analysis based on nine studies of its clinical and laboratory features. Their 1989 effort compared 170 late-onset patients with 1,612 younger-onset patients. They concluded that the older-onset subset had more serositis, interstitial lung disease, Sjögren syndrome, and anti-La/SSB. A significantly lower incidence of alopecia, Raynaud phenomenon, fever, lymphadenopathy, hypocomplementemia, and neuropsychiatric disease was present (26). Only one of the reviewed studies was population based (27). These findings have been confirmed among European (15 ,16 ,17) and Asian populations (28 ,29 ,30 ,31 ,32). In a consortium of lupus centers, 86 patients with onset at 55 years of age or older were compared with 155 who experienced onset younger than age 40 (33). The former group had more cardiovascular, ocular, and musculoskeletal disease, and greater tissue damage, but this could not necessarily be attributed to lupus per se. Hence, this group has a lower 5- and 10-year survival than younger lupus.

Table 32-4: Sex Ratios by Age at Age of Onset or First Diagnosis of SLE

Age at Onset or First Diagnosis (yr)	Female:Male Ratio
0–4	1.4:1
5–9	2.3:1
10–14	5.8:1
15–19	5.4:1
20–29	7.5:1
30–39	8.1:1
40–49	5.2:1
50–59	3.9:1
60 and above	2.2:1

Additional reports have suggested that HLA-DR3 is more common in whites with late-onset lupus (14), autoantibodies other than ANA are much less common in late-onset patients (34 ,35), serositis is the most frequent presenting feature (36 ,37), late-onset lupus is more frequent in whites than African Americans (38), and African Americans with late-onset lupus have a worse prognosis than whites with late-onset disease (39). Braunstein et al. (40) evaluated the joint films of 24 patients with SLE onset older than age 50 years. No differences were noted in the amount of osteoporosis, erosions, or soft-tissue calcification, but soft-tissue swelling was significantly increased in the older group.

In summary, most studies have shown that patients with SLE onset older than age 50 years have more serositis, pulmonary parenchymal disease, and Sjögren syndrome, less central nervous system involvement and nephritis, and a better lupus prognosis.

Male Lupus

Although males constitute only 4% to 18% of those with SLE, their clinical presentation is similar to that observed in women. Hochberg et al. (14) noted a mean age of onset in men of 40.4 years (vs. 31.8 in women) among a 150-patient cohort. Except for a statistically significant increase in peripheral neuropathy, no other clinical, laboratory, or human leukocyte antibody (HLA) phenotypic differences, could be found.

If we restrict our review to studies including at least 30 males, Ward and Studenski (41) compared 62 men with 299 women who were followed at Duke University between 1969 and 1983; 23 clinical and laboratory variables were analyzed. The only significant differences were

more seizures and renal disease in the men. Pistiner et al. (3) compared 125 clinical and laboratory parameters among 30 men and 434 women who were seen in our office between 1980 and 1989. Only four significant differences were observed ($p < 0.01$): men had less alopecia and fibromyalgia but more nephritis and hypocomplementemia. Fries and Holman (42) observed that men had more anti-DNA and skin disease; Urowitz et al. (43) found that men had more pleuritis but less photosensitivity, alopecia, and thrombocytopenia. The 92 males in the Eurolupus cohort (15) had more arthritis and less serositis but no other differences. This includes 30 males who were studied in more detail by Font et al. (44) in Spain. Sixty-one Chinese male patients with lupus had less arthritis and leukopenia and anti-Ro(SSA) than matched females (45). Forty-one males followed by the Hopkins Lupus Cohort had more thrombotic episodes, lower complement, more hemolytic anemia, and seizures (46). Seventy-two males in Taiwan had more renal and skin diseases than females but less arthritis and adenopathy (47). Fifty-nine Danish males had more serositis, nephropathy, and atherosclerotic complications than 454 females (48). Alarcon-Segovia et al. in Mexico City compared 107 males with 1,209 females (49). They had a higher prevalence of anti–double-stranded (ds)DNA antibodies, renal disease, and vascular thromboses and took higher doses of corticosteroids. Another Mexican survey and a study of 30 male Turks (compared with 100 females) with SLE also confirms this (50 ,51). Black males may have a more aggressive presentation of lupus (52). The reader is referred to Isenberg's critical review of the so-far-difficult search for unifying features for male lupus (53).

In summary, male lupus is at least as severe or more severe than female lupus.

Constitutional Symptoms

The generalized symptoms of fever, weight loss, malaise, and fatigue do not fit into any organ-system classification; therefore, they are discussed here.

Fever

Fever secondary to active disease was recorded at some time in 86% of Harvey's patients who were seen in the early 1950s (54), in 84% of Dubois' 520 patients between 1950 and 1963 (55), in 55% of 193 patients at Stanford University in the 1960s and 1970s (42), 52% of the Eurolupus cohort (15), and in 41% of Wallace's 464 patients seen between 1980 and 1989 (3). This consistent, decreasing trend probably reflects better understanding of the disease and the greater availability of nonsteroidal anti-inflammatory drugs (NSAIDs). No fever curve or pattern is characteristic. SLE can present with fever as its sole manifestation (56). Active SLE can result in temperatures as high as 106°F (41°C). It can be difficult to distinguish the fever of SLE from that caused by complicating infections. A review of 617 patients with fever of unknown origin from five classic studies found SLE to be the cause in 0% to 5% of cases (57). Most recently, in 2003 an autoimmune etiology was found in 17% of 192 patients with a fever of unknown origin (out of 290) where a source was identified. Eight (4%) had SLE (58).

Fever in SLE results from endogenous pyrogens that are produced largely by polymorphonuclear leukocytes and monocyte/macrophages. These include tumor necrosis factor α; interleukin (IL)-1, -2, and -6; interferons, and arachidonic acid products. IL-1, in particular, promotes the release of arachidonic acid and, ultimately, prostaglandin E2 (PGE_2). PGE_2 is known to exert a direct pyrogenic effect on the hypothalamic thermoregulatory center (59 ,60).

Stahl et al. (61) at the National Institutes of Health (NIH) studied 106 hospitalized patients with SLE. In 63 patients (38%), 83 febrile episodes were recorded; 60% resulted from SLE activity, 23% from infection (bacteremia was present in one half of these and was fatal in one third), and 17% from other causes (primarily postoperative fevers and drug reactions). The single most useful feature identifying infection was the presence of shaking chills. Leukocytosis (especially in the absence of steroid therapy), neutrophilia, and normal anti-DNA levels also were helpful. The SLE components associated with fever were dermatitis, arthritis, and pleuropericarditis. Although often associated with SLE, a daily low-grade fever, up to 100°F (37.8°C), may be overlooked unless patients are specifically asked to check their temperatures daily. Inoue et al. (62) followed 49 patients with SLE through 74 febrile episodes and found that 25 episodes were secondary to infection. Discriminant analysis showed that 95% of 74 febrile episodes could be correctly classified as to the cause of fever when a combination of white blood cell count (low with SLE, normal to high with infection) and α_2-globulin levels (high with SLE, normal with infection) are used as variables. A close correlation between interferon-α (but not IL-1 or tumor necrosis factor) and degree of fever was observed in 25 untreated patients with SLE (63).

Temperature elevation in an illness that is characterized by a high incidence of this finding should not prevent the physician from carefully searching for other causes. The frequent occurrence of infection in patients with SLE often warrants blood cultures, urine cultures, and chest radiographs. Urinary tract infections are common in young women, who may be asymptomatic. Opportunistic infections and drug reactions should be considered. The cause of the temperature elevation should be investigated before suppressing this helpful clinical finding by administering or increasing the dose of salicylates, NSAIDs, or corticosteroids.

In summary, fever can be a manifestation of lupus, medication, or infection. All fevers, especially in those already on corticosteroids or immune suppressives, warrant prompt attention and aggressive management.

Anorexia and Change in Weight

Anorexia and an insidious onset of weight loss over a period of months were noted in 51% of patients in the Dubois series (55), in 71% of patients in Harvey et al. (54), in 31% of 193 patients followed by Fries and Holman (42), in 63% of Rothfield's 209 patients (64), and in 35% of children with SLE (65). It was a clinical finding in 9% of 704 European patients with SLE who were evaluated at a routine visit (66 ,67). The degree of weight loss almost always is less than 10% and most immediately precedes the diagnosis of SLE. Weight gain in SLE usually results from nephrotic syndrome, ascites, and adjunctive therapies (e.g., antidepressants) or corticosteroid treatment.

Malaise and Fatigue

A sense of malaise and fatigue is common in patients with SLE, especially during periods of disease activity. They feel tired and achy but initially find difficulty in pinpointing the problem. Low-grade fevers, anemia, or any source of inflammation can result in fatigue, as can emotional stress, fibromyalgia, or depression. The administration of certain cytokines, such as IL-2 and interferon-α induce fatigue (68), and SLE is associated with cytokine dysregulation. Rothfield (64) noted moderate to severe fatigue in 81% of 209 patients, and Fries and Holman (42) noted fatigue in 82% of 193 patients. Fifty-nine patients who were followed at the NIH filled out a fatigue questionnaire (69). Their mean fatigue severity (on a scale of 1 to 7) was 4.6. Of these, 53% reported fatigue to be their most disabling symptom, although it did not correlate with any laboratory measure. Three surveys published in the late 1990s suggested that fibromyalgia was the most important component of fatigue in lupus patients (70 ,71 ,72). Omdal et al. associated depression and hysteria with fatigue among 57 lupus patients but did not screen for fibromyalgia (73). No correlations with serum cytokines, antiphospholipid antibodies or other disease characteristics were noted (74). Among 120 lupus patients, those with fatigue tended to be less fit and have reduced exercise capacity andmuscle strength (75 ,76). Nor surprisingly, disease activity correlates with fatigue in groups where more serious lupus is treated (75 ,77).

Goldenberg's review of the literature suggests that the prevalence of fatigue in patients seen in primary-care settings ranges from 14 to 25% and costs $1 billion a year in diagnostic evaluations in the United States (78). (See Chapter 57 , Principles of Therapy and Local Measures, for a discussion of the management of fatigue.)

In summary, most lupus patients complain of fatigue. The most common associations are inflammation, fibromyalgia and psychosocial stressors, deconditioning, and the effects of medication.

Chapter 33

The Musculoskeletal System

Daniel J Wallace

Joints, muscles, and their supporting structures are the most commonly involved system in systemic lupus erythematosus (SLE), affecting 53% to 95% of patients (see Chapter 32 , Table 32-1). Kaposi (1), in 1872, first described the joint manifestations, and the reader is referred to a historical review (2). Most commonly, musculoskeletal symptoms are the chief complaint in lupus (see Chapter 32 , Table 32-2), and articular pain is the initial symptom in 50% of patients (3). The biochemical mediators of joint inflammation in SLE and the pathophysiology of this arthritis have not been well studied. This chapter will review these issues.

Joints: Symptoms, Signs, Deformity, and Radiographic Findings

The chief joint manifestations are stiffness, pain, and inflammation. The pattern of arthritis is recurrent, often evanescent, but can be deforming. Morning stiffness occurs in 46% to 73% of patients (4 ,5 ,6). Fries and Holman (7) found arthritis in 53% of their 193 patients, nodules in 3%, wrist swelling in 31%, metacarpophalangeal (MCP) swelling in 31%, and proximal interphalangeal (PIP) swelling in 40% at any point. Grigor et al. (8) described nondeforming arthritis or arthralgia in 88% of their patients, deforming arthritis in 10%, erosions in 6%, avascular necrosis in 6%, myalgias or myositis in 32%, and tendon contractures in 12%. Petri (9) has associated musculoskeletal damage in SLE with blacks and those of lower socioeconomic status.

Areas Affected

All major and minor joints may be affected, including the wrists, knees, ankles, elbows, and shoulders, in that order of prevalence (6). Most patients with SLE eventually develop some PIP and MCP involvement, and complaints of joint pain without objective physical findings for long periods may be noted. Once symptoms of discomfort became objectively apparent, morning stiffness characteristic of typical rheumatoid arthritis (RA) usually is seen. Marked, diffuse puffiness of the hands also often occurs. Stress fractures caused by corticosteroid-induced osteoporosis can produce swelling and mimic synovitis (10).

Hands and Wrists

Persistent, rheumatoid-like deformities may occur in the hand, as they did in 35% of patients observed by Dubois and Tuffanelli (4), with thickening of the PIP joints, ulnar deviation, and subluxation. Armas-Cruz et al. (11) found similar changes in 22% of 108 patients. Those changes often may appear insidiously over the course of many years while the patient is in an apparent clinical remission. The primary lesion appears to be inflammation involving synovial tissues, with minimal or belated destruction of cartilage and bone.

Hand deformities can include ulnar deviation and subluxation, swan-neck deformities (in 3% to 38%), and subluxation of the thumb interphalangeal joints (5 ,12 ,13 ,14 ,15 ,16). Erosions are rare (seen in approximately 4%). Some authors have noted positive correlations among deforming arthritis, Sjögren syndrome, anti-SSA, C-reactive protein, and the presence of rheumatoid factor (12 ,15 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24) and negative correlations with hypertension (25).

Jaccoud reversible, subluxing, nondeforming arthropathy is seen in 3% to 43% of patients with SLE (13 ,14 ,16). Table 33-1 summarizes the differential diagnosis between SLE and RA of the hand, and Figure 33-1 demonstrates some of the abnormalities mentioned here. In one report, Jaccoud arthropathy was found in 43% of 939 patients with SLE and is associated with a benign prognosis (26).

Whether or not primary antiphospholipid syndrome without SLE is associated with an inflammatory arthritis is the subject of some debate (27). A Dutch group correlated Jaccoud arthropathy with anticardiolipin antibodies, fetal loss, and thrombosis (28). Joint ligamentous laxity with consequent hypermobility is present in half with SLE (29). It does not require surgical treatment, because grip strength is usually intact. Dray et al. (30) treated 10 patients with subluxation excision, MCP arthroplasties, and joint stabilization by ligamentous reconstruction; unfortunately, 70% of the tendon relocations failed to maintain correction. An excellent review of hand surgery consideration in SLE has been published (31).

Table 33-1: Comparison of Hand Involvement in Systemic Lupus Erythematosus and Rheumatoid Arthritis

Parameter	SLE	RA
Raynaud's phenomenon	Approximately 30%	Rare
Joint pain	Mild	May be severe
Recurrent synovitis	In 10–30%	Common
Joint deformity	Caused by loss of soft-tissue support	Caused by loss of soft tissue support and articular surface destruction
Thumb IP joint hyperextension	Not associated with MP joint flexion contracture	Often associated with MP joint flexion contracture
Ulnar drift of fingers	Almost always reversible	Often irreversible, with subluxed MP joints
Wrist	May be lax; normal function	Often subluxed, with carpal bone destruction
Erosive changes	Rare	Common
Cause of deformity	Uncertain; occurs after supporting soft tissue structures are weakened	Synovitis, pannus formation; cartilage and bone destruction

IP, interphalangeal; MP, metacarpophalangeal.

All Hand Imaging Studies

Several reports have examined the radiographic findings of the lupus hand in detail. Weissman et al. (32) evaluated 59 patients, and 34 demonstrated abnormalities. Of these, 10 had acral sclerosis (these probably had mixed connective tissue disease), 7 had alignment abnormalities, and 1 showed an erosion. Leskinen et al. (33 ,34) reviewed joint radiographs of 124 patients with SLE, and cystic bone lesions were found in 51 (41%). Most were subchondral and located in the small joints of the hands and feet, and a vasculitic cause was proposed. In a multicentered European study, 10 of 60 lupus patients with erosive disease (vs. 28% without) had anti-RA33 antibodies ($p < 0.05$) (35). About half with SLE demonstrate evidence for inflammatory arthritis of the hands as determined by uptake on a technetium (Tc) bone scan (36). Ten of 37 Spanish SLE patients who fulfilled the inflammatory arthritis ACR criteria for lupus had imaging abnormalities; most of which was soft tissue swelling (37). MR imaging of the hands were more sensitive than conventional radiography in assessing soft tissue pathology and bony alterations in 14 German SLE patients (38). Twenty-six wrists of SLE patients were ultrasonographically compared with 15 healthy controls. Synovitis (42%), synovial proliferations (19%), effusion (25%), and erosions (4%) were found (39).

Figure 33-1. Jaccoud's arthropathy.

Rarely, a resorptive arthropathy resembling the opera-glass hand syndrome has been reported (40 ,41), as has periosteal elevation secondary to ischemic bone disease or, perhaps, vasculitis (42).

Knees

Jaccoud-like arthropathy (i.e., reversible subluxation) has been observed in the knees (43 ,44 ,45). Deep venous thrombosis (DVT) in a patient with antiphospholipid antibodies may be difficult to differentiate from a Baker cyst, both of which are observed in SLE (46). At least one case of chondrocalcinosis involving the knee joint associated with SLE has been reported (47), and it certainly is more common.

