Acute lupus pneumonitis is an uncommon clinical manifestation of SLE. In Estes and Christian's (55) series of 150 patients, 48% had evidence of pulmonary involvement at some time during the course of their illness, but only 14 (9%) had acute lupus pneumonitis. Other studies found prevalences of between 1% and 7% in their series (18 ,21 ,23 ,57).

Patients with acute lupus pneumonitis usually present with fever, dyspnea, cough productive of scanty sputum, hemoptysis, tachypnea, and pleuritic chest pain (86). Physical findings commonly include basal crepitations, and, when severe, central cyanosis may be present. Chest radiographs demonstrate diffuse acinar infiltrates with a predilection for the bases in all patients and pleural effusion in 50% of patients (86) (Fig. 35-2). The vast majority of patients have some degree of arterial hypoxemia. The white cell count is usually normal, and anti-DNA antibodies are present in these patients with severe active lupus, often with other evidence of multisystem involvement. Multiple cultures and investigations for bacteria, fungi, and viruses are usually negative, and prompt diagnosis of lupus pneumonitis is essential, as the mortality rate may be as high as 50% (86).

Pathology

The histopathology of the lung in acute lupus pneumonitis has been examined in a few untreated patients; light microscopic changes are variable and nonspecific.

An open-lung biopsy obtained before therapy in one of Matthay et al.'s (86) patients showed a diffuse interstitial lymphocytic infiltrate with prominent lymphoid nodules and bronchiolitis. Despite therapy, the patient died, and at autopsy alveolar hyaline membranes and persistent cell infiltrates were found. Other findings at the autopsy of four patients included acute alveolitis, interstitial edema, hyaline membranes, and arteriolar thrombosis. Pertschuk et al. (87) reported eight patients with SLE who presented with a clinical diagnosis of acute lupus pneumonitis and 50% had changes of interstitial pneumonia. The pathologic picture was considered to be nonspecific and similar to that seen in those patients with oxygen toxicity, viral pneumonia, or uremia. The other four patients showed other pathologic changes: bronchiolitis, pulmonary infarction, focal atelectasis, and cytomegalovirus pneumonia, respectively. Vasculitis was not observed in any patient in either study (86 ,87). Widespread thrombosis was found in the lungs and other organs at autopsy of a patient with acute lupus pneumonitis and disseminated intravascular coagulation (88).

The wide variety of histologic changes in the lungs suggests that acute lupus pneumonitis may result from different pathologic processes (10). Many of the patients studied had received prior treatment, however, including oxygen, high-dose steroids, or cytotoxic agents, which can affect lung pathology either directly or indirectly. Thus, some of the pathologic abnormalities in the lungs may be secondary changes rather than resulting directly from SLE.

Granular deposits of IgG, C3, and DNA have been found in the alveolar septa of two patients with acute lupus pneumonitis (89). Electron microscopy revealed electron-dense deposits in the septal interstitium and in the walls of alveolar capillaries. Immunoglobulin eluted from the lung tissue had ANA activity, including IgG anti-DNA antibody. Another study described deposits of immunoglobulin within the nuclei of alveolar lining cells and pleural mesothelial cells, rather than in the septal interstitium, in acute lupus pneumonitis (87). The concomitant presence of C3 within the nuclei suggested that this was an in vivo rather than an artifactual phenomenon. These immunopathologic observations are consistent with the deposition of antigen-antibody complexes and may be important in the pathogenesis of the lung injury.

Parenchymal pulmonary infiltrates that develop acutely in a patient with SLE should not be considered as acute lupus pneumonitis until infectious processes such as viral pneumonia, tuberculosis, and other bacterial pneumonias and fungal and *Pneumocystis carinii* infections have been completely excluded (10). An elevated C-reactive protein (CRP) in such patients should encourage a vigorous search for lung sepsis.

Treatment and Prognosis

High-dose corticosteroids including bolus intravenous methylprednisolone together with supportive measures such as oxygen and mechanical ventilation where necessary are still the mainstay of drug therapy for acute lupus pneumonitis, although no controlled trials have established their efficacy (10 ,89). Cytotoxic agents such as azathioprine are added to the regimen in patients who fail to respond to steroid therapy or who relapse on steroid dose tapering (86). Intravenous pulse cyclophosphamide combined with systemic corticosteroids has also been used successfully (90).

Acute lupus pneumonitis carries a poor prognosis. Of 12 patients reported by Matthay et al. (86), the mortality was 50% during the acute episode—from respiratory failure, opportunistic infection, and thromboembolism. All six surviving patients remained relatively well after more than a year of follow-up, but three developed residual interstitial infiltrates with abnormal pulmonary function tests, indicating that the acute process can progress to chronic interstitial lung disease. Adult respiratory distress syndrome (ARDS) may occur with acute lupus pneumonitis, greatly increasing the risk of mortality (91 ,92).

Pulmonary Hemorrhage

Clinical Presentation and Diagnosis

Pulmonary hemorrhage is a rare, devastating, and frequently fatal manifestation of SLE with mortality rates of 70% to 90% (90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99). For example, Abud-Mendoza et al. (94) described 12 patients with massive pulmonary hemorrhage among 750 patients with SLE (1.6%) of whom 11 died. A further study found 34 patients in a cohort of 630 patients, all of whom had severe respiratory failure (97). A higher prevalence of 3.7% of all inpatient admissions for SLE had pulmonary hemorrhage reported by Zamora et al (93). Autopsy studies found pulmonary hemorrhage to be the cause of death in 11% to 14% lupus fatalities (94 ,98). Several children with SLE and lung hemorrhage also have been reported (100 ,101 ,102 ,103). Single-case reports also describe pulmonary hemorrhage in pregnancy (104) and the antiphospholipid syndrome (105).

The clinical presentation is similar to that of acute lupus pneumonitis, with a sudden onset of fever, dyspnea, cough, blood-stained sputum, and occasionally frank hemoptysis. The clinical course is rapidly progressive over hours or days, with increasing tachypnea, arterial hypoxemia, tachycardia, acute respiratory distress, and frank hemoptysis. The hemoglobin and hematocrit drop suddenly, and chest radiographs show bilateral pulmonary infiltrates, with a predominantly alveolar pattern. The infiltrates are coarsely nodular, fluffy, or homogeneous in pattern, often extending to the bases but occasionally unilateral in distribution. Single breath diffusing capacity for carbon monoxide may well be raised because of the presence of blood in the alveolar spaces, though patients are often too ill to undergo this investigation (106). Mechanical ventilation is frequently required for marked arterial hypoxia (93), and patients usually have clinical and laboratory evidence of

multisystem involvement, including positive anti-DNA antibodies and hypocomplementemia. The mortality in these patients is 62%, rising to 78% to 100% if there is concomitant infection (93).

Frank hemoptysis does not always occur, even with massive intra-alveolar hemorrhage, so the clinical diagnosis is often delayed (94 ,97). For example, in a series of 140 patients with SLE, 3 developed pulmonary hemorrhage, and in 2 of these patients the diagnosis was made only at autopsy (99). In the absence of hemoptysis, a rapidly falling hematocrit and diffuse lung infiltrates in a patient with SLE should alert the clinician to the possibility of lung hemorrhage (94). Bronchoalveolar lavages are universally hemorrhagic, and transbronchial lung biopsies may be helpful (93). Although open lung biopsy is sometimes advocated, these patients are usually very unwell and are poor operative risks. MRI and CT have been reported to be helpful in the diagnosis of diffuse alveolar hemorrhage in SLE (107 ,108).

Although pulmonary hemorrhage is very rarely the presenting feature of SLE, the majority of cases arise in patients with established lupus. The median disease duration of such patients ranges from 31 months to 3.2 years (93 ,98). Multisystem disease is often present in patients with pulmonary hemorrhage and renal disease is the most common occurrence. In one study, 94% of patients had both pulmonary hemorrhage and lupus nephritis (93), justifying the inclusion of SLE in the list of diseases associated with the pulmonary-renal vasculitic syndromes (109).

Pathology

The histopathology of the lung is that of diffuse, intra-alveolar hemorrhage with intact erythrocytes and hemosiderin-laden macrophages in the alveoli (93 ,98 ,110). Other microscopic findings include thickening of the alveolar septa, hyaline membrane formation, and fibrin deposits within the alveolar cavities. Evidence of vasculitis usually is not seen. A distinctive microangiitis that is characterized by acute inflammation and necrosis of alveolar capillaries, arterioles, and small muscular arteries also has been described in four patients (111), while in another study pulmonary capillaritis was seen in 80% of lung tissue specimens (93).

Electron microscopic studies in a small number of cases have shown type II alveolar-lining cell hyperplasia and electron-dense deposits in the alveolar septa within the basement membrane of alveolar capillaries and in the walls of small arteries (93 ,110 ,112 ,113 ,114). Direct immunofluorescence studies have demonstrated the presence of granular deposits of immunoglobulin, principally IgG, and complement components in the alveolar septa and in the walls of small blood vessels (110 ,112 ,113 ,115). Other investigators, however, have failed to find immune deposits in the alveolar septa in patients with SLE and pulmonary hemorrhage (110 ,116).

Pathogenesis

The pathogenesis of pulmonary hemorrhage in SLE is not known. Deposition of immune complexes in the alveolar septa and in blood vessels, with activation of the complement system, has been proposed as being the major mechanism, which is analogous to the lung changes that are seen in experimental models of chronic serum sickness. Brentjens et al. (117) described changes of interstitial pneumonitis with proliferation of septal cells, thickening of the alveolar septa, accumulation of leukocytes in capillaries, and alveolar hemorrhages in rabbits that were hyperimmunized with foreign serum protein. Conversely, Eagen et al. (110) identified several factors that potentially contributed to the pathogenesis of lung hemorrhage in their patients with SLE, including bleeding diathesis, oxygen toxicity, infection, uremia, and shock lung. Desnoyers et al. (116) described a patient with SLE and cutaneous vasculitis, nephritis, and pulmonary hemorrhage but without the complicating factors described earlier that could cause nonspecific alveolar damage. No immune deposits were found in the alveolar septa, although they were present in the renal glomeruli. These authors suggested that pulmonary hemorrhage could occur in SLE by mechanism(s) other than immune complex deposition, such as vascular injury with disruption of the alveolar capillary membrane. Unlike Goodpasture syndrome, in which pulmonary hemorrhage is characteristic, there is no association with smoking (93).

Treatment and Prognosis

The prognosis of massive pulmonary hemorrhage in patients with SLE is grave, despite treatment with high-dose systemic corticosteroids combined with a cytotoxic agent (10 ,86 ,94 ,110). Other investigators have reported a better prognosis, however. Six of eight patients (75%) with SLE and pulmonary alveolar hemorrhage who were reported by Schwab et al. (118) recovered. In another large study the overall survival rate was only 38% (97). The mortality rate of pediatric lupus cases with lung hemorrhage has been reported to be 50% (102).

The poor prognosis in these patients suggests that it may be advisable to employ a regimen of high-dose corticosteroids, cyclophosphamide, and perhaps plasmapheresis (119 ,120 ,121).

Erickson et al. (120) reported dramatic improvement in three patients who underwent intensive plasmapheresis combined with steroids and cyclophosphamide. A review of reported cases of pulmonary hemorrhage in SLE showed that the survival rate of those patients who received corticosteroids with or without cytotoxic agents was 43% (23 of 53 patients). In contrast, 7 of 11 patients (64%) who also underwent plasmapheresis survived (120). Complications (especially a high rate of serious infections) have been reported in patients receiving plasmapheresis combined with steroids and cyclophosphamide (122). Pagnoux et al.

wrote a useful review on the indications for plasmapheresis in severe lupus including pulmonary hemorrhage (123).

Carette et al. (124) reviewed more than 400 SLE patients who were followed over 10 years, of whom 8 became acutely ill with diffuse lung infiltrates. Pulmonary hemorrhage was eventually diagnosed in 6 patients, of whom 4 had other complicating factors, including uremia, coagulopathy, and infection. Based on their experience, a practical management approach was suggested. Four major conditions should be considered in the differential diagnosis: (a) congestive heart failure, (b) noncardiogenic pulmonary edema, (c) infection, and (d) pulmonary hemorrhage. A careful clinical history should be taken, and a thorough physical examination performed. Evidence of lupus activity in other organ systems should be documented. If the diagnosis of congestive heart failure is unclear on clinical grounds, an echocardiogram or Swan-Ganz catheter should be considered. Infection and factors that are associated with noncardiogenic pulmonary edema, including uremia, pancreatitis, and side effects from drugs, should be excluded. If a definite diagnosis is not reached at this point, broad-spectrum antibiotics and high-dose corticosteroids should be considered while bronchoalveolar lavage, transbronchial lung biopsy, and brushings are obtained. If pathogenic organisms are not found after appropriate stains and cultures, antibiotics should be discontinued. Systemic corticosteroids should be continued until clinical improvement occurs, but if the patient fails to respond, an open-lung biopsy sample should be considered, bearing in mind the operative risks that this procedure entails.

Chronic Diffuse Interstitial Lung Disease

Clinical Presentation

Diffuse ILD is a well-recognized pulmonary manifestation of systemic rheumatic diseases, particularly systemic sclerosis, dermatomyositis, and RA. Somewhat surprisingly, it is much less common in SLE than in other connective tissue diseases. ILD in SLE was described in detail in 1973, by Eisenberg et al. (125). The prevalence of symptomatic ILD in SLE has been calculated to be approximately 3% (126 ,127). In an early prospective study of 150 patients, 9 developed radiographic changes of pulmonary fibrosis, but it is unclear whether these patients were symptomatic or how severe the pulmonary functional abnormalities were (55). A retrospective study of 63 SLE patients noted 16 patients (25%) with ILD (127). The high prevalence was partly due to the inclusion of severely ill, hospitalized patients in their series.

The initial presentation of diffuse ILD in SLE can be one of two types. The more common is an insidious onset of a chronic nonproductive cough, dyspnea on exertion, and a history of recurrent pleuritic chest pain. Less commonly, ILD may develop in a patient following acute lupus pneumonitis: two studies suggest that between 43% and 50% of patients with acute lupus pneumonitis may go on to develop chronic diffuse ILD (86 ,127).

The presentation of ILD in SLE resembles that of lung disease in systemic sclerosis and RA. The most common clinical manifestations are persistent dyspnea on exertion, pleuritic chest pains, and nonproductive cough. ILD can occur at any time during the course of SLE, but in most patients it develops in those with long-standing disease. Multisystem involvement is relatively common, and patients usually test positive for both ANAs and anti-DNA antibodies.

In the study by Eisenberg et al. (125), the mean age of their 18 patients with SLE and ILD was 45.7 years, with a mean disease duration of 10.3 years. Pulmonary manifestations were present for a mean of 6 years. Initially, 7 patients presented with pulmonary symptoms developing over weeks to months with dyspnea on exertion, and 3 with dyspnea at rest. Twelve complained of cough with scanty sputum, and a similar number had pleuritic chest pain. All patients had poor diaphragmatic movement, with diminished resonance to percussion over the lung bases. Cyanosis and clubbing were present in 1 patient, and 12 had basilar rales. All 18 had persistent, diffuse interstitial infiltrates on chest radiography that could not be attributed to other complication. Markedly elevated diaphragms were seen in 8 patients, and diaphragmatic excursion was decreased in 6 as evaluated by chest radiography on deep inspiration and expiration. A pleural reaction was present in 9 patients, and plate-like atelectasis in 6, which was usually seen just above the diaphragm and persisted for several months to years. The diffusing capacity of the lung, as measured by the carbon monoxide method, was decreased below the predicted normal values in all but 1 patient.

Laboratory Evaluation

To investigate the possibility of pulmonary infarction, Eisenberg et al. (125), obtained ventilation-perfusion lung scans in 13 patients. Of these, 8 had matched ventilation and perfusion defects occurring at the same site. In seven of 13 patients, ventilation-perfusion defects were noted in areas other than those occupied by long line shadows, effusions, or atelectasis.

Spirometry and lung-volume measurements were consistent with a restrictive defect or loss of lung volume without obstruction to air flow. Diffuse pulmonary interstitial infiltration typically results in this type of ventilatory defect. Infiltrated lung areas are less elastic and change their volume less with each breath. Underventilation results in under oxygenation of the blood perfusing these regions, and if this ventilation-perfusion mismatching is extensive, significant arterial hypoxemia may occur. Obstructive defects were not seen (125).

The arterial blood oxygen tension (PaO_2) was diminished in all patients, and the alveolar-arterial difference for oxygen (PaO_2–PaO_2) increased significantly. The PaO_2 was lowest and the PAO_2–to-PaO_2 difference greatest in patients

with the most extensive pulmonary involvement, as noted in their radiographs. The oxyhemoglobin saturation, however, was above 94% in all but four patients, and ventilation-perfusion mismatching was responsible for these changes. Thickening and fibrosis of the interstitial wall and microinfarcts in the lung alter the elastic properties of the ventilatory lung units, leading to underventilation relative to perfusion. Lung biopsy in four patients showed nonspecific interstitial fibrosis, with chronic inflammation in two (125).

Boulware and Hedgpeth (127) found precipitating anti-Ro/SSA antibodies in 81% of patients with SLE and ILD compared to 38% in their general SLE population. In contrast, the frequency of other specific types of ANA, such as anti-U1 ribonucleoprotein (RNP), and anti-La/SSB, was not significantly increased. This possible association with anti-Ro/SSA has also been found by Mochizuki et al. (128) but not by Weinrib et al. (126), and the discrepancy may result from differences in patient selection.

There is evidence that chronic ILD occurs in a subset of lupus patients with features of scleroderma, including Raynaud phenomenon, sclerodactyly, and nailfold capillary abnormalities (129). Additionally, there is an increased frequency of anti-U1RNP and anti-U1RNA antibodies in these patients. However, in this study, 7 of the 19 patients with SLE and chronic ILD had concomitant connective tissue disease, including RA, scleroderma, and mixed connective-tissue disease (MCTD) (129).

High-Resolution CT Scans

HRCT scans of the lungs are essential in the diagnosis, assessment of disease activity in the lung parenchyma, and provision of prognostic information in patients suspected of having ILD associated with connective tissue diseases (130 ,131 ,132 ,133) (Fig. 35-3).

Johkoh et al. (134) compared HRCT lung scans and pulmonary function tests in idiopathic pulmonary fibrosis and ILD associated with connective tissue disease including SLE. The extent of morphologic changes correlated with the severity of impairment of the DLCO in both patient groups. Steroid-responsive patients showed a ground-glass and alveolar consolidation and no honeycomb lesions on the HRCT scans. In contrast, patients who failed to respond to therapy had severe honeycomb lesions on the HRCT scans. A further study of 15 HRCT scans in ten lupus patients with respiratory symptoms found 14 of the 15 scans to be abnormal (135). The main finding was that of chronic lower zone interstitial lung disease with honeycombing, architectural distortion, parenchymal bands, and pleural changes. Pleural thickening was seen in 87% of scans, and all patients had abnormal lung function tests, especially reduced carbon monoxide diffusion capacity.

Figure 35-3. High-resolution CT chest scan showing bilateral basal interstitial fibrosis with honeycombing.

Pathogenesis of Chronic ILD

Studies in idiopathic pulmonary fibrosis and systemic sclerosis suggest a key role for cytokines and other mediators that are secreted by alveolar macrophages and inflammatory cells as well as resident structural cells of the lung. IL-1, tumor necrosis factor (TNF), endothelin, and especially growth and differentiating cytokines (transforming growth factor, platelet-derived growth factor [PDGF], and granulocyte-macrophage colony-stimulating factor [GM-CSF]) are believed to be important in the alteration of cell phenotypes in the lung, accumulation of inflammatory cells from the circulation, and increased collagen secretion by stimulated fibroblasts (136 ,137).

Chronic ILD is a predominantly T-lymphocyte–mediated immunologic reaction to some unknown antigen, in contrast to acute lupus pneumonitis, which primarily is an immune-complex–mediated condition (138). This study found increased numbers of activated $CD8^+$ T cells, $CD56^+/CD16^+/CD3^-$ NK cells, and other markers of T cell activation in the BAL fluid of patients with SLE (138). These cellular abnormalities were associated with upregulated local production of oxygen radicals and with impaired pulmonary diffusing capacity. Additionally, cells in the BAL fluid of patients with SLE and ILD spontaneously secrete increased amounts of PDGF and TNF, which can induce proliferation of fibroblasts (139).

Treatment and Prognosis

The clinical course of chronic ILD is variable in individual patients, but as a group, most patients follow a slow course, tending to improve or stabilize with time. In one study of 14 patients, all received high-dose prednisone (60 mg daily) for at least 4 weeks early in the course of the pulmonary disease (126). The DLCO and inspiratory vital capacity (IVC) either improved or remained unchanged in most patients, and respiratory symptoms improved in all patients. Two died of progressive pulmonary fibrosis, however, and another succumbed to bacterial pneumonia (126). A study comparing patients with ILD associated

with connective tissue diseases, including SLE, and those with idiopathic pulmonary fibrosis showed that lung function deteriorated significantly over 2 years in the idiopathic group, but remained essentially unchanged in the connective tissue diseases group (140).

Patients with SLE and symptomatic, chronic, progressive ILD should undergo assessment of the extent and activity of the lung disease with pulmonary function tests, gallium lung scan, BAL, and/or transbronchial biopsy. An open-lung biopsy is usually not indicated. HRCT scans of the lungs give useful information on the extent and activity of disease, and repeat HRCT may document changes, especially if the changes are predominantly of ground-glass alveolar shadowing. Serial pulmonary function tests are useful in monitoring the disease and the response to therapy (10).

In the presence of an active inflammatory process in the lung, and once infection has been excluded, high-dose prednisone (40 to 60 mg daily) for at least 6 to 8 weeks should be considered. The dose is tapered depending on the clinical and laboratory responses of the patient. Immunosuppressive agents such as azathioprine and intravenous cyclophosphamide may be needed in patients who fail to respond satisfactorily to steroids.

Corticosteroid therapy of ILD in lupus and other connective tissue diseases results in a decrease in total cell count, immune complexes, and immunoglobulin levels in BAL fluid (141). The efficacy of systemic corticosteroids and immunosuppressive agents in the treatment of ILD and SLE has not been validated by well-designed, controlled trials.

Pulmonary Embolism

Pleuritic chest pain and dyspnea are relatively common, and most patients with SLE presenting with these symptoms usually have pleurisy or pneumonitis. However, pulmonary embolism (PE) should always be considered especially if antiphospholipid antibodies are present or there is a previous history of PE. The predictive value of V/Q scans, D-dimer levels, and CT pulmonary angiography has been discussed above (Table 35-2), and it should be remembered that abnormal perfusion scans may occur in patients with active lung disease in the absence of PE. Nevertheless, if PE is suspected clinically in a patient with a low probability V/Q scan, angiography should be performed.

Peripheral deep venous thrombosis (DVT) is common in patients with SLE and predisposes to PE (13 ,53 ,55 ,142). Perhaps the most widely recognized risk factor for venous thromboembolism in SLE is the presence of circulating lupus anticoagulants and other antiphospholipid antibodies (143 ,144 ,145). In the European study of 1,000 patients, antiphospholipid antibodies including the lupus anticoagulant were significantly associated with thrombosis, fetal losses, thrombocytopenia, and livedo reticularis (57). Patients who develop DVT and/or PE in the context of antiphospholipid antibodies will usually require lifelong anticoagulation (146).

The catastrophic antiphospholipid syndrome is an accelerated form of the antiphospholipid syndrome characterized by the rapid onset of widespread thrombosis and multiorgan failure with a high mortality. Recently classification criteria have been validated for use in research studies (147). The lungs are very commonly involved and the usual presentation is acute respiratory distress syndrome. Thus, Bucciarelli et al. reported pulmonary involvement in 150 out of 220 (68%) patients with catastrophic APS and 47 (21%) patients were diagnosed as having acute respiratory distress syndrome. Prognosis was poor and 19 (40%) of these patients died. Seven of 10 patients had a thrombotic microangiopathy on histology (148). (See Chapter 65 for a further discussion of thrombosis and antiphospholipid antibodies.)

Reversible Hypoxemia

A relatively rare syndrome of acute reversible hypoxemia in acutely ill patients with SLE but without evidence of parenchymal lung involvement may occur (149 ,150 ,151). The first description was by Abramson et al. (149); among 22 inpatients with acute disease exacerbation, 6 (27%) had this syndrome. Although some patients had mild pleuropulmonary symptoms, chest radiographs and lung scans were normal. The patients had hypoxemia and hypocapnia with a wide alveolar-arterial (A-a) gradient, which reversed with corticosteroid therapy. The pathogenesis of the syndrome is unclear, but a correlation between hypoxemia and the level of complement split products was noted, and others have suggested a relationship with disease activity (150 ,151). Complement activation may lead to diffuse pulmonary injury with the aggregation of neutrophils in the lungs similar to that seen in cardiopulmonary bypass, hemodialysis with cuprophane membranes, and ARDS.

Pulmonary Hypertension

Clinical Presentation

Severe, symptomatic pulmonary hypertension (PH) is a relatively rare manifestation of lung involvement in SLE, but mild subclinical cases are surprisingly common with prevalences of between 5% and 14% (reviewed in (12)).

Perez and Kramer (152) were the first to report four patients with severe PH in a group of 43 patients with SLE over a period of 2 years. Other studies, however, found rather lower prevalences (153). Of great interest is a 5-year follow-up study of a cohort of lupus patients that showed that the prevalence of PH rose from 14% to 43%, with the mean pulmonary artery pressures rising from 23.4 mm Hg to 27.5 mm Hg (154).

The clinical diagnosis of PH is difficult to make in early and mild cases, and only the severe cases, with right ventricular hypertrophy and/or congestive heart failure, have been reported in the literature. Pulmonary artery pressure at rest and during exercise is significantly higher in unselected

patients with SLE as compared to normal subjects, probably secondary to increased pulmonary vascular resistance in lupus patients (155). A study of the prevalence and severity of PH in a group of 36 patients with SLE and healthy controls was undertaken by Simonson et al. (156) using two-dimensional and Doppler echocardiographic data to calculate pulmonary artery systolic pressure. Five patients (14%) and none of the controls had PH, as defined by a pulmonary artery pressure of greater than 30 mm Hg. This study suggests that PH is common in SLE, but usually mild in degree. In another study, Shen et al investigated 84 Chinese patients with SLE and 99 healthy controls to investigate the prevalence and the mechanism of pulmonary hypertension with 12 patients undergoing right heart catheter studies as well as echocardiography (157). The lupus patients had significantly higher systolic pulmonary artery pressures, mean pulmonary artery pressures and total pulmonary resistance compared to controls. Nine of the 84 patients had pulmonary hypertension (11%). Pulmonary hypertensive patients had higher endothelin levels than nonpulmonary hypertensive patients, were more likely to have active disease and presented Raynaud phenomenon and positive rheumatoid factors. Endothelin levels correlated with echocardiographic pulmonary pressure (157).

The symptoms of PH in SLE are in general similar to those of patients with idiopathic or primary PH (153). In most of the reported cases, the symptoms of PH occurred within a few years of onset of the multisystem disease, with a mean duration of approximately 2.3 years (153). The most common complaints are dyspnea on exertion, chest pain, and chronic nonproductive cough. Chronic fatigue, weakness, palpitations, edema, and/or ascites may also occur. Symptoms usually develop insidiously and progress gradually. The physical findings may include a loud second pulmonary heart sound, systolic murmur, and right ventricular lift. Chest radiography findings include cardiomegaly with a prominent pulmonary artery and clear lung fields. Electrocardiography may show changes of right ventricular hypertrophy. Although PFTs may show restrictive abnormalities, these are mild in degree and disproportionate to the severity of the PH. Pulmonary angiograms in severe cases demonstrate symmetric dilatation of the central pulmonary artery trunk, with pruning of the peripheral blood vessels. Cardiac catheterization is the definitive investigation and demonstrates the characteristic elevation of the pulmonary artery pressure and normal wedge pressure without evidence of intracardiac or extracardiac shunting.

Pathology

The histopathology of the lung in patients with SLE and PH is that of plexiform lesions similar to those seen in primary PH (153). Medial hypertrophy and intimal fibrosis of the branches of the pulmonary artery may be seen. Thrombosis and vasculitis have also been reported in a few patients (153). Deposits of IgG, IgM, and C3 in the walls of the pulmonary blood vessels have been found (153). These immunoglobulin deposits, when eluted with acidic buffer, showed ANA activity, including anti-DNA antibody and rheumatoid factor activity (153). The putative antigen DNA also was found in the walls of blood vessels, indicating the deposition of immune complexes.

Pathogenesis

The pathogenesis of PH is not well understood, and it is likely that multiple etiologic factors are involved (158). For example, although immune deposits have been found in the large pulmonary vessels, it is not clear whether this is important in the pathogenesis or merely represents a secondary phenomenon. Vasculitis affecting the pulmonary artery is rarely seen and is unlikely to be a major cause of PH (159 ,160 ,161). Occasionally, PH can develop as a complication of diffuse pulmonary fibrosis.

Asherson et al. (162) reported a high frequency of anticardiolipin antibodies in patients with SLE and PH, indicating the possible causative role of recurrent thromboembolic phenomena, but others have not observed this association (159). Additionally, other features of the antiphospholipid syndrome are uncommon in patients with SLE and PH (162), and thrombosis is not commonly seen in autopsied cases (153). Thrombosis of the pulmonary vessels has been confirmed in a small number of patients with antiphospholipid antibody syndrome with PH (163 ,164).

Miyata et al. (165) reported that patients with SLE or MCTD and anticardiolipin antibodies have higher mean pulmonary artery pressures than those without anticardiolipin antibodies. The high frequency of Raynaud phenomenon in the PH group (up to 75%, compared to 25% to 40% of other lupus patients) suggests that PH may be a complication of pulmonary arterial vasospasm (156 ,162). Another intriguing study suggested a significant correlation between nailfold capillary density and pulmonary gas transfer (KCO) in patients with SLE. It may be that in SLE, poor gas transfer may be dependent on alveolar capillary loss and that nailfold capillary density may be a good indicator of alveolar capillary density (166). This group also assessed muscle biopsy specimens in relation to pulmonary involvement in lupus but found no strong correlation (167).

Some studies point to the possible role of endothelial dysfunction and abnormal vascular response in PH. One study showed an increase in the release of thromboxane A2, a potent pulmonary vascular vasoconstrictor and procoagulant, and a decrease in the release of prostacyclin in patients with both primary and secondary PH, including SLE (168). Endothelin levels are elevated in lupus patients with PH and in Shen et al.'s study correlated with echocardiographic pulmonary pressure (157). Antiendothelial cell antibodies, which are associated with lupus nephritis (169) have also been described in patients with SLE and PH (170). More recently the potential role of brain natriuretic peptide (BNP) levels in the assessment of functional status and right heart performance in primary pulmonary hypertension has been highlighted (171) and this may be a useful test in screening for early pulmonary hypertension in lupus.

Primary PH in children is associated with human leukocyte antigen (HLA)-DR3, DRw2, and DQw2, whereas PH in systemic sclerosis is associated with DRw52, suggesting a role for genetic factors (172 ,173). This is supported by a report of fatal PH in identical twins with lupus (174).

Prognosis and Treatment

The overall outcome of severe PH in SLE is poor. Of the patients reported in the literature, cardiac failure or sudden death presumably because of an arrhythmia were the most common modes of death. Although the presence of Raynaud phenomenon is associated with a poorer outcome, the most accurate predictors are pulmonary artery pressure, right atrial pressure, and cardiac index (reviewed in (12)).

A trial of various vasodilator agents is certainly worth trying in these patients. For example, nifedipine was useful in patients with PH associated with MCTD and scleroderma (175), although some cardiologists feel that this is inappropriate, particularly in scleroderma patients with severe PH. However, the effect on exercise tolerance and survival was not examined in this study. In primary PH, high doses of nifedipine and other calcium channel blockers have been shown to improve hemodynamic abnormalities and to prolong survival (176).

Other strategies include anticoagulants, systemic corticosteroids, or cytotoxic agents (reviewed in (12)). Some patients have experienced symptomatic improvement, although hemodynamic abnormalities remained unchanged with drug therapy (153 ,177 ,178). Improvements in cardiac hemodynamics have been reported in a few patients (179) and intermittent intravenous infusions of cyclophosphamide have resulted in partial improvement in hemodynamics in a patient with lupus and PH (180). Sequential administration of cyclophosphamide and cyclosporin A improved the hemodynamic and clinical course of a patient with MCTD and PH (181).

Short-term infusion of prostacyclin and prostaglandin E1 has been tried successfully in the treatment of a patient with lupus and PH (182). Chronic prostaglandin infusion either intravenously and more recently by inhalation and other treatment modalities, including nitrous oxide, have been used in primary PH and may be applicable to SLE, but the evidence in support of these therapies in SLE is anecdotal at present.

Until recently, despite combinations of these drugs, most of the patients reported by Asherson et al. (162) died within 5 years after the diagnosis of PH. Two of their patients underwent heart-lung transplantation, with satisfactory results in one but poor results in the other because of chronic rejection (183). However, in the last 2 years, specific endothelin receptor antagonists against the ETA and or ETB receptors have been subjected to clinical trials. Bosentan has been shown to improve exercise capacity, hemodynamics, echocardiographic and Doppler variables and time to clinical worsening in patients with primary and secondary (to connective tissue diseases) PH (184). Other agents such as sitaxsentan and sildenafil and combinations of endothelin receptor antagonists and prostacyclins such as epoprostenol are undergoing clinical trials with very encouraging results.

Shrinking Lung Syndrome

In 1965, Hoffbrand and Beck (185) described a group of patients with SLE with breathlessness and reduced chest expansion, but no cyanosis, clubbing, or abnormal auscultatory findings. Many of the patients had a previous history of pleurisy. Chest radiography revealed clear lung fields but with an elevated diaphragm, which moved sluggishly and not paradoxically (Fig. 35-4). The vital capacity was extremely reduced. The authors coined the term shrinking lung syndrome and suggested that the main pathologic lesion is that of alveolar atelectasis secondary to deficiency of the surface tension reducing film that lines the normal alveoli. Gibson et al. (186) measured diaphragmatic function in these patients by determining the transdiaphragmatic pressure using a double-balloon technique, and they found it to be grossly abnormal. This finding led them to suggest that diaphragmatic dysfunction, rather than parenchymal or pleural disease, accounts for the unexplained dyspnea in these patients. Martens et al. (187) concluded that the restrictive ventilatory defect in these patients results primarily from the weakness of expiratory and inspiratory muscles. Diaphragmatic dysfunction correlated with the degree of dyspnea but not with overall disease activity, proximal muscle weakness, or serologic markers. Contrary to these reports, however, Laroche et al. (188), using a wide range of tests for determining respiratory muscle strength, found no evidence of isolated weakness of the diaphragm in 12 patients with SLE and this syndrome. The discrepancy between their results and those of previous studies is not entirely clear, but it may result partly

from patient selection and differences in the methods that were used to assess diaphragmatic function.

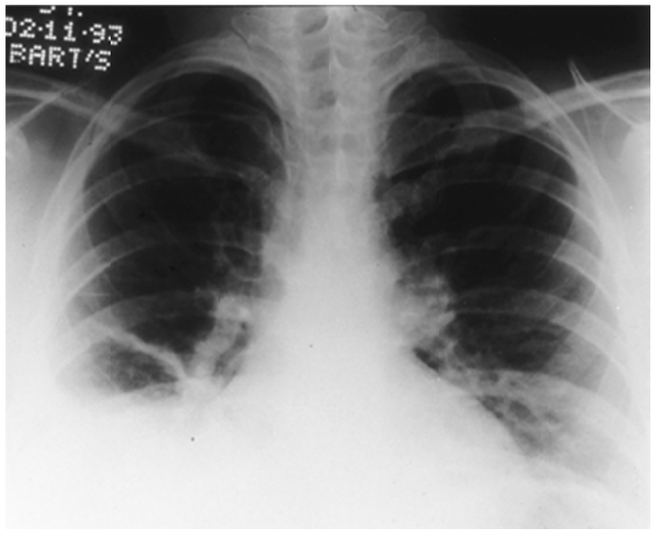

Figure 35-4. Chest radiograph showing raised right hemidiaphragm and a linear atelectasis in the right midzone.

The pathogenesis of the diaphragmatic weakness in patients with SLE is not well understood. Wilcox et al. (189) found no evidence of phrenic nerve neuropathy as the cause of this weakness. Diffuse fibrosis of the diaphragm without evidence of acute inflammatory infiltrates was observed in one patient examined at autopsy (190), supporting an extrapulmonary, restrictive cause for this unusual syndrome. An electromyographic study of the diaphragm and external intercostal muscles demonstrated that fatigue of the respiratory muscles occurs at lower loads in patients with SLE as compared to those in healthy controls (191). Whether myopathy is an isolated process affecting primarily the diaphragm and other respiratory muscles or is part of a generalized muscle disease in SLE is not entirely clear. When the diagnosis of shrinking lung syndrome is suspected, measurements of transdiaphragmatic pressures and elastic recoil of the respiratory system should be considered.

The clinical course of the syndrome is a chronic, low-grade, restrictive defect. Follow-up of some patients over a period of several years has shown that the volume restriction is not progressive (186 ,187). In symptomatic patients, prednisone therapy (30 to 60 mg daily for several weeks) is clinically beneficial and tends to stabilize the PFT abnormalities (191 ,192 ,193 ,194 ,195 ,196 ,197). Agonist agents and theophylline and immunosuppression with methotrexate may also be useful in the treatment of this syndrome (194 ,195 ,196 ,197).

Airway Obstruction

Severe airway obstruction has been reported in a small number of patients with SLE (198 ,199). Lung biopsy in one patient showed obliterative bronchiolitis and an acute inflammatory process that affected small bronchi and bronchioles, resulting in necrosis and eventual endobronchiolar proliferation of epithelial cells and peribronchial infiltration by lymphocytes. Dense plugs composed of alveolar debris and fibrin strands within the bronchioles caused partial or complete obstruction. Bronchiolitis obliterans with organizing pneumonia has been described in SLE (200).

Evidence of airway obstruction has been described in several controlled studies of PFT in patients with SLE (3 ,201 ,202 ,203 ,204). Some series did not take into consideration the effect of cigarette smoking, but in those that did it was evident that airway obstruction occurred even in nonsmoking patients with SLE. The frequency of airway obstruction is variable, primarily because of differences in the criteria that are used to define the abnormality and in the selection of patients. In the only controlled study of lifelong nonsmoking patients with SLE, Andonopoulos et al. (39) observed a high prevalence (24%) of isolated small airway disease in patients with SLE. The clinical significance of this observation remains unclear, however, because a similarly high frequency (17%) of small airway disease was found in their healthy, nonsmoking age- and sex-matched controls.

Very occasionally the upper airways have been affected in lupus. Case reports have described hypopharyngeal ulceration, laryngeal inflammation, vocal cord paralysis, epiglottitis, and subglottic stenosis (reviewed in (12)).

Fatigue, Physical Fitness, and Aerobic Capacity in SLE

Fatigue is a major clinical problem in patients with SLE and is often their most persistent symptom. It is multifactorial in origin and difficult to treat. A number of studies have addressed whether poor physical fitness and aerobic capacity may be contributory factors. Two studies assessed physical deconditioning in SLE (205 ,206). Robb-Nicholson et al. showed that compared to published age- and sex-matched norms, patients with SLE performed at 45% of their expected maximal aerobic capacity (VO_2max) and fatigue, measured using a visual analog scale, was inversely correlated with the duration of the exercise test, although not with VO_2max itself (205). A study by Daltroy et al. measured exercise duration during a graded exercise test in 34 patients with SLE and concluded that the patients were deconditioned compared to published age- and sex-matched norms (206). However, both studies were limited by the small number of patients involved, the use of published normative data, and the insensitivity of the fatigue measure. Tench et al. studied 93 patients with mild stable SLE and 41 healthy, but sedentary female controls and found that the SLE patients had significantly shorter test duration, lower VO_2peak, lower maximum minute ventilation, and lower respiratory exchange ratio, and terminated the exercise treadmill test at a significantly lower maximum heart rate (207). Significantly more of the SLE patients (33%) had a peak respiratory exchange ratio less than 1.1 compared to 12% of the controls. The maximum voluntary quadriceps contraction was also significantly reduced in the SLE patients compared to controls. Furthermore, resting lung function measures were significantly reduced in the lupus patients. There were 15/93 (16%) SLE patients who had FEV_1 less than 75% of predicted and 18/93 (19%) SLE patients who had FVC less than 75% of predicted. One control patient had FEV_1 and FVC less than 75% of predicted. The SLE patients had significantly lower submaximal oxygen uptake compared to controls, but there were no significant differences in submaximal perceived exertion or heart rate between the groups (207). A smaller study of 18 women with SLE and 16 controls described very similar findings with significant functional aerobic impairment (208).

In order to address this a randomized trial of an exercise programme was conducted by the same authors (209). Although fatigue scores and exercise duration improved significantly aerobic capacity did not change in these patients who had no clinical evidence of lung disease.

Infections and the Lung in SLE

Pulmonary infections are common in patients with lupus, especially in those taking corticosteroids and immunosuppressive therapies. Organisms include viruses, bacteria, mycobacteria, parasites, and opportunistic fungal infections. For a more thorough review of infectious complications in SLE, see Chapter 43 .

Chapter 36

Clinical Aspects of Vasculitis and Selected Cutaneovascular Manifestations of Systemic Lupus Erythematosus

Daniel J. Wallace

Inflammation of the blood vessels is a common feature of SLE. Its manifestations in various organ systems are reviewed in their appropriate chapters. This section overviews clinical vasculitis with emphasis on its cutaneovascular features and subsets.

Vasculitis

Defined as inflammation of a blood vessel, vasculitis associated with lupus is defined using clinical, histopathologic, and arteriographic criteria. In SLE, vasculitis is cutaneous or visceral, with the former making up the overwhelming majority of cases. The clinical signs of vasculitis vary from organ to organ and are covered individually in chapters in this book. A literature review by Calamia and Balabanova estimates that vasculitis complicates lupus in only 4% of cases (1). The prevalence of vasculitis varies widely and depends the nature of referral patterns of the reporting center. Lupus usually involves the small- and medium-sized vessels with intimal thickening, medial necrosis, and adventitial fibrosis, but cutaneous vasculitis can include capillaritis. The pathophysiologic mechanisms of inflammation resulting in vasculitis can be found in the basic science chapters of this monograph.

Alarcon-Segovia et al. followed 667 lupus patients in Mexico City. Of 540 who were evaluable, 194 had vasculitis (2). Five percent had vasculitis at 1 year, but 41% at 10 years. As noted above, most of the cases consisted of cutaneous vasculitis (160, or about 80%). Visceral lesions were found in 24 and both in 10. Those with vasculitis tended to be younger and male. The cutaneous lesions were (from most to least) punctuate lesions, palpable purpura, papules, urticaria, ulcers, erythematous plaques, erythema with necrosis, and panniculitis. The visceral lesions included mononeuritis multiplex, digital necrosis, large artery vasculitis (3), mesenteric arteritis, and coronary arteritis. The definitive diagnosis was made by biopsy in 46 and imaging studies in 5. Visceral disease was associated with a poor prognosis. Ramos-Casals et al. reported on 630 patients in their Barcelona cohort seen between 1980 and 2002 (4). Sixty-two, or 10% had vasculitis with 22% being male and a mean age of 32.8. 94% had cutaneous vasculitis; 18% systemic vasculitis (with obvious overlap). The presentation was similar to the Mexican group, except that 27% with vasculitis had cryoglobulins.

Clinical Aspects of Cryoglobulinemia in SLE

The prevalence of cryoglobulinemia varies depending upon referral patterns and the vigor and rigor for which it is defined and looked for, ranging from 16% to 83% (5 ,6 ,7 ,8). The lower figure is probably more accurate if one examines published reports since 1990, because hepatitis C could be differentiated from clinical SLE (5 ,7). Chapter 28 reviews the basic science aspects of this protein.

Cryoglobulinemia is associated with cutaneous vasculitis, rheumatoid factor, hypocomplementemia, antiphospholipid antibodies, and concurrent hepatitis C infection. Two thirds have cryocrits less than 1%, and only hepatitis C is associated with higher values. Hepatitis C accounts for approximately 20% of SLE associated cryoglobulinemia, which responds to antiviral regimens and interferon-α. Anti-inflammatory therapies used to manage active lupus ameliorate cryoglobulinemia with the suggestion that apheresis might be helpful in cases where the cryocrit is critically elevated (9).

Raynaud Phenomenon

Paroxysmal vasospasm of the fingers, or Raynaud phenomenon, is a frequent abnormality in SLE. Raynaud phenomenon represents an abnormally regulated neuro-endothelial

control of vascular tone as a form of dysautonomia (10 ,11) (Fig. 36-1 .) Here again, as with alopecia and fractured frontal hair, incidence varies with the observer's specific questioning of the patient. Raynaud phenomenon was present at some time in 10% to 57% of the patients listed in Table 32-1 . Because a history of Raynaud phenomenon may be vague, nonspecific, and difficult to document, it was deleted from the 1982 revised American College of Rheumatology (ACR) criteria for SLE. Its prevalence takes the middle range between the 95% found in scleroderma and the 3% seen with rheumatoid arthritis (12). Cholesterol emboli, cryoglobulinemia, digital infarcts from the lupus anticoagulant, and reflex sympathetic dystrophy can mimic Raynaud phenomenon and must be excluded. The activity of Raynaud phenomenon usually is independent of SLE disease activity and the presence of antiphospholipid antibodies (13).

Figure 36-1. Severe Raynaud's phenomenon with digital gangrene.

Raynaud phenomenon is nonspecific and may be present years before the development of other changes caused by SLE, scleroderma, or dermatomyositis. De Takats and Fowler (14) reviewed 66 patients with Raynaud phenomenon with follow-up for 1 to 25 years, and they observed that 32 subsequently developed scleroderma, 2 developed SLE, and 1 developed dermatomyositis. Three later reports repeated their survey and found that 0 of 96, 0 of 85, and 0 of 87 patients with Raynaud phenomenon carried a diagnosis of SLE, with a mean 5-, 6-, and 9-years of follow-up, respectively (15 ,16 ,17). Studies of patients referred to rheumatologists because of Raynaud phenomenon revealed that 5% to 9% had SLE (1 ,18 ,19 ,20). Raynaud phenomenon was the first manifestation of SLE in two of Dubois' patients (Table 32-2).

Dimant et al. (21) compared 91 of their 276 patients with Raynaud phenomenon to those without it. Those in the Raynaud phenomenon group had significantly more arthritis, malar rash, and photosensitivity and less renal disease, lower steroid requirements, and fewer deaths than those in the unaffected group. The Raynaud phenomenon that is associated with SLE is similar to that seen in Raynaud disease and is less severe than that in scleroderma. The vasospasm rarely leads to permanent damage; small ulcers on the fingers can occur following prolonged and frequent attacks. Raynaud phenomenon usually operates independent of disease activity and is not steroid responsive. It may be associated with antibodies to hn-RNP protein A1 (22), migraine, and chest pain (23). Arteriograms of 10 patients with SLE and Raynaud phenomenon showed severe vasospasm and severe digital artery involvement that did not correlate with disease activity (24). Evaluation of two studies (25 ,26) leads to the conclusion that cold-pressor testing improved or did not change the diffusing capacities in patients with SLE and Raynaud phenomenon and worsened it in those with primary Raynaud phenomenon. Renal Raynaud phenomenon after cold exposure with 99m-technetium scanning (27), colonic cyanosis (28), Raynaud phenomenon of the tongue (29), and pulmonary hypertension have been associated with Raynaud phenomenon in SLE (30). Single-photon emission computed tomography (SPECT) brain-imaging correlates with hypoperfusion associated with Raynaud phenomenon in SLE (31), as are elevated homocysteine levels (32), and lupus pernio (chilblains) (33).

The treatment of Raynaud phenomenon is not different in those with concurrent SLE. Avoidance of cold or inciting drugs (e.g., beta blockers, ergot alkaloids), along with wearing gloves, biofeedback (34), and use of vasodilators (e.g., nifedipine, nicardipine, nitroglycerin paste, nitroprusside) (35 ,36 ,37) may be advised. Steroids have no effect upon Raynaud phenomenon. Pentoxifylline (38) may be useful. Prostaglandin E1 infusions or sildenafil (39 ,40 ,41 ,42 ,43 ,44) improve digital ulcers and early gangrene in severe cases.

Nailfold Microcapillaroscopy

In 1935, Baehr et al. (45) noted that the involved skin about the nailbed, when viewed under the capillary microscope, contained many more patent and dilated capillaries than normal. In 1968, Buchanan and Humpston (46) observed hemorrhage in 62% of 29 patients and abnormal capillary loops in 93%. These findings were confirmed by others (47 ,48 ,49).

Maricq and LeRoy (50) as well as Kenik et al. (51) have studied these phenomena extensively in connective tissue diseases. Capillary loops in SLE (independent of coexistent Raynaud phenomenon) appear meandering and tortuous, with most having some disorganization and glomerulization (52 ,53) (Fig. 36-2). They claimed that a trained, blinded observer could identify SLE 75% of the time. SLE patients have less frequent microvascular abnormalities (54). Three independent studies have given photomicrographs of patients with scleroderma, rheumatoid arthritis (RA), SLE, and mixed connective tissue diseases to blinded observers. Lefford and Edwards (55) could not find any relation between capillary morphology and those clinical diagnoses. Granier et al. (56) noted that

64% of patients with mixed connective tissue disease (MCTD) had a scleroderma pattern and only 23% an SLE pattern, and McGill and Gow (57) found an 89% specificity and 80% sensitivity in selecting the correct diagnosis. Increased nailfold capillary density may indicate pulmonary capillary loss in SLE (58) and correlate with anticardiolipin antibody along with the presence of microhemorrhages (59 ,60). SLE patterns are similar to those seen in primary Sjögren syndrome (61).

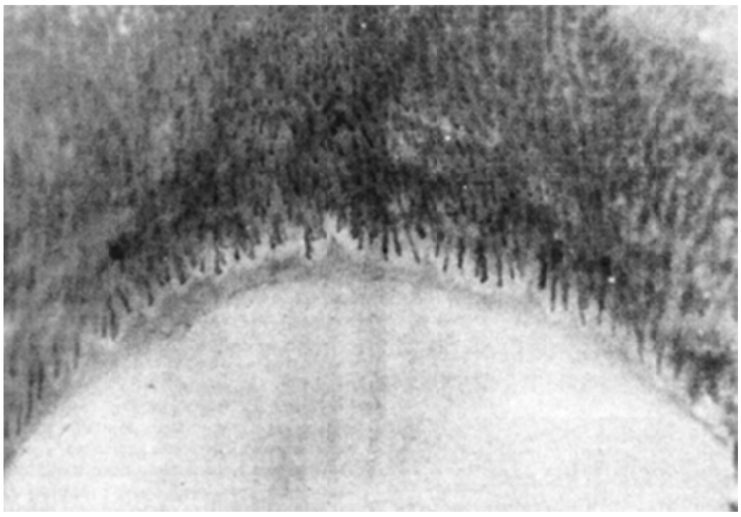

Figure 36-2. Nailfold microcapillaroscopy in systemic lupus erythematosus. (Courtesy of Dr. J. Kenik.)

The presence of anti RNP or Raynaud phenomenon in SLE is associated with greater intercapillary distance, capillary width, and more scleroderma-associated features (62). In one report, 8.5% of 47 patients had a scleroderma capillary pattern (63). Patients with primary antiphospholipid syndrome tend to have swollen capillary diameters and lower flow rates (64).

Complications of Cutaneous Vasculitis: Ulceration and Gangrene

A small percentage of these patients with active vasculitis may manifest necrotic ulcerations, digital and peripheral gangrene, and/or cutaneous infarctions. They frequently have a high-titer antinuclear antibody (ANA), elevated levels of serum anti-DNA and IgG, and reduced serum complement levels (65). Direct immunofluorescence has demonstrated IgG, complement, and fibrinogen, with fibrin in the vessel walls surrounding the involved tissue (66 ,67 ,68). Approximately 10% of patients with peripheral vascular disease have a positive antinuclear antibody or antiphospholipid antibodies. Few of these have an inflammatory process (69).

Vasculitic leg ulcers were found in 29 of Dubois' 520 patients in 1963 (70) and in 3 of Brogadir and Mejers' patients (71), and 6.2% of Petri's Hopkins Cohort (72). Dermal vasculitis was present in 18 to 70 patients in the series listed in Table 32-1 . Of Dubois' 520 patients, 7 developed peripheral gangrene, as did three of Estes and Christian's 150 patients (73).

Ulcerations and gangrene can occur as a result of active vasculitis, the antiphospholipid syndrome, or both (74 ,75 ,76 ,77 ,78) (Fig. 34-3). Asherson et al. (75) followed six patients with gangrene of the extremities. Three had the antiphospholipid syndrome with no vasculitis, two had a classic immune-complex–mediated vasculitis without evidence of a lupus anticoagulant, and one had both. Similar findings were reported by Alarcon-Segovia et al. (74) and by Lockshin et al. (79 ,80). Additionally, the lupus anticoagulant rarely is associated with a syndrome of cutaneous necrosis, not unlike what has been reported in protein C deficiency states (81 ,82). Cutaneous necrosis, antiphospholipid antibodies, livedo reticularis, and central nervous system findings have been termed Sneddon's syndrome (see Chapter 57). The differential diagnosis of cutaneous ulcerations requires ruling out ischemia from degenerative arterial disease, venous stasis, cryoglobulinemia, hyperviscosity syndrome, cholesterol

emboli, and other hypercoagulable states. Thrombosis is reviewed in Chapter 65 .

The optimal treatment of peripheral vasculitis includes systemic corticosteroids, cyclophosphamide, and if necessary, plasmapheresis (79 ,83 ,84). If the antiphospholipid syndrome is present, anticoagulation is advised (79 ,80). Short-term treatment with the prostaglandin E-derivative alprostadil, or sildenafil is the most effective method of managing critical peripheral ischemia of the hands, feet, and legs (39 ,40 ,41 ,85 ,86). Cutaneous vasculitis may respond to colchicine (see Chapter 56).

Livedo Reticularis

Livedo reticularis occurs because of disordered autonomically mediated blood flow through subpapillary and dermal blood vessels. It can be brought on by cold, connective-tissue diseases, fibromyalgia-cold agglutinins, and cryoglobulinemia. In SLE, it presents as a reticulated poikiloderma, most often on the arms and legs. Usually painless, livedo rarely can appear as a cutaneous vasculitis known as livedoid vasculitis (Fig. 36-3). This reddish-purplish mottling on the skin blanches on pressure, is independent of temperature changes, and represents a vasospastic phenomenon of dermal-ascending arterioles (87 ,88 ,89 ,90 ,91). Livedo racemosa is a subset of livedo reticularis with irregular, ill-circumscribed and broken segments and is associated with Sneddon syndrome (92).

Livedo reticularis has been shown in case-controlled studies to be unequivocally associated with cutaneous necrosis, central nervous disease, pregnancy-related morbidity, and the antiphospholipid syndrome (92 ,93 ,94 ,95 ,96 ,97 ,98). Livedo was observed in 11 of 66 patients with SLE in one report (99), and anticardiolipin antibodies were found in 81% of patients with SLE and livedo (see Chapters 29 , 30 , and 31). Unless livedoid vasculitis is present, no treatment is indicated.

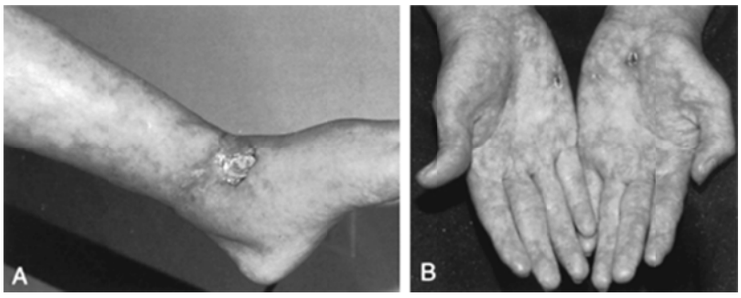

Figure 36-3. A, Livedo reticularis and ulceration of the leg of systemic lupus erythematosus patient with high-titer IgG anticardiolipin antibodies. **B**, Similar changes on the hands on this same patient.

Antiphospholipid Antibodies and the Skin

See Chapter 65 .

Purpura

Ecchymoses and petechiae may be noted depending on the platelet count and whether the patient has received steroid therapy. Cutaneous hemorrhages were seen in 9% to 21% of patients in various series (73). The most common cause of hemorrhagic lesions was steroid therapy, although salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs) also could induce them. NSAIDs can induce ecchymoses through their antiplatelet actions, and long-term steroid administration is associated with skin atrophy. Patients with untreated SLE occasionally report that they bruise easily, and many are thrombocytopenic. Occasionally, petechiae may occur because of active cutaneous vasculitis. Purpuric leg lesions should be differentiated from pigmentary changes resulting from long-term antimalarial therapy. Thrombotic thrombocytopenic purpura, idiopathic thrombocytopenic purpura, cryoglobulinemia, and other dysproteinemias may be seen in SLE and need to be ruled out.

Erythromelalgia

Erythromelalgia consists of burning distress of the extremities that is accompanied by increased redness and skin temperature, initiated by an increase in environmental skin temperature, and diminished by measures that cool the skin (100 ,101 ,102). Mostly seen in myelodysplastic disorders with thrombocytosis, erythromelalgia can occur in patients with SLE and normal platelet counts (87 ,102 ,103 ,104 ,105 ,106). It usually is treated with antiplatelet agents (e.g., low-dose aspirin, dipyridamole) or corticosteroids (107). Clonazepam (105), propanolol with methysergide, or cyclosporin may be useful (108 ,109).

Chapter 37

The Nervous System

Sterling G. West

Neuropsychiatric manifestations of systemic lupus erythematosus (NP-SLE) are frequent, vary from mild to severe, and often are difficult to diagnose and distinguish from those of other diseases. Any location within the nervous system may be affected, with symptoms and signs ranging from mild cognitive dysfunction to seizures, strokes, and coma. At the initial development of neurologic manifestations, many patients have other medical conditions or are receiving medications, which can affect the central or peripheral nervous systems. The challenge to the clinician is to determine the exact cause of the nervous system dysfunction so that appropriate therapy can be instituted. This chapter describes the classification, etiopathogenesis, clinical signs and symptoms, laboratory and radiographic findings, differential diagnosis, and treatment of lupus involving the nervous system.

Historical Considerations

Neurologic involvement in SLE was first noted by Hebra and Kaposi (1) in 1875, who described stupor and coma as terminal manifestations of the disease. Osler (2 ,3 ,4), in several papers on the systemic effects of the erythema group of skin diseases, discussed associated cerebral changes and reported a patient who “imagines all sorts of things.” In 1904, Baum (5) related active delirium, aphasia, and hemiparesis to probable disseminated lupus erythematosus. During the next 40 years, the psychiatric and neurologic correlates of SLE were recognized, but seldom discussed.

The first modern study of NP-SLE was conducted by Daly in 1945 (6). He correlated clinical symptoms with abnormal spinal fluid findings and with the pathologic finding of vasculitis. In 1948, Sedgwick and Von Hagen (7) discussed five cases in detail. In 1953, Dubois (8) described clinical neurologic subsets among 62 cases and, in 1954, Lewis et al. were the first to focus on the importance of electroencephalographic findings and psychometric testing in patients with NP-SLE.

From the 1950s through the 1970s, hundreds of reports delineated the various manifestations of neurologic involvement in SLE. Over the last three decades, however, appreciation of the clinical significance of antineuronal, antiribosomal P, and antiphospholipid antibodies, as well as advances in brain imaging, have again altered our concept of NP-SLE.

Classification and Clinical Presentation

The incidence of neuropsychiatric manifestations in SLE ranges from 14% to 75% depending on the ascertainment methodology. A recent prospective study of 1000 SLE patients followed for 10 years (1990–2000) found that 19.4% developed NP-SLE (9). However, it often is impossible to compare past studies of NP-SLE, because no standardized definition or classification system was used. Some reports included patients with minimal, nonspecific symptoms, while others restricted themselves to those with objective neurologic findings. In 1999, an international, multidisciplinary committee developed case definitions, including diagnostic criteria and important exclusions, for 19 neuropsychiatric lupus syndromes (10) (Table 37-1). This American College of Rheumatology (ACR) nomenclature should help clinicians classify NP-SLE, as well as help investigators in future studies. The complete case definitions are available on the ACR world wide web site: http://www.rheumatology.org/ar/ar.html.

SLE patients with NP-SLE can present with a myriad of diffuse and/or focal symptoms and signs involving the brain, spinal cord, or peripheral nervous system. The central nervous system (CNS) manifestations include headache, confusion, altered consciousness, seizures, focal or generalized neurologic deficits, ataxia, chorea and other movement disorders, papilledema, psychosis, and severe depression. Peripheral nervous system manifestations include cranial nerve dysfunction, acute weakness, paresthesias, and abnormalities of autonomic function. The pathologic abnormalities observed in the nervous system also are diverse (Table 37-2). Oftentimes, there is no clear-cut clinicopathologic relationship between CNS signs and localized CNS lesions. This section discusses the prevalence of NP-SLE as described in some of the principal surveys from the last 50 years (Table 37-3).

Table 37-1: Neuropsychiatric Syndromes of SLE

Central nervous system
Acute confusional state
Cognitive dysfunction
Psychosis
Mood disorder
Anxiety disorder
Headache (including migraine and benign intracranial hypertension)
Cerebrovascular disease
Myelopathy
Movement disorder
Demyelinating syndrome
Seizure disorders
Aseptic meningitis
Cranial neuropathy
Peripheral nervous system
Polyneuropathy
Plexopathy
Mononeuropathy, single/multiplex
Acute inflammatory demyelinating polyradiculopathy
(Guillain-Barré syndrome)
Autonomic disorder
Myasthenia gravis

Important Surveys: 1950–1980

Of Dubois' 520 patients (11) who were followed between 1950 and 1963, 25% had some type of central or peripheral nervous system involvement. In a 1956 review of the cliniconeurologic changes that were observed in 24 of 100 patients with SLE followed at the Mayo Clinic, Clark and Bailey (12) reported changes that varied from convulsive seizures to monoplegia, and they revealed an entire gamut of neurologic findings. Signs and symptoms of neurologic disease alone were noted in 11 patients, and neurologic and psychiatric disease together were present in 13.

Table 37-2: Pathologic Classification of Central Nervous System Changes Observed in SLE

Vasculopathy
Hyalinization
Perivascular inflammation without infection
Endothelial proliferation without infection
Thrombosis
Vasculitis
Infarction
Microinfarcts
Large infarcts
Hemorrhage
Subarachnoid
Microhemorrhages
Subdural
Intracerebral
Infection

In 1966, O'Connor and Musher (13) reviewed 150 patients with SLE who were followed at Columbia Presbyterian Medical Center. Of these, 4 patients presented with NP-SLE. CNS disturbances were more frequent among patients who were

followed through terminal illness. Sixty-seven percent of the 150 patients had psychiatric disorders, and 43% had neurologic disorders. Neurologic signs were seen at one time or another in 46 of the 150 patients.

In 1971, Estes and Christian (14) observed neuropsychiatric manifestations of SLE in 59% of 150 patients who were followed mostly in the 1960s. Disorders of mental function were found in 42% and grand mal seizures in 26%. The neurologic manifestations were cranial nerve involvement (7 patients), oculomotor signs (6 patients), and optic atrophy and blindness (3 patients). Intention tremor was observed in 8 patients and was associated with cogwheel rigidity in 2. Hemiparesis occurred in 8 patients, 6 of whom had chronic renal disease with hypertension and/or uremia. Peripheral neuropathy with predominantly sensory deficits developed in 10 patients.

In 1975, Sergent et al. (15) reported on 52 episodes in 28 patients with SLE: 10 had seizures, 9 encephalopathy, 4 aseptic meningitis, 7 focal neurologic deficits, 15 psychiatric abnormalities, and 1 chorea. They found no evidence that large doses of steroids were helpful in treating these patients. Also in 1975, Klippel and Zvaifler (16) compiled a literature review of NP-SLE in 995 reported patients with SLE (one half of these were Dubois' 520 patients). Overall, neuropsychiatric abnormalities were found in 33%, seizures in 16%, neuropathy in 10%, psychopathology in 18%, and myelopathy and chorea in 4% each.

In 1976, a review of 140 patients with SLE at the Johns Hopkins Hospital revealed neuropsychiatric changes in 52% (17), and 63% of these had episodes in the first year of disease. Only two instances of documented steroid-induced psychosis occurred. Of these 140 patients, 84% improved with treatment of SLE. A striking, positive correlation was noted among CNS involvement, vasculitis, and thrombocytopenia. Five- and 10-year survival rates for those in the CNS group were 94% and 82%, respectively. Urowitz et al. at the University of Toronto published two large SLE series (18 ,19) that emphasized CNS findings; those with CNS disease had lower serum complement levels and more disease manifestations than those without CNS pathology. Grigor et al. (20) found neuropsychiatric symptoms in 50% of 50 patients. No correlations could be found with any other SLE manifestations, including vasculitis and thrombocytopenia.

Gibson and Myers (21) noted episodes of NP-SLE in 41 of 80 patients (51%) who were followed before 1976. More episodes were noted in blacks, and an increased incidence of renal failure as well as a poorer survival were seen in this group as opposed to the non-CNS group. In contrast to most of the preceding reports, Seibold et al. (22) calculated that CNS involvement occurred at a mean of 4.3 years after the onset of disease in 26 patients.

Important Surveys: 1980–2000

The 1980s saw a continuing decline in the reported frequency of classic NP-SLE. Pistiner et al. (23) observed 49 cases of cerebritis and, comparing patients who were evaluated from 1950 to 1963 with those between 1980 and 1989, this represented a decrease from 26% to 11%. Using the ACR definition for CNS-lupus as a criterion (i.e., seizures or psychosis), 30 patients (6%) had seizures and 24 (5%) psychotic episodes. The prevalence of significant CNS abnormalities was 27% in two European multicenter studies (24 ,25) surveying 1704 patients with lupus; 12% had these abnormalities at presentation. West et al. (26) noted CNS lupus in 50 of 184 patients (28%) in Colorado, and others (27 ,28 ,29) noted CNS disease in 48 of 266 patients (18%) in Saskatchewan, in 35 of 222 (16%) in Australia, in 22 of 53 (42%) in Italy, and in 171 of 1203 (14%) in China (30).

The recognition of antineuronal, antiribosomal P, and antiphospholipid antibodies in the 1980s has affirmed the value of clinically classifying CNS episodes into “diffuse” and “focal” presentations. Several studies showed that serum and cerebrospinal fluid (CSF) antineuronal antibodies are found more commonly in patients with diffuse, global dysfunction such as acute confusion, altered level of consciousness, seizures, cognitive dysfunction, and psychiatric abnormalities (31 ,32 ,33 ,34 ,35). Bonfa and Elkon were first to associate antiribosomal P antibodies with psychosis and severe depression (36). Some investigators confirmed this association, whereas others did not (37). Antiphospholipid antibodies were associated with thromboembolic episodes leading to focal manifestations, including strokes, transverse myelitis, and chorea (38).

West et al. reported in a 10-year prospective study of 184 SLE patients that certain combinations of tests were most useful in establishing a diagnosis of severe NP-SLE, depending on whether the patient had a diffuse or focal presentation. Of these SLE patients, 52 developed NP-SLE and 14 had CNS dysfunction because of a nonlupus cause. Cases were divided into diffuse, focal, and complex (both diffuse and focal symptoms) presentations. SLE patients with diffuse presentations were more likely to have elevated CSF antineuronal antibodies, abnormal CSF IgG indices with oligoclonal bands, or serum antiribosomal P antibodies. Patients with focal symptoms had evidence of vasculitis or high-titer antiphospholipid antibodies with abnormal brain MRI showing multiple lesions (26). More recently, Isshi and Hirohata reported that serum antiribosomal P and CSF antineuronal antibodies were detected more frequently in lupus psychosis patients than in lupus patients with other symptoms of NP-SLE or lupus patients without NP-SLE (39).

Clinical surveys confirmed that NP-SLE can occur early in the course of SLE (40 ,41) and usually is associated with lupus that is clinically and serologically active (42). Two studies pointed out that secondary causes such as infection always need to be ruled out in SLE patients presenting with mental confusion or alterations in consciousness. Infections were found in 14 of 91 SLE patients with CNS dysfunction by Futrell et al. (43) and in 28% of 36 acute CNS presentations by Wong et al. (44).

Studies by the Denburgs and others (33 ,34 ,35 ,45) established that mild cognitive dysfunction is common in SLE patients and should be considered a subset of NP-SLE. Symptoms of cognitive dysfunction were often present in

the absence of objective neurologic, clinical, laboratory, or neuroimaging abnormalities, but could be demonstrated on neuropsychologic testing. Some of these patients can progress to more severe neuropsychiatric disease.

Two Canadian studies that followed 900 patients with lupus for 15 to 20 years reported that most CNS events were self-limited, reversible, and not associated with a poor outcome (46 ,47). However, patients with focal findings had a worse prognosis than patients with diffuse presentations (46).

Important Surveys: Since 2000

Since publication of the ACR nomenclature and case definitions for Neuropsychiatric Lupus syndromes (see Table 4-2), several investigators have used these criteria in their surveys (48). In a cross-sectional population-based study from Finland, Ainala et al. found that 42 of 46 (91%) SLE patients had NP-SLE using the ACR nomenclature (49). Many of these were mild syndromes including cognitive dysfunction, headaches, and mood disorders. When these SLE patients were compared to well-matched controls, 56% of the controls fulfilled at least one of the ACR criteria (50). The criteria, therefore, had a high sensitivity (91%) but low specificity (46%). If the ACR criteria were revised to exclude syndromes without objective findings such as anxiety, headaches, mild depression, subjective cognitive complaints, and polyneuropathy symptoms with a negative electromyogram/nerve conduction velocities, the specificity improved to 93%. Other studies have also found a high prevalence of NP-SLE using the ACR nomenclature including investigators from San Antonio (80% of 128 SLE patients), Italy (72% of 61pts), Britain (57% of 323 patients), Canada (37% of 111 patients), Brazil, and Thailand (48 ,49 ,50 ,51 ,52 ,53 ,54).Overall the ACR nomenclature was felt to be useful for major NP-SLE syndromes, although problematic when applied to mild and subjective syndromes such as headaches, cognitive dysfunction, and minor psychiatric symptoms, which are common in patients without SLE. Notably, these mild syndromes are more common than major presentations of NP-SLE (55).

Summary

SLE can involve the nervous system in many ways. Until recently, the presence of specific neuropathology causing seizures, stroke, and paresis was considered to constitute NP-SLE and was found in approximately 25% of patients. Over the last three decades, the incidence of these features has decreased as early intervention and the diagnosis and treatment of active SLE became more common. Over the last decade, however, the recognition of lupus headache and cognitive dysfunction as distinct syndromes, in the absence of specific neuropathology, has resulted in a net increase in the incidence of what many rheumatologists call “CNS lupus.” NP-SLE is now regarded as being present in many patients with SLE at some point during the course of their disease. Specific neuropathology is seen in a minority and usually is short-term, but can lead to chronic neurologic deficits.

Etiopathogenesis

The Clinicopathologic Studies

Several autopsy series have reported detailed analyses of the neuropathology of patients with NP-SLE. Many of these studies are hampered by the inclusion of patients with secondary causes of CNS dysfunction, as well as patients with prolonged intervals between NP-SLE manifestations and death. Despite these limitations, these studies provide important insights into the pathogenesis of NP-SLE. Johnson and Richardson (56) reviewed the brain sections of 24 patients observed at Massachusetts General Hospital in the 1960s. Neurologic and psychiatric manifestations were found in 18 patients (75%). In 9 of these 18, neurologic involvement occurred during the last 6 weeks of life. Death was attributable to CNS disease in 6 patients (intracerebral hemorrhage in 4, status epilepticus in 2). Seizures were present in 54%, cranial nerve disorders in 42%, hemiparesis in 12%, paresis in 4%, peripheral neuropathy in 8%, and mental disorders in 33%. Significant, gross brain abnormalities were found in 10 of the 24 patients, including large intracerebral hemorrhages (3 patients), multiple pontine hemorrhages (1 patient), fresh hemorrhages (2 patients), small areas of old infarction (4 patients), and a small, subapical hemorrhage (1 patient). Microscopic lesions were more common than macroscopic lesions; microinfarcts with increased pericapillary microglia were found in 20 of the 24 patients. Johnson and Richardson concluded that the nervous system involvement of SLE was caused primarily by vascular disease affecting small vessels and producing micro-infarcts with hemorrhages. True vasculitis was rare; inflammatory cells within the vessel wall were found in only 3 of the 24 patients. In contrast, perivascular inflammation was more common. Destructive lesions in the wall of small vessels, which were described as fibrinoid degeneration, were found in 5 patients.

Funata (57) performed detailed neuropathologic evaluations on 26 patients with SLE. Twelve died as a result of uremia, and one half of these 12 had perivascular inflammation in the brain. Thrombi associated with endothelial swelling and proliferation and fibrinoid degeneration were noted in five patients.

Ellis and Verity (58) reviewed 57 autopsied SLE cases at UCLA Medical Center. Vasculopathy was observed in 65%, infarction in 44%, hemorrhage in 42%, and infection in 28%. In the vasculopathy group, hyalinization (54% of patients), perivascular inflammation (28%), endothelial proliferation (21%), thrombosis (7%), and vasculitis (8%) were found. The infarctions consisted mostly of microinfarcts. Hemorrhages included subarachnoid (30%), intracerebral (10%), and subdural (4%) hemorrhages, as well as microhemorrhages (19%). In those with infections, meningitis (18%), perivascular inflammation (14%), septic

hemorrhages (5%), and focal cerebritis (3%) were seen. Many patients in this group had received combined corticosteroids and azathioprine therapy. All of the studies discussed so far have antedated the availability of anticardiolipin antibody testing. They certainly may reflect the most severe end of the NP-SLE spectrum.

In 1988, Devinsky et al. reported autopsy results of 50 SLE patients (59). Neuropsychiatric manifestations had occurred in 74% of the patients. Half of the patients had microscopic lesions, with embolic brain infarcts (10 patients) and intracerebral infection (8 patients) being most common. A cardiac source was found in 9 of the 10 patients with embolic brain infarcts. A true vasculitis was not seen. Interestingly, 14 patients had clinical evidence of thrombotic thrombocytopenic purpura during the terminal phase of their illness. Unfortunately, the antiphospholipid antibody status of these patients was not reported, although Greisman et al. (60) have indicated in a subsequent report that many of them had antiphospholipid antibodies. Importantly, a correlation between the patients' neuropsychiatric manifestations and pathologic brain lesions could only be made in half of the patients. Recently, Hanly et al. associated brain microinfarcts with seizures in 10 patients, but not with antiphospholipid, antiribosomal P, or antineuronal antibodies (61).

These autopsy series agree on several important points. First, there is no distinct typical or pathognomonic lesion that NP-SLE causes in the brain that is diagnostically specific, like the “wire loop” lesion of the kidney or the “onionskin” lesion of the spleen. Notably, vasculitis is unusual at autopsy. The most common finding is a small vessel, bland, noninflammatory, proliferative vasculopathy characterized by hyalinization. These degenerative and proliferative changes in the small cerebral vessels are not distinct from the vascular changes seen in hypertensive encephalopathy and thrombotic thrombocytopenia purpura. The neuropathologic lesions of SLE, however, are characterized as more focal or more scattered and by the fact that they vary in age from region to region, rather than appearing to have occurred simultaneously. Finally, clinical manifestations may not be readily explained by pathologic findings. Some NP-SLE patients, particularly those with diffuse manifestations, may have normal or relatively unremarkable brain pathology.

Table 37-4: Pathogenic Mechanisms Causing Neuropsychiatric Symptoms in SLE

Primary	Secondary
Vascular occlusion/hemorrhage	Infection
Immune complex-mediated vasculitis	Medications
Immune complex-mediated anaphylatoxin	TTP
release causing leukoagglutination	Hypertension
Antiphospholipid antibody-associated	Uremia
hypercoagulability/thrombosis	Electrolyte imbalances
Emboli from cardiac source	Fever
Cryoglobulinemia/hyperviscosity	Thyroid disease
Autoantibody-mediated	Atherosclerotic strokes
Antineuronal antibodies	Subdural hematoma
Choroid plexus dysfunction	Berry aneurysm
Cytokine effects	Cerebral lymphoma
Other mechanisms	Fibromyalgia
Abnormal HPA axis response	Reactive depression
Abnormal noradrenergic response	Sleep apnea
Nitric oxide/oxidative stress	Other primary neurologic or psychiatric disease
Excitatory amino acid toxicity	

HPA, hypothalamic-pituitary-adrenal; TTP, thrombotic thrombocytopenic purpura

Adapted from West SG. Neuropsychiatric lupus. *Rheum Dis Clin North Am* 1994;20:129–158.

Pathogenesis

The pathogenesis of NP-SLE is unknown. However, it is unlikely that a single pathogenetic mechanism is responsible for the myriad of neuropsychiatric manifestations seen in NP-SLE (Table 37-4). Diffuse cerebral manifestations that are often transient, reversible on therapy, and not consistently associated with abnormal brain pathology, most likely have a different pathogenesis from the focal symptoms, which are usually acute in onset, permanent even with therapy, and frequently associated with pathologic lesions at autopsy.

Vascular Occlusion

All clinicopathologic studies have reported that multiple vascular occlusions resulting in large and small infarcts and hemorrhages are commonly observed in the brains of

patients with NP-SLE at autopsy (56 ,57 ,58 ,59 ,60 ,61). These studies report that less than 15% of these arterial occlusions can be attributed to immune-mediated vasculitis. This may be because the tight junctions between endothelial cells and the blood-brain barrier (BBB) hinder deposition of immune complexes in the cerebral blood vessels. However, there have been several case reports of angiographically and/or histologically proven large and small vessel vasculitis occurring in SLE patients presenting with acute symptoms of NP-SLE (62 ,63 ,64 ,65 ,66). Rarely, an isolated phlebitis and venulitis can be observed. Cerebral vasculitis is a dramatic process that presents with fever, confusion, and headache, followed within hours to days by seizures, psychosis, and encephalomyelitis. If untreated, it can lead to coma and death. Cerebral changes usually are generalized. Laboratory investigation often reveals active, multisystem SLE with elevated serologies and decreased serum complement components. The CSF usually demonstrates pleocytosis, an elevated protein level, increased IgG, and an elevated Q-albumin, indicating disruption of the BBB. Magnetic resonance imaging (MRI) of the brain frequently reveals multiple ischemic gray and white matter lesions, and PET scan reveals hypoperfusion.

The most common lesion leading to vascular occlusion is a noninflammatory vasculopathy with marked endothelial proliferation, obliterative intimal fibrosis, thrombosis, and occasionally perivascular lymphocytes. Brain microinfarcts and microhemorrhages frequently occur in association with this microangiopathy. The etiology of this bland vasculopathy is unclear. Some investigators have suggested these lesions are scarring from healed or treated vasculitis or represent a unique response of cerebral arterioles to immune reactants, which can occasionally be demonstrated in the blood vessel walls. Indeed, several animal models have shown that chronic, low levels of circulating immune complexes are associated with an endothelial and intimal proliferative lesion and thrombosis in blood vessel walls, rather than an inflammatory vasculopathy (67 ,68). However, others have pointed out that this bland vasculopathy is similar to lesions observed in patients with antiphospholipid antibodies (60 ,69) and in patients with thrombotic thrombocytopenic purpura (70). Antiphospholipid antibodies have been shown to activate endothelial cells, possibly leading to upregulation of adhesion molecules and release of coagulation proteins, which can contribute to the development of vasoocclusive thrombosis (71). Platelet deposition in this thrombus could result in release of platelet-derived growth factors, resulting in endothelial cell proliferation and intimal fibrosis, commonly observed in this bland vasculopathy. Immunohistochemical staining with monoclonal antibodies have demonstrated CD 31 (endothelial cells), factor VIII antigen, and CD 61 (platelet membrane glycoprotein IIIa) in these thickened vessels, indicating their local incorporation in the thrombus (72 ,73). Finally, although uncommon, vasculitis has been reported to occur in patients with antiphospholipid antibodies (74). Perhaps antiphospholipid antibody activation of endothelial cells results in influx of leukocytes into the blood vessel walls via the upregulated adhesion molecules.

Clinically, Hughes et al. in the 1980s were first to correlate antiphospholipid antibodies with focal manifestations and seizures in NP-SLE patients (75 ,76). Subsequently, Hughes et al. observed neuropsychiatric manifestations in 96 of 340 SLE patients (28%) with 55% of patients with NP-SLE having antiphospholipid antibodies, compared to 20% of patients without NP-SLE ($p < 0.001$) (77). The most common clinical manifestations were transient ischemic attacks and strokes. Chorea, dementia, migraine headaches, transverse myelitis, seizures, cerebral venous thrombosis (78), and anterior spinal artery syndrome have also been associated with antiphospholipid antibodies (79 ,80). Patients with antiphospholipid antibodies in NP-SLE frequently have livedo reticularis (81), although other clinical and laboratory manifestations of active lupus may or may not be present. The CSF usually demonstrates elevated protein, but commonly a low white blood cell count. Antiphospholipid antibodies are not generally present in the CSF (38). Brain MRI shows focal or generalized ischemic white matter lesions (82 ,83).

Other causes of vascular occlusion have also been described. Activation of inflammatory cells by complement-mediated anaphylatoxins (C3a, C5a), resulting in leukothrombi causing vessel occlusion, has been observed in the brains of some patients dying of acute cerebral lupus (84). These leukothrombi have been shown to cause infarction, in the absence of vasculitis, in the brain as well as other organs of SLE patients. Another cause of cerebrovascular occlusion is emboli, usually from a cardiac source. Emboli from Libman-Sacks vegetations can cause acute vascular occlusion resulting in strokes. A recent autopsy series has suggested that a cardiac source of emboli in NP-SLE patients may be more common than previously reported (59). Antiphospholipid antibodies have been associated with cerebral artery embolization with fragments from Libman-Sacks-like endocarditis and abnormal heart valves (85 ,86 ,87 ,88). Whether these antibodies can directly cause valvular damage, or only contribute to thrombus formation (which can subsequently embolize) on already damaged valves, is presently unclear. Finally, although not truly vascular occlusion, sludging as a result of cryoglobulinemia and hyperviscosity has rarely been reported in patients presenting with mental clouding, dizziness, and confusion (89 ,90 ,91 ,92).

Vascular Hemorrhage

Although microhemorrhages are common, larger subarachnoid, intracerebral, and subdural hemorrhages occur in 0.4% to 7.0% of NP-SLE patients. One survey of 500 patients with SLE revealed evidence for cerebrovascular disease in 15, being occlusive in 11 and hemorrhagic in 4 (93). Several cases of subarachnoid hemorrhage caused by a Berry aneurysm have been described in SLE. It is not

known if these aneurysms are more common in SLE patients than in the general population (94 ,95 ,96). A small subset of SLE patients with antiphospholipid antibody have an increased bleeding tendency with neurologic consequences, but this group usually has an associated thrombocytopenia or hypoprothrombinemia. Other causes of cerebral hemorrhage, such as hypertension or thrombotic thrombocytopenic purpura, must be excluded.

Antineuronal Antibodies

Antineuronal antibodies injected into the ventricles of experimental animals cause a variety of neurologic symptoms, such as convulsions and impaired memory, suggesting that brain-reactive antibodies may cause certain NP-SLE manifestations (97 ,98 ,99). Several investigators have reported that up to 75% of SLE patients have elevated levels of serum antineuronal or antilymphocyte antibodies that cross-react with brain tissue (100). Some of these studies indicate that NP-SLE patients, particularly those with diffuse manifestations, have these antibodies more commonly than SLE patients without CNS dysfunction and in close temporal relationship with clinical events (100 ,101).

A variety of epitope specificities have been demonstrated as the targets for some of these antineuronal antibodies. Several studies have demonstrated neural tissue-specific autoantibodies including those directed against a 50-kD antigen in the plasma membrane of brain synaptic terminals (102), neurofilaments (103), glial fibrillary acidic protein (104), and microtubule-associated protein 2 (105). Interestingly, antineurofilament antibodies have been associated more closely with diffuse NP-SLE manifestations (103), while the others have been associated with various neuropsychiatric manifestations.

Other antineuronal antibodies are cross-reactive with nonneural tissue antigens. Early studies showed some of these antibodies are directed against gangliosides, which are a family of acid glycolipids located on many tissues including neuronal and myelin membranes (106). Additionally, lymphocytotoxic antibodies that are cross-reactive with brain tissue have been demonstrated in patients with seizures and diffuse encephalopathy (107). Antiribosomal P antibodies have been shown to react with an homologous 38-kd protein on the surface of human neuroblastoma cells (108). Antiphospholipid antibodies have been shown to permeabilize and depolarize brain synaptoneurosomes (109). This suggests antiphospholipid antibodies have the ability to disrupt neuronal function by direct action on nerve terminals, possibly explaining the nonthrombotic CNS manifestations observed in some lupus patients with antiphospholipid antibodies. Furthermore, anti-β_2 glycoprotein-1 antibodies have been reported to bind to astrocytes and neurons, both in culture and histologic sections, in 11 of 20 SLE patients with these antibodies (110). Recently, DeGiorgio et al. demonstrated that a subset of anti-double-stranded (ds)DNA antibodies cross-react with a pentapeptide consensus sequence that is present in the extracellular, ligand binding domain of the N-methyl-D-aspartate (NMDA) receptor, NR2, in the CNS (111). The NR2 receptors bind the principle excitatory amino acid of the brain, glutamate. Interestingly, the NR2 glutamate receptors are located throughout the forebrain and are in highest concentration in the hippocampus, which is responsible for learning and memory. These cross-reactive antibodies have been demonstrated to cause apoptotic death of neurons by leaking from the serum into the CSF through a breakdown in the BBB. This caused memory impairment in the animal model (112). Studies in human SLE are ongoing.

Serum antineuronal antibodies may be useful markers for NP-SLE, but can only be considered pathogenic if they are demonstrated in the CSF and have the ability to bind directly to brain tissue. Investigators have found CSF IgG antineuronal antibodies in up to 90% of NP-SLE patients compared with less than 10% of SLE patients without CNS manifestations (26 ,31 ,32 ,39 ,114). Furthermore, the antineuronal antibody activity was concentrated to a greater extent in the CSF of these patients relative to a paired serum sample. Similar to serum antineuronal antibodies, the presence and amount of these CSF antibodies correlated best with diffuse manifestations, such as acute confusion, psychosis, generalized seizures, and cognitive dysfunction (26 ,31 ,39 ,113).

Several theories have been proposed to explain how these antineuronal antibodies are generated and get into the CSF. As previously mentioned, some of the serum antineuronal antibodies are cross-reactive with both neural and nonneural epitopes. Other serum antineuronal antibodies may have been generated by neuronal antigens released from the brain. Notably, as shown experimentally, the brain does have lymphatic drainage and antigens in the brain may cause a systemic immune response (115). Although normally the BBB would prevent these antineuronal antibodies from coming into direct contact with cortical tissues, this barrier could be breached at sites of brain microinfarction caused by vascular occlusions, allowing influx of antineuronal antibodies from the serum. Additionally, ischemia without infarction and increased serotonin (from platelet thrombi) can facilitate immunoglobulin transport from the serum to cerebrospinal fluid. Finally, immune-mediated injury and/or endothelial activation leading to cytokine production could result in local breakdown of the BBB allowing serum antineuronal antibodies to access to the CNS (116).

An alternative explanation is that antineuronal antibodies do not come from the serum, but are derived from local production within the CNS. Recent studies have demonstrated that activated T cells, B cells, and monocytes/macrophages can get through the BBB (117). Neuronal antigens, which are normally in an immunologically privileged site protected by the BBB, may stimulate these immunocompetent cells within the CNS. Interleukin-6, which has been found to be elevated in the CSF of patients

with NP-SLE, may facilitate the differentiation of B cells into plasma cells capable of intrathecal synthesis of antineuronal antibodies. The demonstration of an elevated IgG index, oligoclonal bands, a normal Q-albumin ratio (suggesting an intact BBB), and antineuronal antibodies in the CSF in some NP-SLE patients, who lack serum antineuronal antibodies, supports this hypothesis (22 ,26 ,39 ,118 ,119 ,120 ,121 ,122).

Antineuronal antibodies are hypothesized to be able to bind to neuronal membranes and interfere with cell function without causing nerve cell death or inflammation. Binding to neuronal ion channels could lead to recurrent depolarization, increasing susceptibility of the neuron to excitatory amino acid or oxidative, stress-mediated nerve cell injury. Alternatively, antineuronal antibodies could interfere with receptor ligand binding, resulting in neuronal dysfunction. Other immunopathogenic mechanisms are also possible. Each of these mechanisms would explain the reversibility of symptoms and the poor correlation of CNS pathologic changes with clinical manifestations seen in NP-SLE patients with antineuronal antibodies.

Choroid Plexus Dysfunction

The choroid plexus differs from the BBB in that it has a fenestrated capillary bed and glial cells, which have receptors for immune complexes (123 ,124). The choroid plexus is important in the production of CSF and provides a transport-mediated pathway for the influx of certain hormones, vitamins, and other molecules into the CSF. Postmortem examination has demonstrated IgG and complement deposits in the choroid plexus of some SLE patients (125 ,126). This deposition could alter the secretory or transport properties of the choroid plexus or result in cytokine release into the CNS, resulting in neuronal dysfunction. However, the significance of choroidal immune reactant deposition remains unclear, since these deposits are seen in SLE patients with and without neurologic symptoms (126).

Cytokine Effects

Patients with active SLE can have elevated serum levels of interleukin (IL)-2, IL-10, and interferon-α (IFN-α) and IFN-γ (see Chapter 10). Cytokines in the systemic circulation may affect the hypothalamus, which lacks the BBB, and/or the cerebral microvasculature, resulting in upregulation of adhesion molecules (84). These effects, as well as others, can facilitate the recruitment of activated lymphocytes (T cells more than B cells), monocytes, and macrophages to pass through the BBB into the CNS (117). Patients with active NP-SLE can have IL-1, IL-2, IL-6, IL-8, IL-10, TNF-α and IFN-α elevated within their CSF (127 ,128 ,129 ,130 ,131). These cytokines can be produced intrathecally by neurons and glial cells or by infiltrating immunocompetent cells from within the CNS (132). IL-1 is important in neuronal injury and repair, causes release of neurotransmitters from brain structures, and through prostaglandin E causes corticotropin-releasing hormone (CRH) release from the hypothalamus (133). Injection of IL-1 into the CSF of experimental animals causes behavioral disturbances, anorexia, drowsiness, slow wave sleep, and coma with neuronal destruction (134). IL-6 in the CNS can stimulate B cell differentiation into plasma cells with resultant intrathecal synthesis of immunoglobulin. IL-6 is also important in neuronal differentiation, neuronal repair, and hypothalamic CRH release. IL-8 is a chemokine that, after alteration of the permeability of the BBB, attracts B and T cells to the site of the site of inflammation. Thus, the contribution of these and other cytokine effects on the brain in NP-SLE needs to be considered and further investigated.

Neuroendocrine-Immune Systems

There is a complex intercommunication between the nervous, endocrine, and immune systems (135). Most important are the connections between the limbic system (hippocampus, amygdala) of the CNS with the hypothalamic-pituitary-adrenal (HPA) axis and the central noradrenergic and peripheral autonomic nervous systems. The function of these interconnected systems is to restore the body to basal state after being exposed to stress of physical, psychologic, or inflammatory stimuli (136). The degree an individual responds to stress depends on several physical, genetic, and environmental factors, such as age, gender, and reproductive status. Several investigators have postulated that an abnormal stress response partially explains the predilection for SLE to occur in young females in their reproductive years (see Chapter 17).

The systemic immune activation occurring in SLE could result in a chronic stress response, resulting in persistent activation of the HPA axis and noradrenergic systems. Chronically elevated glucocorticoid levels can result in hippocampal atrophy, resulting in abnormalities in spatial and declarative memory (137). Furthermore, excessive cortisol decreases the synaptic uptake of glutamate, resulting in increased glutamate levels, which could cause excitatory amino acid (EAA)–mediated neuronal injury (138). To what extent this plays a role in neuropsychiatric manifestations in SLE patients is presently unclear and is the subject of ongoing research (139).

CNS Tissue Injury

Oxidative stress, EAA toxicity, and matrix metalloproteinase (MMP) injury are the three major mechanisms responsible for nerve cell injury and death within the CNS. Oxidative stress causing nerve cell injury and apoptosis involves the production of nitric oxide (NO). NO is produced by the interaction of the enzyme, nitric oxide synthetase (NOS), and L-arginine (140). There are three major forms of NOS. Two of the isoforms are constitutively expressed (cNOS) (eg., neuronal cNOS and endothelial cNOS). One of the isoforms is inducible (iNOS) and

expressed by many cells, including those that can constitutively express cNOS. Constitutively-expressed nitric oxide synthetase produces small amounts of NO, which plays a protective role in the nervous system and microvasculature. This protection is caused by the capacity of NO to inhibit platelet and neutrophil adhesion to endothelial cells, as well as to inhibit leukocyte superoxide anion production. In contrast to the cNOS isoforms, iNOS is expressed after exposure to various stimuli, including inflammatory cytokines such as IL-1. The inducible form of NOS binds to calmodulin and generates large and sustained amounts of NO. NO is labile and, in the presence of oxygen, is rapidly metabolized to nitrate and nitrite. NO can also react with superoxide anions, resulting in the production of toxic hydroxyl radicals, which leads to nerve cell death. NO also can promote oxidative injury via formation of peroxynitrous acid. Additionally, NO can directly nitrosylate the NMDA receptor, causing inactivation of membrane ion channels and nerve dysfunction (141). Increased expression of iNOS by endothelial cells has been found in patients with active SLE (142). This upregulation of vascular iNOS in SLE patients may be the result of immune complexes, complement components, cytokines, and/or antiphospholipid antibodies. This could result in excessive NO production leading to nerve cell injury as well as other toxicities.

EAA toxicity is a second mechanism for nerve cell injury and death (143). Glutamate is the most important EAA neurotransmitter in the brain and is important in many normal neurologic functions. However, overproduction of glutamate, causing overstimulation of glutamate receptors, can result in excessive influx of positively charged ions and water, resulting in neuronal cell swelling, injury, or death. Some neurons, such as those in the hippocampus, are more vulnerable to glutamate than are other neurons. This is most likely a result of variation in repertoire and density of glutamate receptors in different areas of the brain. Furthermore, stresses such as ischemia, recurrent depolarization (seizures), and cytokines within the CNS can make individual neurons more sensitive to EAA toxicity, even when exposed to only minor insults. The role EAA toxicity has in NP-SLE is unclear and an area of future research.

Another mechanism of nerve cell injury is by MMP, which can degrade extracellular matrix components. MMP-9 is a gelatinase that is secreted by a variety of cells including macrophages, T cells, and endothelial cells. Consequently, MMP-9 could contribute to neuronal and BBB damage. Recently, levels of MMP-9 were found to be elevated in patients with NP-SLE compared to controls (129 ,144). Trysberg et al. further demonstrated elevated levels of free, enzymztically active MMP-9 levels in the CSF of NP-SLE patients, which correlated with elevated intrathecal levels of IL-6 and IL-8, suggesting these cytokines may be involved in the MMP-9 activation pathway (145). This same group has shown elevated levels of soluble molecules indicating neuronal and astrocytic damage such as neurofilaments and astroglial fibrillary acidic protein in the CSF of NP-SLE patients compared to controls. This was particularly apparent in NP-SLE patients with abnormal brain MRIs (144). Interestingly, patients with NP-SLE can make autoantibodies against some of these neuronal and astroglial self-antigens (103 ,104).

Summary

Although our understanding of the pathogenetic mechanisms involved in NP-SLE has advanced over the past three decades, it is still incomplete. Clearly, the cerebral vasculature plays an important role. If the vascular endothelium allows the deposition of immune complexes, then an inflammatory vasculitis can result. Alternatively, simultaneous activation of endothelial cells and neutrophil adhesion molecules by cytokines (IL-1) and biologically active complement split products (C5a desarg) can cause a local Shwartzman phenomenon, resulting in leukothrombosis and vasoocclusive plugs. Additionally, antiphospholipid antibodies are prothrombotic and may result in acute vasoocclusive thromboemboli or chronically cause endothelial cell proliferation and intimal fibrosis, commonly observed in the bland vasculopathy seen in NP-SLE patients. Emboli from cardiac valves can also occur. Each of these mechanisms can lead to vascular occlusion (less commonly hemorrhage) leading to focal neurologic manifestations and seizures.

Antineuronal antibodies with specificity against lymphocytic, neuronal membrane, and neuronal intracellular antigens have been demonstrated to occur with increased frequency in the serum of NP-SLE patients. Some of these may breach the BBB and gain entrance into the CSF. Alternatively, activated lymphocytes within the CNS may make antineuronal antibodies, which can bind to neuronal cells or receptors, resulting in neuronal dysfunction without nerve cell death or inflammation. These antineuronal antibodies could lead to diffuse manifestations such as acute confusion, coma, and seizures.

Cytokine effects and abnormalities in the neuroendocrine- immune system undoubtedly play a role in some of the neuropsychiatric manifestations observed in NP-SLE patients. Cytokines such as IL-1 can upregulate endothelial adhesion molecules, contributing to the development of vasculitis or leukothrombi. Cytokines within the CSF have been shown to cause cognitive and behavioral disturbances commonly observed in SLE patients. Additionally, cytokines such as IL-1 can upregulate iNOS, resulting in excessive NO production and nerve cell injury. IL-8 may facilitate the influx of mononuclear cells into the CNS, whereas IL-6 facilitates the growth of activated B cells into autoantibody producing plasma cells. Intrathecal cytokines may also contribute to activation of MMP-9, which can injure the BBB (allowing influx of cells/autoantibodies) as well as neurons and astrocytes causing neuropsychiatric manifestations. Additionally, inflammatory cytokines within the CNS

can sensitize neurons to be more prone to injury from EAA toxicity.

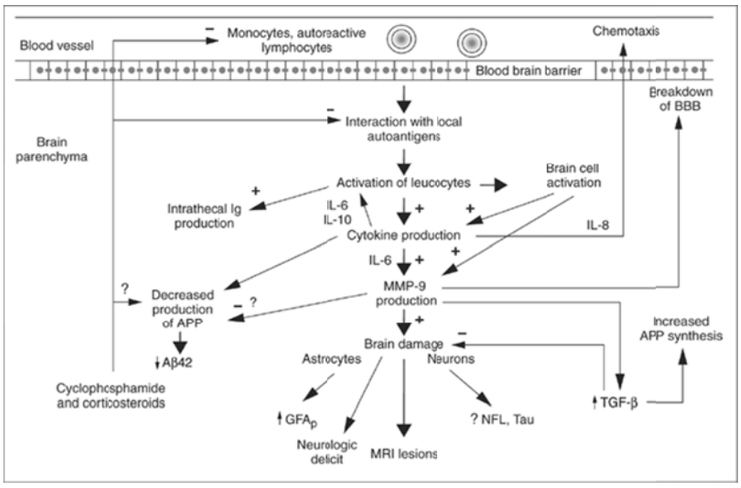

Figure 37-1. Hypothetical mechanisms of inflammation and tissue destruction in neuropsychiatric systemic lupus erythematosus. APP, amyloid precursor protein; BBB, blood-brain barrier; GFAp, astroglial fibrillary acidic protein; Ig, immunoglobulin; IL, interleukin; MMP, matrix metalloproteinase; TGF, transforming growth factor; Aß42, ß-amyloid protein. Finally, the chronic immune stimulation may stress normal homeostasis, resulting in abnormalities in the neuroendocrine-immune system. Persistent activation of the HPA axis may result in chronically elevated glucocorticoid levels, leading to hippocampal atrophy. Likewise, chronic activation of the sympathetic and autonomic nervous systems may cause vasoconstriction and alteration in cerebral blood flow. Both of these mechanisms could lead to the mild cognitive dysfunction, memory problems, and abnormalities in neuro-imaging observed in many SLE patients.

In any single patient with NP-SLE it is likely that a combination of these mechanisms are contributing to their clinical manifestations (Figure 37-1). Some investigators have attempted to relate certain neuropsychiatric manifestations with specific pathophysiologic mecahanisms (146).

Clinical Manifestations

NP-SLE can involve the CNS, the peripheral/autonomic nervous system, and/or myoneural junction. An SLE patient can present with diffuse, focal, or a combination of symptoms (Table 37-1) The chief manifestations are symptoms of global dysfunction without any focal abnormalities, whereas focal symptoms are manifestations that can be attributed to a specific brain area. Clinical signs and symptoms range from mild and transient dysfunction to severe presentations, resulting in permanent neurologic sequelae and/or death. This diversity of manifestations and severity results from the several different immunopathogenic mechanisms that can affect various areas of an anatomically and physiologically complex nervous system. The clinician must always be aware that neurologic abnormalities in SLE patients may not be NP-SLE, but secondary to infection, electrolyte abnormalities, or numerous other causes (Table 37-4) (147 ,148).

Many of the cognitive, level of consciousness, behavioral, and personality abnormalities observed in SLE patients are difficult to classify. In the past, these have been termed acute or chronic organic brain syndrome, which has now been abandoned. This has been replaced by the term encephalopathy, which is diffuse cerebral dysfunction associated with a disturbance in consciousness, cognition, mood, affect, and behavior. The ad hoc ACR committee on neuropsychiatric lupus nomenclature felt that encephalopathy was too generalized and decided to separate it into its more specific presentations (10). This committee's

recommended classification has been used for the discussion of clinical manifestations.

Acute Confusional State

Acute confusional state is defined as disturbance of consciousness or level of arousal characterized by reduced ability to focus, maintain, or shift attention to external stimuli, and accompanied by disturbances of cognition, mood, affect, and/or behavior (10). This has been termed delirium in the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM IV)* and *International Classification of Diseases, 9th Edition (ICD-9)* diagnostic classifications. Disorganized thinking, loss of orientation, agitation, and delusions can be present. Symptoms may fluctuate or progress. An ominous sign is progression to a reduced level of consciousness, such as stupor or coma. Acute confusional state is one of the most common presentations observed in up to 30% of NP-SLE patients (26). Vasculitis, leukothrombosis, and autoantibodies have all been described as causes of acute confusion. Notably, this is also a common presentation of SLE patients with neuropsychiatric disturbances caused by cerebral infections, medications, TTP, and metabolic disturbances, which must always be excluded.

Cognitive Dysfunction

Cognitive dysfunction can range from mild cognitive impairment to dementia, where there are abnormalities on neuropsychological testing in multiple domains of attention, reasoning, memory, language, visual-spatial processing, psychomotor speed, and executive function (10). The recommended ACR neuropsychological battery of tests has recently been validated (149). Mild cognitive dysfunction (“lupus fog”) was first noted in SLE patients without a history of NP-SLE in the 1970s. The Denburgs, as well as others, have extended this observation. A recent review of 14 cross-sectional studies of cognitive function in SLE patients without overt neuropsychological symptoms revealed subclinical cognitive impairment in 11–54% (150). This dysfunction includes various deficits, as there is no specific SLE pattern of abnormalities (151). In the majority of patients, these abnormalities are subclinical and do not significantly impact their quality of life. In a 5-year prospective study, Hanly et al. reported that only 20% of patients, who had mild cognitive impairment on neuropsychological tests, went on to develop clinically overt NP-SLE, while 19% resolved their cognitive dysfunction on follow-up testing without any therapy (152). Those patients most likely to develop NP-SLE were the ones who showed cognitive decline on serial testing. Other investigators have confirmed that cognitive performance remains stable over time in the majority of patients with mild deficits on testing and does not predict the subsequent development in NP-SLE (153 ,154).

The pathogenesis of cognitive dysfunction in SLE is unclear. Most studies have demonstrated an association between cognitive impairment and active NP-SLE, but have not shown an association with active SLE, corticosteroid use, or psychological distress (150). However, Hay et al. reported that many SLE patients with mild cognitive abnormalities have psychiatric problems, which could cause the cognitive dysfunction (155). An association has been reported by some investigators between cognitive abnormalities and elevated serum anti-DNA antibodies, serum antilymphocytotoxic/antineuronal antibodies, serum antiphospholipid antibodies, and CSF IgG antineuronal antibodies, suggesting this dysfunction is a result of autoantibodies or cytokines (33 ,34 ,35 ,155 ,156 ,157 ,158 ,159). The strongest agreement is the association between cognitive dysfunction, cognitive decline, and antiphospholipid antibodies (150 ,160 ,161). Notably, antiribosomal P antibodies are not associated (162 ,163), and some investigators have not confirmed the association between antilymphocytotoxic/antineuronal antibodies and mild cognitive impairment (163). Recently, Omdal et al. have found a significant association between antibodies against the NMDA receptor, NR2, and a decrease in short-time memory and learning (164).

Many SLE patients (up to 88%) with a previous history of NP-SLE have significant cognitive dysfunction on neuropsychological testing (165). Some patients can progress to dementia with global cognitive dysfunction marked by impairment in short and long-term memory and disturbances in judgment, abstract thinking, and other higher cortical functions. The degree of cognitive impairment may be severe, interfering with the patient's ability to live independently. Dementia can be a result of active NP-SLE, the result of scarring from previously active NP-SLE, or from multiple infarctions because of antiphospholipid antibodies (160 ,161).

Most studies of cognitive impairment have used adult SLE patients as study subjects. However, Papero et al. (166) have reported cognitive impairment associated with antineuronal antibodies in children with SLE. Wycokoff et al. reported a study of 8 children with SLE demonstrated mean intellectual scores were in the low-to-average range and visual memory was depressed. Academic achievement was globally depressed and reading comprehension averaged 5 years below grade placement (167). Recently, Sibbitt et al. reported that isolated cognitive dysfunction was present in only 6% of pediatric outpatient SLE patients who did not have other associated NP-SLE syndromes (168).

Psychosis

Psychosis is defined as a severe disturbance in the perception of reality, characterized by delusions and/or hallucinations (usually auditory). Psychosis occurs in 8% of SLE patients with the initial episode occurring within the first year after diagnosis of SLE in the majority (60%). The sudden onset of psychosis in an SLE patient without a prior

psychiatric history or precipitating cause is usually indicative of NP-SLE. Some investigators have reported an association between antiribosomal P antibodies and psychosis (169 ,170). Titers of these antibodies reportedly rise with exacerbation of psychosis and decrease in response to corticosteroid therapy. Other studies have not found a correlation between these antibodies and psychosis (37 ,171 ,172) (see Chapter 38).

Mood and Anxiety Disorders

Severe affective disorders such as major depression and anxiety/panic disorders can be NP-SLE manifestations. Some previous studies have included these manifestations under the category of “lupus psychosis.” Whether these psychiatric problems are a direct manifestation of NP-SLE, or a reaction to a chronic illness or other psychosocial factors, is unclear. However, antiribosomal P antibodies, cytokine effects, and alterations of the HPA and other neuroendocrine axes have each been associated with severe depression (136 ,170), suggesting that mood disorders can be a manifestation of NP-SLE.

Previous studies have reported a high prevalence of nonpsychotic psychopathology in SLE patients (173). However, a recent review noted that previous studies were too methodologically limited to permit drawing confident conclusions about the prevalence and etiology of psychiatric abnormalities in SLE patients (174). An attempt was made to overcome some of these limitations in a population-based study reporting the prevalence of lifetime psychiatric disorders among all SLE patients in Iceland (175). Approximately 50% of SLE patients received one or more psychiatric diagnoses over the course of their disease. This was in agreement with a 46.5% prevalence of nonpsychotic, psychiatric disturbances in a cross-sectional study of 42 SLE patients, compared with 15.6% of healthy controls (176). Another study of 80 consecutively treated SLE patients found that psychiatric dysfunction was more closely associated with psychosocial factors than with measures of disease activity (177). In a study of 52 SLE patients without NP-SLE, Kozora et al. found greater psychological distress and depressive symptoms related to poor coping styles compared to rheumatoid arthritis patients or normal controls (178). These studies found depression, anxiety, phobias, and difficulty coping to be the most common psychiatric abnormalities. Determining if these abnormalities are a result of NP-SLE or emotional stress can be a challenge to the clinician. However, clearly, patients with good disease-coping strategies and better social support have significantly less depression and a better functional outcome, when followed over time (179) (see Chapter 38).

Headache

Headaches are common in SLE patients, occurring in up to 57% of patients (45 ,180 ,181). Because of the high prevalence of headache in the general population (40%), the association between headache and SLE is controversial (182). In 1978, Atkinson and Appenzeller described a headache syndrome that was distinct for SLE and independent of hypertension and other secondary causes of headache (183). Brandt and Lessel studied, in detail, 11 SLE patients that had “migrainous phenomenon.” These patients' headaches were associated with disease activity, abnormal CSF findings, abnormal electroencephelograms (EEGs), and usually responded to corticosteroid treatment (184). Most investigators believe that headache, as a manifestation of NP-SLE, is characterized by an acute presentation during a lupus flare, frequent association with other neurologic complications and abnormal laboratory tests, and resolves with corticosteroid therapy, as the lupus disease activity improves.

Many SLE patients have headaches, which are not related to the disease activity or other manifestations of lupus. Earlier studies suggested that SLE patients had an increased prevalence of headaches, but did not use standardized criteria for definition of headache. A recent pooled analysis of all studies using International Headache Society criteria for diagnosis found that the prevalence of migraine and tension headaches was not different from healthy controls (182). In this study, migraine headaches occur in 31.7% and tension headaches in 23.5% of SLE patients. Studies suggest that migraine headache in the general population has a strong genetic component and is a result of an abnormality of the trigeminovascular system (185). Previous studies have suggested that migraine headache in SLE patients was associated with Raynaud's phenomenon, antiphospholipid antibodies, and/or thrombotic events (186 ,187 ,188). However, three controlled studies of over 275 patients have failed to confirm these observations (180 ,189 ,190).

Benign intracranial hypertension (pseudotumor cerebri) can occasionally occur in NP-SLE patients. Patients present with refractory headaches, papilledema, and no focal neurologic symptoms. Lumbar puncture reveals increased intracranial pressure (greater than 200 mm H_2O), normal protein, and no white blood cells in the CSF. There have been less than 30 reported cases (191). Although it can occur in adults, most patients are young, adolescent females with severe SLE. Several patients had rapid corticosteroid withdrawal and half had dural venous sinus thrombosis as a potential cause of their pseudotumor cerebri. Up to 60% had clinical or laboratory evidence of hypercoagulability manifested by history of thromboembolic episodes, nephrotic syndrome, or elevated antiphospholipid antibodies (191). Therapy included multiple lumbar punctures and/or corticosteroids in all patients. Some patients also received acetazolamide, anticoagulants (two patients), or intravenous gammaglobulin (one patient).

Secondary causes must be ruled out in all patients before ascribing a severe headache to NP-SLE. The most common or important ones include: hypertension, infection, nonsteroidal anti-inflammatory medications, antimalarial

therapy, sleep apnea, subdural hematoma, and intracranial hemorrhage.

Cerebrovascular Disease

Cerebrovascular accidents occur in 5% to 18% of SLE patients (38 ,40 ,192 ,193). Stroke syndromes secondary to NP-SLE can affect any area of the brain (194 ,195). Patients can present acutely with transient ischemic attacks, hemiplegia, aphasia, cortical blindness (196), or other deficits of cerebral function. Strokes usually occur within the first 5 years of the onset of SLE; and between 13% and 64% of patients who have had a stroke will have a recurrent stroke resulting in significant morbidity and a 28% to 40% mortality rate (40 ,197).

The etiology of strokes in SLE can be from vasculitis, a noninflammatory vasculopathy, thrombosis associated with a coagulopathy, leukothrombosis, emboli from cardiac valvular lesions (198 ,199), and intraparenchymal or subarachnoid hemorrhage (see Pathogenesis). Strokes can be from large or small vessel disease. Large vessel strokes because of SLE can be from vasculitis, thrombosis from a coagulopathy, and cardiogenic emboli. Small vessel strokes and TIAs can be from vasculitis, noninflammatory vasculopathy, leukothrombosis, emboli, and antiphospholipid antibody-associated thrombosis.Patients with stroke because of antiphospholipid antibodies frequently have evidence of livedo reticularis, which has been called Sneddon's syndrome (81). Hemorrhagic strokes from intraparenchymal or subarachnoid bleeding also can occur. In any SLE patient with stroke, hypertension and accelerated atherosclerosis must also be considered. There is abundant evidence that accelerated atherosclerosis occurring in SLE patients can lead to early cerebrovascular disease (200).

Several investigators have identified risk factors for strokes in SLE patients. Futrell et al. reported that 94% of their 18 SLE patients with strokes had at least one of the following risk factors: age older than 60 years, previous stroke or TIA, antiphospholipid antibodies, or cardiac valvular disease (40). The five SLE patients with both cardiac valvular disease and coagulopathy had a 100% risk of stroke, compared to the 77 SLE patients who did not have these risk factors and did not subsequently develop a stroke. Levine and Welch reported that over 50% of patients with antiphospholipid antibodies and strokes had hypertension, hyperlipidemia, cigarette smoking, or diabetes mellitus, each of which can contribute to increased stroke risk (201). Each of these factors (particularly smoking) has been confirmed in recent studies (202 ,203). Clinical experience suggests that the use of the specific cyclooxygenase-2 (COX-2) inhibitors in SLE patients with these risk factors may contribute to the risk of subsequent clotting especially in patients with antiphospholipid antibodies. Each of these studies point out that control of hypertension, elevated cholesterol, and blood glucose levels, as well as smoking cessation, must be part of the treatment plan to prevent stroke or recurrence of stroke.

The diagnosis of cerebrovascular disease is made clinically and supported by neuro-imaging studies. A computed tomography (CT) scan of the brain is capable of detecting cerebral hemorrhage and large infarcts, making it a useful study in screening SLE patients with acute neurologic deterioration. Cranial magnetic resonance imaging (MRI) with contrast is superior to CT scan in detecting smaller and frequently transient lesions. MR imaging typically shows hyperintense gray and white matter lesions on T2-weighted images, which account for the patient's clinical symptoms. Additional lesions in clinically silent areas are also frequently observed. Magnetic resonance angiography (MRA), carotid Doppler ultrasound, and echocardiogram are noninvasive procedures, which can be useful in detecting large vessel vasculitis, thrombosis, or sources of emboli, leading to vascular occlusion and stroke. Angiograms are more likely to show abnormalities in patients with larger infarcts. CSF examination may show pleocytosis and high protein in patients with cerebral vasculitis or blood in patients with subarachnoid hemorrhage. Otherwise, the CSF examination is usually normal or demonstrates nonspecific abnormalities, such as a few cells and/or high protein.

Treatment of strokes in SLE patients is based on the suspected pathogenesis. Patients with suspected vasculitis are treated with corticosteroids and cytotoxic drugs, whereas those with a coagulopathy or cardiac emboli are treated with anticoagulation. Treatment of patients with strokes because of a noninflammatory vasculopathy is difficult since the pathogenesis of these vascular lesions is unclear. Although not proven to reduce stroke in SLE patients, most clinicians put these patients on aspirin or other platelet inhibitors and aggressively treat stroke risk factors. The value of corticosteroids in these patients is uncertain and could potentially contribute to stroke risk by increasing hypertension, cholesterol, and blood glucose. Patients, however, are often given corticosteroids to control other accompanying lupus manifestations.

Myelopathy

Spinal cord myelopathy is an infrequent, but devastating, manifestation of NP-SLE. Patients present with progressive or sudden weakness or paralysis (paraplegia or quadriplegia), bilateral sensory deficits, and impaired sphincter control. It occurs in less than 1% of patients and can be the initial presentation of SLE (204 ,205). Dubois (11) found lupus myelopathy in 2 of his 520 patients between 1950 and 1963, and Pistiner found myelopathy in 2 of his 464 SLE cohort followed between 1980 and 1989 (23). Alarcon-Segovia et al. in Mexico reported 4 cases of myelopathy among 500 SLE patients (206). Spinal cord myelopathy can also occur in pediatric and neonatal lupus (207).

There have been several reviews of the reported cases of lupus myelopathy (204 ,205 ,208 ,209). These reports agree that most patients (80%) are young females between ages 20 to 40 years old. Of the first 28 patients, myelopathy was the initial manifestation in 3, and 11 had no prior diagnosis

of SLE. Two were quadriplegic, 7 paraparetic, and 19 paraplegic (205). Weakness, discrete sensory level, and impaired sphincter control were abnormal in all patients, whereas hyperreflexia was seen in less than 25% at initial presentation. These reviews report CSF abnormalities in the majority of patients, including elevated protein (greater than 80%), pleocytosis (50% to 70%), and decreased glucose levels less than 30 mg% (50%). The cerebrospinal fluid, however, can be normal and may contain elevated levels of myelin basic protein and/or oligoclonal bands. Of the 9 patients who underwent myelograms, 8 had normal studies. There have been several additional case reports and case series, which have reinforced these clinical findings.

The diagnosis of myelopathy is made clinically. MR imaging of the spinal cord can help confirm the diagnosis and exclude other causes of spinal cord compression, which may benefit from surgery. MR imaging in lupus myelopathy typically shows edema with abnormalities of T2-weighted images, which may be accompanied by spinal cord enlargement in 75% of patients (210 ,211). Any level of the spinal cord can be involved (212). Notably, some patients (30% to 40%) may have a normal MRI, especially if the examination is delayed (greater than 5 days) or the patient has received treatment (211). The differential diagnosis includes: compressive myelopathy (tumor, abscess, hematoma (213)), epidural lipomatosis (214), vertebral compression fracture (215), anterior spinal artery syndrome (216), infection (herpes zoster, tuberculosis, polyoma JC virus) (217 ,218 ,219), and Guillain-Barré syndrome (220). The etiology of lupus myelopathy is multifactorial. Small series have reported neuropathologic changes to include: arteritis (Fig. 37-2), perivascular lymphocytic infiltrates and myelitis, thrombosis of small and big arteries and veins, ischemic necrosis of the cord, microhemorrhages, spinal cord subdural hematomas, and myelomalacia of the cord (221). Although vasculitis during an acute exacerbation of SLE has been reported, many patients do not have active SLE at the time of their presentation. Lavalle and others have reported that SLE patients with myelopathy frequently have antiphospholipid antibodies (76 ,206 ,222) while other investigators have not (209). Whether or not the recently described antineuromyelitis optica antibodies plays any role in the development of lupus myelopathy is unknown (223).

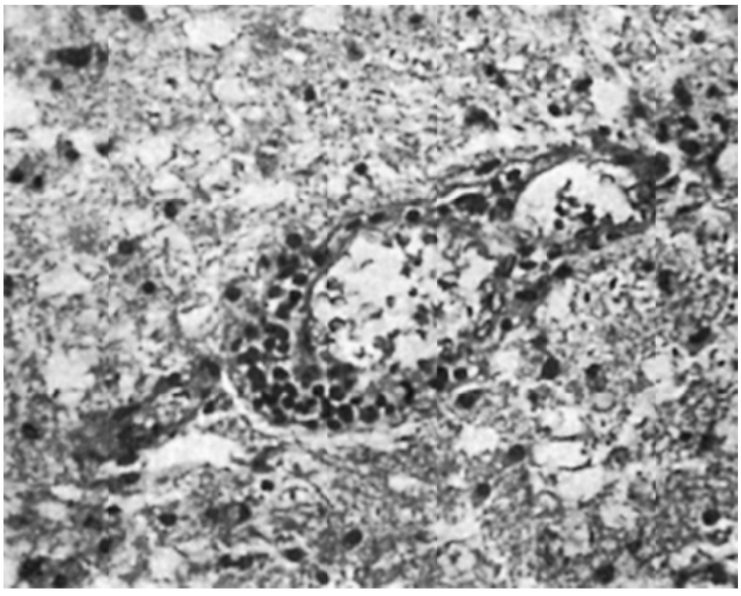

Figure 37-2. Acute arteritis and edema of surrounding tissue in the spinal cord of a 22-year-old patient with a paraplegia caused by lupus vasculitis (H&E; 750).

In their 1989 review, Propper and Bucknall emphasized the poor prognosis of the reported cases of lupus myelopathy (206). Of 26 patients, 7 had a full recovery, 9 a static or slowly-deteriorating course, and 10 died. Of 8 patients who promptly received high-dose corticosteroids, 5 recovered, compared with only 2 of 18 who did not receive steroids. More recent reports have emphasized that the use of pulsed methylprednisolone and cyclophosphamide may improve the prognosis of patients with lupus myelopathy (204 ,222 ,224 ,225 ,226). This therapy must be used early, since 50% of patients will reach their peak severity of myelopathy symptoms within 3 to 5 days of onset. Early use of aggressive therapy has resulted in reversal of symptoms and stabilization in the majority of patients with 50% having a complete recovery and 29% a partial recovery (205). In patients with significant titers of antiphospholipid antibodies, anticoagulation should probably be used, although studies are limited (204). Recurrences of myelopathy, particularly within the first year, are common. Rehabilitation measures to prevent pressure sores; preserve range of motion, strength, and mobility; and institute appropriate bladder management should also be initiated early.

Movement Disorders

Chorea, hemiballismus, cerebellar ataxia, and Parkinsonian- like rigidity/tremor are rare manifestations. Chorea is the most common, occurring in 1% to 4% of patients with SLE. Chorea is characterized by rapid, brief, involuntary, and irregular movements. It may be generalized or limited to the extremities, trunk, or face. Choreoathetosis is diagnosed when chorea is accompanied by slow, writhing movements of the affected extremity. Chorea occurs most commonly in young females, children, and during pregnancy (chorea gravidarum) or the postpartum period (227 ,228 ,229 ,230 ,231). It may be the initial presentation of SLE or precede other manifestations of SLE by as long as 7 years (228). Chorea usually occurs early in the course of SLE, tends to be bilateral, rarely is recurrent, and frequently is associated with other NP-SLE symptoms such as strokes. The cerebrospinal fluid examination is frequently unremarkable (227). The symptoms of chorea usually last for several weeks, but rarely can last for up to 3 years (229).

Infarction of the subthalamic nucleus can result in hemiballismus (232). It rarely has been reported in SLE. Ballismus may be steroid responsive (233) or related to antiphospholipid antibodies (234). Cerebellar ataxia is reported in less than 1% of patients with SLE (235 ,236).

Patients have an inability to stop or end purposeful movements. The abnormalities may involve the trunk or extremities. The etiology is uncertain, but some cases may be a result of cerebellar/brainstem infarction (195 ,237), antiphospholipid antibodies, or associated with Purkinje cell antibodies (238). In patients with cerebellar atrophy associated with antibodies against Purkinje cells, a paraneoplastic syndrome must be ruled out before attributing it to NP-SLE (239).

Tremor of all types has been reported in up to 5% of SLE patients during the course of their disease (240). However, Parkinsonian-like symptoms as a result of alterations of the substantia nigra are an extremely rare manifestation of NP-SLE. Miyoshi et al. (241) presented a case with a literature review of three previous reports. Recently, two adolescent females with severe, extrapyramidal Parkinsonism complicating SLE were reported (242). Patients presented with behavioral alterations (irritability or apathy), rigidity and progressive bradykinesia, and/or akinetic mutism. The EEG showed mild abnormalities, but single-photon emission computed tomography (SPECT) cerebral scanning detected decreased regional cerebral blood flow at the basal ganglia. Treatment with dopamine-agonist drugs led to complete recovery within 3 months along with normalization of the EEG and SPECT scans.

The etiology of chorea is unknown. Autopsy studies have not shown vasculitis (243). Multiple infarction of the basal ganglia (caudate, putamen, globus pallidus, or subthalamic nucleus) has been reported, which may lead to defective control of the thalamus, leading to abnormal movements. Recently, chorea has been associated with antiphospholipid antibodies, which can cause brain infarctions. In 1986, Hadron et al. reanalyzed the previously reported cases of chorea and determined that at least 20 of the patients had spontaneous abortions, false-positive serologic test results for syphilis, or evidence for the lupus anticoagulant (230). Asherson et al. observed chorea in 12 of 500 SLE patients (231). Of these 12 patients, 9 had antiphospholipid antibodies and 7 also had TIAs or cerebral infarcts. Others have confirmed this association (244 ,245); and case reports have claimed an association of chorea with antiphospholipid antibodies, SLE, and oral contraceptive use (246 ,247). Not all patients with chorea have antiphospholipid antibodies or abnormal brain MRIs. Furthermore, the association of chorea with antiphospholipid antibodies does not mean this manifestation is always caused by basal ganglia infarction. Notably, a study of 4 patients with SLE and chorea failed to find basal ganglia hypometabolism, which should be found if the striatum had been infarcted (248). This suggests that, in some patients, other mechanisms such as antineuronal antibodies may be an alternative pathogenetic process. It has been postulated that antiphospholipid antibodies can directly interact with neuronal structures in the basal ganglia.

There is a long differential diagnosis of illnesses rarely associated with chorea. Sydenham's chorea, secondary to rheumatic fever, is the most common and can be ruled out by obtaining antistreptococcal antibodies. However, the onset of chorea in a young woman with a positive ANA should strongly suggest SLE. The recommended treatment of chorea has been corticosteroids and neuroleptic drugs such as haloperidol. Some patients recover spontaneously, whereas others fail to respond to immunosuppressive therapy. Asherson et al. has recommended aspirin or anticoagulation in patients with chorea and antiphospholipid antibodies (231). More studies are needed, however.

Demyelinating Syndrome

A multiple sclerosis-like syndrome, sometimes called lupoid sclerosis, has been described in SLE patients (249 ,250 ,251 ,252 ,253 ,254 ,255). Interestingly, both multiple sclerosis and NP-SLE can share many features including: clinical presentation, Lhermitte's sign (256), positive antinuclear antibody, abnormal CSF with elevated IgG index and oligoclonal bands, and abnormal brain MRIs. Whether both diseases can coexist in one patient, or lupoid sclerosis is just an unusual presentation of NP-SLE, is unclear. Recently, antiphospholipid antibodies have been demonstrated in a number of patients with multiple sclerosis-like illnesses, suggesting these antibodies may be pathogenic in lupoid sclerosis (254 ,255 ,256 ,257).

Patients with definite multiple sclerosis have an acute, relapsing, demyelinating encephalomyelitis with discrete neurologic events distributed in place and time (258). Patients characteristically develop, at different time points, the following: limb weakness with sensory loss, transverse myelitis, optic neuritis, cranial nerve palsies often leading to diplopia, sphincter dysfunction, and/or brainstem or cerebellar abnormalities. Cognitive dysfunction and mood alterations can also be seen. CSF analysis shows elevated IgG index, multiple oligoclonal bands, and myelin basic protein (259). Brain MR imaging (260) shows discreet, low-density lesions often in the periventricular area as well as other areas of the white matter throughout the CNS. Lesions in the corpus callosum are particularly characteristic, since this is an area of relative avascularity, suggesting a demyelinating lesion instead of a vascular etiology. A previous retrospective study reported that 27% of 150 patients with multiple sclerosis had a positive ANA (261). However, a more recent, prospective study found that only 1 of 48 multiple sclerosis patients had a positive ANA (262). Multiple sclerosis patients with positive antinuclear antibodies should not have autoantibodies against specific antigens such as SS-A, SS-B, Smith, ribonuclear protein, or dsDNA, nor should they have hypocomplementemia. Recently, two studies reported that multiple sclerosis patients occasionally have anticardiolipin antibodies (263 ,264). Notably, these MS patients frequently had transverse myelitis, which is a known manifestation of antiphospholipid antibody syndrome. In summary, any multiple sclerosis patient with a positive antinuclear antibody, hypocomplementemia, or antiphospholipid antibodies should be re-evaluated for an alternative diagnosis such as

primary antiphospholipid antibody syndrome, SLE, or Sjögren's syndrome.

Patients with antiphospholipid antibodies can have multiple sclerosis-like presentations (257 ,265). They frequently have transverse myelitis with or without optic neuritis. They may have livedo reticularis of the skin. The MRI of these patients may be indistinguishable from multiple sclerosis (257 ,266), however, the pathophysiology is felt to be different. Patients with antiphospholipid antibodies develop their lesions because of vascular occlusion, whereas multiple sclerosis patients develop demyelinating plaques. Laboratory evaluation shows the patients have the lupus anticoagulant and/or anticardiolipin antibodies (IgG or IgM). When tested, they also have anti-$ß_2$ glycoprotein-1 antibodies, which are felt to be more specific for antiphospholipid antibody-mediated disease. CSF evaluation reveals the majority of these patients have normal IgG indexes, negative oligoclonal bands, and negative myelin basic protein results (267 ,270 ,271). In SLE patients (irrespective of antiphospholipid antibody status) who have oligoclonal bands in their CSF, the average number of bands is less than the number seen in MS patients and may disappear with immunosuppressive therapy, which does not occur in multiple sclerosis (268 ,269 ,270 ,271).

The therapy of patients with lupoid sclerosis differs from multiple sclerosis therapy. Both patient populations may respond to immunosuppressive therapy. However, SLE patients with lupoid sclerosis because of vascular occlusion from antiphospholipid antibodies are best treated with anticoagulation. Therapies used for multiple sclerosis such as ß interferon or Copaxone have not been evaluated in lupoid sclerosis, but are unlikely to be effective.

Seizures

Seizures occur in 10% to 20% of patients with SLE (Table 37-3). They may occur prior to the development of other symptoms of SLE or at any time during its course (51 ,53 ,148 ,272 ,273). Generalized major motor and partial complex seizures are most common, although any kind of seizure can occur. Seizure episodes are usually self-limited, although status epilepticus can occur and frequently signals a preterminal event. Seizures may occur in isolation or accompany other neurologic symptoms.

The etiology of seizures in NP-SLE is multifactorial. Antineuronal antibodies, focal ischemia and infarcts because of vascular occlusion from thrombosis and emboli, hemorrhage, and cytokine or neuroendocrine effects on the seizure threshold have all been implicated. Several studies have shown an association between antiphospholipid antibodies and seizures in SLE patients (53 ,274 ,275 ,276). There is an increased risk of seizures, seizures with strokes, and recurrence of seizures in patients with higher titers of antiphospholipid antibodies (272 ,276). Liou et al. have demonstrated that anticardiolipin antibodies from SLE patients with seizures can inhibit the gamma-aminobutyric acid (GABA) receptor-ion channel complex system, and this may increase cellular excitability (277). Chapman et al. reported that antiphospholipid antibodies may bind, permeabilize, and depolarize brain synaptoneurosomes, possibly leading to neuronal dysfunction by a nonthrombotic mechanism (109). However, most seizures in patients with antiphospholipid antibodies are probably a result of cerebral ischemia from cerebral microinfarctions. Secondary causes of seizures include: infections, medication effects, metabolic disturbances, hypoxemia, and hypertension, which must be ruled out in all SLE patients with seizures.

Most patients with seizures because of NP-SLE will respond to anticonvulsant medications. Although some anticonvulsants have been shown to cause a positive antinuclear antibody and rarely clinical SLE, this is not a reason to withhold these medications when they are indicated for patients with established lupus. Seizure control is important since recurrent seizures increase the vulnerability of neurons to additional injury. Consequently, in patients with status epilepticus, recurrent seizures, or other neurologic manifestations, corticosteroids and other immunosuppressive medications may be used. SLE patients with high-titer antiphospholipid antibodies and seizures should also receive anticoagulation, especially if the brain MRI shows areas of microinfarction.

Aseptic Meningitis

SLE patients with aseptic meningitis present with fever, headache, meningeal signs, and CSF pleocytosis with normal CSF glucose and protein less than 100 mg/dL (278 ,279 ,280). The pleocytosis is most commonly less than 200 to 300 cells/mm^3 and predominantly lymphocytes. Rarely, significantly higher cell counts with a neutrophil predominance can occur in severely ill patients. Infectious meningitis of any cause (281), subarachnoid hemorrhage, carcinomatous meningitis, sarcoidosis, and medication effects, such as from nonsteroidal anti-inflammatory drugs (NSAIDs) (ibuprofen, tolmetin, indomethacin, and sulindac) as well as from intravenous gammaglobulin and azathioprine, must be excluded (282). The etiology of aseptic meningitis in NP-SLE is unclear, but patients usually respond to corticosteroid therapy.

Cranial Neuropathies

Cranial neuropathy occurs in 3% to 16% of SLE patients during the course of their disease. It usually occurs during active SLE, can be transient, and usually responds to corticosteroid therapy. Ptosis (283), third and sixth nerve palsies (284 ,285 ,286), internuclear ophthalmoplegia (287), trigeminal neuralgia (288 ,289), and facial nerve palsies are the most common. Optic neuropathy causing blindness (290), tinnitus, vertigo, and sensorineural hearing loss are less common symptoms (291). The etiology of cranial neuropathies include vascular occlusion and focal meningitis. Autopsy studies have demonstrated lesions in the brainstem as well

as the peripheral part of the cranial nerves (56). Some of these neuropathies have been associated with vasculitis and others with thrombosis associated with antiphospholipid antibodies (292). Keane reported a retrospective study describing eye movement abnormalities in 113 hospitalized SLE patients seen by a neuro-ophthalmology service over a 25-year period (293). Of 55 oculomotor abnormalities, 33 involved limitation of eye movements or abnormal eye position at rest. Many of the abnormalities were subtle or transient. Sixteen of these 33 patients had evidence of brainstem infarcts causing cranial nerve dysfunction.

Other unusual presentations or causes of cranial nerve dysfunction in SLE have been reported. These include bilateral facial nerve palsy caused by angioedema (294), painful ophthalmoplegia (295), Brown's syndrome (296 ,297), Miller-Fisher syndrome (298), cavernous sinus thrombosis (299), and visual disturbances because of lymphocytic hypophysitis (300).

Peripheral Polyneuropathies

Peripheral nervous system involvement occurs in 2% to 21% of SLE patients (Table 37-3). Two cross-sectional studies of 30 and 31 patients, respectively, both found a 6.5% prevalence of peripheral sensorimotor neuropathy on extensive neuromuscular testing (301 ,302). The most common presentation is a distal sensorimotor neuropathy (66% of patients) (301 ,302 ,303 ,304 ,305). Less commonly, patients can have mononeuritis multiplex (14 ,306 ,307), acute or chronic polyradiculopathy (308 ,309 ,310), and rarely, a plexopathy (311). Peripheral nervous system involvement can be the initial presentation of SLE (303 ,306) and has been reported to occur in pediatric SLE patients (312). Symptoms can be severe or subtle and overlooked by the clinician.

Patients with distal, symmetric, peripheral polyneuropathy can present with a mild to severe sensory or less commonly sensorimotor fiber involvement. Patients usually complain of numbness and dysesthesias. Neurologic testing shows cutaneous hypesthesia to pinprick, light touch, and temperature stimuli. A recent controlled immunohistologic study of skin biopsies has demonstrated involvement of small, nonmyelinated afferent nerve fibers (313). Patients with significant paresthesias and abnormal nerve conduction tests are treated with glucocorticoids and antiseizure medications/tricyclic antidepressants. Patients with mild symptoms and/or normal electrodiagnostic studies are treated symptomatically with neuroleptics since 67% will not deteriorate on follow-up (314).

Less commonly, there is large, myelinated afferent fiber involvement, which manifests as deficits of vibratory and proprioceptive sense, areflexia, and sensory ataxia (315) with variable motor dysfunction. When motor axons are affected, weakness and muscle atrophy are seen. Electrodiagnostic studies usually show features of a mixed axonal and demyelinating neuropathy. The pathogenesis of the peripheral neuropathy is unclear. Antineuronal antibodies and vasculitis (304 ,305) from deposition of immune complexes have both been implicated (316).

Mononeuritis multiplex presents as multifocal and random dysfunction of individual, noncontiguous nerve trunks. Patients frequently present with development of sensorimotor deficits in the upper or lower extremities (wrist or foot drop) with an asymmetric distribution (Fig. 37-3). Occasionally, it can be widespread and mimic a distal, symmetric polyneuropathy. It typically occurs in the setting of active SLE, often with other neurologic abnormalities (308). Neurodiagnostic studies usually show an axonal pattern with reduction in amplitude of evoked compound action potentials with relative preservation of nerve conduction velocities. The etiology is felt to be a vasculitis of the vasonervorum (316 ,317 ,318), although this can only be demonstrated on sural nerve biopsy in 50% of cases. Aggressive therapy with corticosteroids and intravenous pulse or daily oral cyclophosphamide with or without plasma exchange is recommended (307 ,308 ,318). Recovery of nerve function takes up to 1 year.

There have been few reported cases of SLE patients with an inflammatory polyradiculoneuropathy (220 ,308 ,309 ,310). There are two forms: the acute form resembles Guillain-Barré syndrome and the chronic form resembles chronic, inflammatory, demyelinating polyradiculoneuropathy (CIDP). Patients presenting acutely have an ascending, predominantly areflexic motor paralysis, which peaks in 10 to 14 days. There is little or no sensory loss. There is little loss of cutaneous sensation since small, nonmyelinated fibers are not involved. Involvement of large myelinated afferent fibers leads to loss of proprioception and vibratory sensation.

There can be an associated autonomic dysfunction in some patients. There is no sphincter disturbance, which helps separate it from transverse myelitis. CSF examination reveals an elevated total protein with a white blood cell count less than 50. Electrodiagnostic studies reveal a demyelinating pattern with slowing of nerve conduction velocities, dispersion of evoked compound action potentials, conduction block, and marked prolongation of distal latencies. The pathogenesis is unknown. Unlike Guillain-Barré syndrome without SLE, patients have been successfully treated with corticosteroids. Recovery can occur within weeks if there has been no neuronal damage. There has been limited experience with the use of plasmapheresis (three cases) or intravenous gammaglobulin (no cases) in SLE patients with Guillain-Barré-like symptoms (308). Rarely, a patient presenting with acute polyradiculopathy will have an axonal pattern on electrodiagnostic studies and evidence of vasculitis (319). These patients should be treated with corticosteroids and cyclophosphamide. Recovery will take many months, since there is axonal damage.

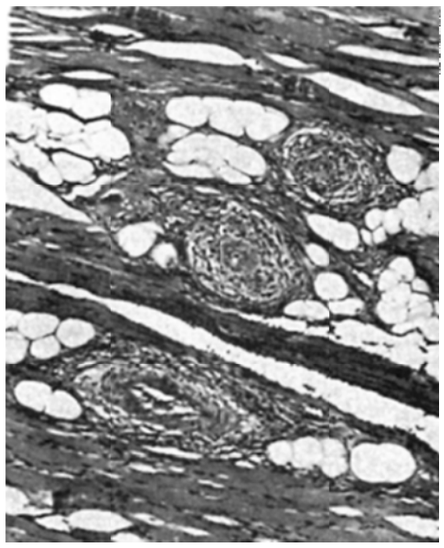

Figure 37-3. Vasculitis in gastrocnemius muscle biopsy of a patient with severe peripheral neuritis of legs and bilateral footdrop (H&E; 150).

SLE patients with chronic, demyelinating polyradiculopathy resembling CIDP can present with recurrent episodes of acute, Guillain-Barré syndrome-like symptoms, a mononeuritis multiplex-like pattern, or as a symmetric polyradiculopathy evolving over weeks to months. Electrodiagnostic studies frequently are confusing, showing a mixed axonal-demyelinating pattern. Nerve biopsy is usually not helpful, but may show inflammation. Therapy includes corticosteroids, plasmapheresis, cyclophosphamide, and intravenous gammaglobulin (310).

There are multiple secondary causes of peripheral nervous system involvement, which must be ruled out before attributing peripheral nerve dysfunction to NP-SLE. Uremia, diabetes mellitus, drug toxicities, vitamin deficiencies, heavy metal/solvent exposure, cancers and paraproteinemias, viral and other infections, sarcoidosis, alcohol and other toxins, hereditary neurologic diseases, and other causes must be considered and evaluated for in the SLE patient.

Autonomic Disorders

The autonomic nervous system is probably more commonly involved in SLE patients than previously reported. Acute autonomic neuropathy with profound dysfunction of the parasympathetic and/or sympathetic nervous system has rarely been reported in SLE (320 ,321). Gastrointestinal (constipation), cardiovascular (orthostatic hypotension), genitourinary (sphincter/sphincteric, erectile/ejaculatory dysfunction), sweating (anhydrosis and heat intolerance), and pupillary abnormalities are evident and, when severe, respond to corticosteroids.

Sensitive tests of autonomic function show that mild dysfunction may be present, although clinically unappreciated. Recently, Straub and colleagues reported that 29% of 31 SLE patients had abnormal pupillometry, reflecting lesions of the pupillary parasympathetic nervous system (302). This may be a result of cytokine effects on the hypothalamic autonomic nervous system (322). Additionally, 9.7% of these 31 patients had abnormal cardiovascular autonomic nervous system findings using a standard battery of tests, age-matched norms, and modern definitions of autonomic dysfunction. This is in agreement with the 2% to 13% prevalence found in two controlled studies of 34 and 23 outpatient SLE patients, respectively (323 ,324). Two recent reports found a 20% to 45% prevalence of cardiovascular autonomic nervous system dysfunction although abnormalities on testing did not correlate with symptoms (325 ,326). Of note, corticosteroids can mask cardiovascular autonomic changes resulting from SLE (327).

Myasthenia Gravis and Related Disorders

Myasthenia gravis and SLE may coexist in the same patient (328). There have been over 50 reported cases. Myasthenia typically precedes the onset of SLE in the majority of these patients. In some cases, SLE develops following thymectomy for the treatment of myasthenia gravis (329). Patients have typical manifestations of myasthenia with neuromuscular fatigue and weakness of bulbar or other voluntary muscles with repetitive muscular contractions. There is no impairment of sensation or loss of reflexes. Antibodies to the acetylcholine receptor can be demonstrated in 85% of myasthenia patients and are felt to cause neuromuscular symptoms by reducing the number of acetylcholine receptors at the neuromuscular junction. Diagnosis is made clinically and confirmed with electromyography and repetitive peripheral nerve stimulation at a rate of two per second showing a characteristic decremental response, which is reversed by the acetylcholinesterase drugs, edrophonium or neostigmine (see Chapter 40).

There have been a few SLE patients reported with Lambert-Eaton myasthenic syndrome (LEMS) (330). Patients present with weakness and hyporeflexia, which improves with exercise. Neurodiagnostic studies show a myopathic electromyogram (EMG) with low-amplitude compound muscle action potential, which increases in amplitude after exercise. High-frequency, repetitive stimulation demonstrates a 50% or more increment in the amplitude of the compound motor action potential. There is no improvement of clinical or EMG findings with anticholinesterase drugs. The etiopathogenesis is suspected to be an IgG antibody against the voltage-gated calcium channels in the presynaptic neuromuscular junction. Plasmapheresis and immunosuppressive medications are effective therapy. There has been one case report of an SLE patient with neuromyotonia (331). This patient presented with persistent myokymia at rest, both clinically and on EMG. The suspected pathogenesis is an IgG antibody against the voltage-gated potassium channels in the presynaptic neuromuscular junction.

Other Neuropsychiatric Lupus Syndromes

There have been other NP-SLE syndromes reported. Schnider et al. reported a patient who developed the acute onset of severe amnesia. MRI of the brain showed isolated hippocampal damage (332). It is unknown if antibodies against the NMDA receptor contributed to the atrophy. A case of limbic encephalopathy because of NP-SLE was reported in a young woman with SLE (333). The patient had fever, headache, encephalopathy, generalized seizures, and antiribosomal P antibodies in her CSF. All tests for herpes simplex and paraneoplastic syndromes were negative. A case of the syndrome of inappropriate antidiuretic hormone (SIADH) was reported as the initial manifestation of SLE in an elderly woman with antiribosomal P antibodies (334). Other cases of NP-SLE with SIADH have been reported (335). Finally, there have been several reported cases of reversible posterior leukoencephalopathy (336 ,337). These patients present with the sudden onset of neurologic symptoms that mimic other neurologic conditions. Imaging shows reversible lesions in the posterior cortex on diffusion-weighted MRI as a result of vasogenic edema. This manifestation has been associated with severe hypertension, uremia, thrombotic thrombocytopenia purpura (TTP), and use of cytotoxic medications. Full recovery usually occurs with control of the precipitating risk factors.

NP-SLE in Children and the Elderly

Several groups have examined NP-SLE in children. Yancey et al. (338) found a 43% incidence in 37 children, and their literature review of 11 pediatric studies found a 33% incidence in 353 children (see Chapter 43). A recent 6-year prospective study of 75 pediatric SLE patients found that 95% had evidence of NP-SLE at some time using the ACR NP-SLE nomenclature (168). If only serious manifestations were considered then the prevalence of NP-SLE fell to 76%. Not surprisingly, NP-SLE was present in twice as many hospitalized patients compared to SLE outpatients. Adolescent SLE patients with antiphospholipid antibodies, particularly the lupus anticoagulant, are most at risk for strokes and need life-long anticoagulation to prevent recurrences (339 ,340).

CNS involvement in older age groups (i.e., >50 years) is reported to be milder and less frequent with an incidence between 6% and 19% (341 ,342 ,343). In one report, however, 9 of 10 patients who were diagnosed with SLE at an age of older than 50 years had neuropsychiatric manifestations. Of these, 5 had peripheral neuritis, 3 had cerebellar ataxia (344), and nearly all were steroid responsive. Two percent of 254 individuals, who were admitted to a psychogeriatric center in England over a 2-year period, turned out to have SLE (345).

Differential Diagnosis of Secondary Causes of CNS Dysfunction in SLE Patients

Secondary causes of CNS dysfunction in SLE patients must always be ruled out before attributing symptoms to primary NP-SLE (Table 37-4) (42 ,43 ,44). Prospective studies point out that 50% to 78% of neurologic events are caused by secondary factors (44 ,54). The most common secondary causes include infections, medications, and metabolic disturbances. Equally important is the clinician must realize that the presence of an antinuclear antibody in a patient with neurologic symptoms does not imply that the patient has NP-SLE or, for that matter, SLE at all (346 ,347). Many other possibilities must be considered in the differential diagnosis.

Infections

SLE patients have an increased susceptibility to bacterial, viral, fungal, and parasitic infections because of disease and medication effects on the immune system (281) (see Chapter 45). The neurologic manifestations of CNS infection can include: confusion, lethargy, headache, neck pain, seizures, psychosis, and fever with or without focal or generalized sensory and motor deficits (42 ,43 ,44). Nearly every organism has been reported to infect patients with SLE (281). Tuberculosis, bacterial endocarditis, herpes simplex encephalitis, bacterial meningitis (Neisserial, *Listeria*, *Nocardia*, *Salmonella*, and syphilitic), and opportunistic central nervous system infections (*Toxoplasma*, *Aspergillus*, amoebic, and Cryptococcal) have all been reported as potentially mistaken for NP-SLE. Human polyoma virus JC has been demonstrated as the cause of progressive multifocal leukoencephalopathy in SLE patients (348).

The most critical test to exclude CNS infection is a lumbar puncture with CSF examination. Although CSF pleocytosis and elevated protein also can be seen in cerebral vasculitis, an associated low glucose, positive Gram stain and/or cultures, or polymerase chain reaction tests for viruses are diagnostic of CNS infections. CT scan with contrast or brain MRI may help to locate an abscess or focal area of involvement. Whenever infection is likely, broad-spectrum antibiotics that cross the BBB should be initiated. After that, corticosteroid doses can be increased to treat possible NP-SLE while cultures are pending or to prevent Addisonian crisis during stress. Unfortunately, unsuspected CNS infections are all too commonly first diagnosed at time of postmortem examination.

Medications

Patients with lupus often take medications that are known to have CNS toxicity. Corticosteroids have been reported to cause psychosis, depression, mania, and delirium (349 ,350 ,351). Notably, mood alteration (depression/mania) is

more common than psychosis. The majority of patients who develop psychiatric disturbances will do so within 2 weeks of starting or increasing the corticosteroid dose. Factors that have predicted psychiatric side effects from corticosteroids include high-dose intravenous methylprednisolone, doses of oral prednisone greater than 40 mg/day, and female gender. Age, previous psychiatric illness, and prior history of steroid psychosis were not predictive of corticosteroid-induced psychiatric side effects (350). Steroid psychosis, however, is extremely uncommon in pediatric SLE patients. Most patients with steroid psychosis improve within days to a few weeks by lowering and dividing the dose of corticosteroids. Antipsychotic medications (chlorpromazine, risperidone), lithium, and electroconvulsive therapy have been used successfully. Tricyclic antidepressants make symptoms worse and should be avoided (352). There is little experience with the use of selective serotonin reuptake inhibitors.

Antimalarial therapy has been associated with a variety of neurologic symptoms, including headaches, irritability, seizures, and neuromyopathy (see Chapter 59). NSAIDs can cause a variety of CNS side effects (353). Ibuprofen and rarely other NSAIDs have caused aseptic meningitis, particularly in SLE patients (282). Acute psychosis with disorientation, paranoia, or hallucinations can occur with indomethacin or sulindac. The indolacetic acid derivatives (indomethacin, tolmetin, and sulindac) can also induce headache. Cognitive dysfunction with memory impairment and depression can occur with indomethacin and less commonly with other NSAIDs, especially in elderly patients. Antihypertensive medications can cause fatigue and depression. Azathioprine can cause aseptic meningitis; intravenous gammaglobulin has also been reported to cause aseptic meningitis (282) and strokes (354). All treating physicians must obtain a careful drug history from their patients. Nearly all of these medications can be withheld for brief periods to determine causation.

Thrombotic Thrombocytopenic Purpura

TTP is characterized by fever, thrombocytopenia, microangiopathic hemolytic anemia, neurologic symptoms, and renal involvement. The thrombocytopenia and hemolytic anemia are nonimmune mediated, which helps separate this from SLE. There have been over 30 cases of TTP and SLE occurring in the same individual (355). In the majority (62%) of cases, SLE preceded the development of TTP, while in 17% the two diseases developed simultaneously. Rarely, TTP preceded the onset of SLE. In 50% of cases, TTP complicated the course of active SLE, whereas in the remaining, it developed in SLE patients with inactive disease.

The etiology of TTP occurring in SLE may be similar to idiopathic TTP. Acute TTP has been found to be a result of an IgG autoantibody against the metalloprotease responsible for cleavage of the monomeric subunits of von Willebrand factor (356). This allows for the accumulation of unusually large multimers of von Willebrand factors secreted by endothelial cells into the plasma. These multimers bind to platelet glycoprotein receptors, causing platelet adhesion and microthrombi. The treatment of acute TTP in SLE patients includes plasmapheresis to remove the autoantibody and large multimers of von Willebrand factor, followed by fresh frozen plasma to replace the metalloprotease. Antiplatelet agents, corticosteroids, and/or immunosuppressive drugs have been used, but are not as effective as plasmapheresis and plasma replacement. However, corticosteroids and immunosuppressives may be needed to prevent recurrence by suppressing autoantibody formation. Precipitating causes of idiopathic TTP include drugs such as ticlopidine and infection. These, however, have rarely been reported in patients with SLE complicated by TTP (355).

Other Causes of CNS Dysfunction

Other secondary causes of CNS dysfunction that must be excluded include: hyponatremia, hypercalcemia, uremia, hypoxia, accelerated hypertension, fever, hypothyroidism, cerebral lymphoma (357), and subdural hematoma (358), as well as others. SLE patients have accelerated atherosclerosis, which can lead to stroke and hypertension, causing intracerebral hemorrhage. Berry aneurysms have been reported in SLE patients and can cause subarachnoid hemorrhage (94 ,95 ,96).

Fibromyalgia is commonly observed in SLE patients. Pistiner et al. reported that 20% of their SLE patients fulfilled established criteria for fibromyalgia (23). A recent review of fibromyalgia in SLE emphasizes these findings (359). Fatigue, myalgias, paresthesias, insomnia, and headaches are frequent in patients with fibromyalgia. Additionally, reactive depression with or without fibromyalgia is also commonly found in SLE patients. Living with SLE can involve lifestyle adjustments and create stress. This can lead to depression, anxiety, and functional symptoms such as sweating, palpitations, diarrhea, and hyperventilation, which are observed with increased frequency in patients with SLE (360). It is important to not confuse these symptoms with active NP-SLE.

Sleep apnea can also occur in SLE patients. Corticosteroid therapy leads to weight gain and weakness of respiratory muscles. This can lead to apnea/hypoventilation during sleep. Patients with sleep apnea complain of fatigue, headaches, and mental clouding, which can be misdiagnosed as NP-SLE. This is a common and underdiagnosed cause of mild CNS symptoms in SLE patients.

Positive ANA Without Lupus

There are patients with nonspecific complaints such as myalgias, arthralgias, fatigue, and headache, who are found by their primary care physician to have a low-titer antinuclear

antibody without other objective or laboratory findings of lupus. These patients may be sent for rheumatologic consultation to confirm a diagnosis of SLE or NP-SLE as a cause of their symptoms (346). Furthermore, there are patients with a drug-induced ANA from procainamide, phenothiazines, or other medications who may have or develop neuropsychiatric symptoms from causes other than SLE or drug-induced SLE (361). Consequently, it is imperative to first confirm a diagnosis of SLE in any patient being sent for consultation to rule out NP-SLE.

Clinical and Laboratory Evaluation

A methodological work-up is essential for the patient with SLE who presents with neuropsychiatric manifestations (26 ,362 ,363). A careful and thorough history and physical examination including a complete neurologic and mental status evaluation must be done on each patient. Additionally, a variety of laboratory, CSF, neurodiagnostic studies, and when appropriate, cultures of bodily fluids are done to assess disease activity and to exclude other diseases, which can cause neurologic symptoms. Earlier studies emphasized that certain clinical signs, such as retinal and dermal vasculitis or livedo reticularis, were more common in NP-SLE patients, particularly those with cerebrovascular disease (17). Furthermore, although NP-SLE can be the initial or sole active manifestation of SLE, many studies have reported that NP-SLE frequently occurs when SLE is clinically and serologically active (17 ,18 ,19 ,21 ,27). However, in all SLE patients with CNS dysfunction, additional tests will be necessary to confirm an NP-SLE diagnosis and exclude other causes (Tables 37.5 ,37.6 ,37.7).There is no single blood test that can diagnose NP-SLE. *After excluding secondary causes, the diagnosis of NP-SLE can only be confirmed if a patient's neuropsychiatric symptoms can be corroborated with objective abnormalities in neuropsychological, spinal fluid, EEG, and/or imaging studies*. Recently, an international, multidisciplinary committee made recommendations of the basic laboratory evaluation and diagnostic imaging which should be obtained on all patients suspected of having NP-SLE (Table 37-5) (10) (Fig. 37-4).

Table 37-5: Laboratory Evaluation and Diagnostic Imaging of SLE Patients with Neuro-Psychiatric Manifestations

Complete blood count/peripheral blood smear
Chemistries: electrolytes, creatinine, glucose
Liver-associated enzymes
Urinalysis
C3/C4 and/or CH_{50}
Anti-dsDNA antibodies
Antiphospholipid antibodies/anti $ß_2$ glycoprotein I
Cerebrospinal fluid: cell count, protein, glucose, IgG index, oligoclonal bands, VDRL
Brain MRI with gadollinium
Electroencephalogram
Other tests when indicated
Serum and CSF antineuronal antibodies
Computerized tomography of brain
Echocardiogram
Magnetic resonance angiogram
Angiogram
Tests for hypercoagulability: protein C, protein S, SAT III, prothrombin mutation, factor V Leiden, homocysteine
Antiribosomal P antibodies
Cryoglobulins
Other tests—investigational
Specific serum and CSF antineuronal antibodies
CSF levels of cytokines, matrix metalloproteinases, or proteins indicating neuronal damage
Single-photon emission tomography
Magnetic resonance spectroscopy
Positron emission tomography

Table 37-6: Frequency of Abnormal Laboratory Tests Commonly Used in the Evaluation of Neuropsychiatric Lupus Erythematosus

Test	Frequency of Abnormal Test Result Range (%)	Comment
Serologic		
Antineuronal antibodies	30–92	Diffuse manifestations
Antineurofilament antibodies	58	Diffuse manifestations
Antiribosomal-P antibodies	45–90	Psychosis/depression
Antiphospholipid antibodies	45–80	Focal manifestations, strokes
Cerebrospinal fluid		
Routine		
Pleocytosis	6–34	Rule out infection and NSAID meningitis
Increased protein	22–50	Nonspecific
Low glucose	3–8	Rule out infection, transverse myelitis
Special		
Antineuronal antibodies (IgG)	40–90	Diffuse manifestations, present in 40% with focal manifestations
Elevated O albumin	8–33	Break in blood-brain barrier
Elevated IgG/IgM index	25–66	Diffuse manifestations
Oligoclonal band (2 bands)	20–82	Diffuse manifestations

Table 37-7: Frequency of Abnormal Diagnostic Tests Commonly Used in the Evaluation of Neuropsychiatric Lupus Erythematosus

Test	Frequency of Abnormal Test Results Range (%)	Comment
Electroencephalogram	54–85	No specific abnormality. SLE pts without CNS Sxs can have abnormal EEG (48%).
Neuroimaging Procedures		
Brain scan	8–19	Some studies report higher prevalence of abnormalities.
CT scan	27–71 (atrophy)	Atrophy may be due to corticosteroids.
	10–25 (infarct or hemorrhage)	CT scan will miss 20%–25% of definite clinical infarcts.
MRI scan		
All NPLE pts	77	No specific lesion, atrophy (28%–71%).
NPLE pts, diffuse Sxs only	Less than 50	More likely abnormal if obtain within 48 hrs of treatment
NPLE pts, focal Sxs	Up to 100	
SLE pts, CNS Sxs unrelated to NPLE	31	
SLE pts (<age 45), no hx CNS Sxs	Less than 5–10	
SPECT scan	44–88	Up to 67% of SLE pts with CNS events unrelated to NPLE have abnormal scans.
Angiography	10	More likely abnormal in embolic strokes.
Echocardiography	40	Definite valvular lesions more common in stroke pts. May have association with antiphospholipid antibodies.

CNS, central nervous system; Sxs, symptoms; pts, patients; EEG, electroencephalogram; CT, computed tomography; MRI, magnetic resonance imaging; NPLE, neuropsychiatric lupus erythematosus; SPECT, single-photo-emission computer tomography; hx, history.

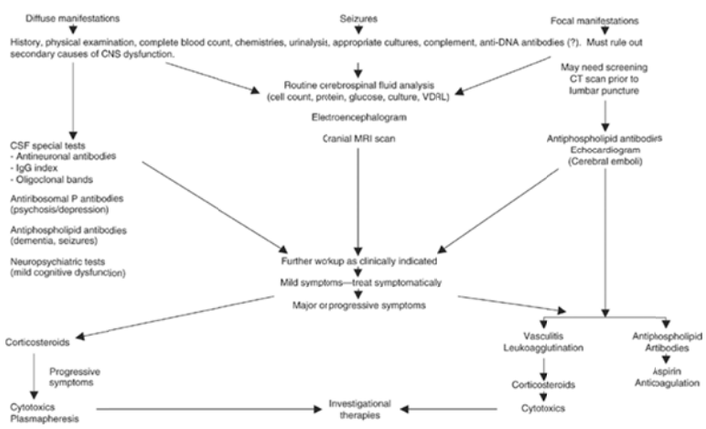

Figure 37-4. Algorithm for the evaluation and treatment of systemic lupus erythematosus patients with neuropsychiatric lupus erythematosus.

Clinical Laboratory Tests

Blood tests include a complete blood count, including platelet count and peripheral smear. The blood smear should be examined for schistocytes and thrombocytopenia to exclude TTP. Chemistries including electrolytes, creatinine, glucose, and liver-associated enzymes are obtained to exclude metabolic abnormalities that can cause neurologic dysfunction. A urinalysis should be obtained for disease activity and to rule out infection. Complement (C3/C4 or CH_{50}) determinations and anti-dsDNA antibodies should be obtained to assess disease activity. Testing for antiphospholipid antibodies includes lupus anticoagulant, anticardiolipin antibodies, and anti-$ß_2$ glycoprotein-1 antibodies. Other tests for hypercoagulable states, including factor V Leiden, protein C and S levels, serum antithrombin III levels, and prothrombin 20210A mutation may be indicated in selected patients. Most patients with SLE will have an elevated erythrocyte sedimentation rate and a normal or mildly elevated C-reactive protein. A significantly elevated C-reactive protein (>6 mg/dL) usually indicates systemic vasculitis or infection. A fasting lipid profile and homocysteine levels are obtained to establish vascular risk factors. Serum antilymphocyte and antineuronal antibodies are considered investigational.

Antiribosomal P Antibodies

Antibodies to the C-terminal region of cytoplasmic ribosomal P protein are found in 12% to 16% of SLE patients and are among the most specific tests for SLE (169 ,170 ,172). Bonfa et al. first observed these antibodies in 18 of 20 SLE patients with psychosis/major depression (169). Several groups have related antiribosomal P antibodies to psychosis and severe depression, but others have failed to confirm this association (171 ,172). Some investigators have found antiribosomal P associated with CNS disease in general, as opposed to psychosis in particular (364 ,365). Serum levels of the antibody may correlate with the severity of the psychosis in selected patients (26 ,39 ,366 ,367), but also vary widely over time without any clinical associations. The antibody usually is not found in the CSF (26 ,39), although it has been in some patients (368). SLE patients with mild depression and/or cognitive dysfunction do not have elevated ribosomal P levels (162 ,163).

Iverson and Reichlin have summarized the available evidence concerning the value of testing for antiribosomal P antibodies (172 ,369). Both noted that studies supported the specificity of antiribosomal P antibodies for SLE, and that these antibodies are not found in patients with neuropsychiatric conditions who do not have SLE. Additionally, several

studies have shown that these antibodies are more prevalent in Oriental patients with SLE than Caucasians or African Americans, regardless of whether these patients had neuropsychiatric manifestations. Combining the studies, Iverson estimated that the sensitivity of antiribosomal P antibodies to neuropsychiatric manifestations was 0.64 to 0.66, the positive predictive value was only 0.29, and the negative predictive value was 0.90. Therefore, he supported the opinion of Teh (37) that, “There is no value in measuring anti-P antibodies, either as a single determinate for identifying patients with lupus psychosis (or depression) or sequentially as a predictor of impending relapse of the lupus psychiatric disorder.” This opinion, however, is not supported by all clinicians who care for patients with NP-SLE (26 ,39). Some feel that the high specificity of this antibody for SLE makes it particularly useful as a diagnostic test in neuropsychiatric cases without a definite diagnosis of SLE (10). Furthermore, in an individual patient who does have NP-SLE and antiribosomal P antibodies, the titer of antibody may become undetectable with successful therapy (39 ,170).

The mechanism of how an antibody against a cytoplasmic antigen can cause CNS dysfunction is unclear. However, ribosomal P antigens have been demonstrated on the surface of endothelial cells (370) and on the surface of human neuroblastoma cells (108). This suggests that these autoantibodies may bind to membrane surface antigens, instead of cytoplasmic ribosomal P proteins. Binding of antiribosomal P to neuronal cells might directly participate in neuronal dysfunction. The binding of antiribosomal P to these surface antigens might explain why antiribosomal P antibodies are not found free in the CSF of patients with NP-SLE, while antiribosomal P antibodies are found in their sera.

Antilymphocyte Antibodies

Antilymphocyte antibodies are not specific for SLE and can occur in other illnesses, including infections, malignancy, inflammatory bowel disease, and multiple sclerosis. A subset of antilymphocyte antibodies, however, cross-react with neurons. Fever, neuropsychiatric symptoms, skin lesions, and hematologic abnormalities are the most common manifestations in patients with SLE and serum lymphocytotoxic antibodies (371 ,372). Denburg et al. has related cognitive dysfunction to the presence of serum IgM lymphocytotoxic antibodies in over 445 patients evaluated (159 ,373). This may reflect the presence of the antineuronal subset of antilymphocyte antibodies. In a prospective study, Temesvari et al. (374) found a correlation between fluctuation in serum lymphocytotoxicity and relapses or remissions of neuropsychiatric involvement in individual patients with SLE (see Chapter 28).

Serum Antineuronal Antibodies

Serum antineuronal antibodies are more common in NP-SLE patients (30% to 92%) than in SLE patients without CNS lupus (5% to 20%) (31 ,32 ,100 ,101 ,102 ,103 ,104 ,105 ,375). They are neither as sensitive nor as specific as CSF antineuronal antibody measurements. Nevertheless, neuroblastoma-binding serum autoantibodies are particularly frequent in NP-SLE patients with diffuse presentations, such as encephalopathy and cognitive dysfunction (32 ,33 ,375). A limited number of studies have investigated the fine specificity of some of these antibodies (376). Several membrane antigens have been identified as targets of these antineuronal antibodies. In neuroblastoma cells, a 97-kilodalton membrane protein of unknown function is the target antigen for autoantibodies from a limited number of NP-SLE patients (377). An immunodominant, C-terminal epitope of ribosomal P antibody has been demonstrated on the surface of human neuroblastoma cells (108 ,378). Hanson et al. have found antibodies against a 50-kilodalton antigen in the plasma membrane of brain synaptic terminals in 19 of 20 NP-SLE patients (102), whereas Denburg and Behmann documented the presence of antilymphocyte/antineuronal antibodies against a 52-kilodalton antigen in patients with NP-SLE (379). Recently, Galeazzi et al. and others have found antiganglioside antibodies (GM1) or antigalactocerebroside antibodies more commonly in SLE patients with NP-SLE (380 ,381 ,382 ,383). Several cytoplasmic antigens including ribosomal P, neurofilaments, and L-fimbrin have been reported as target antigens. Serum antineurofilament antibodies, which react against cytoskeletal neurofilament triplet protein antigens, were found in 58% of patients with diffuse neuropsychiatric manifestations, compared to 20% with focal symptoms and 18% of controls (103). Antibodies to L-fimbrin expressed in cytoplasmic microfilaments of leukocytes have also been found increased in patients with NP-SLE (384). Recently neural tissue-specific autoantibodies against glial fibrillary acidic protein and microtubule-associated protein-2 have been associated with various NP-SLE manifestations (104 ,105). Finally, a subset of anti-dsDNA antibodies have been shown to cross-react with the NR2 subtype of the NMDA glutamate receptor (111) and has been associated with depression and cognitive difficulties (164). The significance of these targets, or how antibodies against them cause disease, is unclear. Notably, each of these autoantibodies is more common in patients with diffuse, as opposed to focal, manifestations of NP-SLE.

Antiphospholipid Antibodies

Antiphospholipid antibodies are a heterogenous group of autoantibodies associated with thromboembolic events. The lupus anticoagulant and anticardiolipin antibodies are the ones best characterized. Lupus anticoagulant prolongs phospholipid-dependent coagulation assays, such as the activated partial thromboplastin time and the kaolin clotting time. Subsequently, more sensitive assays, particularly the dilute Russell viper venom time (dRVVT), have been used to detect and/or confirm the presence of a lupus anticoagulant, even in patients with normal activated partial thromboplastin time (PTT) and clinical features of the

antiphospholipid antibody syndrome. Anticardiolipin and anti-β_2 glycoprotein I (β_2GPI) antibodies are detected by a standard enzyme-linked immunoabsorbent assay. In the meta-analysis by Love and Santora of 29 retrospective studies comprising greater than 1000 patients with SLE, the average prevalence of lupus anticoagulants and anticardiolipin antibodies were 34% and 44%, respectively, with an overall incidence of thrombotic complications of 28% (385). Many studies combine primary antiphospholipid antibody syndrome patients with SLE patients with antiphospholipid antibodies, making interpretation of these studies difficult to apply to SLE patients only (386).

There have been several neurologic syndromes associated with antiphospholipid antibodies in patients with lupus (53 ,292). The most common are stroke, cerebral venous sinus thrombosis (78), ocular ischemia, sensorineural hearing loss (291), dementia, seizures (387), chorea, and transverse myelopathy (204). Each one is felt to be a result of a thromboembolic event resulting in vascular occlusion. A major clinical question is why do some patients with antiphospholipid antibodies develop these neurologic syndromes, whereas others do not. SLE patients at greatest risk are those who have the lupus anticoagulant and/or high-titer IgG (and possibly IgM and IgA) anticardiolipin antibodies with β_2GPI specificity. SLE patients with antiphospholipid antibodies of different specificities have an increased risk of cerebral infarction compared to patients with a single antiphospholipid antibody. The presence of combinations of lupus anticoagulant, anticardiolipin/β_2GPI, and/or antiphosphatidylserine/prothrombin antibodies was strongly associated with stroke (388). Clinically, patients with antiphospholipid antibodies who have a history of a previous thromboembolic event, livedo reticularis, thrombocytopenia, or active lupus (vasculitis, hypocomplementemia, elevated anti-dsDNA antibodies) are at increased risk for thrombosis (389 ,390 ,391). Furthermore, approximately one third of patients with antiphospholipid antibodies have abnormal echocardiograms which demonstrate left-sided valvular lesions, which are a potential cardiac source for an embolic stroke (88 ,198 ,199 ,392). SLE patients with antiphospholipid antibodies, who have cerebral microemboli detected by transcranial Doppler ultrasound, are more likely to develop cerebrovascular ischemic events (393). Up to 30% of SLE patients who develop a thromboembolic event are likely to develop a recurrent episode within one year of the initial event (394). The initial type of thromboembolic event (arterial versus venous) is the most likely type of event to recur in a given patient, although usually not in the same vascular territory (395).

The ability of antiphospholipid antibodies to cause thrombosis is a result of a complex interaction between these antibodies, brain endothelial cells, and cerebral hemostasis, which is poorly understood (396 ,397). Brain endothelial cells display different functional and phenotypic characteristics compared to endothelial cells at other anatomic sites. β_2GPI appears to be expressed in higher amounts on brain endothelial membranes. Annexin V has increased importance in preventing thrombosis in the brain. Antiphospholipid antibodies with anti-β_2GPI specificity with or without anti-endothelial cell antibodies can selectively damage and/or activate these cells leading to prothrombotic consequences. Other mechanisms such as complement activation have also been proposed (398). Notably, certain clinical conditions such as surgery and infection can further increase the risk of thrombosis perhaps through the release of tissue factor. Finally, other cerebrovascular risk factors can be additive to the thrombotic risk conferred by antiphospholipid antibodies (399 ,400). Cigarette smoking, hyperlipidemia, hypertension, diabetes mellitus, and hyperhomocystinemia are all correctable risk factors, which need to be identified and treated.

There are SLE patients with neurologic thromboembolic events who will lack antiphospholipid antibodies on testing during the acute event. This may be a false-negative result possibly because of consumption of the antibody during the acute thrombotic episode. Consequently, these patients should be retested for these antibodies 6 to 8 weeks after the initial thrombotic event, since some patients will become positive for antiphospholipid antibodies at this time. However, approximately 10% of patients with an antiphospholipid antibody-like syndrome will remain negative for the lupus anticoagulant and IgG/IgM anticardiolipin antibodies, even with repeated testing. Some of these patients may demonstrate IgA anticardiolipin antibodies, antibodies against other negatively-charged noncardiolipin phospholipids, such as phosphatidylserine and phosphatidylinositol, or antibodies against specific phospholipid-binding proteins, including β_2GPI, prothrombin, protein C, protein S, thrombomodulin, and kininogens (401). It is not clear how, or if, these autoantibodies put SLE patients at increased risk for thromboembolic events.

CSF Tests

CSF analysis is useful in all SLE patients with a change in neurologic status, particularly to exclude infection or other secondary causes of CNS dysfunction. In patients with NP-SLE, CSF results may be unremarkable. However, patients with NP-SLE may have abnormalities helpful in confirming the diagnosis and guiding management. The NP-SLE consensus panel recommended that routine CSF tests, IgG index, and oligoclonal bands be determined on all patients suspected of having NP-SLE (10).

Routine CSF Tests

Routine CSF tests include cell count with differential, protein, glucose, Gram stain, other special stains, VDRL, and cultures. Pleocytosis and elevated protein are found in some patients with active NP-SLE. Protein abnormalities were found to be more common (range, 22% to 50%) than pleocytosis (range, 6% to 34%) in 10 studies analyzing spinal fluid findings in 250 patients with NP-SLE

(11 ,17 ,18 ,21 ,22 ,118 ,402). Neutrophilic pleocytosis with elevated protein suggests cerebral vasculitis with ischemia, if infection is ruled out (403). Patients with antiphospholipid antibodies and neurologic thromboembolic events frequently have elevated protein with mild or no pleocytosis.

The CSF glucose level is rarely decreased in NP-SLE. It has been reported low in between 3% and 8% of patients (18 ,21 ,22). Patients with acute transverse myelopathy have been reported to have hypoglycorrhea more than patients with other manifestations of NP-SLE (205), although they frequently have normal CSF glucose levels. CSF pleocytosis, elevated protein levels, and low glucose should always raise suspicion of an acute or chronic infection before attributing these abnormalities to NP-SLE.

CSF Immunologic Tests

Several studies have noted that CSF IgG levels are elevated in 69% to 96% of NP-SLE patients (22 ,32 ,402). Bluestein and Zvaifler found that a CSF IgG level greater than 6 mg/dL almost always indicated NP-SLE, but was present in only 40% of their patients (32). An elevated CSF Q-albumin ratio, indicating a break in the BBB, has been noted in up to one third of patients, especially those with progressive encephalopathy, transverse myelitis, and strokes (26 ,118 ,119). Several groups have now confirmed that an elevated IgG index and/or IgG oligoclonal bands are seen in up to 80% of patients, particularly those with diffuse manifestations, such as encephalopathy and psychosis (22 ,26 ,118 ,119 ,120 ,122). Hirohata et al. have also found IgM and IgA indices elevated (120). Patients with focal manifestations, such as stroke because of antiphospholipid antibodies, typically do not have an elevated IgG index or oligoclonal bands, unless they also have a coexistent encephalopathy (complex presentation) (26). These abnormalities have been shown to normalize in some patients after successful therapy (26 ,121).