Feet

Mizutani and Quismorio (48) noted hallux valgus, metatarsophalangeal subluxation, hammertoes, and forefoot widening without erosions or cystic changes in patients with SLE. This is similar to the Jaccoud type of arthropathy in the hands. Other studies have confirmed these findings (49). The deformities result in painful bunions and callosities, and several podiatry publications have reviewed the issues of proper foot care in those with SLE (50 ,51).

Neck

Several cases of atlantoaxial subluxation have been reported (52 ,53). One report postulated that patients who are treated with corticosteroids have increased ligamentous laxity, which promotes the rupture of ligamentous and capsular supporting structures (53), but it seems equally likely that laxity of ligaments in the neck have the same physiologic bond as laxity in any other joint. In another report, 5 of 59 patients with lupus had atlantoaxial subluxation. All were asymptomatic. Subluxation was associated with longer disease duration, Jaccoud arthropathy, and chronic renal failure (52).

Sacroiliac Joint

Several studies of almost 100 patients suggested that over half of all patients with active SLE have radiographic sacroiliitis or increased uptake on joint scanning. I believe this figure is too high. Seronegative spondyloarthropathies were excluded, and most patients had no sacroiliac symptoms (54 ,55 ,56 ,57 ,58 ,59). A French survey of 41 SLE patients found radiographic unilateral sacroiliitis in 6 (15%). Only 1 individual was symptomatic (60).

Hips

Although hip synovitis is not uncommon, any complaints of isolated severe hip pain should lead one to suspect avascular necrosis (discussed below).

Shoulders

Jaccoud arthropathy can be found in the shoulders (61).

Temporomandibular Joint

Jonsson et al. (62) evaluated temporomandibular joint (TMJ) involvement in 37 patients with SLE and compared them to a control group of 37 healthy age- and sex-matched individuals. Of those with SLE referred to an oral surgeon, 59% had severe past TMJ symptoms (vs. 14% of controls), and 14% had present severe symptoms (vs. 3% of controls). Clinical examination revealed TMJ signs, such as clicking, crepitation, jaw fatigue or stiffness, facial pain, tenderness to palpation, pain on movement of the mandible, locking, or dislocation, to be present in 41% (vs. none of the controls). Additionally, of the patients with SLE, 30% had abnormal radiographs (vs. 9% of controls) that included condyle flattening and osteophytes, 11% had erosion, confirming other reports (63 ,64), and 72.5% had renal disease (vs. only 27.5% of the non–TMJ-involved patients with SLE). Although symptoms may be referred to this joint, limitation of the ability to open the jaw is rare unless coexistent scleroderma is present (65 ,66).

Synovial Histopathology

SLE is characterized by a mild to moderate inflammatory synovitis that is similar in character but less angry-appearing than that in RA (11 ,67). Bywaters (68 ,69) reported the presence of chronic synovitis with a fibrotic process in SLE in patients with Jaccoud-type deformities. Only three groups have examined the synovial histopathology of SLE in any detail.

Goldenberg and Cohen (70) studied 13 patients with lupus: 92% had synovial membrane hyperplasia, 100% had microvascular changes, 83% had surface fibrin deposits, and most had a perivascular infiltrate. Several of the biopsy specimens were indistinguishable from those of RA.

Labowitz and Schumacher (20) studied synovial biopsy specimens from seven patients; superficial fibrin-like material was seen in four, and focal or diffuse synovial lining proliferation in six. Five had a primary perivascular inflammatory reaction with predominantly mononuclear cells, and vasculitis was noted in only one patient. Synovial and vascular lesions were found in two patients, who had no objective signs of joint inflammation. On electron microscopy, fibrin was noted in three of four specimens. Type A (i.e., phagocytic), type B (i.e., synthetic), and intermediate cells were seen, but there was no clear predominance. Two patients had platelets and fibrin-like material obliterating small-vessel lumens. Vascular endothelial inclusions of a viruslike type were observed in two patients.

Natour et al. (71) reviewed 30 knee synovial biopsies. The most frequent findings were synoviocyte hyperplasia, minimal inflammation, edema, congestion, vascular proliferation, fibrinoid necrosis, intimal fibrous hyperplasia, and fibrin on the synovial surface.

In conclusion, the synovial histopathology of SLE does not appear to be specific, and it cannot clearly be differentiated from that of RA. Despite the extensive connective tissue change, little cartilage and bone destruction seems to occur. This gross finding tends to separate the deforming arthritis associated with SLE from that typically seen in RA. Large synovial cysts are uncommonly reported in patients with SLE (72 ,73 ,74).

Synovial Fluid

Ropes (75) found that the volume of accessible synovial joint fluid (Table 33-2) ranged from 5 to 1,500 mL in 133 patients. It was unusually clear, but occasionally hemorrhagic, and could be a transudate or an exudate. Pekin and Zvaifler (76) reported synovial fluid findings in 26 patients with SLE, and viscosity was uniformly good. The white count was less than 2,000/mL in 19 and exceeded 10,000/mL in only 2 patients. Granulocytes were always less than 50%, and the synovial fluid complement level was normal in 11. Of the 26 patients, 10 were classified as having noninflammatory transudates. Most had nephrotic syndrome. The exudates had a high protein content but variable complement levels. Serum to synovial fluid complement

ratios generally were elevated in contrast to the total protein or immunoglobulin G (IgG) ratios, suggesting consumption of complement at the synovial level.

Table 33-2: Characteristics of Synovial Fluid in SLE

Clear, yellow, normal viscosity, good mucin clot
White blood cell count: 2,000 to 15,000/mL, with primarily lymphocytic predominance
Low-titer ANAs may be present; LE cells occasionally are seen
Glucose level normal
Protein levels normal or increased
Complement levels normal or decreased

ANAs, antinuclear antibodies; LE, lupus erythematosus.

Schumacher (77) and Schumacher and Howe (78) examined synovial fluid from 17 patients with SLE. All had a white count lower than 40,000/mL. In comparing SLE with RA, Hollander et al. (79) reported a mean white count of 5,000/mL for SLE (vs. 15,000 for RA) with 10% neutrophils (vs. 50 for RA) and a good mucin clot and high viscosity (vs. a poor mucin clot and low viscosity for RA). Pascual (80) found that 14 patients with SLE had a synovial fluid counts ranging from 3,000 to 19,300/mL, and Hasselbacher (81) confirmed the increased viscosity in SLE synovial fluid and generally found low C3 complement levels. Cell counts in joint fluids must be interpreted cautiously, because analysis of the same fluid is subject to a great deal of variability among laboratories (82).

Secondary joint infection or avascular necrosis of bone may occur infrequently in SLE. It should be suspected when a localized effusion persists despite antiinflammatory therapy (83 ,84 ,85 ,86).

Lupus erythematosus (LE) cells can be found in vivo in synovial fluid (83). They were present in six of nine patients in one report (87), in 8 of 17 fluids examined by Schumacher (77), and by Schumacher and Howe (78) with electron microscopy, in 44% of 18 patients (88), in 2 of 14 patients examined by Pascual (80), and in two of three patients with drug-induced lupus (89). Rarely, RA cells (i.e., ragocytes) may be found in SLE synovial fluid (90 ,91).

Antinuclear antibodies (ANAs) are difficult to measure in synovial fluid, which must be treated with hyaluronidase before analysis. ANAs are present in approximately 20 of synovial fluid samples from patients with either RA or SLE (20 ,92 ,93 ,94), irrespective of serum levels. The synovial fluid of those with drug-induced lupus is similar to that reported for idiopathic SLE (89). Lipid synovial effusions rarely occur (95). Table 33-2 summarizes these observations.

On electron microscopy, Schumacher et al. (78 ,96) found meshworks or tubuloreticular structures in monocytes in seven patients. LE cells contained distinct chromatin filaments.

In summary, the synovitis of SLE is usually a bland, milder inflammatory process than rheumatoid arthritis that is deforming in a minority of cases.

Subcutaneous Nodules

Described by Hebra (97) and Kaposi (1) in 1872, subcutaneous nodules are present in 5% to 12% in the large series listed in Table 32-1 (Chapter 32) and in 2% to 10% in other series (98 ,99 ,100). Most occur in small joints of the hand, but nodules as large as 2 cm in diameter frequently occur on the extensor tendons of the hand and wrist. They may be exceedingly tender and often are transitory. Hoarseness secondary to rheumatoid-like vocal cord nodules has been described (101). These nodules are associated with patients who have SLE and rheumatoid-like arthritis and positive rheumatoid factor and rarely are seen without these features (102 ,103 ,104).

Histologically, subcutaneous nodules are granulomas and need to be differentiated from lupus panniculitis (profundus) (105), erythema nodosum, and a benign mesenchymoma. In children, it is important to distinguish them from granuloma annulare. Several reviews of the histology of the nodules in SLE have appeared (98 ,106 ,107). Vascular damage, with structural disarray in areas having collagen degeneration, is found, along with fibrinoid deposits and lymphocytic infiltrates in vessel walls. This microvasculopathy is similar to that observed in rheumatoid nodules.

Tendinitis, Tendon Rupture, Joint Laxity, and Carpal Tunnel Syndrome

Synovitis can induce a carpal tunnel syndrome, which may be the initial manifestation of idiopathic SLE or drug-induced lupus (108 ,109). Numerous reports and reviews have been published regarding tendon ruptures in SLE (110 ,111 ,112 ,113 ,114 ,115). The following conclusions can be derived: (1) almost all occur in weight-bearing areas, especially in tendons about the knee (65%; most are infrapatellar) and ankle (Achilles tendon; 27%); (2) an increased association with trauma, males, long-term oral steroid administration, intra-articular injections, Jaccoud deformity, and/or long disease duration is noted; and (3) most patients are in clinical remission at the time of rupture.

A definitive diagnosis can be made with magnetic resonance imaging (MRI) (116 ,117). Tendon biopsy specimens reveal degeneration, mononuclear infiltration, neovascularization, and vacuolar myopathy (118). One group has correlated hyperparathyroidism (especially in patients with severe renal disease) and hydroxyapatite and urate crystal deposition in the knee tendons, with resulting ligamentous laxity (119 ,120). Pritchard and Berney (113) observed 4 cases of tendon rupture (all patellar) in 180 patients followed over a 10-year period.

The Beighton criteria for joint laxity (hypermobility) is significantly more often fulfilled in SLE compared with controls, especially in those with longer standing disease (121).

Carpal tunnel syndrome was found in 48 (11%) of 436 patients with SLE seen at the University of Pittsburgh between 1972 and 1990 (122).

Calcinosis and Soft Tissue Swelling

Commonly observed in scleroderma, dermatomyositis, and crossover syndromes, soft-tissue calcifications rarely are seen in SLE (123 ,124). Calcinosis has been associated with trauma, pressure points, the TNF-α–308A allele, and subcutaneous edema. Lesions contain deposits of IL-6, IL-1, TNF-α, macrophages, osteocalcin, and bone matrix proteins (125 ,126).

They were observed radiographically in 9 of 130 patients in one study in which SLE was not adequately defined (127). Otherwise, approximately 30 case reports have appeared in the literature. Calcinosis universalis has been noted (128), and deposits of calcium phosphate in muscle, subcutaneous nodules, and periarthritis can occur in those with discoid or systemic lupus (129 ,130 ,131). Literature reviews are available (132 ,133). Periarticular radiographic calcification was present in 13.5% of 52 SLE patients, and was more common in patients taking diuretics (134). Diltiazem, which is a calcium channel blocker, is the probable treatment of choice (135 ,136). Aluminum hydroxide may be helpful (137), although surgical removal may be necessary (138 ,139). Soft tissue edema without calcinosis has been reported (140).

Chondritis

See Chapters 39 and 40 .

Osteoporosis

See Chapter 64 .

Costochondritis

Patients with SLE frequently complain of discomfort at the costochondral junctions. Esophageal spasm, angina pectoris, and pericarditis must be ruled out.

Myalgia, Myositis, and Myopathy

Generalized myalgia and muscle tenderness (Table 33-3), most marked in the deltoid areas and quadriceps (proximal muscles), are common during exacerbations of the disease and have been observed in 40% to 80% of patients (4 ,7 ,141). Muscle perfusion is diminished in SLE, either because of “Raynaud” of the muscles or accelerated atherogenesis (142).

Inflammatory myositis involving the proximal musculature occurs in 5% to 11% of patients (141 ,142 ,143 ,144 ,145) and can be confirmed by muscle biopsy, electromyographic (EMG) studies, and elevation of the serum creatine phosphokinase (CPK) or aldolase levels. Myoglobin levels also may be increased (145). The myositis responds to steroid therapy.

The differential diagnosis of proximal muscle weakness is a common problem in the management of patients with SLE. An inflammatory myositis must be differentiated from a drug-induced myopathy (glucocorticoid or antimalarial). Muscle enzyme levels are only elevated in the former group, but many untreated patients with SLE and myalgias have normal muscle enzyme levels. Frequently, generalized weakness is so prominent that some patients initially are diagnosed as having dermatomyositis (146). Inflammatory myositis can develop at any time during the course of the disease (147 ,148 ,149 ,150 ,151 ,152 ,153 ,154). Three large groups of dermatomyositis/polymyositis patients demonstrated a 7%, 4%, and 1% concurrence of SLE (155 ,156 ,157). The skin lesions of dermatomyositis/polymyositis also can appear in patients with SLE (150 ,151).

Table 33-3: Lupus Myositis and Myopathy in SLE

Myalgias occur in 40% to 80% of patients with SLE and are most marked in proximal muscles; weakness is a common symptom
Inflammatory myositis (often with an increased CPK level) has a cumulative incidence of 5% to 11%
Steroid- and antimalarial-induced myopathies must be excluded
EMG and muscle biopsy findings range from the normal to the classic patterns seen in dermato/polymyositis
Myalgias without myositis may respond to salicylates, NSAIDs, antimalarials, or 20 mg/d of prednisone or less
If diagnostic criteria are met for both SLE and dermato/polymyositis, treatment with 1 mg/kg/d of prednisone should be initiated

CPK, creatine phosphokinase; EMG, electromyogram; NSAIDs, nonsteroidal antiinflammatory drugs.

Tsokos et al. (158) evaluated 228 patients with SLE at the National Institutes of Health (NIH). Of these, 18 (8%) had prominent muscle disease. The CPK level was elevated in 1 patient, and the aldolase level was higher in 11. In 72%, myositis was concomitant with disease onset. No evidence of myocarditis was found, and all responded to 20 mg or less of prednisone daily. Very low CPKs may correlate with increased extra-muscular active lupus (159).

Foote et al. (160) followed 276 patients with SLE at the Mayo Clinic, and 11 met the diagnostic criteria for dermatomyositis/polymyositis. All were female, with a mean age of 29 years. In contrast to the NIH findings, the onset of myositis in these patients occurred 13 years after the onset of SLE. Also, Raynaud phenomenon was more prevalent in this group. The patients were treated with 30 to 60 mg of prednisone daily, and 1 was given azathioprine. After 4 years, 2 were dead and 6 asymptomatic. Isenberg et al. (161) compared 11 patients with SLE and myositis with 19 who had polymyositis. Over a 7-year period, both groups had chronic, relapsing courses and no differences could be noted. Lupus patients tended to have more cutaneous and articular disease (162).

Rhabdomyolysis has never been reported in SLE (163).

Two cases of inclusion body myositis in SLE have been found (164 ,174).

Electromyography

The principal EMG findings in polymyositis and dermatomyositis are (a) spontaneous fibrillation; (b) positive or sawtooth potentials; (c) small-amplitude, complex, polyphasic, or short-duration potentials; and (d) salvos of repetitive, high-frequency potentials. In patients with SLE, the EMG findings range from normal to those of classic dermatomyositis/polymyositis. Only four studies, however, have examined EMG findings in patients with SLE.

O'Leary et al. (165) found nonspecific EMG abnormalities in two of nine patients with SLE but in all with dermatomyositis. Erbsloh and Baedeker (166) performed EMGs on 15 patients with muscle symptoms, and their main findings were a decrease in mean potential duration to only 54% of normal, an increase in the mean phase frequency, and a corresponding decrease in the phase quotient. In only one patient were the findings normal. Tsokos et al. (158) performed EMGs on 8 of their 18 patients with SLE and myopathy. Of these, 5 had normal findings, neuropathy was demonstrated in 1, and the classic polyphasic peaks seen in polymyositis were noted in 2. In a study of 35 unselected patients with SLE, EMGs were suggestive of a myopathy in 23 (167). Also, 34 Norwegian patients with SLE underwent extensive neurophysiologic testing: 62% complained of muscle weakness, and 33% had any EMGs and 21% any nerve conduction abnormalities, neither of which correlated with symptoms (168).

Depending on various parameters, such as observer interpretation, whether an outpatient or inpatient population was used, and whether patients had muscle symptoms, between 22% and 90% of patients with SLE have abnormal EMGs (3 ,158 ,165 ,166 ,167).

Muscle Biopsies

Muscle biopsy findings (Fig. 33-2) range from normal to interstitial inflammation, fibrillar necrosis, degeneration, and vacuolization with fibrosis as a late occurrence seen with dermatomyositis/polymyositis. First used in the 1930s (165 ,169), muscle biopsies can be helpful in distinguishing inflammatory from drug-induced myopathies, as well as in determining reversibility based on the degree of fibrotic changes.

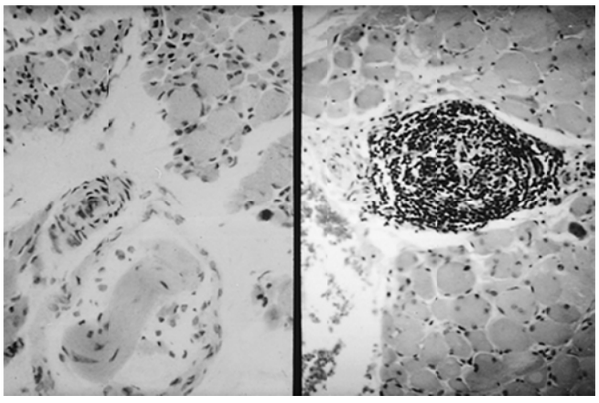

Figure 33-2. Lupus myositis.

Klemperer et al. (169) noted an inflammatory infiltrate in 5 of 30 cases of SLE, and Madden (170) noted the same in 6 of 21 biopsy specimens. The changes were nonspecific. Erbsloh and Baedeker (166) performed biopsies on 16 patients: 2 demonstrated impressive round cell infiltration, and 12 had parenchymal damage that occasionally included necrosis, along with a sparse interstitial infiltrate. Tsokos et al. (158) performed biopsies of 11 of 18 patients with SLE and myopathy: a mixed cellular, perivascular, and inflammatory reaction with interstitial inflammation without much muscle fiber degeneration was noted in 6 patients, and 5 had nonspecific changes or atrophy without inflammation.

Pearson (171) described muscle biopsies in 20 patients with various forms of SLE and noted rare, nonspecific fiber degeneration and interstitial myositis in 10 patients, no change in 3, and minor or insignificant muscle fiber vacuolization in 7 (4 taking steroids and 3 taking antimalarials). The vacuolar lesions were variable in extent and degree, sometimes being focal and scanty and on other occasions appearing widespread and extensive in individual fibers. These changes did not correlate with CPK levels, clinical measures of strength, or steroid administration. No vacuolar myopathy was noted among 16 biopsy specimens at the University of Toronto (172) and was seen in only 1 of 12 cases in another report (173). In the last few years, some centers have started performing less-invasive needle quadriceps biopsies. Lim et al. (175 ,176) also evaluated needle biopsy specimens from 55 patients with SLE. In these studies, lymphocytic vasculitis correlated with high sedimentation rates, inflammatory arthritis, and Sjögren syndrome. Subclinical skeletal muscle lymphocytic vasculitis was present in 10 of 22 patients with active lupus and was not seen with inactive disease. Staining muscle tissue for immune fluorescence revealed evidence for deposits in 37% of 132 European patients (177).

Three studies have included ultrastructural examinations. Oxenhandler et al. (178) evaluated the immunopathologic characteristics of lupus myopathy in 19 patients. Type I fibers predominated in 44%, and type II fiber atrophy was seen in 33%. Eight patients had an inflammatory myositis. Immunoglobulin or complement staining was seen in 13 patients in sarcolemmal-basement membrane areas, 5 had myofibrillar IgG, 5 showed vascular immunoglobulin or complement deposits, and IgG-containing globules were seen in 10. The University of Toronto group (172) emphasized the universality of immunoglobulin deposition in 16 SLE muscle biopsies, despite the rarity of concurrent inflammation. Finol et al. (173) emphasized the presence of muscle atrophy, microtubular inclusions, and a bland mononuclear cell infiltrate in 12 biopsy specimens; necrotic changes were only present in 1 patient, who had an elevated CPK level. This group confirmed earlier suggestions by Norton et al. (179 ,180) that the microvascular circulation of skeletal muscle is decreased

because of capillary basement membrane thickening. Pallis et al. (181) extended these findings and correlated thickening with impaired pulmonary gas exchange (as measured by diffusing capacity) and improvement with steroid therapy. Immunocytochemical studies have suggested increased levels of vascular cell adhesion molecule-1 (VCAM-1) in SLE muscle inflammatory infiltrates (182).

In summary, lupus myositis is mild and uncommon; drugs used to manage SLE can also damage muscles. Myalgias without frank myositis is often observed, and this may coexist or need to be differentiated from coexisting fibromyalgia.

Avascular Necrosis of Bone

Prevalence

First reported in SLE by Dubois and Cozen (183) in 1960, avascular necrosis (AVN), also known as aseptic necrosis or ischemic necrosis of bone, was observed in 26 (6) of Dubois' 520 patients (4), in 25 of Wallace's 464 patients (184), and in 24% to 30% of 150 and 103 patients at Johns Hopkins, which is an AVN referral center (185 ,186). Gladman et al. observed symptomatic AVN in 12.8% of 744 lupus patients followed at the University of Toronto between 1970 and 1985 (187). Other studies have noted AVN in 4% to 9% of patients with SLE (188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198). Asymptomatic AVN was noted on MR imaging in 6 of 30 Greek patients with primary antiphospholipid syndrome (199). AVN is a major source of morbidity and alteration in the quality of life in young women with lupus. This section reviews the pathophysiology, diagnostic testing, clinical presentation, and associations of AVN, as well as its treatment (Table 33-4). The reader is referred to an excellent review of 524 published studies on the subject (200).

Table 33-4: Avascular Necrosis (AVN) of Bone in SLE

AVN occurs in 5% to 10% of patients
Most cases are associated with corticosteroid administration; the remainder probably are induced by Raynaud's phenomenon, a small-vessel vasculitis, fat emboli, or the antiphospholipid syndrome
MRI is the diagnostic method of choice; CT and bone scans are less accurate and do not pick up preradiographic lesions as well; the radiographic appearance can be classified into four stages
Multiple sites can be affected; the femoral head, tibial plateaus, and humeral head are the most common
An association exists between AVN and Raynaud's phenomenon, increased steroid dosage, and duration of treatment
Treatment includes limiting weight-bearing, administration of antiinflammatory analgesics, and core decompression for stage I and II lesions; reconstructive surgery usually is required for stage III and IV disease

Pathophysiology and Classification

The usual mechanism is death of subchondral bone, resulting in osseocartilaginous sequestration with adjacent secondary osteosclerosis. The term osteochondritis dissecans has been used to refer to small areas of this process, such as disease involving a segment of femoral head or condyle.

The initial pathologic lesion probably is obliteration of the blood supply of the epiphysis, followed by reactive hyperemia, which is seen on the radiograph as osteoporosis. At this stage, the necrotic bone is radiographically demarcated from viable bone, because the dead tissue does not take part in the decalcification. By contrast, the necrotic area appears increased in density compared with the osteoporotic bone around it. During the healing stage, as new blood vessels grow in and bone repair occurs, the newly formed bone is soft. With continued pressure on the surface, flattening may occur (e.g., on the medial and superior aspects of the femoral head). These irregularities in the contour of the articular surfaces cause definite and consistent adaptive changes that are manifested later as degenerative arthritis.

AVN can have various types of causes (201 ,202): posttraumatic, nontraumatic, or idiopathic. Fractures, microfractures, or dislocations may cause AVN. Nontraumatic causes include embolic factors (e.g., as in sickle cell anemia, thalassemia, alcoholism, pancreatitis, and decompression states), small-vessel changes (e.g., as in SLE, polyarteritis, or Fabry disease), and deposition ischemic necrosis (e.g., increased lipocytes caused by steroid therapy, Gaucher disease, or Cushing disease). Renal transplant patients who receive pulse steroids and high doses of steroids are especially susceptible. Conditions that are associated with idiopathic AVN include gout, pregnancy, prolonged immobilization, cytotoxic therapy, hyperparathyroidism, familial tendencies, lymphoma, metastatic carcinoma, and degenerative arthritis.

In SLE, Raynaud phenomenon, vasculitis (203 ,204 ,205), fat emboli (206 ,207 ,208), corticosteroids, and defects in fibrinolysis (209) can induce ischemia that results in bony necrosis (210). Zalvaras and colleagues have correlated abnormal values of protein C, protein S, von Willebrand factor, lipoprotein A; factor V Leiden, 677C to T methylene-tetra-hydrofolate reductase, and prothrombin gene mutations with AVN (211 ,212 ,213). Eighty-two percent of 45 patients with AVN at Johns Hopkins had at least one procoagulant, which was significant compared with 30% in controls (214).

That no cases of AVN were recorded before 1960 indicates the importance of the introduction of corticosteroids in the 1950s in regard to our perception of this entity.

Ficat and Arlet (215) have classified AVN using a radiographic scale. In stage 0, only hemodynamic changes have taken place. The patient is asymptomatic, and routine radiographs are normal. In stage I, minimal pain with mild restriction of motion may be present. Stage II is characterized by a dull, aching pain on weightbearing, decreased range of motion, and a slight limp. Radiographs demonstrate

diffuse osteoporosis, sclerosis, or cyst formation. By the time that stage III is reached, advanced radiographic changes are evident, and the patient has taken a quantum leap in restricted movement and pain. Subchondral bone collapse (the crescent sign) with normal joint space is present radiographically. Stage IV represents end-stage disease with osteoarthritis, as seen on the radiograph. Most patients are symptomatic and require surgery.

Diagnostic Techniques and Hemodynamic Studies

MRI can detect AVN months to years before it is evident on routine radiographs (Fig. 33-3). This has made earlier, noninvasive methods of detecting AVN obsolete. MRI should be ordered for a patient with SLE who has hip pain and a normal radiograph if glucocorticoid therapy is being given. Plain radiographs are often unreadable and subject to marked observer variations (Fig. 33-4) (216). Gallium scans (193) and technetium scans with pertechnetate or sulfur colloid (217 ,218 ,219 ,220) generally are accurate but can be subject to false-positive or false-negative interpretation. Scintigraphic images of radiographically negative osteonecrosis tend to contain a photopenic zone, whereas more advanced lesions have increased uptake (221). Several studies have compared bone scanning with MRI (222 ,223 ,224 ,225 ,226 ,227); the latter has better specificity and sensitivity, but both procedures can yield false-positive findings. Although computed tomography (CT) with multiplanar reformation (228) can be useful, MRI derives the same, or more, information with less effort and without exposing the patient to radiation.

On MRI, the reactive interface between live and dead bone at the periphery of AVN lesions has a characteristic double-line sign on T2-weighted images (229). A low-intensity band on T1-weighted images is an early, specific finding for AVN (230). Early changes at the femoral head can demonstrate bone marrow edema (231), and premature conversion to fatty marrow is evident in younger patients. In AVN, the femoral neck usually is surrounded by joint fluid. These findings have been confirmed in patients with SLE (222 ,225 ,232 ,233). Interestingly, the advent of MRI has allowed investigators to detect cases of incidental, asymptomatic, and nonprogressive AVN (259).

Figure 33-3. Avascular necrosis of the hip: plain film.

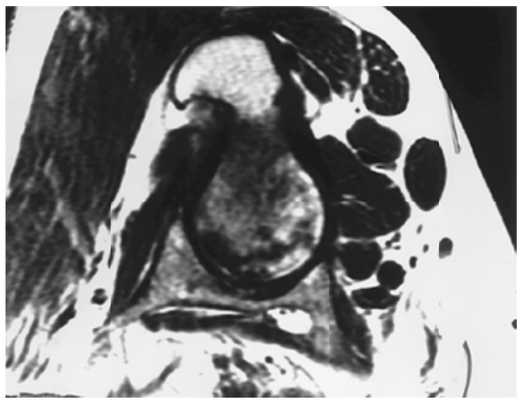

Figure 33-4. Avascular necrosis: T1-weighted magnetic resonance imaging.

Zizic et al. (234 ,235) at Johns Hopkins used invasive techniques to obtain more information about the hemodynamics of AVN. They found increased baseline bone marrow pressure in most patients with SLE after carrying out a stress test (a greater than 10 mm Hg elevation after instillation of 5 mL of physiologic saline into the femoral head). Almost 90% of patients had abnormal intraosseous venography, as characterized by incomplete filling of the main extraosseous veins, diaphyseal reflux, and stasis of contrast material. Venography was abnormal in all stages of AVN, including preradiologic ones. In a follow-up study (236), bone marrow pressure, saline stress test, and/or ischemic intraosseous venography results were abnormal in 254 of 259 ischemic bones (98%) so evaluated, and AVN was detected in 93% of 55 radiologically normal bones. Using these parameters, 36 of 48 joints on the contralateral asymptomatic side had abnormalities, and 15 patients (42%) developed AVN over a 47-month follow-up period. Thus, hemodynamic measurements are of predictive value in identifying the at-risk joints (237), but this procedure is not widely available. Femoral head perfusion is decreased in lupus in general without AVN as a result of greater marrow fat content (238).

Clinical Associations in SLE

In SLE, AVN tends to occur at multiple sites. At the NIH, 90% of 31 cases were polyarticular, and 84% were symmetric (239). Of Dubois' 26 patients, 22 had bilateral femoral head involvement, 1 had unilateral involvement, and 3 had affected knees (240). Zizic et al. (241 ,242 ,243) reported that 91 cases involved the femoral head and 83 occurred in

multiple sites. Reports have appeared of 6, 8, 13, and even 28 different sites in a single patient (244 ,245 ,246 ,247 ,248). Although the hip is the most common site, AVN can involve other joints and often results in a delay in diagnosis. Three of 11 University of Connecticut patients studied by Urman et al. (195) had AVN of the wrist. Most studies have recorded a mean onset of AVN in the fourth decade of life, with an average SLE disease duration of 4 to 7 years (106 ,249).

The diagnosis of AVN should be considered in any patient with SLE who has persistent pain in one or a few joints without evidence of disease activity in other systems, especially if glucocorticoids have been given. The association between vasculitis and AVN in the absence of steroid administration is well documented (203 ,204 ,205). Many studies have addressed the role of corticosteroids in inducing AVN in those with SLE, but early studies were hampered by control groups in which AVN was excluded based on normal radiographs (249 ,250). It has been suggested that increased doses of steroids (especially in the first year of treatment) and the duration of steroid therapy are correlated with a greater risk of AVN in SLE patients (241 ,242 ,251 ,252 ,253). Bolus steroids were not similarly associated (254 ,255). These dose-time relationships were confirmed in a meta-analysis of 22 papers (most patients without SLE) by Felson and Anderson (256), although this confirmation has been challenged (257). The clinical associations observed by our group are shown in Table 33-5 (258). Mok et al. (259) performed a similar survey and found many of the same associations.

SLE also has additional unique features that might predispose a patient to the development of AVN. Zizic (262) and Smith et al. (194) have both commented on the comparative rarity of AVN in steroid-dependent populations of patients with asthma, dermatologic disorders, and inflammatory bowel disease. AVN was found to be associated with Raynaud phenomenon, central nervous system (CNS) lupus, vasculitis, myositis, peripheral neuropathy, and elevated sedimentation rates (251 ,260 ,261). Others have only been able to suggest the association with Raynaud phenomenon (191 ,194).

Does the presence of antiphospholipid antibodies predispose the patient to AVN? Since Asherson et al. (263) originally made the suggestion based on older and less accurate methods of detection, two studies have concurred with this finding (219 ,259) and seven have not (198 ,238 ,258 ,264). The Hopkins cohort has published studies with conflicting results (186 ,265 ,282). It is possible that antibodies to annexin-V may be important (266), and an excellent critical review of this controversy has been published (267).

Treatment

Small areas of AVN can remain asymptomatic or heal spontaneously. Rare reports of spontaneous regression have appeared (268), but most patients with a clearly established diagnosis experience progressive disease if they are treated nonoperatively. Conservative management often is a holding action (especially in the hips) and consists of analgesics, nonsteroidal antiinflammatory drugs (NSAIDs), and limited or nonweightbearing for several months (269). Alcohol use should be discouraged, and efforts to decrease steroid doses should be attempted. Early stage disease may improve spontaneously if the necrotic area is small. Among 99 AVN patients followed in Toronto with 217 affected joints, there was no increase in mortality but increased disability (187).

A number of surgical techniques have been used successfully with AVN of the femoral head, including drilling or core decompression, free bone grafts (cortical or osteochondral allograft), vascularized bone grafts (muscle pedicle graft, free vascularized fibular graft, vascular anastomosis), osteotomy (varus or valgus angulation, rotation), and joint reconstruction (femoral head or total hip replacement) (269 ,270 ,271). Other joints are approached in a conceptually similar manner. The discussion here is limited to results that have been reported for SLE.