CSF Antineuronal Antibodies

Bluestein et al. (31 ,32) found IgG antibodies to neurons in the CSF of 74% of 28 SLE patients with CNS involvement, as compared to only 11% of 18 SLE patients without CNS disease, using a radioimmunoassay with SK-N-SH neuroblastoma cells as the target. Furthermore, 90% of the patients with diffuse manifestations of psychosis, encephalopathy, or generalized seizures had elevated IgG antineuronal antibodies, compared to only 25% of patients with focal manifestations of hemiparesis or chorea. Notably, the antineuronal antibody was concentrated eightfold in the CSF, relative to its concentration in paired serum samples. In contrast, Kelly and Denburg, using a less sensitive hemadsorption assay, detected IgG antineuronal antibodies in only 17% of their patients with NP-SLE, using SK-N-ML neuroblastoma cells as a target (35). They correlated the presence of these antibodies with cognitive dysfunction; diffuse, nonfocal CNS manifestations; abnormal Q-albumin ratios; and active lupus with elevated anti-dsDNA antibody levels (33 ,34 ,35).

More recently, West et al. and Isshi and Hirohata, using sensitive enzyme-linked immunoabsorbent assays (ELISAs) with neuroblastoma cells as the target antigen, found a high percentage of their patients with active NP-SLE had antineuronal antibodies in their CSF. West et al. (26) reported that 12 of 40 (30%) SLE patients with diffuse manifestations had antineuronal antibodies, while Isshi and Hirohata (39) found 39 of 41 (95%) NP-SLE patients had CSF IgG antineuronal antibodies. Moreover, Isshi found in the 1 patient they followed serially that the CSF antineuronal antibody activity markedly fell with successful therapy, but increased along with an elevation of CSF IL-6 during an exacerbation of NP-SLE (39).

Miscellaneous Determinations

Several other laboratory and immunologic tests have been reported to be helpful and/or abnormal in NP-SLE. Brook et al. found CSF lactic acid to be normal in those with NP-SLE, whereas it is increased in patients with bacterial meningitis (404). Occasionally, LE cells can be found in the CSF in patients with NP-SLE, but rarely are they looked for and documented. Myelin basic protein has been reported, particularly in myelopathy patients. Other CSF serologic tests reported to be elevated in NP-SLE include: immune complexes (22), substance P (405), B_2-microglobulin levels, cyclic GMP levels (406), prostaglandin E2 (130), quinolinic acid (407), and CD4+ T cells. Most of these are single center reports or abstracts and generally not available to clinicians.

A past study reported that C4 levels in CSF decrease in those with acute NP-SLE (408). The C4 level turned out to be unstable in CSF, difficult to measure, and its value unconfirmed in other reports (402 ,409 ,410 ,411). However, intrathecal C4 synthesis may be increased in NP-SLE patients with diffuse manifestations (412). Another group reported increased levels of C5b-9 in the CSF of patients with active NP-SLE, suggesting intrathecal complement activation (413). Autoantibodies have rarely been reported in the CSF, including: antiribosomal P (368), antideoxyribonucleoprotein (414), anti-dsDNA (402 ,415), anticardiolipin antibodies, and anti-Ro/anti-La (415). Other groups have failed to detect some of these antibodies (26 ,170).

Several cytokines have been reported to be elevated in the CSF of active NP-SLE patients. Several groups have found elevated IL-6 levels in patients with NP-SLE (127 ,128 ,129 ,130). This is of interest since IL-6 can contribute to B cell differentiation into antibody-secreting plasma cells. Recently, Isshi and Hirohata reported a patient whose CSF IL-6 level and antineuronal antibodies increased during an exacerbation of NP-SLE, whereas the serum antineuronal antibody levels did not increase, suggesting intrathecal synthesis of antineuronal antibodies (39). Other cytokines reported to be elevated in the CSF of NP-SLE patients are IL-1 (127), IL-8 (129), IFN-α (416), and the chemokine CXCL10 (417).

Levels of glial fibrillary acidic protein and neurofilament triplet protein are 3 to 7 times higher in the CSF of patients with NP-SLE compared to controls (129). These levels correlated with the degree of abnormalities found on brain MRI. Measurements of these are evidence of neuronal damage and may be useful in the future.

Summary

When a lumbar puncture is performed in SLE patients with CNS dysfunction, the CSF tests that should be ordered are: cell count with differential, glucose and protein levels, VDRL, and Gram stain and cultures. Additionally, CSF should be sent for antineuronal antibodies and a "multiple sclerosis panel," which includes a CSF IgG level, Q-albumin ratio, IgG index, oligoclonal bands, and a calculated IgG synthesis rate. Patients with diffuse manifestations frequently have elevated antineuronal antibodies and/or an elevated IgG index and oligoclonal bands, suggesting immunologic activity (26 ,39). Patients with only focal manifestations usually do not have antineuronal antibodies, elevated IgG index, or oligoclonal bands, but may have an elevated Q-albumin ratio because of disruption of the BBB. Patients with pleocytosis and elevated protein levels with negative cultures frequently have acute inflammation from vasculitis causing their focal symptoms. In contrast, patients with antiphospholipid antibodies causing thrombosis and focal symptoms usually have elevated protein levels, but mild or no pleocytosis in their CSF. Infection must be ruled in all patients with CNS dysfunction.

Neuroimaging Studies

There have been dramatic advancements in neuroradiographic procedures for a variety of neurologic diseases. Brain imaging is an important part of the evaluation of SLE patients with neurologic dysfunction. Several recent, excellent review by leaders in the field have summarized the scientific basis for the use of neuro-imaging modalities in NP-SLE, point out their limitations, and make recommendations for their use (418 ,419 ,420). Chapter 38 presents an in-depth discussion of the various neuro-imaging modalities.

Angiography

Cerebral angiography is frequently normal in NP-SLE patients, even in those with cerebral infarction on MRI (63 ,64 ,65 ,66 ,421 ,422 ,423 ,424). This lack of sensitivity may be explained by the small size of vessels affected by lupus vasculopathy. Occasionally, vasculitis of larger-size arteries or cerebral emboli can be documented. However, angiograms are an invasive procedure with possible morbidity. A recent study reported angiograms in patients with suspected vasculitis were associated with transient neurologic deficits in 11.5%, which were persistent in 0.8% (425). MR angiography is a noninvasive alternative that can demonstrate abnormalities in medium to large vessels. In patients with suspected emboli, carotid Doppler and echocardiogram (including transesophageal technique) should be done to rule out a source of emboli.

Summary

Currently, MRI with gadolinium is the only imaging modality recommended for the evaluation of NP-SLE (10). CT scan is useful to rapidly rule out a large infarct or hemorrhage in an SLE patient with acute neurologic deterioration. MRI is superior to CT scan for detecting edema, infarcts, and hemorrhage. However, there is no MRI finding that is specific for NP-SLE. Furthermore, patients with NP-SLE, particularly those with diffuse manifestations, may have a normal conventional MRI. Conversely, SLE patients without NP-SLE may have abnormalities on MRI, which may be misinterpreted as NP-SLE. Thus, the results of MRI must be interpreted along with the clinical and other laboratory findings to establish a diagnosis of NP-SLE (26). Other MRI techniques, including MR relaxometry, MR spectroscopy, diffusion MRI, perfusion MRI, magnetization transfer imaging, and transcranial Doppler ultrasound are presently research tools and should be limited to selected cases of symptomatic patients with a normal conventional MRI. In the future, they may increase the sensitivity and specificity of conventional MRI and prove that all patients with NP-SLE will have demonstrable abnormalities. Although MRS cannot be used to specifically diagnose NP-SLE, it is very sensitive and specific for brain injury and may be very useful to confirm an organic basis for neurocognitive dysfunction in a patient suspected of having mild NP-SLE (418 ,419 ,420).

PET and SPECT scans are very sensitive but lack specificity, thus limiting their value in the diagnosis of NP-SLE. These modalities should be considered research neuro-imaging procedures and not used in the clinical evaluation of patients with NP-SLE. However, a normal SPECT scan may rule against significant brain pathology in an SLE patient with nonspecific neuropsychiatric symptoms.

Electroencephalography

Conventional EEG is abnormal in 60% to 91% of adult and pediatric patients with NP-SLE (17 ,18 ,19 ,20 ,21 ,22 ,26 ,338). Recently, EEG abnormalities have been found to correlate with the presence of antiphospholipid antibodies even in the absence of brain MRI abnormalities (426). The most common finding is diffuse slowing with increased β and δ background activity. Focal abnormalities and seizure activity can also be seen. Unfortunately, the EEG findings are not specific for NP-SLE, and other disorders, including metabolic encephalopathies and drug effects, can give similar findings. Furthermore, up to 50% of SLE patients without active NP-SLE can have abnormal EEGs. Consequently, a single abnormal EEG has limited diagnostic value for NP-SLE.

On occasion, however, an EEG may be very helpful, revealing unsuspected seizure activity that was not apparent clinically. EEGs may be able to distinguish steroid-induced psychosis from NP-SLE.

Quantitative electroencephalography (Q-EEG) has been found to be more sensitive and specific compared to conventional EEG (427 ,428). Q-EEG is abnormal in 87% of patients with definite NP-SLE, 74% of patients with probable NP-SLE, and 28% of SLE patients without neuropsychiatric symptoms. Serial Q-EEG reportedly show improvement with therapy.

Visual, brainstem, auditory, and somatosensory evoked potentials have been reported to be useful in detecting subtle cortical dysfunction not detected with conventional EEG (429 ,430 ,431 ,432). Others have failed to demonstrate evoked potential to be of value (433). Further controlled studies on these modalities are needed to establish their usefulness in clinical practice.

Treatment

The therapy of NP-SLE differs depending upon the clinical presentation and suspected pathogenesis (434). A thorough clinical evaluation and appropriate diagnostic evaluation of any SLE patient with new neuropsychiatric symptoms is important to establish the extent of neurological impairment and brain injury, in order to assess future progression and response to therapy. Secondary causes of CNS dysfunction should be excluded quickly and all unnecessary medications should be stopped. Therapy should not be delayed pending test results. If it is unclear whether the CNS dysfunction is a result of primary NP-SLE or a secondary cause, then the patient should be treated for both until diagnostic test results return (Fig. 37-4).

CNS Manifestations

The treatment of NP-SLE is empiric since there have been few controlled clinical trials. The therapy should be tailored to the severity of the presentation and suspected etiology. Patients with mild, diffuse manifestations such as headaches, anxiety/dysphoria, paresthesias, or an isolated seizure may only need analgesics, psychotropic medications and psychologic support, or antiseizure medications, respectively, and observed closely for any neurologic progression. A particularly difficult clinical situation is the SLE patient with a complaint of cognitive dysfunction but a clinically normal mental status examination. In these patients, serial psychometric testing may be helpful in establishing the presence, extent, and progression, if any, of impairment. Secondary causes such as medications, thyroid disease, depression, and especially sleep apnea need to be excluded. Treatment should be supportive, including memory aids, unless progression can be documented. The use of immunosuppressive therapy in this clinical situation is limited (435).

NP-SLE patients with severe or progressive, diffuse presentations such as acute confusional state, psychosis, severe depression, and coma may benefit from immunosuppressive medications. Most clinicians recommend 1 mg/kg/day of prednisone in divided doses. For the most severe cases, pulse intravenous methylprednisolone (1 g daily for 3 days) may be beneficial (436 ,437 ,438). Failure to respond within a few days may necessitate doubling of the prednisone dose. Another alternative is to switch from prednisone to dexamethasone (12 to 20 mg qd), which penetrates the BBB better than other corticosteroid preparations. Continued failure to respond is an indication to add cytotoxic medications and/or a trial of plasmapheresis, particularly for comatose patients. Pulse intravenous cyclophosphamide (0.75 to 1.0 g/m^2) given every 3 to 6 weeks has been reported to be beneficial in both adult and pediatric patients (439 ,440 ,441 ,442 ,443 ,444). Azathioprine has also been used, but with less impressive results. Patients with psychosis or depression should receive appropriate psychotropic medications to aid in the subsequent tapering of immunosuppressive medications.

Other methods of cyclophosphamide administration have been reported. A recent open-labeled study of 13 patients with lupus psychosis showed a favorable outcome in all patients treated with oral cyclophosphamide for 6 months followed by maintenance therapy with azathioprine (445). Two other trials have examined lower doses of intravenous cyclophosphamide. One trial used 500 mg every 2 weeks for three pulses followed by monthly 500-mg pulses for 6 months (446). The other used only 200 to 400 mg monthly (447). Both regimens were effective, had fewer side effects, but higher relapse rates compared to standard monthly therapy doses as used by NIH investigators in the lupus nephritis trials (0.75 to 1.0 g/m^2).

NP-SLE patients presenting with focal manifestations demand an immediate and aggressive evaluation. If vasculitis is suspected, corticosteroids in high doses similar to patients with severe, diffuse manifestations are used. Cytotoxic medications should be used early in patients with vasculitis. Clinical experience suggests that cyclophosphamide is more effective than azathioprine, methotrexate, cyclosporine, mycophenolate mofetil (448), or IV pulse methylprednisolone (449). Once the patient's NP-SLE is controlled on cyclophosphamide, another cytotoxic medication may be substituted to maintain remission. Whether chronic antiplatelet therapy prevents thrombosis or atheroma formation in the damaged vessel is unknown, but often used.

Many patients with focal manifestations of NP-SLE have antiphospholipid antibodies. Since the suspected pathogenesis is thrombosis and not vasculitis, patients are treated with antiplatelet drugs, hydroxychloroquine for its mild anticoagulant effect, and/or anticoagulation. In patients with large or cardioembolic strokes, excessive heparinization is dangerous and may cause hemorrhage into the infarcted area. Consequently, particularly in patients with an elevated PTT because of the lupus anticoagulant,

heparin levels should be followed as well as serial CT scans. Although the intensity of warfarin therapy has been debated (450), most experts recommend lifelong warfarin at an INR of 3.0 to 3.5 for cerebral arterial thrombosis (451 ,452). Patients with the lupus anticoagulant should also have periodic factor II and chromogenic factor X levels followed and maintained at 15% to 20% of normal to assure adequate anticoagulation (453). Patients who continue to thrombose on anticoagulation may respond to intravenous gammaglobulin or plasmapheresis with immunosuppressive therapy (440).

NP-SLE patients with seizures should be treated with antiseizure medications. Patients presenting in status epilepticus or who have recurrent seizures should be treated with high-dose prednisone. Patients with seizures, cerebral infarcts, and moderate to high titers of antiphospholipid antibodies should be anticoagulated once seizures are controlled, although they are at increased risk for falls and cerebral trauma (53). Antiseizure medications may have side effects, which can mimic active lupus. Phenytoin can cause fever, adenopathy, and leukopenia. Ataxia and other neurologic symptoms can occur if the phenytoin level rises above therapeutic levels. Carbamazepine can cause severe leukopenia and must be monitored closely. SLE patients with seizures should remain on antiseizure medications for at least 1 year. If they have no recurrence of seizures, a normal MRI, and normal EEG, then antiseizure medications can be withdrawn, and the patient followed closely. Vehicle driving restrictions should be enforced.

Some patients with NP-SLE will not respond to, may not tolerate, or will have contraindications to aggressive therapy. In these patients, a variety of other therapies have been tried. One novel approach is intrathecal therapy for patients with diffuse NP-SLE. Funauchi et al. recently reported two SLE patients with a good response to intrathecal corticosteroids (454). Other investigators have used intrathecal methotrexate and dexamethasone (10 mg of each, weekly for 3 weeks). Two reports totaling 27 patients with diffuse manifestations of NP-SLE received this therapy with over 90% of patients responding (30 ,455). These observations have recently been confirmed where 22 of 24 NP-SLE patients unresponsive to oral corticosteroids responded to intrathecal therapy (456). Another therapy is intravenous immunoglobulin (IVIG). Six of seven patients with severe, acute NP-SLE responded to IVIG (457 ,458). IVIG should be given at a dose of 400 mg/kg/day for 5 consecutive days, instead of 1,000 mg/kg/day for 2 days, in order to lessen the chance of side effects such as thrombosis, fluid overload, renal function deterioration, and aseptic meningitis. A third therapy is plasmapheresis (459 ,460 ,461 ,462 ,463). For a critically ill patient, 40 to 60 mL of plasma/kg/day is removed for up to 5 consecutive days. For a more stable patient, 40 mL of plasma/kg/day three times a week for 3 weeks constitutes a therapeutic trial. Oftentimes, only 1 week of plasmapheresis is needed to stabilize the patient. Plasmapheresis is particularly useful for patients with cerebral vasculitis to allow time for the corticosteroids and cytotoxic medications to take effect. It is also used in patients with recurrent cerebral infarcts, associated with antiphospholipid antibodies, who fail anticoagulation. However, some investigators are using IVIG in this clinical situation to avoid the catheter-related thrombosis frequently seen in these patients (440 ,464). Notably, immunosuppressive medications are continued during plasmapheresis to prevent rebound antibody production and/or disease flare. Frequent side effects of plasmapheresis are catheter-related problems and infection (465). Patients developing hypogammaglobulinemia should receive replacement immunoglobulin to help prevent infection. Another use for plasmapheresis is in SLE patients with hyperviscosity syndrome (viscosity greater than 4) from circulating immune complexes, severe hypergammaglobulinemia, or cryoglobulinemia (cryocrits greater than 8%) who have symptoms of cerebral insufficiency. Finally, plasmapheresis with fresh frozen plasma replacement is the best therapy for SLE patients with TTP (466). Other therapies reported in isolated case reports to be successful in steroid-unresponsive NP-SLE are B cell depletion therapy with antiCD20 (467), hyperbaric oxygen for cognitive impairment (468), and intrathecal plasmapheresis (469). Hematopoietic stem cell transplantation (470) or high-dose cyclophosphamide therapy (471) may be considered for patients with severe and resistant NP-SLE.

Difficult Clinical Situations

Several difficult clinical situations warrant further comment. First is the SLE patient on corticosteroids who presents with neuropsychiatric symptoms that could be NP-SLE versus steroid psychosis. One approach is to double the dose of corticosteroids for 3 days while awaiting test results. If the psychotic episode is a result of NP-SLE, it will respond to this therapy. Failure to improve lessens the likelihood of NP-SLE and the corticosteroids should be tapered to half of the original dose. If corticosteroids cannot be tapered, then antipsychotics such as haloperidol or lithium can be used (350 ,472). Tricyclic antidepressants should be avoided (352).

A second situation is the young (<40 yr) SLE patient with mild cognitive complaints who is found to have multiple small T2-weighted lesions in the cerebral white matter on brain MRI. Patients in whom cognitive dysfunction is confirmed by formal neuropsychiatric testing should receive antiaggregant therapy (aspirin 75 to 100 mg/d) and/or hydroxychloroquine especially if antiphospholipid antibodies are present (53 ,473). Patients who fail to respond to this therapy as evidenced by progression of cognitive dysfunction and/or accumulation of brain lesions on MRI may benefit from oral anticoagulation with warfarin. A third situation is the SLE patient with dementia from prior NP-SLE or from infarctions related to antiphospholipid antibodies. The dementia in these patients will not respond to corticosteroids and, in fact, may worsen. SLE patients with stable dementia should not be automatically assumed

to have active NP-SLE and therefore should not be treated aggressively with immunosuppressive medications.

Two other difficult clinical situations are transverse myelitis and chorea. Transverse myelitis should be treated aggressively with corticosteroids and cyclophosphamide (204 ,224 ,225 ,226). Patients presenting acutely should receive intravenous pulse methylprednisolone followed by high-dose prednisone and intravenous monthly cyclophosphamide. Patients with chorea usually respond to corticosteroids and haloperidol. Those that do not respond may need cytotoxic medications and/or plasmapheresis (244).

Headaches can be a chronic problem in SLE patients. Initial studies showed that headaches associated with SLE flares would respond to corticosteroids. However, most headaches in SLE patients occur without an SLE flare and do not respond to corticosteroids. Usually symptomatic therapy for migraine or tension headaches is beneficial. In patients with chronic refractory headaches secondary causes such as sleep apnea and saggital vein thrombosis must be excluded. Anecdotal reports have described improvement of headaches in patients with antiphospholipid antibodies who received anticoagulation. However, a recent controlled trial did not show any benefit (474).

Several other neurologic syndromes, including stroke, transverse myelitis, chorea, seizures, and multiple sclerosis-like syndromes, have been associated with antiphospholipid antibodies as well as other pathogenetic mechanisms. When a patient presents with one of these manifestations, the antiphospholipid antibody results may take a few days to return. In the interim, we have treated these patients with corticosteroids and antiplatelet drugs until results of antiphospholipid antibodies return, particularly since vasculitis can coexist with antiphospholipid antibody-associated thrombosis (74). If the antiphospholipid antibodies are positive, the next decision is whether to continue with antiplatelet drugs or to anticoagulant. One approach has been to anticoagulate those patients with the lupus anticoagulant or high-titer (greater than 40 to 50 GPL units) IgG anticardiolipin/anti-$ß_2$ glycoprotein-1 antibodies and/or other manifestations of the antiphospholipid antibody syndrome, including livedo reticularis, previous miscarriages, previous thrombotic episodes, and mild thrombocytopenia (452).

Peripheral Nervous System Manifestations

SLE patients with mild, nonprogressive paresthesias require only symptomatic therapy. Patients with cranial, peripheral, or autonomic neuropathy are treated with high-dose corticosteroids initially. Patients with Guillain-Barré or CIDP frequently have IVIG or plasmapheresis as additional therapy. Patients with mononeuritis multiplex because of vasculitis should also receive cytotoxic therapy such as cyclophosphamide. When using cyclophosphamide in patients with peripheral/autonomic nervous system involvement, it is important to determine if the patient has a neurogenic bladder, which may not eliminate the cyclophosphamide metabolites leading to hemorrhagic cystitis. SLE patients with myasthenia gravis are treated with medications that increase the concentration of acetylcholine at the neuromuscular junction. Other therapy is similar to patients, without SLE, who have myasthenia. The role of thymectomy is controversial since SLE has been reported to flare after the thymus has been removed (329).

Prognosis

The prognosis for NP-SLE patients remains guarded. Recent studies have shown that the overall clinical impact of NP-SLE has a negative impact on quality of life as indicated by lower scores on subscales of the SF-36 as well as a higher frequency of disability (475). Although many NP-SLE patients with major diffuse symptoms of NP-SLE appear to recover, studies using psychometric testing demonstrate that many patients are left with cognitive dysfunction suggesting residual CNS damage (165). Patients with focal manifestations may stabilize, but usually do not reverse their deficits during therapy. Notably, individual neuropsychiatric manifestations differ in their prognostic implications.

Few studies have prospectively followed NP-SLE patients over time. Several studies have shown that mild cognitive deficits detected by formal testing do not appear to progress or adversely affect a person's quality of life over time in the majority of patients (152 ,153 ,154). Patients with major NP-SLE manifestations have a less optimistic prognosis. Recurrences of NP-SLE episodes occur in 20% to 40% of NP-SLE patients, leading to more residual dysfunction. Using the SLICC/ACR Damage Index, Petri has found neuropsychiatric damage steadily accrues and is the second-leading organ system that is damaged in the Hopkin's lupus cohort (476). However, a recent study by Karassa et al. is more favorable (477). They followed 32 SLE patients who had been hospitalized for NP-SLE prospectively for 2 years and found that there was substantial improvement (69%) or stabilization (19%) in most cases. Patients with recurrent episodes of NP-SLE and those with antiphospholipid antibodies generally did worse.

With dialysis and transplantation enabling lupus patients with nephritis to survive longer, NP-SLE and its therapy may now be the leading cause of death with a 7% to 19% mortality rate (21 ,30 ,478 ,479). Previous studies indicate that seizures, especially status epilepticus, stroke, and coma are particularly poor prognostic signs (14 ,17 ,478 ,479), demanding aggressive evaluation and treatment to help prevent residual neurologic damage or death. Whether the therapy improves or contributes to long-term morbidity and mortality from conditions like atherosclerosis and cancer is unclear (480). Consequently, the clinician must make every effort to limit the toxicities of therapy by controlling hypertension, treating hyperlipidemia and hyperglycemia, utilizing osteoporosis prophylaxis, administering pneumococcal vaccine, polyvalent (Pneumovax), advising against smoking, treating hyperhomocystinemia with appropriate vitamins, and using medications for *Pneumocystis carinii* prophylaxis (481).

Chapter 38

Psychopathology of Lupus and Neuroimaging

John G. Hanly

John D. Fisk

Introduction

Involvement of the nervous system by systemic lupus erythematosus (SLE) has been recognized for over 100 years and includes a wide variety of neurologic (N) and psychiatric (P) manifestations. The presentation of neuropsychiatric (NP) disease in individual SLE patients continues to pose diagnostic and therapeutic challenges because of the lack of specificity of the majority of the NP manifestations, uncertainty regarding the pathogenic mechanisms, and a paucity of data to support therapeutic strategies. This chapter will review what is currently known about the more common psychiatric syndromes and cognitive impairment in SLE patients and the role of neuro-imaging in the diagnosis and investigation of NP syndromes.

Classification of Neuropsychiatric Systemic Lupus Erythematosus

The American College of Rheumatology (ACR) classification criteria for SLE (1) include the NP manifestations, seizures, and psychosis. However, it is widely acknowledged that a much broader range of NP disease manifestations occur in SLE patients. Virtually all studies indicate that most NP events reflect involvement of the central nervous system (CNS) compared to involvement of either the peripheral or autonomic nervous systems. A particular NP event may reflect either a diffuse disease process (e.g., psychosis and depression) or focal process (e.g., stroke and transverse myelitis) depending upon the anatomic location of pathology. Although several classifications have been developed for neuropsychiatric systemic lupus erythematosus (NP-SLE) (2 ,3 ,4), most have lacked either definitions for individual manifestations or uniformity in the approach to investigation and diagnosis. In 1999, the ACR research committee produced a standard nomenclature and diagnostic criteria for 19 NP syndromes that are known to occur in SLE patients (5) (Table 38-1). For each of the 19 NP syndromes, potential etiologies other than SLE were identified for either exclusion, or recognized as an “association,” acknowledging that in some clinical presentations definitive attribution is not possible. The identification of other nonlupus causes for NP events in SLE patients is of critical importance and has not been adequately addressed in previous classification systems. Guidelines for reporting NP events were also developed by the ACR research committee and specific diagnostic tests were recommended for each syndrome. Although these criteria were developed primarily to facilitate research studies of NP-SLE, they also provide a practical guide to the assessment of individual SLE patients with NP disease.

Epidemiology of NP-SLE

In a representative selection of studies utilizing the ACR classification criteria for NP-SLE (6 ,7 ,8 ,9 ,10), the overall prevalence of NP disease has varied widely between 37% and 95% (Table 38-2). The most common of the 19 NP syndromes in each of these 5 SLE cohorts were cognitive dysfunction (55% to 80%), headache (24% to 72%), mood disorders (14% to 57%), cerebrovascular disease (5% to 18%), seizures (6% to 51%), polyneuropathy (3% to 28%), anxiety (7% to 24%) and psychosis (0% to 8%). Most of the other NP syndromes were infrequent, with a prevalence of less than 1% in most studies, emphasizing the rarity of many of these NP events in SLE patients.

The attribution of individual NP events to SLE per se or to an alternative etiology remains a challenge. In the absence of a diagnostic gold standard for most of the NP-SLE syndromes, attribution is determined case-by-case on the basis of exclusion using the best available clinical, laboratory, and imaging data. The ACR NP-SLE classification (5) provides a basis for addressing this issue in a systematic manner, because for each NP syndrome there is a comprehensive list of “exclusions” and “associations,” the presence of which may indicate an alternative etiology other than SLE. Utilizing this approach and taking into consideration the temporal relationship between the NP event and the diagnosis of SLE, a recent study has reported that up to 41% of all NP events in SLE patients may be attributed to factors other than lupus (8). This finding is in keeping with data from a Finnish study (6), which concluded that headache, anxiety, mild depression, mild cognitive impairment, and polyneuropathy without electrophysiologic confirmation

should not be considered primary NP manifestations of SLE. The impact of chronic disease was also emphasized by a recent study that reported that NP syndromes commonly associated with SLE may occur with comparable frequency in patients with rheumatoid arthritis (RA) (11), further emphasizing the nondisease-specific nature of many of the NP syndromes in SLE patients. Regardless of attribution, the impact of cumulative NP events in SLE patients is evident from the significant reduction in virtually all domains of the SF-36, a self-report health-related quality-of-life instrument (8) (Fig. 38-1).

Table 38-1: Neuropsychiatric Syndromes in SLE as Defined by the ACR Nomenclature.

Central nervous system	Peripheral nervous system
Aseptic meningitis	Guillain-Barré syndrome
Cerebrovascular disease	Autonomic neuropathy
Demyelinating syndrome	Mononeuropathy
Headache	Myasthenia gravis
Movement disorder	Cranial neuropathy
Myelopathy	Plexopathy
Seizure disorders	Polyneuropathy
Acute confusional state	
Anxiety disorder	
Cognitive dysfunction	
Mood disorder	
Psychosis	

From The American College of Rheumatology nomenclature and case definitions for neuropsychiatric lupus syndromes. *Arthritis Rheum* 1999;42(4):599–608 with permission.

The results of these recent clinical studies serve to both reinforce previous conclusions about NP-SLE and introduce new concepts. Despite the improved definitions for individual NP syndromes, there continues to be substantial variability in the overall prevalence of NP disease between different populations. Whether this represents inherent differences between study cohorts or a bias in data acquisition remains to be determined. None of the individual NP manifestations are unique to lupus and indeed some occur with comparable frequency in the general population and in patients with other chronic diseases. Thus, in research study design, the inclusion of control groups is critical to determine whether the prevalence of NP disease in SLE patients is in excess of that found in the normal population and in other chronic diseases. Because of the fact that many of the NP syndromes are quite rare (<1%), multicenter efforts will be required to assemble sufficient numbers of patients for study. Current evidence suggests that non-SLE factors likely contribute to a substantial proportion of NP disease in SLE patients, particularly the “softer” NP manifestations such as headache, anxiety, and some mood disorders. Future studies will need to define which of the many NP manifestations have the greatest clinical impact.

Pathogenesis of NP-SLE

The rationale for identifying the etiology and pathogenic mechanisms underlying NP disease in SLE (Fig. 38-2) is to facilitate the logical development of appropriate and effective therapies. The diversity of NP manifestations, which have been reported in SLE patients, makes it unlikely that

there is a single pathogenic mechanism. However, the exclusion of a substantial proportion of NP events attributable to non-SLE factors, such as complications of the disease, its therapy, or concurrent illnesses, provides a more homogenous clinical population and the greater likelihood of identifying disease specific mechanisms. There are at least three primary immunopathogenic mechanisms that are implicated in NP-SLE, namely vasculopathy of predominantly small intracranial blood vessels, autoantibody production, and the generation of inflammatory mediators.

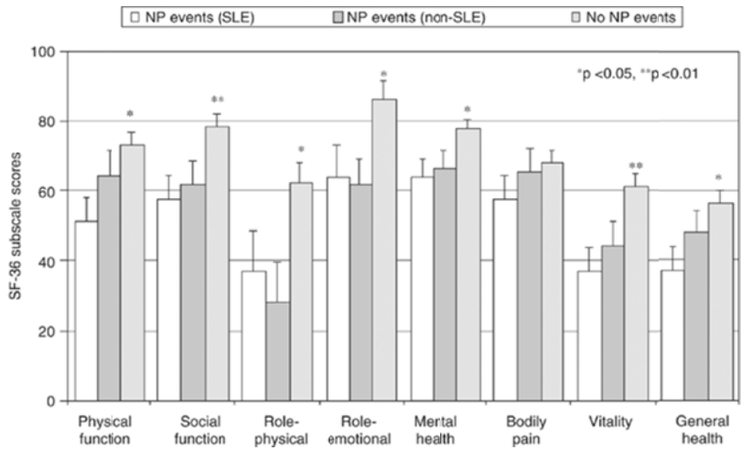

Figure 38-1. Association between cumulative neuropsychiatric events in SLE patients and self-report health-related quality of life as reflected by the SF-36. Derived from Hanly JG, McCurdy G, Fougere L, et al. Neuropsychiatric events in systemic lupus erythematosus: attribution and clinical significance. *J Rheumatol* 2004;31(11): 2156–2162.

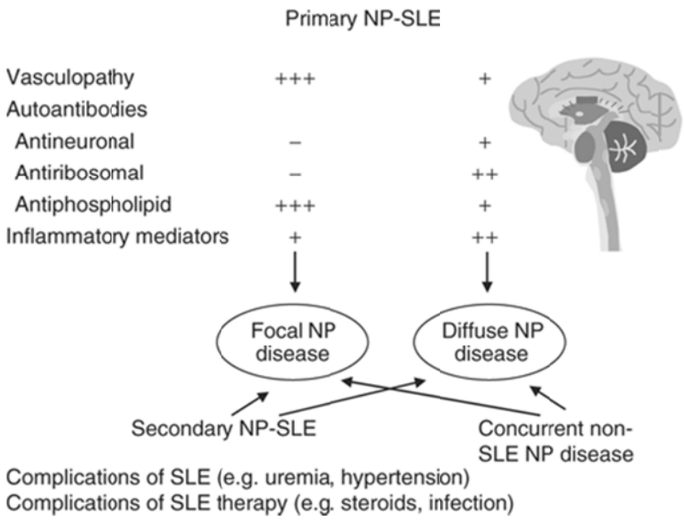

Figure 38-2. Factors contributing to the pathogenesis of neuropsychiatric (NP) disease in SLE. Modified from Hanly JG. Neuropsychiatric lupus. *Curr Rheumatol Rep* 2001;3:205–212.

Vasculopathy

In a limited number of neuropathologic studies (12 ,13 ,14 ,15) the predominant finding was a bland, noninflammatory vasculopathy. In contrast, inflammatory disease of small or large vessels was rare. Brain microinfarcts occurred in close anatomic proximity to the micro-angiopathy (12). Although instructive, the majority of neuropathologic studies in SLE have significant limitations because of a bias in patient selection, a temporal disconnect between the NP event and tissue sampling, and the potential impact of confounding factors, such as infection, hypertension, and corticosteroids on neuropathology.

Autoantibodies

A humoral immune response directed against neuronal antigens, ribosomes, and phospholipid-associated proteins has been implicated in the pathogenesis of NP-SLE. The data from human studies supporting a role for antineuronal antibodies is largely circumstantial. This includes the temporal relationship between clinical events and serologic findings (16), the presence of autoantibodies in the cerebrospinal fluid (CSF) (17) and, to a very limited extent, their identification in neuronal tissues from patients succumbing to the disease (18). Autoantibodies gain access to the CSF of SLE patients by means of passive transfer from the circulation through a permeabilized blood-brain barrier (BBB) (19 ,20) and, independently, by direct intrathecal production (16 ,19). The fine specificity of antineuronal

antibodies has been studied extensively, but in general has not resulted in greater diagnostic specificity.

Most recently, attention has been focused on anti-NR2 glutamate receptor antibodies as a potentially novel system that could explain some of the complexities of NP-SLE. The NMDA (N-methyl-D-aspartate) receptors NR2a and NR2b bind the neurotransmitter glutamate and are present on neurons throughout the forebrain (21 ,22 ,23). The hippocampus, which is the anatomic structure closely linked to learning and memory, has the highest density of brain NMDA receptors (22). In addition to their putative role in learning and memory (24), these receptors display altered expression in major psychoses (25), and if engaged by receptor antagonists, cause hallucinations and paranoia (26). Recent studies (27 ,28) has shown that a subset of anti-DNA antibodies, derived from both murine models of SLE and from a limited number of human subjects with the disease, cross-react with a pentapeptide consensus sequence that is present in the extracellular, ligand-binding domain of NR2 receptors. Moreover, these antibodies induced apoptotic cell death of neurons in vitro and in vivo and were present in the CSF of one SLE patient with progressive cognitive decline. Thus, in contrast to the previously described antineuronal antibodies in SLE, the anti-NR2 glutamate receptor antibodies appear to have a functional consequence leading to neuronal injury in a manner similar to that seen in excitatory amino acid toxicity (29). This effect is mediated via the antigen-binding portion of the antibody (29) and is specifically inhibited by memantine, an NMDA receptor antagonist (27). Moreover, enhanced permeability of the BBB is critical for circulating autoantibodies to enter the CSF and gain access to neuronal cells (27). Although of considerable interest, these findings are preliminary, are largely derived from animal studies and require confirmation in human subjects with NP-SLE. To date, the studies in human lupus examining the association between this subset of antineuronal antibodies and cognitive impairment have yielded conflicting results (30 ,31 ,32).

Antiribosomal P (anti-P) antibodies were first described in SLE patients in 1985 and are quite specific for SLE with a prevalence of 13% to 20% depending upon the ethnic group (33). In 1987, these autoantibodies were first linked to NP-SLE, in particular psychosis (34). Subsequent work either supported, refuted, or extended this initial observation to include depression (33 ,35 ,36 ,37). Potential explanations for the differences in study outcomes include variability in diagnostic criteria for psychiatric disease, variance in the temporal relationship between clinical events and serologic testing and differences in assay technique, particularly antigen preparation and purity. As demonstrated by recent animal work with anti-NR2 glutamate receptor antibodies (27), permeability of the BBB is also a critical factor for anti-P antibodies to exert their putative pathogenic role. One of the largest human studies (36) examined 394 SLE patients, 63 (16%) of whom had anti-P antibodies. There was a significant association with psychosis and depression with odds ratios between 4 and 10. However, because of the low prevalence of clinical events, the positive predictive value was only 13% and 16% for psychosis and depression, respectively. This has important implications for the application of this serologic test in decision making for individual patients. In contrast, a more recent study of 149 patients (37), 12% of whom had anti-P antibodies, did not find an association with any of the NP syndromes as defined by the ACR classification criteria (5).

Additional observations on anti-P antibodies are of interest and may provide insight into their pathogenic mechanisms. One study (38) reported an association between anti-P and antineuronal antibodies and furthermore, demonstrated that anti-P antibodies bind a 38-kd surface protein on human neuroblastoma cells. In another study of 87 SLE patients (39), there was a significant elevation in circulating anti-P antibodies in 34 patients with lupus psychosis, but there was no increase in the level of serum antineuronal antibodies. In contrast, examination of the CSF from the same patients revealed a significant elevation in antineuronal antibodies but not in anti-P antibody levels. These data suggest potential interaction between these two families of autoantibodies in the pathogenesis of NP-SLE and emphasizes the importance of local versus systemic autoantibody production in the causality of a NP event.

Autoimmune antiphospholipid antibodies, which are directed against phospholipid-binding proteins such as $ß_2$-glycoprotein I and prothrombin (40), are associated with predominately focal manifestations of NP-SLE. The most common neurologic disorders are those of vascular origin such as transient cerebral ischemia or stroke, but other associations include seizures, chorea, transverse myelitis, and cognitive dysfunction (9). In a review of over 1,000 SLE patients, NP manifestations occurred in 38% of patients with lupus anticoagulant compared to 21% of patients without these antiphospholipid antibodies (41). The favored pathogenic mechanism for this subset of autoantibodies in NP-SLE is thrombosis within vessels of different caliber and subsequent cerebral ischemia. A procoagulant state may be induced through acquired resistance to protein C and protein S, platelet aggregation, and direct activation of endothelial cells (40). However, the intrathecal production of antiphospholipid antibodies in patients with NP-SLE (19), their association with diffuse cognitive impairment (42 ,43), and in vitro evidence indicating modulation of neuronal cell function (44) and antibody binding to brain tissue (45) all raise the possibility of an alternative and more direct pathogenic mechanism.

Inflammatory Mediators

The potential role of pro-inflammatory cytokines in neuropsychiatric lupus has received increasing attention in recent years. Studies in Japan were the first to report an association between enhanced intracranial production of interleukin (IL)-6 with seizures (46) and interferon-(IFN) α with lupus psychosis (47). Subsequent studies have provided

further evidence for the intrathecal production of IL-6 (48 ,49 ,50 ,51) and have identified other potential candidate cytokines such as IL-10 (51 ,52), IL-2 (53), and IL-8 (50). The sources of intrathecal production of these cytokines include neuronal (47 ,49) and glial cells (47) and the stimulus for, and regulation of, this enhanced cytokine response remains to be determined. Although potentially an epiphenomenon, it may be a consequence of cell activation mediated by autoantibodies within the intrathecal space. However, measuring CSF cytokine levels unselectively in patients with any manifestation of NP-SLE is unlikely to be of value in the diagnostic work-up of individual patients (54).

Other potentially important inflammatory mediators are matrix metalloproteinases (MMPs), a family of endoperoxidases that can degrade extracellular matrix components (55). MMP-9 is a gelatinase and is secreted by a variety of cells in the blood vessel wall including macrophages, T lymphocytes, endothelial cells, and smooth muscle cells (56). Implicated in the pathogenesis of plaque rupture (57), elevated levels have also been associated with other conditions including multiple sclerosis (MS) (58), Guillain-**Barré** syndrome (GBS) (59), and rheumatoid arthritis (RA) (60), as well as SLE (61). A recent study (62) has examined the association between circulating levels of MMP-9 and NP-SLE. Although there was no difference in the levels of MMP-9 between SLE patients and healthy population controls, elevated levels of MMP-9 were associated with NP-SLE and in particular with cognitive impairment. There was a positive correlation between circulating MMP-9 levels and both T1 and T2 lesions on brain MRI scans, which will be discussed in detail later. It is also of interest that increased expression of MMP-9 is found in the disrupted BBB following cerebral ischemia and may facilitate lymphocyte migration into and possibly through the arterial wall (63). Elevated MMP-9 levels have also been detected in CSF samples of patients with NP-SLE compared to SLE patients without NP manifestations and normal controls (64). Furthermore, the positive correlation between CSF MMP-9 levels, pro-inflammatory cytokines, and biomarkers of neuronal and glial degradation (64) supports the suggestion that the enhanced production of MMP-9 is under cytokine control and is responsible for central nervous system (CNS) damage.

Psychiatric Disorders

Psychiatric disorders have been reported to a variable extent in SLE patients (65 ,66) and are likely multifactorial in etiology (67). For example, in a review of 21 studies, Wekking (66) found that the overall prevalence of psychiatric disorders ranged from 17% to 71% with depression being the most common syndrome. They found no consistent relationship with other manifestations of SLE and emphasized the importance of psychosocial stress as an associated factor (66 ,68). Indeed, those studies that have included other chronic disease control groups, such as patients with RA, have reported comparable frequencies and types of psychiatric disorders in control and SLE groups (11). This does not negate the importance of recognizing and managing psychiatric disorders in SLE, however, and one must remember that a particularly tragic outcome of such disorders in SLE patients is suicide (69 ,70). The potential causes of psychiatric disorders in SLE are varied and include acquired brain dysfunction, iatrogenic effects of corticosteroid treatment, psychosocial stressors, and current coping strategies (67). Nevertheless, there is sufficient evidence to support the notion that at least some psychiatric syndromes are primary manifestations of SLE.

The co-occurrence of psychiatric illness and SLE has been well recognized and the diagnostic designation of NP-SLE assumes that psychiatric illness is itself a manifestation of lupus. However, there is a lack of good epidemiologic evidence to support our understanding of these disorders. Many methodologic problems remain including selection bias, lack of adequate comparison groups, differences in case ascertainment criteria (e.g., chart reviews, screening instruments, standardized diagnostic interviews), differences in time-frame and follow-up, failure to account for social and cultural variables, and failure to account for psychiatric illness that predates the diagnosis of SLE.

The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)* was published in 1994 by the American Psychiatric Association and was revised to be consistent with the *International Classification of Diseases (ICD) ICD-9-Clinical Modifications (CM)* and *ICD-10*. This has served as the basis for the terminology in the current ACR nomenclature (5) used to describe the psychiatric manifestations of NP-SLE. As outlined in *DSM-IV,* the term “mental disorders” “persists in the title of DSM-IV because we have not found an appropriate substitute” and it does not reflect a viewpoint of a “reductionistic anachronism of mind/body dualism.” Importantly, the term reflects a “clinically significant behavioural or psychological syndrome or pattern that occurs in an individual and that is associated with present distress … or disability or with increased risk of death, pain or disability, or with loss of freedom.” It must not be a “culturally sanctioned response to a particular event.” For those using the *DSM-IV* as a diagnostic manual it is important to recognize that there is “no assumption that each category of mental disorder is a completely discrete entity” and that “specific diagnostic criteria included in DSM-IV are meant to serve as guidelines to be informed by clinical judgement.” From the standpoint of psychiatric syndromes in the context of NP-SLE it is also important that the use of the term “general medical disorders” and “mental disorders” in *DSM-IV* “are merely terms of convenience and should not be taken to imply that there is any fundamental distinction between mental disorders and general medical conditions.”

The ACR NP-SLE nomenclature (5) includes within its taxonomy, acute confusional state, anxiety disorder, mood disorders and psychosis, which are consistent with the *DSM-IV* classifications. These are discussed separately below.

The concept of “cognitive dysfunction” is operationalized in the ACR NP-SLE nomenclature and is discussed later in this chapter.

Acute Confusional State

The use of this term in the ACR nomenclature for NP-SLE (5) has replaced what was previously called “organic brain syndrome.” It is considered synonymous with the *DSM-IV* and *ICD-9* terms “delirium,” and is presumed to also be synonymous with the term “encephalopathy” as often preferred by neurologists. It encompasses a state of impaired consciousness or level of arousal that can progress to coma. Acute confusional states are characterized by a reduced ability to focus, maintain, and shift attention and are accompanied by disturbances of cognition, behavior and mood/affect. Other features include disturbance of sleep-wake cycles and changes in psychomotor behavior. Of the latter, hyperactivity is most easily recognized, whereas lethargy may mask the other symptoms. In the following discussions, the terms “delirium” and “acute confusional state” will be considered synonymous.

The term delirium was first included in the Third Edition of *DSM* and has subsequently been revised. Estimates of the prevalence and incidence of delirium in the general population suffer from many of the same problems associated with epidemiologic studies of NP-SLE itself namely: “evolving criteria, variable case-finding methods, and disparate criteria for subject selection.” This has given rise to considerable variability in prevalence estimates. For example, the prevalence of delirium upon hospital admission among the elderly varies from 11% to 33%, whereas estimates of the incidence during hospitalization vary from 3% to 42% (71). The prevalence of delirium among SLE patients has generally been lower than these estimates and has been reported in 4% to 7% of SLE patients (6 ,8 ,9). Although the review of Jennekens and Kater of five “index studies” listed “organic brain syndrome” as one of the most frequent NP-SLE syndromes (72), all of these were conducted prior to the development of the 1999 ACR nomenclature (5) and undoubtedly included a number of individuals with persistent cognitive impairments unrelated to delirium. In contrast, Brey et al. (7) in their study of the point prevalence of NP-SLE syndromes using the ACR nomenclature (5) for 128 subjects did not report any cases of delirium in their patients.

However, prevalence estimates for delirium are of questionable value. As the name “acute confusional state” implies, delirium develops over a brief period of time (a few days to hours) and may resolve over hours to weeks. Deficits in attention represent a core feature of delirium, but also contribute significantly to the clinical manifestation of cognitive dysfunction that is discussed further below. Distinguishing the acute onset of a delirium in the presence of a previously unrecognized persistent cognitive impairment can prove difficult, because much of this distinction rests on a clinical history of acute onset of symptoms that must be obtained from informants. A key feature of delirium is also fluctuation throughout the day in level of arousal and attentional capabilities. Thus, careful observation is often required to distinguish between delirium and persistent cognitive deficits, whereas single assessments with mental status screening instruments may misdiagnose delirium as dementia. Delirium is more likely to occur if there is pre-existing cognitive impairment (73). Moreover, delirium appears to be an important marker of risk for dementia, in older people without previously recognized cognitive or functional impairment (74). Thus, the presentation of delirium in a patient with SLE, including those situations in which it is associated with pharmacotherapy, indicates the need for careful follow-up. The onset of delirium also emphasizes a need to search carefully for both a clinical history of pre-existing cognitive impairments and residual cognitive impairments after resolution of the acute phase of delirium.

Delirium in association with SLE meets the *DSM-IV* criteria of “delirium due to a general medical condition” (293.0). However, delirium is by nature a multifactorial condition and establishing attribution to SLE is a challenge. Such attribution, according to the ACR nomenclature (5), requires exclusion of CNS infection, metabolic disturbances, substance-induced or drug-induced (or withdrawal) delirium, and any mental or neurologic disorder unrelated to SLE. In their review of clinical syndromes associated with CNS involvement in SLE, Jennekens and Kater (72) list only five potential causes of SLE-induced delirium/encephalopathy, acknowledging that not all causes can be clearly defined, including small vessel vasculitis/vasculopathy, leukoencephalopathy, perivenous spongiform encephalopathy, brain edema as a consequence of cerebral venous thrombosis and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Although they also exclude “hypertensive encephalopathy” as being a “secondary manifestation,” they state that it “may well be the most frequent cause of delirium/encephalopathy in SLE.”

Anxiety Disorders

Depression and anxiety are common symptoms in lupus and are reported to occur in 24% to 57% of patients (6 ,7 ,8 ,9 ,10 ,37). However, as there are no features of these syndromes that are unique to SLE patients, there is often uncertainty about the etiology and attribution in individual cases.

Anxiety disorders as described in *DSM-IV* include a broad spectrum of behavioral disorders with panic attacks being common among many. In the context of NP-SLE, anxiety disorders are diagnosed on the basis of prominent generalized anxiety or panic attacks or obsessions or compulsions resulting in significant distress or impaired function. An anxiety disorder resulting as a consequence of NP-SLE would be considered as an “anxiety disorder due to a general medical condition” (293.89) according to *DSM-IV*. This requires that the anxiety is “judged to be due to the direct physiological effects of a general medical condition,”

and it is important to make this distinction from an adjustment disorder in which anxiety symptoms result from the stress of having lupus as a medical condition. Although it may be presumed that anxiety arising from an adjustment disorder is the more common presentation of clinically significant anxiety in SLE, there are no studies that have directly addressed this issue. Symptoms of anxiety can also occur in the context of agitation in association with delirium, but such a case could still be a manifestation of NP-SLE. Distinguishing between an anxiety disorder arising from underlying physiologic changes of the CNS versus direct CNS side effects of pharmacologic treatment of SLE or an adjustment reaction to distressing side effects of treatments (e.g., weight gain) can be extremely challenging.

As with all of the "neuropsychiatric" lupus manifestations, attribution of the presenting symptoms is difficult. According to *DSM-IV*, Panic Disorder has an estimated lifetime prevalence of 1.5% to 3.5% and 1-year prevalence of 1% to 2%. Although these figures may not be exceptionally high, panic attacks also have important cultural and gender issues that contribute to the difficulties in attribution for SLE patients because of the overlap with SLE itself. Specifically, Panic Disorder is diagnosed two to three times more frequently among women and the typical onset is from adolescence to the mid-30s, again overlapping with the typical onset of SLE symptoms and its age of diagnosis. Variable prevalence rates of anxiety disorders have been reported in studies of SLE samples. On one extreme is a retrospective chart review of 518 Chinese SLE patients from Hong Kong who had from 1 month to 23 years of follow-up in which apparently only two documented anxiety disorders were identified (75). However, this study stands in stark contrast to a 56% lifetime prevalence of phobia and 12% lifetime prevalence of generalized anxiety reported in Icelandic SLE patients (76). More recently, Sana et al. (9) reported a prevalence of only 7.4% in a sample of 323 SLE patients diagnosed retrospectively, presumably on chart review. Hay et al. (77) had reported a similar 8.2% point prevalence in 73 SLE patients attending a lupus clinic in Manchester, UK, based on responses to the Present State Examination (which determines the presence of anxiety disorders in accordance with *ICD-9* criteria). Chin et al. (78) also reported a similar 7.6% point prevalence of *ICD-9* "anxiety neuroses" in 79 consecutive Malaysian SLE patients. Although these modest prevalence estimates do not detract from the importance of anxiety disorders for those SLE patients experiencing them, it is debatable whether these prevalence rates are significantly higher than the general population. Given this, it may be difficult to consider them as clearly reflecting the consequences of an underlying neuropathologic condition.

In recent studies using the ACR nomenclature (5), Brey et al. (7) reported a 24% prevalence of anxiety disorders in their sample of 128 SLE patients from the San Antonio region who were apparently diagnosed using the Structured Clinical Interview for Psychiatric Diagnosis (79). Similarly, Sibbitt et al. (10) reported a 21% lifetime prevalence of anxiety disorders in 75 "pediatric" (i.e., symptom onset before age 18) SLE cases from New Mexico who were followed for an average of 6 years. Although it is tempting to place greater faith in the accuracy of these latter studies, they do represent selected samples from a relatively constrained geographic region with some racial and cultural variation that may also be relatively unique. Further definitive epidemiologic studies of psychiatric manifestations in SLE using current diagnostic methods are clearly necessary. To date, the studies remain difficult to compare because of case ascertainment differences and because of questions about population base rate differences that may reflect cultural and genetic differences in the populations.

Given these difficulties, one can reasonably ask whether other presenting features can support an association between anxiety disorders and CNS involvement in SLE. While a possible genetic contribution to panic disorders is acknowledged in *DSM-IV*, it is also pointed out that most patients do not have affected first-degree biological relatives. Nevertheless, the possibility that an association between anxiety disorders and SLE arise from a shared underlying genetic basis has been posited (80). A common physiologic mechanism underlying anxiety disorders and SLE is also supported by the presence of "anxiety-like" behaviors in animal models of SLE (80 ,81). However, it is important to distinguish between anxiety symptoms and anxiety disorders, something that must also be considered when examining data derived from self-report screening instruments for mood and anxiety symptoms.

In many respects, studies of anxiety symptoms in SLE must be understood as a line of inquiry distinct from that of studies of anxiety disorders as a manifestation of NP-SLE. This does not diminish their importance, however, and making this distinction evident to patients as well as clinicians may help to separate these possibilities. Based on their prospective study of 23 SLE patients, Ward et al. (82) found that anxiety symptoms changed in parallel with global SLE disease activity as measured by the systemic lupus activity measure (SLAM). Segui et al. (83) also reported a decline in anxiety symptoms associated with the change from active to quiescent disease activity. Although these studies suggest that the distress resulting from active lupus increases anxiety symptoms, such conclusions about causation are tenuous. Ishikura et al. (84) in a sample of 84 female Japanese SLE patients found anxiety symptoms to be associated with lack of knowledge about SLE and its management at the start of treatment. Thus, improved knowledge about SLE and its treatment amongst lupus patients may both reduce the likelihood of future anxiety symptoms and in the process improve the likelihood of recognizing an anxiety disorder that reflects a clinical manifestation of NP-SLE.

Mood Disorders

Mood disorders as described in the ACR nomenclature for NP-SLE (5) include the equivalent of *DSM-IV* major depressive disorder (MDD), that is, one or more major

depressive episodes (2 weeks or more of depressed mood or loss of interest plus at least four other symptoms of depression). Also included is mood disorder with depressive features that is compatible with the *DSM-IV* dysthymic disorder (at least 2 weeks of depressed mood for more days than not plus additional symptoms of depression not meeting the criteria for MDD). As well, mood disorders with manic features and mixed features are included, compatible with *DSM-IV* bipolar disorder (depressive episodes accompanied by manic, mixed, or hypomanic episodes). Such conditions must be distinguished from substance-induced mood disturbances and from *DSM-IV* adjustment disorder with depressed mood (symptoms of depressed mood, tearfulness, feelings of hopelessness developing within 3 months of an identifiable precipitating stressor).

Some recent prevalence studies using the ACR nomenclature (5) have suggested very high prevalence rates for mood disorders among SLE patients. Brey et al. (7) reported major depressive-like episodes in 28%, and mood disorders with depressive features in 19% of their sample of 128 subjects. Mood disorders with manic (3%) and mixed (1%) features were uncommon. Ainiala et al. (85) reported a similarly high prevalence of mood disorders (43%) in their sample of 46 SLE patients. However, a much lower prevalence of mood disorders has been reported by Sanna et al. (9) in 16.7% of their patients, by Hanly et al. in 14.4% (8) and by Mok et al. in 6% (75). Unfortunately, many studies have failed to report the number of SLE patients who were considered to have mood disorders associated with an adjustment disorder. For those reporting the higher prevalence rates, this clearly begs the question. Thus, to date, epidemiologic studies of mood disorders in SLE remain limited despite the common acceptance of an increased prevalence of depressive symptoms in patients with SLE.

Although it is important to distinguish between clinical syndromes of mood disorders such as MDD and depressive symptoms that occur in other contexts, studies using screening and survey methods do not always draw this distinction clearly. Commonly used screening instruments such as the Beck Depression Inventory (BDI) (86) include symptoms, such as fatigue, sleep disturbance, worries about health, concerns about physical appearance and loss of appetite that overlap with those of autoimmune disorders and many other medical conditions. The result of poor specificity can be poor positive predictive value of screening instruments for depression when used in SLE samples (87). Studies comparing the results of various screening measures advance our understanding of these instruments but do little to accurately determine the prevalence of mood disorders per se (87 ,88). Associations between symptoms of depression and other disease manifestations of SLE have been reported in some studies (89 ,90) but not others (84 ,91). However, limited sample sizes and differences in study samples and methodologies make comparisons across studies difficult.

As with anxiety disorders, attribution of mood disorders to a CNS manifestation of SLE is difficult. Patten et al. note that “Young people with long-term medical conditions have a particularly high prevalence of mood disorders” (92). Attributions of mood disorders to SLE require a biologic basis for the association between CNS effects of SLE and mood disturbance. Evidence for this association comes primarily from potential immune system effects on mood states; so-called psychoneuroimmunologic interactions (93). However, complex associations with other social and demographic factors such as knowledge of the disease and social supports (84) must also be considered. As described by Karassa et al. (70) in their study of suicide attempts in a clinic sample of 300 SLE patients, even though increased suicide attempts may be associated with NP-SLE, “we should not underestimate the importance of the psychological factors that coping with life threatening and unpredictable illness creates.” An unpredictable disease course and disabling features are not unique to SLE and it is perhaps not surprising that many of the NP syndromes commonly associated with SLE occur with comparable frequency in RA patients (11) and that appropriately matched groups of SLE and RA patients did not differ on screening measures of symptoms of depression and anxiety.

Psychosis

Using the *DSM-IV* diagnostic criteria, psychosis in the context of NP-SLE represents a psychotic disorder due to a general medical condition (293.0) (i.e., SLE) and is further characterized according to the presence of either delusions (293.81) (false belief despite evidence to the contrary) and/or hallucinations (293.82) (perceptual experiences occurring in the absence of external stimuli) as the predominant symptoms. When present, psychosis must be distinguished from unrelated primary psychiatric disorders such as schizophrenia, which has a similar age of onset as SLE. Also, it is important to recognize that hallucinations and delusions are frequent features of delirium and should be considered as such if they occur strictly within this context. More importantly for SLE patients, perhaps, is the likelihood of an association between psychotic features and pharmacotherapy in SLE including corticosteroids (94 ,95 ,96), antimalarials (97 ,98) as well as nonprescribed drug abuse. Psychosis is reported in up to 8% of SLE patients (6 ,7 ,8 ,9 ,10 ,99). Hanly et al. (8) reported a 3% prevalence, Brey et al. (7) reported a 5% prevalence of psychosis as a NP manifestation of SLE, whereas Sanna et al. (9) reported a 7.7% prevalence. However, Chau and Mok (96) report a 5% incidence of corticosteroid-associated psychosis identified using *DSM-IV* criteria in a 3-year prospective study of 126 SLE patients seen over 3 years. Thus, psychosis appears to be a rare but dramatic manifestation of NP-SLE that must be distinguished carefully from a primary psychiatric illness, delirium, and substance-related disorders. Future epidemiologic studies would benefit from explicit statements about the prevalence and incidence of these conditions in order to provide a better understanding of psychosis as a manifestation of NP-SLE.

Cognitive Function in SLE

Cognition is the sum of mental processes that result in observed behavior. These include reception and perception of external stimuli, processing and manipulation of acquired information, learning and memory, and expression (i.e., observable behaviors including, but not limited to verbal expression). Disturbance of any one of these processes can result in disruption of normal behavior and present as cognitive dysfunction. Cognitive functioning is often conceptualized as consisting of domains of abilities some, but not all, of which have clear neuroanatomical bases. The understanding of these neuroanatomical relationships, to some extent, reflects how broadly or narrowly one defines cognitive domains with those such as attention, memory, or language, being too broad to have simple neuroanatomical correlates. The complexity of cognitive abilities is such that dysfunction may be limited to a particular domain (i.e., focal) or may be extensive enough to cause global impairment, depending on the nature and extent of the domains affected.

When addressing the issue of cognitive dysfunction in SLE, the ACR nomenclature (5) avoided using *DSM-IV* criteria and case definitions. Indeed, no such criteria exist in *DSM-IV,* which addresses cognitive impairment via the construct of “dementia.” Because the case conceptualization of dementia is based on the presenting symptoms of Alzheimer disease, it can be difficult to apply even to persons with significant cognitive impairments arising from stroke (100), let alone persons with more subtle cognitive deficits arising from SLE.

That cognitive problems may be relatively mild and yet have significant functional impact is recognized in the ACR nomenclature (5). Such is known to be the case with multiple sclerosis, a disease with similar demographic characteristics to SLE (101 ,102). Reliance on subjective reports to identify cognitive dysfunction is problematic. Although such complaints are common among SLE patients (103), they also occur in many other clinical contexts and their relationship to objective evidence of cognitive impairment and specific neuropathologic processes remains largely unclear. Still, self-report of cognitive difficulties remains the primary means by which clinicians identify patients who may have significant SLE-associated cognitive dysfunction. The Cognitive Symptoms Inventory is a 21-item, self-report questionnaire designed for patients with rheumatic disease to assess self-perception of one's ability to perform “everyday activities” (104). Although a recent report suggests that this instrument may be useful as a bedside screening tool to identify SLE patients at risk for cognitive impairment (105), it has not been validated in relation to objective measures of cognitive performance. Unfortunately, cognitive status screening instruments developed for use in the diagnosis of dementia also have inadequate sensitivity for the identification of cognitive impairments in SLE (5). Although Leritz et al. (106) using the Mini-Mental State Examination (MMSE) (107) reported that 95% of patients' profiles of responses suggested a “subcortical” pattern of cognitive dysfunction, few of their patients scored within a range typically considered to represent impairment on this measure. Those that did demonstrate problems primarily had difficulties with serial sevens, a task that places demands on the processes of attention, working memory, and mental tracking. The challenge in considering SLE-associated cognitive dysfunction remains how to recognize and document mild, yet significant cognitive impairment.

In clinical practice, “neuropsychology is an applied science concerned with the behavioral expression of brain dysfunction” (108). As described in the ACR nomenclature (5), “documentation by neuropsychological testing” and interpretation “based on normative data appropriate for age, education, sex and ethnic group, wherever possible” is necessary to meet the diagnostic criteria of cognitive dysfunction. The complexity of human behavior is reflected in various classifications of cognitive functions that are examined through neuropsychological assessment with “batteries” of tests used to examine behaviors thought to reflect these functions. As a result, neuropsychological evaluation typically consists of extensive testing that is tailored to objectively detect cognitive dysfunction, especially in those areas identified by the patient as problematic or in those areas likely to be problematic on the basis of the suspected diagnosis. For SLE, the ACR nomenclature (5) has identified eight domains of cognitive functioning of particular importance: simple attention, complex attention, memory, visual-spatial processing, language, reasoning/problem solving, psychomotor speed, and executive functions, at least one of which must be affected in order to meet the case definition of cognitive dysfunction. As with most such classification systems, the distinctions between domains are at best blurred. Lezak (108), for example, excludes “attentional functions” from her classification of cognitive functions, referring to them instead as “mental activity variables” that underlie other cognitive functions. Similarly, “psychomotor speed” or the speed and efficiency with which mentally demanding tasks can be completed, might best be thought of as a “mental activity variable,” whose influence is seen in the performance of tasks that examine other cognitive abilities such as memory, language, visual-spatial processing, or executive functions. These latter domains themselves have numerous subcategories of functions each with accompanying volumes of scientific literature. Nonetheless, the ACR nomenclature (5) provides a valuable framework that establishes the importance of considering both cognitive functions with reasonably well-defined neuroanatomic substrates, and more diffusely represented mental activities that potentially cause the presenting behavioral problems in SLE. This framework then allows for the operationalization of domains of cognitive impairment using a standardized neuropsychological assessment (5).

Attempts to quantify cognitive dysfunction using standardized neuropsychological test batteries and predetermined thresholds for defining abnormal cognition, such as performance greater than two standard deviations below the mean of the general population have been used in

some studies. However, although this “actuarial” approach has the benefit of standardization for population-based studies, it is not ideal for examining complex multidimensional constructs such as cognition in individual cases. For example, a patient with a superior premorbid educational and functional level may report cognitive difficulties, but test at a normal (i.e., average) level compared to the general population. For this individual, however, average test performance may represent a significant decline in their cognitive and functional ability. Furthermore, the common practice of combining individual neuropsychological test scores into index variables can serve to mask deficits in specific areas of cognitive functioning (109). Individual test results may best be expressed in relation to estimated premorbid level of function or competence. Thus, as recognized in the ACR case definition (5), an individualized approach to patient assessment that accounts for psychosocial, demographic, and clinical characteristics is necessary for clinical decision-making.

Cognitive dysfunction, assessed using neuropsychological assessment techniques, has been reported in 12% to 87% of patients (110 ,111 ,112 ,113 ,114 ,115). Since the publication of the ACR nomenclature, at least two studies have applied these case definitions to their general lupus populations and reported prevalence rates of 80% (85) and 11% (9) for cognitive dysfunction. A third study also used the ACR-recommended neuropsychological test battery in conjunction with a new computerized test of cognitive efficiency and identified at least mild cognitive impairment in 78% of SLE patients thereby making it one of the three most commonly identified NP-SLE syndromes in their sample (7). As the majority of SLE patients with cognitive impairment have relatively mild deficits, the careful selection and assessment of cognitive performance in control groups is of critical importance in order to define expected levels of function in comparable groups of healthy individuals and those with other chronic diseases. A variety of neuropsychological testing methods have been used to study SLE patients (77 ,110 ,111 ,113 ,116 ,117 ,118 ,119) with the prevalence estimates for cognitive impairment varying in parallel with the testing methods used, the cut-off or threshold for definition of impairment, and the clinical and demographic characteristics of the study samples (114 ,120). Nevertheless, in spite of the inconsistencies in prevalence estimates for cognitive impairment, recognition that a large proportion of SLE patients may have at least mild cognitive impairment, even without recent disease activity or overt signs of CNS disease (77 ,110 ,113) prompted the emphasis on cognitive assessment in the current ACR nomenclature (5). Whether the development of consensus opinions about the appropriate neuropsychological tests to be used will result in greater consistency in prevalence estimates remains to be seen.

There is no specific or unique pattern of cognitive impairment in SLE but abnormalities include overall cognitive slowing, decreased attention, impaired working memory, and executive dysfunction (e.g., difficulty with multitasking, organization, and planning). Many of these studies provide support for a pattern of cognitive dysfunction consistent with pathology affecting subcortical brain systems (121). For example, the most frequently reported deficits across studies are evident on tests of immediate memory or recall, verbal fluency, attention, information processing efficiency, and psychomotor speed (7 ,113 ,117 ,119 ,122 ,123 ,124). Fisk et al. (118) found that increased SLE disease activity was related to impaired immediate memory and concentration. Denburg et al. (122)) noted that slowed processing is consistent with a diffuse vasculopathy. Loukkola et al. (125) suggested that their findings of predominant problems in psychomotor speed, complex attention, and memory reflect the “nonspecific” nature of CNS involvement in SLE, although this pattern again is consistent with predominant subcortical pathology. A similar “subcortical” pattern is also considered a hallmark of cognitive dysfunction in MS (126). Although SLE and MS are different disease processes, both can present with a spectrum of brain pathology and there are some neuropathologic similarities between the two. For example, diffuse effects on white matter fiber tracts, including demyelination are seen in both MS (127) and in SLE (12 ,128 ,129 ,130 ,131 ,132 ,133). Thus, it is perhaps not surprising that Shucard et al. (134) found SLE and MS patients to have similar cognitive deficits and similar compensatory strategy use when performing a test of information processing speed and efficiency, the Paced Auditory Serial Addition Test (PASAT) (135). MS patients and healthy controls were both known to “chunk” items on this test as reflected by a decreasing percentage of paired correct responses with increasing stimulus presentation rate (136). Shucard et al. (134) found that, as with MS patients, those with SLE showed a significant reduction in the percentage of paired correct responses, even at the slowest presentation rates. This poorer performance by the SLE group was not accounted for by disease duration, disease activity, depression, or fatigue.

Although comprehensive neuropsychological test batteries, using individualized assessment approaches, may have the sensitivity to identify subtle cognitive deficits in SLE, for many individual patients these deficits will be “subclinical” in the context of routine clinical practice. For example, a review of 14 cross-sectional studies of cognitive function in SLE revealed subclinical cognitive impairment in 11% to 54% of patients (120). This latter observation raises a number of important clinical questions. For example, what is the evolution of these cognitive deficits over time and does their detection predict the subsequent development of other more profound clinically overt forms of NP disease? Although cognitive impairment may be viewed as a distinct subset of NP-SLE, it can also serve as a surrogate of overall brain health in SLE patients that may be affected by a variety of factors including other NP syndromes.

Change in Cognitive Function Over Time

Prospective studies that have examined the course of cognitive functioning in SLE patients have not found that the

overall point prevalence of cognitive dysfunction increases over time, with individual subjects oscillating between being impaired and unimpaired at different points in time (124 ,137). For example, in a 5-year prospective study of 70 SLE patients by Hanly et al. (124) using standardized neuropsychological tests the prevalence of overall cognitive impairment in SLE patients fell from 21% to 13% over the period of study. Five patterns of cognitive performance were observed over the 5-year period of this study (Fig. 38-3). Eighty-three percent of patients were either never impaired or had resolution of cognitive impairment without specific therapeutic interventions. An additional 13% of patients demonstrated an emerging or fluctuating pattern of impairment and only 4% (two patients) showed persisting deficits that were stable over time. Thus, patients who were impaired did not demonstrate a marked deterioration in cognitive performance and the most frequent change seen over time was that of improved function. Similar benign changes in cognitive performance over time have been reported by Waterloo et al. (138) in 28 patients over 5 years, by Hay et al. (137) in a 2-year prospective study and by Carlomagno et al. (139).

Attempts have been made to examine predictors of cognitive decline over time. Hanly et al. (124) compared patients who were cognitively impaired at a baseline assessment to those who were not impaired, but found that the differences between groups on tests of recent memory and delayed free recall decreased over the subsequent 5 years. A similar result was reported by Waterloo et al. (138). However, those patients who had had clinically overt NP-SLE at any time in their disease course had a statistically significant decline in memory performance over 5 years when compared to patients without a history of clinically overt NP-SLE (124). These results suggest that although the identification of subclinical cognitive impairment can have important current clinical implications, it is the occurrence of clinically overt NP events that has greater relevance for the accumulation of cognitive impairment over time. Thus, fluctuation in cognitive function in SLE patients appears to be common and although deterioration in cognitive functioning may occur in select individuals, there is little evidence to suggest that it need be inevitable or profound, even in subjects presenting with cognitive impairment.

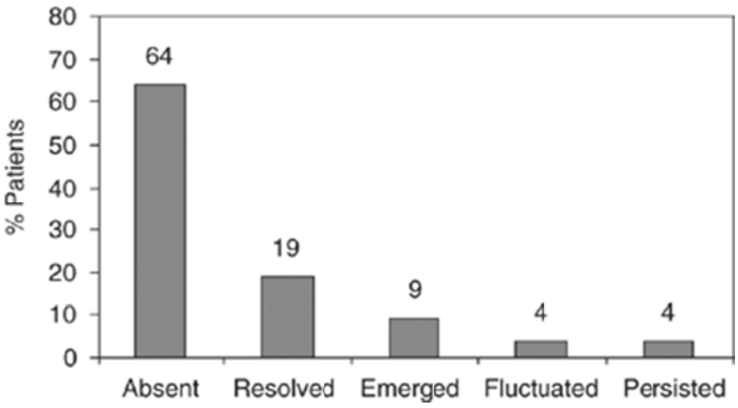

Figure 38-3. Change in cognitive function in 47 SLE patients assessed prospectively on three occasions over 5 years. Derived from Hanly JG, Cassell K, Fisk JD. Cognitive function in systemic lupus erythematosus: results of a 5-year prospective study. *Arthritis Rheum* 1997;40(8):1542–1543.

Etiology of Cognitive Impairment in SLE

Cognitive Function, Global SLE Disease Activity, and Overt NP-SLE

Chronic medical illness provides many potential generic causes of subtle cognitive dysfunction (Table 38-3). Determining whether they cause or contribute to cognitive dysfunction in SLE patients requires careful consideration on an individual basis, but the accumulated evidence suggests that such explanations alone are insufficient to account for the overall burden of cognitive impairment in SLE. The relationship between cognitive dysfunction and overall disease activity in SLE remain unclear. In one study (118), the classification of subjects into groups with inactive, mildly active, or active disease on the basis of the SLE

disease activity index (SLEDAI) scores revealed consistently poorer performance on tests of attention and memory for patients with active SLE. However, another study did not find SLEDAI scores to be significantly associated with global cognitive function (115). Additional studies have also failed to find an association between cognitive impairment and disease activity when using other methods of assessing global SLE disease activity (140 ,141).

Table 38-3: Non-SLE Causes of Cognitive Dysfunction

Causes	Examples
Direct CNS disease or injury	Ischemia Traumatic brain injury Cerebral hemorrhage Neurodegenerative disorders
Systemic illness	Hypertension Hyperthyroidism Hypothyroidism Fever
Medication	Beta blockers Antihistamines Antidepressants Antiepileptics Nonsteroidal antiinflammatory drugs
Psychological or psychiatric	Mania
Disturbance	Depression Anxiety Psychosis
Metabolic disturbance	Hyper or hypocalcemia Hyper or hyponatremia Uremia Hypoxemia
Pain	Acute or chronic
Fatigue	Acute or chronic
Sleep disturbance	Fatigue/daytime somnolence Sleep apnea

Modified from Hanly JG, Harrison MJ. Management of neuropsychiatric lupus. *Best Practice and Research Clinical Rheumatology* 2005;19(5):799–821.

Various cross-sectional studies have compared the rates of cognitive impairment between SLE patients with and without a history of clinically overt NP-SLE, although many of these predated the development of the ACR nomenclature (5). As NP-SLE events, such as stroke and antiphospholipid antibody–associated multifocal infarction, would be expected to have associated, if different, patterns of cognitive dysfunction, it is perhaps not surprising that the prevalence of cognitive dysfunction in patients with past or current NP-SLE has been found to be greater than in those with no such history (110 ,111 ,113 ,114 ,124 ,125).

Cognitive Function and Psychiatric Morbidity

Mood and psychological distress, even in the absence of a frank psychiatric diagnosis, are known to influence cognitive functioning as well as to alter performance on neuropsychological tests (108). The high prevalence of psychological disturbance in SLE has led some to hypothesize that SLE-associated cognitive dysfunction is primarily because of the psychological impact of the underlying disease. However, studies to date have both supported (115) and refuted (142) this hypothesis. Longitudinal data suggest that SLE patients who have psychiatric disturbance experience an improvement in cognition with improved psychiatric status at 1-year follow-up, although this improvement is not observed in patients with persistent psychiatric disorders. Hay et al. found that 21% of their sample of 73 SLE patients had a current psychiatric disorder and that these patients were impaired relative to SLE patients without psychiatric disorders on various verbal tests of cognition (140). Those patients whose psychiatric disorders resolved over the intervening year showed improved performance, whereas those whose psychiatric disorders persisted showed no change, and those who developed new psychiatric disorder showed decline (143). Monastero et al. (144) have also reported an association between the presence and level of depressive symptoms and neuropsychological test performance among SLE patients both with and without NP-SLE. However, while such associations suggest that psychiatric morbidity may coincide with cognitive dysfunction in SLE patients, no clear causal relationship between them has been established to date.

Cognitive Function and Medication

Most cross-sectional studies in SLE patients report no association between cognitive dysfunction and either the use (115 ,140 ,145 ,146) or dose of corticosteroids (115 ,134 ,140 ,146). Only Denburg et al., (147) in a study of a small sample of SLE patients, have suggested that brief exposure to low-dose corticosteroid has a positive effect on cognition. Hanly et al. compared those SLE patients who were receiving prednisone at three assessments during a 5-year follow-up period with those patients who were either not receiving prednisone at any assessments or were intermittently exposed to prednisone (124). A group-by-time interaction occurred only for a single neuropsychological test and no significant differences were found in pair wise comparisons between the three groups at any of the three assessments. Other medications may also have an impact on cognitive function (Table 38-3), but the potential benefits and risks must be considered in the clinical context in which they are used. Further careful study of these issues is required and the potential effects of pharmacologic treatment are best addressed through individualized assessment.

Cognitive Function and Immunologic Variables

The evidence that supports cognitive deficits being primary manifestations of SLE is derived largely from the study of autoantibodies in SLE cohorts with and without cognitive impairment. In particular, the potential role of antineuronal, lymphocytotoxic, anti-P and antiphospholipid antibodies has been examined.

Antineuronal antibodies, determined using human neuroblastoma cell lines as the source of antigen, and brain cross-reactive lymphocytotoxic antibodies have been associated with cognitive impairment in SLE patients studied at a single tertiary referral center (117), but these findings have not been confirmed by independent studies (148 ,149). Furthermore, although the identification of the fine antigenic specificity of antineuronal antibodies has so far not lead to more robust clinical-serologic associations, the possibility of specific antibody-induced brain injury in SLE remains an intriguing possibility. In this regard the recent identification of anti-NR2 antibodies and their clear pathogenic potential in animal models for inducing neuronal injury provides a new opportunity to explore this mechanism of brain injury in SLE patients. However, despite the intriguing results from animal studies, the findings from clinical studies have so far yielded conflicting evidence in support of this association (30 ,31 ,32).

Anti-P antibodies, which have been associated to a variable extent with psychosis and depression in SLE patients (33 ,34 ,36 ,37), have also been examined in for their association with cognitive deficits. Although the studies are limited in number (149), the evidence to date does not support an association.

The strongest association between cognitive impairment and autoantibodies in SLE patients has been found with antiphospholipid antibodies. For example in a study of 118 SLE patients, 33% of whom were positive for the lupus

anticoagulant (LAC) (122), there was a significantly greater proportion of individuals with cognitive impairment in LAC-positive (50%) compared to LAC- negative (25%) patients. The association between cognitive function and anticardiolipin (aCL) antibodies has been examined in a number of cross-sectional and prospective studies. In work completed at our own center, 51 SLE patients were divided into those who were persistently aCL antibody positive or negative on the basis of up to seven antibody determinations over a 5-year period (43). The relative change in performance on individual neuropsychological tests was then compared between patients who were antibody positive and negative. Those who were persistently IgG aCL antibody positive demonstrated a greater reduction in psychomotor speed compared to those who were antibody negative. In contrast, patients who were persistently IgA aCL antibody positive had significantly poorer performance in conceptual reasoning and executive ability. Similar results have been reported by Menon et al. in a 2-year prospective study of 45 SLE patients (42). These data suggest that IgG and IgA aCL may be responsible for long-term subtle deterioration in cognitive function in SLE patients.

Neuro-Imaging

Several neuro-imaging modalities have been used to visualize structural and functional abnormalities in SLE patients, particularly those with neuropsychiatric and cognitive manifestations (Table 38-4). Methods advocated for diagnostic use by the ACR Research Committee in 1999 (5) included computed tomography (CT), standard magnetic resonance imaging (MRI), and electroencephalogram (EEG). A multitude of other methods have also been employed in SLE research studies and in the clinical care of SLE patients, each of which possesses capabilities that offer unique perspectives on nervous system disease. In the management of individual patients neuro-imaging is most frequently used to support a clinical diagnosis of NP-SLE. However, there is also a growing interest in determining whether neuro-imaging can be used to distinguish between nervous system damage and disease activity that is potentially reversible and thereby amenable to therapy. Over the last decade, numerous studies have examined brain structure and function in SLE patients and the relationship to disease activity, disease course, and clinical outcomes.

Differences between Brain Structure and Function

In order to fully appreciate the brain imaging modalities that are currently available for clinical and experimental purposes, it is necessary to draw a distinction between different properties of the brain that these technologies are designed to examine. In particular, it is important to distinguish between the observed structure of brain tissue and brain function.

The distinction between structure and function can be conceptualized as a “brain vs. mind” dichotomy. Although the “brain” is a physical object that is tangible, the “mind” is a concept that can only be inferred indirectly based on observation of behavior or cognitive processes. Structure, therefore, refers to anatomy that can be observed with the naked eye, microscopically, or on an image that provides a static “picture” of the brain. Examination of structure over time can provide insight into dynamic processes of anatomical changes such as changes in the volume of the ventricles with age (150) that reflect cell loss, or to track displacement of anatomic structures in the brain as a result of a tumor. Both normal and abnormal changes in structure can sometimes be correlated with observable behavior and cognitive processes. For instance, it is widely accepted that damage to the medial temporal lobe is associated with difficulties in forming new memories (151). Such associations are thought to represent what different areas of the brain or distinct parts of the brain “do.” This is function.

Clearly, brain function is closely tied to structure but there is no precise mapping of one onto the other. For example, although the function of speech production is known to be associated with Broca's area (opercular and triangular sections of the inferior frontal gyrus), this function is complex and involves much more than simply verbal production of words. Thus, numerous other brain regions are implicated in the various cognitive processes necessary for the final outcome of speech production (152). From the standpoint of imaging and physiology, function can be conceptualized as the biological and biochemical mechanisms within the anatomical structures. Thus, brain function is often measured in terms of blood flow, brain metabolism, and biochemistry. Quantification of these physical phenomena requires more than an image, because they are not static.

Imaging Modalities: Uses and Efficacy

Modern neuro-imaging originated with the discovery of x-rays, and has evolved from the production of rudimentary two-dimensional brain images to highly sensitive and spatially detailed three-dimensional structural imaging and to quantification of functional indicators (153). The following section will briefly describe various imaging modalities that have been applied in the diagnosis and investigation of CNS abnormalities, including those occurring in SLE patients.

Computed Tomography (CT)

CT was the first neuro-imaging technique to be applied in research and in clinical practice in the 1970s and revolutionized our ability to examine brain tissue in vivo (153). This x-ray technique produces two-dimensional images of the organ of interest according to variable x-ray densities produced by differential concentrations of electrons in brain tissue. To obtain a CT image of the brain, an x-ray source and a detector are rotated around the head at ear level.

The source emits a narrow x-ray beam that is attenuated as it passes through the tissue, which absorbs the energy. The detector measures this reduction in the density of the x-ray from its origin to its destination on the other side of the head (152 ,153). The structure of the brain is reconstructed based on the strength of x-ray signals that reach the detector at different points of rotation, so the tissue types or substances in the brain are spatially mapped according to their x-ray permeability. Substances like bone that efficiently absorb x-rays allow only a fraction of the originally emitted energy to reach the detector and appear very light on the final image. CSF, which is highly permeable to x-ray energy, appears dark, whereas blood and other tissue types appear as different shades of gray (152 ,153). If x-ray opaque contrast agents are injected intravenously it is also possible to visualize blood vessels.

Table 38-4: Neuroimaging Modalities and Findings in NP-SLE

	Structural Imaging Techniques				Metabolic and Functional Imaging Techniques			
	CT	**MRI**	**MTI**	**DTI**	**MRS**	**fMRI**	**PET**	**SPECT**
Technique	Based on variable x-ray permeability of different tissues to reconstruct a 3D image of a structure.	Uses radio waves in presence of a strong magnetic field. The 3D image is reconstructed on the basis of differential tissue energy reemission rates.	Uses MRI platform. MTI measures transfer of protons between myelin and free water. Results expressed as magnetization transfer ratio histograms reflecting structural integrity of the tissue.	Based on the MRI platform. DTI produces histograms that reflect structural integrity of white matter tracks.	MRS utilizes the MRI platform and provides an MR spectrum with peaks for individual brain metabolites in circumscribed areas of the brain. MRS is an experimental technique and is not yet in clinical use.	Based on the MRI platform, this technique monitors blood flow and oxygen utilization to determine areas of brain activity associated with various tasks.	Based on the CT platform this technique detects areas of brain activity by tracking primarily glucose and oxygen metabolism.	Similar to PET, SPECT uses imaging of single photons emitted by radiologic tracers to track relative changes in regional cerebral blood flow.
Detectable Pathologies	1. Cerebral atrophy, 2. Focal white matter damage, 3. Infarcts, 4. Hemorrhage, 5. Meningeal thickening,	T1-weighted images: Same pathologies as CT. T2-weighted images: 1. Gray and white matter hyperintensities that may reflect edema and inflammation. 2. Potential to differentiate acute from chronic lesions.	1. Global brain damage and total lesion load. 2. Loss of myelin or axons in brain that may appear normal on conventional MRI.	Damage to the parenchymal structure even in absence of detectable abnormalities on conventional MRI scans.	1. Decrease in number and integrity of neurons 2. Myelin loss, 3. Inflammation 4. Abnormalities found in brain lesions or in normal appearing brain on conventional MRI.	1. Potentially useful in localization of brain function 2. May assist in assessing functional disconnectivity among brain regions.	1. Multifocal metabolic and blood flow abnormalities that may have functional correlates 2. Decreased metabolism and/or blood flow in areas that appear normal on MRI or CT may reflect damage in afferent pathways from areas with visible damage.	1. Multifocal metabolic and blood flow abnormalities that may have functional correlates 2. Decreased metabolism and/or blood flow in areas that appear normal on MRI or CT may reflect damage in afferent pathways from areas with visible damage.
Findings in SLE	Sensitive to gross abnormalities that are poorly correlated with specific neuropsychiatric manifestations. Abnormalities detected indicate structural changes, which are irreversible.	In presence of chronic cognitive deficits, MRI can detect associated focal damage. May detect gadolinium enhanced acute brain lesions indicative of active disease. White matter hyperintensities of uncertain significance Gray matter hyperintensities and edema may be indicative of active NP-SLE.	Measures of global brain damage using MTI are associated with neurologic and psychiatric symptoms.	DTI indicates loss of white matter tracks in patients with NP manifestations but it is unclear if these abnormalities are reversible.	Reduction in NAA is associated with various clinical manifestations of NPSLE including psychosis, confusional states, and cognitive impairment. Elevation of Cho is indicative of cell membrane or myelin loss and inflammation. Increase of Myo may be indicative of inflammation.	This technique is still largely experimental, and no studies with SLE patients are available at this time.	Patients with active NP-SLE experiencing psychiatric symptoms show decreased glucose metabolism in prefrontal and inferior parietal lobes bilaterally and in the anterior cingulate region.	Patients with active NP-SLE experiencing psychiatric symptoms and cognitive impairment are more likely to exhibit hypoperfusion compared to NP-SLE patients without such manifestations. Up to 50% of SLE patients may have such abnormalities in the absence of clinical findings.