Early series documented excellent results with total hip replacement (272 ,273). Between 1971 and 1982, 39 of 43 prosthetic hip replacements performed at the Mayo Clinic on patients with SLE were for stage III or IV AVN (274). Of these, 29 patients had conventional hip replacements, and 14 had bipolar endoprosthetic replacements. Over a 66-month follow-up period, all were rated as having good or excellent results. Complications included delayed wound healing (15%) and superficial wound infection (10%). In our group, all seven patients who underwent total hip arthroplasties with at least a 10-year follow-up reported excellent results (258). Success rates are equal to patients with AVN and rheumatoid arthritis (277). Other groups also have reported greater than 90% long-term success rates (275 ,276 ,277). Joint arthroplasty in SLE has not been associated with increased rates of infection or lupus flare risks (278). Total knee arthroplasty for corticosteroid associated AVN yielded excellent results in only 11 of 25 patients treated at Johns Hopkins (186).

Whereas few disagree about the management of stage III and IV AVN, the indications for core decompression in earlier stages are controversial. First reported by Zizic et al. (234 ,280) as removal of an 11-mm diameter core of bone from the central axis of the femoral head, success was claimed in treating stages I, II, and III disease. Two studies of SLE failed to confirm these findings (175 ,214), however, and our results at UCLA Medical Center have been mixed. Zizic's (262) review of the literature (including other diseases) suggests a 77% success rate for preradiologic disease and a 52% success rate for stage II AVN. At Johns Hopkins, 68% of 31 patients undergoing core decompression for AVN required total hip replacements over a mean 12-year follow-up period (279). The coring procedure probably is not indicated for patients with stage III or IV disease.

In summary, AVN is a painful and debilitating complication found in 5% to 10% of SLE patients. It is usually associated with corticosteroid use, may be associated with a coagulopathy and responds to surgical interventions.

Table 33-5: Comparisons between Systemic Lupus Erythematosus Patients with and without Avascular Necrosis (AVN)

Characteristic	Percentage[a] of Patients with AVN (*n* = 26)	Percentage[a] of Patients without AVN (*n* = 462)	*p* value[b]
Female	96.15	93.29

Chapter 34

Cardiovascular Manifestations of Lupus

Kathleen Maksimowicz-McKinnon

Susan Manzi

Cardiovascular Manifestations of SLE

The cardiovascular (CV) system shares the same vulnerability as other systems to the immunologically mediated processes in SLE that result in organ damage and dysfunction. Manifestations of cardiovascular disease (CVD) from SLE range from asymptomatic findings to life-threatening disease, and include pericardial disease, myocardial dysfunction, conduction system abnormalities, valvular heart disease, and premature atheromatous disease with its associated morbidity and mortality. Some of these emerging comorbidities are a consequence of better disease therapy; half a century ago SLE patients with organ-threatening disease did not live long enough to experience these manifestations. Advances in technology have provided the means for earlier and better detection of these conditions, but we are still in the process of delineating their mechanisms and designing directed interventions toward their reversal and prevention.

Pericardial Disease

Epidemiology and Pathogenesis

Pericarditis is the most common clinically diagnosed CV manifestation of SLE. The prevalence of pericardial disease is reported from 16% to 61%, depending on the criteria chosen to establish the diagnosis (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12) (Table 34-1). Echocardiographic evidence of pericardial thickening or effusion is detected in 18% to 54% of SLE patients (4 ,5 ,6 ,7 ,8 ,9 ,10 ,11), whereas pericardial disease at autopsy has been reported in up to 61% (1). Symptomatic pericarditis is less common but has been estimated to occur in about 25% of patients with SLE.

Clinical Presentation and Diagnosis

Symptoms of acute pericarditis include positional chest pain, often worse when supine or with inspiration (pleuritic), and located in the precordium or substernal region. Other associated symptoms include, fever, dyspnea, and tachycardia. Clinical signs may include decreased heart sounds, a pericardial rub, hypotension, or pulsus paradoxus (an exaggeration of the normal respiratory variation of the pulse, becoming weaker with inspiration and stronger with expiration). Diagnostic testing that may be useful in substantiating the diagnosis of acute pericarditis includes electrocardiography (ECG), chest radiography, and echocardiography. ECG findings in acute pericarditis include PR segment depression and widespread, upwardly concave ST segment elevation. T-wave inversions usually occur several days into the clinical course. Electrical alternans and reduced QRS voltage are most often seen when large effusions are present. Chest radiographs may reveal an enlarged cardiac silhouette when an effusion is present, and pericardial fat lines may be visible. Echocardiography is the most common method used to confirm the diagnosis of pericardial disease because of its high sensitivity and specificity. Additionally, this noninvasive technique can grossly estimate the amount of pericardial fluid, and also identify findings such as the loss of collapse of the inferior vena cava during inspiration and the right ventricle during diastole that are indicative of pericardial tamponade. In some patients, right heart catheterization is necessary to confirm a diagnosis of tamponade. Computerized tomography (CT) and magnetic resonance imaging (MRI) studies are frequently utilized in the evaluation of chronic pericardial disease, and may be helpful in identifying pericardial thickening and constrictive pericarditis.

From a practical standpoint, the diagnosis of pericarditis is most often made clinically, based on characteristic symptoms and physical examination findings. However, other disorders can mimic acute pericarditis and should be considered in this setting, including pneumonia, pulmonary embolism, infection, myocardial infarction (MI), and aortic dissection.

Treatment

Symptomatic pericarditis may respond to therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), particularly in mild cases. However, if the symptoms are severe or refractory to NSAIDs, corticosteroid therapy (20 to 40 mg/day prednisone or equivalent) is usually effective. Pericardiocentesis and/or pericardial window is necessary in the setting of a pericardial effusion that causes hemodynamic compromise or in patients with severe refractory symptoms associated with the effusion. Pericardial effusions in SLE are generally inflammatory, with an elevated leukocyte count and a predominance of polymorphonuclear leukocytes. The fluid is exudative, with elevated protein levels and normal to low glucose. Effusions may be serosanguineous or overtly

hemorrhagic, and may test positive for antinuclear (ANA) and double-stranded DNA antibodies, and LE cells. It should be noted that ANA testing of pericardial fluid may be positive in other etiologies of pericarditis, such as tuberculous and neoplastic disease, which prohibits these autoantibodies from providing significant diagnostic utility (13 ,14).

Table 34-1: Pericardial Disease in SLE

Author	Year	Patient #	Prevalence (%)	Diagnostic Modality	Comment

Jouhikainen et al. (10)	1994	74	22	Echo	Consecutive patients
Kalke et al. (11)	1985	54	18	Echo	
Houman et al. (12)	2004	100	16	Not available	Retrospective analysis

Pericardial effusions may also occur in SLE patients from other comorbid conditions, including uremia, nephrotic syndrome, hypothyroidism, and infection. In this setting, treatment of the underlying condition is the most appropriate management. Asymptomatic pericardial effusions are frequently detected in SLE, but it is unclear whether these represent a benign manifestation or indicate early disease activity that will progress to clinically manifest disease. There currently are no data to support treatment of asymptomatic, hemodynamically insignificant pericardial effusions in patients with quiescent disease.

Pericardial thickening may occur from recurrent episodes of pericarditis. Although rare, chronic pericardial disease can result in constrictive pericarditis, which may require pericardial stripping.

Prevention

There are no specific measures targeting the prevention of pericardial disease. However, treatment and control of disease activity may help decrease its incidence. In patients with end-stage renal disease, maintaining regular dialysis with good clearance is important in preventing uremia-associated pericardial effusions.

Myocardial Dysfunction

Epidemiology and Pathogenesis

Impaired myocardial function has been reported in 5% to 64% of SLE patients, and is frequently associated with comorbidities such as hypertension and ischemic heart disease (7 ,8 ,11 ,15 ,16 ,17 ,18 ,19) (Table 34-2). Abnormalities in both systolic and diastolic function have been detected, as well as an abnormal response to exercise. del Rio et al. demonstrated that SLE patients have decreased left ventricular ejection time and a longer pre-ejection period when compared with controls (20). One study of 5 SLE women without any clinically evident cardiac disease undergoing cardiac catheterization demonstrated increased wall stiffness, decreased pump function and contractility, and diminished coronary artery reserve (15).

As with pericardial disease in SLE, differences in prevalence of myocardial abnormalities reflect the methods of detection. The studies reported in Table 34-2 include those demonstrating myocardial dysfunction that may arise from various etiologies; autopsy studies are most likely to reliably represent inflammatory disease of the myocardium. Since numerous factors can lead to transient and sustained myocardial depression, it is unclear how often SLE-associated myocarditis is the lone cause of this condition. Wijetunga et al. noted that clinically apparent myocarditis in SLE occurs on average in 9% of patients (combined studies) (19). Autopsy studies attest that subclinical myocarditis may occur more frequently, with a reported prevalence as high as 57% in combined studies from the presteroid era. Since the introduction of glucocorticoid therapy, however, combined series report prevalence as low as 7%. It has been hypothesized that myocarditis in SLE arises from an immune-complex mediated process, in which complement activation and inflammatory cytokine activity orchestrate damage to myocardial vessels, rather than a primary myopathic disorder. Circulating autoantibodies have been examined in the context of myocarditis in SLE, but no consistent or specific association has been found. Myocarditis can result in global myocardial depression from necrosis and

fibrosis of myocytes, or in conduction system disturbances from inflammatory and degenerative changes in conduction tissues.

Table 34-2: Myocardial Dysfunction in SLE

Author	Year	Patient (#)	Prevalence (%)	Diagnostic Modality	Comment

Although SLE-associated myocarditis may lead to cardiomyopathy and impaired ventricular dysfunction, a number of other more commonly occurring conditions should be considered prior to this diagnosis. Ischemic heart disease, often an afterthought when evaluating premenopausal females, should be considered immediately in the setting of abnormal myocardial function in SLE. Valvular stenosis or insufficiency may also result in dilated, poorly contractile chambers and congestive heart failure. Pulmonary embolism and pulmonary hypertension can lead to impaired ventricular function and right-sided heart failure. Long-standing hypertension is another common cause of ventricular dysfunction.

Chloroquine-associated cardiomyopathy occurs in SLE infrequently. The English literature reports less than 20 cases, with fewer than half of these biopsy-proven (21). Other manifestations of cardiotoxicity from antimalarial agents include atrial and ventricular conduction system disorders. Lysosomal disruption, a mechanism purported to have an important role in the beneficial effects of antimalarial therapy in rheumatic disorders, is considered a possible factor in its associated cardiotoxicity. Animal studies have demonstrated both acute and chronic adverse cardiac consequences of chloroquine use, including depressed contractility, conduction abnormalities, and myocardial necrosis and fibrosis (22 ,23 ,24 ,25).

Clinical Features and Diagnosis

The diagnosis of myocardial dysfunction in SLE is usually considered based on clinical signs and symptoms, but is not one that can be established solely by clinical means. The manifestations of lupus-associated myocardial dysfunction are not specific for lupus, but are reflective of the degree of myocardial dysfunction. Symptoms and signs include fatigue, dyspnea, tachycardia, cough, orthopnea, paroxysmal nocturnal dyspnea, and pleural effusions. The cardiac examination may be unremarkable in patients with mild disease. More severe cases can manifest with jugular venous distention, peripheral edema, murmur, or overt congestive heart failure. Electrocardiographic changes may include nonspecific ST-T changes, premature atrial or ventricular complexes, dysrhythmias, or conduction abnormalities. In lupus myocarditis, patients may present with asymptomatic disease, detected only by ECG changes, or with a clinical picture mimicking acute MI with chest pain, ECG changes, and elevated cardiac enzymes.

Diffuse myocardial dysfunction can result in global chamber dilatation, and may appear as cardiomegaly with or without pulmonary edema on chest radiograph. Echocardiographic findings in myocarditis include prolonged relaxation time, decreased deceleration of early diastolic flow velocity, reduced E/A ratio (filling of left ventricle in early vs. late diastole), and increased chamber size. Echocardiography is a rapid and noninvasive means of diagnosing impaired myocardial function, but other

modalities such as functional nuclear imaging studies and cardiac catheterization can also be useful in diagnosis. Since SLE may be associated with a number of other conditions leading to the generalized impairment of myocardial function, such as hypertension, coronary artery disease (CAD), medication effect, and infection, it may not always be possible to readily identify SLE-associated myocarditis as the culprit of myocardial dysfunction. It is imperative that the underlying etiology of myocardial dysfunction be sought. Heart failure from severe valvular insufficiency would require a different therapeutic approach than heart failure from three-vessel obstructive CAD or from SLE-associated myocarditis.

The presenting signs and symptoms of chloroquine-associated myocardial dysfunction are those of congestive heart failure, with or without associated dysrhythmia. Imaging studies are useful in demonstrating depressed myocardial contractility, but are nonspecific. The small numbers of patients who are affected by chloroquine-associated cardiomyopathy prohibit reliable identification of its risk factors, but analysis of the limited data suggests that its risk factors are the same as for retinal toxicity: older age, higher dose per unit body weight, and duration of therapy (25).

Other means of diagnosing myocarditis are also being investigated, including echocardiographic evaluation of diastolic function (purported to be an early sign of myocarditis), myocardial gadolinium uptake on citrate scintigraphy, and MR imaging to evaluate myocardial enhancement and relaxation (11 ,26 ,27). None of these diagnostic methods are specific for SLE-associated myocardial dysfunction.

Although myocardial biopsy may be supportive of the diagnosis of lupus myocarditis when an immune-mediated process is identified, findings may be nonspecific, demonstrating inflammatory cell infiltration, immunoglobulin deposition, fibrinoid necrosis, or fibrosis and scarring. Myocardial biopsy also is fraught with potential technical problems including small tissue specimen size, sampling error, subjective pathologic interpretation of findings, and no well-established sensitivity and specificity for biopsy findings (28). A study of 845 patients examining the role of myocardial biopsy in diagnosing unexplained cardiomyopathy demonstrated that biopsy provided increased sensitivity over clinical diagnosis (100 vs. 66%), but did not improve specificity (86 vs. 87%) (29). Seven SLE patients were part of this study; in six patients, the diagnosis was made by clinical and laboratory evaluation prior to biopsy (the diagnosis of the seventh patient was also established by an unspecified diagnostic evaluation noted as “other interventions”). Unless circumstances are extenuating, biopsy is not frequently performed for this diagnosis alone. A diagnosis of myocarditis in the setting of myocardial dysfunction is generally reserved for cases where other etiologies have been excluded.

The high frequency of cardiac involvement in SLE from disease-associated processes makes the diagnosis of chloroquine-associated cardiomyopathy one of exclusion, with myocardial biopsy the only means of definitive diagnosis. The histologic abnormalities associated with chloroquine cardiotoxicity include myocyte necrosis and fibrosis, myeloid bodies, curvilinear bodies, and intracytoplasmic vacuoles (30 ,31 ,32). These histopathologic findings were also noted in the animal studies and appeared to be dose-related. The presence of myocyte necrosis and fibrosis implies some permanent consequences to affected tissues; however, patients often have significant clinical improvement and reversal of myocardial dysfunction upon discontinuation of antimalarial therapy. Unfortunately, as with lupus myocarditis, biopsy findings may be nonspecific and fail to establish the suspected agent as the precipitating factor even when this disorder is present. Other more common etiologies, such as ischemic heart disease or infection should be investigated prior to making this diagnosis.

Treatment

The treatment of myocardial dysfunction and heart failure in SLE should be focused upon its cause. For example, dysfunction arising from ischemic heart disease might require medical or operative intervention to improve myocardial oxygen supply and decrease metabolic demand. Treatment of congestive heart failure arising from uncontrolled hypertension would include intensive blood pressure control. Heart failure not readily attributable to other causes and thought to be from SLE-associated disease activity would require immunosuppressive therapy. In patients with irreversible, significant left ventricular failure, anticoagulation therapy may be considered for prevention of thromboembolic disease (33). Moderate to severe left ventricular dysfunction is associated with cardiac dysrhythmias and also with sudden cardiac death (34). Any SLE patient with impaired myocardial function with signs and symptoms of or with an established dysrhythmia should be considered for Holter monitoring to detect potentially lethal arrhythmias.

SLE-associated myocarditis is generally treated with systemic glucocorticoids, usually beginning with high dose or pulse intravenous therapy followed by several weeks of oral therapy, based on clinical response and other disease manifestations. Although no immunosuppressive agents have been studied in controlled trials in SLE myocarditis, case reports of therapy with agents such as azathioprine, intravenous immunoglobulin, and cyclophosphamide suggest that these agents may also be beneficial (35 ,36 ,37). Clinical manifestations usually improve significantly with therapy, and often resolve. In patients with clinical signs and/or symptoms of congestive heart failure, standard therapy, including sodium and fluid restriction, diuretics, inotropic agents (e.g., digitalis), and afterload reducing agents may provide significant abatement of symptoms. However, afterload reduction should be avoided in patients with hemodynamically significant aortic stenosis, and angiotensin-converting enzyme (ACE) inhibitors should be used cautiously in patients with renal insufficiency. Patients with stable myocardial dysfunction (i.e., not in

overt congestive heart failure) may also benefit from the use of beta-blocking agents; these should be initiated at a low dose and under close surveillance. Conduction system involvement associated with myocarditis resulting in dysrhythmias may require anti-arrhythmic therapy, anticoagulation, or, in severe cases, placement of an automated implantable cardiac defibrillator.