Limitations of CT include its relatively rudimentary resolution. Although the contrast of the image can be adjusted to target the tissue types of interest, the results may still be difficult to interpret. In diseases that alter brain tissue density, it can be difficult to differentiate damaged tissue from the healthy tissue of similar x-ray permeability. For example, because white matter is less permeable to x-rays than gray matter because it contains more fat (e.g., myelin) and less water, demyelination serves to minimize contrast between the two on CT. Thus, diffuse, as opposed to focal, white matter demyelination can be difficult to resolve on CT images. This difficulty in distinguishing between soft tissue types because of relatively small differences in x-ray density is exacerbated by the substantial difference in x-ray permeability between soft tissue and bone. As a result, CT images tend to exhibit white artifacts in the “bony” areas of the brain (e.g., posterior fossa, temporal lobe, or any area close to the scull) that overwhelm small differences on the gray scale (152).

CT is sensitive to cerebral atrophy, which has been detected in 29% to 59% of the patients with NP-SLE (154). Other pathology, such as infarction, hemorrhage, and meningeal thickening as a consequence of inflammation may be detected as well. Although there has been some evidence that CT may also detect white matter abnormalities reflecting edema (154), these findings have not been substantiated. Also, CT may well be insensitive to the diffuse pathologies most frequently associated with NP-SLE, including chronic white matter demyelination and small infarcts (155). Overall, while CT may detect chronic damage in SLE, it is not helpful in identifying active inflammatory disease processes within the nervous system (156 ,157).

Conventional Magnetic Resonance Imaging (MRI)

Since its introduction into clinical use in the early 1980s, MRI has overtaken CT as the standard neuroimaging technique. MRI offers a number of advantages compared to CT in terms of clinical assessment and research design, because it is noninvasive and poses no health hazards even across multiple scans (as opposed to x-rays). Therefore MRI can be used repeatedly for longitudinal studies (153). Additionally, most commonly used MRI images offer better spatial resolution than those produced using CT. Although MRI still relies on the capacity of the tissue to absorb and re-emit energy in proportion to the concentration of water (hydrogen ions) in the tissue (153), the energy is delivered via radio waves in the presence of a strong magnetic field that is thousands of times greater than that of the Earth. The strength of an MRI magnet is expressed in Tesla units, a measure of magnetic flux density. Since hydrogen nuclei have an odd number of protons, they can be conceptualized as small magnets with their own local fields (153). Therefore, these nuclei align themselves with the direction of the main magnetic field when the patient is placed into the bore of the magnet. Once aligned, the nuclei absorb and emit electromagnetic energy at a resonant frequency that is specific to their surroundings (e.g., water, brain tissue) (152). The signal used to construct an MRI image is obtained by disturbing the alignment of the nuclei via application of radiofrequency (RF) pulses at various angles to the direction of the main magnetic field. MRI allows for application of RF pulses to highly circumscribed areas of the brain, allowing imaging of “slices” of tissue as thin as 1.5 mm. These pulses “flip” the nuclei into the plane transverse to the direction of the main field and rotate them in sync. Once disturbed in this manner, the nuclei re-emit the absorbed energy at different rates, producing a measurable signal (152). Nuclei in tissue that contains a high proportion of water (e.g., CSF) re-align with the dominant field, whereas tissue that is high in fat (e.g., white matter) and low in mobile water ions re-emit energy slowly. These processes of energy re-emission and re-alignment with the magnetic field generate two main time constants that form the foundation of the signal: T1, which is the time it takes the nuclei to “relax” and to return to their normal alignment within the magnetic field and T2, which measures how fast the nuclei lose alignment with each other. Both of these vary among tissue types within the healthy human brain and change in the presence of pathology (153 ,158). Focusing on one of these two time constants (i.e., weighting the image) by varying the times between applications of the RF pulses emphasizes different parameters of the tissue. A T1-weighted image is characterized by dark CSF and light white matter, whereas the opposite is true in a T2-weighted image (152). Such contrast allows visualization and detection of various pathologies. For example, white matter demyelination, which is not easily observed using CT, is readily apparent on T2 MRI images (152). A third MRI time constant, T2*, is used predominantly in functional MRI (fMRI) rather than in structural MRI (159). This relaxation type provides image effects that are similar to those produced by T2-weighted images, but while T2 decay is a result of magnetic fluctuations at a molecular level, the T2* decay is a result of large-scale inhomogeneities in the dominant applied magnetic field. Such inhomogeneities may be caused by the imperfection in the

magnet itself, or because the human head contains a variety of areas of differing magnetic susceptibility. Thus, inhomogeneities are especially profound at the boundaries between areas with different susceptibilities (e.g., air/tissue interfaces and in blood vessels), which causes very rapid T2* relaxations in such regions (159).

MRI is the preferred method of structural imaging in SLE (155). It is much more sensitive than CT for the detection of focal deficits (155) and allows visualization of large infarcts, hemorrhage, aneurysms, and transverse myelitis. Abnormalities on MRI scanning may be found in 19% (160) to 70% (161) of SLE patients. T2-weighted MRI images identify pathologic processes that cause edema and are more sensitive than T1-weighted images for the detection of abnormalities in patients with NP-SLE. Applying the technique of fluid attenuated inversion recovery (FLAIR), in order to dampen the CSF signal and highlight areas of edema, further enhances the utility of T2-weighted images (162 ,163). T2-weighted imaging also detects subcortical and periventricular white matter lesions. These lesions of increased signal intensity or brightness, referred to as “white matter hyperintensity” (WMHI) are often missed by CT, and are found in 20% to 50% of SLE patients regardless of the presence or absence of clinical NP disease. They can occur in up to 75% of SLE patients with antiphospholipid syndrome (APS) (164) but the strongest correlation is with age of the patient, overall disease severity, and disease duration (158). If the lesions are larger, occur in the corpus callosum or predominantly in a periventricular distribution and are seen on T1-weighted images, then the diagnosis of multiple sclerosis must be considered (162 ,165). Magnetic resonance angiography (MRA) permits visualization of cerebral blood flow, although it is probably not optimum for visualization of flow in small caliber vessels that are the ones primarily involved in NP-SLE.

Thus, although MRI is a sensitive technique it does not easily allow for differentiation of chronic CNS lesions from those that indicate acute changes attributed to SLE, or from CNS changes unrelated to lupus (158). This differentiation of chronic from acute disease is important in clinical decision making, because treatment often depends on determining whether the presenting symptoms are caused by active lupus, by pre-existing but currently quiescent SLE, or by non-SLE factors (155). Some guidelines have been suggested to facilitate interpretation of MRI findings in terms of disease activity or chronicity. For example, acute and reversible lesions often lack clear borders, have a filamentous pattern, and usually follow the gray-white matter junction along the sulci and gyri (154). Gray matter hyperintensity and edema in the cerebral hemispheres, the brain stem, or in the cerebellum are additional indicators of inflammatory disease (154 ,155). Determining the chronicity or acuity of a lesion can also be facilitated by intravenous gadolinium, which enhances active lesions on T1-weighted images (154) and indicates breakdown of the BBB. However, this method is not entirely reliable.

Gray matter edema may resolve over 2 to 3 weeks (160) following an acute NP event, especially in patients undergoing corticosteroid therapy (154). In a case study, Kashihara (166) examined the reversibility of MRI findings in association with treatment of NP-SLE. They suggested that laminar cortical necrosis visible on T1- and T2-weighted MRI images may be related to disease activity because of the co-occurrence with psychiatric symptoms and resolution with therapy. Their patient presented with a variety of NP symptoms including headache, fever, psychosis (olfactory hallucinations and delusions of persecution and reference), and psychomotor impairment. MRI images revealed laminar lesions bilaterally in the parietal and temporal cortex. Once the patient started steroid therapy, the clinical symptoms were alleviated within 7 months, and the lesions visible on T1- and T2-weighted images resolved in 1 and 5 years, respectively.

It is important to remember, however, that while detection of active disease is possible, it is very difficult with conventional structural imaging techniques such as CT and MRI. It is not uncommon for patients with active NP-SLE to show the same MRI results as those who are not in the active stage of the disease, and sometimes both groups of patients may exhibit normal MRI scans even when psychiatric symptoms are clearly present (154 ,155). Presentations that are likely to be accompanied by normal CT and MRI results include confusional states, affective disorders, and headaches (154). Finally, neither of these techniques can reliably differentiate SLE from other non-SLE disorders with similar behavioral and neurologic presentations, including vascular incidents unrelated to SLE, infectious meningitis, noninflammatory edema, or non-SLE related infarcts and hemorrhage.

Nonconventional MRI Imaging

Although conventional MRI is the most frequently used imaging technique, there are a multitude of other imaging modalities based on the principles of MR that provide unique information about brain structure, function, and biochemistry. These include magnetic resonance relaxometry (MRR), magnetization transfer imaging (MTI), diffusion-tensor imaging (DTI), magnetic resonance spectroscopy (MRS), and functional magnetic resonance imaging (fMRI).

Magnetic Resonance Relaxometry (MRR)

MRR is a method of quantifying T1 or T2 relaxation times in brain tissue. This has been used to identify potential structural markers of active NP-SLE associated with major NP events, such as seizures, psychosis, or coma (167). Since relaxation times of tissue may change in pathologic states because of changes in tissue density or chemical composition, relaxometry can add sensitivity to conventional MRI scans, particularly if changes in the tissue do not produce easily observable contrast changes on the conventional image.

Patropoulos et al. (167) used this technique to quantify T2 relaxation times in gray matter of NP-SLE patients in an attempt to detect edema. They included 10 patients experiencing major NP-SLE manifestations and 10 patients experiencing minor NP-SLE who were matched on measures of brain atrophy. Some patients with minor NP-SLE had a history of major symptoms that had resolved prior to the commencement of the study. They found an increase in the T2 relaxation time of the normal appearing gray matter in all patients within the major NP-SLE group compared to only 2 in the minor NPSLE group. This was interpreted as gray matter edema occurring predominantly in the major NP-SLE group. Cerebral edema may have various causes in active disease including vascular injury, release of neurotoxins from areas of inflammation, or the breakdown of the BBB (167) and MRR may yet prove to be a valid and feasible measure of the inflammatory component of active disease among patients with NP-SLE.

Magnetization Transfer Imaging (MTI)

MTI is a structural imaging modality that allows for detection of tissue damage, especially in terms of integrity of white matter tracks, that cannot be easily visualized using conventional MRI (153). The technique is based on quantification of the exchange of magnetization between macromolecule-bound protons in myelin and water protons in biologic tissues. As mentioned previously, MR derives its signal from free water protons. The bound protons are magnetized with a saturation pulse and a standard MR sequence is applied. When the pulse is terminated, there is a transfer of magnetization from the bound proton pool to the pool of free protons. The magnitude of the MR signal is measured before and after the application of the pulse and the change between the two measurement times allows for calculation of the magnetization transfer ratio (MTR) (153). The MTR is directly influenced by the amount of bound protons, which is proportional to the amount of myelin and can be assessed in regions of interest or in the whole brain (153 ,155). Therefore, a decrease in MTR usually signifies demyelination. The data obtained from three-dimensional MTI is displayed as a histogram that represents the pixel population of the entire brain image with an MTR value calculated for each pixel. As a pixel is the smallest two-dimensional component of an image, the histogram is very precise. A histogram consisting of a single, narrow, high peak represents a brain that is homogeneous in terms of MTR and has uniformly healthy tissue. On the other hand, when demyelination is present, the peak on the histogram becomes wider and lower because there is an increase in pixels with low MTR values. This indicates a reduction in healthy white matter and reflects the global lesion load in the brain (155). Such information cannot be easily obtained using conventional MRI that produces an image alone.

Studies of MTI in SLE patients conducted by Bosma et al. (168) indicated global brain damage in patients with NP-SLE. The findings on MTI significantly correlated with indicators of general neurologic functioning (Expanded Disability Status Scale) (169), psychiatric functioning (Hospital Anxiety and Depression Scale) (170) and cognitive functioning (cognitive impairment scores derived from the Wechsler Adult Intelligence Scale, Revised [WAIS-R]) (171). Furthermore, MTI abnormalities were detected in patients with a history of NP-SLE who were no longer in the active stages of the disease, and who had normal conventional MRI scans. This suggests that although psychiatric, cognitive, and neurologic symptoms of NP-SLE may resolve, the brain pathology that underlies them does not (172). Thus, MTI may assist not only in detecting pathology that cannot be seen with conventional imaging methods, but may also be useful in measuring progression of brain pathology resulting from NP-SLE, even after acute NP symptoms and signs resolve.

Diffusion Tensor Imaging (DTI)

DTI or the closely related but less sophisticated diffusion-weighted imaging (DWI) (173) provides additional information on white matter homogeneity and connectivity. DTI is based on the principle of isotropy (Brownian motion), which refers to unrestricted, chaotic movement of proton-containing molecules in free water. However, in the highly structured tissue of the brain, such as white matter and white matter tracks, it is easier for molecules to move in some directions than in others, thus creating preferential diffusion, or anisotropy. Pathologic conditions can disturb the highly structured integrity of the white matter fibers, causing loss of anisotropy and changing the diffusion behavior of the molecules (155). If RF pulses are applied at certain intervals, it is possible to obtain information about water molecule movement between pulses. This information is provided in the form of diffusion coefficients and contains vector information regarding the directions of diffusion. The level of fractional anisotropy (FA) can be calculated for individual pixels within a region of interest or for the whole brain, and the results are presented as a histogram with lower FA peaks indicating more pixels with higher diffusion values (155). Lower FA peaks indicate damage or degeneration in white matter tracks (153). DTI has been used to examine brain tissue changes in NP-SLE in terms of degeneration of parenchymal structure. Although patients with NP-SLE have been found to have more pixels with low FA values than healthy controls (174 ,175), it is unclear whether there is a difference in diffusion pattern between patients with active disease and patients who have chronic brain damage.

Thus, both MTI and DTI are capable of detecting changes in brain tissue that are not apparent on conventional MRI, but the interpretation of the results must take into account changes in the integrity of white matter that occur with age. Silver (176) collected MTI data from 41 healthy individuals for the purpose of establishing a normative database of MTR ratios for the white matter of healthy adults. They determined that ageing results in

decreased integrity of the white matter in the corpus callosum and frontal white matter and that these changes become apparent as early as 35 years of age.

Magnetic Resonance Spectroscopy (MRS)

Biochemical changes within living brain tissue can be examined by MRS (Fig. 38-4). This produces very different results from other MR techniques in that it provides information about the neurochemical composition of the tissue within a designated region of interest. Spectroscopy is most often added to an MRI scan as an extra series and adds approximately 7 minutes or more to the duration of the scan, depending on the number of regions of interest that are examined (155). It is generally sensitive to the presence of neurochemicals with fairly high concentrations (>1 mM). MRS results are displayed in form of spectra with peaks representing concentrations of various brain metabolites (158).

Proton magnetic resonance spectroscopy (1H-MRS) is the most commonly used method because, as with conventional MRI, it utilizes the signal provided by hydrogen, which is abundant in human tissue. The metabolites detected using this method typically include N-acetylaspartate (NAA). Choline compounds (Cho), Inositol (Ins), Lactate and Creatine (Cre) (155 ,158). NAA is found primarily in neurons and is represented by the highest peak on the spectral profile in healthy adult brains. This metabolite is considered to primarily indicate neuronal integrity, so a reduction in NAA indicates neuronal loss (158 ,177). The Cho peak reflects concentrations of phosphocholine and glycerophosphocholine, acetylcholine, and choline. It is associated with cell membrane breakdown and synthesis and loss of myelin. It is often elevated in patients who have suffered a stroke, brain inflammation, or acute white matter disease, all of which include membrane metabolism (177). The inositol peak represents concentrations of myoinositol and other inositol compounds and reflects membrane stabilization and turnover especially in glial cells. The concentrations of these substances may increase permanently or temporarily in conditions where membrane metabolism occurs. Lactate is undetectable in healthy brain tissue and its presence indicates anaerobic metabolism usually attributable to ischemia. The Cre peak on the spectral profile reflects concentrations of creatine and phosphocreatine. These substances are believed to be stable in most neuropsychiatric disorders, so Cre concentrations are often used as internal references to determine whether the quantities of other metabolites are elevated or diminished. However, the validity of this approach has been questioned as Cre can change in certain conditions, such as tumors (177). Although all of these metabolites can be observed at the standard clinical MRI field strength of 1.5 T, the inositol peak is only revealed when short echo time (TE) is used (35 ms or less) and is only evident as a single peak (177).

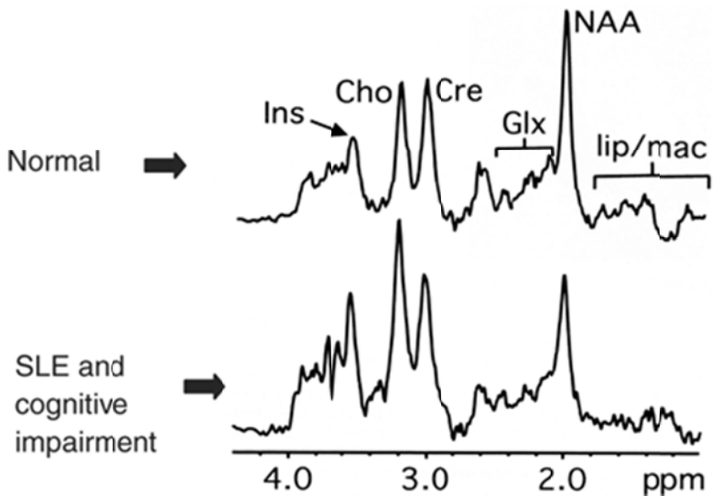

Figure 38-4. 1H magnetic resonance spectra from normal brain (upper panel) and SLE patient with neuropsychiatric SLE including cognitive impairment. From

Sibbitt WL Jr, Sibbitt RR, Brooks WM. Neuroimaging in neuropsychiatric systemic lupus erythematosus. *Arthritis Rheum* 1999;42(10):2026–2038 with permission.

Phosphorus-31 MRS (31P-MRS) is a less frequently used technique that assesses energy metabolism in the tissue as well as the concentrations of phosphorus-containing compounds involved in membrane synthesis (158). The principle measures of energy metabolism in tissue include phosphocreatine (PCr) and inorganic phosphate (158).

Some of the biochemical changes that have been noted with proton MRS in SLE and that have been linked to neurocognitive dysfunction include reduction in NAA in brain lesions seen on T2 conventional MRI images and in otherwise normal appearing gray and white matter (155 ,158). The findings are especially striking in focal lesions and likely represent areas of neuronal loss (158). Although reduction in NAA is by no means unique to SLE, it is strongly associated with various symptoms of NP-SLE, including psychosis, confusional states, and cognitive dysfunction (158). Although recovery of NAA levels has been observed (158 ,178), the circumstances governing the reversibility of decline in this neurochemical are poorly understood. It is clear, however, that reduced NAA is not characteristic only of active NP-SLE but is also seen in irreversible chronic brain injury (155).

The Cho peak has also been found to be elevated in NP-SLE in the absence of obvious structural abnormalities on conventional imaging. It has been suggested that elevation in Choline compounds can be a prognostic indicator, because it often reflects disease activity or inflammation (158). Elevation in Choline, combined with reduction in NAA has been linked to cognitive impairment in NP-SLE patients (155 ,158). Myo-inositol has also been found to be increased in normal appearing white matter of patients with NP-SLE, particularly in those with major CNS manifestations. This is felt to indicate inflammation (179). While 1H-MRS findings cannot be used to diagnose NP-SLE or to reliably differentiate it from disorders with comparable clinical presentations, MRS may be helpful in characterizing brain tissue damage particularly in the presence of otherwise normal imaging results (154).

Phosphorus MRS has been successful in identifying reduction of ATP and PCr in white matter of NP-SLE

patients (154). This is consistent with various features of NP-SLE, including cerebral ischemia, neuronal death, cell injury, or membrane turnover/degeneration (154). However, it is unclear whether these findings are unique to NP-SLE, whether they have diagnostic or prognostic utility, or whether they are correlated with specific neuropsychological or psychiatric manifestations.

There is some indication that changes observed in NP-SLE using CT and various MR techniques reflect the same pathologic processes from different perspectives. For instance, a feature of SLE that represents structural brain changes that are readily detected using CT or MRI is cerebral atrophy. Zanardi et al. (157) used CT to evaluate the relationship between the frequency and severity of cerebral atrophy and corticosteroid use, disease activity, and psychiatric manifestations in SLE patients taking steroids, non-SLE patients taking steroids, and healthy controls. Although SLE patients and non-SLE patients taking steroids were more likely to exhibit atrophy, SLE patients had more severe atrophy that was not accounted for by the corticosteroid use, disease duration, or disease activity. Nevertheless, the causes of cerebral atrophy in SLE patients remain unclear and studies are divided on the relative contributions of SLE per se and corticosteroid use (168 ,172). Cortical atrophy constitutes permanent damage that does not resolve with disease quiescence, and seizures have been reported as the most common clinical NP manifestation associated with cortical atrophy (157). Bosma et al. (168) found that brain parenchyma loses integrity and structure during active NP-SLE but that this abnormality in normal-appearing parenchyma can be detected using MTI even in absence of active disease. Damage in normal-appearing white matter can also be measured as decline in NAA on MRS and all of these measures may be used as markers of disease progression even in absence of active clinical disease (168 ,172). Loss of parenchymal uniformity using MTI and the metabolic abnormalities indicated by MRS may result from the same pathogenic mechanisms and lead to similar outcomes in patients with NP-SLE (180). The loss of parenchymal integrity and loss of NAA both indicate neuronal degeneration and axonal damage (180). Correlations between abnormal MTI findings (i.e., low MTR), abnormal findings on DWI (i.e., isotropy in diffusivity), and increased T2 on MR relaxometry support this suggestion (180).

Functional Imaging

MR imaging can also provided an assessment of brain function by means of fMRI. Activation of brain regions and networks during various types of tasks and cognitive states can be inferred by measuring physiologic changes, such as blood flow and oxygen utilization that accompany brain activity (181). The underlying assumption is that activity in a certain area of the brain causes an increase of blood flow to that area because of greater energy utilization at a molecular level. Although intuitive, it is important to appreciate that in the brain the relationship between activation and blood flow is complex. For example, some areas of the brain may be activated in response to a task and show an increase in blood flow, although involvement of other areas may manifest inhibition of synaptic activity and no increase in energy utilization. However, even inhibition can be associated with an increased demand for energy (181). Although there is a plethora of fMRI techniques that can be used to detect changes in blood flow and energy consumption, the method used most frequently is blood oxygenation level-dependent (BOLD) fMRI. In addition to being the most well developed method, it also does not require intravenous administration of contrast agents to track activation patterns. The presence of iron atoms in hemoglobin means that blood has magnetic properties, which reduces its MRI relaxation time. Blood also serves as a delivery mechanism for oxygen, and since oxygen is not very soluble in blood, it is transported bound to the iron atoms. When oxygen is bound to a hemoglobin molecule, the molecule's magnetic effect on its environment is reduced, which makes it a sensitive magnetic marker of blood oxygenation, and thereby indirectly reflects neuronal activity. As deoxyhemoglobin decreases, so does the signal from blood on the T2- and the T2*-weighted images. The opposite is true if blood oxygen levels rise. Thus, a positive change in signal on fMRI images in response to tasks (i.e., neuronal activation) is reflected by an increase in concentration of oxygenated hemoglobin (159).

Although fMRI has great potential, it has a number of limitations that have to be resolved before it can become a more efficient experimental or clinical tool. One of the problems is the need for multiple measurements and long scanning sessions. The signal changes generated by shifts in cognitive states or tasks are relatively small and in order to detect them numerous MRI acquisitions are required. The second limitation of fMRI is that, because this currently remains a new and experimental imaging procedure, there are no clear standards for interpreting associations of hemodynamic responses and neuronal activity (181). Understanding of this association is further impeded by a lack of knowledge about the exact mechanisms regulating regional blood flow. Additionally, fMRI is mainly useful for identifying activity in the gray matter where synapses are found, and not in the white matter and it has been argued that the fMRI signal reflects combinations of synaptic and dendritic charges (i.e., synaptic activity), rather than neuronal activity itself. Finally, there is no consistent relationship between excitatory synaptic activity and increase in the fMRI signal, perhaps because the contribution of inhibitory synaptic activity is variable and still poorly understood (181). Determining the exact area of activation is also problematic since the increased perfusion in the local tissue that results in the change in fMRI signal occurs on a larger spatial scale than the actual electric activation. Thus, the area of activation generally looks larger than it actually is (159). Functional MRI can be very informative of the “functional connectivity” (153) of brain

regions and disconnections can be indicative of pathology. To date, fMRI studies have not been conducted in SLE patients.

Thus, the MRI platform is a fruitful source of diagnostic and experimental information about the CNS and holds immense promise for the future of imaging in SLE. Nevertheless, it does have limitations. First, the integrity of the image is highly susceptible to movement, a particular issue in fMRI where acquisition is very time consuming (153). Additionally, MRI techniques are contraindicated for people who are claustrophobic, because the bore of the magnet is a confined space, and for individuals who have metal embedded anywhere in their bodies, as this could pose a fatal risk when exposed to high magnetic fields (153). Finally, the various abnormalities that have been detected are not restricted to a particular disease, but rather represent biochemical, functional, or structural changes, which may be the consequence of several immunopathogenic, inflammatory, or degenerative mechanisms.

When functional assessment is of interest, but fMRI is unavailable or contraindicated, positron emission tomography (PET) can be used. To some extent, this technique combines examination of brain function and biochemistry. It is based on the assumption that blood supply and glucose/oxygen metabolism within a region of the brain varies with changes in the biochemical processes that underlie the function of that anatomical region (182 ,183). Thus, as neuronal activity within an area of the brain increases, so does the blood flow to that area, and the demands for oxygen and glucose (183). One of the most valuable aspects of PET is that it is a fairly efficient method of detecting diffuse abnormalities or for localization of pathology (182). PET employs two technologies that allow for in vivo measurement and localization of neurologic processes: examination of radiological tracer kinetics and CT (182). The former provides information about the compartmental kinetics of glucose and oxygen metabolism, and blood flow, and can even assist in mapping white matter fibers and axonal projections (154 ,182 ,183). The PET scanner is designed to provide a CT image of the brain combined with concentration distributions of tracer-labeled products (182). Disadvantages of PET scanning include the exposure of patients to large doses of radiation (154 ,182), availability of radiopharmaceuticals, and cost.

Single-photon emission computed tomography (SPECT) is a more commonly available method of studying brain function. This technique was developed after PET and uses much of the same techniques (184). In contrast to the use of coincidental pairs of photons in PET scanning, SPECT uses brain images generated by CT to image single photons emitted by radiologic tracers in order to determine cerebral blood flow (185). Since photons are detected one at a time, their emission from tissue do not have an easily detectible spatial correlation, and have to be traced to their point of origin by the process of collimation (184). Collimation is key to obtaining a viable SPECT image and is “the process where electromagnetic radiation can be made into parallel beams” (185). As with PET, the data produced by SPECT is also in the form of slices that can be reconstructed in various planes over the entire 360 degrees of rotation around the patient (185). Most SPECT systems use a “gamma camera” that rotates around the subject either continuously or in discrete increments (”step-and-shoot”), where the imaging is taking place only when the system is stationary (185). SPECT also involves exposure to radioactive substances via intravenous injection or inhalation of tracers, with the latter method being more widely used (185). Some of the most commonly used tracer substances include: Iodine-123-IMP (Spectamine), Technetium-99m, Technetium-99mECD, and 99mTc-HMPAO (184).

Like other imaging techniques, SPECT also has drawbacks that must be considered (186). As with PET scanning, this technique requires exposure to radioactive substances. Since the tracers used in SPECT imaging of the CNS are most often injected into the blood stream, they circulate throughout the body before they reach the brain, and affect other organs that are not the focus of imaging (185). Furthermore, although there are over 1,000 known radioactive nucleotides, many of which can be used as tracers, SPECT radioisotopes for brain imaging must meet the following requirements: they must be able to cross the BBB; they must have a half-life sufficient to produce the images, but short enough to avoid prolonged radioactive exposure; the decay must produce photons with enough energy to escape the tissue, but not the detection system; the decay must produce more high-energy photons than low-energy ones to reduce the amount of the absorbed radiation; and the tracer must attach to the substance of interest without changing its properties (184 ,185). The substances mentioned above possess these characteristics to varying degrees, but they often underestimate regional cerebral blood flow (184). Also, the image resolution and detail produced by SPECT is inferior to other CT techniques, including both CT and PET. This is because the decay of the radioactive nuclides used to reconstruct the image is random, so only a fraction of it is detected (184 ,185). Finally, as is the case with other functional imaging modalities, SPECT does not provide a direct measure of brain activity, but rather measures concurrent physiologic changes in brain tissue that are correlated with it (184).

Despite these limitations, PET and SPECT scanning are two of the most frequently utilized procedures in studying NP-SLE. PET scans have often been found to be abnormal in NP-SLE patients, indicating multifocal metabolic and blood-flow abnormalities undetected with structural imaging methods, such as MRI and CT (154). However, just as with the other imaging techniques, the data obtained using PET have to be interpreted with caution as abnormalities in glucose absorption, oxygen use, and blood flow may not be indicative of active CNS disease. In general, nervous system damage associated with SLE, such as focal disease, may cause cell death, and the consequent decreased neuronal density may produce the same results on PET and SPECT as active NP-SLE. Furthermore, changes in blood flow and

metabolism can also occur in sites distant from those of the pathologic lesion, a phenomenon known as diaschisis (187), in which local neuronal activity is diminished in normal appearing brain as a result of loss of afferent input from a remote area of brain damage. Therefore, although PET may provide valuable functional information about NP-SLE that is not otherwise available, this technique has relatively high associated hazards and costs, and requires parallel anatomic imaging to be useful on a routine basis (154). SPECT may overcome the issue of cost and may be a valuable means of detecting various abnormalities in patients with NP-SLE. However, abnormalities observed using SPECT have not been found to differentiate patients with major NP-SLE features, such as stroke, seizures, or psychosis, from patients with milder NP-SLE features such as headaches, dizziness, and mild cognitive impairments (154). Furthermore, most such findings can be seen in SLE patients without NP-SLE, and may be chronic in some patients and reversible in others (154).

Komatsu et al. (188) used PET to compare 12 patients with active SLE, with and without psychiatric symptoms. They found that patients with active psychiatric symptoms showed decreased metabolic rates for glucose in prefrontal and inferior parietal lobes and in the anterior cingulated regions bilaterally that were not related to steroid use. These results are intriguing in that patients with active SLE but without psychiatric symptoms had normal PET scan results. In patients with psychiatric symptoms, the PET scan abnormalities and symptoms resolved concurrently with treatment. Similar results have also been reported by others using SPECT scanning (189 ,190). Huang et al. (190) examined 78 SLE patients: 48 with NP-SLE exhibiting psychiatric symptoms and 30 SLE patients without NP symptoms. They found that 90% of patients with psychiatric symptoms had regions of hypoperfusion compared to 20% of patients without such symptoms. The regions of hypoperfusion were most commonly found in the parietal lobe, and to a lesser extent in the frontal and temporal lobes, in the region of the middle cerebral artery. These results reflect the composite literature on SPECT scanning in SLE with areas of diminished uptake in 86% to 100% of patients with major NP events (e.g., stroke, seizures, psychosis), in 33% to 85% of patient with minor NP events (e.g., headache, subjective memory loss) and in 10% to 50% of SLE patients with no apparent NP disease (158 ,173).

Most functional imaging techniques suffer from similar pitfalls: lack of direct measurement of brain activity, long scan times, a lack of standards for environmental conditions during scanning, and lack of consensus on thresholds for defining brain activation. Regional and general cerebral blood flow, which is often the focus of functional imaging may be affected by a number of sensory events that are often uncontrolled (e.g., visual, auditory, or somatosensory stimulation) and by a variety of subject variables, including age, gender, anxiety, or level of arousal, time of day, blood pressure, or even ingestion of certain common substances, such as caffeine (184). Such confounding factors are difficult to control and are often ignored during imaging, possibly leading to unreliable and invalid results.

A review of the various neuro-imaging methods used in studies of NP-SLE illustrates the need for cautious interpretation of the findings. Most of the techniques that have been commonly used reveal changes that are not unique to NP-SLE and, therefore, cannot be relied upon to differentiate NP-SLE from other diseases that affect the nervous system. Additionally, sensitivity of the various imaging methods is a double-edged sword. Less sensitive modalities, like CT, cannot provide information beyond gross abnormalities, other, more sensitive techniques, such as MRI, MRS, and SPECT, may reveal unexpected abnormalities that are of dubious clinical significance. Finally, of the imaging modalities reviewed, only MRI seems to currently have the potential to distinguish active disease from chronic CNS changes, although this issue will need considerably more research to confirm. If so, MRI may be helpful in confirming favorable treatment responses.

Treatment of Psychiatric Disorders and Cognitive Impairment in SLE

Management will need to be tailored according to individual patient's needs (Table 38-5) and there remains a paucity of controlled studies to guide treatment decisions. Once a diagnosis of NP-SLE is established the first step

is to identify and treat potential aggravating factors, such as hypertension, infection, and metabolic abnormalities. Symptomatic therapy with, for example, antidepressants and antipsychotic medications should be considered, if appropriate. Immunosuppressive therapy with high-dose corticosteroids, azathioprine, and cyclophosphamide are used to varying degrees. With the exception of one study (147) there are no placebo-controlled studies examining the benefit of either oral or intravenous corticosteroids (191 ,192) in NP-SLE. Similarly, pulse intravenous cyclophosphamide therapy (193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 ,201), akin to that which has been used in the treatment of lupus nephritis, has also been reported to be beneficial in NP-SLE, although only one controlled study has been performed. A recent open-label study of 13 patients with lupus psychosis reported a favorable outcome in all patients treated with oral cyclophosphamide for 6 months followed by maintenance therapy with azathioprine (202). Another study by Barile-Fabris et al. (203) compared intermittent intravenous cyclophosphamide to intravenous methylprednisone given for up to 2 years in SLE patients with predominantly neurologic disease and reported a significantly better response rate with cyclophosphamide (95%) compared to methylprednisone (54%) ($p < 0.03$). In virtually all of these studies, immunosuppressive therapy was used in conjunction with corticosteroids in addition to symptomatic therapies, such as antipsychotic medications. More targeted immunosuppressive therapies, for example B-lymphocyte depletion with anti-CD20 used alone or in combination with cyclophosphamide (204 ,205), are promising, but require further study. Anticoagulation is strongly indicated for focal disease when antiphospholipid antibodies are implicated and such therapy will usually be lifelong (206 ,207 ,208).

Table 38-5: Management of NP Events in Patients with SLE

Treatment Strategy	Examples
• Establish diagnosis of NP-SLE	CSF examination primarily to exclude infection Autoantibody profile (antiphospholipid, antiribosomal P) Neuro-imaging to assess brain structure and function Neuropsychological assessment
• Identify aggravating factors	Hypertension, infection, metabolic abnormalities
• Symptomatic therapy	Anticonvulsants, psychotropics, anxiolytics
• Immunosuppression	Corticosteroids, azathioprine, cyclophosphamide, mycophenolate mofetil B-lymphocyte depletion
• Anticoagulation	Heparin, warfarin

Modified from Hanly JG. Neuropsychiatric lupus. *Curr Rheumatol Rep* 2001;3:205–212.

The identification of a potentially reversible cause (Table 38-3) is the first step in initiating treatment for SLE patients with cognitive impairment. Simple causes of new cognitive difficulties are often identified by review of the patient's history. Recent changes in medication are among the most common. Antidepressants, anticonvulsants, and antihypertensive treatments frequently used in SLE may cause reversible cognitive problems; adjustments in drug selection and dose may result in cognitive improvement. Treatment of even mild anxiety and depression may also improve cognitive symptoms.

At present, any additional attempt to address the issue of treatment of cognitive dysfunction in SLE is at best speculative. Two approaches, pharmacologic treatment and cognitive rehabilitation, can be considered although neither have yet been systematically attempted in SLE let alone have established evidence of efficacy. Only one placebo-controlled study of pharmacologic therapy for SLE-associated cognitive dysfunction has been performed (147). Ten SLE patients who were not using corticosteroids prior to the study were enrolled in an N of one double-blind, controlled trial using 0.5mg/kg prednisone daily. Except for complaints related to cognition, these patients presumably had inactive SLE at enrollment. The authors reported improvement in cognition in 5 of the 8 subjects who completed the trial. The use of antiplatelet or anticoagulant therapy in SLE patients with antiphospholipid antibodies for the treatment of cognitive dysfunction without evidence of thromboembolic phenomena has a theoretical basis but lacks evidence for efficacy and remains controversial. Pharmacologic treatment aimed at “cognitive enhancement” has not yet been studied in SLE and has only recently been attempted in conditions such as MS (209). Such treatments may ultimately prove to be efficacious in disorders such as MS (210) and may also have potential applications in SLE. Other pharmacologic agents have been developed for the treatment of cognitive dysfunction-associated conditions, such as Alzheimer's disease and attention deficit disorder. However, the variability in the presence and persistence of cognitive deficits in SLE patients, as described earlier in the chapter, as well as the lack of biologic plausibility for efficacy remain major hurdles for the design of clinical trials. Although the actions of such medications are not disease-specific, there is currently no data to support or refute their use in the treatment of SLE-associated cognitive dysfunction.

Cognitive rehabilitation, which typically involves intensive retraining of cognitive skills, suffers from the same problems of variability in the nature, persistence, and biologic basis when considering the design and implementation of a trial of program efficacy. Although individualized cognitive rehabilitation programs may indeed prove useful for some SLE patients, demonstrating the generalized effectiveness of this approach is challenging. Cognitive rehabilitation programs have been employed in other conditions (e.g., stroke, dementia, traumatic brain injury, MS) to teach patients with cognitive dysfunction the means to functionally adapt to their impairments in order that they can maintain, if not regain, some level of independence. Until recently, no cognitive rehabilitation programs specifically intended for SLE patients have ever been developed. A novel psycho-educational group intervention targeted specifically at SLE patients with self-perceived cognitive dysfunction was designed to improve the performance of common cognitive activities they found problematic (211). Results of a pilot study of this program demonstrated that participation may result in improvement in memory self-efficacy, memory function, and ability to perform daily activities that require cognitive function (212 ,213). Although rehabilitation programs like this are not generally available, lupus patients with verified cognitive dysfunction can be referred for cognitive rehabilitation to a neuropsychologist or occupational therapist with expertise in cognitive retraining.

Summary

Neuropsychiatric manifestations of SLE are an important and challenging aspect of the disease in part because of to the diversity of NP events and their lack of specificity for lupus. Although the ACR nomenclature and case definitions have provided a much needed template for more

precise characterization of NP events in lupus cohorts, there continues to be significant variability in the reported prevalence of NP disease. This includes psychiatric disorders and cognitive impairment, which are amongst the most frequently reported NP syndromes. The primary pathogenic mechanisms contributing to NP-SLE include microangiopathy, production of autoantibodies, and inflammatory mediators. Neuroimaging is a potentially powerful tool for advancing our understanding of NP-SLE, and in the future may also facilitate the selection of the most appropriate therapies and objectively document their effectiveness.

Sjögren Syndrome

The most common eye and mouth symptoms found in SLE patients are “dryness” and may fulfill criteria for Sjögren syndrome (SS) (keratoconjunctivitis sicca [KCS]). Table 39-1 lists the current diagnostic criteria for primary SS. There has been considerable confusion about diagnostic criteria for primary SS during the past decade with the incidence of disease varying over 10-fold from the European Economic Community (EEC) criteria (2% to 5% of the general population) to the San Diego criteria (0.5% to 1% of the population). The current consensus European-American criteria for SS (Table 39-1) has incidence about 0.5%. When these symptoms occur in patients who fulfill criteria for SLE, the SS is termed 2° SS.

At the level of pathogenesis, there is a close overlap between primary SS and systemic lupus erythematosus (SLE). Indeed, if one considers SLE to be a group of diseases with each group characterized by particular autoantibodies and HLA-DR predisposition, then SS patients are very similar to the subset of SLE patients who have antibody to SS-A antibody and human leukocyte antigen (HLA)-DR3. A convenient way to think of SS is that it is “SLE with a homing receptor” for the lacrimal and salivary glands (as well as other extraglandular organs that may be affected). Thus, SS patients present with more cellular infiltrative manifestations (lacrimal and salivary glands leading to sicca symptoms, interstitial pneumonitis and nephritis, and lymphoproliferative disorders), whereas generally, our SLE patients have characteristic manifestations that appear more antibody mediated (glomerulonephritis rather than interstitial nephritis, pleurisy rather than interstitial nephritis, hemolytic anemia rather than lymphoma). However, the overlap of both cellular infiltrative and antibody-mediated mechanisms in particular SS and SLE patients often makes the diagnostic differentiation difficult or impossible (1). The main reason for labeling a patient as SS is to bring attention to their particular ocular and oral needs, as well as to their tendency toward cellular infiltrative extraglandular manifestations, including lymphoma.

History

The first descriptions of SS were reported by European clinicians between 1882 and 1925 (2). In 1892, Mikulicz observed a man with bilateral parotid and lachrymal gland enlargement that was associated with massive round-cell infiltration. In 1925, Gougerot described three patients with salivary and mucus gland atrophy and insufficiency progressing to dryness. In 1933, Henrik Sjögren reported detailed clinical and histologic findings in 19 women with xerostomia and KCS, of whom 13 had chronic arthritis. In 1953, Morgan and Castleman (3) concluded that SS and Mikulicz disease were the same entity. The distinction between primary and secondary SS was suggested by Bloch in 1960 (4). The concurrence of SS and SLE was described first by Morgan in 1954 (5), and numerous investigators in the 1950s and 1960s observed lupus erythematosus (LE) cells in patients with SS and lupuslike features. The incidence of SLE in patients with SS has been estimated to be about 20%.

Clinical Manifestations of SS

SLE patients may exhibit a wide range of symptoms involving the head and neck. These include local manifestations of their systemic autoimmune disease, infectious processes related to immune suppression, and noninfectious complications from their medications. The differential diagnosis and treatment of these problems is often difficult. Dryness can result from many other causes including drugs with anticholinergic side effects (including certain herbal supplements) and is associated with infections such as hepatitis C or retroviruses, autonomic neuropathy, depression, and fibromyalgia. In many instances, the patient may have low-titer, positive antinuclear antibodies (ANA) and have vague symptoms of dryness, fatigue, and myalgia. The differential diagnosis of these patients represents a challenge because these symptoms are so common in the population and “false-positive” ANA titers frequently are found in the normal population (6). For example, low-titer antinuclear antibodies (1:40) are found in up to 23% of normals, and the misleading “cut-off” values that come as an interpretation with these laboratory reports results in confusion of the patient and the referring physicians (6). Even at a higher titer ANA of 1:640, the actual risk for developing SLE (or SS) is less than 1 in 100 (7). Thus, it needs to be emphasized that an ANA may be used to confirm the clinical diagnosis of SLE or SS, but these tests lack the specificity to serve as a sole basis

for diagnosis (7). Further, enzyme-linked immunoabsorbent assays (ELISAs) to detect antibodies to SS-A and SS-B antigens depend heavily on the quality of the antigen used in the assay and have great variability (discussed below) (8). There is a frequent misconception that commercial kits for detection of these autoantibodies utilize cloned gene products and thus are entirely reliable; in fact, difficulties with production of cloned antigens (particularly because of the importance of their structural folding and their glycosylation) has led to difficulty in their use in the clinical laboratory and most commercial assays continue to depend on antigens prepared by affinity chromatography (8). Thus, there is lack of reproducibility for the detection of antibody to SS-A and SS-B, resulting in further confusion in diagnosis when antibody titers are used as a primary tool for diagnosis. In summary, there are several "take home lessons" for rheumatologists: (1) all patients with complaints of dryness do not suffer from a systemic autoimmune disease, but it is important that all patients with objective ocular and oral dryness deserve instruction in conservative treatment; (2) the most difficult diagnostic problem is the decision whether symptoms are from a systemic autoimmune process and thus require a more aggressive therapeutic intervention; and (3) laboratory methods can be used to support a clinical diagnosis, but should not be the sole basis for diagnosis. Also, it is important to recognize that the clinical presentation and severity of SS appears to vary in different ethnic groups and in different parts of the world. For example, in ethnic groups such as Greek or Chinese SS patients there is a higher incidence of severe interstitial nephritis (patients often present with severe hypokalemia) (9) and the types of rashes (i.e., facial erythema annulare) is more common in Japanese SS patients (10) than seen in Caucasian SS patients. Different viruses (ranging from hepatitis C, HTLV-1, and human immunodeficiency virus [HIV]) that can mimic SS have very different incidence among these groups. As the world becomes increasingly filled with international travelers, a spectrum of patients and medications not used in the United States (particular herbal and "nutritional" medications) may increasingly lead to confusion in diagnosis.

Table 39-1: Preliminary Classification Criteria Developed by the EEC

I. Primary Sjögren syndrome (SS) (if at least 4 items present)

A. Ocular symptoms (at least 1 present)
   1. Daily, persistent, troublesome dry eyes for more than 3 months
   2. Recurrent sensation of sand or gravel in the eyes
   3. Use of a tear substitute more than 3 times a day

B. Oral symptoms (at least 1 present)
   1. Daily feeling of dry mouth for at least 3 months
   2. Recurrent feeling of swollen salivary glands as an adult
   3. Drink liquids to aid in washing down dry foods

C. Objective evidence of dry eyes (at least 1 present)
   1. Schirmer I test
   2. Rose Bengal
   3. Lacrimal gland biopsy with focus score ≥1

D. Objective evidence of salivary gland involvement (at least 1 present)
   1. Salivary gland scintography
   2. Parotid sialography
   3. Unstimulated whole sialometry (≥1.5 mL per 15 minutes)

E. Laboratory abnormality (at least 1 present)
   1. anti-SS-A or anti-SS-B antibody
   2. Antinuclear antibody (ANA)
   3. IgM rheumatoid factor (anti-IgG Fc)

Differential Diagnosis of Primary Sjögren Syndrome and Sjögren Syndrome with Systemic Lupus Erythematosus

The rheumatologist often is faced with the diagnostic difficulty of distinguishing 1° SS from 2° SS associated with SLE. These patients frequently share similar symptoms (arthralgias, myalgias, fatigue, rashes, and visceral involvement from vasculitis) as well as laboratory test findings including positive ANA and antibody to SS-A (Ro) (11). Indeed, it has been argued that SLE represents a spectrum of patients where subsets are "artificially" subdivided on the basis of their serology and the serology (i.e., antibody against SS-A) correlates better with their genotype than with their clinical features (12 ,13). If one accepts the premise that patients with SLE constitute a heterogeneous group of patients in terms of pattern of organ involvement and ANAs (13), then it reasonably can be argued that 1° SS patients represent a forme fruste of SLE where patients have only four of the necessary five criteria for diagnosis of SLE (14). The group of patients with 1° SS is genetically heterogeneous even among patients who have similar ethnic backgrounds. However, a significant proportion of Caucasian 1° SS patients have similar human leukocyte antigen (HLA) associations (HLA-DR3, and the linkage associated DQ alleles) that are found in a subset of SLE patients (15 ,16). Further, our experience with multiplex families (i.e., one member with 1° SS and another member with autoimmune disease such as RA, SLE, or scleroderma) in China (17) and in another study of a multiplex Caucasian family (18), family members (siblings, mothers, daughters) of 1° SS patients had an almost equal frequency of 1° SS or SLE. Similarly, in a large, multiplex family with multiple cases of SLE, family members with SS were noted (19). Thus, it might be postulated that certain genetic factors predispose to either 1° SS or a subset of SLE, whereas environmental (or gene recombination

events) then propel the genetically susceptible patient down the clinical pathway of either 1° SS or SLE. In this regard, the close overlap of clinical symptoms of 1° SS and a subset of SLE would be expected. We would propose that SS develops in those patients with a more lymphocyte- aggressive disease, as manifested by the infiltration of lymphocytes (predominantly $CD4^+$ T cells) into tissues normally lacking lymphoid infiltrates (i.e., lacrimal and salivary glands, as well as lung or renal parenchyma), as extension of this hypothesis is the increased frequency of lymphoma in SS patients (20). In comparison, many of the manifestations of SLE patients appear to result from pathogenetic antibodies that lead to immune-complex disease or specific antibodies against platelets or glomerular antigens. Although there is clearly a great deal of overlap in 1° SS and SLE in this regard, this is a relatively simple model for prognostically evaluating patients' symptoms (e.g., interstitial pneumonitis, interstitial nephritis, or increased lymphoma) with features of SS or SLE. Table 39-2 lists some differential points between primary SS and secondary SS with SLE.

Table 39-2: Differential Points between Primary Sjögren and Secondary Sjögren with Systemic Lupus Erythematosus

1. Sjögren syndrome (SS) is a systemic autoimmune disease characterized by objective signs of ocular and oral dryness.
2. It often is difficult to distinguish primary SS from patients with systemic lupus erythematosus (SLE) because a subset of SLE patients have secondary SS and have antibody to SS-A. Glomerulonephritis is more common in SLE and interstitial nephritis is more common in SS. Certain types of skin rashes are more common in SS patients (especially hyperglobulemic purpura) than in SLE (malar rashes), whereas both may have vasculitis rashes.
3. It often is difficult to distinguish primary SS, secondary SS, and fibromyalgia, where sicca symptoms are common and low-titer antinuclear antibody (ANA) are relatively common (up to 20% of normal adults at titer 1:40, and 5% at titer 1:160); minor salivary gland biopsies and antibodies against SS-A help distinguish SS from fibromyalgia.
4. The lip biopsy must be read by individuals experienced in their evaluation, because only focal lymphocytic infiltrates should be quantitated and nonfocal infiltrates are nonspecific. An increased sensitivity and specificity of diagnosis may be achieved by evaluating several serial sections of minor salivary gland biopsies (183), in a method analogous to examination of serial sections of temporal artery biopsies in patients with giant cell arteritis (183).
5. Hepatitis C patients often have sicca symptoms and a subset have a positive ANA.
6. Symptoms of ocular irritation may result from blepharitis in addition to aqueous tear deficiency and symptoms of oral discomfort may be from superimposed oral candida infections.

Presently, the label “Sjögren syndrome” alerts the rheumatologist to the particular ocular and oral needs of the patient with sicca symptoms as well as to their particular problems of lymphoproliferative disorders. Thus, it is important for rheumatologists not to get bogged down in currently fashionable debates over classification criteria. The key point is that diseases are best classified by etiology and that the etiology of SLE and SS remains unknown; thus, we are left with classifying clusters of symptoms/signs and the key point is how to determine prognosis and treatment. The pattern of rashes in 1° SS patients differs somewhat from those in most SLE patients. Malar rashes are more common in SLE, because of the presence of malar rash serving as criteria for SLE. However, the malar rash of SLE must be distinguished from rosacea, which can contribute to blepharitis and ocular symptoms mimicking 1° SS (21). Patients with 1° SS have a relatively higher incidence of hyperglobulinemic purpura based on retrospective studies (22), and the purpura may be associated with a type II mixed cryoglobulin (23) containing a monoclonal rheumatoid factor with a particular idiotype (24). In Japanese patients, particular types of rashes such as erythema annulare (particularly with location on the face) are more common in SS than SLE patients) (10 ,25). In the past, a psoriaform skin rash termed “subacute” lupus when associated with a negative ANA (done using mouse kidney substrate) and a positive anti-SS-A antibody (26). These patients had a high frequency of SS-like symptoms. In recent years, a different substrate for detection of ANAs (Hep 2 cells) has been used and patients with “subacute lupus” now are shown to have a positive ANA (27) and are frequently diagnosed as SS (28 ,29 ,30). A wide range of additional skin lesions is found in both SLE and SS, ranging from leukocytoclastic vasculitis to the purpura associated with low platelets (31). Mouth (intra-oral) lesions occur in both SS and SLE. However, the characteristic SLE lesion is an oral ulcer. The most common mouth lesion in SS patients is from oral candida (32). These lesions are recognized by the presence of angular cheilitis and erythematous patches (often resembling telangiectasias) on the hard palate (33). The use of corticosteroids and antibiotics predispose to oral candida in a patient with decreased salivary flow. Also, oral lesions in patients on methotrexate may not be a result of drug allergy, but to oral candida.

Sjögren Syndrome: Pathogenesis of Symptoms

It is important to recognize that SS patients complain about their dry, painful eyes, and mouth, whereas rheumatologists talk about the patient's lacrimal and salivary glands, their autoantibodies, and acute phase reactants. The patient is describing ocular symptoms because of increased friction as the eyelid (particularly the upper lid) passes over the orbital globe. When the tear film is inadequate and the “viscosity” of movement between the eyelid and globe is inadequate, the lid adheres to the surface layers of the globe and can

actually pull epithelial cells away from the surface layer of the conjunctiva and cornea. It is these epithelial defects that are viewed clinically as “keratoconjunctivitis sicca” and corneal abrasions. As a result of the “insult” to the epithelial surface, an inflammatory response (release of cytokines and influx of inflammatory cells) occurs. As a result of the lack of adequate tear film, the “wounding” process continues and the normal healing process is impaired because an adequate tear film is required to provide “nutritive” and anti-inflammatory substances. Thus, in SS patients, exposure to certain environmental stresses can lead to KCS lesions that are very slow to heal. Similarly, the tongue and buccal mucosal surfaces require lubrication for the tongue to move around the mouth and for the actions of speaking and swallowing. However, there are important differences in the oral symptoms and the ocular symptoms. The eye is a “clean” environment (i.e., not colonized) while the mouth has high levels of resident aerobic and anaerobic organisms. A dry mouth is not necessarily a painful mouth. Common problems in the mouth involve changes in the microbial flora, especially with the emergence of chronic candidiasis (discussed below) or periodontal disease as a result of particular organisms. Further, there are important differences in the types of neural innervation, mucins, cytokines, and enzymes in the secretions of the mouth and the eye. Figure 39-1A shows normal lacrimal and salivary flow regulated through feedback mechanisms. The mucosal surfaces of the eye and mouth are heavily innervated by unmyelinated fibers that carry afferent signals to the lacrimatory or salvatory nuclei located in the medulla. These medullary nuclei, which are part of the autonomic nervous system, are influenced by higher cortical inputs including taste, smell, anxiety, medications, and depression. The efferent neurons innervate both glandular cells and local blood vessels. The blood vessels provide not only water for tears and saliva, but also growth factors including hormones (e.g., insulin) and matrix proteins (e.g., fibronectin and vitronectin) of the lacrimal and salivary glands. In response to neural stimulation through muscarinic M3 receptors and vasoactive intestinal peptide (VIP) receptors, glandular acinar and ductal cells secrete water, proteins, and mucopolysaccharides (mucins). This complex mixture forms a hydrated gel that lubricates the ocular surface (i.e., tears) and the oral mucosa (i.e., saliva). In the simplest model of SS (Fig. 39-1B), the lacrimal or salivary gland is incapable of adequate response to neural signals as a consequence of local immune infiltrates and their derived cytokines. The actual processes in SS or autonomic neuropathy are more complicated than indicated in these schematic diagrams, which are designed primarily to emphasize that salivation or lacrimation are part of a regulatory circuit involving the central nervous system (CNS) (34). The stages in pathogenesis of SS include: (1) the change of small endothelial vessels to high endothelial venules that express adhesive molecules and release chemokines, such as regulated on activation, T cell expressed and secreted (RANTES) and lymphotactin; (2) the migration

of CD4+ T cells into the gland in the center of the lobule of the lacrimal or salivary gland where they form a cluster (or foci) of lymphocytes; (3) release of cytokines including interferon-γ and tumor necrosis factor (TNF)-α by the T cells and interleukin 1 (IL-1) by the epithelial cells; (4) upregulation of HLA-DR, DQ, and invariant chain (Ii) by the epithelial cells and perhaps costimulatory molecules such as B-7; (5) upregulation of perforin and granzyme that may lead to damage of ductal cells; (6) increased expression of Fas on CD4+ T cells and Fas-ligand on the epithelial cells, that may lead to increased apoptotic death of epithelial cells; (7) increased production of bcl-2, and bcl-x by the lymphocytes that helps prevent their own apoptosis; and (8) clonal expansion of B cell clones and increased risk of karyotypic translocation [t 14:18] associated with transformation to a non-Hodgkin lymphoma (35). As a result of mutual stimulation of T cells, B cells, and epithelial cells, cytokines such as IL-1, IL-6, and TNF-α are released and lead to increases of acute phase reactants including ESR (fibrinogen) and C-reactive protein that are measured in clinical assays. Table 39-3 , summarizes several of the pathogenetic steps. Figure 39-2A shows the lymphocytic infiltrates in a minor salivary gland biopsy, in comparison to a normal gland (Fig. 39-2B). The infiltration of the lymphocytes (shown to be CD4+ T cells by immunohistology) under the basement membrane and in direct contact with the epithelial cells is shown in frames C and D. The changes in the high endothelial cells containing red blood cells (frames E and F) and adherent T cells that are migrating through the vessel wall are seen under low-power electron microscopy.

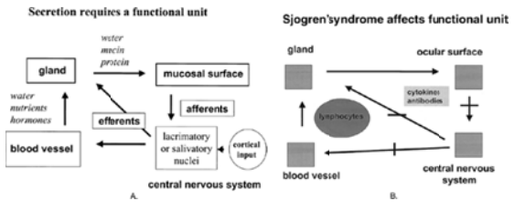

Figure 39-1. A, "Circuit" that controls normal tear flow or salivation and interruption of the circuit in patients with Sjögren syndrome. The stimulation of the ocular or oral mucosal surface leads to afferent nerve signals that reach the lacrimatory or salivatory nuclei in the medulla. Efferent neural signals stimulate both blood vessels and glandular epithelial cells. The medullary signal may be affected by cortical inputs that reflect stimuli such as taste, smell, anxiety, or depression. The efferent neural signal to the gland is mediated by acetylcholine. The gland contains receptors for acetylcholine of the muscarinic class, particularly M3 receptors (shown by arrow). **B**, In Sjögren syndrome, lymphocytic infiltrates in the gland secrete cytokines that inhibit the release of neurotransmitter and the response of receptors that initiate glandular secretion.

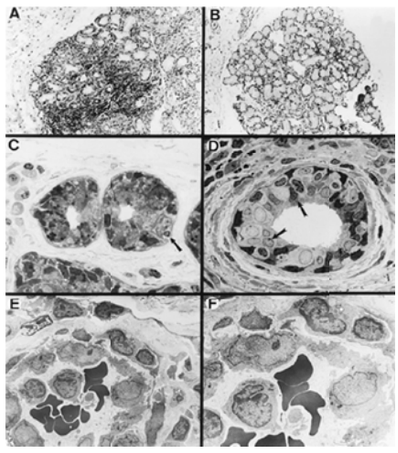

Figure 39-2. Minor salivary gland biopsy from patients with Sjögren syndrome **(A)** and from a patient with fibromyalgia (a histologically normal biopsy) in **(B)**. Higher power views of the Sjögren biopsy are shown in frames **(C)** and **(D)**, with low power electron microscopic views in frames **(E)** and **(F)**.

Table 39-3: Pathogenetic Features of Sjögren Syndrome

1. Sjögren syndrome is a systemic autoimmune disease. The target organs (lacrimal or salivary glands) are accessible to biopsy, making this disease well suited for clinical-pathologic correlations.
2. Biopsies of lacrimal or salivary glands indicate that only about 50% of the acinar or ductal structures are destroyed. Thus, the severe dryness results from dysfunction of the residual glands. This may be the result of release of cytokines, metalloproteinases, or autoantibodies that interfere with glandular function or their response to neurotransmitters.
3. The predominant infiltrate in the glands is CD4+ T cells (memory phenotype) that release Th1-like cytokines. However, the lymphomas that develop with increased frequency are because of B cell non-Hodgkin lymphomas.
4. The epithelial cells are not merely innocent targets in the pathogenesis. In animal models, intrinsic defects in glandular development may play a role in generating tissue-specific autoantigens. Early in the disease, chemokines are secreted and later in the disease, the epithelial cells express class II histocompatibility antigens and secrete proinflammatory cytokines.

A new way to look at both SS and SLE is that the immune system is hyperreactive to different "danger" signals that usually work by triggering the innate immune system (i.e., activation of dendritic cells to liberate type I interferon) (36). Using methods of immunohistology and gene profiling, numerous IFN-α–producing cells were detected in salivary gland biopsy specimens, despite low IFN-α levels in the serum (37). Autoantibodies to RNA-binding proteins, combined with material released by necrotic or late apoptotic cells, were potent inducers of IFN-α production in plasmacytoid dendritic cells (PDCs). It appears that RNA-containing immune complexes (such as anti-SS antibody) triggering PDCs by means immune complexes that interact with Toll 7 receptor and Fc-γ receptor IIa (37).

Thus, a unified theory of SS pathogenesis might include the ability of multiple pathways (including viral injury) to initiate the production of IFN in the salivary/lacrimal glands as a result of activation of "danger" pathway (36 ,38), and the continued IFN-α synthesis is perpetuated by RNA-containing immune complexes (particularly SS-A antigen/anti–SS-A antibody) (37). These locally produced immune complexes contain dsRNA (hYRNA) that activate local PDCs to prolong IFN-α production at the tissue level. The SS patient is predisposed to make anti-SS antibody because of HLA-DR3, (and linked DQ loci) and perhaps complement C4 deficiency. This IFN-α promotes the

autoimmune process by a vicious circle-like mechanism, with increased autoantibody production and formation of more endogenous IFN-α inducers.

Evaluation of Symptoms in the Dry-Eye Patient

SS patients usually describe a burning or “foreign” body sensation in their eyes. The symptoms often are worse at the end of the day and are relieved by the use of over-the-counter (OTC) artificial tears (which most patients have tried prior to seeing a rheumatologist). Symptoms of itching are poorly correlated with objective findings of keratoconjunctivitis (39). Patients may be relatively symptom free until their condition is precipitated by the use of medications with anticholinergic side effects (such as OTC cold remedies or prescription medications) or environmental stress to the tear film (such as airline travel or exposure to dry winds). Often identification and alteration of the offending medication may be all that is required. Contact lenses, especially the soft gas-permeable type, can contribute to corneal abrasions because adequate tear film may not be available to wash out foreign substances trapped under the lens. Thus, if contact lenses are worn, they should be taken out at night and the patient needs to be cautioned about the risk of corneal abrasions. One study has suggested that SS patients should be offered photorefractive surgery (i.e., excimer laser keratectomy) if they do not tolerate contact lenses (40); however, caution about the use of invasive procedures involving the cornea needs to be exercised until long-term follow-up of SS patients with refractive surgery (essentially a cosmetic procedure) is available.

When evaluating the patient with a complaint of dry eyes, it is important to determine if the objective signs of dry eyes are commensurate with the patient's symptoms. Methods to measure the integrity of the corneal surface and tear film include rose bengal, fluorescein staining, lissamine green staining, or the tear breakup time are described below. For example, the absence of a significantly abnormal exam using rose bengal (a test that is performed easily by the rheumatologist) should suggest a search for additional causes to explain the patient's ocular complaints. These may range from eye strain (poor refraction), blepharitis (irritation and low-grade infection of the Meibomian glands in the lids), blepharospasm (uncontrolled blinking from an increased local neural reflex circuit), or symptoms resulting from anxiety or depression (41). Unstimulated tear flow is referred to as basal flow. This tear secretion derives from the minor tear glands located predominantly in the upper lid. They probably are stimulated by a local reflex arc involving neural receptors in the lid and probably do not involve neural loops that regulate the major salivary glands. This decrease in basal secretion correlates fairly well with symptoms of dryness but not closely with KCS. Decrease in basal tear flow is very common in the general population, especially the elderly, and does not signify an autoimmune condition. A decrease in basal tear flow also may be the initial symptom in SS patients. These symptoms of eye discomfort occur even though the patient can generate tears when they cry (i.e., supratentorial stimulation) or are exposed to certain stimuli such as onions (nasal lacrimal reflexes). Tear volume usually is measured by the Schirmer test; however, this test is performed routinely in several distinct ways and the results are often quite different. It is important for the rheumatologist to note the methods of quantitation of tear flow when evaluating patients clinically (or reports by their ophthalmologist) or reviewing the published literature. Many ophthalmologists (and clinical studies) measure the Schirmer I test with topical anesthetic (Ophthaine) and reflects the basal secretory rate of the minor lacrimal glands in the eyelids (i.e., not the major lacrimal glands). This test is sensitive but not specific and may be diminished for many reasons. Most commonly, rheumatologists perform the Shirmer I test in the absence of anesthetic. This value reflects both the minor glands and the stimulation of the major glands. However, the extent of stimulation of the major lacrimal glands is variable. This test is convenient, has less sensitivity, and has more specificity. In addition to the Schirmer I test (either with or without anesthesia), the Schirmer II test provides a rapid way to measure the maximal output of minor plus major lacrimal glands. The Schirmer II test is performed by gently inserting the cotton end of a cotton swab into the nose, where it stimulates the nasolacrimal gland reflex (42). The volume of tearing is measured by Schirmer paper strips without anesthesia. The stimulated tearing reflex involves a neural loop in which afferent fibers from the ocular surface travel to the midbrain (lacrimatory nucleus) where they stimulate efferent adrenergic and cholinergic nerves that travel back to the lacrimal gland (cholinergic) and its blood vessels (adrenergic) (43). A diminished Schirmer II test has good specificity for SS, but lacks sensitivity to early stages of SS. The presence of an increased tearing on the Schirmer II test has been a good predictor of response to oral pilocarpine as a way to stimulate secretions, in the author's experience. A wide range of tear volume flow (i.e., values on the Schirmer I test with anesthesia) occurs in SS patients as well as in normals, and is poorly correlated with signs and symptoms of KCS. Similarly, the volume of saliva produced as basal secretion or after stimulation correlates poorly with symptoms of dry mouth and objective signs of severe periodontal problems (44). This suggests that the qualitative content of tears and saliva (i.e., specific glycoproteins and mucins) plays an important role in the maintenance of ocular and oral mucosal integrity and that decreases in tear volume are not the sole cause of problems. An important implication of these findings is that the next generation of artificial tears, artificial salivas, and toothpastes may contain bio-engineered products that provide these important functions lacking in the currently available products. In

addition to the volume of tears, the quality of the tear film is assessed by simple procedures such as rose bengal. This material is readily available from pharmacies that carry ocular supplies and a single drop is administered into the lower eyelid. After rinsing the rose bengal out with a preservative-free tear, the residual staining of the conjunctiva and cornea can be determined with an ophthalmoscope. Although this evaluation by the rheumatologist does not replace the more accurate evaluation of KCS by slit lamp performed by ophthalmologist, the test does provide a rapid method for assessing the significance of patient's complaints. The rose bengal should not be left in the patient's eye (before rinsing out with an artificial tear) for a prolonged period, as this may lead to local irritation. In comparison, lissamine green is reported to cause less irritation, but requires a slit lamp for adequate quantitation. The results obtained with both rose bengal and lissamine green methods are very dependent on the methods for performing the test and the “training” of the observer. In research studies (or in the evaluation of published studies by the rheumatologist), it is important to recognize limitations of the different methods and the variable between different observers.

Evaluation of Symptoms of Dry Mouth

The principal oral symptom of SS is mouth dryness with a broad range of severity. Not all patients complain of dryness specifically; many describe difficulty in swallowing food, problems in wearing dentures, changes in their sense of taste, increased incidence of dental caries, chronic burning symptoms, intolerance to acidic or spicy foods, and the inability to eat dry food or speak continuously for more than a few minutes. Nutrition may be compromised and patterns of sleep disturbed. On examination of the mouth, the SS patient lacks the normal salivary pooling under the tongue and may have rapidly progressive caries. The mouth frequently exhibits petechial (i.e., small, red, nonpalpable) lesions on the hard palate and/or a lichen planus-like appearance (fine white, lacy strands) on the buccal mucosa. Also, these lesions only may be detected in the recesses of the buccal mucosa on careful examination. These petechial and lichen planus-like lesions result from chronic oral candidiasis infection in the SS patient; it is uncommon for an SS patient's mouth to exhibit the plaquelike appearance (thrush) found in severely immunocompromised patients. Another manifestation of oral candidiasis in the SS patient is angular cheilitis, a condition that must be treated at the same time as the buccal mucosal candidiasis. Progressive periodontal disease should be suspected based on the increased need for dental restorations and the presence of cavities at the gum line. The loss of teeth and requirement for dentures at any age, but particularly in the younger patient, may have significant emotional and economic consequences. Patients with dentures may change their social patterns of interpersonal interactions. For example, their social life frequently involves eating meals with friends and the patient may feel uncomfortable about not being able to eat the same foods. Further, the patient's diet may be shifted over to preprocessed foods that often are higher in sugars and thus further accelerates the rate of their periodontal problems.

Systemic Manifestations of Sjögren Syndrome

Patent's with 1° SS as well as those with 2° SS associated with SLE may have a wide variety of systemic manifestations. Table 39-4 lists most of their manifestations, which are also covered in other chapters. However, several of these manifestations (i.e., CNS, lymphoma) have been reported more commonly in 1° SS and will be discussed more fully below.

Table 39-4: Extraglandular Manifestations in Patients with Sjögren Syndrome

Respiratory	Chronic bronchitis secondary to dryness of upper and lower airway with mucus plugging Lymphocytic interstitial pneumonitis Pseudolymphoma with nodular infiltrates Lymphoma Pleural effusions Pulmonary hypertension
Gastrointestinal	Dysphagia associated with xerostomia Atrophic gastritis Liver disease including biliary cirrhosis and sclerosing cholangitis
Skin and Mucous membranes	Candida—oral and vaginal Vaginal dryness Hyperglobulinemic purpura Raynaud phenomenon Vasculitis
Endocrine, neurologic, and muscular.	Thyroiditis Peripheral neuropathy involvement of hands and/or feet and/or feet Mononeuritis multiplex Myositis
Hematologic	Neutropenia, anemia, thrombocytopenia Pseudolymphoma Lymphadenopathy Lymphoma and myeloma

CNS Symptoms of Sjögren Syndrome

Similar to SLE (45), a wide variety of CNS manifestations has been reported in SS patients (46 ,47). These range from vasculitic lesions of the CNS, thrombotic lesions associated with anticoagulants, affective disorders (48), autonomic neuropathy (49), myelopathy (50), cranial nerve neuropathy (51), dystonias (45), and autoimmune hearing loss (52 ,53). One of the main diagnostic problems for the clinician is that many patients with poorly defined neurologic diseases and a positive ANA (and perhaps a positive anti-SS-A antibody) are defined as having SS (or a forme fruste SS) even when they lack objective signs of KCS (54). It is again worth emphasizing that a relatively high normal proportion of the normal population have a false-positive ANA (6), the variation in results among assays for anti-SS-A antibody (8) and that positive ANA have been found in increased frequency in patients with other hematologic disorders that appear distinct from either SLE or SS. Thus, rheumatologists often are faced with a patient with predominantly neurologic or affective disorder problems and a positive ANA for the question of whether immune suppressive therapy is indicated for SS. This problem is certainly most commonly encountered in the patient with symptoms of fibromyalgia where sicca symptoms are a prominent complaint. During litigation regarding the relationship of silicone breast implants and autoimmune disease (55), a slightly higher association (relative risk about 1.5) was found for SS than for SLE or scleroderma (relative risk about 1.0) (56). However, minor salivary-gland biopsies did not support the diagnosis of SS (57 ,58) in those patients studied and suggested that the cause of their dryness could be because of a mild autonomic neuropathy, perhaps associated with their fibromyalgia (59). Several earlier studies suggested a relatively high frequency of demyelination in the CNS in primary SS patients (60 ,61). Although patients with sicca SS may develop symptoms and signs similar to multiple sclerosis patients, several issues remain unclear. First, the markedly increased frequency of demyelinating features was reported during a relatively short period at a single medical center. Longer-term follow-up studies in the same medical center did not confirm the earlier reports of a markedly increased frequency (62). The most likely explanation for the earlier reports derive from the later improved sensitivity of magnetic resonance imaging (MRI) brain scans where it was possible to better distinguish vascular lacunae from regions of demyelination and the improvement of assays for detection of antinuclear antibodies. Second, it was recognized that multiple sclerosis patients may develop dryness as a result of an associated autonomic neuropathy at the level of the CNS, rather than as a consequence of an autoimmune process involving the lacrimal or salivary glands (63). Depression can present in many clinical forms including difficulty concentrating, poor appetite, or as a sleep disorder in both SLE and SS (64). The precise role of inflammation and hormone imbalances

associated with SS as a contributing factor to depression remains unclear, but certainly depression is caused in part by chemical alterations in the brain (65 ,66). Stress, poor sleep, and chronic illness can all contribute to depression. When antidepressant medications are used to help regulate sleep patterns and treat fatigue, drugs with relatively less anticholinergic side effects (such as selective serotonin reuptake inhibitor [SSRI] agents that interfere with serotonin uptake) are preferred over tricyclic antidepressants (often given for fibromyalgia).

Systemic Medications and SS Patients

The overall approach to systemic therapy in the patient with SS is similar to that in the SLE patient. Disease manifestations are subdivided into nonvisceral (arthralgias, myalgias, skin, fatigue) and visceral (lung, heart, kidney, brain, peripheral nervous system). Nonvisceral manifestations generally are treated with salicylates, nonsteroidal agents, and often hydroxychloroquine. Particular attention to difficulty in swallowing pills in the SS patient is necessary, because the decreased salivary content can lead to pills becoming stuck in the midesophagus with resultant erosions of the mucosa. Little improvement with salivary or lacrimal flow rates has been noted with nonsteroidal anti-inflammatory drugs (NSAIDs), although some increase in tearing and salivation may occur after systemic corticosteroids. In terms of NSAIDs for the SS patients, indomethacin is the only agent readily available as a suppository for the patient with difficulty swallowing tablets. Flurbiprofen has been shown in a pilot study to decrease periodontal inflammation and resultant gum disease (67). Among the slow-acting drugs, antimalarials (hydroxychloroquine) have proven useful in decreasing the arthralgias, myalgias, and lymphadenopathy in SS patients (68 ,69), similar to its benefit in some SLE patients (70). We have used hydroxychloroquine (6 to 8 mg/kg/day) in SS patients where there is elevation of erythrocyte sedimentation rate (ESR) and polyclonal hyperglobulinemia, because these laboratory abnormalities suggest that symptoms of arthralgia and myalgia may have an inflammatory cause. In a European study (71), hydroxychloroquine improved ESR but did not increase tear-flow volumes. Comparison of drug benefit in SS patients in European and United States studies is strongly influenced by the very different inclusion criteria for diagnosis of SS (described above). When taken at the proper dose (6 to 8 mg/kg/day), hydroxychloroquine has a very good safety record, although there remains a remote possibility (probably less than 1/1,000) (72) of significant build-up in the eye. For this reason, periodic eye checks (generally every 6 to 12 months) are recommended so that the medicine can be discontinued if there is any significant build-up. The general safety of hydroxychloroquine at these doses has been recently confirmed, particularly in comparison to other available therapies (73 ,74). However, toxicity still must be considered in rare patients and may be associated with abnormalities in electroretinograms (75). In patients with cognitive features associated with SS, the use of atabrine has been advocated (70). However, the patients should be screened for G6PD deficiency prior to this drug and a “yellowing” of the skin is common. This skin change can be partially ameliorated using oral vitamin A (solatene). These agents are not readily available from most pharmacies but can be obtained from compounding pharmacies. For visceral involvement including vasculitic skin lesions, pneumonitis, neuropathy, and nephritis, corticosteroids are used in a manner similar to SLE patients. As in other autoimmune disorders, a key question is how to taper the corticosteroids because these agents have additional problems of accelerating their periodontal problems. Drugs such as hydroxychloroquine, azathioprine, and methotrexate are used to help taper the corticosteroids. In one study, methotrexate appeared most useful (76). It seemed likely that several of the newer agents approved for rheumatoid arthritis (leflunomide and TNF antagonist, etanercept) will prove useful in selected SS patients. Although an initial report suggested benefit of TNF inhibitors (infliximab) (77), subsequent studies by the same group of investigators in a large multicenter trial failed to demonstrate benefit (78). Similarly, etanercept therapy was not statistically beneficial in SS patients including their sense of fatigue and fibromyalgia like symptoms (79 ,80). In early open labeled studies, rituximab may be useful in SS patients with extraglandibular manifestations (81). In some SS patients, cyclosporin may be used (82), but the tendency toward interstitial nephritis in many SS patients limits the usefulness of the drug. For life-threatening illness, cyclophosphamide occasionally is required. However, the increased frequency of lymphoma in SS patients (83) requires caution in the use of cyclophosphamide and has suggested its use as a pulse therapy rather than daily administration.

Topical Therapy for the Dry-Eye Patient

The mainstay of treatment for the dry-eye patient is the regular use of artificial tears (84). When evaluating a particular artificial-tear preparation (Table 39-5), the patient must carefully determine whether: (1) the tear gives benefit but does not last long enough, or (2) the tear burns immediately upon installation. Artificial tears can be considered to have at least two distinct components: the moisturizing component and the preservative. If the tear is helpful, but does not last long enough, then a more viscous tear (such as a higher concentration of hydroxyethylcellulose) or a different vehicle to concentrate the moisturizing element (such as a polymer-like dextran) is indicated. If the tear burns soon after installation, then an irritant reaction to a preservative in the tear must be considered (85). These reactions were much more frequent in the past when benzalkonium chloride and thimerosal commonly were used in artificial tears. However, it should be remembered that these preservatives still are widely used in other ophthalmologic preparations (particularly topical antibiotics) and may contribute to ocular irritation. Irritation of the eyelids in some patients with blepharitis may be related to the preservatives present in some ocular lubricants (used at night), as well as the use of excessive amounts of lubricant at night that plug the Meibomian glands. It is important for the patient to identify environmental factors and medications that contribute to dry-eye symptoms. For example, symptoms of dry eyes will be exacerbated by low-humidity environments such as airplanes, highly air-conditioned offices or department stores, and outdoor areas with strong dry winds. The increased use of tears before the onset of symptoms will be symptomatically helpful and prevent corneal abrasions. The use of cool-mist humidifiers at night (or even in the office) and wrap-around sunglasses when outdoors will help retard tear evaporation. Among patients who wear glasses, the optometrist can add moisture shields to the frames. In patients who like or need to be outdoors, ski goggles can provide a local “moisture chamber.” If the particular artificial tear seems helpful, but benefit does not last long enough, punctal occlusion may be performed on a temporary or permanent basis (86). The puncta are the small openings at the medial aspects of the lids. Blockage of the puncta can be done with silicone plugs or by electrocautery (86). Previously, a trial of “temporary” punctal occlusion with collagen plugs (i.e., temporary occlusion that lasts several days) was advocated. However, clinical experience has indicated that adequate occlusion with collagen plugs only is achieved in a minority of patients and this procedure is no longer advocated as an adequate trial. In some patients, a prior punctal occlusion may reopen and this can be determined easily by instilling fluorescein in the patient's eye. If the puncta has reopened, the fluorescein will drain into the

nasopharynx and the patient will experience the characteristic taste of fluorescein. This simple test will indicate the need (or absence) for repeat punctal occlusion. Topical cyclosporin has been used to improve the keratoconjunctivitis in two multicenter trials of patients with SS, leading to its Food and Drug Administration (FDA) approval (87). High levels of cyclosporin are achieved in the tear film, but there is little absorption into the systemic circulation. The beneficial effects of cyclosporin are as a result of its ability to serve as an anti-inflammatory agent. However, additional benefits may result from stimulation of prolactin receptors on the cell surface of corneal cell and lacrimal gland acinar cells (88). Adjuncts to therapy have included acetylcysteine 10% drops to break up mucous strands, but these drops have the smell of rotten eggs and are thus objectionable to most patients (89). Vitamin A and related preparations have a theoretical role in the treatment of dry eye, because vitamin A-deficient patients have increased keratinization of the corneal surface (90); however, more recent studies have not supported the initial enthusiasm for this form of treatment (84).

Table 39-5: Therapeutic Principles

1. Therapy includes topical replacement of lubrication (artificial tears and saliva), as well as preservation of tears by punctual occlusion.
2. Local inflammation of the ocular surface may be treated by use of anti-inflammatory substances such as topical cyclosporin.
3. The normal tear film or saliva lubricants contain mucins as well as saliva. Although current therapies can replace aqueous secretions, they are still deficient in replacement of the mucin components.
4. New oral medications help stimulate muscarinic M3 secretions to lead to increased water content of secretions.
5. The overall treatment program for Sjögren syndrome is similar to systemic lupus erythematosus with the use of corticosteroids (that can be used for short intervals), nonsteroidal agents, and slow-acting antirheumatic drugs (hydroxychloroquine, methotrexate, and perhaps newer agents such as leflunomide and tumor necrosis factor inhibitors) for chronic management of extraglandular manifestations, and the use of cytotoxic agents (i.e., cyclophosphamide) for life-threatening vasculitis.

Oral Therapy for the Dry-Eye Patient

Pilocarpine, an agonist for muscarinic M3 receptor, has been used as an oral preparation to stimulate the salivary and lacrimal-gland secretion. Initial studies in 1986 indicated the benefit of pilocarpine in SS patients (91). The effects on salivation were more marked than effects on lacrimal stimulation. Also of note, the relationship between subjective symptoms and objective measurements of saliva flow showed a weak correlation. These results were interpreted to indicate that pilocarpine stimulated “water” flow, whereas symptoms correlated with mucin secretion, which was not adequately quantitated in the studies. During recent years, a series of additional studies on oral pilocarpine have been presented (92 ,93 ,94) and led to approval to market for symptoms of dry mouth. The available dosage is 5 mg up to four times daily. The most common side effect is increased sweating or gastrointestinal intolerance, which generally is controlled by decreasing the dose. A recent clinical study using a different oral-muscarinic agonist (cevimeline, Snow Brand SNI-2077) was presented in abstract form (95). In comparison to pilocarpine: (1) cevimeline has a longer half life (4 hours) than pilocarpine (1.5 hours); and (2) cevimeline has a higher specificity for muscarinic M3 receptor (salivary and lacrimal gland) in comparison to muscarinic M2, (cardiac tissues) by about 10-fold. This ratio of binding to M3 receptor (i.e., efficacy) and M2 receptor (i.e., toxicity) may prove important. In the clinical studies, an objective improvement in tear film as measured by exfoliative cytology was reported with cevimeline, which the same investigators had not seen in their prior studies with pilocarpine in the same population of study patients (95). In SS patients and normal controls treated with cevimeline, the secretion rates of amylase and IgA showed significant increases in both groups (96). The secretion rate of lysozyme significantly increased only in the control group, whereas the secretion rate of secretary component C (SCC) significantly increased only in the SS group. Cevimeline augments not only the salivary flow rate but also the secretion rate of some digestive and/or defense factors from infections. It may be beneficial for SS patients to continue taking cevimeline to prevent oral infections, and other serious sequelae. Systemic sialagogues have been used to increase salivation. Three agents have been studied in controlled trials. Bromhexine, a mucolytic agent, was not found to increase salivary flow rate but patients described subjective benefit (97). Anetholethrithione (Sialer) showed significant effects on saliva output in one study of SS patients with mild secretory hypofunction (98); however, a later study failed to find a significant response in patients with severe hypofunction (99). A series of controlled studies have indicated that pilocarpine exerts stimulatory properties in SS and postradiation therapy (91 ,100). The drug acts primarily as a muscarinic-cholinergic agonist with mild ß-adrenergic activity. In these studies, pilocarpine 5 mg three times a day increased salivary flow for several hours, in comparison with placebo (101). Side effects were common, including sweating, flushing, and increased urination (101). Further studies will be required to compare this treatment with other agents containing iodide (SSKI or organidin) that are occasionally helpful in some SS patients. A dry mouth is not necessarily a painful mouth. It is common for an SS patient to develop a low-grade oral yeast infection (33). Predisposing factors include recent use of antibiotics and/or corticosteroids. Treatment of this problem is particularly difficult in the patient with dentures, because continued excoriation of the mucosal surface occurs. Many topical antifungal drugs (including Mycelex troches) are available, but these oral preparations suffer from a low content of antifungal agent and a high concentration of glucose (to improve the taste) and thus contribute to dental decay if used chronically (33). The reason for inclusion of dextrose (rather than aspartame as a “sweetener”) was because of concern about long-term effects of aspartate by the FDA at the time when the drug was first introduced; attempts by the author to have Mycelex reformulated without dextrose by the manufacturer have not been successful. Nystatin and clotrimazole (available as vaginal suppositories that can be sucked) are both helpful, but must be sucked for about 20 minutes twice daily for at least 6 weeks to prevent recurrence of oral candidiasis (102). Patients with very dry mouth will require periodic sips of water to help dissolve the troches. For angular cheilitis, topical antifungal creams are used two to three times per day for several weeks. This must be done concurrently with the treatment of intraoral candida treatment, because the angular cheilitis serves to reinfect the buccal mucosa (and vice versa). To permit drug access to all intraoral mucosal sites, patients must remove their dentures while antifungal tablets are dissolving. The dentures

also must be treated to remove traces of candida, and the method of disinfectant must be discussed with the dentist. However, it usually is sufficient to soak the complete denture overnight in benzalkonium chloride (for example, a1/700, dilution of the surgical-scrub solution, Zephiran). The dentures must be carefully cleaned with a toothbrush and nystatin powder must be applied to the fitting surfaces of the upper denture before reinserting the denture. In extreme cases, a short course of oral antifungal therapy (such as ketoconazole or fluconazole) may be required to control oral candidiasis. The use of topical fluorides may help protect dental enamel. In some patients, a neutral fluoride drop may be applied by toothbrush or by their oral hygienist. In other patients, direct contact of the dental surfaces and the fluoride gel can be achieved by using dental plates at night to apply the fluoride. These plates are made specifically for each patient by their periodontist. Additionally, varnishes may contain fluoride, and a new generation of varnishes additionally release antibiotics that may retard periodontal disease, oral candidiasis, and caries (87). The use of correct technique of toothbrushing to massage the gums and remove debris is important, because this normal function of saliva is diminished in SS patients. In some patients, a rotating toothbrush (such as Oratec [Oratec Products, Inc.]) is useful, together with regular oral hygiene from a technician experienced in dry-mouth care. A variety of saliva substitutes are available. They differ in their flavoring agents and preservatives. MouthKote (Parnell Pharmaceuticals, Inc.) and Salivart (Xenex Laboratories, Inc.) sprays contain mucins, which are glycoproteins that help lubricate the mouth and thus provide relief for a longer time than simply rinsing with water (103). They can be obtained by calling 1-800-457-4276. After administration of these sprays, parotid flow rates are increased for 7 to 8 minutes in SS patients; however, the sense of “oral well-being” may last for several hours. Also, the use of oral balance gel at night may prove helpful and may be obtained by phone (. Electrical (vibrating) stimulation was used to stimulate saliva in some patients with mildly decreased flow rates (104), although the cost of the apparatus has precluded wide usage. A single-blinded, controlled trial was conducted to test the efficacy of low-dose oral human IFN-α to improve salivary function in patients with SS (105). Fifty-six outpatients with primary and four patients with secondary SS were assigned randomly into treatment groups of either IFN-a or sucralfate (control). The IFN-α (150 IU) or sucralfate (250 mg) was given orally three times a day for 6 months. After 6 months of treatment, 15 of 30 (50%) IFN-α-treated patients had saliva production increases at least 100% above baseline, whereas only 1 of 30 (3.3%) sucralfate patients had a comparable increase ($p = 0.001$). Serial labial salivary- gland biopsies of nine IFN-α responder patients showed that lymphocytic infiltration was significantly decreased ($p = 0.02$) and the proportion of intact salivary-gland tissue was significantly increased ($p = 0.004$) after the IFN-α treatment. This agent is currently in double-blind trials.