Discontinuation of the agent with clinical and echocardiographic improvement suggests, but does not establish, the diagnosis of chloroquine cardiomyopathy. Biopsy may be required in patients with severe myocardial dysfunction, or in those who fail to improve upon discontinuation of the agent.

Prevention

Myocardial dysfunction may arise from numerous etiologies in SLE. Preventative measures should focus on maintaining suppression of disease activity, to diminish the likelihood of immunologic injury to the myocardium and associated structures. Since ischemic heart disease is a common cause of myocardial dysfunction, screening for and intensive management of CV risk factors is important to decrease the risk of ischemia-related dysfunction. The potential benefits of antimalarial therapy in SLE far outweigh the risks of use in the great majority of patients. These agents are a rare cause of this condition, which implies that other more common conditions should be considered first.

Conduction System

Epidemiology and Pathogenesis

Conduction system abnormalities have been described in SLE, affecting from 10% to 74% of patients depending on the definition of abnormality, when the study was performed, and if underlying CVD is present (5 ,9 ,38 ,39 ,40) (Table 34-3). Low grade (first- and second-degree blocks) are more commonly reported, while high-grade or complete heart block occurs rarely. Intraventricular (bundle branch) conduction abnormalities have also been noted. Conduction system abnormalities more often occur in young and middle-aged SLE women, and in patients with a longer duration of disease. Conduction system defects may be transient, or may persist and progress from limited to more widespread involvement.

Table 34-3: Conduction System Abnormalities in SLE

Author	Year	Patient (#)	Prevalence (%)	Diagnostic Modality	Comment
Shearn (38)	1959	73	62	ECG	
Hejtmancik et al. (39)	1964	137	52	ECG	
Badui et al. (5)	1985	100	74	ECG	Any abnormality

Logar et al. (40)	1990	67	10	ECG	Conduction defect 6/7 anti-Ro antibody +
Sturfelt et al. (9)	1992	54	17	ECG	Any abnormality

Conduction system involvement in SLE has been attributed to both immune-mediated injury to the conduction tissues and to the small vessels of the myocardium. In patients with CAD, it may be difficult to discern whether the conduction defects arise from ischemic insult or disease-associated inflammation of the myocardium. Although neonatal heart block in children of women with SSA/anti-Ro antibodies is well established, this relationship does not appear to be as strong in adults with the autoantibody. The anti-U1RNP antibody has also been associated with derangements of the conduction system in SLE (41).

Clinical Features and Diagnosis

Patients with conduction system abnormalities may be asymptomatic, or may have symptoms such as weakness, syncope, and heart failure with higher grade or intraventricular blocks. Electrocardiography is the usual means of detecting conduction system abnormalities. Exercise testing may also reveal atrioventricular block in patients with acquired conduction system disease. It is important to evaluate for other causes of conduction system disease, such as drugs or ischemia, before attributing disease to lupus activity alone.

Treatment

Asymptomatic patients with well-controlled disease, a negative evaluation for other etiologies, and low-grade block may only need close observation. Higher-grade block with or without symptoms frequently requires intervention. Long-standing involvement with tissue inflammation and immune complex deposition may lead to conduction system fibrosis, which can be irreversible. Medical therapy or pacemaker implantation may be needed to maintain hemodynamic stability.

Valvular Heart Disease in SLE

Epidemiology and Pathogenesis

Valvular heart disease is prevalent in SLE, with abnormal echocardiographic findings reported in 21% to 61% of patients

(7 ,8 ,9 ,10 ,16 ,18 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49) (Table 34-4). The classic valvular abnormality associated with SLE is Libman-Sacks endocarditis, which is characterized by noninfectious verrucous vegetations that may be found on any or all valves. Libman-Sacks endocarditis most commonly manifests as valvular thickening, noted in 51% of 61 patients in a study of valvular heart disease in SLE (18). An autopsy series of 36 SLE patients noted the presence of Libman-Sacks lesions in 50% of cases (3). Other reported abnormalities that contribute to the prevalence figures in Table 34-1 include valvular stenosis and insufficiency.

Table 34-4: Valvular Heart Disease in SLE

Author	Year	Patient (#)	Prevalence (%)	Diagnostic Modality	Comment

Leszczynski et al. (48)	2003	52	35	Echo	Valvular abnormality
Morelli et al. (49)	2003	71	43	Echo	Valvular abnormality

Valvular abnormalities are commonly associated with the antiphospholipid antibody syndrome (APS). This relationship was initially described in the late 1980s, when several published reports identified the presence of valvular heart disease in patients with known antiphospholipid antibodies (aPL) (50 ,51). During this time period, the association between anticardiolipin antibodies and the presence of CV abnormalities in SLE patients was also identified (52 ,53). An early case series of 11 patients detailed a syndrome consisting of aPL, recurrent thrombosis, valvulitis, and thrombocytopenia (54). These patients also had associated valvular insufficiency, with two having multiple valves affected. Although there has been speculation that aPL may be the primary etiology of valvular heart disease in SLE, data supporting this view has been inconsistent and suggests that other factors are involved in the pathogenesis of SLE-associated valvular lesions. Data supporting the role of aPL contributing to valvular disease was reported by Leszczynski et al., who evaluated 52 SLE patients and compared echocardiographic findings with those of 34 healthy controls (48). SLE patients more frequently had valvular abnormalities than healthy controls (35% vs. 6%). They also found that anticardiolipin antibodies were strongly associated with valvular heart disease, detected in 77% of the SLE patients with valvular disease. Another study of 93 SLE patients suggested that the influence of aPL on cardiac disease might go beyond valvular dysfunction. Fifty patients (54%) had elevated levels of anticardiolipin antibodies. Of these 50 patients, 40 (78%) had at least one cardiac abnormality including valvular disease (20), pericardial effusion (15), and myocardial dysfunction (5 ,8). However, data from Gleason et al. comparing primary APS patients with SLE patients (aPL negative) and healthy controls demonstrated no statistically significant difference in the prevalence of cardiac valvular disease among the patient groups (APS vs. SLE) (45). Gabrielli et al. compared the prevalence of valvular heart disease in a group of SLE patients with primary APS patients (46). Thirty-nine percent of SLE patients had valvular abnormalities, compared with no patients in the primary APS group. Among the patients with SLE there was no significant association between the presence of aPL and valvular disease. Although aPL are unlikely to be the sole pathogenic factor in valvular disease in SLE, the high prevalence of valvular

disease in both primary APS and in SLE patients with aPL implicates their role in valvulopathy.

Libman-Sacks lesions were initially reported most often affecting the tricuspid valve, but more recently have been noted to preferentially occur on the mitral valve (7 ,18 ,48 ,55). Similarly, valvular lesions in aPL-associated valvular disease more commonly occur on the valves of the left heart (16). Valvular lesions can affect valve leaflets, rings, and commissures; less often the chordae tendinea, papillary muscles, and endocardium. These lesions are visually indistinguishable from vegetations caused by infectious organisms, but have a more distinctive histopathologic appearance. In addition to proliferating and degenerating cells and fibrin, Libman-Sacks verrucae contain fine granular material composed of hematoxylin bodies and immunoglobulin deposits (56 ,57). Valvular disease associated with aPL is similar to Libman-Sacks lesions, both in gross morphology and in histopathologic appearance. A study comparing valvular specimens of primary APS patients with secondary APS patients demonstrated linear subendothelial deposition of immunoglobulins with complement components in both groups (58). These changes were not noted in any of the normal valve specimens. In both groups, anti-idiotypic antibody to anticardiolipin was detected in the same location with the same pattern of staining. aPL-associated valvulopathic changes probably represent part of the spectrum of Libman-Sacks endocarditis, but comparative systematic histopathologic studies to support this assertion are lacking.

The pathogenesis of Libman-Sacks endocarditis has not been clearly elucidated, however, several mechanisms have been considered. It has been assumed that the lesions are initially formed by fibrin-platelet thrombi that propagate and lead to structural deformation of the valve and associated structures, resulting in valvular dysfunction. However, this does not address what the inciting insult is to the valvular structure that leads to the development of these lesions. The presence of complement and immunoglobulin deposition in Libman-Sacks lesions has been postulated as evidence for a role of immunologic injury, perhaps related to immune complex formation associated with disease activity.

The pathogenic mechanisms of APS-associated valvular disease are not well understood. The presence of immunoglobulins and complement components in verrucous valvular lesions again implies an immune-mediated process (58). Furthermore, the presence of anticardiolipin antibodies in the immunoglobulin deposits suggests either a direct immunologic interaction with valvular tissue or secondary participation following a primary immunologic response elicited by another pathogenic source. Additionally, there are inflammatory changes noted in the valvular lesions associated with APS (59). These findings suggest that aPL contribute more than just a prothrombotic milieu.

Clinical Features and Diagnosis

The clinical presentation of Libman-Sacks endocarditis may be indistinguishable from that of infective endocarditis. Patients may manifest with fever, anemia, tachycardia, splinter hemorrhages, and other embolic phenomena. Murmurs are neither sensitive nor specific for Libman-Sacks endocarditis. Although more frequent in infective endocarditis, patients with Libman-Sacks may also develop hemodynamic changes from chordae tendinea rupture or papillary muscle or valve ring involvement. Echocardiography may reveal verrucous lesions, but they cannot be distinguished from infective vegetations or thrombotic lesions reliably on the basis of appearance. As in infective endocarditis, transesophageal echocardiography is more sensitive for detecting the presence of valvular vegetations in SLE and should be employed in SLE patients in whom valvular disease is suspect when transthoracic echocardiography is unrevealing. The presence of disease activity also is not specific for Libman-Sacks endocarditis, since disease activity and infection often occur simultaneously. Additionally, infectious and/or thrombotic valvular lesions can occur concurrently with Libman-Sacks lesions. The critical aspect in evaluation of valvular lesions in SLE is to identify other causes that would merit therapy other than treatment of SLE.

Although initially thought to have minimal clinical consequences, conflicting data exists regarding outcomes of Libman-Sacks endocarditis. One large retrospective analysis determined that only 3% to 4% of patients had clinically significant valvular dysfunction, with 1% to 2% requiring surgical intervention (43). A small prospective study had less optimistic findings; 18% of SLE patients were found to have clinically significant valvular dysfunction, with 8% requiring surgery (42). Roldan et al. detected valvular vegetations in 43% of patients, while valvular insufficiency and stenosis were noted in 25% and 4% respectively (18). In this study, valvular disease was not related to clinical disease features, age, disease duration, disease activity or severity, or disease therapy. Upon followup imaging, valvular vegetations were not static in most patients, with both the appearance of new vegetations and disappearance of prior vegetations noted. By a mean of 57 months of follow-up, 21% of patients developed complications of valvular disease including stroke, peripheral embolism, congestive heart failure, and infective endocarditis. Another study evaluating the consequences of left-sided heart valve abnormalities (thickening, regurgitation, stenosis, prolapse) followed 71 SLE patients over a mean period of 5.8 years (49). At baseline, 43% had evidence of left-sided valve involvement on transthoracic echocardiography. In the 40 patients who received followup echocardiographic studies, new valvular disease was present in 5 patients, worsening of valvular disease in 5 patients, and stable disease in 10 patients. Twenty-six percent suffered ischemic strokes during the study period. The odds ratio was 10.84 for the association of left-sided valvular disease with ischemic cerebrovascular events. Jensen-Urstad et al. demonstrated that valvular abnormalities might also be associated with the presence of CVD in SLE (47). In a study of 26 SLE women with CVD (cases), 26 SLE women without CVD (controls), and 26 healthy women, thirteen

SLE cases had valvular abnormalities as compared to one SLE control and one healthy control. Valvular abnormalities in the cases were associated with higher levels of serum triglycerides and homocysteine.

Valvular dysfunction requiring surgical repair or replacement has also been reported in patients with aPL-associated valvular disease (60 ,61).

Treatment

In patients in whom infection is suspected, antibiotic therapy directed at the most likely organism should be initiated immediately. If no infection is detected but is still considered likely, the most prudent course is to treat the patient with the appropriate full course of antibiotic therapy. There is no specific therapy directed at Libman-Sacks endocarditis. If disease activity is present by clinical and/or laboratory means, immunosuppressive therapy will be required for other disease manifestations. The impact of immunosuppressive therapy on Libman-Sacks endocarditis is not clear. There is some suggestion that the use of glucocorticoids has changed the natural history of valvular lesions in SLE. Bulkley and Roberts reported complete or partial healing of these lesions at autopsy, with resultant fibrous thickening and valvular calcification in patients from the poststeroid era (3). These changes were not noted in autopsies of SLE patients in the presteroid era. Valvular lesions leading to clinically significant valvular dysfunction need to be treated as those from any etiology. It should be noted that Libman-Sacks lesions might recur after surgical intervention (62).

Treatment of aPL-associated valvular disease in patients with primary or secondary APS is centered on the management of APS. The focus is on anticoagulation with agents such as warfarin or heparin, usually in the range described as high-intensity (INR 2.5 to 3.5 or equivalent). APS associated with SLE, or in catastrophic APS, therapy may also include immunosuppression. In patients with aPL antibodies and valvular disease without a prior history of thrombosis, the lack of evidence-based data makes management less straightforward. There is no evidence to support anticoagulation, the use of platelet inhibitors such as aspirin, or immunosuppressive therapy.

Prevention

Although no evidence points to proven means of preventing SLE- and aPL-associated valvular disease, it seems reasonable to focus efforts on controlling the underlying disease activity. No recommendations have been made by the American Heart Association (AHA) specifically regarding endocarditis prophylaxis in SLE, but based on their risk stratification many SLE patients with valvular disease would merit consideration. According to the 1997 guidelines, patients with prosthetic valves or the presence of valvular vegetations are considered high risk, while patients with mitral valve prolapse with mitral regurgitation or other acquired valvular dysfunction are considered moderate risk (63). By these criteria, a significant number of SLE patients would be considered moderate or high-risk, and antibiotic prophylaxis prior to undergoing bacteremia-inducing procedures would be indicated. A survey of dentists regarding endocarditis prophylaxis in SLE found that about 95% of those queried would not recommend prophylaxis in SLE, suggesting lack of awareness of the prevalence of valvular abnormalities in SLE (64). Hence, it falls upon the rheumatologist to ensure that SLE patients with valvular involvement receive appropriate prophylaxis.

Atherosclerotic Disease

Epidemiology and Pathogenesis

The description of a bimodal mortality pattern in SLE patients by Urowitz et al. in 1976 was an instrumental step toward identifying their increased risk of premature atheromatous CVD (65). Patients who succumbed to lupus early in the disease course were noted to die most often from complications of disease activity (e.g., organ failure) or therapy. Patients who died later often had quiescent disease, and died from CV events. These findings were substantiated by an autopsy series reported by Bulkey et al. in which the majority of a cohort of young women with a mean age of 35 years had significant obstructive atherosclerotic disease of at least one major coronary artery (3). As survival has improved from better means of disease detection and treatment, atherosclerotic CVD has emerged as a significant cause of morbidity and mortality in SLE. The prevalence of CV and cerebrovascular events in SLE ranges from 6% to 26% (9 ,10 ,18 ,49 ,65 ,66 ,67 ,68 ,69 ,70) (Table 34-5). Ischemic cerebrovascular events (stroke/transient ischemic attack) have been reported in 10% to 26%, (18 ,49 ,68 ,69 ,70), whereas MI and angina have been reported in 6% to 11% of SLE patients (9 ,10 ,65 ,66 ,67 ,68 ,69 ,70).

Not surprisingly, autopsy studies as well as the examination of surrogate markers of coronary atherosclerosis in SLE suggest that the prevalence of subclinical atherosclerosis is higher than overt events (3 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82) (Table 34-6). Autopsy studies reveal atherosclerotic disease of the coronary arteries in SLE in 22% to 54% of cases (3 ,71 ,72). Noninvasive studies including vascular ultrasound, electron beam tomography, and myocardial perfusion studies demonstrate atherosclerotic vascular disease in 17% to 40% of SLE patients (73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 ,81 ,82). In a cohort of SLE women with a mean age of 44.9 years, 40% were found to have focal carotid plaque as measured by ultrasound (73). Another study of 75 SLE women with a mean age of 38.8 years demonstrated that 28% had coronary artery calcifications (77). Roman et al. found carotid plaque in 37% of SLE patients, compared with a prevalence of 15% in age, sex, and race-matched controls (78).