Special Therapeutic Considerations in the Dry-Eye Patient

Anesthesia and Surgery

SS patients have particular problems during the preoperative, perioperative, and postoperative periods. The normal preoperative instruction is no fluids by mouth after dinner or midnight on the day prior to surgery. In the absence of normal saliva flow, these patients have great discomfort that can be reduced by the use of artificial salivas. Because the main concern is aspiration of stomach contents during anesthesia, these patients can safely use oral mouth sprays such as MouthKote (described above) without increased risk. These also are useful in postoperative patients including those who are not able to take food by mouth. Operating rooms and postoperative recovery areas are maintained at extremely low humidity, particularly as nonhumidified oxygen blows over a face mask. Therefore, SS patients have increased risk of developing corneal abrasions during surgery and in the postoperative setting. The decreased blink reflex of the patient during anesthesia further contributes to this problem. The administration of ocular lubricants prior to surgery and in the postoperative recovery suite will reduce the chance of this complication. The patient is advised to take their Refresh PM (Allergan) or GenTeal (CIBA) ointment with them to the hospital. This will allow the ointment to be readily available for the anesthesiologist. It is increasingly common for hospitals to tell the patient to not bring their medications with them to the hospital (because all medications must be identified by the nurse for medical legal reasons) but specialty medications such as ocular or oral lubricants are not readily available in most hospitals. The patients should bring their medications in labeled containers (including patient name and name of medication) to minimize the work in “logging in” their own medications. The patient may expect a certain resistance from the nurse when they present their own medications (more work for the nurse), but they should persist, explaining that their rheumatologist wanted them to have their ocular and oral lubricants available. (We have yet to see a first-morning case delayed while the anesthesiologist waited for the pharmacy to send them a tube of lubricant, so better for the patient to bring their own. Indeed, we often tape the chart shut with a tube of lubricant attached to make sure it is “seen” by the anesthesiologist). Upper airway dryness of the SS patient may lead to mucus plug inspissation during the postoperative period, followed by obstructive pneumonias. The use of humidified oxygen and avoidance of medications that excessively dry the upper airways (i.e., used by anesthesia to control secretions) will help prevent this problem. Also, adequate hydration and respiratory therapy to keep airways clear is important. This problem has become more common because current practice is for one anesthesiologist to take the history and a different one to perform the procedure. Therefore, we advocate that the patient take the “special

instructions at time of surgery" page in this chapter with them at the time of surgery. An additional problem for the anesthesiologist is the poor state of teeth in the SS patient. Thus, a higher risk of damage to teeth during intubation must be considered. Not only can this lead to loss of the teeth and their subsequent aspiration, but these patients have great expense in preparing dentures to their remaining teeth that will be greatly affected by any further tooth loss. Finally, assessment of the "fluid status" of the SS patient in the postoperative period may be relatively difficult. Normal clinical clues such as the moisture in the ocular and oral membranes may be quite misleading. Further, some SS patients have a tendency for interstitial nephritis, which prevents adequate urine concentration and fluid balance. This problem may be exacerbated by antibiotics such as aminoglycosides.

Chapter 40
Ocular, Aural, and Oral Manifestations

James T. Rosenbaum

SLE and the Eye

Systemic lupus erythematosus (SLE) may affect any organ or tissue in the body and the eye is no exception. Although the human eye measures less than 3 cm from cornea to retina, the eye contains a diverse array of structures, and almost any of these can be the target of inflammation. The manifestations of SLE in the eye are therefore varied and range from dry eye, infiltrative keratitis, scleritis, episcleritis, retinal vasculitis, optic neuropathy, and orbital inflammation.

The commonest of these manifestations is dry eye in the form of keratoconjunctivitis sicca as a result of secondary Sjogren syndrome. Chapter 39 discusses this topic in detail. Of the other ocular pathologies, retinal vasculopathy in the form of cotton wool spots is the next most common, with ominous systemic implications. Optic neuropathy, although rare, is associated with poor visual prognosis. Less common manifestations will also be briefly covered in this section, in addition to the known side effects of a common medication used in SLE—anti-malarials.

Retinal Vascular Disease

Retinal vascular lesions are the commonest intra-ocular manifestations of SLE. The most common of these are localized retinal infarctions at the level of the retinal nerve fiber layer. These are visible on ophthalmoscopy as cotton wool spots (Fig. 40-1) and are often asymptomatic if they are located in the periphery of the retina. Occasionally, these cotton wool spots may be associated with intraretinal hemorrhages and may result in a “Roth spot” (Fig. 40-2).

The published prevalence of retinal cotton wool spots in patients with SLE varies from 3% to 29% (1 ,2 ,3). However, the largest prospective study over 15 years of serial observation of 550 patients with SLE found that these lesions were present in 7% of their population (4).

Severe, occlusive retinal vasculopathy is far less common but is usually visually devastating, with one series reporting a final acuity of worse than 20/200 (i.e., legal blindness) in 55% of eyes affected by this type disease (2). The manifestations seen in this type of vaso-occlusive disease include central retinal artery occlusions (Fig. 40-3), multifocal retinal arteriolar occlusions (Fig. 40-4), capillary bed occlusion resulting in widespread retinal ischemia with secondary retinal and optic disc vitreal heme that may lead to vitreal hemorrhage (Fig. 40-5) or tractional retinal detachment, and central and branch retinal vein occlusions (Fig. 40-6) (2 ,4 ,5 ,6 ,7 ,8 ,9). Patients presenting with any of these occlusions usually complain of a sudden, painless loss of vision and/or a loss of visual field that classically respects the horizontal meridian. Fortunately, this subtype of retinal vasculopathy is rare with an incidence of less than 1% in the above prospective series of 550 patients (4). Other smaller series have reported an incidence of 2% to 8% (1 ,10).

Although retinal vascular involvement is most commonly asymptomatic in SLE patients, its presence is associated with active SLE in 88% of patients and lupus cerebritis in 73% (2 ,4). A strong correlation between the presence of retinal vascular involvement and lupus anticoagulant or antiphospholipid antibodies has also been found in several studies in addition to a decreased survival time (2 ,4 ,5 ,10 ,11). The presence of lupus retinal vascular disease is therefore a marker of poor prognosis for survival.

Choroidal Vascular Disease

Retinal vessels are readily seen with an ophthalmoscope and therefore, retinal vascular disease is relatively easy to assess. In contrast, the choroidal vasculature is deep to the retina and usually obscured by the retinal pigment epithelium. Abnormalities of choroidal vessels in SLE are rarely reported but also much more difficult to appreciate than retinal vascular disease. A choroidal vasculopathy usually results in multiple foci of serous retinal detachments that eventually resolve with residual scarring of the retinal pigment epithelium and some degree of permanent visual impairment (5 ,12 ,13).

Optic Neuropathy

Central nervous system (CNS) involvement occurs in up to 39% of patients in SLE (14 ,15). Optic nerve involvement is

far less common and is estimated to occur in up to 1% of all SLE patients (4 ,16).

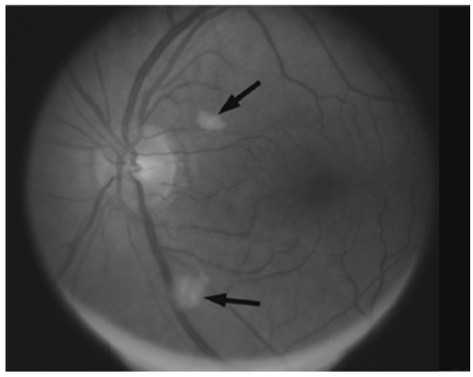

Figure 40-1. (See color plate.) Color fundus photograph of cotton wool spots (arrows).

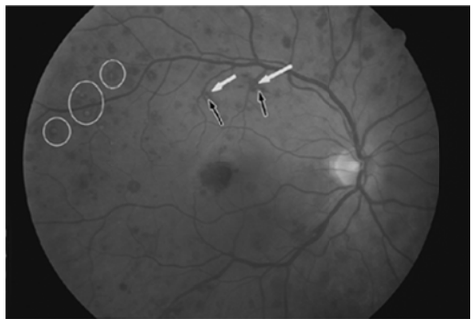

Figure 40-2. (See color plate.) Roth spots circled, with central white spot that may either represent fibrin or retinal infarct (black arrow) surrounded by intraretinal hemorrhage (white arrow).

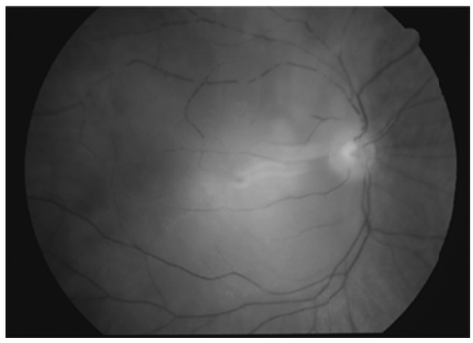

Figure 40-3. (See color plate.) Central retinal artery occlusion of the right eye. Note the ischemic, pale, edematous retina.

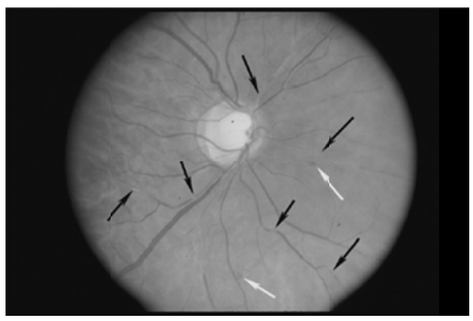

Figure 40-4. (See color plate.) Retinal vasculitis in SLE manifest by multiple arteriolar occlusions (black arrows) and intraretinal hemorrhages (white arrows).

The pattern of optic nerve involvement in SLE is varied. In some cases, the patients present with symptoms and signs consistent with an acute optic neuritis (16 ,17) characterized by the acute onset of retrobulbar pain aggravated by ocular movement, an afferent pupillary nerve defect, visual field loss or scotomata and either a swollen (Fig. 40-7) or normal appearing optic disc.

In others, the presentation may be more insidious. The patient instead may present with painless loss of vision that may be gradual in its onset (18) with an afferent pupillary defect and an arcuate or altitudinal visual field defect present on examination.

In both patterns of presentation, the pathogenesis is thought to be the same: microvascular occlusion leads to demyelination of the optic nerve in milder cases and optic nerve infarction in severe cases (16).

The visual prognosis in individuals with SLE optic neuropathy is poor, as it is notoriously difficult to treat. The standard treatment is corticosteroid either orally or pulsed.

However recovery (if any) is slow, with final visual acuities of 20/200 or worse in several series (16).

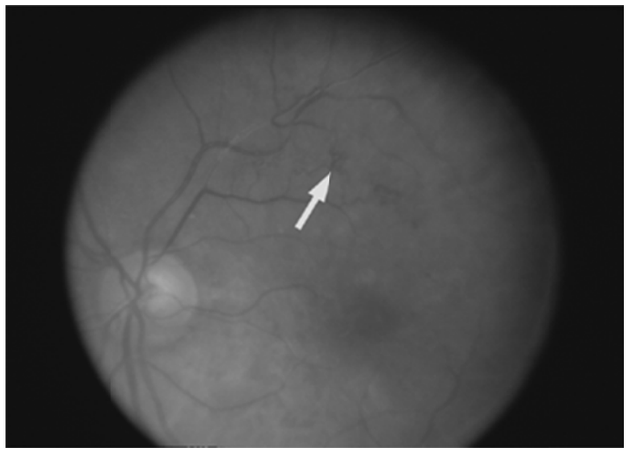

Figure 40-5. (See color plate.) Neovascularization of the retina (white arrow).

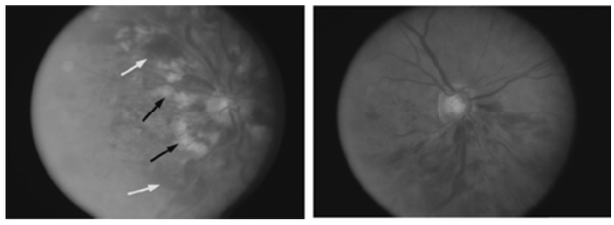

Figure 40-6. (See color plate.) **A**, Central retinal vein occlusion with widespread intra-retinal hemorrhages (white arrows), dilated tortuous retinal veins and cotton wool spots (black arrows). Note that cotton wool spots are not a consistent finding in retinal vein occlusions. **B**, Branch retinal vein occlusion. Note the sectorial distribution of the hemorrhages that distinguishes this from a central vein occlusion.

More recently, some success has been reported with the use of intravenous cyclophosphamide in addition to steroid treatment. Rosenbaum et al. (17) reported a marked improvement in visual acuity and visual function in three patients treated with this regimen with a later series of 10 patients reported similar results with 50% of patients regaining normal visual acuity after treatment (19).

It should also be mentioned that SLE optic neuropathy is a rare cause of optic nerve disease in comparison to other causes of optic neuritis, such as multiple sclerosis (MS).

Certainly the distinction between SLE optic neuropathy with CNS involvement and multiple sclerosis can be difficult, as both may result in the same signs and symptoms and the two conditions have even been described to co-exist (20). However, the response of lupus optic neuropathy to treatment is slow in comparison to the rapid response of MS related optic neuritis (17).

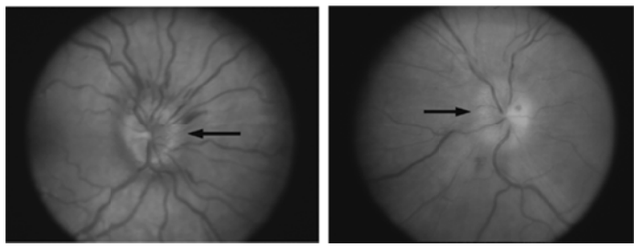

Figure 40-7. (See color plate.) Swollen optic disc. Note the blurred margins (black arrow) that distinguishes this from other causes of a prominent disc such as disc drusen.

Episcleritis and Scleritis

Both scleritis and episcleritis may occur in SLE (21 ,22) and are a result of small vessel vasculitis affecting the tissues of the ocular coat—namely the sclera and episclera.

Episcleritis is a benign, non–vision-threatening disease that results in ocular injection and mild to moderate periocular discomfort. It usually runs a benign course and often resolves spontaneously after period of a few weeks. It responds well to topical steroid drops or oral nonsteroidal anti-inflammatory medications. Although it may occur in SLE, the vast majority of patients presenting with episcleritis do not have an underlying systemic inflammatory disease.

Scleritis is a deeper and more severe inflammation that runs a more chronic course. It can result in visually debilitating complications if left untreated. These complications include severe scleral thinning (scleromalacia) resulting in prolapse of intra-ocular structures, corneal

scarring, glaucoma, and serous retinal detachments. Clinically, scleritis is often characterized by severe periocular pain, deep ocular injection, and marked tenderness of the affected area to palpation. Less commonly, scleritis may instead present with severe pain and blurred vision without ocular injection if the posterior sclera is involved. More importantly, the development of scleritis is thought to be a serious development in SLE, as it has been described to parallel the degree of disease activity elsewhere (23 ,24 ,25).

Although those presenting with scleritis are more likely to have an underlying systemic inflammatory disease than those presenting with episcleritis, the vast majority of patients with scleritis have rheumatoid arthritis (26 ,27), with other vasculitic diseases such as Wegener granulomatosis coming a distant second. In comparison, SLE is an extremely rare cause of scleritis.

Corneal Disease/Keratitis

As mentioned previously, the commonest ocular manifestation in SLE is keratoconjunctivitis sicca (KCS), which results in a poor tear film and secondary corneal changes such as small dry spots or epithelial erosions (superficial punctuate keratopathy) (1). However, other corneal disease may rarely occur, with a few cases of ulcerative keratitis and deep keratitis or inflammation of the deeper corneal layers (stroma) with secondary impairment of vision being described (28 ,29). These presentations are thought to be related to vasculitis affecting the surrounding limbal vessels. Ulcerative keratitis can also occur in association with scleritis.

Uveitis

Although described, uveitis, or intra-ocular inflammation, is an extremely rare association with SLE (23).

Orbital Inflammation

As SLE may affect any tissue of the body, orbital tissues such as the lacrimal gland (most commonly resulting in sicca), extraocular muscles and other orbital tissues may also be involved, leading to symptoms of pain, proptosis, lid swelling, and diplopia. Such an orbitopathy from SLE alone is exceedingly rare, with only a handful of case studies being reported (22).

Chloroquine and Hydroxychloroquine Toxicity

Chloroquine or hydroxychloroquine toxicity is classically characterized by the development of a bilateral bull's eye maculopathy that is visible on fundoscopy (30) (Fig. 40-8). At this stage, observant patients may complain of a paracentral scotoma, whereas others may be asymptomatic. However, should drug exposure continue, further irreversible damage to the retina occurs that is manifest by retinal pigment atrophy resulting in widespread retinal pigmentary changes and retinal vascular attenuation. By this stage patients have severe visual field loss, decreased visual acuity and impaired night vision (31 ,32).

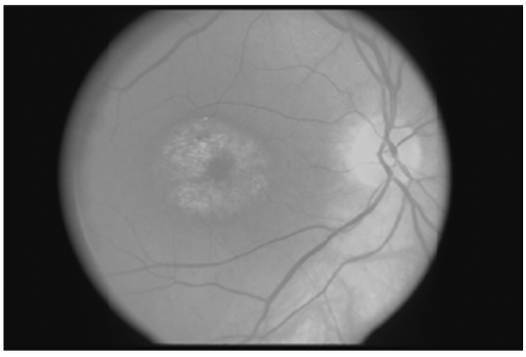

Figure 40-8. (See color plate.) Bull's eye maculopathy.

The first sign of toxicity is thought to be decreased visual function in the paracentral visual field that is detectable prior to the development of clinically visible bull's eye maculopathy. Cessation of the drug at this early stage is thought to reverse these changes. However, once signs of maculopathy are visible clinically, these changes have been shown to be irreversible (32).

The risk of retinal toxicity with chloroquine is higher than for hydroxychloroquine and occurs at lower doses (>3 mg/kg/day) (32 ,33). The risk of retinal toxicity for hydroxychloroquine is far lower with only 20 cases being reported, with the majority occurring in individuals on high doses (>6.5 mg/kg/day) (32).

However, hydroxychloroquine toxicity has occurred in individuals at lower doses (i.e., <6.5 mg/kg/day), particularly if treatment is continued for more than 5 years (34). Other risk factors have also been identified, such as co-existing retinal, renal, and liver disease, obese body habitus, and age older than 60 years (32). Recent research has also suggested that carriers of an ABCR gene polymorphism, which has been linked to Stargardt disease, a form of hereditary maculopathy, may also be prone to developing either chloroquine or hydroxychloroquine toxicity at low doses despite a normal ophthalmic examination prior to treatment (35). Therefore it would appear that the development of hydroxychloroquine (and chloroquine) toxicity may not purely be related to the dose, but also a variety of genetic and environmental factors.

Several recommendations for regular ophthalmic screening of patients treated with chloroquine and hydroxychloroquine have been proposed to detect patients prior to developing irreversible, severe vision loss. However, no “gold standard” for screening has yet been established with major drawbacks being the high cost of most screening recommendations given the relative rarity of this complication

(36) and the variability in the susceptibility of individual patients (as discussed above).

The American Academy of Ophthalmology currently recommends that a baseline ophthalmic examination be done prior to commencing treatment that at a minimum includes a dilated fundal examination and an Amsler grid or Humphrey 10–2 visual field examination that assesses the paracentral visual field (32). This examination would therefore also identify those with pre-existing retinal disease that would place the individual at higher risk.

Those at high risk were identified as those with:

- Doses > 6.5 mg/kg/day
- Treatment duration more than 5 years
- Obese habitus
- Co-existing retinal, renal, or liver disease
- Age greater than 60 years

A repeat examination for high risk individuals is recommended on a yearly basis. Those not in the high risk category are screened at the same rate that is recommended in the general population (i.e., approximately 2 to 4 yearly in those younger than 65 years of age and 1 to 2 yearly in those 65 years or older).

Another investigation that has been proven useful in the diagnosis of early hydroxychloroquine toxicity includes multifocal electroretinography (mfERG). This is an electrophysiologic test that assesses the electrical function of various parts of the retina when it is stimulated by specialized light stimuli. Several studies have now shown that mfERG is more sensitive than standard examinations (e.g., visual field testing, visual acuity, clinical examination) in cases of suspected toxicity (37 ,38). However the role of mfERG in widespread screening is still to be determined.

More recently, a potentially more cost effective method of screening using a modified Amsler grid has been proposed (39). This test could be easily administered in a nonophthalmic clinic, such that only those with an abnormal test are referred for a full ophthalmic examination. This screening tool is currently still under development and its true sensitivity is still unknown. However, it certainly may prove to be a far more cost effective screening method than the current recommendations that exist today.

Antiphospholipid Antibody Retinopathy

Retinal vascular disease associated with antiphospholipid antibodies is characterized by diffuse retinal vascular occlusion, often in association with symptoms of a rheumatologic disease (40).

However, the vast majority (>90%) of cases of occlusive retinal vascular diseases (e.g., retinal arterial or venous occlusions) occur in the elderly who have other systemic vascular risk factors, such as atherosclerosis or hypertension (41 ,42). Therefore, primary and secondary antiphospholipid antibody disease accounts for a very small proportion of these presentations.

Despite the rarity of this condition, several studies have shown that up to 24% of patients with occlusive retinal vascular disease and no cardiovascular risk factors have high titers of antiphospholipid antibodies. This is significantly higher than in control populations in which these antibodies were present in less than 9% (40 ,43 ,44 ,45).

Therefore, young patients (i.e., younger than 50 years of age) who present with diffuse occlusive retinal vasculopathy should be investigated for the presence of these antibodies, because of the possible ocular and systemic complications that may require prophylactic therapy.

Oral Manifestations

Painless oral ulcers are included in the 1982 classification criteria of SLE and thus were found to be more specific for the recognition of lupus than such common manifestations as alopecia, Raynaud phenomenon, sicca, or fever. Oral ulcers are frequently present during an acute flare of systemic lupus and could occur on any part of the oral mucosa (46). Lesions on the hard palate may range from patches of erythema to frank ulceration and mucosal hemorrhage. Inclusion of these nonspecific erythematous patches resulted in an estimated frequency as high as 45% based on a Swedish series of 51 patients with lupus (47). Pathology of oral lesions includes epithelial acanthosis or hyperplasia, disturbed epithelial maturation, and liquefactive degeneration of basal epithelial cells (47). Immunofluorescent testing of skin and mucosal biopsy tissue frequently shows subepithelial immunoglobulin and complement deposition (the lupus band). Although its presence is not limited to clinically involved tissue, a lupus band is associated with systemic lupus as opposed to rarely being associated with chronic cutaneous lupus (48).

Extensive and diffuse inflammation of the oral cavity, oral mucositis, is a relatively frequent occurrence in lupus and could be a result of immune mediated mucosal inflammation (49). A drug reaction such as seen with methotrexate could have a similar appearance and may require the addition of high doses of folic acid supplementation. There is a curious syndrome of isolated and extensive oral mucositis without any systemic disease, negative ANA using Hep 2 cells but positive ANA using stratified epithelial cells. The recurrent oral lesions are responsive to hydroxychloroquine and probably share the same pathophysiology as the mucositis seen in patients with multisystem disease (50). Oral candidiasis and herpes simplex viral infection should always be suspected, actively sought, and treated especially in patients on steroids and other immunosuppressives (49 ,51). The only finding of oral candidiasis, especially in patients with xerostomia, may be a burning tongue with a characteristic smooth and red surface. Recurrent aphthous stomatitis and cutaneous lesions with discoid lupus features have been reported in patients suffering from X-linked chronic granulomatous disease. The presence of severe recurrent and chronic infections in childhood is a clue to this rare disorder (52).

Discoid lesions could occur on mucosal surfaces and are frequently painful (47 ,49). The lesions frequently involve the labial and buccal mucosae. Lesions have an irregular outline with slightly elevated patches and striated surface, the latter sometimes becoming eroded and transformed into indurated, whitish, raised, scar-like tissue. Biopsy of oral mucosal discoid lesions reveals a similar appearance to that seen in skin and include hyperkeratosis, normal or decreased thickness of the stratum granulosum, irregular acanthosis and atrophic stratum spinosum, focal liquefaction of stratum basale, single cell keratinization, lymphocytic epithelial inflammation, homogeneous thickening in a band like distribution at the basement membrane, and perivascular lymphocytic infiltration with tissue edema.

There is an association between lichen planus of the oral cavity and lupus (53 ,54 ,55). Oral lichen planus lesions usually occur on the buccal mucosa, lips, and tongue with lesions rarely found on the palate or gingiva. The lesions may be asymptomatic or may present with burning or itching. In many cases oral lichen planus lesions occur without concomitant skin lesions. The lesions may vary from a coalescence of small pearly gray, hyperkeratotic nodules to a lace-like pattern of hyperkeratotic streaks on an erythematous background with erythema most pronounced at the border. Bullous lichen planus is a rare variant of lichen planus and patients present with ulceration of the tongue and cheeks and less commonly of gingivae and lips. Bullous lesions are rarely preceded by vesiculation. The ulcers are smooth and adjacent mucosa is atrophic and erythematous with linear white striae. A biopsy is frequently required to make this diagnosis and needs to be taken from nonulcerated erythematous areas. The histopathology demonstrates dense subepithelial lymphocytic infiltration with liquefaction of the basal epithelial layers (49). Bullous SLE is a chronic, wide spread, nonscarring, subepidermal, blistering eruption associated with circulating antibodies to type VII collagen (56). Oral blistering lesions may be found in association with cutaneous disease and can be confused with oral bullous lichen planus.

Xerostomia as a result of secondary Sjögren syndrome is often associated with periodontal disease and poor dentition and is discussed in Chapter 39 .

Therapy of oral mucosal lesions is empiric and includes treatment of the underlying systemic disease with corticosteroids, antimalarials, or immunosuppressives. Intra-oral topical or intralesional steroids may be required for limited oral disease. Oral swish and swallow of antifungal agents for oral candidiasis or tetracycline for aphthous ulceration may be helpful. Avoidance of spicy foods and frequent sips of liquid with meticulous dental hygiene are important ancillary therapies that are often overlooked.

Scalp and Hair Involvement

Patients with lupus may lose hair for a variety of reasons and several patterns of hair loss have been described. Diffuse hair loss is generally nonspecific and has a broad differential including stress associated with acute multisystem disease (57) side effects from immunosuppressives, or hypothyroidism (58). Patients with severe acute systemic lupus are prone to developing diffuse hair loss from telogen effluvium, a condition in which an abnormally high percentage of normal hairs from all areas of the scalp enter telogen, the resting phase of hair growth. A lag of 3 to 4 months between the acute flare of lupus and diffuse hair loss is common because of the time taken for hair to cycle from anagen through catagen and finally telogen phase. Initially the patient complains of increased hair shedding followed by diffuse hair thinning. Hair thinning occurs on all parts of the scalp as well as pubic and axillary hair. Since this is a noninflammatory condition, the scalp has a totally normal appearance. The root tip of the extracted hairs has a clubbed structure of normal telogen hair with a normal shaft. Since there is no structural damage to hair follicles, the hair loss reverses with resolution of the systemic illness, withdrawal of immunosuppressives, or correction of hypothyroidism (59).

Patchy alopecia in lupus is usually associated with loss of hair follicles in association with discoid lesions of the scalp (49 ,59 ,60). Biopsy reveals marked erythema, atrophy, telangiectasia, and follicular hyperkeratosis. This may require therapy with intralesional steroids, antimalarials, steroids, or retinoids.

Other causes of scarring alopecia should be considered and include trauma, burns, lichen planus, acute severe fungal infections, such as tinea capitis, viral infections, such as herpes zoster, or bacterial infections (60). Damaging hair grooming or hair coloring practices may result in nonscarring hair loss from traction or fragile damaged hair (hair breakage) respectively and are reversible causes of alopecia in patients with lupus (59).

A peculiar abnormality of individual hairs has been termed “lupus hair” and is characterized by hair fragility and increased waviness especially in a frontal distribution (61). Lupus has been found in association with porphyria cutanea tarda and the latter disorder is a known cause of temporal hirsutism. Vitiligo of the scalp with concomitant patches of white hair is associated with patients suffering from lupus and is also found among their first-degree relatives (62). A deep scalp biopsy with transverse and longitudinal sections of the tissue block has been reported to provide useful information in patients with scalp and hair abnormalities (63). Transverse sections demonstrate the perifollicular and follicular interface changes of lupus as well as anagen/telogen ratio. Vertical sections demonstrate changes of lupus at the dermo-epidermal junction and papillary dermis as well as the subcutaneous tissues changes of lupus panniculitis. A good history and careful examination of the scalp and hair will frequently negate the need for a scalp biopsy (59 ,60).

Nasal Septal Disease

The nasal septum is an easily overlooked tissue bed where inflamed blood vessels are easily visualized utilizing an otoscope. Unfortunately the finding of nasal septal inflammation

in lupus is nonspecific and confounded by nonlupus causes, such as environmental dryness and airborne irritants, allergic rhinitis, upper respiratory tract infections, excoriations from self-inflicted trauma and sicca as part of secondary Sjögren syndrome. In association with active lupus, nasal septal inflammation may progress to deep ulceration and rapid destruction of septal cartilage with nasal septal perforation (64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72). Nasal symptoms of nasal inflammation include stuffiness, hyposmia, epistaxis, or a high-pitched whistling sound, but nasal disease may be totally asymptomatic. The largest study to date is from the University of Toronto Lupus clinic, where 40 (4.6%) of their 885 patients studied had a nasal septal perforation (65). This group found an association with involvement of other mucosal beds as well as with active multisystem disease. They postulate vascular inflammation as an etiology.

Overt or occult nasal cocaine use should always be sought in patients with destructive nasal septal disease. A strong association with Raynaud phenomenon was found with nasal septal perforation in a variety of disparate rheumatic diseases including rheumatoid arthritis, psoriatic arthritis, progressive systemic sclerosis, SLE, and mixed connective-tissue disease (MCTD) (68). Other causes of nasal septal perforation include Wegener granulomatosis, sarcoidosis, Behcet disease, lymphoma, tuberculosis, syphilis, midline lethal granuloma (probably a form of lymphoma), and cryoglobulinemia.

Nasal biopsies, although frequently obtained, provide limited useful information unless the biopsy specimen includes inflamed blood vessels (64 ,66). Treatment consists of control of the systemic disease, active, nasal irrigation and humidification. Closure of the defect, although seemingly an attractive option, may be associated with poor healing of the tissue flap as a result of ongoing vasculitis. A silastic button may avoid this complication (67).

Relapsing Polychondritis

Patients with lupus may have a clinical syndrome of inflammation of cartilage including nasal bridge, external ear, and upper airways akin to that seen in relapsing polychondritis. Ultimately lupus will involve the skin, other organs, and characteristic autoantibodies, distinguishing it from relapsing polychondritis will be detectable. In a series of 62 patients with relapsing polychondritis 22 patients had a total of 27 associated diseases including rheumatoid arthritis (7), myeloproliferative syndrome (4), SLE, or systemic vasculitis (three each), ulcerative colitis, autoimmune thyroiditis, ankylosing spondylitis, or autoimmune hemolytic anemia (two each), Crohn disease, pulmonary fibrosis, or insulin-dependent diabetes mellitus (one each) (73). A case report and review of the 16 patients reported in the literature with relapsing polychondritis and SLE provided fairly convincing evidence that this a true association rather than two diseases occurring together by coincidence (74).

Laryngeal Involvement

Hoarseness may occur in patients with lupus and may be caused by laryngeal and pharyngeal edema of obscure origin or inflammatory vocal cord nodules (75 ,76 ,77). The incidence of laryngeal involvement in lupus ranges from 0.3% to 30% (78 ,79). The cricoarytenoid joint is a synovial joint and is much less commonly involved in lupus than in rheumatoid arthritis. Involvement of this joint may lead to vocal cord edema, immobility, and stridor. Several case reports have been published with acute and life-threatening involvement of the cricoarytenoid joint in patients with lupus, requiring treatment with high-dose steroids and in a particularly severe case a tracheotomy (80 ,81 ,82 ,83). Gastroesophageal reflux disease with hoarseness may occur in association with lupus-related motility disorder of the distal esophagus. Oral candidiasis may spread into larynx and esophagus resulting in odynophagia and hoarseness.

Angioedema

Angioedema refers to a group of disorders characterized by the sudden onset of one or more localized swellings up to several centimeters in diameter affecting the skin and/or mucous membranes without pain, itching or erythema, and fading without scarring within 24 to 72 hours (84). Attacks of angioedema are caused by the absence of C1-esterase inhibitor and spontaneous and uncontrolled activation of C1, which cleaves and inactivates C4, resulting in a cascade of events and subsequent release of factors affecting vascular permeability (85 ,86 ,87). Cutaneous swelling overlying joints may be confused with frank arthritis. Abdominal pain because of visceral edema may be confused with serositis. Respiratory or gastrointestinal tract edema occurs only in the inherited form.

Angioedema is divided into hereditary and acquired categories with the acquired group caused by cold, exercise, sun, autoantibodies to C1-esterase inhibitor (88), and excessive consumption of C1-esterase inhibitor in lymphoproliferative disorders (84). Only 1 (0.53%) of 193 patients with lupus was found to have a high titer IgG antibody to C1-esterase, whereas localized angioedema or urticarial vasculitis was found in 8 patients (4%) (89). Three patients with severe lupus and acquired angioedema, reduced levels of C1 esterase inhibitor, and no demonstrable antibodies to C1 esterase inhibitor were reported with normalization of C1-esterase inhibitor levels following steroid treatment (90). This association has been questioned (91). A case of acquired C1-esterase inhibitor and lupus was reported with resolution following treatment with hydroxychloroquine (92). A patient with hypocomplementemic urticarial vasculitis, angioedema, and SLE was resistant to steroids and intravenous immunoglobulin (IVIG), but responded to a course of four infusions of rituximab (93).

The association of lupus and hereditary angioedema has been known for decades. The first cases were reported in

identical male twins who had discoid lupus erythematosus and hereditary angioedema. They had low levels of C1-esterase inhibitor and C4 and their mother had lupus with a spontaneous mutation in C1-esterase inhibitor (94). A daughter of one of the twins developed full-blown lupus, angioedema, and reduced C1-esterase levels and function (95). Hereditary angioedema is an autosomal dominant disorder with deficiency of C1-esterase inhibitor and is divided in type I with quantitative deficiency in C1-esterase inhibitor and type II with reduced or normal levels of C1-esterase inhibitor levels, but a nonfunctional enzyme (84). A characteristic finding is reduced C4 in patients with C1-esterase inhibitor, which in turn may predispose patients to the development of lupus, likely a result of disordered immune complex clearance. The National Institutes of Health (NIH) series of 157 patients with hereditary angioedema included 1 patient with full-blown lupus and a second patient with hydralazine induced lupus (96). The Cleveland Clinic experience of 220 patients with hereditary angioedema described a lupus-like illness in 4 patients (1.8%) (97). Treatment of hereditary angioedema include infusions of C1-esterase inhibitor (98 ,99 ,100) and plasmapheresis (101).

In addition to the classic C1-esterase inhibitor deficiency, other inherited complement deficiencies have been associated with angioedema and lupus. A low C4 level as a result of C4 null allele has been associated with discoid lupus or urticaria/angioedema syndrome (102). Heterozygous C2 deficiency was found in a patient with angioedema, myasthenia gravis, and SLE and responded to treatment with cimetidine and steroids (103).

Cervical Lymphadenopathy

Cervical lymphadenopathy in association with diffuse lymphadenopathy may occur in patients with lupus. Biopsy demonstrates nonspecific reactive lymphoid tissue. Lymphadenitis, characterized by prominent necrosis with typical hematoxylin bodies, may occur in lupus, and in severe cases may require immunosuppressive agents (104 ,105). Kikuchi-Fujimoto disease most commonly occurs in young females and is usually a self-limiting illness characterized by a fever, constitutional symptoms, and cervical as well as diffuse lymphadenopathy with histiocytic necrotizing lymphadenitis, but no hematoxylin bodies on biopsy (106 ,107 ,108). Painful cervical lymphadenopathy is a hallmark of Kikuchi-Fujimoto disease and has been reported in association with lupus (109 ,110 ,111 ,112). Although rare, death can occur from multisystem disease in lupus with associated Kikuchi-Fujimoto disease and may warrant aggressive immunosuppression (113). Rosai-Dorfman disease, a rare proliferative syndrome of histiocytes, can present with enlarged major salivary glands and painless cervical lymphadenopathy and one case has been reported in association with lupus (114). Infections with atypical organisms such as mycobacteria other than tuberculosis (TB) and cat-scratch disease may occur in patients with lupus, especially if on immunosuppressive agents. Lymphoma in association with Sjögren syndrome should always be considered in asymmetrical or rapidly enlarging painless lymphadenopathy. Spontaneous jugular vein thrombosis may mimic cervical adenopathy and has been reported in a variety of associated disorders including discoid lupus and antiphospholipid antibody syndrome (115).

Thyroid Disease

Autoimmune thyroid disease, characterized by antibodies directed against thyroid antigens including thyroglobulin and microsomes is relatively common in lupus. Antithyroglobulin and antimicrosomal antibodies are also found in lupus patients even in the absence of thyroid disease. In a group of 300 lupus patients, 7.3% were found to have thyroid disease (116). Hypothyroidism was found in 5.7%, significantly more than the background rate of 1% in the community. Hyperthyroidism was found in 1.7%, which is similar to the community background rate. Fourteen percent of the total cohort had thyroid autoantibodies, whereas these antibodies were present in 15 of the 22 patients with overt thyroid disease. The NIH experience of 332 hospitalized lupus patients provided very similar figures with 7.5% prevalence of thyroid disease with the majority (6.6%) being hypothyroid (117). This ill group of patients not surprisingly demonstrated features of the sick euthyroid syndrome. Multiple abnormalities were found in the pituitary-thyroid and pituitary-gonadal axes among 11 newly diagnosed lupus patients (118). These patients had normal T4 and TSH but an exaggerated TSH response to TRH indicating latent hypothyroidism. Another group provided data in support of the hypothesis of slow universal progression of the autoimmune process—progression from mild thyroiditis to clinical disease over time (119).

Interestingly, 58 of 168 (35%) patients with autoimmune thyroid disease (Hashimoto thyroiditis and Grave disease) were ANA positive compared to 7 of 75 (9%) healthy controls. Five of these patients had Sjögren syndrome and 2 had lupus (92). Two patients with lupus, acutely painful neck swelling and fever were reported from Hong Kong with suppurative thyroiditis caused by *Staphylococcus aureus* and tuberculosis, respectively, indicating the need for a needle aspiration and bacteriology to distinguish infectious causes thyroiditis from acute autoimmune thyroiditis (120). Antithyroid medications, such as methimazole, used for the treatment of diffuse goiter or frank hyperthyroidism have been implicated in the development of drug-induced lupus (121 ,122).

Temporomandibular Joint

The temporomandibular joint is less frequently involved in lupus than in juvenile chronic arthritis, rheumatoid arthritis, or osteoarthritis and may present with aural pain, clicking, and difficulty with jaw opening (123 ,124 ,125). Because there is a high rate of fibromyalgia in patients with lupus, temporomandibular joint syndrome could be expected in

this subset of patients with lupus. The fibromyalgia-associated joint dysfunction may be a result of bruxism or masticatory muscle myofascial pain dysfunction in distinction to structural temporomandibular joint defects seen in temporomandibular degeneration/dysfunction and other inflammatory conditions.

Ear Involvement and Lupus

SLE often has a significant impact on the inner ear to cause hearing loss, tinnitus, and vertigo (126 ,127 ,128 ,129 ,130 ,131 ,132). Ear involvement can be unilateral or bilateral, the latter often asymmetric. Although often reported as predominantly affecting mid to high frequencies, low frequencies are affected as well. Onset of hearing loss can be sudden (hours to days), rapidly progressing (days to weeks), or slowly progressing (weeks to months).

Reported prevalence rates of ear manifestations in SLE vary (15% to 57%). This is attributable to small studies (less than 20 patients) and variables such as inclusion criteria for lupus, definitions of hearing loss (self-reporting versus comprehensive audiometric testing), and age of patients (autoimmune hearing loss masked by age-related hearing loss). Detection and diagnosis also are confounded by status of systemic disease, noise-induced hearing loss, and ototoxic drugs, such as antimalarials, nonsteroidal anti-inflammatories, aminoglycoside antibiotics, and diuretics (133 ,134).

Often inner ear dysfunction (hearing loss or vertigo) is the first manifestation of autoimmune disease, prior to any other systemic symptoms (135 ,136). Ear problems also commonly occur during a period of lupus remission or inactivity (126). Thus, many patients are initially seen by otolaryngologists and not rheumatologists, which slows the correlation with autoimmune disease. Nevertheless, ear problems are generally responsive to glucocorticoid and cytotoxic drug treatment (131 ,134 ,137 ,138), as well as plasma exchange (139 ,140) and anticoagulants (141). Permanent hearing loss because of autoimmune disease has been restored with cochlear implants (142), offering some hope to patients who no longer respond to medical management.

It is interesting that other common autoimmune diseases have a similar prevalence of hearing loss, vertigo, and/or tinnitus, including rheumatoid arthritis (143 ,144 ,145 ,146 ,147 ,148), Wegener granulomatosis (149), Cogan syndrome (150), relapsing polychondritis (151), Behçet disease (152), and progressive systemic sclerosis (153). Ear manifestations in these other autoimmune diseases imply that a similar immune process is responsible for ear pathology.

Mechanisms of Immune-Mediated Inner Ear Disease

Ear manifestations of systemic autoimmune disease are part of the general classification of immune-mediated inner ear disease. Ear dysfunction, with or without other organ involvement, often is associated with circulating antibodies or immune complexes, but how they impact the inner ear is unknown (134 ,154 ,155). Hearing loss in SLE has been inconsistently correlated with circulating autoantibodies to deoxyribonucleic acid (DNA), cardiolipin, phospholipids, and endothelial cells (126 ,127 ,129 ,156). However, some patients with sudden hearing loss and MéniÜre disease also have the same elevated antibodies, but without any other autoimmune disease symptoms (157 ,158 ,159 ,160). These patients may represent those in whom the ear is the first organ impacted by disease.

It has been proposed that circulating antibodies or immune complexes interfere with vasculature of the inner ear, compromising its function. Endothelial cell tight junctions of inner ear vessels create the blood-labyrinth barrier (similar to the blood-brain barrier) and its breakdown causes loss of inner ear potentials and hearing loss. In fact, temporal bones from autoimmune disease patients commonly show vasculitis, vascular necrosis, connective tissue proliferation, and new bone formation, all presumably secondary to such vascular breakdown (161 ,162 ,163 ,164).

Some insight into potential mechanisms of immune-mediated inner ear disease has come from studies of mouse models for SLE. All commonly studied autoimmune mice (MRL/lpr, C3H/lpr, New Zealand Black, Palmerston North) have been shown to have inner ear disease and hearing loss (165). In fact, these mice have elevated antibodies against most of the antigens reported for human autoimmune hearing loss. The predominant area affected is the stria vascularis, a vascularized epithelium responsible for ion homeostasis of inner ear fluids. The blood labyrinth barrier normally protects this region, but considerable deposition of immunoglobulin and other inflammatory factors is seen on these vessels with progression of systemic disease. As a result, the tight junctions leak and endocochlear potentials decline. Hearing loss in the mice can be restored with glucocorticoid treatments.

Chapter 41

Hematologic and Lymphoid Abnormalities in Systemic Lupus Erythematosus

Francisco P. Quismorio Jr.

Lymphadenopathy

Lymphadenopathy, a common clinical manifestation of systemic lupus erythematosus (SLE), can be generalized or regional in distribution, especially in the cervical and axillary regions. Hilar adenopathy rarely is seen in SLE (1). In their series of 520 patients, Dubois and Tuffanelli (2) observed adenopathy in 59%, with axillary adenopathy in 42% and cervical adenopathy in 24%. Cervical adenopathy was an initial manifestation in 2% and generalized adenopathy in 1% of patients. The nodes usually were nontender and discrete, and they varied in size from shotty to 3 to 4 cm in diameter. The glandular enlargement was so pronounced in some patients that malignant lymphoma was suspected. Lymphadenopathy as the presenting manifestation of SLE has been reported by other authors (3 ,4).

Lymphadenopathy was more common in children than in adults and most marked among African-American patients. Meislin and Rothfield (5) reported similar findings, with lymphadenopathy or hepatosplenomegaly in 69% of children as compared to 35% in adults with SLE. Among 698 adult patients with SLE collected from six large series in the literature, the frequency of regional and generalized lymphadenopathy ranged from 30% to 78%, with a mean prevalence of 50% (6 ,7 ,8 ,9 ,10 ,11).

Shapira et al. (12) observed SLE patients with lymphadenopathy to have more constitutional symptoms, lupus skin rash, hepatomegaly, splenomegaly, higher anti–double-stranded DNA (dsDNA) antibodies, and hypocomplementemia than those without lymphadenopathy.

Histopathology of the Lymph Node

The characteristic finding in the lymph nodes in SLE is a diffuse, reactive hyperplasia (13 ,14 ,15). Varying degrees of coagulative necrosis and lymphoid follicular hyperplasia are seen. Hyperplastic germinal centers with plasmacytosis and varying number of immunoblasts in the interfollicular areas are found. In the necrotic areas and within the sinuses are occasional extracellular amorphous bodies, 5 to 12 μm in diameter, that stain intensely with hematoxylin. These hematoxylin bodies contain aggregates of deoxyribonucleic acid (DNA), immunoglobulins, and polysaccharides (13), and when present, they are considered to be characteristic of lupus lymphadenitis (16). Cells resembling Reed-Sternberg cells also have been described in patients with SLE (17).

Necrosis of small blood vessels located in the necrotic areas of the lymph nodes has been reported. Deposits of immunoglobulin and C3 were found in the walls of venules and arterioles suggesting that vasculitis because of deposition of immune complexes may be important in the pathogenesis of the lymph node necrosis in SLE (18).

Medeiros et al. (19) examined the immunohistologic features of the lymph node in SLE and found both follicular and paracortical hyperplasia, with paracortical foci of necrosis. Two predominant cell populations within and surrounding the necrotic areas were identified: $CD11b^+CD15^+$ histiocytes, and $CD8^+CD3^+$ lymphocytes. The interfollicular regions in the nonnecrotic areas were populated by T cells, and the lymphoid follicles were composed of polytypic B cells. $CD4^+/CD3^+$ T lymphocytes outnumbered $CD8^+/CD3^+$ T cells by a 3:1 ratio. The immunohistologic characteristics bear similarities to those of the necrotizing lymphadenitis of Kikuchi and Fujimoto.

Three histologic patterns of reactive follicular hyperplasia have been described by Kojima et al. (20) in SLE. These are histologic findings of multicentric Castleman disease, T-zone dysplasia with hyperplastic follicles, and nonspecific follicular hyperplasia. Reactive hyperplasia with numerous enlarged coalescing (giant) follicles with distortion of the architecture has also been reported in SLE (21). These observations emphasize the variety of histopathologic findings in lupus adenopathy.

Deftos et al. (22) reported an SLE patient with lymphadenopathy and hypercalcemia. There was no malignant transformation; however, there was

an abundant expression of parathyroid hormone–related protein in the lymph nodes. This finding suggests that the hypercalcemia was a result of an increased production of the hormone.

Kikuchi-Fujimoto Disease and SLE

Kikuchi-Fujimoto disease (KFD) or histiocytic necrotizing lymphadenitis is a self-limited lupus-like illness of unknown cause in young women that is characterized by cervical adenopathy, fever, weight loss, and a prodrome of upper respiratory tract infection. Other than a mild leukopenia in 50% of patients, laboratory investigations generally are unremarkable. The disease may be confused clinically with SLE and histologically with malignant lymphoma (23). Diagnosis is based on the characteristic histologic changes in the lymph nodes with paracortical necrosis, mononuclear infiltrate, and absence of neutrophils and plasma cells (24). These morphologic changes may be indistinguishable from lupus lymphadenitis (25) and especially when the histology is atypical. The presence of hematoxylin bodies, prominent plasma cells, and deposition of DNA in the blood vessel wall in lupus lymphadenitis help differentiate it from Kikuchi disease (24 ,26). Before a diagnosis of nodal KFD is made, serologic tests are necessary to exclude SLE.

Fatal cases of KFD are uncommon (27). Extranodal involvement is rare and has been documented in the skin, bone marrow, and myocardium. The skin rash in KFD is noncharacteristic and appears as single or multiple erythematous papules or plaques on the face, extremities, and trunk lasting for weeks to months and can mimic SLE. Spies et al. (28) described a constellation of histopathologic features in the cutaneous lesions of KFD, including the presence of cells that stain with the CD68 marker for histiocytes.

Coexistent KFD and SLE have been reported in a few patients (29 ,30 ,31 ,32 ,33). The disease can occur along the course of SLE, simultaneously with the onset of SLE, or can precede the development of full-blown SLE (29 ,33 ,34). Two of 108 patients with KFD who were examined retrospectively developed SLE (24). Two of 61 KFD patients from China developed SLE 1 month and 5 years later (35). The concurrent onset of mixed connective tissue disease and KFD also has been reported (36).

Castleman Disease and SLE

Castleman disease or angiofollicular lymph node hyperplasia is a rare lymphoproliferative disorder of unknown etiology characterized by lymphadenopathy with or without constitutional symptoms and clinically resembles malignant lymphoma. There are three histologic variants (hyaline vascular, plasma-cell, and mixed) and two clinical types (localized and multicentric) (37). The multicentric type can present with clinical features that may mimic systemic connective tissue disease including rheumatoid arthritis (RA), Sjögren syndrome, and SLE (38 ,39 ,40). Castleman disease should be considered in a patient with lupus-like presentation and with persistent lymphadenopathy despite corticosteroid therapy. Castleman disease can also develop along the course of a connective tissue disease (41).

Kojima et al. (42) found histopathologic features of Castleman disease in the lymph nodes of 5 of 19 (26%) of SLE patients presenting with peripheral lymphoadenopathy. The significance of these findings at this time is not clear.

Recent studies have provided evidence to support the role of human herpesvirus 8 or Kaposi sarcoma-associated herpesvirus in the pathogenesis of Castleman disease (43).

The Spleen in SLE

Splenomegaly is not an uncommon finding in patients with SLE. In large series, the frequency of splenic enlargement ranges from 9% to as high as 46% (2 ,7 ,10 ,44 ,45 ,46 ,47). Dubois and Tuffanelli (2) found splenic enlargement in 9% of their 520 patients. When present, splenomegaly often is associated with hepatomegaly. In some patients, the spleen is so large that it can extend to the iliac crest (48).

The characteristic histopathologic picture of the spleen in SLE is periarterial fibrosis or onionskin lesion. First described in 1924 by Libman and Sacks (49), this lesion is defined as the presence of at least 3 to as many as 20 separated layers of the normally densely packed periarterial collagen of the penicillary or follicular arteries, producing the appearance of concentric rings. Larson (46) found the lesion in 40 of 51 SLE spleens (78%) that were examined at autopsy. Calcified fibrous nodules that are continuous to the onionskin lesions have been described (51).

Although considered to be highly characteristic of SLE, periarterial fibrosis may be seen in a few other diseases. Kaiser (52) examined the specificity of the splenic lesion in 18 patients with SLE and 1,679 control cases at autopsy. Of these, 15 patients with SLE (83%) and 53 of the control subjects (3.2%) with various diagnoses were positive. In addition to SLE, the only group of patients in whom the lesion was found to be significantly more prevalent than in the rest of the controls was composed of those with essential thrombocytopenic purpura, with a frequency of 4 in 13 (3%).

Isolated infarction of the spleen that is associated with circulating lupus anticoagulant and thrombosis may occur (54). Spontaneous rupture of the spleen and the splenic artery in the absence of vasculitis also has been reported (55 ,56).

Functional Asplenia

Functional asplenia is a condition that is characterized by failure of the splenic uptake of radiolabeled sulfur colloid and the presence of Howell-Jolly bodies, Pappenheimer bodies, spherocytes, and poikilocytes in the peripheral blood smear. Functional asplenia is associated with a number of diseases, including sickle cell anemia, and it

predisposes to infections, especially by pneumococci or other encapsulated organisms. In 1980, Dillon et al. (57) described its occurrence in a patient with lupus, and since then, several other cases have been reported (58 ,59). Most patients with SLE and functional asplenia who develop pneumococcal or salmonella bacterial sepsis die (58).

The condition is relatively uncommon in SLE. Of 70 patients who were screened by peripheral blood smear, 5 showed changes that were suggestive of functional hyposplenia; however, only 3 patients had no splenic uptake of the radiolabeled sulfur colloid, yielding a frequency of 4.3% (57). In another study, functional asplenia was found in 2 of 44 patients with SLE (4.6%) who were studied by determining the presence of vacuolated red blood cells using phase-contrast microscopy, a method that is more reliable than examination of the peripheral blood smear for assessing splenic function (60 ,61).

The mechanism of functional hyposplenia in SLE is unclear. In those patients who died, the spleen showed atrophy without evidence of vasculitis (58). Functional hyposplenia also can be transient and reversible (58). It does not seem to be related to disease activity in SLE, and it may manifest clinically as an overwhelming infection in a patient who is in disease remission. Other mechanisms that have been proposed include thromboses of the splenic vessels, circulating serum factors, and reticuloendothelial blockade (59 ,62). The rare occurrence of congenital asplenism and SLE has been reported as well (63).

Because of the apparent high risk for pneumococcal infection, the peripheral blood smear of patients with SLE should be screened routinely for Howell-Jolly bodies. Polyvalent pneumococcal vaccine should be considered in patients with functional asplenia, because despite the splenic dysfunction, they can still mount an antibody response (58 ,64). In general, the antipneumococcal antibody titer is lower in patients with SLE than in vaccinated healthy subjects (65), and only half of the SLE patients develop a fourfold antibody response (66). Nevertheless, Uthman et al. (67) showed that the 23-valent pneumococcal vaccine is protective in SLE with autosplenectomy.

The Thymus Gland in SLE

Structure of the Thymus

A central lymphoid organ, the thymus gland is critical in the development and differentiation of T cells and the induction of autoimmunity. Lymphocytes originate in the bone marrow and must migrate to the thymus to acquire immunocompetence. Microscopically, the thymus gland is composed of several lobules; each lobule consists of a lighter-staining medulla, which is populated predominantly by epithelial cells, and a darker-staining cortex, which is populated by lymphocytes. Hassall corpuscles in the thymic medulla are mature epithelial cells that form concentric layers and become keratinized. Myoid cells with cross-striations are located adjacent to the Hassall corpuscles.

At puberty, when the thymus has reached its maximum size, the organ begins to undergo gradual physiologic involution, which is characterized by the loss of cortical thymocytes, spindling of epithelial cells, and an increase in adipose tissues. During periods of acute stress, cortical lymphocytes are rapidly depleted (i.e., stress involution) (68).

The size of the thymus in SLE, as assessed by pneumomediastinography, was found to be small, even in patients who had not received corticosteroids (69). Serial measurements in patients receiving prednisone showed a significant reduction in thymic size following steroid therapy. Most information on the histology of the thymus in SLE comes from early studies in 13 patients with SLE, which were conducted before thymic functions were fully understood (68 ,70). Changes that were associated with stress involution included a pronounced depletion of lymphocytes, resulting in cortical atrophy and disorganization of the medulla. Aggregates of epithelial cells and cystic Hassall corpuscles were seen in the medulla. These abnormalities were not specific for SLE and also were seen in patients with long-standing terminal illness. An increased number of plasma cells, Russell bodies, and germinal centers in the thymus, similar to those found in patients with myasthenia gravis (MG), was present, suggesting an immunologic reaction within the thymus (71).

The activity of thymic hormone decreases in patients with SLE, especially in those with clinically active disease (72 ,73). This decreased activity is a result of its low serum concentration rather than the presence of a circulating inhibitor.

Thymectomy has been performed in a small number of patients with SLE. No significant clinical improvement was noted, however, and the titer of the antinuclear antibodies (ANAs) remained unchanged (68 ,74).

Myasthenia Gravis and SLE

MG is a neuromuscular disorder that is characterized by a fluctuating weakness of the skeletal, bulbar, and respiratory muscles. Like SLE, MG has a predilection for young adults, with a female predominance. In MG, however, neuromuscular fatigue and an inability to sustain repeated muscular contractions are present. The basic defect is the reduction of available acetylcholine receptors (AChRs) at the neuromuscular junction because of an autoimmune process. Immunoglobulin G (IgG) antibodies to AChRs are present in 85% of patients.

The association between MG and SLE has fascinated investigators for some time. In 1963, Alarcon-Segovia et al. (75) reported the appearance of SLE in two patients several years after thymectomy for the treatment of MG, and they collected nine other patients from the literature. Since then, several reports of coexistent SLE and MG have appeared, although it is questionable whether some of these reported cases had definite SLE (76). Of 20 cases reviewed by Killian and Hoffman in 1980 (77), only 10 fulfilled the 1973 American Rheumatism Association (ARA) criteria for the

classification of SLE. Ciaccio et al. (78) reported 2 patients with co-existent SLE and MG and found an additional 42 in the literature. Most of the 24 patients who were reported before 1972 failed to meet at least four of the 1982 ARA criteria, whereas 12 of the 20 patients reported after 1972 fulfilled these criteria.

Of the 44 reported patients with co-existent MG and SLE, MG preceded SLE in 32 (72%), and in the remaining 12, MG followed SLE. In 13 patients, SLE developed following thymectomy for the treatment of MG (78). Polyarthritis and serositis were the most common presenting features of SLE. Malar skin rash was present in 20%, discoid lupus erythematosus (LE) lesions in 11%, and photosensitivity in 7%. The disease that develops later tends to dominate the clinical picture and prognosis.

A study of the immunologic effects of thymectomy in MG showed that long-term thymectomized MG patients had mild T cell lymphopenia, expansion of some Vß T cells, polyclonal increase in serum immunoglobulins, and high levels of autoantibodies, including anti-dsDNA and anticardiolipin antibodies. In contrast, these immunologic abnormalities were not seen in nonthymectomized and recently thymectomized MG patients. Two long-term thymectomized patients developed SLE and undifferentiated connective tissue diseases (80). Thus, thymectomy is effective in the treatment of MG, but the clinical data suggest that it may lead to the development of systemic autoimmunity in genetically predisposed subjects.

A patient with widespread cutaneous and mucosal eruption following MG and a thymoma with features of cutaneous LE and pemphigus erythematosus has been described (81). A pair of monozygotic twins who were concordant for MG underwent thymectomy, and one twin developed frank, severe SLE 18 years later. The other twin remained relatively well after thymectomy except for mild symptoms, leukopenia, and positive ANA (82). Primary antiphospholipid syndrome developed 2 years after thymectomy in patients with MG (83).

Both SLE and MG are characterized by the presence of autoantibodies. ANAs are found in 30% of patients with MG, and IgG anticardiolipin antibodies are seen in 25%, especially those with thymic abnormalities (84). Additionally, antibodies to organ-specific antigens, such as skeletal muscle, thyroid, and thymic cells, are abundant (85). The most characteristic serologic abnormality in MG is the presence of IgG antibodies to AChRs. No cross-reactivity between anti-DNA and AChRs antibody has been noted (86). SLE and MG differ in regard to certain cell-mediated immune functions. Whereas patients with SLE have decreased cellular immunity, as measured by skin testing, migratory inhibition factor production by mononuclear cells, and peripheral blood lymphocyte response to mitogens, patients with MG have a normal lymphocyte response to mitogens (87). Enumeration of lymphocyte subsets have yielded normal to abnormal numbers (85). Diaz-Jouanen (87) suggested that SLE and MG represent opposite extremes in the spectrum of abnormalities and modulations of the immune response by the thymus that may lead to autoimmunity.

The coexistence of autoimmune disorders in 721 patients with MG has been examined (88). Sixty-six other autoimmune diseases were found in 60 subjects (8.3%), including 3 patients with SLE and 5 patients with RA. Oosterhuis and de Hass (89) found a 1% prevalence of SLE in a large series of patients with MG. Of their 142 patients with MG, 2 had SLE and 7 RA, suggesting that RA and not SLE was more frequently associated with MG. Killian and Hoffman (77) found 5 cases of SLE among 1,604 cases of MG that were collated from five large series. Taking the prevalence rate of SLE as between 1/2,000 and 1/25,000 and that of MG as 1/20,000, they concluded that the 5 patients with SLE in the population of 1,604 patients with MG occurred other than by chance. These numbers would be even more significant if the patients with SLE who did not fulfill the ARA criteria were included in the computation. A population-based study of MG in Norway showed a prevalence rate of 9.6 per 100,000 inhabitants; SLE was found in 8.3 of the patients with MG, which was 200 times higher than the prevalence of SLE (0.039%) in the general Scandinavian population (90).

Transient neonatal MG is a syndrome in infants that is mediated by the transplacental transfer of maternal IgG antibodies to AChRs, causing a weak suck, hypotonia, and difficulty in swallowing and respiration. A case of co-existent neonatal LE and transient MG in an infant who was born of a lupus mother with acetylcholine antibodies but without myasthenic symptoms has been reported (91).

Thymomas are uncommon neoplasms arising from thymic epithelial cells with variable morphology. They predominantly occur in adults, with no gender predilection (92). Of patients with thymoma, 40% have parathymic syndromes (93), the most common being MG, pure red cell aplasia, and adult-onset acquired hypogammaglobulinemia. Thymomas are found in 15% of patients with MG and also have been described in those with connective tissue diseases, including SLE. Of 598 patients with thymomas who were collected from the literature, 8 had SLE (94). In some cases, thymoma and SLE have been associated with another disorder, such as progressive multifocal leukoencephalopathy (95), vacuolar myopathy (96), or red cell aplasia (97). The effect of removal of the thymoma on the clinical course of SLE is variable (98 ,99). Larsson (100) described a 62-year-old woman with SLE and coexistent thymoma; the tumor enlarged while the SLE improved. In contrast, a thymectomy in another patient temporarily reduced the clinical and laboratory manifestations of SLE (79).

In summary, SLE and MG occasionally may co-exist, with the MG preceding SLE in 75% of patients. Thymectomy for MG appears to be a precipitating factor for development of SLE in some patients. Table 41-1 summarizes the

lymphoid and thymic abnormalities that are seen in patients with SLE.

Table 41-1: Lymphoid and Thymic Abnormalities in Systemic Lupus Erythematosus (SLE)

Lymphadenopathy is seen in 30% to 78% of patients with SLE; the nodes are discrete and nontender; prominent enlargement of lymph nodes may develop particularly in children and blacks.
The spleen is palpable in 9% to 46% of patients; an enlarged spleen is present in 67% of autopsy cases; the onionskin lesion in the splenic arterioles is a characteristic finding; hyposplenism is noted in <5%.
Germinal centers consisting of focal collections of lymphocytes are noted in the thymic medulla of patients with SLE; myasthenia gravis and SLE occasionally co-exist.

Hematologic Changes in SLE

Hematologic abnormalities are exceedingly common in SLE and often are presenting manifestations of the disease. Sometimes, their features may mimic those of primary blood dyscrasias, and the nature of the underlying disorder can be completely overlooked unless SLE is considered in the differential diagnosis and specific diagnostic studies performed.

Anemia

Prevalence

Most patients with SLE develop anemia at some time during the course of their disease. Michael et al. (101) reported that 87 of 111 patients with SLE (78%) had a hemoglobin level of lower than 12 g/dL at diagnosis. Subsequently, 15 of 24 patients who had normal hemoglobin level on presentation developed anemia. In general, anemia was moderate, but it was severe in some patients. The anemia usually was normochromic and normocytic, and it appeared to depend partly on the severity and duration of the illness. Three of their patients had autoimmune hemolytic anemia. The experience of other investigators has been similar to that of Michael et al. Hemoglobin of below 11 g/dL was present in 51% of the 520 patients of Dubois and Tuffanelli (2), in 73% of the 150 patients of Estes and Christian (7), and in 98% of the 275 patients of Haserick (44).

Classification

Anemia in SLE can be classified into two broad categories according to putative mechanisms: nonimmune and immune. The nonimmune-mediated group includes anemia of chronic disease, iron deficiency anemia, sideroblastic anemia, anemia of renal disease, drug-induced anemia, and anemia secondary to another disorder (e.g., sickle cell anemia). Immune-mediated anemias in SLE include autoimmune hemolytic anemia, drug-induced hemolytic anemia, aplastic anemia, pure red cell aplasia, and pernicious anemia.

A prospective study of 132 SLE patients with anemia (defined as hemoglobin of 12 g/dL or less in women and 13.5 g/dL or less in men) found the most common causes to be anemia of chronic disease (37%), iron deficiency anemia (36%), and autoimmune hemolytic anemia (14%). Other causes (13%) included pernicious anemia, chronic renal failure, cyclophosphamide-induced myelotoxicity, and miscellaneous conditions (102). It is not uncommon to see combination of two or more factors in the etiology of anemia in individual patients.

Anemia of Chronic Disease

The most common type of anemia in SLE is anemia of chronic disease. The red cells on the peripheral blood smear are normochromic and normocytic. The serum iron concentration is reduced, and the total iron-binding capacity is unchanged or slightly low. A decrease in the iron saturation of transferrin is present. The bone marrow examination usually is normal, with adequate iron stores (101). The anemia develops slowly unless it becomes complicated by other factors, such as blood loss. The reticulocyte count is low for the degree of anemia (103).

Iron Metabolism

Iron metabolism was investigated by Burger et al. (104) in 11 patients with SLE using 59Fe. Iron use was decreased in 7 of these patients. Radioactivity over various organs differed from normal, with increased levels of radioactivity over the spleen and liver. The increased amount of absorbed iron did not appear to serve the purpose of hemoglobin synthesis, but was stored instead. Plasma iron turnover, on the other hand, was elevated in most patients. The life span of erythrocytes was reduced in the absence of hemolysis. It was concluded that the anemia of chronic disease in patients with SLE may be attributed to insufficient bone marrow activity, shortened red-cell life span, and, possibly, poor uptake of iron.

Whittingham et al. (105) found low mean serum iron levels in SLE. Following the administration of prednisolone, a two- to fourfold rise in the serum iron level occurred. This increase in the serum iron concentration was not sustained.

Pathogenesis

Recent investigations on the pathogenesis of the anemia of chronic disease indicate that multiple factors are involved, including a modest shortening of red cell survival,

impaired erythropoiesis, and disturbances in the storage and mobilization of iron stores in the reticuloendothelial system. There is blunting in the production of erythropoietin in response to the anemia and the responsiveness of erythroid progenitors to erythropoein is reduced. Inflammatory cytokines including interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)-α, IL-10 are believed to be implicated in these abnormalities (106 ,107 ,108).

Tzioufas et al. (109) found serum antibodies to erythropoietin in 15% of SLE patients, and the presence of these antibodies was associated with severe anemia and active disease. Whether these antibodies can directly inhibit erythropoiesis in SLE or not remains to be investigated. Schett et al. (110) found decreased serum level of erythropoietin in SLE patients when related to the degree of anemia indicative an inadequate response. Although anti-erythropoetin antibodies were detected in 40% of patients their presence was not associated with the severity of the anemia.

Hepcidin, a hormone synthesized by liver during inflammation, regulates iron metabolism and is implicated in the anemia of chronic disease. Hepcidin inhibits iron intestinal absorption and the release of stored iron in macrophages resulting in hypoferremia and decreased delivery of iron to maturing red cells in the bone marrow. Recent studies have shown that IL-6 induces the synthesis of hepcidin (111). Serum levels of hepcidin have not been measured in SLE, however, it has been reported that elevated levels of IL-6 correlate with anemia, suggesting that possible linkage of lupus anemia with hepcidin (112).

Iron Deficiency Anemia

Iron deficiency anemia is most commonly a result of menorrhagia and to GI blood loss secondary to the chronic use of nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids.

Differentiating between anemia as a result of iron deficiency and anemia of chronic disease may be difficult in some patients. In general, a low serum ferritin level is associated with depletion of body iron stores. However, in inflammatory conditions such as RA, ferritin is an acute-phase reactant and the serum level may become elevated. Thus, serum ferritin may be normal or elevated in an iron-deficient anemic RA patient. In SLE, the serum ferritin level is positively correlated with disease activity and high anti-dsDNA titer (113). Measurement of the serum level of soluble transferrin receptor and the ratio of the transferrin receptor to serum ferritin have been reported to be useful in diagnosing iron deficiency in the presence of chronic inflammation and anemia of chronic disease (108 ,114).

Hemoglobinopathies

Sickle cell anemia and SLE share common clinical manifestations, including arthralgias, chest pain, pleural effusion, cardiomegaly, nephropathy, strokes, and seizures. Additionally, my group has found that patients with sickle cell hemoglinopathies have an increased prevalence of autoantibodies, including ANAs (50). The co-existence of SLE and sickle cell anemia has been reported (50 ,53 ,115 ,116 ,117 ,118 ,119), and in some of these patients, the recognition of SLE was delayed because of similarities in the clinical features of these conditions (120 ,121). Wilson et al. (122) postulated that abnormalities in the alternative pathway of complement in sickle cell hemoglobinopathy may predispose patients to immune complex disorders, including SLE, but no evidence has been found to show that SLE is more prevalent in those with sickle cell hemoglobinopathies. The risk for infectious complications is increased in both conditions. Hydroxyurea has been reported to reduce the severity and frequency of vaso-occlusive crises in a patient with sickle cell anemia and SLE (123).

In northeast Italy, where there is a high prevalence of ß-thalassemia, Castellino et al. (124) reported that the ß-thalassemia trait was seen less frequently among SLE patients than in the general population. However, SLE patients with the ß-thalassemic trait tended to have Sjögren syndrome and more severe course.

Sideroblastic Anemia

A few cases of sideroblastic refractory anemia in SLE have been reported, including one terminating in erythroleukemia (125). Another patient who had refractory anemia with excess of blasts, which is a myelodysplastic syndrome, developed SLE (126). These cases probably are incidental and do not represent a true association with SLE.

Immune-Mediated Anemias

The inhibition of erythropoiesis by cellular and serum factors may be important in the pathogenesis of chronic anemia in patients with SLE. The number of colony-forming unit-erythroids (CFU-Es), which are the late erythropoietic precursors, has been found to be significantly reduced in the bone marrow of anemic patients with SLE (127). Moreover, the formation of CFU-E was inhibited in vitro by autologous and allogeneic T lymphocytes from untreated subjects, but not by those from steroid-treated patients with SLE (127). The activity of monocytes to stimulate bone marrow fibroblasts to produce a hemopoietic growth factor was found to be diminished in SLE (128). Bone marrow stromal cells play an important role in hemopoiesis, and the diminished production of growth factor may be another cause of hemocytopenia in SLE.

Circulating inhibitors of erythropoiesis also have been described (129 ,130 ,131 ,132 ,133 ,134). Sera from patients with SLE and anemia of chronic disease suppressed CFU-E formation (132). Dainiak et al. (130) characterized the serum inhibitor as having the physical properties of an immunoglobulin, and its presence was associated with disease activity. The inhibitor was removed by plasma exchange and by steroid therapy.

Pure Red Cell Aplasia

Pure red cell aplasia (PRCA) is an autoimmune hematologic condition that is characterized by severe normochromic normocytic anemia, reticulocytopenia, absence of red cell precursors, and normal white cell and megakaryocyte lines in the bone marrow. Different pathogenetic mechanisms have been proposed for PRCA, including humoral suppression of erythropoiesis by serum antibodies to erythroblasts, to CFU-Es, or to erythropoietin, and T cell mediated suppression of erythropoiesis.

PRCA is associated with a number of autoimmune conditions, and rare cases of co-existent PRCA and SLE (and procainamide-induced LE) have been reported (135 ,136 ,137 ,138). In a review of 24 cases in the literature, Habib et al. (139) found that SLE was diagnosed either before or concomitantly with PRCA and the clinical features of these patients were not different from the general SLE patient population, with the exception of less frequency of pleuritis.

The pathogenesis of PRCA in SLE probably involves different immune mechanisms and may vary from one patient to another. Elevated serum titer of antibodies to erythropoietin has been reported in PRCA and SLE, and the antibody titer decreased with response to therapy (140). Serum and IgG fraction from SLE patients with PRCA inhibited the growth of red cell precursors (129 ,141). T cell suppression of erythropoeisis has been described in a SLE patient without evidence of a humoral inhibitor (142).

Several therapeutic modalities have been used in the treatment of PRCA, including corticosteroids, immunosuppressive agents, plasmapheresis, and lymphapheresis. PRCA coexistent with SLE responded to corticosteroid therapy, however many of the patients remained steroid-dependent (139). Good response to recombinant erythropoietin (143), high-dose intravenous (IV) γ globulin (140), plasmapheresis (144), and cyclosporine alone or in combination with mycophenolate (142 ,145) have been reported in SLE patients with PRCA.

Aplastic Anemia

Aplastic anemia is an uncommon hematologic condition characterized by pancytopenia, low reticulocyte count, and a hypocellular bone marrow. It rarely occurs in SLE secondary to the use of nitrogen mustard derivatives, azathioprine, antimalarials, or other agents, such as chloramphenicol (146) and dapsone (147). Wang et al. (148) reported severe pancytopenia and bone marrow hypoplasia among Chinese patients receiving chlorambucil for lupus membranous nephropathy. In a few published cases, the aplastic anemia was considered to be caused primarily by the underlying disease; however, the role of drugs cannot be completely excluded (131 ,149). Rarely, pancytopenia and aplastic anemia can be the initial manifestation of SLE antedating the other clinical features of the disease (150). Aplastic anemia has been reported in an infant with neonatal lupus erythematosus (LE) (151).

The presence of circulating antibodies to precursor bone marrow cells suggests that some cases of aplastic anemia may be the result of an autoimmune process. Brooks et al. (152) identified a complement-dependent IgG antibody that suppressed the growth of allogeneic granulocyte-macrophage progenitor cells in vitro. Bailey et al. (153) found a noncomplement IgG antibody that inhibited in vitro granulocyte-macrophage progenitor cells and erythroblast-forming units in a patient with SLE and aplastic anemia. The IgG antibody disappeared on recovery of the patient. Other investigators have suggested T cell–mediated suppression of hematopoiesis in aplastic anemia (154). Erythroid progenitor burst-forming units colonies were cultured from the patient's bone marrow. Removal of $CD8^+$ lymphocytes led to a marked increase in immature erythroid progenitors, suggesting that suppressor lymphocytes inhibited the development of erythroid progenitors (151).

Various regimens have been used successfully for the treatment of aplastic anemia that is associated with SLE. These include androgens, cyclophosphamide, cyclosporine, antithymocyte globulin, and plasmapheresis in conjunction with systemic corticosteroids (153 ,154 ,155 ,156 ,157).

Bone Marrow Findings and Function

Michael et al. (101) examined the bone marrow aspirates of 32 patients with SLE and found them to be normal in most. Plasma cells were increased in 13 patients. One patient had a hypoplastic marrow, and two patients with autoimmune hemolytic anemia had a hypercellular marrow. Similar findings have been reported by others (158).

Careful studies by Burkhardt (159) of bone marrow biopsy specimens in 21 patients with SLE have shown significant alterations in the blood vessels, cellular elements, and intercellular substance. Compared with those of control subjects, an increased frequency of the following changes in SLE was found:

- Subintimal swelling of the arteries and arterioles, with evidence of the deposition of proteins in the vessel wall, was seen.
- Endothelial swelling and dissociation were found in the sinusoids.
- The ground substance was edematous, with fibrinoid and sclerosing changes.
- A proliferation of histiocytes bearing cytoplasmic inclusions of iron-positive protein material was noted.
- Diffuse plasma cell proliferation occurred, with the formation of Russell bodies.
- There was a reduction of granulopoiesis with predominantly immature forms, and necrobioses with opal nuclei were observed.

Feng et al. (160) examined the bone marrow of 23 SLE patients presenting with pancytopenia. The most common abnormalities, which were seen in 9 patients (39%), were hypoplasia and dyserythropoiesis. The latter refers to nuclear budding and immaturity in the presence of full

cytoplasmic hemoglobin. Lymphocytosis was found in 5 patients (22%). Other abnormal findings included gelatinous transformation, plasmacytosis, and marrow hyperplasia. Pereira et al. (161) found global hypocellularity (48%), increased reticulin proliferation (76%), and necrosis (19%) to be the most common abnormalities in the bone marrow in 21 SLE patients with peripheral cytopenias. An interesting finding is the presence of storage and hemophagocytic histiocytes in the bone marrow of SLE patients during episodes of hemocytopenia (162).

These morphologic changes are not specific for SLE; and may be seen in patients with RA and other diseases (159). Nevertheless, these findings, as well as the presence of autoantibodies and cellular factors that impair bone marrow precursor cells, suggest that the bone marrow is a major target organ in SLE.

The number of $CD34^+$ primitive hematopoetic stems cells in the bone marrow were found to be decreased in active SLE and the reduction may be a result of increased apoptosis (163). Recent data suggest that autoreactive T-lymphocytes in the bone marrow of SLE patients may damage stem and progenitor cells and impair the capacity of the bone marrow stroma to support hematopoeisis. Intensive immunosuppression and autologous stem cell transplantation in one SLE patient presumably to eliminate autoreactive lymphocytes restored some of the abnormalities of hematopoesis (164).

Sera from leukopenic SLE patients containing anti-dsDNA antibodies induced apoptosis of allogeneic normal $CD34^+$ bone marrow cells in vitro. The nature of the serum factor and its significane on bone marrow function in SLE are unclear (165).

Autoimmune Myelofibrosis

Myelofibrosis is characterized by excessive deposition of collagen and extracellular matrix proteins in the bone marrow stroma, hypercellularity, and neoangiogenesis. These changes may be associated with a variety of conditions including myeloproliferative disorders, hematologic and nonhematologic malignancies, endocrine disorders, and other conditions. Myelofibrosis occurring in the setting of SLE has been described in a few cases (129 ,166 ,167 ,168 ,169 ,170 ,171). Conversely, SLE is a rare etiology of myelofibrosis.

Paquette et al. (172) introduced the term “autoimmune myelofibrosis” in their report of eight patients with myelofibrosis and SLE. Myelofibrosis developed either before or concurrent with the diagnosis of lupus in five patients, while in the remaining three, myelofibrosis developed after the onset of SLE. Five patients fulfilled four or more American College of Rheumatology (ACR) criteria for SLE, and three patients met three criteria. All had positive ANAs, anti-DNA antibodies, and/or positive LE cell test. The patients presented with pancytopenia, and bone marrow biopsy showed fibrosis with increased amounts of fibrillar reticulin, collagen, and fibroblasts. Half of the patients had splenomegaly.

Steroid therapy improved the peripheral blood cytopenias in half of the patients with SLE and even reversed the myelofibrosis in a few (173 ,174 ,175). Compared to patients with idiopathic myelofibrosis and myeloid metaplasia, patients with SLE and this condition tended to be younger, had a lower frequency of splenomegaly, and were responsive to steroid and immunosuppressive therapy. High-dose γ globulin has also been used successfully in the treatment of myelofibrosis in SLE (176).

Gelatinous Transformation of the Bone Marrow

Gelatinous transformation of the bone marrow is characterized by atrophy of fat cells, loss of hematopoetic cells, and accumulation of extracellular mucopolysaccharides abundant in hyaluronic acid. It has been reported in a wide spectrum of chronic diseases including SLE and is associated with cachexia and severe illness. Ng and associates (177) reported 3 of 30 SLE patients with pancytopenia had gelatinous transformation of the bone marrow. Two of these patients were cachectic, one of whom had concomitant tuberucolosis.

Hemophagocytic Syndrome

Hemophagocytic syndrome (HPS) is severe acute febrile illness characterized by pancytopenia, hepatosplenomegaly, lymphadenopathy, liver dysfunction, and pathologic finding of macrophage activation with phagocytosis of mature and precursor blood cells in the bone marrow and other tissues. Elevated serum ferritin and triglycerides may be present. HPS may be a primary condition or a reactive event in infections, malignancy and autoimmune diseases, including adult-onset Still disease and SLE.

Wong et al. (178) described six patients with SLE who presented with fever and severe pancytopenia related to HPS. A study of 40 consecutive cases of reactive hemophagocytic syndrome in Hong Kong identified two patients with SLE (179). A review of 14 SLE cases in France showed that HPS occurred frequently with the onset of SLE although some cases were triggered by an infection (180). Relapses of HPS occurred in four patients during lupus disease flares. HPS associated with Epstein-Barr virus (EBV) activation during immunosuppressive therapy for lupus nephritis has been reported (181).

The pathogenesis of HPS in SLE is not known but its occurrence during disease flares suggests that it may be related to increased IL-18 production (182).

Various modalities have been used for the treatment of HPS in SLE including corticosteroids, IV γ globulin and plasmapheresis (179 ,183 ,184). Concomitant infection should be treated aggressively.

Pernicious Anemia and SLE

Pernicious anemia often is associated with other autoimmune disorders, such as Sjögren syndrome and Hashimoto

thyroiditis, yet only a few cases of co-existent SLE and pernicious anemia have been reported (185 ,186 ,187 ,188). The treatment of pernicious anemia when accompanied by SLE requires the administration of both vitamin B12 and systemic corticosteroids. Replacement therapy with vitamin B12 usually is not sufficient to reverse the hematologic abnormalities in patients with lupus and pernicious anemia (189).

Molad et al. (190) found that 18.6% of 43 female patients with SLE had abnormally low serum cobalamin levels, but none had pernicious anemia. As a group, SLE patients had lower mean levels of cobalamin than control subjects did. Low serum levels of transcobalamin II and unsaturated vitamin B12 capacity correlated with lupus disease activity (191).

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AIHA) is not an uncommon cause of anemia in patients with SLE. Approximately 7% to 15% of those in large series developed AIHA (47 ,192 ,193 ,194). Among a group of 186 patients with SLE who were studied by Alger et al. (192), 17 (7%) had Coombs-positive hemolytic anemia. Of these 17 patients, 6 had Evans syndrome (i.e., the concurrence of AIHA and immune thrombocytopenic purpura). In a prospective study of 126 SLE patients, 16 (12.7%) developed AIHA, and 3 had Evans syndrome (195).

AIHA may be the initial manifestation of SLE, occurring in 2% to 6% of patients (29 ,196). In five of ten patients who were studied by Videbaek (197), AIHA was the initial and dominant clinical feature of the disease for several months, and years, before other manifestations of SLE appeared. AIHA developed during the course of SLE in the other patients.

Classification

AIHA can be classified into two major types with respect to the anti-erythrocyte antibody and the optimal temperature of antibody reactivity with antigens on the red cell surface. The warm type of AIHA is mediated by IgG antibodies that are capable of reacting with antigens optimally at 37°C. Cold agglutinin AIHA is mediated by IgM complement-fixing antibody, which binds optimally to red cell antigens at 4°C. (Chapter 27 discusses the immunology of anti-erythrocyte antibodies in SLE.)

Warm AIHA

Warm AIHA is the predominant type in patients with SLE. Red blood cells that are coated by the warm IgG antibodies are removed from the circulation, primarily by sequestration in the spleen. The antibody-coated red blood cells undergo membrane alteration in vivo, resulting in the formation of spherocytes. Matsumoto et al. (198) examined the fine structure of the spleen in AIHA during SLE and found that erythrocytes coated with IgG and complement were phagocytosed completely by splenic macrophages and, to a lesser extent, by sinus endothelial cells. In contrast, in the liver, only evidence of occasional phagocytosis of sensitized erythrocytes by the Kupffer cells was found, confirming that the spleen is the major site of red blood cell destruction.

The symptoms and clinical findings in AIHA are variable. Symptoms that are referable to the anemic state, such as weakness, dizziness, and fever, are common. Evidence of hemolysis, including jaundice and dark urine, may be found. AIHA in the setting of SLE develops gradually in most patients, but occasionally it may present as a rapidly progressive hemolytic crisis (196 ,197).

With a significant degree of hemolysis, anisocytosis and macrocytosis often are noted in the peripheral blood smear. Nucleated red blood cells are seen in patients with marked hemolysis. Occasionally, polychromatophilic red cells, stippled cells, and Howell-Jolly bodies are found. The bone marrow is hyperplastic, frequently with a shift to the left in the myeloid series (196). Reticulocyte counts are elevated in association with a significant degree of hemolysis after hemorrhage and during systemic corticosteroid therapy.

The serum haptoglobin level usually is reduced during active phases of hemolysis (199 ,200 ,201). In the presence of infection, cancer, or steroid treatment, the serum haptoglobin level rises; consequently, if hemolysis coexists with these factors, the serum level may be normal (199 ,201). This also is observed when bone marrow function is impaired.

AIHA with Positive ANA

Tan and Chaplin (202) found low-titer ANA in 39% patients with idiopathic AIHA who did not have an underlying systemic connective tissue disease or lymphoproliferative disorder. No correlation was found among ANA and various clinical or serologic parameters. Favre et al. (203) described three patients with AIHA and one with immune thrombocytopenic purpura with positive ANA and anti-dsDNA antibodies that did not develop the full clinical picture of SLE after long-term follow-up. None had evidence of clinical renal disease, but on kidney biopsy, all had mild mesangial proliferation of focal glomerulonephritis. Miescher et al. (204) enlarged their series to ten patients. All had AIHA and/or autoimmune thrombocytopenia with positive ANA and low-titer or negative anti-dsDNA antibodies. Two of their patients had mild arthralgias; however, none developed clinical features of SLE. The authors suggested that these patients represent a transitional form between SLE and AIHA and autoimmune thrombocytopenia.

SLE Subset with Hematocytopenia

Alger et al. (192) compared the features of 31 patients with SLE who presented with AIHA and/or immune thrombocytopenia to a group of 62 patients with SLE but without

hematologic manifestations. The former group, which was younger and included a greater percentage of females, had a lower prevalence of fever, polyarthritis, serositis, cutaneous vasculitis, nephropathy, and central nervous system (CNS) disease, and had fewer complement abnormalities. It was suggested that patients with SLE who develop AIHA and/or immune thrombocytopenia constitute two related subsets of lupus patients with a relatively better prognosis. The high frequency of antiphospholipid antibodies in SLE patients with hemocytopenia further supports this concept (205 ,206). In contrast, Nossent and Swaak (146) reported that hemolytic anemia, neutropenia, or lymphopenia did not influence the survival rate of patients with lupus. Moreover, late-onset thrombocytopenia was associated with a decreased probability of survival.

Kokori et al. (207) reported that the recurrence rate of hemolytic anemia in a group of SLE patients with AIHA was low among treated patients (4 per 100 persons-years). They also found an association between AIHA and IgG anticardiolipin antibodies and thrombosis.

Combined Warm and Cold AIHA

Sokol et al. (208) found that 7% of 865 patients with AIHA who were referred to a blood transfusion center had warm IgG and cold IgM anti-red cell antibodies, and that both antibodies contributed to the hemolysis. Of the patients in this group, 20% had SLE. The high frequency of SLE was confirmed by Shulman et al. (209), who found that 5 of 12 patients (42%) with combined warm and cold AIHA had SLE.