A striking feature of this comorbid condition of SLE is its predilection for premenopausal women. Ward evaluated rates of hospitalization for CV events in a cohort of SLE women compared to a control group (83). Younger SLE

women (age 18 to 44) were 2.27 times more likely to be hospitalized with MI and 3.8 times more for congestive heart failure than controls. In the middle-aged women (45 to 64 years), the frequency of hospitalization for heart failure was just 1.39 times higher, and the frequency for MI hospitalization did not differ significantly from that of controls. A study comparing SLE women with age-similar women from the Framingham offspring cohort demonstrated a 50-fold increased risk of MI in the SLE women between 35 and 44 years of age (84). In sharp contrast to women in the general population, where the risk of atherosclerotic CV events is highest after menopause, the mean age at the first event in SLE women is about 49 years (85).

Traditional risk factors for CVD occur frequently in SLE, both as a consequence of disease activity and treatment. The presence of subclinical inflammation in the general population has been demonstrated to correlate with the development of a number of traditional risk factors, including

insulin resistance, visceral obesity, and hypertension (86 ,87 ,88). It is possible that the sustained systemic inflammation and immune activation in SLE has similar influences on the development of CV risk factors. The Toronto Risk Factor Study compared 250 SLE patients with 250 controls and found that SLE patients had a higher number of CV risk factors per patient as well as a higher prevalence of diabetes, hypertension, and elevated levels of low-density lipoproteins, triglycerides, and homocysteine (89). Additionally, both Bruce et al. and Costenbader et al. have demonstrated that even when CV risk factors are identified in SLE patients, they often are not adequately treated (90 ,91). Although a large part of CVD risk in SLE is likely a result of a high prevalence of traditional CV risk factors, Esdaile et al. demonstrated that the presence of CV risk factors alone does not explain the increased incidence of CV events (92).

Glucocorticoid therapy has been implicated in atherosclerosis in both lupus and nonlupus patients, but it is unclear whether this reflects pro-atherogenic effects of the underlying disease process or adverse metabolic effects associated with steroid use (93 ,94 ,95).

Antiphospholipid antibodies have been considered as a contributory factor to SLE-associated atherosclerotic disease. In addition to their postulated role in arterial endothelial damage, they have been associated with renal arterial disease (both thrombotic and stenotic), which may result in hypertension from activation of the renal-angiotensinogen-aldosterone axis from renal hypoperfusion (96 ,97). Although cohort studies have failed to identify an association between the presence of antiphospholipid antibodies and surrogate markers of coronary atherosclerosis, there is a strong association between surrogate markers of CVD and CV events with hypertension with in SLE (68 ,98 ,99). The importance of this association becomes apparent when more closely evaluated.

Hypertension and Lupus

Hypertension occurs commonly in SLE, with its prevalence ranging from 22% to 48% (5 ,12 ,78 ,79 ,82 ,91). Several studies examining CVD risk factors in SLE document an increased risk of hypertension in SLE when compared to age- and sex-matched healthy controls, but this relationship has not been consistently demonstrated in other studies (75 ,78 ,81 ,82 ,83). As in the general population, hypertension in SLE patients is associated with surrogate markers of CVD including carotid plaque, carotid intimal-medial thickness (IMT), vascular stiffness, and abnormal myocardial perfusion scintigraphy (73 ,76 ,78 ,79 ,80). Hypertension in SLE has also been demonstrated to correlate with vascular events (MI, angina, stroke, and peripheral vascular disease) and with the presence of severe coronary artery narrowing on autopsy (66 ,68 ,71).

Hypertension in SLE may arise from a variety of etiologies, including essential onset, medication side effects (e.g., sodium and fluid retention or weight gain from glucocorticoids), increased arterial stiffness (from systemic inflammation or atherosclerotic disease), or renal disease. Fortunately, this risk factor is one that is readily amenable to therapy.

It has been assumed that there exists a “lupus factor” that explains the increased prevalence and incidence of CVD in SLE. However, serologic and clinical scales reflective of disease activity have not demonstrated a consistent association with surrogate markers of CVD or CV events. Despite these findings, disease activity could be an important pro-atherogenic factor. Patients with clinically apparent, severe disease activity generally receive the most aggressive and sustained therapies. This could lead to better control in patients with “worse” disease, while patients with low level, less severe manifestations continue to have “grumbling” disease, with low-grade but persistent systemic inflammation. The importance of low-grade inflammation has been demonstrated in the general population, in whom higher levels of C-reactive protein within the “normal” standard range predict future CV events (100 ,101). It could be that duration of systemic inflammation, rather than intensity, is more influential on atherogenesis. Additionally, it could be that the sicker patients, with more frequent visits and closer scrutiny, are more likely to have CV risk factors detected and treated.

In the general population, the recent identification of myeloperoxidase, a source of reactive oxidants, as a surrogate marker for coronary artery disease and independent predictor of CV events demonstrates the emerging utility of markers of subclinical inflammatory processes in CV detection and risk prediction (102 ,103). Additionally, in the general population, myeloperoxidase levels are associated with the presence of traditional CV risk factors (104). Oxidant stress is abundant in SLE, and is associated with disease activity, but its role in CVD risk prediction has not yet been evaluated (105 ,106).

Lastly, it may be that our current means of identifying traditional risk factors in SLE is not optimal. For example, the Quebec Cardiovascular Study recently revealed that lipoprotein subfractions, rather than the standard quantitative measures of serum lipoproteins, better predict the presence of and risk for CVD and related events (107). A pro-atherogenic subfraction distribution may be present even in the presence of a “normal” lipid profile. Furthermore, studies of lipoprotein subfractions in other inflammatory disorders suggest that the presence of systemic inflammation promotes a pro-atherogenic lipoprotein subfraction distribution (108 ,109). It is likely that lupus disease activity, which increases oxidant stress and may also influence production of pro-atherogenic lipoprotein subfractions, plays a significant role in the excess CVD risk seen in SLE.

Clinical Features and Diagnosis

Signs and symptoms of atherosclerotic CVD in SLE are similar to those reported in the general population. Symptoms of ischemic heart disease may include chest pressure or

pain (with exertion and/or rest pain), dyspnea, dizziness/lightheadedness, diaphoresis, nausea, “heartburn,” shoulder/jaw/arm pain, upper back pain, and fatigue. A unique caveat in SLE is the prevalence of atherosclerotic disease in young women, a group once thought to be at very low risk in general for CVD. Signs and symptoms that would prompt immediate CV evaluation in a middle-aged male may not provoke the same concern in many physicians when reported by a premenopausal female, and could be attributed to any number of SLE and non-SLE–related conditions.

Diagnosing atherosclerotic CVD in SLE utilizes the same diagnostic studies as for evaluation of CVD in the general population. Stress echocardiography, nuclear imaging modalities, and cardiac catheterization all are appropriate studies for the evaluation of coronary atherosclerotic disease in SLE. Limited exercise capacity in many SLE patients in addition to the poor sensitivity and specificity of isolated treadmill stress testing in women limits its usefulness as an investigative study. Carotid ultrasound, electron beam tomography, and MRI have been generally used as research tools for determining prevalence and association with risk factors of CVD in SLE. The utility of these imaging tools on an individual basis is less clear. The presence of carotid plaque or coronary calcification may prompt more aggressive management of traditional CV risk factors, although many experts believe that all lupus patients should be treated as coronary heart disease equivalents with rigorous CV risk factor management. The critical factor in detecting atherosclerotic vascular disease in SLE is maintaining an appropriately elevated index of suspicion of CVD, especially in young women. Any symptoms suspicious for ischemic heart disease, regardless of the patient's age, should prompt a thorough evaluation.

Treatment/Prevention

Hypertension is strongly associated with the development of surrogate markers of CAD and with CV events, and thus warrants aggressive management and diligent monitoring. The protective effects of antihypertensive therapies in the general population appear to come from both lowering of blood pressure and from beneficial metabolic effects (110 ,111 ,112). It is likely that the same effects are present in SLE patients receiving therapy. ACE inhibitors are efficacious in controlling blood pressure, but are also beneficial in maintaining renal function by decreasing proteinuria and possibly by their antioxidative effects. These agents should be used with caution in patients with known renal artery stenosis. Angiotensin-receptor blockers have been purported to have protective effects comparable to ACE inhibitors, and may be a reasonable substitute (113 ,114). Beta-blockers and aldosterone antagonism provide additional benefit for patients with compensated heart failure (115 ,116). The focus should be on obtaining and maintaining strict blood pressure control.

Dyslipidemia in SLE should be managed as in the general population. Diet modification and regular exercise may help improve lipids, but in many patients will prove insufficient to attain a desirable lipid profile. The use of beta-hydroxy-beta-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) in SLE is currently under study in two large, randomized placebo controlled trials. Interestingly, these agents are demonstrating anti-inflammatory and antioxidative effects in the general population, and in a small study of rheumatoid arthritis patients, were shown to have disease-modifying activity (117 ,118 ,119). Regular monitoring of hepatic function is mandatory with the use of these agents, and may be required more frequently when used with other hepatically metabolized drugs.

Obesity in SLE may arise from disease or treatment-associated physical disability, glucocorticoid use, poor dietary habits, or lack of exercise. Patients should be counseled at disease onset and periodically advised regarding proper nutrition and exercise habits, individually suited to their other comorbidities and physical capacities.

It has become clear that insulin resistance exists prior to the development of clinically detectable hyperglycemia. A high index of suspicion for this condition should be maintained, especially when other metabolic syndrome features are present. However, it has not yet been determined what measures are indicated to best manage this condition prior to glucose elevation other than other risk factor management, including dietary and exercise interventions. Steroid-induced hyperglycemia warrants treatment, rather than observation.

The major focus of CVD therapy in SLE should be on prevention. As the awareness of the presence of traditional risk factors in SLE has grown, the numbers of patients receiving screening, counseling, or therapy for these factors has increased, but remains suboptimal. Costenbader et al., examined a cohort of 110 SLE patients with mean disease duration of 15.3 years and found that only 58% of the modifiable risk factors had been addressed (91). Twenty-three percent had never had cholesterol screening, and only 21% with dyslipidemia had this risk factor treated by dietary or pharmacologic intervention. Even diabetes mellitus, which is globally recognized as a CVD risk equivalent, was not treated in 25% of patients in this cohort. A key facet in prevention of CVD and related events in SLE is patient education. Patients and their physicians need to be informed of the increased risk of CVD associated with SLE, and should be aware of CVD risk factors. This awareness may be helpful when providing counseling regarding modification of risk factors that require significant lifestyle changes, such as tobacco cessation, dietary habits, and body weight. The accelerated and premature atherosclerosis in SLE is reminiscent of that in diabetes mellitus, suggesting that we might be justified in considering SLE in the same manner-as a CVD equivalent. Risk factor screening should be initiated at the time of diagnosis, and be continued annually. Modifiable risk factors present, such as dyslipidemia, hypertension, hyperglycemia, hyperhomocysteinemia, and the lifestyle factors previously noted should be treated and monitored. The recent data regarding the contribution of inflammation to the atherogenesis implies that control of

disease will also be an essential component of CVD prevention. This is a straightforward undertaking in patients with clinically active and organ-threatening disease. Until we have a more sensitive means of detecting subclinical SLE activity and understand of how “grumbling” activity directly impacts CVD, it will be difficult to formulate a comprehensive approach to CVD prevention.

Cardiovascular manifestations occur frequently and can result in significant morbidity. An elevated index of suspicion for and familiarity of the differential diagnosis associated with each of these manifestations is essential for timely diagnosis and treatment. The increased prevalence of CV risk factors and the markedly increased risk of CVD in SLE mandate vigilant surveillance for modifiable risk factors and for their aggressive treatment and monitoring in all patients, regardless of age or sex. Although progress continues to advance in this area, there remains much to be understood about key mechanisms that result in the CV manifestations of SLE.

An approach directed at maintaining CV health in SLE must begin at disease onset and continue throughout the lifespan of the patient. At the time of diagnosis, patients should be screened for CV risk factors and treated appropriately (Table 34-7). Monitoring the response to therapy and adjusting therapy to attain treatment goals must be given equal priority. A low threshold of suspicion for CVD needs to be maintained throughout the patient's lifetime, regardless of the age at diagnosis. The prevalence of valvular heart disease in SLE dictates careful evaluation for this condition when cardiac abnormalities are detected by physical examination or by other means (e.g., imaging or functional studies). Additionally, in characterizing SLE as conferring the risk of a CVD equivalent, any signs or symptoms suggestive of ischemic heart disease must be promptly and thoroughly evaluated. The same concerns should be reflected in the preoperative evaluation of patients with SLE. Since many factors that are contributory to CVD and CV risk in SLE are initiated and/or intensified by disease activity, the control of disease activity has a central role in the prevention and treatment of the CV manifestations of SLE.

Table 34-7: Addressing CV Risk Factors in SLE

Factor	Intervention
Obesity	Nonpharmacologic interventions (weight loss, dietary, activity) Regular monitoring and feedback
Hypertension	Nonpharmacologic interventions Antihypertensive therapy Regular monitoring and medication adjustment
Dyslipidemia	Nonpharmacologic interventions Lipid-lowering therapy Regular monitoring and medication adjustment
Insulin resistance	Weight maintenance (loss if necessary) Regular exercise
Hyperglycemia/diabetes	Nonpharmacologic interventions Hypoglycemic therapy at onset of hyperglycemia Regular monitoring and medication adjustment
Hyperhomocysteinemia	Folic acid supplementation Monitoring and adjustment of dose
Tobacco use	Counseling Medical therapy
Inflammation	Aggressive control of disease activity Adequate control of above risk factors (they both result from and propagate inflammation)

Chapter 35

Pulmonary Manifestations of Systemic Lupus Erythematosus

David D'Cruz

Munther A. Khamashta

Graham Hughes

Systemic lupus erythematosus (SLE) and the adverse effects of treatment may affect all regions of the thorax. Pulmonary involvement is common in SLE and may affect up to 60% of patients during the disease course and is part of the spectrum of presenting symptoms in 4% to 5% of patients (1). Furthermore, other complications of lupus such as cardiac failure or nephrotic syndrome may lead to lung involvement with the development of pleural effusions. Pulmonary involvement may increase the risk of mortality—in one study, lung involvement was one of several factors that was predictive for increased mortality (2).

The prevalence of pulmonary manifestations in SLE depends on the referral pattern to the unit where patients are studied, the population under scrutiny, and the methods used to detect pulmonary involvement. For example, the total cumulative prevalence of clinically apparent lung involvement was approximately 20%, with serositis seen in 45% of patients in a large cohort of patients (1). However, in a cross-sectional study of lung function, 90% of patients had subclinical abnormalities of pulmonary function tests (3).

The lungs may conveniently be considered in six main regions: the pleural space, the parenchyma, the pulmonary vasculature, the airways, the diaphragm, and the chest wall including the ribs and respiratory muscles. This chapter describes the clinical features, investigation, pathologic features, and management of the various pulmonary manifestations of SLE. Recent advances in diagnostic tools and therapy will also be addressed.

Historical Perspective

The contributions of Osler and Jadasson established that SLE was a distinct syndrome, and in 1904 Osler (4) described the occurrence of pneumonia in SLE. Further reports in the 1930s and 1940s described polyserositis, patchy lung consolidation, and other pulmonary changes including “atelectizing pneumonitis” in patients with SLE (5 ,6). Autopsy of these patients showed diffuse lung consolidation with hyaline alveolar thickening and marked obliterating cellular infiltration. Purnell et al. extended these observations and described a peculiar basophilic, mucinous edema of the alveolar walls and the peribronchial and perivascular tissues in association with interstitial pneumonitis and alveolar hemorrhage (7). These pathologic changes were distinct from the ordinary pyogenic and fibrinous bronchopneumonia that frequently complicates the terminal stages of SLE, but they were not pathognomonic of SLE (7). In atelectizing pneumonitis, the alveolar walls as well as the peribronchial and perivascular connective tissues appeared to be the primary sites of an inflammatory process that obliterated alveolar spaces.

In 1953 and 1954, two reports of radiographic studies in SLE emphasized the high frequency of pulmonary involvement. Israel (8) showed that non-specific pneumonia occurred frequently, not only during the terminal stages of SLE but throughout the course of the disease. Garland and Sisson (9) reported lung parenchymal changes in one third of their patients and observed both pleural and cardiac abnormalities to be prevalent. Comprehensive reviews of the pulmonary manifestations of SLE in adults (10 ,11 ,12) and in children (13) have appeared.

Pathology

A wide variety of lesions have been described in the lungs, but none are specific for SLE. For example, an autopsy study of 54 patients showed the following pathologic abnormalities in more than 50% of cases: bronchopneumonia, hemorrhage, pleural effusion, edema, interstitial pneumonia, and congestion (7). Fibrinoid necrosis and hematoxylin bodies occasionally were seen (14), whereas bronchiolar dilatation and foci of panacinar emphysema were often found (15). Fayemi (16) noted a high frequency of occlusive vascular changes of varying severity in the lungs of 8 of 20 patients with SLE; these changes affected arterioles, arteries, and veins. The acute lesions consisted of fibrinoid necrosis and vasculitis, and the chronic lesions included intimal fibrosis, medial hypertrophy, alteration of the elastic laminae, and periadventitial fibrosis.

Haupt et al. (17) examined pathologic changes in the lungs of 120 patients seen at autopsy and correlated these with their clinical features. In contrast to the high frequency of lung involvement in a clinical series (10), they showed that many of the pathologic lesions were not caused by SLE

itself but rather by secondary factors, such as congestive heart failure, infection, aspiration, and oxygen toxicity. Only 18% of the lung parenchymal lesions were found to be directly attributable to SLE.

Although informative, analyses of autopsy cases may not represent a cross-section of the general population of lupus patients and probably underestimate the prevalence of lung involvement. Certainly in the clinical setting pulmonary abnormalities can change rapidly and subside either spontaneously or with drug therapy, so anatomic lesions may not be evident later at autopsy.

The Clinical Assessment of Pulmonary Involvement

As with any other branch of medicine the clinical assessment of pulmonary disease in lupus patients is based on a careful history, thorough examination, and appropriate further investigations.

A useful screening question is: “Have you been short of breath or had chest pains?” The most common early symptom of serositis is pleuritic chest pains, which occur on both inspiration and expiration. There is nothing particular about the pain that differentiates lupus from other causes of pleurisy such as infection or pulmonary embolism. Resolution of pleuritic pain does not always imply improvement, because the pain at a particular site of the chest may disappear if a significant pleural effusion develops. Dyspnea may be the presenting symptom of many of the other complications of lupus to affect the lung. A sudden onset is more likely to be a result of pulmonary embolism, but the more usual presentation is an insidious onset of breathlessness. An estimate of the patient's walking distance is a useful guide to exercise tolerance and the extent of lung involvement. A careful history to exclude cardiac disease should be undertaken. Hemoptysis may be the presenting feature of infection, infarction, cardiac failure, or very rarely pulmonary hemorrhage.

The examination of the respiratory system should be part of a comprehensive clinical examination that includes blood pressure and urinalysis. For example, vasculitic lesions may indicate more widespread disease activity. Splinter hemorrhages raise the possibility of small vessel vasculitis or cardiac valvular disease in a breathless patient with SLE. Interestingly, although finger clubbing is common in patients with idiopathic fibrosing alveolitis, it is relatively unusual in patients with interstitial lung disease of lupus (12). The presence of central cyanosis should be noted and a careful search should be made for late inspiratory basal crepitations—a sensitive sign of interstitial lung disease that should prompt further investigation. Pleural rubs and effusions should be sought as indicated by a history of pleuritic pains, though other causes of pleural effusions should be considered such as infection, nephrotic syndrome, cardiac failure, and malignancy. A thorough cardiac assessment is essential, with particular attention to signs of cardiac valve disease, left or right ventricular failure, and pointers toward pulmonary hypertension.

Investigation of Pulmonary Involvement

Imaging

Chest Radiography in SLE

The chest radiograph is a simple and useful extension of the clinical examination of the patient with SLE. Previous films, when available, may give valuable information on disease progression or the appearance of new lesions.

Chest radiograph abnormalities are reasonably common in patients with SLE. For example, in a prospective study of 50 unselected patients, abnormalities were found in 38% (18), and in a study of 43 patients who were examined specifically for pulmonary dysfunction, 23% had abnormal chest radiographs (19). In contrast, none of 70 non-smoking patients with SLE who were free of respiratory complaints and enrolled in a study of pulmonary function had abnormal chest radiographs (20). Several factors may explain this difference in the prevalence of abnormalities, including patient selection, the many manifestations of the disease that may be transient, and the timing of the radiographic study.

Radiographic Findings

A wide variety of abnormalities may be seen in chest radiographs. Early studies documented radiographic changes in the pleura, lung parenchyma, and heart (21). However, none of these abnormalities are specific or diagnostic for SLE and may be seen in other conditions such as rheumatoid arthritis and systemic sclerosis.

Pleural changes as an isolated abnormality or in combination with cardiac or parenchymal lesions are the most common radiographic changes (21 ,22). The pleura may appear as a shaggy thickening of the pleural surface. Pleural effusions are usually small and, in 50% of patients, bilateral (12). With clearing of the effusion, residual pleural thickening may be seen. Parenchymal lesions are characterized by ill-defined focal patches, linear bands, infiltrates, and small nodules or plaques at the bases (22). Diffuse granular, reticular, or reticulonodular lesions throughout the lung fields, but especially at the bases, are found in a small number of patients with SLE and chronic interstitial fibrosis (10). Cardiomegaly, if present, is usually mild to moderate (21), and isolated cardiac enlargement is almost as frequent as isolated pleural disease. In patients with cardiomegaly, there are often other factors such as hypertension, pericarditis, valvular disease, myocardial involvement, and anemia to explain the cardiac enlargement (21). Elevated diaphragms are found in 5% to 18% of patients (18 ,19).

Early investigators often ascribed parenchymal changes in chest radiographs to primary lung involvement caused by SLE. The term lupus pneumonitis was used indiscriminately to encompass various types of pulmonary lesions and has been reported in 15% to 50% of patients (12 ,23). In 111 patients with SLE, Levin (23) found that radiographic parenchymal changes (infiltrates or small nodules) were mostly the result of secondary complications, such as infections, uremic pulmonary edema, and basilar atelectasis. Primary lupus pneumonitis was relatively rare, being found in only three (2.7%) patients, and the diagnosis therefore became one of exclusion.

High-Resolution Computed Tomography and Magnetic Resonance Imaging

High-resolution computed tomography (HRCT) is an essential tool in the evaluation of lung disease in SLE. Early inflammatory lesions may be visualized as alveolar or ground-glass shadowing, and later in the disease course fibrotic lesions may be visible as fixed reticular honeycombing. These appearances usually correlate with the clinical finding of late inspiratory crackles at the lung bases.

Two studies from the same group have demonstrated the usefulness of HRCT scans of the chest in determining the prevalence of pulmonary involvement (24 ,25). The most common computed tomography (CT) findings were interstitial lung disease (ILD), bronchiectasis, mediastinal or axillary lymphadenopathy, and pleuropericardial abnormalities. No correlation was found between disease activity, duration of disease, chest symptoms, drug therapy, smoking history, and the presence of abnormal HRCT findings. Interestingly, no correlation was found between pulmonary function abnormalities and the presence or grade of interstitial lung disease or bronchiectasis as determined by HRCT, and the prevalence of pleuropulmonary disease was lower than in previous studies. Thus, HRCT evidence of airways disease and interstitial lung disease was frequently present despite an absence of symptoms, a normal chest radiograph, and normal pulmonary function testing. Furthermore, the study by Sant et al. (25) showed that 72% of HRCT scans were abnormal when only 34% of plain chest radiographs were abnormal.When combined with contrast injections, CT pulmonary angiography is a highly accurate method of detecting pulmonary emboli where ventilation/perfusion (V/Q) scans give indeterminate results, especially if the clinical suspicion of pulmonary embolism is high. The use of D-dimer assays in this clinical situation may increase the predictive value of diagnosing pulmonary emboli considerably and is less invasive than the gold standard of pulmonary arterial angiography. However, if the V/Q scan is indeterminate, the CT angiogram is inconclusive, and the clinical suspicion of pulmonary embolism is high, then pulmonary arterial angiography should still be considered, especially if D-dimer assays are positive (26). It should be remembered however that elevated D-dimer levels may simply be a reflection of active lupus or infection as it is an acute phase reactant and negative D-dimers are more useful in excluding thrombosis.

The role of MRI in the evaluation of pulmonary disease in lupus remains the subject of continuing studies. Case reports suggest that MRI may be useful in the evaluation of pulmonary artery thrombosis and pulmonary hemorrhage in SLE (27 ,28). In other fields MRI has been useful in assessing respiratory diaphragmatic and chest wall dynamics in pulmonary emphysema (29) and chronic infiltrative lung diseases (30). The major limitation of MRI of the lung parenchyma is image degradation because of breathing, though breath-hold techniques are now possible with faster acquisition times and gadolinium enhancement (30).

Pulmonary Function Tests

Simple spirometry gives useful information on the pattern of pulmonary involvement. The ratio of forced expiratory volume at one second to forced vital capacity ratio (FEV1/FVC) distinguishes restrictive patterns, most often because of interstitial lung disease, from obstructive patterns as a result of lesions that may affect the larger airways as well as documenting lung volumes. The pulmonary transfer factor using a single breath carbon monoxide technique is particularly useful in the detection of early interstitial lung disease, documenting disease progression and monitoring responses to treatment.

Pulmonary Function Test Abnormalities

Pulmonary function test (PFT) abnormalities are exceedingly common in patients with SLE, even in those without respiratory complaints and with normal chest radiographic findings (18 ,19 ,31 ,32) (Table 35-1). In 1965, Huang et al. (32) studied 28 consecutive patients with SLE and found a high prevalence of physiologic abnormalities with a restrictive pattern. Reduction of the diffusing capacity was the most common finding with a mean value of 65% of the predicted value. Importantly, they observed a disparity between clinical and chest radiographic findings and PFT abnormalities.

In 1966, another study of PFTs in 20 patients with SLE and respiratory symptoms described three major abnormalities: (a) restrictive disease, (b) airway obstruction, and (c) pulmonary vascular obstruction (33). Twelve of the patients had evidence of restrictive disease, three had severe airway obstruction without pulmonary restriction, and five had pulmonary vascular obstruction. Three patients died, and the pathologic findings in the lungs correlated with the physiologic abnormalities observed during life.

Wohlgelernter et al. (3) found PFT abnormalities in 90% of their patients with SLE and a previous history of pleuritis and/or pneumonitis, and in 71% of their patients without

pulmonary complaints. The most common abnormalities were a decreased carbon monoxide diffusing capacity of the lungs for carbon monoxide (DLCO), lack of response to breathing helium, restrictive ventilatory defect, and arterial hypoxemia. None of their patients with chronic discoid lupus erythematosus had an abnormal PFT, which is a finding consistent with the limited disease process in this condition. Rolla et al. (34) suggested a relationship between disease activity and KCO, indicating that systemic inflammation correlated with alveolar inflammation. Likewise, disease severity was related to airway patency and airway reactivity indices, suggesting cumulative damage to the airways in these patients (34). A similar study in children confirmed that transfer factor measurements were related to disease activity, and decreases in disease activity with treatment resulted in better pulmonary function (35). An interesting study described elevated nitric oxide (NO) levels in the exhaled air of lupus patients and correlation with disease activity in addition to pulmonary function testing (36). It was not clear, though, whether the NO arose from lung or systemic inflammation.

Table 35-1: Respiratory Function Studies in Systemic Lupus Erythematosus (SLE)

Authors	Year	No. of Patients	Conclusions
Uncontrolled studies			
Huang and Lyons	1965	*n* = 20 with compared to *n* = 8 without lung disease	↓ DLCO in 57%, ↓ lung volumes; no correlations between PFT, CXR, or clinical findings
Gold and Jennings	1966	*n* = 20, 5 with lung	Restrictive pattern in 60%, obstructive symptoms in 10%. ↓ DLCO most common finding
Holgate et al.	1976	*n* = 30 SLE all with lung disease	All abnormal
Wohlgelernter et al.	1978	*n* = 10 (group 1) with and *n* = 14 (group 2) without lung symptoms or signs	↓ DLCO, arterial hypoxemia and/or restrictive pattern in 90% (group 1) and 71% (group 2); small airways disease in*n* = 10
Silberstein et al.	1980	*n* = 43	88% abnormal: ↓ DLCO (72%), ↓ lung volumes (44%), obstructive pattern (7%); no correlation between PFT and disease activity
Nakano et al.	2002	*n* = 110 SLE followed for up to 195 days	↓ Dlco in 47%. Restrictive defect in 8%. Correlation with Raynaud.
Zheng et al.	2002	*n* = 48 SLE	↓ Dlco in 42%. HRCT showing ILD in 5/14
Longitudinal studies			
Eichacker et al.	1988	*n* = 25 followed for 2-7 years	No changes in DLCO, forced vital capacity or lung volumes; reduction in small airway function unrelated to smoking
Cerveri et al.	1996	*n* = 15 children followed for 5 years	↓ TLCO 45% at baseline, 35% at follow-up; TLCO correlated with disease activity
Controlled studies			
Chick et al.	1976	*n* = 28 SLE and no lung symptoms, *n* = 28 controls	↓ DLCO, lung capacity and functional residual volume in SLE; smoking effects similar in both groups
Andonopoulos et al.	1988	*n* = 70 SLE nonsmokers, *n* = 70 control nonsmokers	Abnormal PFT in 63% SLE and 17% controls; isolated ↓ DLCO in 31% SLE and 0% in controls; small airways disease in 24% and 17%, respectively
Rolla et al.	1996	*n* = 24 SLE and *n* = 24 controls	↓ lung capacity, ↓ bronchial threshold to metacholine, increased AaO_2 gradient (n = 12); KCO correlated with disease activity

CXR, chest radiograph; DLCO, carbon monoxide diffusing capacity; KCO, pulmonary gas transfer; PFT, pulmonary function test; TCLO, total lung carbon monoxide diffusing capacity.

In a prospective study of 43 ambulatory, consecutive patients with SLE, Silberstein et al. (19) attempted to correlate PFT abnormalities with other measures of lupus activity. Pulmonary dysfunction was noted in 88% of patients. An impaired DLCO (72% of all patients), reduction in lung volume (49%), and hypoxia (44%) were the most common abnormalities that were found. No correlation was found between the type or severity of the abnormality and serum complement levels, anti-DNA antibody, lupus band test, or nephritis. Patients with SLE and abnormal PFT results did not differ from those with normal PFT results in regard to their clinical or immunologic features. In contrast, Holgate et al. (37) reported that patients with SLE and prominent pleuropulmonary disease had a lower prevalence of lupus nephritis, suggesting that this is partly a result of the low frequency of anti-DNA antibodies in this group of patients. These two studies are not comparable,

however, because the latter included only patients with SLE and pleuropulmonary disease.

Chick et al. (38) compared the PFT findings in 28 patients with SLE but without pulmonary involvement to those of healthy individuals matched for age, gender, and height. A restrictive pattern with reduced lung volume and vital capacity was seen in the SLE group. DLCO was reduced in patients with SLE in proportion to the reduction in lung volume, suggesting that this results from pleural thickening rather than from parenchymal disease. Cigarette smoking caused a reduction in flow at low lung volumes in both patients with SLE and normal controls.

Andonopoulos et al. (39) conducted the largest controlled study to date of PFTs in patients with SLE. They studied 70 lifelong nonsmoking SLE patients and an equal number of age- and sex-matched, nonsmoking healthy subjects. None of the patients had active pulmonary disease, and all had normal chest radiographs at the time of the study. An isolated reduction in the DLCO was the most prevalent abnormality found in the SLE patients. Isolated small airway disease, defined as less than 60% of the predicted value of the maximal flow at 25% of vital capacity, was common in both patients with SLE (24%) and controls (17%). Restrictive and obstructive patterns were uncommon in SLE, being seen in only 5.7% of patients. Overall, only 33% of the patients with SLE had normal PFT results, compared with 83% of the controls.

Eichacker et al. (40) evaluated the PFTs of 25 patients with SLE serially over a period of 2 to 7 years. Reductions in diffusing capacity, forced vital capacity, and total lung capacity did not change significantly with time. In contrast, small airway function decreased significantly with time and was unrelated to smoking history. The significance of this finding is not clear in view of the data found by Andonopoulos et al. (39) that the prevalence of small airway disease in SLE patients is the same as that in healthy controls.

More recently, Nakano retrospectively studied 110 patients with SLE who underwent HRCT and PFTs. Although only 5 had obvious pulmonary disease and 13% had clinical or radiological evidence of pulmonary fibrosis, 47% of patients had DLCO values <80% predicted and only 8% had restrictive defects (41). Furthermore, although reduced DLCO values were more common in patients with pulmonary fibrosis, reduced DLCO values were frequently observed even in patients with neither pulmonary fibrosis nor a restrictive pattern (39%; 34/88) (41).

Table 35-2: Comparison of Techniques in the Diagnosis of Pulmonary Embolism

	Sensitivity	Specificity	Advantages	Disadvantages
D-dimer	85%-100%	41%	High negative predictive value; cheap	Not compared to pulmonary angiography yet
Ventilation/perfusion				
High probability	41%	97%	Well validated, widely available	High proportion of nondiagnostic result
Highly/intermediate				
Probability	82%	52%		
Low probability	98%	10%		
Spiral CT	53%-100%	81%-97%	Well validated, widely available, detects other conditions	Cost, contrast load, subsegmental emboli may be missed
MR Angiography	50%-100%	91%-100%	Low contrast load, may be used to diagnose DVT	Cost, subsegmental emboli may be missed

CT, computed tomography; DVT, deep venous thrombosis; MR, magnetic resonance.