IgG and C3d usually are present on the patient's red blood cells. In the serum, both IgG warm antibodies and high-thermal-amplitude cold IgM auto-agglutinins are detectable. The IgM antibodies are reactive over a broad temperature range, from 0°C to 30°C or higher (209). Patients with this type of AIHA have severe hemolysis but generally are responsive to corticosteroid therapy (209).

Treatment

Medical Therapy

Systemic corticosteroids, 1 to 1.5 mg/kg of prednisone daily or its equivalent, are efficacious, and remain the mainstay of the treatment for AIHA in patients with SLE. It is preferable to administer steroids parenterally to the symptomatic and acutely ill patient and later switch to an oral preparation when the patient has stabilized and improved. The dose is maintained for at least 4 to 6 weeks and gradually tapered, provided that a continued and/or sustained response occurs. No controlled trials have been reported on the use of corticosteroids in the treatment of AIHA in SLE, but our clinical experience (and that of others) indicates that approximately 75% of patients respond satisfactorily to steroid therapy (210). The response rate is similar to the 76% reported in patients with idiopathic warm AIHA (210 ,211). All 16 patients with SLE and AIHA who were followed prospectively responded to steroid therapy (120).

The mechanism of action of corticosteroids in AIHA is multifactorial, including an effect on tissue macrophages, altering of antibody activity, and a decrease in antibody production (211). In steroid-responsive patients who were studied by Priofsky (210), the clinical response was evident within a week. Stabilization of the hematocrit occurred within 30 to 90 days after the initiation of therapy.

In patients with severe and rapidly progressive hemolytic anemia, pulse methylprednisolone should be tried, 1 g intravenous for 3 consecutive days, followed by the conventional steroid dose (212). The reticulocyte count can be used to monitor the response to treatment and to detect any relapse as the steroid dose is tapered. A drop in the reticulocyte count is associated with a relapse in the hemolytic process.

Various treatment measures have been tried in patients who fail to respond to systemic corticosteroids alone or in those who continue to require a moderate to high dose of prednisone to control hemolysis. Most of the experiences have come from uncontrolled clinical studies. Priofsky (210) used azathioprine, 2 to 2.5 mg/kg, in conjunction with prednisone, 10 to 20 mg/day, in patients with AIHA who failed to respond to full therapeutic doses of prednisone. Danazol in conjunction with high-dose corticosteroids has been reported to be useful in the treatment of warm AIHA, including that associated with SLE (213). A combination of prednisone and danazol has been reported to be effective as a first line as well as for refractory AIHA including SLE (214). Plasmapheresis (215), high-dose IV γ globulin (216), and vinca-laden platelets (217) have been used with some success in a small number of patients with idiopathic AIHA refractory to conventional therapy. Intravenous IgG has been shown to be effective in 40% of 73 patients with warm AIHA; thus, it is not recommended as a standard therapy but may be useful as an adjunctive therapy for selected patients, such as those with toxicity to other treatments (218). Mycophenolate mofetil may be an effective second-line agent in the treatment of AIHA in SLE (219).

Rituximab, a chimeric monoclonal antibody to CD20 that depletes B cells and is used for the treatment of B cell lymphomas has been tried in autoimmune diseases including SLE. Our preliminary experience and those of others in severe SLE including patients with AIHA and immune thrombocytopenia indicate that Rituximab is an effective agent (220 ,221 ,222). Controlled trials are needed to establish its therapeutic use and safety in SLE.

Splenectomy

Splenectomy is used to treat patients with idiopathic warm AIHA who require a high maintenance dose of prednisone (20 mg/day or more), patients who have frequent relapses, or those with serious side effects to steroid therapy. In general,

splenectomy as a treatment is less effective for warm AIHA than for immune thrombocytopenia. The response rate to splenectomy in those with idiopathic warm AIHA is 50% to 60% (223), with reduction in the steroid maintenance dose or amelioration of the hemolysis.

It was suggested by early workers that splenectomy for idiopathic immune thrombocytopenia or idiopathic AIHA somehow unmasks occult or latent lupus, thus causing a dissemination of the disease. Best and Darling (224) reviewed the pertinent evidence both for and against this controversial issue, and they concluded that splenectomy does not lead to the dissemination of SLE, but on the contrary, has a beneficial effect for many patients.

Early studies on a small number of cases suggested that splenectomy is not efficacious in the treatment of warm AIHA associated with SLE (2 ,197). More recent studies have shown that splenectomy is of some value in the treatment of selected cases, but that this benefit may not be long-lasting. Of seven patients with SLE and warm AIHA (five had concomitant immune thrombopenia) who underwent splenectomy, six showed a sustained increase in hematocrit of greater than 20% (225). Rivero et al. (226) compared the clinical course of 15 patients with SLE and AIHA and/or immune thrombocytopenia who underwent splenectomy and 15 SLE patients who were treated medically for the hemocytopenia. Splenectomy produced short-term benefit, but at follow-up, no clear-cut difference in the clinical course of the two groups was seen. The splenectomy group had a significantly higher frequency of cutaneous vasculitis and serious infections after surgery. More of the splenectomized patients eventually required immunosuppressive therapy than did those in the medically treated group at follow-up.

Patients with SLE and AIHA who fail to respond to systemic corticosteroids alone should be given immunosuppressive agents next. The role of other measures in these patients, including IV γ globulin, plasmapheresis, mycophenolate, cyclosporine, and other agents, remains to be defined. Splenectomy probably should be reserved for the patient with acute fulminant AIHA who fails to respond to aggressive medical treatment (226). Laraparoscopic splenectomy has been shown to be a relatively safe procedure for most patients including those with SLE (227). Polyvalent pneumococcal vaccine should be given to splenectomized patients, such as those with functional asplenia.

Blood Groups and Transfusions in SLE

The distribution of ABO and Rh blood types of 138 patients with SLE who were studied by Dubois and Tuffanelli (2) was normal; 86 of the patients were Rh positive. Similar results were obtained by Leonhardt (228), who found no differences in the major blood groups of 54 patients with SLE, 221 of their relatives, and 5,668 healthy blood donors.

The prevalence of adverse reactions to blood transfusion has been low. In 82 patients (16%) studied by Dubois who received one or more blood transfusions, only 3 developed reactions, 1 developed urticaria, and 2 developed fever. Of the patients of Harvey et al. (10), 39 (35%) received one or more blood transfusions. Over 200 blood transfusions were administered, and the frequency of untoward reactions was low. Occasionally, a brief febrile response or urticaria occurred, but these patients subsequently were transfused without recurrence of the reaction. In contrast, Michael et al. (101) commented that in their experience, transfusion reactions appeared to be more common in patients with SLE than in the general hospital population, but no statistical data were presented.

Blood transfusions should be avoided whenever possible, not only because of the risks but also because of the observation that patients with SLE develop iso-antibodies against red cell antigens. Callender et al. (229 ,230) reported a patient with SLE who, in response to multiple blood transfusions, developed iso-agglutinins to five different red cell antigens that usually are ignored by most individuals. Multiple types of iso-agglutinins were found in the serum of another transfused patient with probable SLE (231). Another patient with SLE developed hemolytic anemia following multiple blood transfusions, with the appearance of three atypical hemagglutinins (232). A hemoglobinuric transfusion reaction resulting from Rh isosensitization has been described as well (233).

The antibody response of patients with SLE to blood group antigens has been examined following experimental immunization. The intravenous injection of 1 mL of incompatible whole blood led to the appearance of an unusually high isoagglutinin titer in a patient with SLE (234). Zingale et al. (235) immunized 15 SLE patients and matched controls with incompatible blood group substances. Patients with SLE developed higher titers of isohemagglutinin antibodies than the controls, as well as the transient appearance of a false-positive test for syphilis, circulating anticoagulants, antithyroglobulin, and antikidney antibodies. In contrast, the antibody production to various exogenous antigens following immunization in SLE has been either normal or depressed (236 ,237).

The few indications for blood transfusions in patients with SLE include those with acute massive bleeding, symptomatic patients with severe anemia, or those with concomitant severe heart disease or cerebrovascular ischemia. The response of patients with SLE and autoimmune hemolytic anemia to systemic corticosteroids generally is prompt and favorable, so that blood transfusion may not be necessary. Circulating anti-erythrocyte antibodies make blood cross-matching difficult (238).

Recombinant Erythropoietin Therapy

The anemia of chronic renal failure can be treated effectively with recombinant human erythropoietin, provided that sufficient iron stores are available (239). Used mainly for patients with end-stage kidney disease who are on maintenance hemodialysis, it improves quality of life and avoids

blood transfusion. Epoetin therapy is also efficacious in the chronic anemia of cancer, HIV infection and in surgical patients. It is well tolerated except for a mild “flu-like” symptoms, and development or aggravation of hypertension. Thrombosis and seizures have been reported (240). Recently, rare cases of pure red aplasia associated with neutralizing anti-erythropoetin antibodies have been described (241).

Whether patients with SLE who are on hemodialysis with anemia respond differently to erythropoietin therapy than patients without SLE has not been specifically investigated. My group has treated SLE patients on chronic hemodialysis before renal transplantation, and with good results.

Lim et al. (242) have shown that erythropoietin also is effective in ameliorating the anemia in a group of predialysis patients with chronic renal failure as a result of SLE and other conditions. Patients with SLE and end-stage renal disease who are on hemodialysis may become resistant to erythropoietin therapy if the underlying disease becomes active (243). Erythropoietin also has been found to be useful in a pregnant SLE patient with nephritis (244) as well as in patients with RA and anemia of chronic disease (245).

In vitro studies have shown that recombinant erythropoietin can increase the production of immunoglobulins by B cells, cause proliferation of bone marrow progenitor cells, and increase the expression of erythrocyte complement receptor type 1 (246). Theoretically, recombinant erythropoietin can be beneficial to patients with lupus by increasing clearance of immune complexes or be harmful by stimulating autoimmune responses. A longitudinal study of five patients with SLE but without renal failure who self-administered recombinant erythropoietin, however, showed no significant changes in anti-dsDNA, antiphospholipid antibody titers, C3, and renal function. One patient with anticardiolipin antibodies who was on estrogen replacement therapy developed thrombophlebitis that related temporally to erythropoietin therapy (247). Further studies are necessary to examine the possible relationship between erythropoietin therapy and thrombotic episodes in SLE.

Thrombocytopenia and Platelet Disorders

Frequency and Significance

Thrombocytopenia, which is defined as a platelet count of less than 150,000 cells/mL, is not an uncommon finding in SLE. The prevalence among seven large series in the literature has ranged from 7% to 52%, with a mean cumulative percentage of 14.5% (2 ,7 ,10 ,11 ,46 ,101 ,248) (see Chapter 30 , Table 30-1).

The degree of thrombocytopenia is variable, but profound thrombocytopenia is uncommon. Mild thrombocytopenia often appears during an exacerbation of SLE without causing bleeding tendency. Platelet counts were available for 86 patients in a series of studies by Harvey et al. (10), and in 23 they were definitely depressed. Of the 12 who had platelet counts of less than 50,000/mL, patients were included in whom thrombocytopenia purpura was a predominant feature of their disease. Also, 7 had counts of between 50,000 and 100,000/mL, and 4 had counts of between 100,000 and 150,000/mL. None of these patients had abnormal bleeding. In a series by Larson (46) of 196 patients, 15 (8%) had platelet counts of below 100,000/mL on at least two occasions. Nine patients had purpuric lesions at the time that platelet counts were depressed, but six patients did not. An additional group of 9 patients had purpuric skin rash as a prominent feature of their illness, but the platelet count in these patients was never found to be below 100,000/mL. In 112 patients with SLE who were studied for hemostatic functions, Gladman et al. (248) found 18 patients with a platelet count of less than 150,000/mL. In this group, 10 patients had counts of below 100,000/mL, yet only 1 patient developed petechiae.

In association with thrombocytopenia, the usual coexistent laboratory abnormalities, such as a prolonged bleeding time and diminished clot retraction when the platelet count is below 50,000/mL, are noted. A positive tourniquet test may be present without any platelet deficit, however, and simply may reflect vascular fragility resulting from SLE or prolonged steroid therapy (249). Coexistent hemostatic defects often are observed in patients with SLE and low platelet counts (248). A correlation between the presence of anticardiolipin and other antiphospholipid antibodies and thrombocytopenia in SLE, as well as in chronic immune thrombocytopenic purpura, has been recognized (see Chapters 25 and 52).

The clinical significance of thrombocytopenia in SLE has been examined. A prospective study of 19 patients with platelet counts of less than 100,000/mL revealed two distinct clinical groups: patients who were thrombocytopenic only during severe multisystem disease flares and patients with a chronic low platelet count and intermittent mild flares in other systems. None of the patients in either group developed severe bleeding, and whether acute or chronic, thrombocytopenia itself did not determine the subsequent course and prognosis of the patient (250). In two large studies on survivorship, the presence of thrombocytopenia appeared to be a significant risk factor for a worse prognosis in SLE (251 ,252). When the significance of thrombocytopenia was examined in a highly selective subset of patients with SLE and biopsy-proven nephritis, Clark et al. (253) found that thrombocytopenia was a useful index of disease activity.

Immune Thrombocytopenic Purpura

A special relationship exists between SLE and autoimmune thrombocytopenic purpura (also referred to as idiopathic or immune thrombocytopenic purpura; ITP), both of which primarily afflict young females. Some patients with ITP who initially are considered to be idiopathic later may develop a classic clinical picture of SLE. Further, a thrombocytopenic purpura, clinically indistinguishable from ITP, may occur along the course of SLE.

From 3% to 15% of patients with ITP go on to develop SLE (254). In a group of 62 adults with chronic ITP who were studied by Difino et al. (255), 3 patients (4.8%) developed SLE. Perez et al. (256) found that 6 of 18 patients with ITP (33%) tested positive for ANA at presentation, and that four of them developed classic SLE, within a mean duration of 2.3 years. A retrospective study of 117 patients with ITP showed a positive ANA in 24 patients, and 4 of them developed SLE (257). Patients with high-titer ANA tested positive for anti-Ro/SSA and anti-La/SSA antibody. Thus, patients with ITP and high-titer ANA and precipitating antibodies to Ro/SSA may develop later SLE (258). It is noteworthy that anti-Ro/SSA antibody is associated with thrombocytopenia in SLE (259). Firkin et al. (260) coined the term lupoid thrombocytopenia to refer to a group of patients with chronic ITP who were ANA positive but did not have other clinical or laboratory findings of SLE. None had anti-DNA, anti-Sm, or anti-Ro/SSA. The value of using this label is questionable, however, because the ANA-positive patients were similar in every other respect to those in the ANA-negative group.

In 1956, Dameshek and Reeves (257) emphasized the high frequency of SLE that occurs following splenectomy for apparent ITP. In a series of 51 consecutive patients, 8 subsequently developed definite SLE, with 2 others being probable and 6 possible. Thus, at least 31% of the patients in this group eventually developed clinical manifestations of SLE, and 15 had definite SLE (261). A study of 115 ITP patients who underwent splenectomy revealed that 14 (12%) patients subsequently developed SLE. The high percentage may in part be a result of a referral bias in a tertiary care center (262).

Other investigators have since disputed this claim and found that splenectomy in ITP does not lead to the development of SLE (224 ,263 ,264 ,265). In 1960, Doan et al. (264) reviewed their experience with 381 cases of thrombocytopenic purpura over a 28-year period and found that SLE caused the syndrome in 2% of patients. After splenectomy, the prevalence of new SLE cases was 1.2%. Splenectomy did not precipitate or disseminate the symptoms or signs of SLE in any patient, and the investigators believe that the hazards to life during acute hypersplenic thrombocytopenic crises outweigh the danger of developing subsequent SLE. Best and Darling (224) undertook a critical analysis of the existing data on this issue, and they concluded that splenectomy does not lead to the dissemination of latent SLE but actually is beneficial to some patients with drug-resistant cytopenias.

Clinical Presentation

The clinical manifestations of thrombocytopenia in SLE generally are similar to those seen in patients with ITP or other causes of thrombocytopenia, and they depend on the platelet count. When the platelet count is below 50,000/mL, spontaneous bleeding or purpura may occur. In addition to the platelet count, however, other factors, including qualitative platelet defects and platelet age, are important in the development of spontaneous bleeding (266). Bleeding usually presents as petechiae and/or ecchymoses, especially in the lower limbs, which experience increased capillary pressure. Nasal and buccal mucosal hemorrhage, heavy menstrual blood flow, epistaxis, and gum bleeding also may be present. Spontaneous bleeding into the brain is the most feared complication and can be fatal.

Chapter 27 discusses the immunologic properties of antiplatelet antibodies in ITP and SLE.

Treatment

The mainstay of drug therapy is systemic corticosteroids, 1.0 to 1.5 mg/kg/day of prednisone equivalent. Corticosteroid therapy is considered to be the equivalent of medical splenectomy, because it prevents the sequestration of antibody-coated platelets in the spleen (266). In most patients, a clinical response is seen within 1 to 8 weeks. High-dose intravenous pulse methylprednisolone also has been used for profound thrombocytopenia in SLE, but its superiority over conventional steroid therapy has not been established (267). Moreover, repeated courses may result in a diminished platelet response (268).

In idiopathic ITP, splenectomy generally is recommended for patients who fail to respond to systemic corticosteroids or for those who require moderate doses of steroids to maintain the platelet count (266). Splenectomy removes the major site of destruction of damaged platelets and the source of antiplatelet antibodies. In SLE patients, however, it is preferable to try other agents before recommending splenectomy for steroid-resistant thrombocytopenia, because of the increased risk of severe infections following splenectomy, the apparent efficacy of other agents and the disputed value of splenectomy (226 ,269).

Danazol, which is an androgenic steroid with few virilizing effects, has been shown to be effective in some patients with SLE and thrombocytopenia refractory to steroids, cytotoxic drugs, and/or splenectomy, and it is given at an average dose of 200 mg, three or four times a day. Often, however, danazol cannot be discontinued without recurrence of the thrombocytopenia (270 ,271). Danazol has been used in the therapy of thrombocytopenia associated with antiphospholipid antibody syndrome (272). A retrospective study of 59 SLE patients (15 subjects had “incomplete” SLE) with autoimmune thrombocytopenia reported a high long-term remission rate with prednisone combined with either hydroxychloroquine or danazol (273).

Intermittent intravenous cyclophosphamide was shown to be effective in the treatment of thrombocytopenia in seven patients with SLE refractory to splenectomy or steroids or requiring excessive doses of steroids (274 ,275). Other agents that have been reported to be useful in the treatment of thrombocytopenia, although in a limited number of patients with SLE, include azathioprine (276), cyclosporine (277), dapsone (278), vincristine (279), and mycophenolate (280). In chronic ITP not associated with SLE, azathioprine has been found to be effective in 64 of

patients who are refractory to steroids and/or splenectomy. Clinical response was delayed in many patients, requiring a course of at least 4 months on the drug (281).

Extracorporeal immunoadsorption of plasma to remove IgG and circulating immune complexes using staphylococcal- A-silica columns has been reported to be effective in refractory ITP (282). The mechanism is unclear but the procedure may decrease platelet activation (283).

IV γ globulin also is effective, but its effect may not be long-lasting (284). As in idiopathic ITP, gamma globulin is most useful in the treatment of life-threatening bleeding or in preparing the patient for urgent surgery or elective cesarean section (285 ,286 ,287). A prospective, randomized, clinical trial showed that intravenous IgG offers no advantages over systemic corticosteroids as the primary form of therapy in untreated patients with ITP, including patients with SLE (288). My group also has used γ globulin successfully as an adjunctive measure patients with SLE and thrombocytopenia who failed to respond optimally to corticosteroids and had a concomitant serious bacterial infection.

Maier et al. (289) studied the mechanism of action for intravenous IgG in SLE-associated thrombocytopenia. Five of seven patients with lupus who received IV IgG showed a greater than 50% increase in platelet count. The beneficial response was not dependent on the reduction of circulating platelet-binding IgG or circulating immune complexes, suggesting that blockade of the Fc receptor may be the major mechanism of action.

Anti-D immunoglobulin IV has been reported to be an effective treatment of nonsplenectomized children and adults with chronic or acute ITP in 70% of patients (290). The mechanism of action is not clear but in part it works via blockade of the reticuloendothelial system with autologous red blood cell antibody complexes. Treatment with anti-D immunoglobulin may be a means of preventing splenectomy and for long-term maintenance for ITP. Although its use in lupus thrombocytopenia has been described (291), there are no controlled drug trials in SLE.

The effectiveness of splenectomy in the treatment of steroid-resistant thrombocytopenia in SLE is controversial. Holman and Dineen (292) followed ten patients who underwent splenectomy for thrombocytopenia. Two died postoperatively, and eight had excellent results, with up to a 30-year follow-up. Breckenridge et al. (293) reported that 9 of 16 patients with SLE had normal platelet counts without medications a year after splenectomy. A similar experience was reported by others (262 ,294). Splenectomy in refractory thrombocytopenia associated with primary and SLE-related antiphospholipid syndrome showed a high rate of good and long-term response (295 ,296). In a retrospective analysis of 18 SLE patients with ITP who underwent splenectomy, only 65% had a sustained long term remission (273). In contrast, Hall et al. (297) found that only two of 14 splenectomized thrombocytopenic patients with SLE refractory to drug therapy went into remission at a mean follow-up of 6 years. A controlled but retrospective study of splenectomy in SLE patients with ITP and/or AIHA by Rivero et al. (226) found that splenectomy does not prevent recurrent episodes of thrombocytopenia. Moreover, the splenectomized patients had higher frequency of cutaneous vasculitis and infection after the surgery.

When feasible, laparoscopic is preferred over open splenectomy because of fewer complications and shorter postoperative stay (298). Splenic irradiation has been reported to be effective in the treatment of older patients with steroid-resistant ITP, including SLE (299). This modality may be useful in selected older patients because of the high morbidity that is associated with splenectomy in this age group.

Rituximab, a chimeric anti-CD20 monoclonal antibody, has been reported to be useful in a retrospective study of 35 patients with severe idiopathic immune thrombocytopenia refractory to conventional therapy, with an overall response rate of 44% (300). Rituximab has also been reported to be efficacious in autoimmune thrombocytopenia associated with SLE and with antiphospholipid syndrome (301 ,302). Controlled studies are needed to better clarify the efficacy and safety of rituximab in SLE and other nonmalignant hematologic disorders.

In summary, profound and persistent immune thrombocytopenia (less than 50,000/mL) in patients with SLE should be treated with systemic corticosteroids. Patients who become refractory to steroids or who experience undesirable side effects should be given a trial of azathioprine or danazol. Rituximab is a promising agent. Monthly intravenous cyclophosphamide therapy probably is preferable for patients with multisystem involvement, especially nephritis. Splenectomy may be necessary in some patients, although its long-term sequelae are not completely understood and disputed.

Amegakaryocytic Thrombocytopenia

Acquired thrombocytopenia that is associated with decreased numbers of megakaryocytes in the bone marrow, amegakaryocytic thrombocytopenia (AMT) is a rare disorder with different causes and pathogenetic mechanisms. A few cases of amegakaryocytic thrombocytopenia associated with SLE have been reported (303 ,304). In a well-studied patient with SLE, peripheral T lymphocytes, but not serum, inhibited autologous colony-forming megakaryocytes in vitro, suggesting an underlying cell-medicated pathogenetic mechanism (305).

Kuwana et al. (306) described IgG antibodies to c-Mpl, the thrombopoietin receptor, in a subset of SLE patients with thrombocytopenia and megakaryocytic hypoplasia. The autoantibody maybe pathogenic by blocking the the intereaction between thrombopoetin and its receptor resulting in impaired thrombopoesis.

Acquired Abnormalities of Platelet Function

Acquired abnormalities of platelet function include disorders of platelet adhesiveness to the vessel wall and subendothelial

matrix, platelet aggregation, and platelet secretion. Platelet function, as measured by in vitro qualitative tests and by bleeding time, is affected by several factors, including aspirin and NSAIDs, common foods, spices, the presence of systemic conditions (including SLE and chronic renal failure, lymphoproliferative diseases, and other hematologic disorders), and circulating antiplatelet antibodies (307). These factors should be considered when interpreting the results of qualitative tests of platelet function in an individual patient.

Activation of normal platelets can be induced by adhesion to collagen and by soluble agonists such as epinephrine and adenosine diphosphate (ADP). The activation process involves a complex system of metabolic reactions acting in concert to stimulate platelet aggregation and granule secretion. Regan et al. (308) found that platelets from 12 of 21 patients with SLE failed to aggregate in response to collagen and showed impaired aggregation with ADP and epinephrine. These abnormalities are similar to those induced by aspirin, but none of their patients was on aspirin or any drug that is known to affect platelet function. Others have confirmed these abnormalities in SLE (309 ,310).

In 1980, Parbtani et al. (311) found that the concentration of serotonin and adenine nucleotides, as stored in the dense granules of platelets, was reduced in patients with acquired platelet function defects, including SLE. Weiss et al. (312) extended this observation and reported that levels of substances stored in platelet-dense granules, including thromboglobulin, were decreased in SLE. Because these findings were similar to those observed in patients with congenital storage pool deficiency, it has been suggested that the platelet defect in SLE represents an acquired storage pool disease. The reduction of the intraplatelet concentration of serotonin in SLE has been confirmed by other investigators (309 ,310 ,311 ,313 ,314 ,315). Although the concentration of plasma serotonin is normal in patients with SLE, the urinary excretion of serotonin is increased (311).

The low concentration of intraplatelet serotonin has been shown to correlate with disease activity and been taken to indicate in vivo platelet activation in SLE (310 ,315). This is supported further by the findings of elevated levels of plasma ß-thromboglobulin and decreased amounts of platelet factors III and IV (248 ,316 ,317). ß-Thromboglobulin, which is a specific constituent of granules, is released on stimulation of platelets.

The mechanism of in vivo platelet activation in SLE is not known. Parbtani et al. (311) suggested that the functional platelet defects result from the circulation of exhausted platelets following their in vivo exposure to factors that induce a release reaction, such as damaged endothelium, thrombin, and immune complexes. The globulin fraction of SLE sera has been shown to contain factors that cause the release of serotonin from normal platelets (313). These plasma factors probably include circulating immune complexes and specific antiplatelet antibodies. Additionally, the level of platelet-activating factor (PAF), which is a mediator of inflammation with a wide range of biologic activities (including platelet activation), is increased in the plasma of patients with SLE and active disease (318). PAF, which is synthesized by a number of cell types after immunologic stimulation, including monocytes, macrophages, granulocytes, platelets, and endothelial cells, may be involved in SLE (319).

Studies in experimental models of immune complex glomerulonephritis have established that platelets participate in the pathogenesis of renal injury. Platelets can facilitate the deposition of immune complexes and augment the subsequent inflammatory response. The involvement of platelets in SLE nephritis also has been examined. By infusing radiolabeled autologous platelets to patients with diffuse lupus nephritis, Clark et al. (320) found the sequestration of platelets not only in the spleen and liver but also in the kidneys, suggesting intrarenal platelet consumption. Complexes of DNA and specific anti-DNA that are important in lupus glomerulonephritis have been identified on the surface of platelets of patients with SLE (321). Moreover, Duffus et al. (322) have localized platelet surface antigens and platelet factor IV at sites of glomerular injury in SLE. Persistent platelet activation may also contribute to increased thrombosis risk in SLE (323).

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a diffuse disorder of the microcirculation of unknown cause that is characterized by a pentad of fever, thrombocytopenic purpura, microangiopathic hemolytic anemia (MAHA), fluctuating neurologic findings, and renal dysfunction. It is a rare disorder, usually seen in females 10 to 40 years of age, and may follow a prodrome of upper respiratory tract symptoms or arthralgias and myalgias (324). Patients present with nonspecific constitutional symptoms, including malaise, fatigue, weakness, and fever. Therefore, the other manifestations appear in rapid sequence, often baffling the clinician by the subtle appearance and diversity of features. Delays in establishing a correct diagnosis are not uncommon. Half of patients experience neurologic symptoms at presentation, most commonly headaches, confusion, and paresis. MAHA is diagnosed by the presence of fragmented red blood cells (i.e., schizocytes), nucleated red blood cells, an elevated lactate dehydrogenase (LDH) level, reticulocytosis, negative Coombs test, indirect hyperbilirubinemia, and hemoglobulinuria. Severe thrombocytopenia is a characteristic finding. Coagulation parameters generally are normal or show only mild abnormalities, such as elevation of fibrin split products. Pathologically, intravascular microthrombi consisting of fibrin and platelet aggregates in capillaries and precapillary arterioles in several organs are found. No histologic evidence of vasculitis is seen. Systemic corticosteroids, antiplatelet agents, splenectomy, plasma infusions, and plasmapheresis are among the therapies that are used (325). Before 1965, cumulative

experience showed that over 90% of patients succumbed to the disease (326). In the last 20 years, the introduction of effective therapy has led to a dramatic improvement in the survival rate to between 70% and 80% (324 ,325).

The association between TTP and SLE has been debated for years (326). In 1964, Levine and Shearn (327) reviewed the English-language literature, emphasizing the possible relationship to SLE. They presented two cases of their own showing overlapping features and analyzed 147 cases that were reported with adequate autopsy protocols. In 34 cases (23%), evidence of concomitant SLE was found. Libman-Sacks endocarditis was noted in 25 patients, onion-ring changes in the spleen in 8, wire-loop glomeruli in 7, and a positive LE-cell test in 5. Patients with features of both SLE and TTP appeared to constitute a clinical variant and had a higher female predominance, a higher frequency of biologic false-positive tests for syphilis, elevated serum globulin levels, splenomegaly, arthritis and arthralgia, and pleuritis. Amorosi and Ultmann (328) found 13 cases of SLE among 271 cases of TTP reviewed. In contrast, other investigators concluded that the combination of SLE and TTP is rare (329).

There has been an increase in the number of published reports of the association (330 ,331 ,332 ,333). When prior reports were reviewed using the 1982 ACR criteria for SLE, Musio et al. (334) identified 41 reported patients with SLE associated TTP. The patients were divided into three groups: 30 (73%) patients who developed TTP after the diagnosis of SLE; 6 (15%) patients had TTP preceding SLE, and 5 (12%) patients presented simultaneously with TTP and SLE. TTP developed from 3 months to 25 years after the diagnosis of SLE in the first group. SLE antedated TTP for several years in three patients with hemolytic uremic syndrome variant (335 ,336). In half of the patients, TTP occurred in the setting of active SLE, while in the other half it occurred during an inactive phase (330). TTP can antedate the onset of SLE and also can occur as a terminal event in SLE (326 ,337 ,338 ,339 ,340 ,341 ,342). Dixit et al. (343) reported a patient with probable SLE, C2 deficiency, and chronic relapsing TTP.

Several mechanisms have been proposed to explain the microvascular thrombosis in acquired TTP, including the presence of serum platelet-aggregating factor, circulating immune complexes, endothelial injury, defects in the fibrinoloytic system, and prostacyclin abnormalities (344). Autoantibodies to microvascular endothelial cells (345) and to CD36, a single chain membrane polypeptide (also known as GPIV) that is expressed in platelets and endothelial cells, have been reported in TTP (346). In SLE, Itoh et al. (347) suggested the role of antiplatelet antibodies in the development of TTP in some patients.

The formation of platelet aggregates in the microcirculation in TTP is mediated by large multimer forms of von Willebrand factor. Synthesized by endothelial cells and released into the circulation the von Willebrand factor binds to platelets causing aggregates, thrombocytopenia, and hemolysis. A specific enzyme, the von Willebrand Factor protease (ADAMTS 13) cleaves the large forms of von Willebrand factor (348). Tsai and Lian (349) found IgG antibodies in TTP patients that inhibited the protease enzyme and the resulting defect in the proteolysis of multimers of Van Willebrand factor can lead to platelet thrombosis. Rick et al. (350) used a functional assay for ADAMTS 13 activity and inhibitory antibody level in an SLE patient to confirm the diagnosis of TTP. Serial measurement of ADAMTS 13 and the inibitor showed correlation with the clinical course of TTP.

The treatment of TTP associated with SLE is similar to that for idiopathic acquired TTP. Systemic corticosteroids (347) and plasma infusion (351), with or without plasmapheresis, have been used successfully in a few cases. A Canadian study of 102 patients has shown that plasma exchange alone with fresh-frozen plasma is more effective than plasma infusion in the treatment of TTP (352). Fourteen of 41 (34%) SLE patients with TTP died, and the mortality rates were significant in all forms of therapy: plasma exchange (32%), plasma infusion (20%), steroids alone (20%) (334). A review of 53 reported cases of co-existent SLE and TTP suggests that cytotoxic agents may be helpful in those with severe disease refractory to plasmapheresis (353) Rituximab was found to be efficacious in the treatment of relapses in a small number of TTP patients (354 ,355) presumably by inhibiting the synthesis of the autoantibodies to von Willebrand Factor cleaving protease (ADAMTS13).

White Blood Cell Disorders

White Cell Count and Leukopenia

The characteristic change in the leukocyte count in SLE, which first was observed in 1923 by Goeckerman (356), is a depression of the white blood cells to between 2,000 and 4,500/mL. In large series of SLE patients reported in the literature, leukopenia has been observed in over 50% (2 ,7 ,8 ,9 ,10 ,46).

Leukopenia, which is defined as a white blood cell count of below 4,500/mL, was noted in 43% of 520 patients of Dubois and Tuffanelli (2) and in 66% of 150 patients of Estes and Christian (7). Severe leukopenia, with counts of below 2,000/mL, was uncommon. Of 122 patients with SLE who were studied serially by Harvey et al. (10), 75 patients had counts of below 5,000/mL. Larson (46) found that 18% of 200 patients had leukocyte counts of below 4,500/mL on two or more occasions, and that the usual range of leukopenia was between 2,500 and 3,500/mL. Among 111 hospitalized patients with SLE, Michael et al. (101) found a white blood cell count of below 500/mL in 66 (60%) patients at some time. In a series of 142 patients studied by Ropes (11), a white cell count of less than 4,000/mL was found in 67%, but in 12% the white cell count was always normal.

Leukopenia in SLE has been shown to be significantly associated with a high frequency of skin rash, lymphopenia,

and elevated anti-DNA titer. Anemia, fatigue, arthritis, anemia, and elevated sedimentation rate also were more common in patients with leukopenia (357). A leukocyte count of 4,000/mL, and occasionally as low as 2,500 mL, may occur in patients with active and untreated discoid LE. This may arise after treatment of the skin lesions with antimalarials. Leukopenia and fever can be a rare manifestation of allergic reaction to prednisolone (358).

Differential White Cell Count

An increase of nonsegmented neutrophils in patients with SLE was first reported by Rose and Pillsbury (359). This increase was observed in patients with normal as well as elevated total white cell counts (101). Estes and Christian (7) noted a normal differential count in 50% of their patients with leukopenia. These data are similar to the findings of other investigators.

Of 111 patients who were studied by Michael et al. (101), 64% had an increase in nonsegmented neutrophils together with an increase in mature granulocytes. Also, 14 patients had one to seven myelocytes when first seen, and a few others showed a similar increase in later counts. This occurred more frequently in those with normal or low white cell counts than in those with elevated total leukocyte counts. Before the institution of therapy, 24% of 105 patients studied by Harvey et al. (10) had neutrophilic granulocyte counts of 80% to 89%, and 5% of patients had counts of over 90%.

Eosinophilia

In my experience, eosinophilia is uncommon in patients with SLE without concomitant parasite infection, allergic reaction, or some other known cause. Eosinophilia is not mentioned in several series of patients in the literature (7 ,9 ,357). In contrast, earlier workers observed that eosinophilia is not rare in SLE. In a series of 200 patients studied by Larson (46), 10 had counts of 3% or more, and 5 patients had persistent eosinophilia in excess of 10%. Harvey et al. (10) found eosinophilia of 3% or more in 15 of 46 patients who were studied before therapy. Of these, 2 patients had counts of 17% and 24%, respectively, associated with extensive skin lesions and not attributable to causes other than SLE. Direct eosinophil counts were performed in 60 patients. Counts of less than 50/mL were found in 31 patients, of between 50 and 100/mL in 11, of between 100 and 200/mL in 10, of between 200 and 400/mL in six, and of more than 400/mL in only two. Ropes (11) observed a high prevalence of eosinophilia; an eosinophil count of more than 5% was seen in 21 of 142 patients at some time along the course of the illness. Michael et al. (101) noted an eosinophil count of over 3% in six of 111 untreated patients (17).

Two rare causes of eosinophilia, hypereosinophilic syndrome with diarrhea, and Loffler endocarditis have been reported in SLE (360 ,361).

Basophils

Hunsiker and Brun (362) enumerated basophils in patients with various skin disorders and found a moderate reduction of basophils in those with discoid LE and a marked diminution in patients with SLE. Egido et al. (363) found the absolute basophil counts in SLE to be inversely related to anti-DNA antibodies and the level of circulating immune complexes and to be directly related to serum complement level. Basophils and tissue mast cells possess Fc receptors that are specific to IgE antibodies. If such antibodies are cross-linked by binding to antigen, basophils and mast cells degranulate, releasing granules that contain vasoactive substances and producing a hypersensitivity allergic reaction. High levels of IgE have been found on the surface of basophils in SLE patients. More important, SLE basophils underwent degranulation when incubated with soluble DNA antigen, suggesting the presence of cell-bound, specific IgE anti-DNA antibodies. Although glomerular deposits of IgE have been reported in SLE, the pathogenic role of these antibodies remains to be established.

Granulocytopenia

Granulocytopenia occurs infrequently in patients with SLE and can have a number of causes, including drug reaction, severe infection, decreased bone marrow production, and destruction mediated by antigranulocyte antibodies. At times, the total white blood cell count may decrease to levels as low as 1,000/mL without any apparent cause other than SLE. Nevertheless, in this situation, the physician should always be aware of the possibility that the granulocytopenia may be the result of medications used in SLE, such as antimalarials (10 ,364). A prospective study, however, showed a high prevalence (47%) of neutropenia at some time during the course of lupus, although it was severe (<1,000 polymorphonuclear neutrophils [PMNs] per mL) in only six of 126 patients (4%) who were studied (120).

My group has observed agranulocytosis in SLE caused by atabrine, levamisole, and triethylenemelamine (365). Agranulocytosis in SLE has occurred because of reaction to sulfadiazine (366). McDuffie (367) reported three patients with SLE who developed agranulocytosis secondary to medications that are not commonly associated with blood dyscrasias: hydroxychloroquine, dextropropoxyphene, and nitrofurantoin. Bone marrow examination showed the absence of myeloid precursors in two patients and aplastic changes in the third.

Both humoral and cell-mediated immune mechanisms are important in the pathogenesis of neutropenia in SLE. Starkebaum et al. (368) examined the in vivo neutrophil kinetics of a patient with lupus and severe neutropenia, and they found changes that were indicative of increased peripheral destruction of granulocytes combined with ineffective granulocytopoiesis by the bone marrow. Elevated levels of surface-bound IgG were detected on the patient's neutrophils. Monomeric IgG antibodies, but not immune complexes,

isolated from the serum of the patient opsonized normal neutrophils for in vitro ingestion by other phagocytic cells. These observations provide a basis for the role of humoral factors in some cases of neutropenia. Additionally, Hadley et al. (369) found an inverse correlation between the neutrophil count and the ability of SLE sera to opsonize granulocytes for recognition and clearance by human monocytes. Impairment of reticuloendothelial system function in SLE (370) may allow antibody-sensitized granulocytes to remain in the circulation. Neutropenia in SLE has been reported to be associated with anti-Ro/SSA antibodies. Moreover, these antibodies bind to a 64-kd membrane protein that cross-react with the 60-kd Ro antigen, implying that anti-Ro/SSA antibodies may mediate neutropenia in SLE (371). Anti-La/SSB antibodies from SLE patients have also been shown to bind and penetrate normal PMN and impair phagocytosis and enhance apoptosis and IL-8 production. Whether anti-La/SSB antibodies contributes to the neutropenia remains to be established (372).

The number of progenitor cells of granulocyte and monocytes in the bone marrow (colony-forming unit culture [CFU-C]) has been found to be reduced in patients with SLE, and this correlated with the peripheral granulocyte and monocyte counts (127 ,373). Moreover, T lymphocytes suppressed the generation of autologous bone marrow CFU-C in vitro, suggesting a role of cell-mediated mechanisms in the impairment of granulopoiesis in SLE.

Courtney et al. (374) found an increased number of apoptotic neutrophils in SLE patients, especially those with anti-dsDNA and active disease as well as those with neutropenia. Whether increased neutrophil apoptosis contributes to neutropenia in SLE or not remains to be investigated.

Severe neutropenia in SLE is responsive to systemic corticosteroid therapy (375). Recombinant human granulocyte colony-stimulating factor (rhG-CSF) has been used successfully in combination with pulse methylprednisolone or with low-dose prednisone in the treatment of lupus neutropenia (375 ,376).

In the presence of infection in the patient who is not receiving systemic corticosteroids, leukocyte counts often may rise to between 15,000 and 20,000/mL. Unfortunately, other patients with SLE may have intercurrent infections without a demonstrable rise in the white cell count, so this valuable guide cannot be depended on in these cases. Marked leukocytosis with counts higher than 30,000/mL has been observed by my group and others in the presence of concomitant infections. During treatment with corticosteroids, the usual range of leukocytosis is 15,000 to 25,000/mL regardless of the initial white blood cell count.

Bone Marrow Granulocyte Reserve

The leukocytosis that occurs following the administration of endotoxin, etiocholanolone, or glucocorticoids primarily is caused by the release of PMNs from bone marrow reserves (377). The amount of PMN reserve is considered to be important in the host defense against infections, and it also serves as a guide in predicting the ability of the patient to tolerate a myelotoxic drug. Paulus et al. (378) found that the granulocyte reserve, as measured by etiocholanolone injection, in patients with SLE and nephritis was higher in those who were on azathioprine than in those on no medications or in patients on combined prednisone and azathioprine therapy. Kimball et al. (379) found that 62% of 59 patients with SLE had an abnormally low granulocyte reserve when challenged with etiocholanolone. No correlation among deficient granulocyte reserve and other clinical or laboratory parameters was found. Most of their patients were on corticosteroids, however, which now are known to challenge the bone marrow reserves (380), so that possibly the administration of etiocholanolone did not augment the maximally stimulated bone marrow, resulting in a subnormal response (381). This subnormal response to etiocholanolone of untreated patients with SLE suggests that the disease itself can suppress bone marrow reserves. Evidence suggesting the role of one or more circulating humoral factors for this abnormality has been described (379).

The number of bisegmented neutrophils (i.e., Pelger anomaly) was significantly higher and the lymphocyte count lower in patients with leukopenia associated with SLE and other autoimmune disorders (382).

Lymphocyte Counts

Lymphopenia is one of the most common hematologic findings in SLE (8 ,383). Early investigators noted lymphopenia but failed to emphasize it, probably because relative percentages rather than absolute numbers of lymphocytes in the peripheral blood were used (10 ,101). The mechanism of lymphopenia in SLE is not clear. Delbarre et al. (384) followed lymphocyte counts in 19 patients with SLE, and they noted that lymphopenia developed in 84% during the acute stage and was associated with an increased sedimentation rate. At remission, the lymphocyte count increased and the sedimentation rate fell. Grigor et al. (8) found absolute lymphopenia to be more common than leukopenia.

Rivero et al. (383) examined the significance of lymphopenia in 158 patients with SLE. At diagnosis, 75% of these patients had a significantly reduced absolute lymphocyte count, but on follow-up, additional patients became lymphopenic. Therefore, the total cumulative frequency of absolute lymphopenia was 93%. Lymphopenia was found to be independent of, although contributory to, leukopenia, so these two findings were not primarily interrelated. Absolute lymphopenia was correlated with disease activity, and patients with an absolute lymphocyte count of less than 1,500/mL at diagnosis had a higher frequency of fever, polyarthritis, and CNS involvement but a lower prevalence of thrombocytopenia and/or hemolytic anemia. Life-table analysis, however, showed no adverse influence of lymphopenia on survival of patients with lupus (120).

Table 41-2: Red Cells, White Blood Cells and Platelets in SLE

Anemia occurs in over 50% of patients at some time during the course of the disease; anemia can result from one or a combination of factors including chronic disease, autoimmune hemolysis, iron deficiency, and chronic renal failure.
Autoimmune hemolytic anemia characterized by the presence of warm-reacting immunoglobulin G (IgG) antibodies to erythrocytes develops in up to 16% of patients and may be the presenting manifestation of the disease; a combined warm- and cold-antibody type of autoimmune hemolytic anemia occurs occasionally.
Leukopenia is common and may result from active disease or a drug reaction; lymphopenia is a characteristic finding in untreated, active SLE; in vitro studies of granulocyte function generally are abnormal in SLE.
Leukocytosis in SLE is associated with a concurrent infection or corticosteroid therapy.
A platelet count of lower than 150,000 cells/mL is seen in 7% to 52% of patients (mean, 14%); in vitro platelet functions including aggregation in response to collagen are frequently abnormal in SLE.
Autoimmune thrombocytopenic purpura is not uncommon in SLE; 3% to 15% of patients diagnosed as having idopathic autoimmune thrombocytopenic purpura go on to develop classic SLE.
Thrombotic thrombocytopenic purpura is a rare, life-threatening complication of SLE.

Lymphopenia was found to be associated with the presence of anti-Ro, anti-La, anti-Sm, and anti-RNP in SLE and cutaneous LE (385).

Table 41-2 summarizes the changes in red cells, platelets, and white cells in patients with SLE.

Granulocyte Function in SLE

To understand the importance of granulocyte function as a factor in the susceptibility of patients with SLE to infections, studies have been undertaken to examine the phagocytic, opsonizing, chemotactic, and oxidative functions of neutrophils and monocytes. Most of these studies have concluded that in general, granulocyte function in SLE is abnormal, but the specific qualitative and quantitative abnormalities reported in them were either inconsistent or contradictory.

Phagocytosis and Opsonization

Brandt and Hedberg (386) reported that the ability of neutrophils of SLE patients to ingest yeast particles is significantly lower than those of RA patients and of healthy subjects. Phagocytic activity was not reduced when normal granulocytes were suspended in normal plasma, and the lowest phagocytic activity tended to be associated with neutropenia. Orozco et al. (387) confirmed this observation and found that the phagocytosis of *Escherichia coli* by SLE leukocytes decreased by 62% in those with active disease. In contrast to Brandt et al. (386), they also observed that the phagocytic activity normalized if the SLE granulocytes were incubated with fresh normal serum rather than with SLE serum. The presence of a serum factor that inhibits phagocytosis in SLE also has been reported by others (381 ,388), although the nature of this factor is not known. Sera from SLE patients with active disease failed to support normal granulocytes in phagocytosis, indicating a defect in opsonic capability. The low serum complement level, rather than a deficiency in natural antibodies, was the limiting factor in the deficient serum opsonic activity of SLE sera (387). The initial rate of phagocytosis of lipopolysaccharide-coated paraffin droplets by neutrophils from untreated patients with active SLE was significantly lower than that in normal subjects (389). In contrast to these results, Al-Hadithy et al. (390) found the phagocytosis of *Candida* sp. by neutrophils of SLE patients to be normal when the patients were considered as a group, but 20 of their patients had impaired phagocytic values. Additionally, Hallgren et al. (388) described an increased ability of SLE granulocytes to phagocytose IgG-coated latex particles in a serum-free system, to exclude the effects of circulating inhibitors. Phagocytosis of *E. coli* particles by monocyte and granulocytes in SLE was not reduced when compared to age-matched healthy controls in a whole blood system (391).

Chemotaxis and Migration

The in vitro chemotactic response of the neutrophils in SLE, when compared as a group to that of healthy subjects, has been observed to be normal (392 ,393). Clark et al. (393) noted that the generation of chemotactic factors in SLE serum clearly was depressed, and that the defect correlated with an elevated titer of anti-DNA antibodies, low serum immunoglobulin level, and high frequency of infections. Alvarez et al. (392) showed that the generation of serum chemotactic activity by the classic pathway of complement, but not by the alternative pathway, was impaired in patients with SLE. Serum inhibitors of chemotaxis, including a specific inhibitor of C5-derived chemotactic activity, also have been found in SLE patients (390).

Oxidative Functions

Wenger and Bole (394) investigated the reduction of nitroblue tetrazolium (NBT) dye by peripheral blood leukocytes of patients with SLE, and they found the activity to be low in resting leukocytes. When the leukocytes were stimulated by allowing them to phagocytose latex particles, an incremental increase in NBT dye reduction, comparable to

that seen in healthy individuals, was noted. On the other hand, neutrophils from patients with SLE who were infected failed to demonstrate the anticipated increase in NBT dye reduction. Others have confirmed the abnormal NBT dye reduction test results in patients with SLE (389 ,395). This test is considered to be a measure of the oxidative events associated with phagocytosis and intracellular killings, so it further supports the role of abnormal granulocyte function in the increased incidence of infection found in those with SLE.

The apparent inconsistencies in the studies of in vitro SLE granulocyte function by various investigators probably reflect differences in methodology and in the selection of patients. This also emphasizes the importance of other factors that affect these tests, such as the use of steroids and other drugs, activity of SLE, and the presence of inhibitory factors in the serum. The clinical significance of in vitro functional abnormalities is not entirely clear, but in vivo studies in SLE using the Rebuck skin window technique have shown abnormalities in granulocyte functions (396). Whether the observed abnormalities in granulocyte function are primary cellular defects or secondary to the disease process is not completely clear. Hurd et al. (397) have postulated that the ingestion of immune complexes by SLE neutrophils can alter their functions. In vitro exposure of normal granulocytes to SLE sera, especially those from patients with active disease, resulted in increased adhesiveness, aggregation, and oxygenation activity (398 ,399 ,400).

Neutrophils from patients with lupus, and especially those with active disease, express increased amounts of adhesive molecule ß-integrin CD11b/CD18 but not L-selectin (401). Exposure in the circulation to complement products may lead to the intravascular activation of neutrophils (402). Activated neutrophils then can contribute to the development of vasculitis, transient pulmonary dysfunction, CNS involvement, and leukopenia, as well as to an increased susceptibility to infections.

Chapter 42
Gastrointestinal and Hepatic Manifestations

David S. Hallegua

Daniel J. Wallace

Gastrointestinal Involvement

Although gastrointestinal (GI) manifestations are common in patients with systemic lupus erythematosus (SLE) (Table 42-1), their incidence varies with the interest and methods of the observer who is studying the illness. For example, two major studies failed to mention GI complications (1 ,2), and another made only brief reference to it (3). Abdominal symptoms and signs may be the result of SLE, medications that are used to treat SLE, or intercurrent processes.

Historical Notes

Osler (4) was impressed with the frequency of GI manifestations or, as he called them, GI crises. He believed that they might mimic any type of abdominal condition. In 1939, Reifenstein et al. (5) found evidence of peritonitis in 13% to 18% autopsied SLE cases, with perihepatitis and enlargement of the liver in one third. The most feared GI complication of SLE is lupus enteritis, caused by vascular involvement of the bowel wall, with infarction or hemorrhage. The first modern description of this was by Klemperer (6) in 1941.

Prevalence

GI complaints were the initial presentation in 10% of Dubois' patients (7); 25% to 40% had protracted symptoms. Haserick et al. (8) divided the GI symptoms of SLE among 87 patients into three groupings: none (63%), minor (29%), and major (8%). We have found this breakdown to be clinically useful. Subclinical involvement of the GI tract also is common. For example, Landing et al. at Children's Hospital of Los Angeles found chronic mucosal infiltration in 96% of 26 autopsied children with SLE (9). Younger patients with lupus are more susceptible. Among 272 patients with SLE, the prevalence of GI manifestations ranged from 10% in children to none over the age of 50 (10). Sultan et al. published a recent review on GI manifestations in SLE and found anorexia to be the most common reported manifestation with a prevalence of 36% to 71% in published studies (11).

Pharyngitis, Dysphagia, and Esophagitis

Persistent sore throat is not an infrequent finding, especially in children (12). (Chapter 29 discusses mucous membrane lesions and other features of oral pathology.) Dysphagia occurs in 1% to 6% (7 ,13 ,14 ,15 ,16 ,17 ,18) and heartburn in 11% to 50% of patients (13 ,19). In a literature review, Zizic (17) related that although only 5% of patients with SLE complained of dysphagia, 25% had impaired esophageal peristalsis, compared with 67% of patients with scleroderma. Several studies using esophageal manometry noted aperistalsis or hypoperistalsis of the esophagus in approximately 10% of patients with SLE (18 ,19 ,20 ,21 ,22 ,23). Aperistalsis sometimes correlated with the presence of Raynaud phenomenon. Gutierrez et al. (24) compared esophageal motility in 14 patients with SLE and 17 with mixed connective-tissue disease (MCTD). A definite correlation was found between Raynaud phenomenon and hypoperistalsis, with the latter being more common in MCTD. The SLE group had only a slightly decreased lower esophageal sphincter pressure. Esophageal motor dysfunction in SLE also can produce diffuse spasm and result in symptoms of chest pain (25). The aperistaltic group can show atony and dilatation of the esophagus on upper GI radiography (26). Dysphagia is usually a result of complications of acid reflux disease, but a rare association of a bullous skin disease called *epidermolysis bullosa acquisita* involving the esophagus has also been reported (27).

Ramirez-Mata et al. (28) performed esophageal manometric studies in a group of unselected patients with SLE and noted abnormalities in 16. Absent or abnormally low contractions were found at the upper one third in 7 patients, at the lower two thirds in 3, in the entire esophagus in 2, at the lower esophageal sphincter in 2, and at the lower two thirds plus the lower sphincter in the remaining 2. They found no relationship among the presence of esophageal dysfunction and activity, duration, or therapy of SLE. Interestingly, 5 of the 34 patients who had normal studies complained of dysphagia and heartburn. Upper esophageal skeletal muscle fiber atrophy also was found in 2 of 26 autopsies on children with SLE (9). One report confirmed these

findings and suggested that hypoperistalsis or aperistalsis may be caused by an inflammatory reaction in the esophageal muscles or by ischemic or vasculitic damage to Auerbach plexus (19). Esophageal imaging with gastrograffin, computed tomography (CT) scanning, or endoscopy is required to make the diagnosis of esophageal ulceration or perforation from systemic vasculitis (18).

Table 42-1: Systemic Lupus Erythematosus and the Gastrointestinal Tract

1. Gastrointestinal (GI) symptoms are common in systemic lupus erythematosus (SLE). Secondary causes such as concurrent disease, stress, and medication must be ruled out.
2. Sore throat and oral ulcers are common.
3. Dysphagia is present in 2% to 6% of patients, especially in association with Raynaud's phenomenon.
4. Anorexia, nausea, vomiting, or diarrhea may be prominent in one third of patients when the disease is active. Chronic intestinal pseudoobstruction (CIPO) causes the above symptoms and is a disturbance of the enteric nervous system. Inflammatory bowel disease, infection, and concomitant drug administration must be ruled out as other causes.
5. The incidence of peptic ulcer disease was 6% in patients presenting with acute abdominal pain; it usually is caused by antiinflammatory medication.
6. Ascites is found in 8% to 11% of patients. If a result of nephrosis, cirrhosis, or congestive heart failure, it is a painless transudate. Exudative causes might be painful and include serosal inflammation. Patients with lupus peritonitis often are steroid-responsive.
7. Pancreatitis is a serious complication of SLE. It is associated with pancreatic vasculitis, activity of SLE in other systems, and rarely, with subcutaneous fat necrosis. Mild elevation of pancreatic enzyme levels may occur in SLE without pancreatitis; high levels suggest pancreatitis. Steroids are the treatment of choice, but they (along with thiazide diuretics and azathioprine) can induce pancreatitis.
8. Abdominal pain, distension, and tenderness warrant a search for ischemia or bowel ulceration especially in patients with a SLEDAI of 4 or more. In the outpatient settin g, these signs may suggest the presence of small-bowel bacterial overgrowth (SIBO).
9. Malabsorption syndromes are rare but do occur.
10. Mesenteric or intestinal vasculitis is a life-threatening complication of SLE, usually associated with multisystem activity. High doses of steroids are required, and surgical intervention is indicated if extensive bowel infarction (with hemorrhage) and/or large intestinal perforations occur. Patients succumb from complications of obstruction, perforation, or infarction.

The treatment of esophageal symptoms is the same as that of esophageal problems associated with Raynaud disease. Small and frequent meals, avoidance of postprandial recumbency, and the administration of antacids, proton pump inhibitors, H_2 antagonists, or parasympathomimetic agents play a therapeutic role.

Anorexia, Nausea, Vomiting, and Diarrhea

The most common cause of anorexia, nausea, vomiting, and diarrhea in SLE is related to the use of salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), antimalarial drugs, corticosteroids, and cytotoxic agents. These symptoms even can occur for weeks after therapy is stopped. When caused by the disease, manifestations are persistent and are not explained by other factors.

Anorexia occurs in 49% to 82% of patients (7 ,13 ,29), especially if untreated. Nausea has been reported in 11% to 38% (7 ,13 ,15 ,29 ,30). When medications are excluded as a cause, however, the incidence is approximately 8% (16). Vomiting can be prominent (7 ,8 ,13 ,14 ,29 ,30); my own group has observed it as a symptom in 7% of patients (16). Diarrhea occurs in 4% to 21% of patients (7 ,13 ,14 ,29 ,30), and children have an increased incidence of all these symptoms (31).

Motility Disorders

Recently, motility problems have been associated with SLE. Hirschsprung disease has been reported in two patients with neonatal lupus (33). Chronic intestinal pseudo-obstruction (CIPO) reflects a dysfunction of the visceral smooth muscle or the enteric nervous system (31 ,32 ,33 ,34). Hill reported the second case of CIPO in lupus where a pathologic

specimen was available and was found to have smooth muscle atrophy in the bowel wall as the etiology for the altered motility (32). Symptoms and signs of this complication in SLE include a subacute onset of abdominal pain and distension associated with vomiting and constipation and a distended tender abdomen with hypoactive or absent bowel sounds and lack of bowel sounds. Radiologic examination reveals dilated, fluid-filled bowel loops and occasionally bilateral ureteral dilatation with a reduced bladder capacity. Antroduodenal manometry demonstrates intestinal and esophageal hypomotility. Nojima et al. described two patients with CIPO who had antibodies to proliferating cell nuclear antigen (PCNA) but no other specific antibodies or clinical manifestations of SLE (35). Treatment of CIPO usually involves high doses of steroids, broad-spectrum antibiotics, and promotility drugs. Perlemuter et al. reported the use of octreotide in a dose of 50 µg twice a day subcutaneously in CIPO in SLE and scleroderma (36). The symptoms of CIPO resolved in the three patients receiving treatment within 48 hours. Recurrence of symptoms responded to increasing the dose of octreotide.

Abdominal Pain and Acute Abdomens

Abdominal pain is found in 8% to 37% of patients with SLE (7 ,12 ,13 ,14 ,16 ,30), with the lowest incidence being reported in series that exclude medication-related symptoms. In 412 consecutive admissions to Cleveland hospitals for collagen vascular diseases, 63 patients had abdominal complaints; of these, 48 had SLE. Pain was present in 85%, and fever was noted on examination in 76% of patients and peritoneal signs in 10%. Corticosteroids were being given to 64%. An acute cause was determined in 33 patients, including duodenal or gastric ulcer, gastritis, and pancreatitis. Mesenteric vasculitis was present in 3 patients; in 16, the pain was of undetermined cause. Surgery was performed on 21 patients; in 11, it was exploratory. Al-Hakeem et al. identified 13 patients with a principal diagnosis of abdominal pain out of 88 patients with SLE who were admitted to the hospital during a 15-year period (37). Diagnoses accounting for abdominal pain–included adhesions (3), diverticulitis (3), cholecystitis (2), perforated ulcer and colon, gastroenteritis, duodenitis, and inflammatory bowel disease (1 each). Nine of the 13 patients required surgery. In another survey of 63 procedures, 16% morbidity and 6% surgical mortality rates were recorded (38). Rojas-Serrano evaluated the causes of emergency room consultation for patients with SLE and found that abdominal pain was the third most frequent reason accounting for 18 out 180 lupus patients visiting the emergency room (39). Min et al. studied the etiology of acute abdominal pain in patients visiting an emergency room (40). Twenty-six patients with SLE and abdominal pain made 44 visits to the emergency room. Twenty-seven (59.1%) of these visits were for ischemic bowel disease. Other diagnoses included pancreatitis, serositis, splenic infarction, angioedema, renal vein thrombosis, pelvic inflammatory disease, upper GI bleeding, and ectopic pregnancy. CT scanning and ultrasound help establish the diagnosis of ischemic bowel disease.

Small Intestinal Bacterial Overgrowth

In the outpatient setting, abdominal pain in SLE may be from serositis, small-bowel bacterial overgrowth, or non-SLE causes. Serositis can present as an acute surgical abdomen as reported by Wakiyama et al. (41). Low et al. reported the characteristics of lupus serositis on barium radiograph and CT imaging (42). The small-bowel barium series showed segments of spiculation with tethering, angulation, and obstruction. CT scanning demonstrated ascites and asymmetric thickening of the small-bowel wall. Albano et al. investigated the prevalence of small intestinal bacterial overgrowth in 14 SLE patients using a lactulose hydrogen-breath test (43). Symptoms of small-bowel bacterial overgrowth such as bloating (50%), diarrhea (64%), constipation (42%), and abdominal pain (42%) were present in these SLE patients without any clear identifiable cause on history and physical examination. Breath hydrogen above 20 million parts per million (ppm) with two distinct peaks of hydrogen production was diagnostic for small intestinal bacterial overgrowth (SIBO). Twelve patients (86%) were found to have SIBO by predefined criteria. Apperloo-Renkema et al. (44 ,45) documented that patients with SLE have lower colonization resistance to indigenous bacteria of the intestinal tract. IgG-class antibacterial antibodies to fecal microflora are decreased in active SLE, which suggests sequestration in immune complexes that could play a role in mesenteric vasculitis. Small-intestine bacterial overgrowth (SIBO) in SLE may be a result of decreased neutralizing antibodies to intestinal flora.

Helicobacter Pylori Infection in SLE

Sawalha et al. studied the prevalence of seropositivity against *H. pylori* and four other control antigens in 466 SLE patients and compared them with 466 control patients matched for age (+/-3 years), sex, and ethnicity. Most of the control patients were from the same pedigree multiplex for SLE. The frequency of sereopositivity to *H. pylori* only was lower in the SLE cohort compared to the control and this difference could be explained by the lower prevalence in African-American patients (38.1 versus 60.2; OR = 0.4, p = 0.0009, 95% CI 0.24–0.69) (46). The mean age of onset of illness in the *H. pylori* group was significantly older (34.4 versus 28, p = 0.039) compared to the *H. pylori* seronegative SLE patients. Though no conclusions can be drawn from this study, a relationship between SLE and a decreased seroprevalence of *H. pylori* infection in African-American lupus is evident. Direct biopsies of the gastric antrum were not performed in this study.

Acute Abdomen Associated with SLE

Abdominal pain and tenderness in patients with SLE can be the first manifestations of an intraabdominal disaster. Patients presenting with abdominal pain, even without tenderness, need an aggressive and comprehensive evaluation, including a complete blood count, amylase-level determination, blood-chemistry profiles, and abdominal radiography. If free air, moderate amount of free fluid, acidosis, or hyperamylasemia without pancreatitis is present, diagnostic laparoscopy should be performed. If pseudo-obstruction and/or thumbprinting of the bowel are seen without free peritoneal fluid, appropriate work-up and treatment should be instituted. Specialized tests, such as an upper GI, barium enema, CT, magnetic resonance imaging (MRI), gallium and indium white-cell scanning, and visceral angiography, may be helpful in specific cases.

Patients suspected of having an intraabdominal crisis should be placed on nothing by mouth and supported with intravenous fluids while undergoing these initial diagnostic evaluations. If peritonitis is suspected, broad-spectrum antibiotics should be administered. Symptoms of hypotension or third spacing warrant monitoring the urine output with a urinary catheter and inserting a central venous catheter or pulmonary artery catheter if required. Aggressive fluid replacement, antibiotics, and steroid stress dose coverage precedes laparoscopic or open surgical exploration. Steroid therapy can mask bowel ischemia and perforation. The best application of diagnostic laparoscopy is in the evaluation of a patient with equivocal findings. It can avoid an unnecessary laparotomy and offer an aggressive diagnostic approach.

Peptic Ulcer Disease

The incidence of peptic ulcers in SLE has been reported as being from 4% to 21% (9 ,15 ,47 ,48), but these studies antedated the present era of endoscopy and gastroprotective therapy. Perforated ulcers have been reported (8 ,9 ,47 ,48) and were found in 3 (5.8%) out of 55 SLE patients presenting with an acute abdomen in a more recent report (49). Therapy with acetylated salicylates and NSAIDs probably is a more frequent cause of peptic ulcer disease than is active SLE. Siurala et al. (50) performed gastric biopsies on 17 patients with SLE; 4 had superficial gastritis and 8 had atrophic gastritis in this 1965 report. Forty years and ten gastroprotective agents later, this area is overdue for re-examination. Junca et al. investigated the prevalence of intrinsic factor and pernicious anemia in 30 patients with SLE and 45 control patients (51). Pernicious anemia characterized by the presence of low-serum cobalamin concentration, macrocytic anemia, and the presence of intrinsic factor antibody was found in only 1 patient (3.3%), although 23% had low cobalamin levels and 10% had intrinsic factor antibody out of the 30 patients with SLE.

Inflammatory Bowel Disease

Ulcerative Colitis

Persistent diarrhea may result from ulcerative colitis that is rarely associated with SLE. Dubois noted concurrent disease in 2 of his 520 patients (7), and my own group has noted concurrent disease in 2 of our 464 patients with idiopathic SLE (16). Kurlander and Kirsner (52) elegantly documented the clinicopathologic correlations and remarked that lupus colitis and ulcerative colitis can be indistinguishable. Lupus colitis can be focalized to a single, small area (53). In 1965, Alarcon-Segovia et al. (54) reviewed the literature extensively and collected 19 cases of concomitant SLE and ulcerative colitis. They also presented 8 additional patients in detail from their Mayo Clinic experience, which accounted for four of their SLE cases. Additionally, 100 patients with ulcerative colitis were evaluated for SLE, which was found in 3 patients. Both sulphasalazine and olsalazine have been associated with the development of a drug-induced SLE (55 ,56). Folwaczny et al. found an increased prevalence of positive antinuclear antibody (ANA) in patients with Crohn disease and ulcerative colitis compared to first-degree relatives and normal controls (57). Eighteen percent of Crohn and 43% of ulcerative colitis patients had a positive ANA test whereas 13% of relatives of Crohn patients and 24% of relatives of ulcerative colitis patients had a positive test. Two percent of healthy controls had a positive test.

Regional Ileitis

Concurrence of SLE and regional ileitis (i.e., Crohn disease) is surprisingly rare and has been reported in about 10 patients (58). Evidence that inflammatory-bowel disease may respond to methotrexate, azathioprine, anti–tumor necrosis factor therapy, and antimalarial drugs is intriguing, and this emphasizes the importance of initiating studies to delineate the relationship between inflammatory-bowel disease and SLE.

Collagenous Colitis

Collagenous colitis is a distinct disorder that is characterized by colonic lymphocytic infiltration of the surface epithelium. Patients have watery diarrhea, but a normal endoscopic appearance and radiographic findings (59). This recently described condition responds to sulfasalazine and corticosteroids. Several reports have associated this condition with lupus (60 ,61 ,62 ,63).

One case of Canada-Cronkhite syndrome associated with SLE has appeared (64).

Celiac Disease in Association with SLE

Gluten sensitive enteropathy is one of the most common autoimmune conditions with a prevalence of 1:100.

An overlap of this condition with SLE has not been cited frequently. Zittouni et al. reported 5 patients with celiac disease who had lupus concomitantly (65). Lupus occurred before and after the diagnosis of celiac disease in one patient respectively. Eighty percent of the patients had positive serologic tests for celiac disease and three out of five patients had abdominal symptoms. Mader et al. screened 61 patients fulfilling ACR criteria for SLE for the presence of anti-endomysial antibodies (AEAs) and antigliadin (AGLA) antibodies and compared the prevalence of seropositivity with 35 healthy controls (66). None of the lupus patients or the controls had AEA but 27 (44.3%) lupus patients and 6 (17.1%) control patients had AGLA. A positive correlation was found between the presence of AGLA and arthritis in lupus. Other manifestations including cutaneous rashes and individual components on the SLEDAI were negatively correlated. The authors conclude that the presence of AGLA is an epiphenomenon, although small intestinal biopsies were not done to rule out celiac disease. They recommend AEA as the preferred screening test for celiac disease in association with SLE. Similar results were reported by Rensch et al. in their SLE cohort of 103 patients where a false-positive rate of 23% was reported for the antigliadin antibody (67).

Protein-Losing Enteropathy and Malabsorption

The presence of severe diarrhea and marked hypoalbuminemia (reported to be as low as 0.8 g/dL) without proteinuria should raise the suspicion of a protein-losing enteropathy. Approximately 32 reports of clinically evident protein-losing enteropathy have been published, along with several literature reviews (49 ,55 ,68). Siurala et al. (50) studied the small intestine in patients with SLE and diarrhea. Among small intestinal biopsies in 19 cases, 12 were normal, and villous atrophy was noted in 2. Radiographic signs as well as signs of intestinal malabsorption were found in 7 patients. Subclinical cases can occur. Hizawa et al. described the radiologic findings in six SLE patients with PLE (69). He reported that there were two types of PLE, four patients presenting with acute onset of enteritis with abdominal pain, nausea, vomiting, and watery diarrhea, and the remaining two patients having mild diarrhea and developed progressive hypoalbuminemia. The first clinical presentation was associated with irregular spiculation and thickening, and thumb printing suggestive of ischemia, whereas the latter had thickened folds with nodules in them, which at biopsy were shown to be lymphangiectasia. Both groups responded well to steroids.

The villi can be lustrous and swollen and may be of various sizes (70). Increased fecal excretion of intravenous radiolabeled albumin is the best quantitative study for following disease activity, although one report (71) has suggested that α_1-antitrypsin clearance also can monitor response to therapy.

The cause of protein-losing enteropathy is unknown, but several theories have cited vascular damage, bacterial overgrowth, fat malabsorption, abnormalities in bile salt metabolism, thrombosis, and mesenteric venulitis as possibilities (70 ,72 ,73). Intestinal permeability may be altered in most patients with SLE as measured by Cr-51-labeled ethylenediaminetetraacetic acid (EDTA) scans (68 ,74). Most patients have abdominal pain, and this can be the initial manifestation of their SLE (72). Cases have been reported of protein-losing enteropathy in association with Sjögren (75) syndrome, interstitial cystitis (76), red blood cell aplasia (77), and as the initial manifestation of the disease (78). It may occur more often in children than in adults (79 ,80). Laboratory investigation may reveal normal lymphocyte counts, elevated serum cholesterol levels, low serum complement levels, antiribonucleoprotein (anti-RNP) antibody (81), and sterile paracentesis fluid with low white-cell counts (82). Lymphangiectasia is uncommon.

Response to corticosteroids is nearly universal but resistant cases may require cyclosporine or intravenous pulse cyclophosphamide. Octreotide, a somatostatin antagonist is useful in treating protein losing enteropathy by decreasing intestinal blood flow and by modulating activated inflammatory cells by binding to the surface somatostatin receptor. Medium chain triglycerides are also useful, because they are carried through the portal system, thereby decreasing lymphatic flow, and also by virtue of being absorbed via the large bowel thus correcting lipid deficits in this condition. Some patients also may require a gluten-free diet (68 ,83 ,84 ,85).

Mader et al. investigated a cohort of 21 SLE patients for malabsorption with a screening D-xylose absorption test, examination of the stool for fat droplets and with histologic examination of a specimen of the duodenum obtained during endoscopy (86). Two patients (9.5%) had evidence of malabsorption manifested by an abnormal D-xylose absorption and excessive fecal fat excretion. Two other patients showed excessive fecal fat excretion. One of the patients with malabsorption had abnormal small bowel histology with flattened villi and an inflammatory infiltrate. There was no excessive deposition of immunoglobulins in the mucosa on immunoperoxidase staining. The etiology of the malabsorption was uncertain.

Ascites and Peritonitis

Ascites can be the initial presentation of SLE. It occurs in 8% to 11% of patients, often as a manifestation of the nephrotic syndrome (15 ,31 ,87 ,88 ,89). Sterile peritonitis was observed in 3 of 704 European patients with lupus (90). In an excellent review of ascites in SLE, Schousboe et al. (78) classified ascites as either acute or chronic. Acute causes include lupus peritonitis, infarction, perforated viscus, pancreatitis, mesenteric vasculitis (91), and hemorrhagic and bacterial peritonitis (92). Chronic causes of ascites include

lupus peritonitis, congestive heart failure, pericarditis, nephrotic syndrome, Budd-Chiari syndrome, protein-losing enteropathy, underlying malignancy (93), cirrhosis, and tuberculosis. Ascitic fluid can be inflammatory or noninflammatory. Noninflammatory lesions are always painless and associated with transudative fluid; most patients have nephrotic syndrome. Peritonitis usually is inflammatory and exudative. It generally is painful, but not always (89 ,94 ,95). Peritoneal tissue can contain immune complex deposits and inflammatory infiltrates (96 ,97). ANA, anti-DNA, and low complement levels can be present in peritoneal fluid (96 ,98 ,99). Reports also have appeared of concurrent familial Mediterranean fever (100 ,101) and of oligoclonal protein bands (102 ,103) inducing ascites in patients with SLE. Fetal ascites in babies with Ro/SSA-positive mothers may result from congestive heart failure or from various immune mechanisms (104). Low et al. reported the characteristics of lupus serositis on barium radiograph and CT imaging (105). The small-bowel barium series showed segments of spiculation with tethering, angulation, and obstruction. CT scanning demonstrated ascites and asymmetric thickening of the small bowel wall.

Ascites caused by lupus peritonitis usually is steroid-responsive. Other causes may require additional interventions (78), including azathioprine (106) and cyclophosphamide (107). Gentle diuresis is an important adjunctive measure that often provides symptomatic relief, provided that renal function is not impaired by this approach.

Pancreatitis

Prevalence

Pancreatitis can be the initial manifestation of SLE (108). First reported by Dubois in 1953 (29), it presents with severe epigastric pain radiating to the back, nausea, vomiting, an elevated serum amylase level, and dehydration. Seven of 704 European patients with SLE had a history of pancreatitis (90). Neither Fries and Holman (13) nor Ropes (14) noted pancreatitis in any of their combined experience with 350 patients. Ropes attributed this to the sparing use of steroids. Rothfield (109), however, observed pancreatitis in 8 of 365 patients. Of 168 consecutive SLE admissions to the University of Alabama Medical Center, 7 (4%) had pancreatitis; 5 of these 7 succumbed (110).

Etiopathogenesis and Clinical Presentation

Corticosteroids are not considered to play a role in the in causing pancreatitis in SLE patients. Hernandez-Cruz et al. reviewed their database of SLE patients and found 18 patients with 26 episodes of pancreatitis with an average SLEDAI score of 6.5 at the time of the acute pancreatitis episode (111). Eleven out of the 26 episodes were severe episodes and 4 patients died—3 of pulmonary hemorrhage and 1 from septicemia. The most common cause was felt to be medication use (8 episodes) and hypertriglyceridemia, alcohol, and cholelithiasis were thought to be the etiology in 4, 2, and 2 patients, respectively. Pascual examined their database of SLE patients from July 1984 to July 2001 and found 49 separate acute pancreatitis episodes in 35 lupus patients giving a prevalence of 3.5% (112). Of the 49 episodes, 14 (28.5%) were considered to be biliary disease and 10 (20.4%) were considered to be toxic-metabolic (alcohol, increased triglycerides, uremia, etc) in etiology. The remaining 17 (34.7%) were considered to be idiopathic or because of SLE. Mex-SLEDAI was significantly higher in the idiopathic group (median of 9 (3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19) in the idiopathic versus 5 (0–23) in the toxic metabolic and 3 (0,1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18) in the biliary group). A case control analysis with a ratio of controls to cases ratio of 4 to 1 showed an increased prevalence of acute pancreatitis in SLE (46% versus 14%). The odds ratio for the severity of pancreatitis and mortality was significantly higher in pancreatitis associated with SLE than in non-SLE controls (OR 8.6 versus 7.5). In conclusion, pancreatitis is a more often a severe and often fatal manifestation of lupus than an illness from other factors such as biliary disease or medications including corticosteroids, Similar conclusions were drawn by Derk et al. in their review of all hospital admissions for lupus patients to Thomas Jefferson Unversity Hospital between 1982 and 2002 (113). Of the 2,947 hospitalized SLE patients, 25 (0.85%) had acute pancreatitis. The majority (76%) has active SLE pm admission with a average involvement of 4.4 organs. Eighteen of the 25 patients had an increase in their corticosteroid doses with improvement of their clinical and laboratory parameters.

Pancreatitis can be the initial presentation of SLE and may appear in childhood (114 ,115 ,116). Several cases of panniculitis and subcutaneous fat necrosis have been reported as being associated with SLE and pancreatitis (117 ,118 ,119), as has type I hyperlipidemia (120) with increased levels of chylomicrons and thrombi in pancreatic arteries, because of antiphospholipid antibodies (121 ,122 ,123 ,124).

Corticosteroids, azathioprine, and thiazide diuretics are used in the treatment of SLE and may induce attacks of pancreatitis that are independent of the disease (125 ,126 ,127). Cases of pancreatic vasculitis were documented in the presteroid era (5). In 25 lupus necropsies, 8 cases of pancreatitis were found (128 ,129 ,130). Four of these had pancreatic vasculitis, and 4 were thought to have steroid-induced disease. Pancreatitis also can be caused by hypovolemia, ischemia, cholecystitis, alcoholism, carcinoma, and viral infections, all of which can occur in SLE.

Mild elevations of serum amylase levels may be noted in patients with SLE in the absence of pancreatitis. Hasselbacher et al. (131) studied 25 patients with SLE but without pancreatitis and 15 non-SLE controls. Amylase levels were elevated in 5 patients, and 6 had macroamylasemia, compared with none of the controls. The mean amylase level in the SLE group was 161.7 mg/dL, compared with 116.4 mg/dL in the control group; this difference was statistically significant. Macroamylasemia results from

decreased renal clearance of an immunoglobulinamylase complex. The presence of a pathogenic autoantibody to amylase was proposed. Tsianos et al. (132) found elevated pancreatic and salivary amylase components in 11 of 36 unselected patients with SLE. Thirty-five percent of 20 children with SLE, most of whom were asymptomatic, had elevated serum cationic trypsinogen levels; this is indicative of subclinical pancreatic dysfunction (133). These reports have associated active SLE with elevated amylase levels without abdominal pain.

In their definitive study on lupus pancreatitis, Reynolds et al. (134) combined a literature survey with a review of 20 patients (75% were female). The mean age of their group was 34 years, and the mean disease duration was 3.75 years. The mean prednisone dose was 11 mg, and 5 patients also were taking azathioprine. Of the 20 patients, 8 had recurrent attacks of pancreatitis, and amylase levels did not correlate with renal function or steroid doses. The mean duration of each episode was 15.5 days. The chief clue to the cause (i.e., lupus vs. drug induced) was that most of the patients with SLE-induced pancreatitis had multisystem SLE involvement (an average of 6.2 organ systems were involved) and responded well to increased steroid administration.

Management

Treatment includes immediate discontinuation of nonessential drugs that can induce pancreatitis (e.g., azathioprine, diuretics), intravenous hydration, nothing by mouth, antibiotics if needed, and sparing use of analgesics. The decision to use high dose corticosteroids is difficult if the patient has evidence of active SLE and is on glucocorticoid therapy. Careful observation is essential.

The prognosis of pancreatitis associated with SLE is very poor especially with those with active SLE with involvement of multiple systems. Two literature reviews have been published (135 ,136). One reported on 66 patients, 26 of whom were not taking steroids (133). Nearly 75% of the 66 patients had a fatal outcome. Pancreatitis may induce diabetes (see Chapter 39).

Mesenteric and Intestinal Vasculitis, Melena, and Bowel Hemorrhage

Prevalence and Presentation

Mesenteric vasculitis, with or without infarction, is one of the most serious complications of SLE. Although Ropes (15) found peritoneal involvement (from serositis) at autopsy in 63% of patients, with adhesion being common, only a small percentage had mesenteric vasculitis or acute abdomen. Vitali et al. (90) found that 1.1% of 704 European patients with lupus had intestinal vasculitis. Conversely, Landing et al. noted ischemic bowel in 60% of 26 necropsies on children (9). Melena has been observed in from 1% to 6% of patients with SLE (7 ,13 ,14). Most mesenteric vasculitis presents with cramping or with constant abdominal pain, vomiting, and fever. Diffuse direct and rebound tenderness usually are present.

Four detailed and authoritative studies of lupus enteritis and other abdominal complications have been published (17 ,137 ,138 ,139). Zizic et al. (138) detailed five patients with large bowel perforation. All had active SLE and mesenteric or intestinal vasculitis. The presentation was insidious, with lower abdominal pain. Abdominal rigidity was present in only one patient. Most had nausea, vomiting, diarrhea, and bloody stools. All had tenderness, and most had rebound tenderness and distention. Bowel sounds were diminished or absent. Prior or concurrent administration of steroids masked symptoms in some, and it may have promoted the bowel wall thinning that led to perforation.

Chase et al. (137) recounted 15 cases of acute surgical abdomen in 140 patients with SLE. An increased incidence of peripheral vasculitis, central nervous system (CNS) disease activity, ischemic necrosis of bone, thrombocytopenia, and rheumatoid factor was present. Of the 15 patients, 11 underwent exploratory laparatomies, 9 were found to have vasculitis, and 2 were found to have polyserositis. Eight patients died, primarily from complications of infarction or perforation.

Shapeero et al. (140) reviewed the hospital records of 141 patients with SLE who were admitted to the Hospital of the University of Pennsylvania over a 20-year period. Of these, 68 had abdominal symptoms, and 20 were thought to have ischemic abdominal disease. In 9 patients, this was confirmed radiographically by pseudo-obstruction of the gastric outlet, duodenal stasis, effacement of mucosal folds, spasticity, and thumb printing. Of these 20 patients, most had anorexia, nausea, vomiting, postprandial fullness, and abdominal pain. Only 10 had melena, 35 had fevers, and 50 had guarding. Additionally, 20 had leukocytosis, and 65 were anemic. All responded to steroid therapy.

Lupus enteritis can produce gastritis, mucosal ulceration, bowel edema with ileus, hemorrhagic ileitis, intussusception, perforation, and/or infarction (8 ,14 ,141 ,142 ,143 ,144 ,145). Spontaneous hemoperitoneum can be secondary to thrombocytopenia (146) or to ruptured aneurysms (147 ,148). Colonic diverticula (146) and mesenteric vasculitis (149 ,150) may induce perforation. Antiphospholipid antibodies may play a prominent role in inducing intestinal infarction (150 ,151 ,152 ,153 ,154). Medina et al. studied the relationship between SLEDAI scores and the sources of an acute abdomen in 51 SLE patients (155). Patients with intraabdominal vasculitis (19 patients) or thrombosis (3 patients) had higher SLEDAI scores than 14 active SLE patients with non-SLE related acute abdomens (mean 17.5 [range, 13 to 24] versus 8.2 [range, 5 to 11]). Fifteen patients with inactive SLE (SLEDAI 1.7, range, 0 to 4) had intra-abdominal pathology that was diverse and not related to lupus. Buck et al. found that a SLEDAI greater than 8 appeared to indicate bowel vasculitis in patients with SLE admitted to the

hospital for abdominal pain without peritoneal signs (156). The authors emphasize imaging and early laporotomy in active SLE with high SLEDAI scores whether an acute abdomen is present or not. When all patients with SLE who are hospitalized are evaluated, lupus patients with GI vasculitis differed from SLE patients hospitalized for abdominal pain without vasculitis only with regard to having leukopenia at the time of perforation (157). Lupus patients presenting with an GI syndrome with abdominal pain, vomiting and diarrhea as a result of serositis and bowel involvement often resolve with immunosuppressive therapy without surgical intervention (158). SLEDAI scores in this cohort requiring hospitalization were lower at 4 or above.

Laboratory, Pathogenetic, and Radiographic Findings

Laboratory evaluations are not particularly helpful. Acute-phase reactants and general indicators of active SLE usually are present. Paracentesis may be useful in ruling out pancreatitis or infection.

Radiographic changes include pseudo-obstruction of the gastric outlet, duodenal stasis, effacement of the mucosal folds, and thumbprinting. Thumbprinting represents bowel submucosal edema or hemorrhage on a barium or gastrografin enema; this finding is relatively specific for ischemic bowel disease. Similar findings can be found using CT with contrast. CT of the abdomen has identified intra-abdominal abscesses, lymphadenopathy, serositis, bowel-wall thickening, edematous and distended loops of bowel, pancreatic pseudocysts, and enlarged liver and spleens in patients with SLE (159 ,160 ,161). Ko et al. published their findings on radiologic assessment of lupus mesenteric vasculitis (162). Of the 15 patients with mesenteric vasculitis, CT scans done within 3 to 4 days of the onset of abdominal pain revealed the characteristic palisade and comblike pattern of mesenteric blood vessels with vasculitis in 11 out of 15 patients. Peritoneal enhancement of ascitic fluid (11 patients), small-bowel wall thickening (10 patients) and a double halo or target sign (8 patients) were other common signs of mesenteric vasculitis (Fig. 42-1). Abdominal ultrasounds can show bowel-wall thickening (163). Gallium scans and indium-111 white-cell scans can light up areas of inflammation and sepsis (164).

The histologic characteristics and distribution of mesenteric vasculitis are similar to those that are seen in polyarteritis nodosa (138 ,165). The colon and small bowel often are involved with vasculitis in the submucosa. This results in ulcerated mucosa, submucosal edema, necrosis, and infarction (166). Two cases of appendiceal arteriolitis (167) have been documented. Pneumatosis cystoides intestinalis may coexist with necrotizing vasculitis (168 ,169 ,170 ,171 ,172 ,173), and although usually benign, it occasionally can cause perforation.

Figure 42-1. Lupus vasculitis involving mesenteric arteries causing bowel edema and necrosis of the small and large intestine. Histological examination showed vasculitis with small-vessel thrombosis. (Printed with permission from Cedars-Sinai Medical Center, Los Angeles.)

Treatment and Outcome

The treatment of choice for lupus enteritis is 1 to 2mg/kg/day of parenteral methylprednisolone (8 ,144 ,174 ,175 ,176 ,177 ,178), or its equivalent, in addition to complete bowel rest. If a rapid response is not noted, surgical intervention may become necessary in cases of perforation or large areas of ischemia (140 ,144 ,175). Mesenteric vasculitis has a high mortality rate. One survey of patients with SLE undergoing surgery documented the widely held belief that in and of itself, steroid therapy increases the risk of postoperative complications (178). Grimbacher et al. reported successful treatment of relapsing intestinal vasculitis with intravenous pulse cyclophosphamide therapy (179). Table 42-1 presents a summary of SLE and the GI tract.

Liver Abnormalities

Hepatomegaly

Enlargement of the liver was present in 10% to 32% of patients in the series listed in Table 42.1 , with the frequency decreasing over the last three decades. An enlarged liver was present in 28 of 108 children with SLE who were studied by King et al. (12), and Ropes reported a palpable liver in one half of her patients (15). The liver usually extends 2 to 3 cm below the costal margin, but it occasionally can reach the iliac crest. Tenderness is uncommon unless viral hepatitis or peritonitis is present. Hepatomegaly and tenderness may be present with normal liver function tests. An enlarged liver can be histologically normal (180 ,181).

Jaundice

Jaundice was present in 1% to 4% of the patients listed in Table 42-1 and in 9 (3%) of Rothfield's 375 patients (109).

The most common causes of jaundice in SLE are hemolytic anemia and viral hepatitis; cirrhosis and obstructive jaundice from a biliary or pancreatic mass are responsible for the remainder.

Vascular Lesions: Hepatic Vasculitis, Portal Hypertension, the Budd-Chiari Syndrome, and Antiphospholipid Antibodies

Dubois described the first case of hepatic arteritis in 1953 (29). It was found in one of 58 necropsies reported by Ropes (15) and in 11 of 52 necropsies in Japan where it was specifically looked for (182) (Fig. 42-2). This rare complication of SLE (183) can be associated with ruptured hepatic aneurysms (184 ,185).

Five specific complications are attributable to antiphospholipid antibodies: (1) Budd-Chiari syndrome, (2) hepatic veno-occlusive disease, (3) nodular regenerative hyperplasia (182 ,186), (4) liver infarction, and (5) transient elevation of hepatic enzymes resulting from multiple fibrin thrombi (187).

The Budd-Chiari syndrome is occlusion of the hepatic veins with secondary cirrhosis and ascites. It almost always is caused by thromboses in patients with antiphospholipid antibodies (188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196). This usually leads to portal hypertension, which rarely is seen by itself. In one study, the disease was associated with antibody to proliferating-cell nuclear antigen (168). Hepatic infarction may be associated with pregnancy (197 ,198). The diagnosis of nodular regenerative hyperplasia may be missed on clinical grounds as well as by ultrasound or CT imaging but show up as high signal on T1-weighted images and isotense on T2-weighted images (199).

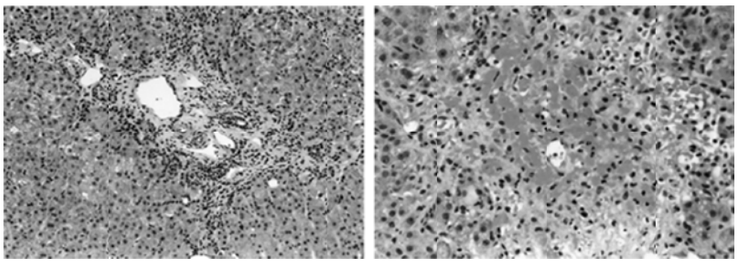

Figure 42-2. Biopsy of the liver in a 14-year-old Asian girl with classic systemic lupus erythematosus. Patient had a subacute onset of severe hepatitis (transaminases >tenfold) with negative hepatitis virus serologies and other hepatic autoantibodies and strongly positive antiribosomal P antibody. Patient had a complete recovery with high-dose steroids and azathioprine (H&E; 1:200). (Printed with permission from Cedars-Sinai Medical Center, Los Angeles.)

Neonatal Lupus Liver Disease

Lee et al. (200) found liver disease in 4 of 35 cases of neonatal lupus. Transient, although often severe, cholestasis was the principal finding, and no liver-specific antibodies were found. In a series of four cases (201), hepatic fibrosis was found along with giant-cell transformation, ductal obstruction, extramedullary hematopoiesis, and cholestasis.

Liver Function Test Abnormalities: Clinicopathologic Correlates

Liver function tests usually are obtained incidentally as part of blood chemistry panel. In SLE, nonspecific liver enzyme elevations are seen in a minority of patients and usually are of little significance. In our own experience, most liver function test abnormalities in SLE result from the administration of NSAIDs or methotrexate, or they are elevated because of increased muscle enzyme levels. Pathologic changes also are nonspecific and mild.

Rothfield (109) found elevated liver enzyme levels at diagnosis in 30% of patients with SLE, and Gibson and Myers (202) reviewed liver disease in 81 patients with SLE. Of these, 45 (55%) had abnormal liver function tests at some point, and 27% had enlarged livers. These abnormalities were accounted for by nonhepatic sources in nine patients, were drug-induced in 14, and from congestive heart failure in three. Of 19 biopsies that were reviewed, 7 were normal, 5 had portal-inflammatory infiltrates, 1 had a fatty liver, and 1 had chronic active hepatitis. Only 3 of the 81 patients ever had transaminase levels exceeding 100 mg/dL. In another survey (203), elevations in liver function tests were associated with disease activity and liver membrane autoantibodies.

Peliosis hepatis is a condition where blood-filled spaces occur in the liver from diverse causes causing injury from drugs and infections on the flow of blood from the sinusoids to the centrilobular veins. Three cases have been reported in association with lupus with reported improvement with immunosuppressive treatment (204).

Altomonte et al. (205) compared 18 females with SLE but without known liver disease to 20 healthy controls. Significant differences included the following: delayed Bromsulphalein excretion (27%), elevated fasting serum bile acid levels (50%), and increased γ-glutamyl transpeptidase levels (38%). Miller et al. (206) followed 260 patients with SLE and 100 controls for 12 months. Of the 60 patients with SLE and abnormal liver function testing, 41 could be traced to an identifiable cause (aspirin in 27, alcohol in 6, and others in 7). In 12 of 15 patients with elevated transaminase levels, subclinical liver disease was a probable cause.

Runyon et al. (207) noted that 124 of 206 patients with SLE who they tested had abnormal liver-enzyme values; liver disease was identified in 43 patients. Biopsies were performed on 33 patients; 3 of the 206 patients died in hepatic failure. The ultimate diagnosis was steatosis in 12 patients, cirrhosis in 4, chronic active hepatitis in 3, chronic granulomatous hepatitis in 3, centrilobular necrosis in 3, chronic persistent hepatitis in 2, and microabscess in 2. None were positive for hepatitis B antigen. The pathology was thought to be drug-induced in 21% of patients. Corticosteroids were beneficial in 8 of the 12 patients who received them. One third of 216 patients with SLE at Johns Hopkins had abnormal liver function tests over 1,717 visits, and elevations of their liver enzymes correlated with disease activity (208). On the other hand, severe liver disease can be present in patients with SLE and only minimal laboratory abnormalities (209).

Tsuji et al. reviewed the records of hospitalized lupus patients over a decade and found 73 patients with elevated transaminases (210). Of these, 43 (58.9%) did not have an identifiable cause of elevated transaminases and was attributed to active SLE. Of the identifiable cause of elevated liver enzymes, 7 (9.6%) were identified to have hemophagocytic syndrome on the basis of a marked elevation of serum ferritin levels (mean, 14,671 mg/dL; range, 370–84,651). This group also had the highest elevation in liver enzymes. Viral infection were not ruled out as the cause of hemophagocytic syndrome in this retrospective review. Maeshima reported a case of established systemic lupus who was admitted with a very low white blood cell (WBC) count and high transaminases (211). The ferritin level was 2306 ng/mL and a bone marrow biopsy was consistent with hemophagocytosis. Epstein-Barr and cytomegalovirus infections were ruled out and the patient responded to betamethasone and cyclosporin A treatment.

Ropes (15) reported on 58 necropsies in SLE. Of these, 50% had an enlarged liver, moderate to marked fatty infiltration was observed in 44%, and portal congestion was noted in 47%. Hematoxylin bodies were seen in 3, arteritis in 1, and hemosiderosis in 1. Fatty livers usually are associated with corticosteroid therapy, and several reports have commented on the presence of nodular regeneration and hyperplasia in SLE (190 ,212). The patients in these reports had normal liver function test results; this underdiagnosed finding could be secondary to steroid or danazol administration. Concentric membranous bodies in hepatocytes are found in hepatomas but occasionally are seen in lupus, and they reflect increased protein synthesis during regeneration (213).

Van Hoek reviewed the causes of elevated liver enzymes in SLE and found that medications such as nonsteroidal anti-inflammatory medication, aspirin, or azathioprine were the most common etiology (214). Liver-function test abnormalities may result from non-liver–related causes such as unconjugated hyperbilirubinemia, hemolysis or hepatitis resulting from immunologic, infectious, or drug-related causes. Hepatitis resulting from SLE was most likely to be lobular and associated with autoantibodies such as anti-double-stranded DNA and antiribosomal P antibodies. In contrast, autoimmune hepatitis was more likely to be periportal (chronic active hepatitis) with rosetting of liver cells and dense lymphoid infiltrates and often has specific autoantibodies to anti-liver-specific protein or have anti-liver–kidney–microsomal antibody. Both conditions are associated with features of autoimmunity such as polyarthralgia, hypergammaglobulinemia, and a positive ANA.

In summary, most patients with SLE and elevated liver function tests have liver biopsy specimens that reveal nodules, mild fatty changes, or mild fibrosis. Rarely, features of chronic active hepatitis are found.

Lupus Hepatitis

Definition and Clinical Features

Lupus hepatitis may be defined as an insiduous, rarely acute onset of transaminitis in patients who fulfill American College of Rheumatology (ACR) criteria for SLE, frequently have a positive test for ribosomal P antibody, and biopsy findings of lymphocytic infiltration of periportal areas with isolated areas of necrosis (214) (Fig. 42-2).

Ohira et al. found that 15 (44.1%) of the 34 SLE patients with liver dysfunction were positive for ribosomal P protein antibody (215). Of these 34 patients, 16 had SLE associated hepatitis and 11 out of 16 (68.8%) were positive for ribosomal P protein antibody whereas a control group of 20 patients with autoimmune hepatitis were negative for the antibody.

Our group found evidence for autoimmune hepatitis among 22 of 464 patients with SLE (4.7%) who fulfilled ACR criteria for SLE (16). Hepatitis was present in 2.4% of 704 European patients with lupus (90), and SLE was present in six (4.2%) of a group of Japanese patients with chronic active hepatitis (216). Chronic active hepatitis was found in 2.4 of 1,468 autopsied Japanese patients with lupus (182).

Patients usually present with nonspecific symptoms of fatigue, malaise, and anorexia. Jaundice is present in fulminant hepatitis. Mild liver enlargement, jaundice, or ascites in severe cases and other joint- and organ-threatening manifestations of SLE are found on physical examination.

Laboratory and Serologic Abnormalities

Elevations in serum glutamic-oxalocetic transminase (SGOT) and serum glutamatic pyruvate transaminase (SGPT) usually are less than two- to threefold but in severe cases, marked elevation in transaminases (more than tenfold) with mild increase in bilirubin and alkaline phosphatase may be seen. Antibodies such as a positive ANA, dsDNA, Smith, and hypergammaglobulinemia are seen. Antibody to ribosomal P protein is a strong marker for lupus hepatitis (217 ,218). Patients with autoimmune hepatitis and primary biliary cirrhosis characterized by antibody to smooth muscle, liver-kidney microsomal and mitochondria rarely fulfill criteria for SLE. Of 89 patients with lupoid hepatitis who were followed at the Mayo Clinic, 43 had arthritis, 10 had thrombocyotopenia, 9 had pleurisy, and 8 had leukopenia. Malar rash, pericarditis, neuritis, hemolytic anemia, and proteinuria were observed in 2 patients or less. Only 9 fulfilled the ACR criteria for SLE (219 ,220). The overwhelming majority of patients are women, and an increased association with human leukocyte antigen (HLA) haplotypes B8 and DR3 has been noted (221). In a comparison to 50 patients with SLE and 50 with chronic active hepatitis, 95% of the SLE group and 20% of the chronic active hepatitis group fulfilled ACR criteria for SLE (222).

Type I Autoimmune (Lupoid) Hepatitis

In 1955, Joske and King (223) first called attention to the coexistence of LE cells in patients who had apparent viral hepatitis. Mackay et al. (224) continued their studies and, in 1956, coined the term lupoid hepatitis, believing it to be a manifestation of SLE. Despite steroid treatment, however, these patients all succumbed to liver failure an average of 3 years after presentation (225 ,226). Many early studies were conducted before the availability of ANA, smooth muscle antibody, antimitochondrial antibody, or hepatitis virus serologic tests. These reports are of historic interest and were reviewed on pages 91 to 93 of the second revised edition of this text (227). Mackay's 1990 review also is useful (228).

Definition and Clinical Features

Type I autoimmune (lupoid) hepatitis is defined serologically and histologically, and it is a subset of chronic active hepatitis (229). Histologic hepatic changes include periportal piecemeal necrosis, dense lymphoid infiltrates, and prominence of plasma cells. Serologically, patients have a positive ANA and high levels of γ globulins, and antibodies to smooth muscle may be found. Chronic active hepatitis is associated with HLA-B8, DR3, and DR4, and it has many causes, including viral hepatitis A, B, or C; drug-induced hepatitis; Wilson disease; alcoholism; primary biliary cirrhosis; and α1-antitrypsin deficiency, all of which must be ruled out (220 ,230).

Autoimmune hepatitis has an insidious onset. Generally found in a young or middle-aged female who complains of fatigue, malaise, anorexia, and low-grade fevers, there are usually no physical findings at first. Hepatosplenomegaly, jaundice, and signs of cirrhosis or liver failure occur late.

Sherlock (231) observed that 42% of patients with chronic active hepatitis have keratoconjunctivitis sicca and xerostomia. She thought that the incidence of ulcerative colitis, which is reported to be 10%, could be as high as 30%; it was found in five of Mackay's first 40 patients with lupoid hepatitis (225 ,226 ,232).

Laboratory and Serologic Abnormalities

Liver enzyme, γ globulin, alkaline phosphatase, and bilirubin levels are elevated, the albumin level is decreased, and the prothrombin time may be prolonged (221 ,233 ,234). LE preparations usually are positive, but they may become negative with claimed improvement (235). The ANA of autoimmune hepatitis has specificities for histones and granulocytes (221). ANAs are positive in approximately 10% of patients with nonautoimmune, chronic active hepatitis (235). Anti–single-stranded DNA (anti-ssDNA) is found in approximately 0% to 16% of patients with chronic active hepatitis (214 ,235 ,236 ,237 ,238). Other autoantibodies, such as anti-dsDNA, anti-Sm, anti-RNP, anti-Ro/SSA, anti-La/SSB, and anticardiolipin antibody, are found in 0% to 5% of patients (236 ,238 ,239).

Smooth-muscle antibodies and antimitochondrial antibodies were present in 81 (30%) of Mackay's series (240) and in 64 (16%) of those reported by Leggett et al. (241). Antimitochondrial antibodies to M5 may cross-react with antibodies to phospholipids and yield false-positive readings in SLE (242). Smooth-muscle antibodies have specificity for actin (228). Antibodies to bile canaliculi have been claimed but not confirmed (240 ,243).

Other autoantibody systems that are found in autoimmune hepatitis include antibodies to liver-kidney-microsomal autoantigen, soluble cytoplasmic autoantigen, and M2 mitochondrial autoantigen. Five percent of patients with autoimmune hepatitis have false-positive antibodies for hepatitis C (231).

Association with Nephritis

Several studies have noted nephritis in patients with autoimmune hepatitis (244 ,245 ,246). Hepatitis B surface antigenemia is associated independently with glomerulonephritis (247).

In one previous report (248), five patients with SLE who were hepatitis-B surface antigen positive underwent renal biopsy and found lupus nephritis present in two and hepatitis B antigen-associated nephritis in three. Lai et al. compared clinicopathologic features of 22 patients with hepatitis B virus membranous nephropathy with 26 patients with Class V lupus membranous nephropathy (249). Other than being male and lacking the autoantibodies of lupus patients, there were no reliable distinctions between the two groups and antisera to hepatitis B virus antigens is required to identify the antigens in the glomerular pathology. Renal tubular acidosis has been found in chronic active hepatitis (232 ,250 ,251).

Treatment and Prognosis

Steroids remain the mainstay of treatment, prolonging life and making the patient more comfortable (221 ,232 ,252 ,253). In a controlled study comparing prednisolone alone (40 mg daily at initiation of treatment and 15 mg daily maintenance), azathioprine alone (150–200 mg daily), and prednisolone azathioprine combined (10 mg and 100 mg daily, respectively), Mackay (254) reported that the relapse rate was lowest and overall survival longest in the combined-treatment group. All three regimens suppressed the disease, and indices of liver function showed improvement. Between-group comparisons for certain indices showed prednisolone alone to be superior to azathioprine alone. It was concluded that prolonged suppressive treatment has ameliorative effects while treatment is maintained, but that a long-term cure is infrequent.

Mistilis and Blackburn (255) recommended a daily dose of 60 mg of prednisone for the first 2 or 3 weeks, with gradual reduction over several months to a maintenance level of 5 to 20 mg daily. Steroids alone did not improve survival but did reduce early mortality. This group recommended a daily dose of 1.5 mg/kg of azathioprine to control disease activity, but other controlled studies have questioned the efficacy and safety of azathioprine (250).

Newer treatments for chronic, active hepatitis include interferon, colchicine, and liver transplantation. Our group has shown that patients with SLE can safely undergo liver transplantation (256).

The prognosis of autoimmune hepatitis varies depending on the patients included in the survey. The 5-year survival wasreported by Mackay to be 65% in 1968 and 80% in 1988 (231 ,240). Poulsen et al. examined a sicker hospital patient registry between 1977 and 1993 and identified 96 patients with a discharge diagnosis of lupoid hepatitis (Poulsen). After a mean follow-up of 7.5 years, only 50% of patients were alive. The standardized mortality rate was 3.7 (95% CI, 22.1–100.9) compared to the general population. The risk of dying from liver cirrhois was increased by 51.2%. Patients with autoimmune hepatitis have a increased risk of developing hepatocellular cancer with the risk found to be 1 out of a cohort of 212 patients followed for 1732 patient-years. One of out 88 patients with cirrhosis developed liver cancer after 1002 patient-years of observation (mean-123+/-9 months) (257).

Other Causes of Hepatitis in Systemic Lupus Erythematosus

Hepatitis A and B Infection

SLE cohorts have the same incidence as control groups of hepatitis virus A or B antigens and antibodies (248 ,258). Autoimmune hepatitis rarely is observed in patients who are hepatitis B surface-antigen positive (234 ,258 ,259 ,260). Seventy-six patients with SLE in Singapore were tested for hepatitis B virus (HBV) infection; 15 (19.7%) had one or more of the three serologic markers for infection (260). This was comparable to the 19% positivity in 100 sex- and age-matched, healthy individuals. Lu et al. investigated the prevalence of hepatitis B in patients with SLE in Taiwan, which is a hyperendemic area for hepatitis B infection (261). The study also examined the level of interferons (IFNs) in both these disorders, which has been found to be low in both. The prevalence of HBV infection was lower than in the general population (3.5% versus 14.7%). The six patients out of the 173 SLE patients who had co-existing HBV infection and SLE had less active SLE with lesser degree of proteinuria and lower autoantibody levels than patients with SLE, but no evidence of HBV infection. These patients and patients with HBV infection had near normal levels of IFN-γ levels when compared to SLE patients. However, their levels of IFN-α were lower than in normal controls as well as patients with SLE. This suggests that subjects with low IFN-α levels are at increased risk for HBV infection and that IFN-γ, which is probably induced by the HBV infection, ameliorates the activity of SLE patients who have coexistent HBV infection. Abu-Shakra et al. found no evidence of HBV infection in 96 SLE patients in Israel where the prevalence of HBV infection in the general population is 2% (262).

Hepatitis C

Some autoimmune hepatitis may be associated with the hepatitis C virus (HCV) (263). Antibodies to hepatitis C were found in four of 71 patients with SLE in an Italian clinic (264). Bronson et al. published a case report of a 35-year-old woman who developed an acute onset of SLE with manifestations of arthralgia, malar rash, low-titer dsDNA antibody, negative tests for cryoglobulin, and diffuse proliferative glomerulonephritis coincident with a HCV infection (265). McMurray et al. reviewed the serologic and clinical manifestations associated with HCV infection (266). Autoantibodies that are specific for autoimmune hepatitis such as anti–smooth-muscle antibody are seen in up to 66% of patients with HCV infection (267). Nonspecific antibodies such as low-titer ANA (30%), anticardiolipin antibody (22%), and rheumatoid factor (76%) also are found in

chronic HCV infection prompting the investigation of the prevalence of HCV infection in patients with SLE. Kowdley et al., Karakoc et al., Abu-Shakra et al., and Chavez et al. investigated the prevalence of HCV infection in patients with SLE (262 ,267 ,268). The true prevalence of HCV was estimated to be close to that in the general population (0.5% to 1% in most studies). Chavez et al. reported a fourfold increase in the prevalence of hepatitis C in their cohort of 112 SLE patients even after eliminating 4 out 10 RIBA-III positive cases with HCV viral load testing (269). A case-control study was performed by Perlemutter et al. comparing 19 patients with SLE with hepatitis C virus (HCV) coinfection with 42 randomized SLE patients matched for age and sex but negative for HCV infection (270). The two groups were similar with respect to the prevalence of organ involvement and the levels of antinuclear and doublestranded DNA antibodies and C3 complement. The total hemolytic complement and C4 complement levels were higher in the SLE-HCV cohort along with a higher prevalence of mixed cryoglobulinemia. Serum ALT levels were elevated in 12 patients and cirrhosis was found on biopsy in 2 out of 11 SLE-HCV patients who were biopsied. Interferon or ribavirin therapy did not flare up SLE and conversely SLE or cumulative steroid treatment of up to 20 g per patient did not cause an increase in liver failures in the SLE patients who were infected with HCV. Conversely, although 25% of a cohort of 122 consecutive patients with SLE tested positive for cryoglobulins, a cryocrit greater than 1% was associated with hepatitis C infection (271).

Table 42-2: Systemic Lupus Erythematosus and the Liver

1. Hepatomegaly occurs in 10% to 31% of patients with systemic lupus erythematosus (SLE) and is seen in 50% at necropsy.
2. Jaundice is present in 1% to 4% of patients and is secondary to hemolysis, hepatitis, or pancreatitis.
3. Hepatic vasculitis is uncommon.
4. Budd-Chiari syndrome is associated with the presence of antiphospholipid antibodies.
5. Elevated liver enzyme levels are found in 30% to 60% of patients with SLE at some time. Most are caused by infections, salicylates, or NSAIDs. Enzyme levels greater than three times normal are rare.
6. Lupus hepatitis usually is insiduous in onset, varying in severity and frequently associated with ribosomal P antibody. These patients usually fulfill criteria for SLE and have biopsy findings of periportal infiltration of lymphocytes and isolated degeneration of hepatocytes.
7. Autoimmune hepatitis (lupoid hepatitis) is a form of chronic active hepatitis with malaise, arthralgia, fever, anorexia, jaundice, and negative hepatitis viral studies. Antimitochondrial and antismooth muscle antibodies often are present. Abnormalities associated with SLE, such as lupus erythematosus cells and antinuclear antibody are found. Most of these patients should be classified as being in a subset of chronic active hepatitis. Only 10% fulfill ACR criteria for SLE. Biopsy findings include piecemeal necrosis and are identical to chronic active viral hepatitis B and C.
8. The prevalence of Hepatitis B and C infection in SLE patients is not different to the prevalence in the general population.

Drug-induced autoimmune hepatitis has been reported after ingestion of the laxative oxyphenisatin (272) or after chlorpromazine (273). The picture can be confusing (without liver biopsy), especially because patients with lupus can develop viral hepatitis (as can any otherwise healthy person). Aspirin and NSAIDs are used to treat SLE but are hepatotoxic, and their effects can mimic those of chronic active hepatitis (274 ,275). Perihepatitis has been reported as well (276 ,277). Minocycline use has been reported to be associated with drug-induced lupus and autoimmune hepatitis in about 12 cases. An additional case of minocycline-induced SLE was described in Angulo et al. after taking the drug for 1 year for acne. A 22-year previously healthy woman developed arthritis, elevated liver function tests, and a positive ANA, anti–smooth-muscle antibody, and an antihistamine antibody (278). The hepatitis resolved after stopping the minocycline. The arthritis resolved after taking tapering doses of prednisone over 18 months.

Table 42-2 presents a summary of SLE and the liver.

Biliary Abnormalities: Cholecystitis, Cholangitis, and Biliary Cirrhosis

Gallbladder disease is no more common in patients with SLE than it is in the general population. Cholecystitis and serositis can be difficult to tell apart (279). Cystic duct artery vasculitis commonly is seen in polyarteritis, but only a few reports have noted this in SLE (280 ,281 ,282). Kamimura et al. reported a case of acalculous cholecystitis in a SLE

patient with abdominal pain and fever (283). Examination revealed positive Murphy's sign and pericholecystic edema with no gallstones on imaging. Treatment with corticosteroids resulted in rapid improvement of her symptoms and resolution of the pericholecystic edema in 5 days. The authors report that there were six previous cases of acalculous cholecystitis reported in SLE patients. The authors recommend surgical treatment if there is gall bladder distension on radiographs.

Four cases of sclerosing cholangitis and SLE have appeared (284 ,285 ,286).

Primary biliary cirrhosis (PBC) is associated with females who have features that are consistent with the calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia (CREST) syndrome and antimitochondrial antibodies. Only ten patients with PBC who developed SLE later have been reported in the past (287 ,288 ,289 ,290 ,291 ,292 ,293 ,294). In one of the patients recently reported, the diagnosis of SLE antedated the diagnosis of PBC, which has not occurred in the previous cases.

Chapter 43

Systemic Lupus Erythematosus in Childhood and Adolescence

Thomas J.A. Lehman

Children and adolescents with systemic lupus erythematosus (SLE) represent both a special challenge and a special opportunity. Early onset allows us to observe the natural history of SLE and investigate potential etiologies, free from the confounding factors that frequently are present in older patients (1). The impact of SLE on children and adolescents, however, often is profound. Recognition of the special considerations that relate to ongoing physical and emotional growth directly influences the choice of medications and the likelihood of success. Satisfactory outcome for a child or adolescent with SLE is not 5- or 10-year survival, into the earliest years of adulthood, but 50- or 60-year survival, which more closely approximates the normal human lifespan. Every aspect of the medical care for a child or adolescent with SLE must take this into account.

Awareness of the complex interaction between the child's illness and the needs of his or her family is critical to successful care. Children and adolescents are emotionally immature individuals just beginning to formulate their concept of self. They are extremely vulnerable to the psychological impact of both chronic illness and medications that dramatically alter their appearance (Fig. 43-1). Family and peer-group pressures, which are difficult even for normal children, may be overwhelming for the child or adolescent with SLE. The interaction of these special needs with the complexities of SLE makes caring for children and adolescents with SLE a unique process. Optimal results require excellent medical care coupled with multidisciplinary patient and family education and support. Compliance is one of the most profound determinants of outcome for children with SLE. It should not be taken as a given that the child and family will comply. Without extensive educational efforts it is more likely that they will not comply and this may have a significant negative impact on the long-term prognosis.

Childhood-onset SLE often is described as more severe than adult-onset disease (2), and early age of onset has been correlated with a worse prognosis (3). Other studies, however, have suggested an improved prognosis for children and adolescents with SLE (4 ,5). In published series, a large proportion of both children and adolescents with SLE have significant renal or central nervous system (CNS) involvement (6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14), but many cases of mild SLE in children and adolescents probably go unreported, either because they are not recognized or they never warrant referral to specialized centers. Delayed diagnosis, because physicians failed to consider SLE in the differential diagnosis of a young or male child, is one of the greatest risks to children and adolescents with SLE. Severe damage to the evolving self-image and sense of worth is another complication of SLE that is unique to children and adolescents. Both of these problems may profoundly affect the prognosis.

English-language reports of children with SLE appeared as early as 1892 (15). Sequeira and Balean (16), writing from the London Hospital in 1902, noted that the disease commences early in life in a much larger proportion of cases than is commonly believed. Eight children with SLE were among 71 cases they reported. Further reports of SLE in childhood continued to appear throughout the 1920s, 1930s, and 1940s (17 ,18 ,19 ,20 ,21 ,22).

The modern era began in the 1950s and 1960s, when series of children with SLE began to be published. Zetterstrom and Berglund (23) described 10 patients in 1956, and Gribetz and Henley (24) described an additional 15 in 1959. Between 1960 and 1968, more than 150 additional children with SLE were described (2 ,8 ,12 ,25). The total number of children with SLE in published series now far exceeds 500 (5 ,6 ,7 ,9 ,11 ,13 ,14 ,26 ,27 ,28).

In the presteroid era, childhood-onset SLE was a rapidly evolving, and usually fatal, multisystem disease. Since the 1960s, however, corticosteroids and improved pediatric care have resulted in greatly enhanced survival (4 ,29). SLE now is a common diagnosis in every large pediatric rheumatology program. Systematic management and vigorous treatment protocols are rapidly improving the outlook for children with even the most severe disease (30 ,31 ,32). With proper care, most children and adolescents with SLE now have an excellent prognosis.

Epidemiology

Despite the many published cases of childhood SLE, its true incidence and prevalence are unknown (33). Fessel's 1973 survey of 126,000 members of the Kaiser Permanente

plan did not report any patients with onset of SLE before 15 years of age (34). Siegel and Lee (35) estimated the annual incidence of SLE in childhood to be 0.6 per 100,000. Hochberg (36) found a similar incidence in Baltimore. Studies coordinating multiple regional pediatric rheumatology centers in New England and in Canada found a similar annual incidence of approximately 0.4 per 100,000 (36 ,37 ,38). The Canadian study (38) was complicated by wide differences in the incidence of SLE in the data from various reporting institutions. Every effort to provide an accurate determination of the incidence of SLE has been complicated by the recognized variations in racial incidence and geographic referral patterns. Although better numbers have been provided by countries where every child with a specific diagnosis is reported to a central registry, these countries have lacked the ethnic diversity that is found in larger countries, making their data inapplicable. Efforts to develop a central registry for children with SLE to provide demographically more diverse information are underway.

Figure 43-1. Markedly altered facial appearance resulting from skin manifestations in a teenage female with systemic lupus erythematosus.

Because of the difficulties in assessing the true incidence of SLE, the prevalence of childhood SLE can only be estimated. Figures from the regional referral center in Los Angeles suggest there are between 5,000 and 10,000 children with SLE in the United States (5). A similar estimate arises from the assumption that children with SLE are 0.10 as common as children with juvenile rheumatoid arthritis (JRA) (33). (The corresponding prevalence of SLE is 5 to 10 per 100,000 children (39 ,40 ,41 ,42), again suggesting 5,000 to 10,000 children with SLE in the United States.) Unfortunately, these figures represent only a first approximation of the true prevalence of SLE in children and adolescents. The influences of sex and racial origin on the occurrence and manifestations of SLE are widely recognized (5 ,35 ,43 ,44). In childhood, the influence of race is striking. The age and sex-adjusted prevalence of SLE in African American, Asian, and Hispanic children were more than threefold that of white children at one large center (5). Female sex, age, and race were even more striking influences when the incidence of SLE among pre- and postpubertal children was considered. For all male children, the frequency of SLE rose from 1 per 100,000 male children aged 1 through 9 years to 1.61 per 100,000 male children aged 10 through 19 years (i.e., a 60% increase with puberty). For white females, the increase with puberty was from 1.27 to 4.40 per 100,000 (246%); for African-American females, 3.72 to 19.86 per 100,000 (434%); and for Asian females, 6.16 to 31.14 per 100,000 (406%). In contrast, the increase for Hispanic females was only 4.62 to 13.00 per 100,000 (181%) (5). Although based on a limited sample, these data suggest a marked variation in the influence of sex hormones and puberty on the predisposition to SLE among different races.

Causative Factors

The cause of SLE remains unknown. The availability of parents and siblings who live in the same household as children with SLE, however, provides a unique opportunity to evaluate environmental and genetic hypotheses. Many studies have demonstrated an increased frequency of immunologic abnormalities in first-degree relatives of both adults and children with SLE (45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57). These studies have been interpreted as evidence both of an infectious cause and of a genetic predisposition. Current evidence suggests that both environmental and genetic factors are important with preliminary data suggesting that Epstein-Barr virus (EBV) infection may have a pivotal role in the susceptible host (1). (These theories are discussed in detail in other chapters.)

Much of the evidence for a genetic predisposition to SLE has come from studies of twin and sibling pairs. Many twin pairs have onset of SLE in childhood or adolescence. Identical twins with the onset of SLE as early as 3 years of age have been reported (58). The percentage of identical twins who are concordant for lupus may be as high as 70 (59), but this figure has been challenged. When both twins develop SLE, they typically have the onset of disease at a similar and earlier age when compared to nonidentical siblings who develop SLE (16.5 + 7.9 vs. 26.2 + 20.5 years) (60).

Additional evidence for a genetic component of SLE has come from the study of immunologic abnormalities in family members of children with SLE. Expression of this genetic component appears to be promoted by female sex hormones. In a study of 34 families having children with SLE, Ro/SSA antibody-positive mothers were more likely than Ro/SSA negative mothers to have Ro/SSA antibody-positive daughters (7/11 vs. 4/18, $P < 0.05$ probands excluded). There was no association between Ro/SSA antibody-positive fathers and sons: however, Ro/SSA antibody-positive fathers had fewer male children than expected (5 sons/12 daughters for Ro/SSA antibody-positive fathers vs. 19 sons/19 daughters for Ro/SSA antibody-negative fathers, $P < 0.05$) (61). The explanation for the decreased number of male offspring remains under investigation.

The frequent occurrence of serologic abnormalities in the families of children with SLE strongly supports the hypothesis that family members of children share genes that predispose to the development of autoimmune disease. Formulated in response to the occurrence of multiple autoimmune diseases within some families (62 ,63), the “supergene” hypothesis proposes the existence of a single gene or group of genes that predisposes to autoimmune disease. The subsequent occurrence of autoimmune disease in carriers is determined both by the interaction of these predisposing factors with the remainder of the genome and by environmental events. In such children the development of autoantibodies may precede the development of clinically evident disease by decades (64). This finding makes the routine reassurance of the family of a child with a significant antinuclear antibody titer, but no clinical findings, difficult. Additional, new evidence suggests that interferon-regulated genes may play a key role in the development of active SLE, but their full significance has not yet been elucidated (65 ,66). The increased frequency and amount of antibodies to Ro/SSA in mothers of children with SLE may be evidence of altered immunoregulatory gene expression in otherwise well individuals (51). Ro/SSA antibody expression is linked to histocompatibility antigens in patients with SLE and Sjögren syndrome (67).

Antiphospholipid antibodies are an additional immunologic abnormality, which occurs with increased frequency in children with SLE and in their family members (68 ,69 ,70). Because the antiphospholipid syndrome often appears to be independent of SLE, the explanation for this association is unclear. The report of Mujic et al. (71) describing an adolescent with evidence of antiphospholipid antibodies at age 16 who did not manifest SLE until 17 years later is a reminder that SLE may evolve over an extended period of time.

An increased frequency of SLE in childhood occurs in children with defects of the immune system. This is especially true of genetic defects in the complement system (most often C2 or C4 deficiency) (60 ,72 ,73 ,74 ,80). Such an association may occur because the genes controlling C4 synthesis are closely linked to the human leukocyte antigen (HLA) histocompatibility complex, or because the complement defect directly increases the likelihood of autoimmune disease (75 ,76 ,77 ,78 ,79 ,80 ,81 ,82). HLA linkages in this region have been demonstrated for adults with SLE, but they have not been independently evaluated in children (83 ,84). A Turkish family has been reported in which homozygous C1q deficiency was associated with the development of SLE in one sibling and IgA nephropathy in another (85). Interestingly a common pattern of hypergammaglobulinemia, cytopenias, and rash, which may be associated with other findings suggestive of SLE, has been described in a group of individuals with CD95 (Fas/APO- 1) mutations (86).

IgA deficiency is another defect of immune function that occurs more frequently than expected among children with SLE (6 ,87 ,88). In one study (87), IgA deficiency was found in only 0.03% of the normal population but in 4.6% of children with SLE. The association of SLE in childhood with defects in the immune system strongly suggests that defective antigen processing predisposes to the development of SLE. The development of discoid lupus (and in one case, SLE in children with chronic granulomatous disease and their mothers) is another observation suggesting an association between defective antigen processing and the development of SLE (79 ,89 ,90).

Despite the associations between defective immunoglobulin and complement function and SLE, treatment with intravenous immunoglobulin therapy has not been of benefit. Most patients with SLE are hypergammaglobulinemic, even if IgA-deficient. Further, because IgA is a secretory immunoglobulin, intravenous immunoglobulin therapy does not restore effective mucosal immunity, and administering intravenous immunoglobulin to IgA-deficient individuals may be associated with dangerous allergic reactions.

Children and adolescents with SLE are a valuable resource for large-scale efforts to understand the genetics and molecular biology of this disease. The opportunity to study SLE in populations such as young white males (who lack the known predisposing factors) may facilitate the identification of new risk factors. Each risk factor is a piece in the puzzle that ultimately will lead to understanding the pathogenesis of SLE (51).

Clinical Manifestations

Unexplained fever, malaise, and weight loss are the most common manifestations of SLE in children and adolescents. However, these manifestations are nonspecific and are often underreported by physicians in specialized rheumatic disease clinics. Because these nonspecific symptoms may be associated with many chronic illnesses, the physician should actively seek evidence of arthritis or a photosensitive rash, hematuria or proteinuria, hypergammaglobulinemia, and hypocomplementemia. Any of these findings should prompt consideration of SLE, but one cannot rely on their presence. On initial evaluation, the patient and family often do not describe findings such as arthritis of the small joints of the hands, alopecia, or photosensitivity. Unless they are specifically questioned, they do not relate these findings to the primary complaint. The reported

frequency of many complaints varies widely among series of children with SLE, and this variation reflects not only selection and referral criteria but also the care with which the complaint was sought and validated by the investigators (Table 43-1) (91).

Table 43-1: Clinical Manifestations of Systemic Lupus Erythematosus in Children and Adults*

	Cases (n)		
Parameter	Cassidy et al. (6)	King et al. (12)	Pistiner** et al.
Renal involvement	86	61	28
Hypertension	28	—	25
Musculoskeletal findings	76	79	91
Cutaneous	76	70	55
Photosensitivity	16	—	37
Hair loss	20	—	31
Oral, nasal ulceration	16	—	19
Cardiac involvement	47	17	12
Pulmonary involvement	36	19	12
CNS involvement	31	13	11
Anemia	47	—	30
Leukopenia	71	—	51
Thrombocytopenia	24	—	16

*The findings from Cassidy et al. and King et al. represent two large pediatric series; those from Pistiner et al. represent a large adult series.

**From Pistiner M, Wallace DJ, Nessim S, et al;. Lupus erythematosus in the 1980s: a survey of 570 patients. *Semin Arthritis Rheum* 1991;21:55–64.

Most children with SLE present with chronic illness, but some children and adolescents with SLE are acutely ill at presentation. These children may present with seizures, psychosis, uremia, profound anemia, pulmonary hemorrhage, or sepsis as the initial manifestation (92). Often, the diagnosis of SLE is not considered until the clinicians note that the child is not recovering as expected despite adequate therapy for the presenting event.

Confirming the diagnosis of SLE in children and adolescents is based on criteria developed by the American Rheumatism Association (ARA) for use in adults (93). Classification as definite SLE is based on the fulfillment of four criteria, but the diagnosis should not be discarded automatically in children who meet only three. Although the ARA criteria are useful guidelines, fulfillment of four criteria does not exclude other diagnoses; likewise, failure to fulfill four does not exclude SLE. Antinuclear antibody (ANA) testing is useful, but a positive test is not sufficient for the diagnosis of SLE in childhood. Correlation of this information with the titer of antibody and the age of the child improves the predictive value of a positive test (94). ANA-positive children who fulfill at least one other criterion should be periodically re-evaluated. Definite SLE may manifest decades after the initial presentation (64 ,95).

Renal Disease

Renal disease is evident in approximately two thirds of children and adolescents with SLE (2 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,96). Renal manifestations range from mild glomerulitis with a normal urine sediment to sudden renal failure (92 ,97). The most common signs of renal involvement are hematuria, proteinuria, and hypertension. Although children and their families may complain of malaise, headache, swollen feet, and/or swollen eyelids (if nephrotic syndrome is present), the signs of renal involvement commonly are silent in childhood.

Renal biopsy of children and adolescents with SLE without regard to clinical manifestations demonstrates varying degrees of renal involvement in nearly every case (97 ,99). Although most children with a normal urine sediment have only mild glomerulitis, diffuse proliferative glomerulonephritis (DPGN) may be present. The significance of silent DPGN is uncertain. Series reporting follow-up of silent nephritis in SLE have described a benign prognosis (97 ,98 ,99), and this makes proper interpretation of such biopsies and the importance of detecting silent DPGN uncertain. Most investigators agree that renal biopsy may be deferred if the creatinine clearance and urinalysis are normal. However, renal biopsy should be performed whenever necessary to confirm the diagnosis, to investigate unexplained changes in renal function, and when considering or monitoring the effects of aggressive therapy (31 ,100).

Renal involvement in childhood SLE is categorized according to the World Health Organization (WHO) criteria (101).

Mild glomerulitis is the most benign form, followed by focal segmental glomerulonephritis and membranous glomerulonephritis (102). DPGN carries the greatest risk of chronic renal failure. DPGN was the most frequent abnormality in children who underwent biopsy because of abnormal urine sediment (58), but in a series in which all children with SLE underwent biopsy, only 20% of children had DPGN (4 ,7 ,11 ,13 ,29 ,103). Combining the data from several large series, 42% of children (108 of 256) had DPGN at the time of initial biopsy, 26% had either mild glomerulitis or no abnormality, 25% had focal glomerulitis, and 6% had membranous glomerulonephritis.

Focal glomerulonephritis and membranous glomerulonephritis generally are benign, but either may progress to DPGN, with ultimate renal failure (4 ,10 ,13 ,29 ,101 ,104 ,105 ,106). Repeat renal biopsy should be performed in these patients if renal function continues to deteriorate or they manifest persistent hypocomplementemia. Long-term studies indicate that renal scarring (i.e., chronicity index) is a better predictor of ultimate outcome than the WHO classification (101 ,106 ,107). In the absence of scarring, active disease (including glomerular crescents) is not automatically associated with a poor prognosis (105 ,106); however, good outcome for these children is contingent on aggressive management of their renal disease to prevent the development of scarring (discussed later). Most children with SLE do not develop renal disease after the first 2 years following diagnosis (2 ,7), but one third of those who ultimately do develop significant renal disease lack evidence of renal involvement at presentation.

The sudden onset of renal failure in a child with SLE may result from active nephritis (92), but alternative explanations must be appropriately excluded. Renal vein thrombosis and renal artery thrombosis are other causes of sudden renal deterioration in children with SLE, and both are more frequent in association with anticardiolipin antibodies (108 ,109). Drugs and self- or family-administered health food supplements that interfere with glomerular filtration or are directly nephrotoxic also must be considered when seeking the cause of sudden onset renal failure. A mild rise in the blood urea nitrogen level (BUN) usually follows the initiation of acetylsalicylic acid or other nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with renal involvement, but some children with SLE are unusually sensitive to their effects. An unexpectedly sharp rise in the BUN following initiation of NSAIDs should prompt further investigation for previously unsuspected renal involvement.

Mild clinical manifestations of renal involvement usually are well controlled with corticosteroids and diuretics. Persistent renal disease may require immunosuppressive therapy (116). Chronic glomerular scarring is prevented by cyclophosphamide over the intermediate term (31 ,111 ,112). The major concern of the physician caring for a child with lupus nephritis is preserving sufficient renal function to support normal growth and development. For adolescent females, this includes the preservation of adequate renal function to support pregnancy. These concerns dictate intervention before significant renal compromise has occurred. Physicians who normally care for adults must be reminded that the normal serum creatinine level of children is much lower. Levels of serum creatinine elevation that might represent minimal impairment in an adult may indicate severe renal compromise in a child.

Current treatment regimens for children and adolescents with SLE have led to a steady improvement in 5- and 10-year renal function survival (30). It is not yet clear, however, whether these improvements result in significantly enhanced survival 20 and 30 years following diagnosis. Maintaining adequate renal function is important for children and adolescents with SLE. In contrast to adults, they do poorly on long-term dialysis (101). Children with SLE coming to dialysis with active disease often die of sepsis or other complications within the first year. However, those who have gradually developed global glomerular sclerosis often do well with dialysis and subsequent renal transplantation.

Children whose proteinuria and hematuria improve with corticosteroid therapy but whose creatinine clearance slowly deteriorates are of particular concern. Often, these children do well over a 5-year period but progress to renal failure between 5 and 10 years following diagnosis. Routine monitoring of creatinine clearance and, if deterioration is evident, early intervention, are important. In the event of chronic deterioration, the clinician should intervene aggressively while adequate function can still be preserved. Adult series suggest that maintaining a creatinine clearance of 70 mL/min per 1.75 m^2 is adequate (111 ,113), but intervention at this point may not preserve sufficient renal function for the satisfactory growth and development of children and adolescents.

Optimal therapy for children and adolescents with lupus nephritis remains uncertain. In large part, this results from the failure of many investigators to properly stratify the patients in their studies (102). The systematic use of intermittent intravenous cyclophosphamide has been successful in children with DPGN and useful for children with membranous glomerulonephritis (31 ,116 ,117). Others have reported excellent results with the combined use of large doses of prednisone and, when necessary, azathioprine (9 ,29 ,114). When 10-year renal survival is considered, the systematic use of intravenous cyclophosphamide appears to offer the best outcome (117) Individual physicians who proclaim excellent results in their institution with other regimens rarely have prospective data to support their claims. Reservation of routine use of cyclophosphamide only for those with well established severe disease is generally associated with a poor outcome (118). The consistent failure of reporting centers to stratify patients according to age, race, sex, and severity of disease despite the fact that these factors are all recognized to impact survival and the varied populations served by various centers make comparative analysis difficult.

At present, a large-scale study of staging criteria for children with SLE is underway (102). Use of these criteria should improve our ability to assess the various therapeutic regimens that have been advocated for children with lupus nephritis. Routine use of intravenous cyclophosphamide has

many advantages, including accurate assessment of patient compliance and clinical status at each dosage interval. Poor compliance is a major determinant of poor outcome (115). Additionally, periodic inpatient cyclophosphamide therapy allows the physician to monitor renal function status and clinical status before each immunosuppressive drug dosage, thus minimizing complications. New regimens for the treatment of SLE continue to appear on the horizon. Although consistent use of high dose mycophenolate mofetil has been recommended for control of lupus nephritis in adults (119), its sustained benefit is unproven. Rituximab is a new biologic agent directed against activated B cells bearing the lymphocyte marker CD20. There are several case reports published regarding its use in SLE and several small series have been presented (120 ,121 ,122). The ultimate utility of rituximab seems likely, but further evaluation is required. Other agents that block or eliminate activated B cells (such as BLyS antagonists) are also being evaluated. New regimens utilizing a combination of “conventional” agents and the newer biologic agents may hold the greatest promise.

All of the recommended regimens for treatment of lupus nephritis fail in some patients. Continued efforts to improve care are necessary for these children and adolescents, who may relentlessly progress to renal failure and, often, death. Systematic therapy modeled on the experience of pediatric oncologists may hold the key to enhanced survival for children and adolescents with severe lupus nephritis (116 ,123). Evolution of current therapeutic regimens to include multiple agents that are given at fixed intervals to induce a remission of disease, followed by prolonged maintenance therapy, seems to provide the best long-term outcome.

Low-dose oral methotrexate has been an effective adjunctive therapy in a few children (124), but it has not proven to be successful when used in isolation. Low-dose oral methotrexate may be a beneficial addition to immunosuppressive regimens to provide improved maintenance after the induction phase (e.g., children who have reached 3-month dosage intervals on cyclophosphamide). Higher dosages of intravenous methotrexate have been used successfully in protocols for the treatment of children who have failed conventional immunosuppressive therapy (125).

Autologous stem-cell transplantation has been proposed and utilized for a variety of autoimmune diseases including some children with SLE (126 ,127 ,128 ,129). This technique may hold great promise, but this technique is associated with a significant mortality and the majority of the reported responses have not persisted over time. Whether the beneficial effect results from the stem-cell transplantation or is from the immunosuppressive chemotherapy given at the time of stem-cell transplant is under active investigation.

Central Nervous System Manifestations

Psychosis, sudden personality change, seizures, chorea, transverse myelitis, peripheral neuropathy, and pseudotumor cerebri all may be presenting manifestations of SLE in childhood (130 ,131 ,132 ,133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142). Most series have reported CNS involvement in 20 to 30 of children (2 ,6 ,11 ,13 ,29). If carefully sought, mild evidence of CNS involvement is present in up to 45 of children and adolescents (23 ,141). In every instance appropriate investigation should be undertaken to exclude stroke as the etiology of sudden CNS changes, even in the patient who is not known to be anticardiolipin antibody positive.

Subtle CNS changes, including impaired judgment and poor short-term memory, are the most common CNS manifestations of SLE (132 ,137 ,143 ,144). These alterations often are ascribed to steroid therapy or situational stress, but they occur with greater frequency in SLE than in other chronic childhood rheumatic diseases that require similar corticosteroid therapy. Adolescents with SLE often have difficulty complying with their medications or appointments, and they often alienate friends and family in ways that are inconsistent with their prior behavior. Physicians must be acutely aware of these changes, because they may have disastrous consequences. A trial of increased corticosteroids may be beneficial in children with SLE whose behavior has become erratic or uncharacteristic, even in the absence of objective findings. Others have argued for reducing the corticosteroids in such circumstances, but this rarely is effective.

Delirium, hallucinations, seizures, and coma are the most common objective neurologic signs in childhood. Psychosis that is unrelated to corticosteroids typically occurs in 4 to 10 of children (2 ,7 ,13 ,28 ,29 ,141). Caeiro et al. (6) reported significant neuropsychiatric findings in 30 of children in an English series. The reported frequency of neuropsychiatric manifestations in children and adolescents with SLE is lower than that in adults (145). This may be a true finding, but it more likely represents a decreased appreciation of neuropsychiatric involvement in childhood.

Chorea is more frequent in children than in adults with SLE (145). Although it is infrequent, it has been documented as being the initial manifestation of childhood SLE in multiple reports (135 ,140 ,146 ,147 ,148), perhaps because it is such a striking finding. Of children with SLE, 4% to 10% are affected by chorea at some point (2 ,7 ,23 ,28 ,29 ,141). This increased incidence may reflect an increased sensitivity of the basal ganglia to damage by autoreactive antibodies or vascular events accompanying SLE in childhood (149).

Most often, acute CNS involvement occurs early in the natural history of childhood SLE (150). Frequently, it first becomes evident during, or worsens immediately after, initiation of corticosteroid therapy. The explanation for this is uncertain, but these symptoms frequently resolve with pulse methylprednisolone therapy. Late-onset CNS involvement more often results from stroke, uremia, or an infectious process (151).

Both sudden onset of optic neuritis and acute sensorineural hearing loss may occur in children with SLE (152 ,153). However, the most striking CNS damage in children and adolescents with SLE typically results from seizures or strokes, including cerebral vein thrombosis. These complications may occur in the presence or absence of anticardiolipin antibodies (154 ,155 ,156).

Cognitive defects and aberrant behavior present a more difficult management problem. Aberrant behavior may have dramatic effects on social acceptance, grades, and compliance, thereby directly affecting both self-image and long-term prognosis. Efforts to ascribe behavioral change to a single cause rarely are successful (132 ,137 ,143). Unfortunately this often results in failure to aggressive treat these problems with resultant progression.

Nonspecific problems in children with diffuse CNS involvement most likely represent the combined effects of SLE, situational factors, and corticosteroid therapy. When such symptoms are present, increasing the corticosteroid dosage more often is successful than a dramatic reduction.

No single objective test for the presence of CNS-SLE is accurate in childhood. Computed tomography (CT) of children and adolescents with SLE who have received long-term corticosteroids commonly demonstrates diffuse cortical atrophy (157 ,158 ,159). Alterations in cerebrospinal fluid protein or sugar levels or cell count cannot be relied on (132 ,141 ,150), but these studies often are necessary to exclude infection and other explanations for altered CNS function (151). Single-photon emission CT may be a more sensitive test for cerebral perfusion abnormalities in these children (160), but other studies suggest that magnetic resonance imaging (MRI) is more sensitive (161). Antibodies to ribosomal P have been found to correlate with CNS manifestations of SLE in adults, but their presence correlates less reliably with CNS disease in children and adolescents (162 ,163).

Treatment of CNS manifestations in children and adolescents with SLE is a challenge. Because the manifestations may result from corticosteroid therapy, physicians frequently hesitate to increase the dosage; nonetheless, this often is the most effective therapy. For severe CNS manifestations, pulse methylprednisolone therapy often is effective. When other measures fail, intravenous cyclophosphamide frequently is beneficial. Children with short-term psychosis or coma often respond to therapy, but when significant impairment has been present for long periods, the prognosis is guarded. It is important to respond aggressively when faced with continuing evidence of CNS deterioration. Chronic “mild” problems for which intervention is not felt to be warranted often progress to dementia over time.

Psychosocial Concerns

Psychologic reactions that relate to the many issues affecting children and adolescents with SLE often are confusing. Children with SLE commonly demonstrate an impaired quality of life that is impacted by the activity of their disease (164 ,165). Adolescents who are afflicted with chronic disease are caught between their need to establish an independent personality and the dependency of the sick role. Just as they are struggling to assert their independence, they must be taken for doctor's visits, forced to undergo examinations and blood tests, and required to take unpleasant medications. This situation is intensified by the almost universal need for dosages of corticosteroids that increase acne and produce obvious cushingoid facies. It is the unusual adolescent who does not rebel under these circumstances. This rebellion may take the form of noncompliance with scheduled physician visits, overt or covert medication noncompliance, or familial disruption. The physician who expects the adolescent with SLE to act like an adult should expect an unsatisfactory patient-physician relationship that often results in a poor outcome.

Anger frequently is the adolescent's predominant response to his or her situation. It is important to remember that there is no well-defined target for this anger. The adolescent obviously is angry about having SLE, but the disease has no direct embodiment. The physician, the medications, and the required examinations, however, all are direct manifestations of the disease and thus easy targets for the adolescent's rage. This may be expressed overtly by refusing to cooperate, but it is more difficult to deal with when covert and unrecognized.

There is no single, successful method for dealing with adolescent rebellion in the setting of chronic illness. Because adolescents frequently believe that important information is being kept from them, it is important to emphasize honesty, trust, and integrity. The physician cannot demand these from the adolescent patient without promising to provide them in return. Often, the situation is handled best by excusing the family from the room, because there may be many issues that the adolescent is afraid to voice in front of parents or siblings. It often is useful to ask the patient directly what the physician or family has done to provoke the behavior. Frequently, it takes only a few minutes of conversation to elicit a recognition that the anger is primarily over being ill. Dealing with this honestly and directly is a key step in developing a healthy patient-physician-family relationship.

For some children, no amount of discussion and reassurance is sufficient. Often, this is in response to unspoken fears or needs in the family of which the physician may not be aware. In these circumstances, it is best to recommend family counseling. Individual counseling of the adolescent furthers their feeling of having been singled out and often is counterproductive (unless it develops out of initial family-centered care). Situations where both honest discussion and family counseling fail, are unusual. When they do occur, it is important to determine whether the adolescent behavior may be a manifestation of unrecognized cerebritis, for which increased medication may be required. If a satisfactory patient-family-physician relationship cannot be established despite every possible effort, then referral to another physician or center may be indicated. Because this forces the adolescent and family to reevaluate their conduct and initiate new relationships, it may be beneficial even when no additional steps are taken.

Pulmonary Manifestations

Pleurisy and pleural effusions are the most common pulmonary manifestations (166 ,167). Severe manifestations, including pneumothorax, pneumonia, chronic restrictive

lung disease, pulmonary hypertension, and acute pulmonary hemorrhage, may occur (166 ,167 ,168 ,169 ,170 ,171 ,172 ,173 ,174). Pleuritic chest pain, pleural effusions, and chronic interstitial infiltrates affect from 10% to 30% of children with SLE (2 ,6 ,11 ,13 ,14 ,28 ,29). When a series of Canadian children with SLE was reviewed for manifestations of respiratory involvement, 17 of 24 patients (77%) had evidence of pulmonary involvement (166).

Chronic pulmonary involvement may result in slowly progressive diaphragmatic dysfunction and restrictive lung disease. These changes appear as malaise and dyspnea on exertion (166 ,168 ,172 ,175 ,176). Diaphragmatic dysfunction may contribute to frequent infection (166 ,168). Diaphragmatic involvement also may be more common than previously recognized. Changes ranging from wide variation in fiber size to calcinosis were common in autopsy specimens of children dying from SLE (169). It is useful to note both pulse rate and respirations as part of the routine examination. Gradual increases in either or both parameters recorded over time may be the earliest clue to developing cardiac or pulmonary dysfunction, which are not clinically evident to either the patient or physician.

Significant restrictive lung disease may be present in children with normal chest radiographs. A study of 15 children with SLE by Trapani et al. found pulmonary involvement in 6 who were without pulmonary symptoms (177). Children with dyspnea or tachypnea at rest should be monitored with periodic pulmonary function testing. As the ability to ameliorate renal and CNS manifestations of SLE in children and adolescents improves, chronic pulmonary involvement is becoming an increasing concern.

The most common fatal complication of pulmonary involvement in children and adolescents with SLE is pneumonia (170). Pneumonia was the primary cause of death for 9 of 26 children with SLE coming to autopsy in one reported series; pulmonary hemorrhage contributed to the death of 5 others. In contrast, renal failure and CNS involvement were the primary causes of death in only 4 and 3 children, respectively.

Pulmonary hypertension, denoted by accentuation of the second heart sound, is an ominous finding in children and adolescents with SLE. Once established, it progresses steadily to right-sided heart failure and death (168). Pulmonary hemorrhage may occur in the setting of preexisting pulmonary hypertension or in isolation (168 ,171 ,172 ,175). Sudden, unexplained pallor and tachypnea often indicate the onset of pulmonary hemorrhage (162), which if left untreated is rapidly fatal.

Minor manifestations of pulmonary involvement normally respond to corticosteroids (166 ,167 ,178). Deaths from pneumonia, in which *Escherichia coli, Klebsiella sp.,* or *Staphylococcus aureus* were the predominant organisms, illustrate the need for broad-spectrum antibiotic coverage (170). *Pneumocystis carinii* and other nonbacterial organisms may be present (179). When pneumonia is superimposed on active pulmonary SLE, the contributions of infection and active SLE cannot be differentiated with certainty. Both antibiotics and increased doses of corticosteroids may be appropriate.

Children with pulmonary hypertension may benefit symptomatically from the addition of calcium channel blocking agents to reduce pulmonary vascular resistance. No therapy is known to reverse the course of this complication. Cytotoxic drugs have been ineffective, except in rare anecdotal reports. Pneumonia is a frequent complication in children with established pulmonary hypertension and may progress rapidly to sepsis. Massive pulmonary hemorrhage may respond to large doses of corticosteroids with ventilator support and, perhaps, plasmapheresis or extracorporeal membrane oxygenation (171 ,179).

Musculoskeletal Manifestations

The arthritis of SLE generally is nondeforming and responds well to anti-inflammatory medications. Significant arthritis at presentation is found in 40% to 60% of children and adolescents with SLE, and it occurs in over 80% of children with SLE at some point (2 ,6 ,7 ,11 ,13 ,14 ,29 ,41). Usually, the arthritis affects the small joints of the hands and feet, with swelling and pain on motion. Asymptomatic knee effusions frequently are present in children with active disease who may not have arthritis elsewhere.

Rarely, children with well-documented JRA and erosive changes develop definite SLE (180). These children appear to have two independent diseases. Although this is an infrequent occurrence, the greater than expected frequency of this overlap suggests that SLE and JRA share some common genetic predisposition.

Avascular necrosis is the most significant musculoskeletal complication of SLE in children and adolescents, and it may result from SLE alone, corticosteroid therapy, or their interaction. A cross-sectional radiographic study of 35 children with SLE found evidence of avascular necrosis in 40% (181). However, these children were drawn from a program that routinely uses high-dose corticosteroids (i.e., 2 mg/kg/day). The frequency of avascular necrosis in a general population of children and adolescents with SLE is unknown.

Avascular necrosis usually affects the hips and knees of children with SLE. Children report gradual onset of progressive discomfort in the affected joints, and the initial evaluation may prove negative. MRI and, later, routine radiography ultimately reveal evidence of osteonecrosis. Although no clear association of avascular necrosis with the total dosage of corticosteroids or their mode of administration has been found, the incidence of avascular necrosis is far higher in children who have received corticosteroids for prolonged periods (181 ,182).

Meaningful muscle involvement is rare in children with SLE. Diffuse weakness may be the result of steroid myopathy (183). Mild elevations of serum creatinine phosphokinase levels often are seen but rarely are associated with clinical weakness. Antibodies to the acetylcholinesterase receptor may produce a myasthenia gravis–like picture, and transplacental passage of antibodies to this receptor is

reported to have caused weakness in the child of a mother with SLE (184). Dermatomyositis, which may be associated with a positive ANA, arthritis, a heliotropic rash, and significant proximal muscle weakness, must be excluded if significant weakness is present. The presence of antibodies to double-stranded DNA (dsDNA) does not automatically exclude the diagnosis of dermatomyositis, but hypocomplementemia is not expected in children with this condition.

Dermatologic Manifestations

Rashes occur frequently in children with SLE (2 ,6 ,7 ,11 ,13 ,14 ,28 ,29), but only 30% to 50% ever manifest the typical butterfly rash (11 ,28) (Fig. 43-2). Vasculitic involvement of the hard palate frequently accompanies the facial rash of SLE, and these lesions are a useful confirmatory sign if the cause of the facial rash is in question. Cutaneous lesions may take the form of recurrent urticaria, bullae, vasculitic nodules, or chronic ulceration. Vasculitic lesions frequently are a manifestation of active disease. Other dermatologic manifestations may wax and wane without exacerbation of systemic disease.

Figure 43-2. Typical bilateral malar rash in a young Asian female with systemic lupus erythematosus.

Bullous lesions resembling bullous pemphigoid are the predominant manifestations of SLE in some children (185). Boys with this manifestation predominate. Often, they have mild systemic disease, and renal involvement is rare. Little information is available about these children in the literature. Dapsone often is helpful but has not been uniformly useful (186).

Dermatologic manifestations usually are not of long-term significance. Most respond to treatment without significant scarring. All the dermatologic lesions of SLE may be aggravated by sun exposure, and children with SLE should be counseled to use sun-blocking agents and to avoid unnecessary sun exposure, which may provoke increased systemic disease activity. Definite photosensitivity occurs in 16% of children (187).

It is important to discuss photosensitivity and its attendant precautions with great sensitivity. Adolescents often resent being told they cannot go to the beach or other all day outdoor activities (e.g., theme parks) with their friends. One must make every effort to accentuate the positive. For example we encourage our patients to participate in these activities in the evening when the risk of significant ultraviolet exposure is less. However, we recommend long sleeves, hats, and sun block at all times. One also must be sure to emphasize the exact nature of the risk. A recent patient suffered severe skin irritation after going to a tanning salon. They professed not to understand that this too was ultraviolet exposure and included in the photosensitivity precautions explained to them.

Discoid lupus erythematosus (DLE) is unusual in childhood. Most children referred for DLE have systemic manifestations when questioned and examined carefully. Some children with DLE progress to SLE, but this is rare (171). Isolated DLE is of concern because of associated disfigurement and psychologic effects. In the past dermatologic lesions of SLE in childhood have been treated primarily with topical corticosteroids. However, with sustained use these have adverse affects on the skin. More recently topical ointments containing tacrolimus or related compounds have been found to be effective. However there may be an increased risk of skin cancer if their use is sustained (188).

Cardiac Manifestations

Cardiac manifestations rarely are prominent in children and adolescents with SLE, but occasionally, they are catastrophic (189). Pericarditis, myocarditis, and mild valvular involvement are common and may not be symptomatic (6 ,7 ,13 ,14 ,190 ,191 ,192 ,193). Clinically evident pericarditis or myocarditis occurs in 10% of children (11 ,13 ,14 ,28), but occasional series report a higher frequency (2 ,7 ,170). Children with SLE may develop cardiac tamponade, but this complication is uncommon (194). Severe and recurrent pericarditis may warrant surgical intervention.

Many children with SLE are anemic and develop flow murmurs. Libman-Sacks endocarditis may occur in childhood, however, and this predisposes to bacterial endocarditis.

In large series of patients with SLE, bacterial endocarditis occurs with a greater-than-expected frequency (170 ,178 ,195). All children with significant valvular lesions must receive antibiotic coverage for dentistry and other invasive procedures; some recommend routine bacterial endocarditis prophylaxis for all patients with SLE.

Circulating lipid abnormalities occur in adolescents and young adults with SLE and may contribute to premature myocardial infarctions and coronary arteritis, and septic thrombosis. These lipid abnormalities are in part related to prolonged corticosteroid therapy (105 ,178 ,196 ,197 ,198 ,199 ,200). Preliminary studies to determine whether statins are safe and effective for children with SLE are underway (201). The association of prolonged corticosteroid therapy with premature myocardial infarction is well documented and raises significant questions about the long-term safety of high-dose corticosteroid regimens.

Gastrointestinal Manifestations

Mild gastrointestinal (GI) involvement is common in children and adolescents with SLE; 30% to 40% manifest hepatomegaly or splenomegaly at diagnosis (7 ,13 ,14). Chronic abdominal pain, anorexia, weight loss, and malaise also are frequent presenting complaints (2 ,7 ,11 ,13 ,14 ,29) that often resolve with corticosteroid therapy. In some cases the onset of the abdominal pain may be acute (202 ,203). Abdominal pain that is unresponsive to corticosteroids may result from small-vessel vasculitis that may not be detected by routine testing (204). These children may respond to a further increase in their corticosteroid dosage (14). Retroperitoneal fibrosis is a rare cause of abdominal pain in children with SLE (205). More often, abdominal pain is the result of pancreatitis that is induced either by SLE, corticosteroids, or both (2 ,13 ,206 ,207 ,208 ,210). Fulminant pancreatitis resulting in death has occurred.

Pneumatosis cystoides intestinalis may be discovered radiographically in patients who have complained of abdominal pain without evident explanation for weeks or months (13 ,209 ,210 ,211). This may be the result of chronic ischemia. Frank bowel ischemia often is found at autopsy (209). Although severe ischemia probably is a terminal event, its frequency suggests that the bowel often is compromised by lesser degrees of vascular insufficiency during life in children with severe SLE. This may be the explanation for some children with unexplained chronic abdominal pain.

Less frequent GI manifestations of SLE include hepatitis and ileitis (2 ,209). Protein-losing enteropathy and marked hyperlipoproteinemia (212 ,213) also have been reported. The relationship of these manifestations to SLE is uncertain. GI irritation secondary to drugs used in treating SLE is frequent, and aspirin-induced hepatotoxicity is particularly common. Severe gastritis and ulcers may occur as well. Additional rare manifestations of SLE in childhood include the simultaneous occurrence of GI inflammation and cystitis (214).

Although infarction of the spleen may produce acute abdominal pain, splenic involvement in SLE usually is asymptomatic. Functional asplenia is a very worrisome complication, because it is associated with increased susceptibility to infection (215). The presence of Howell-Jolly bodies on the peripheral smear should alert clinicians to the possibility of functional asplenia and prompt hospitalization if the child is febrile without adequate explanation.

Infection

Infection is a major cause of both morbidity and mortality for children and adolescents with SLE (2 ,6 ,11 ,13 ,29). Platt et al. (29) documented 55 separate infections occurring in 70 patients over a mean follow-up of 9 years. Sepsis was a contributing cause of death in 25% to 85% of deaths in various series (2 ,6 ,11 ,13 ,29), and it was a cited factor in 35 of 83 deaths (42%) occurring in 374 children collected from six large studies (2 ,6 ,11 ,13 ,29).

The increased frequency of sepsis most likely results from the combined effects of SLE and the drugs that are used to mediate it (216 ,217). The frequency of infection increases with increasing steroid dosage (216). Not only do bacterial infections increase, but opportunistic infections and infections caused by viruses, fungi, and related organisms are more common in children with SLE (29 ,170). The indiscriminate use of immunosuppressive drugs also may contribute to the increased incidence of infection; however, careful use of periodic intravenous cyclophosphamide accompanied by a reduced dosage of corticosteroids often leads to a reduced frequency of infections. In contrast to children taking a prescribed daily dosage of azathioprine or other immunosuppressive agents, children receiving periodic intravenous cyclophosphamide therapy can be intensively screened prior to receiving each dosage of the immunosuppressive agent. For all children with SLE potentially fatal infections, including both bacterial endocarditis and meningitis, occur with a greater-than-expected frequency (151 ,195). Functional asplenia, decreased phagocytosis, poor complement metabolism, and corticosteroid effects all may contribute to this problem.

Hematologic Manifestations

The most common hematologic manifestation of SLE in children and adolescents is anemia. Usually, this is not a Coombs-positive hemolytic anemia with a reticulocytosis; rather, it is a microcytic anemia of chronic disease. Leukopenia and thrombocytopenia are common but not invariably present. Sickle cell anemia is not directly associated with SLE, but it is common in African Americans, who have an increased incidence of SLE. When SLE and sickle cell disease occur together, the similarity of symptoms between the two illnesses may produce confusion. If the physician cannot distinguish the etiology of problems with certainty, he or she may have to treat as appropriate to both conditions.

Children often are seen who have ANAs and thrombocytopenia, which has been labeled idiopathic thrombocytopenic purpura (ITP). A false-positive biologic test result for syphilis or prolonged partial thromboplastin time (PTT) in this setting may suggest SLE. Children with ITP may have antibodies to Sm, Ro, La, or RNP. All children with serologic markers such as these should be carefully followed and periodically re-evaluated for evidence of systemic disease including periodic testing for hypocomplementemia, renal impairment, and proteinuria or hematuria. Some of these children ultimately develop SLE (218 ,219) (Table 43-2). In the absence of other manifestations of SLE, therapy for these children is similar to that for ITP alone.

Menorrhagia may be the presenting feature of SLE in teenage females. Prolonged bleeding or a prolonged PTT resulting from the lupus anticoagulant may be the initial manifestation of SLE in a patient who is being screened for other reasons. However, these findings alone do not establish the diagnosis of SLE. Management of these complications is the same for children and adolescents as for adults.

Anticardiolipin antibodies (aCL) occur in children with SLE with a similar frequency to that of adults (68 ,69 ,220). They are associated with an increased risk of thrombosis and CNS disease (221 ,222). Children with high titer aCL, lupus anticoagulant, and thrombocytopenia may be the group at highest risk of thrombosis (223). Others have suggested that SLE patients with the SA1 anti-DNA idiotype may be at increased risk of vascular complications in the setting of aCL (224). The risk for children with low titer aCL in the absence of lupus anticoagulant appears to be low (225). Low-dose aspirin therapy may be beneficial in reducing the risk. Children have been reported who presented with acute thrombosis and were found to be anticardiolipin antibody-positive but who did not have additional findings to support the diagnosis of SLE (226). Proper categorization of such children is uncertain, because over time, some have gone on to develop SLE (71).

Table 43-2: Incidence of Serologic Antibodies in 92 Children with Systemic Lupus Erythematosus*

Antibody	Incidence (%)	
	Ouchterlony	ELISA
Ro/SSA	16	46
La/SSB	11	17
Sm (RNP)	27	58

*The presence of these antibodies did not correlate with disease activity, except that Ro/SSA antibodies by Ouchterlony were significantly more common in children younger than 10 years of age (11 of 28 vs. 4 of 64, $P < .001$). Children younger than 10 years of age also had a significantly higher mean ELISA titer of Ro/SSA antibodies.
ELISA, enzyme-linked immunosorbent assay.

Laboratory Evaluation

No laboratory feature of SLE in children and adolescents is unique to this age group. For clinicians, the diagnosis of SLE is strongly suggested by the constellation of hypergammaglobulinemia, leukopenia, anemia, and thrombocytopenia. A positive ANA is confirmatory, but none of these findings is essential.

ANAs are present in over 90% of children and adolescents with SLE (6 ,11 ,14 ,192 ,227). Antibodies to various other nuclear and cytoplasmic antigens also are found (50 ,228 ,229 ,230 ,231 ,232 ,233 ,234 ,235). One study that compared the incidence of antibodies to DNA, Sm, and RNP found a lower frequency in children with SLE than in a simultaneously studied population of adult patients with SLE (50). Antibodies to Ro/SSA and La/SSB were found in similar numbers of adult- and childhood-onset patients. These antibodies also are found with increased frequency in the relatives of children with SLE (50). Their presence in asymptomatic relatives has been variously interpreted as being evidence of environmental exposure or genetic predisposition. Recent findings suggest that one may be genetically predisposed to manifest anti-Ro antibodies in response to viral infections such as Epstein-Barr virus suggesting that both environmental exposure and genetic predisposition play an important role in the development of SLE.

Antibodies against dsDNA are both sensitive and specific for active SLE in childhood (228 ,230) but may occur in other conditions (228). Decreased serum levels of the third component of complement (236) correlate well with active SLE in childhood, but neither decreased C3 levels nor antibodies to dsDNA can be relied on as a specific indicator of active renal disease (228 ,237).

Decreased C4 levels often are correlated with decreases in C3, but they may occur in isolation. Decreased C4 levels also frequently are found in the relatives of children with SLE. This may be evidence of the C4 null allele, a manifestation of subclinical disease, or both (30 ,75 ,238 ,239).

Hypergammaglobulinemia frequently is present in children with SLE but also may be found in various chronic inflammatory states (2 ,6 ,11). IgA deficiency occasionally is seen, as is panhypogammaglobulinemia (6 ,87 ,88). Panhy-pogammaglobulinemia is a common complication of cyclophosphamide therapy, but it also occurs in patients with SLE who have not received immunosuppressive agents (88).

False-positive test results for syphilis formerly were found in many children with SLE (2 ,14), but more recent studies report fewer false-positive results (6 ,11). In the United States, it is important to warn the family that positive results may be reported to the public health department. Unwarranted investigation can be halted if questions are referred to the physician. The diagnosis of SLE, however, does not exclude the possibility of treponemal disease. False-positive fluorescent treponemal antibody (FTA) test results may occur because of nonspecific agglutination resulting from hypergammaglobulinemia (240), but FTA-positive individuals in whom the possibility of treponemal

disease cannot be reliably excluded should receive appropriate therapy.

Therapy

NSAIDs provide useful control of the arthritis and musculoskeletal manifestations of SLE in children and adolescents (Table 43-3). Renal function and blood pressure must be monitored because of their known effects on glomerular filtration, but significant undesired effects are infrequent. Acetylsalicylic acid (i.e., aspirin) often is used in low dosage (5 mg/kg/day) in children with anticardiolipin antibodies. Antiinflammatory doses of aspirin (80 mg/kg/day) have been advocated, but children with SLE are very susceptible to salicylate-induced hepatotoxicity. Alternate NSAIDs are preferable.

Hydroxychloroquine sulfate (Plaquenil) and chloroquine routinely are used in children and adolescents with SLE (2 ,7 ,8 ,11 ,12 ,14). They are believed to have a useful steroid-sparing effect at a dose of 7 mg/kg/day. Although rare ocular toxicity is a concern, it was not reported in children or adolescents in any of these series (Table 43-4).

Intravenous pulse methylprednisolone (30 mg/kg daily, up to 1 g) given as an intravenous infusion has been used to control flares of nephritis (241) or CNS disease. Therapy was associated with dramatic short-term improvement in renal disease, but was not superior over the longer-term, to daily prednisone (241). Long-term benefit from pulse methylprednisolone is more likely in children with acute CNS involvement and other manifestations of SLE that appear to result from an acute event. Although rare, side effects may occur with pulse methylprednisolone, including significant hypotension, hypertension, and pancreatitis. Deaths have rarely occurred.

Table 43-3: Immunosuppressive Treatment of Childhood SLE

Drug(s)*	Suggested Dosage	Useful For	Remarks
NSAIDs,	—	Mild disease	Monitor for idiosyncratic effects of NSAIDs on renal and central nervous system (CNS) function.
Prednisone	1–2 mg/kg/d	More severe or unresponsive disease.	Rarely exceed 80 mg/day; may be divided up to q.i.d., if necessary.
Methylprednisolone	30 mg/kg/d, IV	Acute manifestations of CNS or renal disease	Maximum: 1,000 mg for 3 days
Cyclophosphamide	500–1000 mg/m2/mo for 7 months, then every 3 months for 30 additional months	DPGN	May be helpful for some children with severe nephrotic syndrome or CNS disease

*Other agents have been used, with differing reports of their efficacy.
DPGN, diffuse proliferative glomerulonephritis.

Table 43-4: Dosages of Medications Commonly Used for Children with SLE*

NSAIDs
- Naproxen 10–15 mg/kg divided BID (Usual maximum, 500 mg BID)
- Tolmetin 20–40 mg/kg divided BID (Usual maximum, 600 mg BID)
- Diclofenac 1–3 mg/kg divided BID (Usual maximum, 75 mg BID)
- Ibuprofen 20–40 mg/kg divided TID or QID (Usual maximum, 800 mg TID) may be associated with idiosyncratic reactions in SLE.

Other Drugs
- Hydroxychloroquine 7 mg/kg up to 200 mg/d (Some centers use 400 mg/d maximum dose)
- Dapsone 1 mg/kg up to 100 mg/d

Immunosuppressives
- Azathioprine 1–3 mg/kg/d (Usual maximum 100 mg/d)
- Cyclophosphamide (See text for intravenous administration.

Not recommended PO because of hemorrhagic cystitis risk)
- Methotrexate 10 mg/m2/wk (Safety and efficacy in SLE not yet established)

*These typically are used dosages only. Full prescribing information provided by the manufacturer should be consulted for possible side effects, interactions, and other consequences of the use of these medications.

In the 1970s, most children were treated with high-dose corticosteroids (2 mg/kg/day) followed by a gradual tapering once their disease came under control (2 ,78 ,11 ,14 ,28). Children with continuing active disease and evidence of renal involvement received immunosuppressive agents (7 ,9 ,13 ,29). Cushingoid facies, cataracts,

avascular necrosis, and other complications were common (9 ,11 ,28).

In the late 1980s, systematic use of intravenous cyclophosphamide became common. It has been argued that corticosteroids are preferable to cytotoxic agents, because corticosteroids do not have life-threatening side effects. However, overt suicide resulting from the psychosocial stresses of Cushingoid facies and chronic disease has occurred, and covert suicide in the form of noncompliance (e.g., stopped corticosteroids against medical advice) is not uncommon (29).

Although the therapeutic role of cytotoxic drugs remains controversial, data supporting their safety and efficacy have become increasingly convincing (31 ,242 ,243 ,244). Concerns regarding sterility, risk of infections, and risk of neoplasia have limited their use to children with significant disease activity that is unresponsive to acceptable doses of corticosteroids (6 ,7 ,9 ,10 ,13 ,14 ,29 ,110 ,245). Immunosuppressives have been used in those with CNS disease, with varying results (6). Although a few centers report good results using high-dose prednisone and azathioprine over both 5- and 10-year periods (9 ,29), others have had less success with this regimen. Controlled trials in adult patients with SLE have found cyclophosphamide to be as effective as, and less toxic than, the combination of cyclophosphamide and azathioprine (110 ,111). Proper stratification of patients at study entry may be the key to resolving these issues (Table 43-5). We have found the systematic use of cyclophosphamide to be associated with a far greater and faster improvement in clinical parameters, and sense of well being, although allowing a more rapid reduction in corticosteroid dosage. A large number of children initially treated with systematic intravenous cyclophosphamide for a period of 3 years, are now off all immunosuppressive agents and disease free (112). As noted in the section on nephritis, a number of new biologic agents have begun to be used in the treatment of patients with SLE. Their ultimate safety and utility remain uncertain. It is hoped that the combined use of a variety of agents (much as is used in the treatment of childhood neoplasms) will ultimately lead to development of a regimen with maximum efficacy and minimum toxicity.

For children and adolescents with SLE, the desire to avoid iatrogenic injury must be balanced against the goal of sustained survival. Cyclophosphamide administered with vigorous intravenous hydration and careful inpatient monitoring has proven to be both safe and effective (31 ,110). Although sterility and late-onset neoplasia are theoretic risks, neither has been documented in children receiving cyclophosphamide with rigorous intravenous hydration. In contrast, avascular necrosis, cataracts, and Cushingoid facies commonly are experienced by children receiving high doses of corticosteroids over a prolonged period.

At the Hospital for Special Surgery in New York City, children who fail to respond adequately to corticosteroid therapy receive intravenous cyclophosphamide according to a well-defined protocol. Children initially receive 500 mg/m^2 of cyclophosphamide, followed by monthly increases to 750 mg/m^2, and then 1,000 mg/m^2 if the WBC count does not fall below 2,000/mL at its nadir. (It should be noted that 875 mg/m^2 often is the maximum dose that does not produce too great a fall in white count for children smaller than 1 m^2. In addition, the dosage should not exceed 40 mg/kg, because larger doses have been associated with cardiac toxicity in oncologic studies.) The induction phase of cyclophosphamide therapy continues with monthly cyclophosphamide infusions for a total of seven doses. Many children do not show evidence of major improvement until after the third monthly dose. If a child has deteriorated despite 6 months of therapy with cyclophosphamide, however, further therapy may not be warranted.

Children who respond well to monthly cyclophosphamide continue on therapy at 3-month intervals at the same dosage for an additional 10 maintenance doses. After 36 months of therapy, a repeat renal biopsy is performed and the cyclophosphamide discontinued if no evidence of active disease is found. Some children demonstrate renewed disease activity (e.g., decreasing hemoglobin, decreasing complement levels, falling creatinine clearance, increasing hematuria or proteinuria) following the transition from monthly therapy to therapy every 3 months. These children are treated with three additional monthly doses of cyclophosphamide, following which therapy every 3 months is resumed. Acute flares are managed with intravenous bolus doses of methylprednisolone for 3 days (30 mg/kg/day, up to a maximum of 1,000 mg) as necessary.

Most children who complete 36 months of therapy are withdrawn from cyclophosphamide and do well on low-dose corticosteroids. Some of these initial children are now alive, more than 15 years later, off all medications despite having biopsy-proven DPGN when therapy was initiated. Children who respond to monthly cyclophosphamide but who deteriorate whenever the frequency of therapy is decreased to every 3 months or flare after the initial course of cyclophosphamide has been completed, represent a different situation. Children with persistent disease activity without established chronic renal damage currently are treated with an aggressive program of combination therapy, using both intravenous cyclophosphamide and intravenous methotrexate. For those with only moderate disease activity but persistent hypocomplementemia, therapy with mycophenolate mofetil (up to 1 g BID) may be beneficial. For those children with severe disease recurrence, we have combined a 9-month course of intravenous cyclophosphamide with high-dose intravenous methotrexate (300 mg/m^2). This regimen has allowed us to bring four previously resistant patients under good disease control. In these children, methotrexate should be initiated carefully at 50 mg/m^2 or less and gradually increased if significant renal compromise is present. They should receive daily folic acid, and may require folinic acid “rescue” if there is significant renal compromise. Creatinine clearance of less than 60 mL/minute may be associated with increased risk of methotrexate toxicity.

Table 43-5: Staging Criteria for SLE

Stage 0	Patients with serologic evidence of SLE without clinical manifestations
0	Positive ANA without other manifestations
0a	Positive ANA plus false positive VDRL; or anticardiolipin antibodies; or antibodies to Ro, La, or RNP
0b	Positive ANA plus antibodies to Sm or anti-DNA antibodies.
Stage 1	
1	Serologic evidence of SLE plus at least one nonserologic criterion from the ACR criteria for the diagnosis of SLE, but without sufficient findings to fulfill criteria for a definite diagnosis of SLE or constitutional symptoms. (Note that any patient who fulfills the ACR criteria, or has >25 RBC/HPF or 1+ or greater protein by dipstick on urinalysis automatically is classified stage 3 or higher.)
1a	Criteria for stage 1 plus an elevated total protein [>8 g, or Hb <11.0 g/dL (without hemolytic anemia)].
1b	The above plus an ESR >25 mm/H Westergren
Stage 2	
2	Serologic evidence of SLE plus at least one nonserologic criteria for the diagnosis of SLE with recurrent fever, weight loss, or other significant constitutional symptoms.
2a	The above plus hypocomplementemia (C3 <80% of lowest normal value)
2b	The above criteria plus an elevated total protein [>8 g, or Hb <11.0 g/dL (without hemolytic anemia)]
Stage 3	
3	Any patient who fulfills the ACR criteria for the diagnosis of definite SLE, or patients with renal involvement who do not fulfill the ACR criteria for a definite diagnosis of SLE
3a	The criteria for stage 3 plus hypocomplementemia (C3 <80% of lowest normal value)
3b	The criteria for stage 3 plus an elevated total protein level [>8 g, or Hb <11.0 g/dL (without hemolytic anemia)]
Stage 4	
4	Definite SLE with renal involvement characterized by consistent finding of >5 RBC/HPF or >500 mg total protein in a 24-h urine specimen (normal serum creatinine and creatinine clearance). These patients would be expected to have either minimal glomerulitis or focal segmental nephritis on biopsy
4a	These criteria plus hypocomplementemia (C3 <80% of lowest normal value)
4b	These criteria plus an elevated total protein [>8 g, or Hb <11.0 g/dL (without q hemolytic anemia)]
Stage 5	
5	Definite SLE with membranous glomerulonephritis on biopsy and >2.0 g total protein in a 24-h urine specimen
5a	These criteria with clinical evidence of nephrotic syndrome including serum albumin <3.0 g/dL or cholesterol >300. (Note presence of persistent hypertension with diastolic blood pressure >90 mm Hg without treatment automatically indicates stage 7.)
5b	These criteria with pitting edema
Stage 6	
6	Definite SLE with renal biopsy demonstrated diffuse proliferative glomerulonephritis; or seizure, or other neurologic manifestations (e.g., cerebritis) sufficient to warrant hospitalization
6a	These criteria plus hypocomplementemia (C3 <80% of lowest normal value)
6b	These criteria plus an elevated total protein [>8 g, or Hb <11.0 g/dL (without hemolytic anemia)]
Stage 7	
7	Definite SLE with CrCl <100 mL/min/1.75 m2 or serum Cr >1.5
7a	The above plus hypocomplementemia (C3 <80% of lowest normal value) or diastolic blood pressure consistently over 90 mm Hg before therapy
7b	These criteria plus an elevated total protein [>8 g, or Hb <11.0 g/dL (without hemolytic anemia)]
Stage 8	
8	Definite SLE with CrCl <50 mL/min/1.75 m2 or serum Cr >2.0
8a	Plus hypocomplementemia (C3 <80% of lowest normal value) or diastolic blood pressure consistently over 90 mm Hg before therapy
8b	These criteria plus an elevated total protein [>8 g, or Hb >11.0 g/dL (without hemolytic anemia)]
Stage 9	
9	Definite SLE with CrCl <30 mL/min/1.75 m2 or serum Cr >3.0
9a	These criteria plus hypocomplementemia (C3 less than 80% of lowest normal value) or diastolic blood pressure consistently over 90 mm Hg prior to therapy
9b	These criteria plus an elevated total protein [>8 g, or Hb less than 11.0 g/dL (without hemolytic anemia)]
Stage 10	Definite SLE with end stage renal failure requiring dialysis; or chronic psychotic or neurologic state unresponsive to corticosteroid or immunosuppressive drug therapy

HPF, high-powered field.