Another study by Zheng et al. assessed DLCO values in 93 patients with autoimmune connective tissue disorders including 48 with SLE. Of the SLE patients 7/48 (15%) had ILD by chest radiography. HRCT abnormalities of ILD were noted in 5/14 (36%) and abnormal DLCO values were present in 42% of the SLE patients (42).

Many of the studies of PFTs in patients with SLE that have been summarized here were uncontrolled, and did not consider the effects of cigarette smoking. In the absence of respiratory symptoms, isolated abnormalities in PFT such as a reduced DLCO do not require treatment but should be monitored, and further investigation with HRCT chest scanning should be considered.

Nuclear Medicine Imaging

Ventilation/Perfusion Scans

In any patient with SLE presenting with breathlessness and pleuritic pains, the possibility of pulmonary embolism should be considered. V/Q scans offer a simple and reasonably reliable screening test for pulmonary embolism that can be used with CT pulmonary angiography where the results are indeterminate. V/Q scans may also be abnormal in the absence of pulmonary embolism, and severe pulmonary hypertension may produce an appearance of hypoperfusion in the peripheral areas of the lung. The combined use of D-dimer assays, V/Q scanning, and, where appropriate, CT pulmonary angiography may raise the accuracy in diagnosing pulmonary embolism (26) (Table 35-2).

Gallium-67 (Ga-56) scans have been useful in the diagnosis and monitoring of patients with sarcoidosis, but there is little data on their use in the assessment of pulmonary disease in lupus. Witt et al. (43) studied lupus patients with interstitial lung disease and found an association between the presence of late inspiratory crackles clinically and increased uptake on Ga-67 scanning and abnormal bronchoalveolar lavage. However, abnormal Ga-67 scans were seen in only 37% of SLE patients compared to a prevalence of 74% with late inspiratory crackles and 95% of patients with abnormal CT chests, making the scans somewhat insensitive at picking up interstitial lung disease.

Diethylenetriamine Pentaacetic Acid Scans

An estimate of pulmonary epithelial permeability may be obtained by measuring the clearance of inhaled technetium- 99m-labeled diethylenetriamine pentaacetic acid (99mTc-DTPA) from the alveolar space to the blood. This technique has been used to diagnose early lung involvement in a variety of autoimmune connective tissue disorders even when HRCT scans are normal. In simple terms rapid clearance of the isotope implies active interstitial lung disease.

In the largest controlled study so far, Dalcin et al. (44) studied 46 SLE patients and 30 healthy controls. The SLE patients were divided into those with clinically active or inactive disease although no disease activity scores were given. Pulmonary clearance of 99mTc-DTPA was significantly faster in patients with active disease compared to either healthy controls or those with inactive disease. Neither carbon monoxide transfer factors nor imaging with HRCT was performed making it difficult to assess the place of 99mTc-DTPA clearance in the diagnosis of early lupus lung disease. Furthermore, although a correlation with cough and rapid 99mTc-DTPA clearance was found, there was no correlation with dyspnea or radiologic appearances (44). Although this does appear to be a very sensitive technique its use should be considered in the clinical context of the patient's symptoms and other investigations. It is also unclear whether asymptomatic patients with rapid isotope clearance will necessarily progress to overt lung disease or if treatment may influence outcome.

Another nuclear medicine technique being used in SLE is the use of technetium-99m hexamethylpropylene amine oxime (Tc-99m HMPAO) to assess pulmonary vascular endothelial damage. The degree of damage may be expressed as the lung/liver uptake ratio. There are two studies of this technique in SLE with conflicting results. Shih et al. measured lung uptake of Tc-99m HMPAO in 20 SLE patients and 25 controls without SLE, referred for brain imaging due to dementia or stroke (45). Of the 20 SLE patients, 10 had significant clinical pulmonary manifestations. The lung/liver ratio was significantly higher in the SLE patients. However, Chang et al., using Tc-99m HMPAO as well as quantitative Ga-67 citrate lung scans to evaluate the severity of inflammation in the SLE lungs found no correlations with clinical or radiologic features (46).

Arterial Blood Gases

Arterial blood gases give an accurate estimate of alveolar ventilation. It is essential in the assessment of pulmonary embolism, extensive pulmonary infiltration, severe pneumonia, pulmonary hemorrhage, and acute reversible hypoxemia where hypoxia (type I respiratory failure) may occur.

Bronchoscopy and Bronchoalveolar Lavage

These techniques may be useful when evaluating the etiology of interstitial pulmonary shadowing in patients with lupus. BAL fluid may be examined to exclude opportunistic infections especially in immunosuppressed patients. In patients with suspected interstitial lung disease where CT chest images show ground-glass shadowing with a honeycomb appearance, elevated cell counts in BAL fluid may suggest alveolar inflammation and direct treatment with immunosuppressive agents once infection has been excluded.

The technique of BAL facilitates the analysis of cellular and soluble components from the epithelial surface of the lower respiratory tract. BAL has yielded valuable information about immune responses and the pathogenesis of lung injury in the connective tissue diseases, especially systemic sclerosis and rheumatoid arthritis (RA). BAL findings may be diagnostic in some diseases, such as infections; in others, however, findings are nonspecific but may contribute to the management of these diseases. For example, an increased number of BAL eosinophils were associated with progressive lung disease in idiopathic interstitial pulmonary fibrosis, RA, and scleroderma (47).

In a multicenter study designed to standardize the test procedure, BAL was performed in 24 patients with diffuse ILD secondary to rheumatic disorders, including SLE (48). The total number of cells in the BAL fluid was increased with the percentage increase in neutrophils and decrease in macrophages. Total protein, immunoglobulin M (IgM), IgG, and IgA, but not albumin, increased in concentration in the BAL fluid. Walaert et al. (49) studied BAL fluid in 61 patients with collagen vascular disease without respiratory symptoms, and included in their study were 11 patients with SLE, all of whom had normal PFT results. An abnormal differential count of BAL fluid leukocytes was found in 48 of patients, including 3 with SLE. In contrast to patients with RA and systemic sclerosis, who had a predominant polymorphonuclear alveolitis, patients with SLE showed a lymphocytic predominance. An increased percentage of BAL fluid eosinophils was also found in two patients with SLE and ILD (47). Similarly, Witt et al. (43) found elevated lymphocyte and neutrophil counts in the BAL fluid from 19 lupus patients.

Alveolar macrophages in BAL fluid from 17 patients with inactive SLE were found to be normal in number, viability, and respiratory burst activity, but had severely impaired antibacterial function (49). This dysfunction, which was observed in both steroid-treated and untreated patients, may contribute to the increased frequency of pulmonary infections in this disease.

Walaert et al. (50) introduced the concept of subclinical alveolitis in SLE and in other systemic rheumatic diseases, which is characterized by the accumulation of inflammatory and immune cells in the BAL fluid of patients without respiratory complaints, with a normal chest radiograph, and with or without significant PFT abnormalities. The clinical significance of subclinical alveolitis, however, is not clear since it is not known how many of these patients will progress to develop overt interstitial lung disease.

Higher concentrations of soluble immune complexes have been observed in BAL fluid compared to the corresponding serum specimen from patients with ILD associated with rheumatic diseases, including SLE (51). Immune complexes were also seen within the cytoplasm of BAL neutrophils, indicating that locally formed immune complexes may induce an inflammatory response in the lungs of these patients.

Increased numbers of activated $CD8^+$ T lymphocytes and natural killer (NK) cells were found in the BAL fluid of lupus patients with abnormal pulmonary function tests and correlated with reduced carbon monoxide transfer factor and diffusing capacity values (52). In contrast, the number of $CD19^+$ B cells in the BAL fluid was lower than that seen in the fluid of healthy controls, despite the high percentage of these cells in SLE peripheral blood. These observations suggest a cell-mediated immune response in the lungs in SLE (52).

BAL, therefore, may be a potentially useful technique in the assessment and follow-up of patients with SLE and pulmonary involvement, especially in those with acute lupus pneumonitis and chronic diffuse ILD.

Clinical Manifestations of Pulmonary Involvement in Lupus

Respiratory tract involvement occurs in about half of lupus patients over their disease course (12). The following sections describe the main features of lung disease in SLE.

Pleurisy

Prevalence

Pleurisy is the most common manifestation of pulmonary involvement in SLE, and the pleura is involved more commonly in lupus than in any other connective tissue disease. Several early studies documented the prevalence of pleural involvement. For example, in Dubois and Tuffanelli's (53) 520 patients, the cumulative incidence of recurrent pleuritic pain was 45% and that of pleural effusions was 30%. McGehee et al. (54) reported pleurisy in 56% of their patients with recurrent pleuritic episodes in 13%, while 16% had associated pleural effusions. Several other studies have documented high prevalences of pleuritis, ranging from 41% to 56% (18 ,55), being found more commonly in blacks than whites (56). The largest study to date of 1,000 European lupus patients found a prevalence at disease onset of serositis (including both pleural and pericardial inflammation) of 17% with a cumulative incidence of 36%, with pleuritis occurring more commonly in men than in women (57). Lung involvement defined as acute or chronic lupus pneumonitis was much less common, with a prevalence at disease onset of 3% and cumulative incidence of 7%—almost certainly an underestimate. At follow-up, 10 years later, the prevalence of most manifestations had decreased and the prevalence of serositis had decreased significantly to 6.2% possibly reflecting the response to long term treatment and close medical supervision in a prospective study (58). The highest prevalence comes from a postmortem study: Ropes (59) described pleural changes in 93% of 58 patients with SLE at autopsy, with fluid in the pleural cavity in 33 cases.

Clinical Features

Pleurisy as the initial manifestation of SLE was noted by Dubois' (60) in 13 of 520 patients. Pleuritic symptoms may antedate other manifestations of lupus by months or even years, resulting in a delay in the diagnosis of SLE (61).

Pleuritic chest pain may be unilateral or bilateral, and is usually located at the costophrenic margins, either anteriorly or posteriorly. Attacks of pleuritic pain often last for several days, and, when associated with effusions, the pain may persist for weeks often accompanied by cough, dyspnea, or fever. The effusion generally occurs on the side of the chest pain (Fig. 35-1). Pleural effusions may also occur

in patients with SLE and nephrotic syndrome; infections, such as tuberculosis; or cardiac failure (23). Massive bilateral pleural effusion is a rare presenting feature of the disease (62). It is important to remember that the differential diagnosis of pleuritic pain in a patient with lupus may include infection and pulmonary embolism, especially in the presence of antiphospholipid antibodies.

Figure 35-1. Computed tomography (CT) chest scan showing bilateral pleural effusions and right lower lobe consolidation in a woman presenting with pleuritic chest pain and breathlessness. There was rapid resolution with low-dose prednisolone.

Pleural Fluid

The volume of pleural effusions usually is small to moderate (400 to 1,000 mL) and may be unilateral or bilateral. Large pleural effusions are uncommon (10 ,63). Thoracocentesis is not always necessary in lupus patients unless the cause of the pleural effusion is uncertain and infection is suspected. The pleural fluid in SLE is usually exudative in character, although transudates have also been reported (10). The fluid can be yellow, amber, or slightly turbid in color. In a study of 14 patients with lupus pleuritis (63), the white cell count in the pleural fluids ranged from 325 to 14,950 cells/mL (mean, 4,895 cells/mL). Half the specimens showed a predominance of polymorphonuclear leukocytes, with cell counts ranging from 10% to 100% (mean, 57%). Kelley et al. (64) examined pleural effusions from 10 patients with SLE and found atypical cells resembling plasma cells. The presence of these cells with other inflammatory cells, fibrinoid debris, erythrocytes, and few mesothelial cells and in the absence of pathogenic organisms or malignant cells constituted a pattern that was characteristic of SLE in 4 of the 10 patients studied.

In most patients with lupus pleuritis, the pleural fluid glucose concentration is greater than 60 mg/dL, with a pleural fluid/serum glucose ratio of greater than 0.5. Good et al. (63) found the mean pleural fluid/serum glucose ratio to be 0.3 or lower. This contrasts with the finding of low glucose levels in the pleural fluid of patients with RA and pleurisy, in whom the glucose concentration is less than 30 mg/dL in 75% of patients (65). Low glucose concentrations, or a low pleural fluid/serum glucose ratio, may also occur in those with malignant effusions, empyema, or tuberculosis (65). The pH of SLE pleural fluid usually is greater than 7.35. A few patients have a pH of less than 7.3, which is associated with a low pleural fluid glucose level (63 ,65).

Classic LE cells have been documented in smears of pleural fluids from patients with SLE (63 ,66 ,67). It has been suggested that the presence of in vivo LE cells in the pleural fluid is highly characteristic of SLE (68). However, the LE cell test is now largely obsolete and has been replaced by searching for antinuclear antibodies (ANAs) in pleural fluid (12).

The presence of ANAs in the pleural fluid may be a useful diagnostic test for patients with undiagnosed pleural effusions. For instance, Leechawengwong et al. (69) tested pleural fluid from 100 consecutive patients with pleural effusion and found positive ANA in all 7 patients with SLE and in 1 patient with drug-induced LE, but not in patients with other diagnoses. Conversely, Small et al. (70) found that a positive ANA in the pleural fluid was not specific for SLE; it also was found in patients without SLE but with pleural effusions who tested positive for ANA in the blood. Khare et al. (71) found positive ANA in 8 of 74 nonlupus pleural effusions (10.8%), including those associated with malignancy.

Good et al. (63) measured the ANA titer in paired samples of pleural fluid and serum of patients with SLE. In lupus pleuritis, the pleural fluid/serum ANA ratio was greater than 1. In contrast, the ratio was less than 1 in patients with SLE who had pleural effusions from other causes, such as congestive heart failure. Moreover, none of 67 patients with pleural effusions of different causes had a positive ANA.

Pathogenesis

The pathogenesis of pleural effusion in SLE differs from that of RA. For example, immune complexes in RA are thought to be produced locally in the pleura, whereas immune complexes are derived from the circulation in SLE. Additionally, the concentration of soluble interleukin-2 (IL-2) receptor in the pleural fluid in RA is significantly higher than that in SLE. This suggests that a local T cell–mediated immune reaction may be a more important mechanism in rheumatoid pleurisy than in lupus (72).

In an autopsy study, 54 of 58 patients (93%) in Ropes' series showed pleural involvement (59). Fluid was found in the pleural space in 33 patients, and adhesions were seen in 63%. Microscopic changes of varying degrees were observed in 24%; these consisted of accumulations of lymphocytes and macrophages, pleural thickening, perivascular fibrinoid necrosis with neutrophilic and mononuclear infiltrates, fibrinous exudate, and rare hematoxylin bodies. Pleural biopsy in one patient with SLE and bilateral effusions revealed noncaseating pleural granulomas (73).

Several early studies demonstrated reduced levels of hemolytic complement, C1q, C4, and C3 in pleural fluid from lupus patients when compared to pleural effusions from patients with cancer, heart failure, and other conditions (74 ,75 ,76). These complement levels remained low even after adjustment for the total protein content of the pleural fluid (74). However, low pleural fluid complement levels are not specific for SLE, and may occur in patients with RA or empyema (76 ,77).

There is some evidence that low pleural fluid complement levels in SLE results from activation of the complement cascade by immune complexes. Thus, conversion products that are generated by activation of the complement cascade are present in SLE pleural fluid (77 ,78), and immune complexes abound in SLE pleural fluid (77 ,78 ,79). Furthermore, perivascular deposits of immunoglobulins and complement components in the parietal pleura have been found in patients with lupus pleuritis (77). The nature of the immune complexes in SLE pleural fluid is not clear, though they may well be DNA–anti-DNA complexes (80).

The immunologic abnormalities described in pleural fluid are not diagnostic of lupus pleuritis. Thus, the presence of immune complexes, complement activation products, and immune deposits in the parietal pleurae all have been reported in pleurisy associated with other rheumatic diseases, such as RA, as well as in nonrheumatic conditions, including cancer and empyema (70 ,77). This suggests that an immune-mediated mechanism(s) is a common pathway by which SLE and other diseases can cause pleurisy.

Treatment of Lupus Pleurisy

Analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) are useful treatments for mild lupus pleurisy. If the patient fails to improve or the symptoms are severe, systemic corticosteroids (10 to 20 mg of prednisone daily) are usually rapidly effective. Hydroxychloroquine may be added to provide longer-term benefit after tapering the prednisone dose. When present, the effusion begins to clear within days of beginning steroid therapy, though it may take several weeks for the radiographic changes to clear up completely. It is not necessary to consider chest tube drainage of these effusions. When clinical or radiographic changes are slow to improve, the addition of a steroid sparing agent such as azathioprine may be considered. In those very rare patients with chronic, unremitting lupus pleurisy that is refractory to medical therapy, pleurectomy (81), talc poudrage (82), and tetracycline pleurodesis (83 ,84) may be used. Intravenous immunoglobulin therapy was of limited value in a patient with lupus and refractory pleural effusion (85). Our own anecdotal experience of rituximab in a patient with lupus nephritis and refractory pleuritis was very successful both for the renal and pleural disease (unpublished data).