Adapted from Lehman TJA, Mouradian JA. Systemic lupus erythematosus. In: Holliday MA, Barrat TM, Avner ED, eds. *Pediatric nephrology.* 3rd Ed. Baltimore, MD: Williams & Wilkins, 1994:849–870, with permission.

The major risks associated with the aggressive use of cytotoxic agents are bone-marrow suppression (often complicated

by infection), hemorrhagic cystitis, infertility, and the induction of neoplastic disease (early or late). Infectious complications can be minimized by careful evaluation before the administration of each dose of cyclophosphamide and a high index of suspicion for infection if the patient experiences difficulty during the period of maximal marrow suppression following each dose. Cystitis, infertility, and the induction of neoplastic disease are the remaining concerns. In my experience, none of these has occurred among children receiving intravenous cyclophosphamide with in-hospital hydration, during a 3-year course of therapy. One child with severe recalcitrant disease who received 62 grams of cyclophosphamide over an 8-year period developed a renal papillary-cell carcinoma, which was removed in situ. Presently, any similar patient would be treated with the combination of intravenous cyclophosphamide and intravenous methotrexate to limit the total dose of cyclophosphamide received. Children failing such regimens may be candidates for autologous stem cell transplantation (see below).

Studies of older patients with SLE indicate that the risk of sterility following cytotoxic drug therapy increases with increasing age. Premenarchal children may have some protection. In children with amenorrhea that is secondary to active SLE, menses often return during cyclophosphamide therapy. Several successful pregnancies have been reported following cyclophosphamide therapy in adolescents, and one pregnancy that originated during cyclophosphamide therapy (despite counseling) was successfully carried to term without difficulty. (No further cytotoxics were given after the pregnancy was discovered.) No definitive data about the risks of infertility or neoplasia are available, however, for children with SLE. Both have occurred in children who received cyclophosphamide as part of multidrug regimens for neoplastic disease. Families should be warned about these concerns before therapy is begun, and patients should be selected accordingly.

The ratio of risk to benefit for cytotoxic drugs in children and adolescents with SLE is minimized by appropriate patient selection. Progressively deteriorating creatinine clearance, prolonged hypertension (>6 months), and significant nonhemolytic anemia identify children who are at high risk of ultimate renal failure (101). These findings may occur without significant evidence of extra-renal disease activity, and such children should be aggressively treated. With corticosteroid therapy alone, many children progress inexorably to renal failure. Controlled studies at the Hospital for Special Surgery and at the National Institutes of Health (NIH) have indicated that routine use of intravenous cyclophosphamide prevents or retards this deterioration (31 ,111 ,113 ,242 ,246).

Methotrexate, cyclosporine, and intravenous γ globulin all have been used in small numbers of children with SLE (124 ,247 ,248). Sufficient data have not been obtained to judge their efficacy. Recently, autologous stem cell transplantation has received extensive attention for the treatment of rheumatic diseases including SLE and some teenagers are included in the reported series (127 ,128 ,249 ,250). There are some who question whether to good responses reported are a result of the stem-cell transplantation or the preparative immunosuppressive regimen alone (251).

Most investigators who have taken care of children with SLE over an extended period are aware of children who were inadvertently profoundly immunosuppressed as a result of unexpected sensitivity to a drug or drug interactions. Many of them went into remission of their disease, but few remained in remission for longer than 24 months. Whether the benefits of autologous stem-cell transplantation will endure is unclear. The early European BMT consortium results already describe patients with SLE who have relapsed following autologous stem-cell transplantation. It increasingly is recognized that SLE is a chronic, recurrent disease that may require prolonged therapy, even in the absence of active disease. However, for the patient with continued active disease in the face of intensive chemotherapy these regimens may be warranted. Significant improvements in the therapy of children with SLE will require careful collaborative studies.

Prognosis

The prognosis for children and adolescents with SLE has improved dramatically over the past 20 years (123). With improved anti-inflammatory therapy as well as improved pediatric care, 10-year survival rates now are approaching 90% (11 ,29). Nonetheless, significant numbers of children continue to progress to chronic renal failure and/or death (101) (Tables 43-6 and 43-7).

Often, children and adolescents with SLE do poorly because of the child's, and the family's, inability to cope with the chronic, relapsing nature of the disease. Success requires a sustained relationship among the child, family, and the treating facility. Institutions serving stable populations with good socioeconomic status and easy access to care consistently report superior survival to those serving disadvantaged populations (11 ,29 ,101 ,115 ,252). Poor understanding of the importance of medications for silent manifestations of SLE, such as hypertension, remains a familiar cause of morbidity. These preventable deaths have become increasingly frustrating, as our ability to control the manifestations of SLE has improved.

Table 43-6: Incidence of Adverse Outcomes in 72 Children with Systemic Lupus Erythematosus

Outcome	Incidence (%)
Renal failure	15
Severe central nervous system disease	11
Stroke	1
Chronic thrombocytopenia	7
Chronic active disease	56
Death	18

Table 43-7: Predictors of Poor Prognosis in Childhood Systemic Lupus Erythematosus

1. Persistent anemia: Hb <10 g for >6 mo
2. Persistent hypertension: diastolic BP >90 mm Hg for >6 mo
3. Persistent hematuria: >20 RBC/HPF for >6 mo
4. Pulmonary hypertension
5. Recurrent emergency admissions

HPF, high-powered field.

The quality of survival must be addressed in efforts to improve the outcome for children and adolescents with SLE. Long-term survival of a Cushingoid adolescent with aseptic necrosis who requires dialysis may not be satisfactory to the patient. Platt et al. (29) described three young adults who died more than 10 years following diagnosis; two of the three died after they had discontinued their medications against medical advice.

Although end-stage renal failure and dialysis have been associated with decreased SLE activity in some reports (253 ,254), both children and adolescents requiring chronic dialysis often fare poorly. In one series, nine of 16 children with SLE succumbed within 5 years of beginning dialysis (101).

For children and adolescents with SLE, a satisfactory outcome is measured in decades. Our goal should be to report 90% 50-year survival. Children without renal disease who have survived 5 years are at low risk. Children with renal disease of any type, however, remain at risk. Gradual progression to renal failure over 5 to 10 years or more, despite clinically inactive disease, has been reported in both children and adults with SLE (28 ,104 ,225). Health care professionals dealing with children and adolescents who have SLE must strive to aid patients and their families through a normally difficult period under even more difficult circumstances. Every effort must be made to guarantee the availability of appropriate services. Not only must medical therapy be aggressive, so should patient and family education to ensure their compliance. With the increasing presence of specialized pediatric centers for children with rheumatic diseases and growing numbers of collaborative studies to determine optimal therapy, survival measured in decades now should become the norm.

Summary

The information in this chapter can be summarized as follows:

- Children and adolescents represent both a special challenge and opportunity. Success in caring for this group requires awareness of the complex interactions among the child's illness, the needs of their family, and their own needs as developing individuals.
- Childhood-onset SLE has been recognized since the early 1900s. Although it frequently is described as a more severe disease than adult SLE, this may result from failure to properly diagnose many mild cases.
- No thorough studies of the epidemiology of SLE in childhood have been completed. It is estimated that the annual incidence is approximately 0.6 per 100,000, and that between 5,000 and 10,000 US children have SLE today. The incidence of SLE is much higher in females than in males and in nonwhites than in whites.
- The cause of SLE remains unknown, but the high frequency of immunologic abnormalities among family members of children with SLE suggests that a combination of genetic and environmental factors plays an important role. The presence of Ro/SSA in a large proportion of the mothers of young children with SLE may indicate predisposing genetic factors in the family. SLE also is more frequent in children who have defects of the immune system, suggesting that defective antigen processing may predispose to the development of SLE.
- The most common clinical manifestations of SLE are fever, malaise, and weight loss, but these are nonspecific manifestations of many chronic ailments. The typical butterfly rash is present only in about one third of children with SLE. Diagnosis is based on fulfillment of the ARA criteria, just as in adults.
- Renal disease occurs in two thirds of children with SLE in most reported series. Although the renal disease may be mild, severe DPGN remains a leading cause of morbidity in childhood SLE. Mild renal disease often can be controlled with corticosteroids, but active renal disease that does not respond fully to corticosteroids and DPGN with a falling creatinine clearance requires therapy with cytotoxic agents. Children with active SLE do poorly on dialysis.
- All of the CNS manifestations that are described in adults with SLE also occur in children. Behavioral disturbances, which may be ascribed to acting out by an adolescent with SLE, often represent CNS disease that may respond to increased therapy. Chorea also is seen more commonly among children with SLE.
- Pulmonary involvement in childhood SLE takes many forms, including pleurisy, pleural effusions, pulmonary fibrosis, and pulmonary hemorrhage. Diaphragmatic dysfunction is common and may be the underlying factor predisposing to recurrent episodes of pneumonia. Pulmonary hypertension often is a life-threatening complication. Abnormal pulmonary function may be present despite a normal chest radiograph.
- Musculoskeletal manifestations of SLE include arthritis and mild inflammatory myopathy, and they often are predominant at presentation. Both are responsive to corticosteroid therapy, however, and rarely contribute to long-term morbidity. The exception is avascular necrosis,

which may occur as a complication of SLE with or without corticosteroid therapy and ultimately requires ultimate joint replacement.

- Dermatologic involvement is common in childhood SLE but rarely is a significant problem except when the face is prominently disfigured, causing psychologic problems (Fig. 43-1). DLE is unusual in childhood.
- Cardiac manifestations of SLE include pericarditis and myocarditis, sometimes with recurrent effusions. These usually can be controlled with NSAIDs or low-dose corticosteroids. Valvular involvement is common and may predispose to bacterial endocarditis. Careful consideration should be given to antibiotic prophylaxis whenever bacteremia is expected. Premature myocardial infarctions have occurred in young adults, with significant atherosclerosis following prolonged corticosteroid therapy.
- GI manifestations of childhood SLE are varied. Nonspecific findings such as chronic abdominal pain and anorexia are frequent, and significant bowel infarction may occur. Pneumatosis intestinalis may result from recurrent microvascular insults.
- Infection is a major cause of morbidity and mortality in children and adolescents with SLE. Active SLE pre disposes to infection. Often, it is unclear whether a child's rapid deterioration is the result of infection or of active SLE. In this setting, increased doses of both corticosteroids and antibiotics may be necessary. Reticulo-endothelial system overload and functional asplenia may predispose to rapid progression of sepsis in children with active SLE.
- Hematologic manifestations are common in children and adolescents with SLE. Most are nonspecific. Thrombocytopenia is a frequent presenting complaint, particularly in young males, and menorrhagia also may be a significant problem in adolescent females. As in adults, the presence of anticardiolipin antibodies predisposes to clotting dysfunction and stroke in children.
- Laboratory manifestations of childhood SLE are identical to those of adults. One unique concern is awareness that a positive serologic result for syphilis in a child or adolescent is reported to the school district and warrants prompt investigation by public welfare authorities. Families should be warned about this possibility, and inquiries should be promptly diverted to the physician.
- Therapy for childhood-onset SLE is similar to that for adults. Because of the increased burdens of growth and development on renal function, however, it may be important to institute aggressive intervention earlier in children with DPGN. The goal must be to develop therapies that provide acceptable 50-year survival, not 5- or 10-year survival, for children and adolescents with SLE. The systematic administration of cytotoxic drugs may provide superior quality of life and long-term survival.

Chapter 44
Drug-Induced Lupus

Robert L. Rubin

Historical Perspective

Within 1 year after the introduction of hydralazine to control malignant hypertension in 1952, the first report appeared of a late onset “collagen disease” resembling systemic lupus erythematosus (SLE) in 17 out of 211 hydralazine-treated patients (1). However, because the treatment regiment of these patients was combined with hexamethonium chloride, the first definitive association between hydralazine and lupus-like disease should be attributed to Dustan et al. at the Cleveland Clinic (2) in which 13 out of 139 patients became ill after receiving 400 to 800 mg hydralazine per day for an average of 12 months. In their follow-up paper in 1954, Perry and Schroeder (3) demonstrated that hexamethonium ion was not implicated in the lupus-like reaction of the 17 patients described by Morrow et al. (1) because patients fully recovered after discontinuation of only hydralazine. Although procainamide was introduced for the treatment of cardiac arrhythmia at about the same time, it was not until 1962 that Ladd reported a patient who developed lupus-like features after 6 months of procainamide therapy (4). During the next 3 years, another 11 cases of procainamide-induced lupus were reported (5). By 1966, a scattering of cases of lupus-like disease as a side effect of therapy with isonizid, diphenylhydantoin, sulphamethoxypyradazine, primidone, and tetracycline appeared. It is now clear that patients on a diverse array of drugs can develop autoantibodies and clinical features similar to those seen in patients with idiopathic SLE. Since this subject was reviewed 5 years ago, at least six additional drugs have been reported to induce lupus-like abnormalities, suggesting that the spectrum of drugs with capacity to induce lupus will continue to increase.

It is important to distinguish drug-induced lupus-like disease from the more common condition of drug-induced autoimmunity. When patients receiving drug therapy develop autoantibodies or other laboratory features of autoimmunity such as elevated immunoglobulin levels, but are clinically asymptomatic, the term “drug-induced autoimmunity” (DIA) should be used. In contrast a minority of drug-treated patients develop de novo clinical signs and symptoms similar to the spectrum of features associated with idiopathic SLE. This syndrome is referred to as drug-related lupus or drug-induced lupus (DIL). Although DIA may be a more homeostatically regulated form of DIL as suggested by the quantitative differences in their overt autoimmune abnormalities as discussed below, most asymptomatic drug-treated patients with persistently high levels of autoantibodies do not progress into developing lupus-like symptoms (6).

Drugs Implicated in Drug-Induced Lupus

Table 44-1 lists currently used drugs reported to be associated with a lupus-like syndrome. In all cases drugs that induce lupus also induce autoantibodies in a much higher frequency. Excluded from this list are drugs implicated only in the exacerbation of SLE or with the onset of chronic SLE prior to diagnosis as discussed below. Also excluded are drugs that induce non-multisystem cell, tissue, or organ abnormalities, such as cytopenias or cutaneous manifestations, although these may have an autoimmune etiology similar to DIL as discussed below. Also not shown are drugs that were initially reported to be associated with a lupus-like syndrome, but no confirmation has appeared despite many decades of prescriptions with countless patients. However, several infrequently used drugs are included in which only a single case of autoimmune-like disease has been reported to heighten vigilance for these possible lupus-inducing drugs. Eight drugs previously listed have been removed from this table because they are no longer in use. Macromolecular immunotherapeutics that have potential for induction of autoimmunity such as cytokines and tumor necrosis factor (TFN)-α inhibitors (reviewed in (7)) are included, although the mechanism underlying this phenomenon is probably different from classical DIL as discussed below.

Thus, 46 drugs currently in use have a propensity for inducing autoantibodies and occasionally a lupus-like syndrome. Table 44-1 divides these drugs into therapeutic classes and indicates their approximate risk levels based on the number of reports. Although listed separately, some drugs such as enalapril and lisinopril or simvastatin and atorvastatin are essentially the same chemical structure and could be considered a single agent. By far the highest risk drugs are procainamide and hydralazine, with approximately
20% incidence for procainamide and 5% to 8% for hydralazine during 1 year of therapy at currently used doses. The risk for developing lupus-like disease for the remainder of the drugs is much lower, considerably less than 1% of treated patients. Quinidine can be considered moderate risk, whereas sulfasalazine, chlorpromazine, penicillamine, methyldopa, carbamazepine, acebutalol, isoniazid, captopril, propylthiouracil, and minocycline are relatively low risk. The remaining 33 drugs should be considered very low risk based on the paucity of reports in the literature; for some, there is only one case report. Obviously, the perception of risk is not rigorous since it depends on dose and frequency of prescriptions as well as occasion to publish case reports and should not be equated with a fundamental, lupus-inducing propensity. New drugs are suspect as case reports accumulate; for example, amiodarone has been added to the list of drugs with lupus-inducing propensity because of three case reports over the past few years (8 ,9 ,10). Four patients have recently been described with antihistone antibodies, arthritis, and constitutional symptoms that appear to be a result of ticlopidine (11). Some drugs listed as very low risk may be falsely implicated or are currently of negligible risk, because customary treatment doses have been decreased, but most reports on drug-induced lupus are convincing because cessation of therapy usually results in prompt resolution of symptoms and eventually autoantibodies. It should be appreciated that criteria for reaching a diagnosis of drug-induced lupus-like disease are not as rigorous as those for diagnosis of SLE (see Diagnosis) (Table 44-7).

Table 44-1: Drugs Reported to Induce Lupus-Like Disease and Associated Autoantibodies

Agent*	Risk**
Antiarrhythmics	
Procainamide (Pronestyl)	High
Quinidine (Quinaglute)	Moderate
Disopyramide (Norpace)	Very low
Propafenone (Rythmol)	Very low
Amiodarone (Cordarone)	Very low
Antihypertensives	
Hydralazine (Apresoline)	High
Methyldopa (Aldomet)	Low
Captopril (Capoten)	Low
Acebutolol (Sectral)	Low
Enalapril (Vasotec)	Very low
Clonidine (Catapres)	Very low
Atenolol (Tenormin)	Very low
Labetalol (Normodyne)	Very low
Pindolol (Visken)	Very low
Minoxidil (Loniten)	Very low
Prazosin (Minipress)	Very low
Lisinopril (Privinivil)	Very low
Antipsychotics	
Chlorpromazine (Thorazine)	Low
Phenelzine (Nardil)	Very low
Chlorprothixene (Taractan)	Very low
Lithium carbonate (Eskalith)	Very low
Perphenazine (Trilafon)	Very low
Antibiotics	
Isoniazid (INH)	Low
Minocycline (Minocin)	Low
Nitrofurantoin (Macrodantin)	Very low
Anticonvulsants	
Carbamazepine (Tegretol)	Low
Phenytoin (Dilantin)	Very low
Trimethadione (Tridone)	Very low
Primidone (Mysoline)	Very low
Ethosuximide (Zarontin)	Very low
Antithyroidals	
Propylthiouracil (Propylthyracil)	Low
Anti-Inflammatories	
D-Penicillamine (Cuprimine)	Low
Sulfasalazine (Azulfidine)	Low
Phenylbutazone (Butazolidin)	Very low
TNF-α inhibitors† (Remicade)	Very low
Mesalamine (Asacol)	Very low
Zafirlukast (Accolate)	Very low
Diuretics	
Chlorthalidone (Hygroton)	Very low
Hydrochlorothiazide (DiuchlorH)	Very low
Antihyperlipidemics	
Lovastatin (Mevacor)	Very low
Simvastatin (Zocar)	Very low
Atorvastatin (Lipitor)	Very low
Miscellaneous	
Aminoglutethimide (Cytadren)	Very low
Interferon-α (Wellferon) -ß-γ	Very low
Timolol eye drops (Timoptic)	Very low
Ticlopidine (Ticlid)	Very low

*Commonly used brand name is enclosed in parentheses.
**Risk refers to likelihood for lupus-like disease, not autoantibody induction, which is usually much more common.
†Refers to a drug family possessing similar pharmacologic properties (see text)

As early as 1957, it was suggested that anticonvulsants can induce lupus-like features (12). However, manifestations of convulsive disorders may precede typical SLE by many years, and some anticonvulsants are associated with only renal or cutaneous disease (13). It is also difficult to identify the drug that may be responsible for DIL or DIA reactions, because many of these patients are using more than one drug including an additional anticonvulsant

medication. Dubois and Wallace (13) have doubted many of the reports suggesting a causative relationship between anticonvulsants and DIL, and some of the anticonvulsants in Table 44-1 may be unfairly implicated. However, DIL associated with the use of phenytoin (diphenylhydantoin) and carbamezepine is well documented.

As with anticonvulsant therapy, patients who develop DIL or DIA associated with antituberculous drugs are on more than one medication. Triple therapy with isoniazid (INH), paraaminosalicylic acid (PAS), and streptomycin was once standard practice. The best evidence, however, points to isoniazid as the drug most likely to cause DIA or DIL (14). The major manifestation of autoimmunity in patients on INH appears to be the development of low-titer antinuclear antibodies (ANA), and clinically diagnosed DIL is rare (13). Interestingly, antihistone antibodies in these patients are predominantly IgA, suggestive of the involvement of the mucosal immune system in INH-induced autoimmunity (15). Some reports have suggested that the incidence of SLE is increased after taking oral contraceptives, and that remissions follow cessation of their use (16 ,17). These findings could not be substantiated (13 ,18 ,19). Gold therapeutics, such as disodium aurothiomalate frequently appear on lists of drugs associated with SLE induction or exacerbation. However, although late-onset toxic reactions to gold requiring discontinuation of therapy occur in up to one third of treated patients, the vast majority of episodes occur during the first few months of therapy and are limited to skin reactions or buccal irritation; rash occurs in about one half the toxic gold reactions, and it is of a generalized or upper body distribution (20). Approximately 1% of treated patients develop leukopenia, thrombocytopenia, or proteinuria (20). These abnormalities are generally considered immune-mediated (21), but no report of gold-induced lupus has appeared despite over six decades of treatment experience. Gold toxicity does not appear to behave as a classical delayed-type hypersensitivity reaction in that only one of 30 patients with gold reactions had rapid recurrence of skin symptoms upon re-challenge with gold therapy (20).

Table 44-2: Prospective Studies of Drug-Induced Lupus

Drug	Approx Dose (gram/day)	Average Duration (yr)	ANA Incidence	Drug-Induced Lupus Incidence	Reference
Procainamide	2–4	1	75%	15%–20%	(22,23,24,25,26,27)
Hydralazine	0.1–0.3	3	15%–45%	5%–10%	(28,29,30,31,32,33)
Isoniazid	0.35	0.6	22%	<1/102*	(14)
Methyldopa	1–2	2	19%	<1/53*	(34)
Levodopa	1.5–8.0	1	11%	<1/80*	(35)
Estrogen/Progest	0.05/1**	1.3	<1/80*	<1/80*	(18)

*No patients developed symptoms; the denominator is the number of patients in the prospective study.

**mg/day.

A broad variety of therapeutic purposes are encompassed by lupus-inducing drugs including control of convulsion disorders, psychoses, hyperthyroidism, hypertension, fungal and bacterial infections, heart arrhythmias, edema, and even anti-inflammatory agents. Consequently, the structures of these drugs show wide disparity and this is reflected in their diverse biochemical action. Although some of these drugs are aromatic amines (procainamide, practolol, and sulfapyridine, a metabolite of sulfasalazine) or aromatic hydrazines (hydralazine, INH), there is no common denominator of a pharmacologic, therapeutic, or chemical nature that links the drugs with capacity to induce lupus-like disease. Nevertheless, the remarkable similarity in clinical features and laboratory findings in lupus induced by most of the drugs other than the biologics strongly suggests that the same mechanism underlies the process regardless of the inciting agent. How this process may be related to drug chemistry is discussed later (see Oxidative Drug Metabolism).

Prospective Studies

Relatively few prospective studies have been undertaken to establish the true incidences of induction of lupus and ANA by drugs (Table 44-2). Because clinicians' choice of drugs and their doses depend in part on the country in which they practice, there is considerable geographic variability on the incidence of DIL. Even within the United Kingdom the incidence of hydralazine-induced lupus was reported to be 6.7% after 3 years of treatment (32) and 4.3% after 13 years (36). Women treated with a daily dose of 200 mg hydralazine showed a 3-year incidence of DIL of 19.4% (32). Most patients develop symptoms between 6 months and 2 years treatment, but it is not uncommon for a patient to require more than 3 years of treatment with a total intake of more than 1 kg hydralazine before symptoms become manifest (33). With procainamide, the typical patient (i.e., the arithmetic median (37)) develops symptoms after 10 months of treatment. However, variations in therapeutic response to control ventricular arrhythmias, as

well as differences in drug clearance and metabolism (see Acetylator Phenotype), result in dose requirements that vary from 0.25 to 6 g procainamide/day. As a result, approximately 25% of patients do not develop symptoms until more than 2 years and some as long as 6 years of continuous treatment with procainamide (22 ,23 ,38 ,39). Discrepancies in the literature on the incidence of procainamide-induced lupus (23 ,24 ,25) and especially hydralazine-induced lupus (32 ,33 ,36) appear to be related to the use of lower doses of these drugs in recent years just to minimize the chances of lupus-like disease. Prospective studies of INH, α-methyldopa, L-dopa, and oral contraceptives failed to reveal a single case of lupus-like illness during the observation period. Thus, the incidence of lupus induced by these latter drugs must be less than 1% but is probably considerably lower.

Autoantibody induction is relatively common with approximately one fifth of patients treated with INH and methyldopa and one tenth of patients treated with L-dopa developing ANA during 6 months to 2 years of treatment. Studies of patients receiving procainamide therapy have shown that 75% of patients develop ANA within 1 year of treatment (25 ,26) and almost 100% develop ANA after 2 years (24 ,40). Most of these patients remain asymptomatic. The incidence of ANA positivity in patients who remain asymptomatic during approximately 3 years of treatment with hydralazine has been reported as low as 15% (31) to as high as 44% (28). Although formal prospective studies have not been performed, several other medications shown in Table 44-1 also have a high propensity for inducing ANA, anti-denatured DNA, and/or anticardiolipin antibodies, especially chlorpromazine in which prevalences of 15% to 40% have been reported (41 ,42 ,43) and acebutalol with reported ANA prevalences from 15% to 89% (44 ,45 ,46 ,47 ,48 ,49). It should be appreciated that the fine specificity and predominant isotype of the ANA in asymptomatic patients is generally not the same as in patients with symptomatic DIL (see anti-[(H2A-H2B)-DNA] Antibodies), and there is no evidence that patients who convert to ANA positivity are more likely to develop symptomatic disease.

Table 44-3: Reappearance of Lupus-Like Symptoms after Rechallenge with the Lupus-Inducing Drug

	First Drug-Induced Lupus Episode			Second Drug-Induced Lupus Episode		
Drug	Dose/Day	Time for Symptoms Manifestation	Washout Period	Dose/Day	Time for Symptoms Manifestation	Reference
Procainamide	4–5 g	20 months	8 days	2 g	36 hours	(50)
Procainamide	1 g	25 months	3 months	1 g	“promptly”	(51)
Hydralazine	0.25 g	12 months	few days	not stated	“immediately”	(3)
Hydralazine	0.5 g	10 months	6 weeks	0.15 g	1–2 days	(52)
Hydralazine	0.4 g	14 months	2–3 weeks	0.6 g	1–2 days	(53)
Isoniazid	0.3 g	14 months	2 weeks	0.3 g	1 day	(54)
Penicillamine	2 g	27 months	18 months	0.5 g	never during 12 mo	(55)
Chlorpromazine	0.4 g	13 months	6 weeks	0.2 g	1–2 days	(56)
Quinidine	0.5 g	3 weeks	1 week	0.5 g	4 days	(57)
Minocycline*	N.R.	22 months	5 weeks	N.R.	5 days	(144)

*Values are the average of 6 patients
N.R. = not reported.

Rechallenge Studies

Between 1954 and 1973, reports appeared on the rapid re-occurrence of symptoms of DIL upon re-introduction of hydralazine (3 ,29 ,33 ,52 ,53), procainamide (50 ,51), INH (54), penicillamine (55), and chlorpromazine (56). These studies contributed to the notion that DIL behaves like a hypersensitivity reaction or that DIL occurs in patients predisposed to this side effect. However, examination of these reports reveals that in most cases, re-introduction of the implicated drug occurred just a few weeks after therapy was discontinued because of DIL (Table 44-3).

Typically, these patients displayed symptom recurrence within 1 to 2 days after resuming therapy. It is now clear that although subjective symptoms of DIL may resolve in a few weeks, serological abnormalities, especially antihistone antibodies, persist for much longer. Thus, immune abnormalities in most of these patients probably had not normalized when rechallenged with the drug, suggesting that a combination of autoantibody and another, unknown factor dependent on the presence of the drug is required for the pathology of DIL. In perhaps the most thorough study

of this phenomenon in 11 patients with hydralazine-induced lupus after a “long” (although unstated) washout period, Perry (33) reported that three patients had symptom recurrence within 1 day, two within 14 days, two within 2 months, one after 7 months, and three never developed symptom recurrence during the second treatment period of 1 to 5 years. It remains debatable whether variability in symptom recurrence reflects differences in putative predisposing factors for development of DIL or differences in time for the hyperimmune state to normalize prior to re-introduction of the drug.

Drug-induced lupus does not behave like a classical drug hypersensitivity reaction in that patients with DIL generally lack drug-specific T cells or antibodies, and the target autoantigens are not directly altered by the inducing drug. Also, the time course for development of drug-induced lupus tends to be much slower than that of classical drug allergies, which are usually immediate (58), and re-introduction of a lupus-inducing drug is not generally associated with memory of prior exposure if systemic autoimmunity had been allowed to normalize. Finally, although drug hypersensitivity can be triggered by relatively low or transient doses of the inciting agent at least after sensitization, the probability of expressing drug-induced autoantibodies and symptomatic lupus increases as the dose and duration of exposure increases (24). This feature suggests a phenomenon that depends on at least one event of low probability, so that drug-induced lupus is more likely as time and dose increase. Circumstantial evidence strongly suggests that this event is metabolic transformation of the drug to a reactive product.

Other Late-Onset Toxic Drug Reactions

Drugs That May Exacerbate SLE

The report of Hoffman in 1945 describing a 19-year-old army recruit who developed cutaneous, hematologic, and renal disease with features of SLE after treatment with topical and oral sulfadiazine (59) is often cited as the first description of DIL. In actuality this patient had a hypersensitivity-like reaction to sulfadiazine coincident with exacerbation of preclinical SLE or with the onset of SLE. This and subsequent, similar reports (although only one involving an oral sulfa-drug (60)) helped to entrench the view that many cases of idiopathic SLE are “unmasked” during drug therapy in patients with a lupus diathesis (61). This idea is difficult to discount or prove. Various drugs have been noted to have a temporal relationship with the exacerbation of SLE or with the onset of chronic SLE prior to diagnosis (13). In the latter cases SLE remains after withdrawal of the implicated agent. In the most recent case-controlled study of this phenomenon 12% of SLE patients with drug allergies were considered to display disease exacerbation, predominately lupus rash (62 ,63). Because SLE patients are significantly more prone to develop drug allergies especially to antibiotics such as sulfonamides, penicillin/cephalosporin, and erythromycin (62), these agents should be avoided in patients with SLE (64). Two SLE patients who developed lupus flares after ciprofloxacin treatment required hospitalization (65), and severe clinical relapses temporally associated with therapy with sulfonamides have been reported in the older literature (66). Drugs that appear to exacerbate SLE can be classified as antibiotics, anticonvulsants, hormones, nonsteroidal anti-inflammatory drugs (NSAIDs), and dermatologic agents. Sulfonamides (67), tetracyclines (68), griseofulvin, (69 ,70 ,71), piroxicam (72), and benoxaprofen (73) are reported to be photosensitizers of varying frequency. Rash or dermatitis related to drugs typically has a history of rapid onset and behaves as a drug hypersensitivity-type reaction that may be triggered by exposure to ultraviolet light (74). The majority of adverse drug reactions in previously diagnosed SLE patients are of this category (62 ,63). Another, possibly related category of patients are those with acute or subacute cutaneous lupus erythematosus related to photo-active medications; these patients may have systemic disease and can fulfill criteria for a diagnosis of SLE (75). Table 44-1 includes some of these drugs also associated with typical DIL. Drug-induced aseptic meningitis in SLE patients as a result of therapy with ibuprofen (76) and other NSAIDs (e.g., sulindac (77), tolmetin (78), diclofenac (79)) is an important consideration for the physician involved in the care of SLE patients who present with signs of meningeal irritation. Hypersensitivity reactions that have been interpreted as initiating or aggravating factors in SLE are associated with hydralazine (80), sulfonamides (59 ,60 ,67 ,81 ,82), penicillin (62 ,67), paraaminosalacylic acid (83), hydrochlorothiazide (84), cimetidine (85), phenylbutazone, (86 ,87), mesantoin (12), and various NSAIDs (13 ,88).

Unknown or suspected environmental chemicals are also occasionally implicated as causal agents in SLE or other distinct autoimmune diseases such as eosinophilia-myalgia syndrome associated with L-tryptophan ingestion, toxic oil syndrome associated with ingestion of aniline-adulterated cooking oil, silicosis associated with inhaled silica or asbestos dust, and autoimmunity associated with vinyl chloride exposure. These syndromes have unique features (reviewed in (89)) and should not be confused with DIL.

Whether or not an environmental or pharmaceutical agent might aggravate or unmask incipient SLE should be considered a clinical problem distinct from DIL because, by definition, symptoms of DIL resolve after discontinuation of therapy, although in severe cases full recovery may require up to 1 year. (Although this view is not in accord with the influential study of Alarcon-Segovia et al. (80) in which 60% of patients with hydralazine-induced lupus had persistence of several symptoms 0.5 to 9 years after withdrawal of hydralazine, three fourths of these patients were reported to have pre-existing rhematologic problems.) If drugs or environmental agents are truly causative in initiating

or aggravating SLE, the mechanistic basis is probably different from that of DIL because the steady-state blood levels of bonafide lupus-inducing drugs must generally be sustained for many months to years (i.e., medications two to six times daily) for development of DIL. In contrast for most cases believed to be aggravated or unmasked, exposure is of very low level or infrequent when the suspected agent is environmental or of relatively short duration when a drug is implicated. The association between drugs and the exacerbation or onset of SLE resembles the lupus flares following exposure to sunlight, exercise, or pregnancy.

Some environmental agents are suspected of causing lupus-like disease based largely on studies in experimental animals. A lupus-like syndrome was induced in monkeys by alfalfa sprouts and L-canavanine (90), and several case reports of lupus-like disease associated with the ingestion of abnormally large amounts of alfalfa seeds or tablets (91 ,92) implicate L-canavanine as capable of inducing or exacerbating lupus if excessive quantities are ingested. The other principal example in this category is a scleroderma-like autoimmunity associated with heavy metals in rats and mice (93 ,94). The major target of mercury-induced autoantibodies is the nucleolar protein fibrillarin, a specific serologic marker for a subset of patients with scleroderma (94). Although these animal models are of considerable mechanistic interest, these agents have not been definitely implicated in autoimmune disease in humans.

Autoimmunity Associated with Biologics and Other Immune-Modulating Agents

Various immune modulating agents can paradoxically induce autoimmune features. Cyclosporine A has been reported to precipitate graft-versus-host disease (GVHD) after withdrawal from patients receiving autologous bone marrow transplants (95 ,96). As discussed above, gold therapeutics have been implicated in immune-mediated disease (21), although this falls outside the usual presenting symptoms and clinical progression of SLE (Chapter 32) or DIL.

Therapeutic biologics, such as interleukin (IL)-2, interferon (IFN)-α, ß and γ, and tumor necrosis factor α (TNF-α) inhibitors have been occasionally associated with a variety of musculoskeletal and/or skin manifestations, especially serologic features suggestive of lupus-like autoimmunity. Autoimmune-like features related to INF therapy and to TNF-α blockers have been particularly well documented. De novo induction of ANA and cell-specific autoantibodies have been observed in IFN-α–treated patients with chronic myelogenous leukemia, many of whom were reported to have clinical features of autoimmune disease (97), especially thyroid and autoimmune hematologic disorders (98). A wide range of clinical abnormalities including SLE, RA, Raynaud phenomenon, and Behcet disease have been seen in these patients, which required discontinuation of IFN-α treatment (98 ,99). However, features typical of DIL were rare. A recent report on the de novo appearance of myalgia and arthalgia in a patient with multiple sclerosis treated for 2.5 years with IFN-ß (100) may echo a DIL-like process.

The bulk of data on induction of autoimmunity by biologics is related to TNF-α inhibitors because of the widespread use of these drugs to treat RA. There are currently three forms of TNF-α inhibitors: etanercept (Enbrel), which is the p75 TNF-α receptor type II fused to the Fc region of IgG1; Adalimumab, D2E7 (Humira), which is a human IgG1 anti-TNF-α monoclonal antibody, and infliximab, cA2 (Remicade), which is a chimeric (mouse/human) anti-TNF-α monoclonal IgG4 antibody. The best documented autoimmune-related side effect of these agents is induction of ANA and anti-DNA: in RA 23% to 61% of patients developed ANA compared to 6% to 32% of controls, and anti-DNA developed in 8% to 49% of patients treated with TNF-α blocking agents compared to none of the controls (101 ,102 ,103 ,104 ,105) (Table 44-4). It should be noted that, where studied, anti-DNA antibodies were predominately of the IgM isotype (102 ,105 ,106) and, less frequently IgA anti-DNA (105); IgG anti-DNA, which is specifically associated with SLE (Chapter 23), was rarely seen in significant titer. In Crohn disease in which the baseline ANA was positive in only 7% of patients, 52% of the patients became ANA+ after five injections of infliximab (107). Interestingly, although 62% and 71% of patients with spondylarthropathies (SpA) developed ANA and (IgM) anti-DNA, respectively, after 1-year treatment with inflixamab, there was no significant induction of ANA or anti-DNA in SpA patients treated with etanercept for up to 2 years (Table 44-4); ANA and (IgM) anti-DNA largely disappeared within 1 to 3 years after discontinuing therapy with inflixamab (105).

The majority of patients who were considered to have systemic autoimmunity related to TNF-α blocking agents presented only with cutaneous manifestations; this is clearly outside the typical presentation of DIL (see Diagnostic Criteria). The literature describes over the past 15 years (excluding abstracts and highly atypical presentations such as nephritis or neuritis suggestive of a demyelinating process) approximately 25 cases of lupus-like autoimmunity that were temporally related to TNF-α blockers (Table 44-4). Based on a recent survey of more than 10,000 patients in France treated with TNF-α blockers, the prevalence of DIL-like disease related to infliximab or etanercept (excluding rash-only patients) was 0.1% (108), and this is probably an overestimate. These patients usually had constitutional symptoms (fever, weight loss, fatigue), either myalgias or arthalgias, or serositis of the lung or heart; notably, 23 of 25 patients also had substantial cutaneous symptoms rarely seen in DIL. Symptoms of lupus typically occurred approximately 6 months after initiation of treatment and usually resolved within 1 to 4 months after discontinuation, an unusually long period.

In many of the cases purported to be DIL as a result of TNF-α blockers, other explanations were not excluded. These patients already had a pre-existing autoimmune or inflammatory disease, so the possibility increases that new

symptoms attributed to DIL were merely a coincidence. Flares or new symptoms of a pre-existing autoimmune disease or the coincident development of another type of autoimmune disease are not unusual in patients with a rheumatic disease. Articular symptoms attributed to DIL are obviously especially problematical in patients with RA, and the wide range of disease manifestations together with the relapsing–remitting nature of autoimmunity adds to the ambiguity. This means that there is a greater burden of proof to establish a convincing case of DIL related to anti-inflammatory biologics. In particular a long-term follow-up should be required to establish that the patient's clinical status remains free of lupus-like symptoms after discontinuing therapy with a TNF-α blocker and withholding corticosteroids; this has rarely been demonstrated. Naturally, strong consideration should be given to stopping treatment with a TNF-α blocking agent if new symptoms appear, whether or not they reflect true DIL. On the other hand, there is no evidence that RA patients who develop positive ANA or anti-DNA during treatment with a TNF-α blocker are at increased risk for the development of DIL.

Table 44-4: Prevalence of Autoantibodies and Lupus-Like Symptoms in Patients Treated with TNF-α Blocking Agents

Biologic	Patient Diagnosis*	Autoantibody Induction (% of Patients)**	Symptomatic Disease†	Reference
Etanercept	RA		4	(111)
	RA		2	(112)
	RA		3/3000	(108)
	SpAc	10%|10%	0/20	(105)
Infliximab	RA		1	(112)
	RA		2	(113)
	RA		1	(114)
	RA		9/7700	(108)
	RA	45%|33%	0/42	(103)
	RA	53%|14% vs. 32%|0%	1/156	(102)
	RA	23–61|%8–16% vs. 6–8%|0%		(101,104)
	Crohn's	7%|→52%| (0→5 infusions)	2/125	(107)

	RA	41%|49%	0/34	(105)

*RA, rheumatoid arthritis; SpA: spondylarthropathy
**ANA|anti-DNA treated vs. ANA|anti-DNA controls
†Number of patients with lupus-like symptoms/total number of treated patients in the study. Patients displaying only cutaneous manifestations were not included.

It is currently unknown how a cytokine inhibitor might induce autoimmunity, but extensive studies in murine lupus have demonstrated both beneficial and damaging effects of manipulating the cytokine milieu (109). SLE is associated with dysregulation of cellular immunity, and some studies have shown that TNF-α protects against lupus nephritis as autoimmunity emerges in NZB/NZW mice (110). It is possible that therapeutic manipulation of cytokine levels in individuals predisposed to autoimmunity may disrupt cytokine-mediated immune homeostasis, leading to autoantibody induction and disease. However, the fact that anti-TNF-α monoclonal antibody (infliximab) but not soluble TNF-α receptor (etanercept) induces autoantibodies (105) makes any explanation on the mechanistic basis of this phenomenon highly speculative.

Regardless of the explanation, DIL related to small molecule pharmaceuticals occurs by de novo induction of autoimmunity in the setting of a formerly normal immune system and would be expected to have a mechanistically different basis.

Drug-Induced Immune Hemolytic Anemia

Long-term therapy with some drugs is associated with development of hemolytic anemia because of antibodies bound to red blood cells (RBC) in vivo (direct Coombs test positivity). In the penicillin-type, antibody to the drug binds to RBC as a result of adsorption of the drug or its metabolite to the RBC membrane. In the methyldopa-type, the drug is not required for (and does not effect) antibody binding, and anti-RBC antibodies typically have specificity for rhesus locus or other intrinsic RBC antigens. These antibodies rarely produce frank hemolytic anemia, possibly because their isotype or low avidity does not support complement fixation. Hemolytic anemia is commonly associated with the stibophen-type of drug-induced antibodies (as is quinidine and quinine) in which immune complexes

consisting of the drug or drug metabolite bind to RBC presumably via Fc or complement receptors.

The mechanism underlying the penicillin-type of anti-RBC response is frequently used as the basis for models for autoantibody elicitation in DIL (see Mechanisms). Interestingly, the autoantibodies associated with DIL behave more like the methyldopa-type of immune response in that the likelihood for autoantibody appearance is dose-dependent, but the drug is not required for antibody binding to its target antigen. In fact, many of the drugs associated with Coombs positivity of this drug-independent type (methyldopa, L-dopa, mefanamic acid (Ponstel), procainamide, chlorpromazine, and streptomycin (115)) are also known to cause DIA or DIL (Table 44-1), although there is generally no correlation between positive Coombs test and ANA or DIL. However, patients with methyldopa-induced hemolytic anemia have been reported to have positive lupus erythematosus (LE) cells and ANA (47 ,116 ,117 ,118 ,119 ,120). As with the autoantibodies associated with DIL, Coombs positivity gradually disappears after cessation of therapy, and individuals with a history of methyldopa-induced anti-RBC do not display significantly increased propensity for induction of anti-RBC upon reinstitution of therapy with the same drug (121). The mechanism for induction of this type of anti-RBC is unknown. However, despite the drug independence of anti-RBC binding, a drug-altered RBC model is commonly invoked (115) and incorrectly applied to the origin of autoantibodies associated with DIA and DIL.

Epidemiology

The incidence of DIL had been estimated as 15,000 to 20,000 new cases annually in the United States (122). However, most of these cases were a result of procainamide, a drug that has now been largely replaced by other antiarrhythmics. Therefore, the incidence of DIL is currently probably considerably lower but is unknown. The incidence of DIL in other countries is also unknown, but has been estimated to be 10% that of idiopathic SLE (13). Lee et al. (123) reviewed the medical histories of 285 consecutive SLE case records and found that drugs were a possible causative factor in 12%. Fries and Holman identified 12 DIL cases in a population of 198 lupus patients (124). In a more recent retrospective study of 30 patients with elevated antimyeloperoxidase antibodies and vasculitis usually involving the kidney, lungs, and/or skin, 60% were exposed to a lupus-inducing drug for 1 to 10 years, usually hydralazine or propylthiouracil, suggesting that the majority of patients with high-titer antimyeloperoxidase antibodies may be drug-induced (125). The frequency of DIL may be underestimated because most cases are mild, and only a small proportion are correctly diagnosed or seen by a rheumatologist. Because drugs such as INH are more frequently administered in certain countries, studies in such countries could provide a more thorough epidemiologic picture of DIL.

The age of patients developing DIL reflects the age of the population undergoing treatment with the implicated drug. Because procainamide and hydralazine, the most common lupus-inducing drugs, tend to be administered to the older population displaying cardiac arrythmias or hypertension, respectively, DIL usually occurs in people of age 50 or older.

Two epidemiologic features distinguish DIL from SLE. First, the high female-to-male predominance seen in SLE (9:1 to 7:1) is not seen in DIL largely because the majority of patients treated with the major lupus-inducing drugs are men. Nevertheless, procainamide-(25 ,126) and hydralazine-induced lupus (32 ,36 ,127 ,128) appear to be disproportionately more common in females. In the study of Totoritis et al. (25), the female-to-male ratio of procainamide-treated patients who developed lupus-like symptoms was 0.52:1 compared to a ratio of 0.19:1 for those who remained asymptomatic. A similar twofold to fourfold predominance of women over men for development of hydralazine-induced lupus has been reported (32 ,36 ,128). In the study of Cameron and Ramsey (32), the overall incidence of hydralazine-induced lupus during a 4-year observation period was 11.6% in women and 2.8% in men. In this same study, women treated with a daily dose of 200 mg hydralazine had a 19.4% incidence of hydralazine-induced lupus over a 3-year period. This is in contrast to the development of ANA in patients treated with hydralazine over a 3-year period, during which no gender differences were noted (127). Secondly, unlike SLE, the frequency of hydralazine-induced lupus in blacks was reported to be fourfold (29) to sixfold (33) lower than in whites. African Americans seem to be protected from lupus induced by procainamide as well (6).

Clinical and Laboratory Features

Table 44-5 shows the clinical and laboratory features of procainamide- and hydralazine-induced lupus compared with SLE. Musculoskeletal complaints are commonly observed, with arthralgia heading the list for both drugs. Arthritis is a less common feature with lupus induced by procainamide (20%) than by hydralazine (50% to 100%), whereas serositis (pleuritis and/or pericarditis) and/or myalgia are more common presenting features of procainamide-induced lupus. By contrast, hydralazine-induced lupus is associated with a higher frequency of skin rashes. However, in any one patient, lupus induced by procainamide, hydralazine, or other drugs can not be distinguished by clinical features. The onset of symptoms can be slow or acute, although an interval of 1 to 2 months typically passes before the diagnosis is made (23 ,24 ,25 ,26 ,29 ,126 ,127).

Because arthralgia is such a common feature of patients in the age group at risk, the presence of other features, such as pleuritis, pleural effusion, fever, splenomegaly, skin rash,

pericarditis, and certain autoantibodies should alert the clinician to consider the diagnosis of DIL. Approximately 50% of patients have constitutional symptoms of fever, weight loss, and fatigue. The symptoms of DIL usually resolve within days to weeks after discontinuing the offending drug and, therefore, this maneuver provides a key (although retrospective) diagnostic tool.

Table 44-5: Prevalence of Clinical and Laboratory Abnormalities in Drug-Induced Lupus and SLE

Feature	Hydralazine-Induced Lupus*	Procainamide-Induced Lupus**	Systemic Lupus Erythematosus†
Symptom			
Arthralgia	80%	85%	80%
Arthritis	50%–100%	20%	80%
Pleuritis, pleural effusion	<5%	50%	44%
Fever, weight loss	40%–50%	45%	48%
Myalgia	<5%	35%	60%
Hepatosplenomegaly	15%	25%	5%–10%
Pericarditis	<5%	15%	20%
Rash	25%	<5%	71%
Glomerulonephritis	5%–10%	<5%	42%
CNS disease	<5%	<5%	32%
Sign			
ANA	>95%	>95%	97%

Each prevalence represents a consensus value ± 5 percentage points. Abnormalities occurring in fewer than 5% of patients are not listed.

In addition to classical DIL with associated antihistone antibodies and polyarthritis (136 ,139 ,140), Cohen, et al. (57) reported that quinidine was associated with a mild drug reaction characterized only by polyarthalgias within 7 days to 3 months after initiation of therapy. These patients were ANA and antihistone antibody negative, and showed prompt recurrence of symptoms upon rechallenge with quinidine.

Lupus-like disease associated with minocycline is also atypical. Patients frequently present with symmetrical polyarthritis and may have evidence of hepatitis (elevated liver transaminases) and pneumonitis (as a result of pulmonary lymphocytic infiltrates) (141 ,142 ,143 ,144), which are assumed to be autoimmune in nature. These patients may not have ANA but frequently have perinuclear antineutrophil cytoplasmic antibodies (pANCA) because of antimyeloperoxidase (145). Nevertheless, as with classical DIL, symptoms and signs resolve after discontinuation of minocyline. Autoimmune

hepatitis in addition to systemic autoimmunity suggestive of DIL has also been associated with atorvastatin (146) and with mesalamine (5-aminosalicylic acid) (147).

The frequency of serologic abnormalities in lupus induced by procainamide and hydralazine are essentially identical (Table 44-5). The immune response in this setting is characteristic and restricted. The most commonly observed abnormality is a positive ANA, which is largely a result of histone-reactive antibodies (148 ,149). These antibodies are presumably responsible for the positive LE-cells reported in the synovial fluid of two patients with procainamide-induced lupus (150), although recent studies could not produce LE-cells in the indirect LE-cell test using sera from patients with procainamide-induced lupus but only with DIL and SLE sera containing anti-H1 antibodies (151). Although generally of low titer, antibodies to denatured (but not native) DNA are also common in DIL. Less common laboratory features include rheumatoid factor (procainamide) (152), circulating immune complexes (153 ,154 ,155) and antineutrophil cytoplasmic antibodies (hydralazine (156 ,157), propylthiouracil (125 ,158) and minocycline (144 ,145), positive Coombs test (methyldopa (34), chlorpromazine (159), and procainamide (152)), complement activation (procainamide) (37 ,160 ,161), hypocomplementemia (quinidine) (57), and a positive lupus band test (LBT) (162). Phospholipid and cardiolipin antibodies, circulating anticoagulant activity, and biologic false-positive serologic test for syphilis (STS) results are discussed below. It should be appreciated that many of these laboratory abnormalities are not linked to symptomatic DIL. Thus, appearance of antibodies to RBC, denatured DNA, and total histones (but not a histone-DNA complex described below) is independent of lupus-like symptoms. Nevertheless, like the clinical features, these autoantibodies are truly drug-induced, and they gradually subside after drug therapy is discontinued.

Other laboratory features noted in a minority of patients include a mild anemia, leukopenia, and thrombocytopenia (37 ,122 ,152 ,163 ,164 ,165), a hypergammaglobulinemia that is not as frequent as in SLE (37 ,163 ,164 ,165 ,166 ,167 ,168 ,169), and an elevated erythrocyte sedimentation rate (ESR) (139 ,153 ,170) which commonly reverts toward normal as symptoms resolve (57 ,139 ,164). Pancytopenia has been reported in association with procainamide therapy (171 ,172), but it is unlikely that these patients had DIL. Agranulocytosis or severe neutropenia develops in about 0.6% of procainamide-treated patients (173), but this condition is serologically and clinically distinct from DIL (174). Hydralazine-induced lupus has been reported to be associated with acute neutrophilic dermatosis (Sweet syndrome) (175 ,176).

Although the spectrum of clinical abnormalities in DIL are indistinguishable from those observed in SLE, the severity of disease is usually milder in DIL. The number of symptoms and their intensities tend to increase with duration of therapy, but patients who have inadvertently remained on procainamide for up to 2 years after onset of polyarthralgias did not progress to fulminant status (5). Interestingly, patients with more severe clinical problems and higher autoantibody levels tended to be treated with procainamide for shorter duration than those with milder DIL (27), suggesting the existence of clinical subsets differing in susceptibility to DIL. Patients with established SLE have been treated with procainamide for long duration without exacerbation of symptoms (124). These observations are contrary to the expectations of the hypothesis that drugs unmask a predisposition to SLE (61), and help to establish the view that DIL is a fundamentally different disease from SLE.

Histone Autoantibodies

Histone-reactive antibodies were discovered to be commonly present in patients with procainamide-induced lupus based on binding in a histone-reconstituted ANA assay (148). Although patients with hydralazine-induced lupus (177) and asymptomatic drug-treated patients (178 ,179) also have ANA, they tend to be negative for antihistone antibodies by the histone reconstituted ANA assay. However, with the advent of solid phase immunoassays using pure histones, it was found that most patients with DIL and asymptomatic patients with ANA (i.e., DIA patients) induced by a variety of drugs including procainamide, hydralazine, chlorpromazine, acebutolol, and isoniazid also have antihistone antibodies (15 ,44 ,136 ,177 ,180). Formal demonstration that histone-reactive antibodies constituted the bulk of the ANA was provided by chromatin-absorption studies (149).

Histones consist of five dissimilar proteins, and the fine specificity of antihistone antibodies in SLE, DIL, and DIA has been examined in detail (see Chapter 24). Considerable disagreement on the characteristic antihistone antibody profile in DIL accumulated (detailed in (181) and in (182)). However, these reports generally indicated that antihistone antibodies react with only limited regions of the protein, especially their N- and/or C-terminal tails, possibly reflecting the solvent accessibility of these regions within the nucleosome. More importantly, the diagnostic value of antihistone antibodies is limited. A positive test for antihistone antibodies may help to confirm a suspicion of DIL, but the conventional assay for antihistone antibodies can not distinguish patients with DIL from patients who develop ANA yet remain asymptomatic (i.e., DIA). In fact recent studies suggest that Ig interaction with solid phase histone occurs by binding via the Fc region of immunoglobulin rather than through the classical, antigen-binding site of specific antibody (183 ,184).

Anti-[(H2A-H2B)-DNA] Antibodies

Histones exist in the cell not as individual proteins but as a huge macromolecular complex termed chromatin which is formed by highly organized histone-histone and histone-DNA interactions. The repeating unit of chromatin structure is the core particle of the nucleosome, which consists of a $(H3\text{-}H4\text{-}H2A\text{-}H2B)_2$ histone octamer wrapped with approximately two turns of DNA (Fig. 44-1).

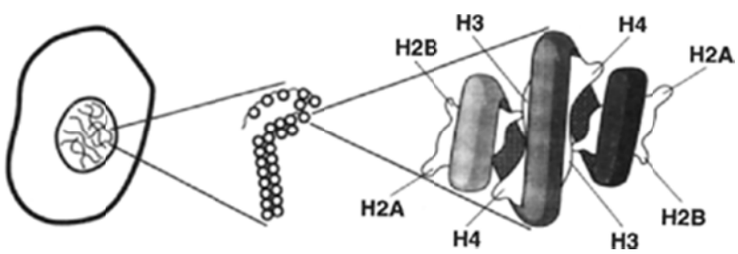

Figure 44-1. Organization of histones in chromatin. The core particle of the nucleosome (right) consists of 8 histone molecules arranged in a tripartite structure (two H2A-H2B dimers and one $(H3\text{-}H4)_2$ tetramer) around which is wrapped 146 base-pairs of DNA. For clarity, the core particle is depicted in an artificially loosened form; the actual structure is compact, and the DNA largely covers everything but the H2A-H2B side faces (190,191). A continuous strand of DNA connects each core particle to its adjacent core particles, forming the “beads-on-a-string” polynucleosomes fiber (center). After higher ordered supercoiling mediated in part by histone H1, the chromatin fiber becomes visible in the light microscope as a mitotic chromosome (left).

The pronounced antigenicity of the H2A-H2B complex, a subunit of the nucleosome, was first detected in SLE patients (192) and subsequently found to dominate the serology of patients with procainamide-induced lupus (6 ,126 ,193 ,194 ,195).These antibodies also react with the components H2A and H2B (126 ,196), but the magnitude of antibody binding to the H2A-H2B complex is often fivefold greater than to the individual histones. A systematic study of the antigenicity of nucleosome subunits revealed that the (H2A-H2B)-DNA complex contained the complete epitope for these antibodies and could largely account for the capacity of procainamide-induced lupus sera to bind to nucleosomes, chromatin, and nuclei (136).

IgG anti-[(H2A-H2B)-DNA] antibodies occur in over 90% of patients who develop procainamide-induced lupus (136 ,185) and have been detected in individual patients with lupus induced by penicillamine (185 ,186), INH (185 ,187), acebutalol (185), methlydopa (120), sulfasalazine (189), opthalmic timolol (189), and lisinopril (197). However, only approximately 50% of patients with quinidine- and 35% with hydralazine-induced lupus have detectable anti- [(H2A-H2B)-DNA] (Table 44-6). IgG anti-[(H2A-H2B)-DNA] has a sensitivity for procainamide-induced lupus of 84% at the time of diagnosis and a prognostic value of 70% 1 year before recognition of symptoms (27).

Table 44-6: Prevalence of IgG Anti-[(H2A-H2B)-DNA] in Lupus Induced by Various Drugs

Lupus-Inducing Drug	Patients with Elevated Anti-[(H2A-H2B)-DNA]	Reference
Procainamide	23/24	(136,185)
Quinidine	9/17	(136,185)
Hydralazine	6/14	(136)
Penicillamine	1/1	(185,186)
Isoniazid	1/1	(185,187)
Acebutalol	1/1	(185)
Methyldopa	2/2	(120,185)
Timolol	1/1	(188)
Sulfasalazine	2/2	(189)
Lisinopril	1/1	(197)

The use of an IgG-specific detecting reagent in testing for anti-[(H2A-H2B)-DNA] is important because procainamide-treated patients who remain asymptomatic commonly produce IgM and/or IgA antibodies of this specificity (27 ,196). There is no evidence that patients with these Ig classes of drug-induced antibodies (and who are ANA positive) have an increased risk for converting to IgG anti-[(H2A-H2B)-DNA] and symptomatic drug-induced lupus. Additionally, asymptomatic, procainamide-treated patients who develop DIA commonly have low levels of IgG antibodies to the DNA-free H2A-H2B complex (126 ,195 ,196 ,198), because of antibodies to the individual histones H2A and/or H2B. Therefore, a sensitive test for DIL that will exclude DIA patients requires employing the complete (H2A-H2B)-DNA complex.

Denatured DNA Autoantibodies

Denatured (single-stranded) DNA (dDNA) autoantibodies are found in up to 50% of DIL sera (31 ,129 ,130 ,163 ,168 ,185 ,193 ,196 ,199 ,200). These autoantibodies probably have multiple reactivities, which have also been identified as binding to the nucleoside guanosine (126 ,201), polyriboadenylic acid (31 ,196), the phospholipid cardiolipin (202), and unusual conformations of DNA, such as Z-DNA (196 ,203). Even antibodies directed to lymphocytes described in hydralazine- (204) and procainamide-induced

lupus (205 ,206) may be related to the dDNA (or possibly chromatin) reactivity, because lymphocyte membranes can bind DNA (207). Anti-dDNA antibodies bearing the 16/6 and 32/15 idiotypes have been reported in one third of procainamide-induced lupus patients (208), idiotypes which are also commonly expressed in idiopathic SLE. However, the clinical significance of anti-dDNA is doubtful, because these antibodies are commonly seen in asymptomatic (normal) people and in those with a wide variety of rheumatic and inflammatory conditions (209).

Antibodies to Drugs

Antibodies to the offending drugs have been reported in lupus induced by procainamide (210) and hydralazine (130). Other studies have been unable to detect drug-specific antibodies in patients treated with various lupus-inducing drugs (149 ,167 ,199 ,211). In a prospective study of patients treated with hydralazine, only 1 of 27 sera bound to the drug (31). The significance of antibodies to drugs is unclear, because they have been reported in varying amounts in asymptomatic and symptomatic patients. Additionally, it is unlikely that drug-binding antibodies represent cross reactions with anti-dDNA or antichromatin autoantibodies (211 ,212 ,213).

Phospholipid Antibodies

The observation that DIA patients can have antiphospholipid (cardiolipin) antibodies, circulating anticoagulants, or a biologic false-positive STS activity is noteworthy because much attention has focused on the clinical and pathogenic significance of these autoantibodies. The presence of the lupus anticoagulant (LAC) or of cardiolipin antibodies has been described in patients on hydralazine (214 ,215), procainamide, (216 ,217 ,218 ,219 ,220), chlorpromazine (43 ,159 ,221 ,222 ,223 ,224 ,225 ,226), quinidine, and quinine (226). In one study, up to 75% of patients treated with chlorpromazine for up to 2.5 years developed a lupus anticoagulant (159). Canoso and deOliveira (43) reported that 54 of 93 chlorpromazine-treated psychiatric patients had IgM LAC activity. Of the 54 LAC-positive patients, 31 also had IgM cardiolipin antibodies, 4 also had IgG cardiolipin antibodies, and 5 had cardiolipin antibodies alone. During a mean follow-up period of 5 years, thrombotic events occurred in three patients (one with LAC, two with IgM cardiolipin antibodies). In a Canadian study, Lillicrap et al. (227) evaluated 97 psychotic patients treated with chlorpromazine, fluphenazine, or promazine. Of these, 25% developed a positive ANA, 4% had elevated titers of antibodies to cardiolipin and phosphatidylserine, and 5% had elevated titers of antibodies to phosphatidylinositol. None of the patients developed features of SLE or evidence of thrombotic events. Drug-induced LAC in a group of 13 patients had a narrower range of specificities than LAC in SLE or in primary antiphopholipid syndrome, rarely reacting with phosphatidylserine or phosphatidylcholine (226). None of these patients had thrombosis, indicating that there is no increased risk of thrombotic events associated with chlorpromazine- or quinidine-induced LAC. The antibody isotype in drug-induced LAC is usually IgM (43 ,159 ,221) as was the associated ANAs (41). It is likely that these observations also apply to procainamide and hydralazine, because thrombosis appears to be a rare clinical event in lupus induced by these drugs as well (228). The clinician should be cautious, however, because recurrent thrombotic events have been reported in phenothiazine- (229) and occasional procainamide-induced (216 ,220) lupus patients. It has not been determined whether the antiphopholipid antibodies associated with DIL interact with β_2-glycoprotein I, a correlative feature of SLE patients with a history of thrombembolisms (230).

The origin of lupus anticoagulants and cardiolipin antibodies in patients on various drugs, especially those in the phenothiazine group, is unknown. The pharmacologic action of drugs such as procainamide and chlorpromazine (Table 44-2) depends in part on their membranotropic nature, intercalation into plasma membranes, and interaction with phospholipids or lipoproteins (225 ,231 ,232). Based on these features, it has been postulated that the binding of the drug lipid moieties exposes cryptic epitopes or creates neoantigens that then serve as the stimulus for the production of antiphospholipid antibodies (225). However, since antiphospholipid antibodies are also common in SLE patients (Chapter 27), induction of lupus anticoagulants in DIL probably does not involve a drug-altered antigen mechanism.

Other Autoantibodies

Rheumatoid factor (RF) has been reported in procainamide- induced lupus patients (163). Prospective studies suggest that RF is not drug-induced, and might merely reflect the increased prevalence of this autoantibody in the population treated with the drug (155 ,233). One study has reported antibodies in DIL sera directed against poly(adenosine diphosphate-ribose) (234). Nassberger et al. (156 ,157 ,235) first demonstrated neutrophil myeloperoxidase (MPO) and elastase antibodies in hydralazine-induced lupus patients, and this has been confirmed (236); these specificities as well as antiproteinase-3 antibodies were also reported in patients treated with propylthiouracil (125 ,158), and anti-MPO antibodies were observed in patients with lupus induced by sulfasalazine (237) and minocycline (145). These observations are of considerable interest, because these antibodies contribute to the p- and c-ANCA neutrophil staining patterns that is associated with vasculitis of the capillaries and Wegener granulomatosis, respectively (238). The occurrence of glomerulonephritis in some patients with hydralazine-induced lupus (Table 44-5) may be related to anti-MPO antibodies (125 ,235 ,236). Although anti-MPO antibodies occur in more than 50% of patients

with hydralazine-induced lupus, they are not found in lupus induced by procainamide (unpublished observations), consistent with the absence of kidney disease in procainamide- induced lupus. Antinuclear ribonucleoprotein (RNP) antibodies were reported after short-term (prophylactic) procainamide treatment (38). This observation has not been confirmed, and anti-RNP antibodies have not been observed in DIL (148 ,149 ,167 ,199). Slightly elevated antinative DNA antibodies were observed in four patients with mesalamine- induced lupus (147). Cold-reactive lymphocytotoxic antibodies (LCTA) have been reported in procainamide-induced lupus (205 ,206), but these reactivities were also detected in procainamide-treated patients at initiation of therapy and in asymptomatic procainamide-treated patients (31 ,149 ,155), and are unrelated to DIL. LCTA were also reported in four of seven patients with hydralazine-induced lupus, but also in 13 of 40 asymptomatic hydralazine-treated patients (28 ,204). Antibodies to high mobility group (HMG) proteins, especially HMG-14 and -17, were detected in approximately half the patients treated with procainamide, hydralazine, and quinidine, whether or not they expressed symptomatic DIL (239). This finding is of interest, because the HMG proteins bind to the core particle of the nucleosome especially on transcriptionally active chromatin, consistent with the central role of chromatin in the autoantibody response in drug-treated patients.

Nature of the Immune Response in Drug-Induced Lupus

Humoral Response

Numerous features of DIL point to the activation of the humoral immune system as its principal overt abnormality. As discussed above, the autoimmune response in DIL is largely restricted to antibodies reactive with ((H2A-H2B)-DNA) in native chromatin and to denatured histone and DNA components of nonnative chromatin. IgM, IgA, and IgG anti-[(H2A-H2B)-DNA] antibodies often appear to arise simultaneously during procainamide treatment, although patients who remain asymptomatic fail to develop IgG of these specificities (27). In a normal humoral immune response, recognition of a foreign antigen results in rapid clonal expansion of B cells, isotype switching to IgG, and somatic mutation to higher affinity antibodies. With drug-induced autoantibodies there appears to be a slow development of autoantibodies of the IgG, IgA, and IgM isotypes or the perpetuation of IgM autoantibodies for many years in asymptomatic, procainamide-treated patients (6 ,27), suggesting a weak adaptive immune response and/or evidence of homeostatic downregulation of autoimmunity. Nevertheless, the restriction in the immune response to chromatin-derived antigens suggests that B cells develop with immunoglobulin receptors for certain parts of chromatin, possibly the highly solvent exposed (H2A-H2B)-DNA region. In mouse models of SLE autoantibody secretion has been shown to require T cell help (see Chapters 9 and 18), and drug-induced autoantibodies are likely to have a similar requirement. In fact, initiation of autoimmunity by drugs may be at the T cell level (see Mechanisms) with activation of autoreactive B cells merely a manifestation of this process. This view is supported by the observation that serum autoantibodies have an apparent half-life of 2.5 to 5.0 months after withdrawal of procainamide (27), approximately five times longer than the stability of immunoglobulin in the circulation, suggesting persistent, autoreactive T cell help independent of the drug. Also, increased numbers of $CD4^+$ T cells of the $CD29^+$ activated phenotype along with soluble IL-2 receptor were detected in the pleural effusion of a patient with procainamide-induced lupus (169), consistent with the involvement of T cell help in DIL.

Cellular Immune Response

Studies of in vivo cellular immune abnormalities in procainamide- and hydralazine-treated patients have been minimal and conflicting. Forrester et al. (240) observed increased spontaneous IgM and especially IgG secretion by circulating B cells from procainamide-induced lupus patients compared to B cells from patients with DIA or from normals, but whether polyclonal B cell activation was being measured in patients with DIL or these were plasma cells secreting specific autoantibody was not distinguished. This result is consistent with older studies that failed to detect antibody-secreting cells in the circulation of procainamide-treated, asymptomatic patients (241 ,242). Although some or most of these patients would be expected to have serum ANAs (i.e., display DIA), whether these B cell assays are too insensitive or antibody-secreting cells are primarily noncirculating and reside in lymphoid organs is unclear. One study reported that B cells from procainamide-treated patients were hyper-responsive to pokeweed mitogen (242), although just the opposite effect (241) or no difference (243) was seen by others. Reports of B cell responses from procainamide-treated patients to procainamide in vitro have also been discrepant, with some detecting an increase (205 ,244) and others no effect (245 ,246). Only marginal or no capacity of hydralazine to activate peripheral blood lymphocytes from patients with hydralazine-induced lupus was observed (130), although another study reported that lymphocytes from 50% of asymptomatic hydralazine-treated patients showed a three- to fourfold stimulation index in the presence of hydralazine- albumin conjugates (31). Taken together, these older observations argue against the development of drug-specific T or B cells that would have been expected in a drug hypersensitivity response as discussed (247), consistent with other features of DIL such as its slow kinetics (delay of months to years from the onset of drug therapy to the development of autoantibodies and clinical symptoms), correlation with drug dose and the inconsistent recurrence of symptoms upon drug rechallenge.

Diagnostic Criteria for Drug-Induced Lupus

Specific criteria for the diagnosis of DIL have not been formally established. Although some of the criteria for the classification of SLE are applicable to DIL, the requirement for four manifestations as established by the American College of Rheumatology (ACR) (248) is overly rigid for DIL and is obviously not useful for distinguishing between drug-induced and idiopathic SLE. Patients with DIL often do not fulfill criteria for SLE, and a diagnosis of DIL can readily be missed if SLE diagnostic criteria are strictly applied. In particular, symptoms common to SLE such as malar or discoid rash, photosensitivity, oral ulcers, alopecia, and renal or neurologic disorders are very unusual in DIL. Patients frequently present with mild or few lupus-like symptoms that typically worsen the longer the patient is maintained on the implicated drug, so that patients could readily be underdiagnosed if SLE criteria are strictly applied.

Table 44-7 shows guidelines for a diagnosis of drug-induced lupus.

Elaboration of Diagnostic Guidelines

Treatment Duration

Drug-induced lupus usually occurs after several months or years of continuous therapy and should not be confused with the short-term toxic side effects that are often suffered by patients treated with pharmaceuticals. Time for manifestation of lupus-like symptoms varies greatly among drug treated patients—for procainamide, a median of 10 months was calculated, although one fourth of the 50 patients did not develop symptoms until 2 or more years of therapy (37); for hydralazine, the majority of patients require 6 months to 2 years of exposure (33), but it is not uncommon for a patient to be treated for more than 3 years before symptoms become manifested. This variation may be largely a result of differences in the steady state drug concentrations employed in order to maintain therapeutic control, but genetic factors may also be involved as discussed below.

Table 44-7: Guidelines for Diagnosis of Drug-Induced Lupus

1. Continuous treatment with a known lupus-inducing drug for at least 1 month and usually much longer.
2. Presenting symptoms:

   Common: arthralgias, myalgias, malaise, fever, serositis (pleuropericarditis, especially with procainamide), polyarthritis (especially with quinidine and minicycline).

   Rare: rash or other dermatologic problems, glomerulonephritis (primarily with hydralazine).
3. Unrelated symptoms suggestive of SLE: multisystem involvement especially neurologic, renal, and skin symptoms.
4. Laboratory profile

   Common: ANA which is a result of antihistone antibodies especially IgG anti-[(H2A-H2B)-DNA], leukopenia, thrombocytopenia and mild anemia, increased erythrocyte sedimentation rate;

   Absent or rare: antibodies to native DNA, Sm, RNP, SS-A/Ro, SS-B/La, hypocomplementemia.
5. Improvement and permanent resolution of symptoms generally within days or weeks after discontinuation of therapy. Serologic findings, especially autoantibody levels, often require months to resolve.

Symptoms

In some patients, symptoms gradually appear and worsen over the course of many months of treatment with the implicated drug, whereas in others, symptom onset is rapid. In one study of 21 patients, diagnosis of procainamide- induced lupus was based on one symptom in 20% of patients, two symptoms in 25%, and three or more symptoms in 55% of patients (126). Some suggestion of a drug-specific symptomatology in addition to the usual musculoskeletal and constitutional symptoms is suggested by the literature, with pleuritis and pericarditis common to procainamide-induced lupus, polyarthritis common to quinidine- and minocycline-induced lupus, glomerulonephritis, and rash reported in hydralazine-induced lupus and autoimmune hepatitis in lupus related to minocycline (141 ,142 ,144) and atorvastatin (146). Lung involvement in procainamide-induced lupus occurs in approximately 50% of patients and consists of pleuritis, pleural effusions and/or pulmonary infiltrates; pericardial effusions are also common. In most patients symptoms are mild, although indistinguishable from SLE and consist of fever, malaise, weight loss, polyarticular arthralgias, and symmetric myalgias.

Probable Exclusionary or Unrelated Symptoms

Central nervous system (CNS) disease is distinctly uncommon in drug-induced lupus, but because of possible independent neurotoxic effects of drugs or the occurrence of stroke, convulsions or dementia syndromes in the elderly commonly treated with these drugs, CNS disease should not be an exclusion criterion. Similarly, although serious kidney disease is hardly ever reported for most lupus-inducing drugs, glomerulonephritis has been associated with hydralazine-induced lupus (235 ,249 ,250 ,251 ,252) so should also not be a formal exclusion criterion. In the latter cases, it is difficult to distinguish hydralazine-induced glomerulonephritis from that related to the underlying hypertension for which hydralazine was administered. Mucocutaneous manifestations are also rare in DIL. Although a history of rheumatologic disease independent of the suspected drug tends to negate a diagnosis of DIL, obviously a patient can have two diseases. This situation is characteristic of patients

with various forms of arthritis who also develop DIL from penicillamine, sulfasalazine, minocycline, or TNF-α inhibitor therapy. In these difficult cases, serologic findings are especially informative.

Laboratory Abnormalities

Most patients with DIL have ANA, which are largely restricted to histone-containing antigens (148). IgG antibody to the (H2A-H2B)-DNA complex is an especially sensitive marker for lupus induced by a large variety of drugs except hydralazine (Table 44-6). This test is particularly useful for distinguishing asymptomatic drug-treated patients who develop benign ANA (i.e., DIA) from patients with symptomatic DIL because only the latter have IgG anti-[(H2A-H2B)-DNA] antibodies (27). Some patients with DIL also have mild leukopenia, thrombocytopenia, and/or anemia and elevated sedimentation rate, but rarely hypocomplementemia. Approximately 1% of procainamide-treated patients will present with neutropenia, but these patients do not have classical DIL (173 ,174). Although antihistone and anti-[(H2A-H2B)-DNA] antibodies are also common in SLE (137), these patients are rarely monospecific for this activity. Therefore, when a diagnosis of SLE or DIL can not be clearly distinguished on clinical grounds, the presence of antibodies to native DNA, Sm, RNP, SS-A/Ro, SS-B/La, or other nuclear antigens should be considered as evidence against a diagnosis of DIL.

Symptom Resolution

Resolution of symptoms and laboratory abnormalities by withdrawing the offending drug is a defining feature of DIL. This simple manipulation and follow-up is obviously a retrospective diagnosis but can be very reassuring. Although there is a strong temptation to treat patients suspected of DIL with anti-inflammatory agents (see Treatment), this maneuver may confound the diagnosis and should not be required for recovery from DIL. Although autoantibody activity also resolves after discontinuation of therapy, these abnormalities often take much longer than symptom resolution and can still be present 1 to 2 years after withdrawal of therapy. However, quantitative measurements of autoantibodies should show a systematic decline in activity once the causative agent is withdrawn.

Differential Diagnosis

One concern of clinicians is how to differentiate DIL from SLE, and from other systemic rheumatic diseases. The reasons for this concern are threefold. First, the elderly SLE patient often does not present with the classic features of SLE (e.g., butterfly rash, glomerulonephritis) (253 ,254). Indeed, the clinical features of SLE in the elderly and DIL have significant overlap. Second, the treatment of DIL is generally straightforward, requiring only withdrawal of the drug and short-term anti-inflammatory therapy, whereas the treatment of SLE can involve the prolonged use of corticosteroids or other immune modulators. Third, the outcome of DIL is better than SLE because these patients rarely, if ever, develop renal or neurologic disease. As discussed above, SLE is usually characterized by a much broader array of autoantibodies than is DIL, so the serologic profile can be very helpful in these difficult cases.

Because the clinical features of DIL are protean, a differential diagnosis should be considered (164). Viral syndromes and infectious diseases may present with arthralgia, fever, and pleuropericarditis. Dressler syndrome should be considered in a patient with a previous myocardial infarction. An additional ischemic myocardial event may present with fever and pericarditis. The postpericardiotomy syndrome, which may occur after cardiac surgery and is similar to Dressler syndrome, can be confused with DIL because these patients are often treated with antiarrhythmics such as procainamide. Other diagnoses to be considered in the appropriate setting are rheumatoid arthritis, polymyalgia rheumatica, underlying malignancy, adverse or hypersensitive drug reactions, and GVHD.

Treatment

Once the diagnosis of DIL has been established, the first step is discontinuation of the offending drug. Treatment with anti-inflammatory agents, including corticosteroids, may be indicated for those with severe manifestations of the disease such as pericarditis with tamponade, inflammatory pleural effusions, or debilitating polyarthritis. The judicious use of nonsteroidal anti-inflammatory agents and corticosteroids in the elderly is important because of potential side effects. The prolonged use of high doses of corticosteroids, or the use of chloroquine, hydroxychloroquine, or immunosuppressive agents is not indicated in the treatment of DIL. If DIL is associated with the rare feature of glomerulonephritis, as reported with hydralazine-induced lupus (235 ,249 ,250 ,251 ,252), corticosteroids can be used. Although some DIL patients have been restarted on procainamide or hydralazine without incident, this is not advisable if insufficient time (which may be as long as 1 year) has elapsed since the first episode of DIL (see Rechallenge Studies).

Clinicians are often consulted to consider the safety of drugs associated with DIL in the treatment of patients with idiopathic SLE. The use of hydralazine to treat hypertension in SLE patients has not been associated with exacerbations of the disease (13). Prockop (50) described an SLE patient treated for myotonia with 4 g procainamide per day for 15 months with no exacerbation of SLE despite the occurrence of lupus flares before and after the period of drug administration. The use of anticonvulsants to treat seizure disorders in SLE patients has not been associated with flares or acceleration of disease activity. INH has been given to SLE patients on corticosteroids without aggravating lupus (164). Despite the apparent safety of these drugs in the setting of SLE, the clinician should use the drugs

judiciously and carefully document the clinical and serologic status of the patient being considered for treatment.

Genetic Factors

HLA Phenotype

The immunogenetic factors that underlie DIL are of interest because only a small proportion of drug-treated patients develop symptomatic disease, and the immune response is restricted to a relatively narrow range of autoantigens. These observations implicate a role for the class II major histocompatibility complex (MHC) human leukocyte antigens (HLA), which are required for T cell–dependent antibody responses. In a recent study of 13 patients with minocyline-induced lupus, all the patients had either HLA-DR4 or HLA-DR2 of subtypes that share a structural similarity ($p < 0.01$ vs. normals) (145). A study of 25 hydralazine-induced lupus patients by Batchelor et al. (128 ,255) showed a 73% frequency of HLA-DR4 versus a frequency of 25% in asymptomatic patients, representing a relative risk of 8.1. Another study using some of these same patients found a 70% frequency of HLA-DR4 in hydralazine-induced lupus patients (36). HLA-DR4 has been reported in individual patients with penicillamine-induced lupus (256 ,257), hydralazine-induced Sweet syndrome (175) and atorvastatin-induced lupus (146). However, hydralazine-induced lupus patients from Australia (258) and a limited study of American procainamide-induced lupus patients (126) failed to find a significantly increased incidence of any HLA markers. Re-examination of the hydralazine-induced lupus patients in the English study for complement protein phenotypes demonstrated that 76% of these patients had one or more C4 null alleles compared to 43% of normal controls ($p < 0.01$) (259). The genes encoding the C4 complement proteins are situated between the HLA-B and HLA-DR loci, and the C4 null/DR4 haplotype displays linkage disequilibrium in Caucasians. Therefore, the reported association of hydralazine-induced lupus with HLA-DR4 is probably a result of the C4 null trait (260), and linkage disequilibrium between HLA-DR4 and C4 may not occur in the Australian study group.

In chlorpromazine-treated patients, HLA-B44 was a significant risk factor in the induction of ANA (relative risk = 3.6) (261) and LAC (relative risk = 2.1) (262), and HLA-DR7 was also weakly associated with chlorpromazine-induced LAC (262). Among procainamide-treated patients, there was a significant association between HLA-DQw7 and IgG antibodies to histones and H2A-H2B (198). These results may suggest that these class II MHC antigens have a propensity to present histone peptides to T cells. However, because most patients treated with hydralazine or procainamide develop ANA, it is unlikely that paticular HLA allotypes are necessary for autoantibody induction by these drugs. More controlled studies using DNA typing for MHC class II alleles rather than the less accurate serological typing are required to determine whether MHC genes are important in the development of DIL.

Complement

The complement genes are part of the MHC class III region, and C4A and C4B are encoded by separate loci. Individuals with genetic deficiencies in one, and especially both, C4 genes have greatly increased susceptibility to SLE (263) (see Chapters 6 and 13), presumably because of insufficient classical pathway activation, resulting in poor immune complex clearance. As mentioned above, 76% of hydralazine-induced lupus patients had one or more C4 null alleles compared to 43% of normal subjects (259), suggesting a congenital defect in immune complex clearance may also predispose to DIL. It has not been determined, however, whether patients treated with hydralazine who remain asymptomatic have a low frequency of C4 null alleles. Similarly, it is not clear whether the occasional hypocomplementemia associated with procainamide-induced lupus (264) may be related to C4 deficiency. In most patients with DIL, serum complement levels are within the normal range (154). Interestingly, the null alleles of either C4A or C4B were also significantly more frequent in patients with procainamide-induced lupus than in normals at $p = 0.05$ (198).

A small but significant reduction ($p < 0.01$) in the mean number of type 1 complement receptors for C3b on erythrocytes (CR1) was observed in patients with a prior history of hydralazine-induced lupus, and these individuals tended to have elevated circulating immune complexes (154). However, based on restriction fragment polymorphism analysis, there was no difference between symptomatic and asymptomatic hydralazine-treated patients in the frequency of the allele encoding the low expression CR1 phenotype (265), indicating that hydralazine-induced lupus patients may have acquired a deficiency (perhaps a result of persisting immune complexes) in CR1 expression. However, measurements of Fc-receptor-mediated immune clearance in patients treated with chlorpromazine, procainamide, penicillamine, or hydralazine with or without associated symptomatic disease demonstrated no differences and normal clearance function (153). These data suggest that, unlike in SLE, handling of circulating immune complexes by the reticuloendothelial system in DIL is not overloaded, possibly explaining the lack of kidney and CNS disease in DIL.

Acetylator Phenotype

Acetylator phenotype is the best described genetically determined predisposing factor in DIL, but its significance is often misunderstood. The studies of Perry et al. demonstrated that the level of hepatic acetyltransferase activity was inversely associated with the likelihood for development of DIL (30). The acetyl group of acetyl-CoA can be transferred to the amino group of many small molecules by the action of acetyltransferases. North American white and black populations can be almost evenly divided into slow or fast acetylators based on their acetyltransferase activity. The acetylator phenotype can be determined by administering

a tablet of dapsone, INH, or caffeine to a patient and analyzing the serum or urine for acetylated and unacetylated drug. A preferable method is to determine acetylator genotype by amplyifying lymphocyte genomic DNA by polymerase chain reaction followed by restriction nuclease digestion. Slow acetylators are homozygous for a recessive gene that controls hepatic acetyltransferase activity and have an approximately twofold higher serum level of unacetylated drugs at equivalent therapeutic doses.

Compared to rapid acetylators, autoantibodies and clinical symptoms develop more quickly and in higher frequency during the treatment of slow acetylators with hydralazine (30 ,128) and procainamide (24), although in a recent study seven out of nine patients (78%) with procainamide-induced lupus were rapid acetylators (6). Development of clinical symptoms can occur in up to 20% of rapid acetylators (36), but both the dose and duration of drug administration are generally higher in these patients (24). These studies generally support the hypothesis that the steady-state concentration of unacetylated procainamide and hydralazine and the duration of exposure are important elements in the development of DIL. Such observations have led to the use of N-acetyl procainamide (NAPA) in the successful control of cardiac arrhythmias while bringing about the remission of procainamide-induced lupus (266). NAPA did not induce lupus, ANA, or anti-dDNA (267 ,268). Furthermore, if the procainamide dose was adjusted so that all patients have the same steady state plasma concentration by increasing the dose for rapid acetylators, no difference was observed between slow and rapid acetylators in the time for development of ANA or DIL (23). Nevertheless, a recent study did not observe a tendency for the use of higher procainamide dose in rapid acetylators (6).

The importance of the free amino/hydrazino group in these drugs in the development of autoantibodies and lupus has been interpreted in two ways. A commonly held view is that these chemical moieties play a direct role in the induction of autoimmunity, and acetylation prevents this action. Alternatively, in vivo metabolism (other than acetylation) of the drug at this moiety generates the active, autoimmunity-inducing compound, and that N-acetylation blocks drug metabolism. With this view, the putative reactive metabolites, rather than the parent molecule, would interact with a key immune target, leading to induction of autoimmunity (see Oxidative Drug Metabolism). The association of the slow acetylator phenotype with symptomatic DIL can then be explained by a higher steady-state concentration of the metabolizable form of the drug. Although INH, like hydralazine, is a substrate for hepatic acetyltransferase, there is no difference in the development of ANA in fast and slow acetylators on INH therapy (269). The lack of an association between acetylator phenotype and induction of ANA by INH (269) or by captopril (270) as well as idiopathic SLE (271), indicates that the slow acetylator phenotype is not a general predisposing factor for the autoimmune state, nor is it genetically linked to a putative autoimmunity-inducing or autoimmunity-accelerating gene.

Gender and Race

As discussed under Epidemiology, lupus induction is three- to fourfold more likely in females than males and four- to sixfold more likely in whites compared to blacks.

Oxidative Drug Metabolism

The following features of drug-induced autoimmunity are difficult to explain by a direct action of the ingested, parent compound on some component of the immune system:

- Lupus-inducing drugs are highly diverse in chemical structure (Fig. 44-2) and pharmacologic action, yet the laboratory and clinical features of lupus induced by all the drugs are essentially the same.
- Except for their pharmacologic action, lupus-inducing drugs are largely inert at normal doses; nonspecific or generalized toxicity would preclude their use as therapeutic agents. DIL is an idiosyncratic drug reaction not predicted by any known property of the implicated drugs.
- Drugs reach a steady-state concentration within a few hours, but drug-induced autoimmunity and lupus require many months for manifestation.

The requirement for metabolic transformation of the ingested drug to a reactive compound would account for many of the features of DIL. In vivo metabolism of dissimilar drugs to a product with a common, reactive property could explain how compounds with widely different pharmacologic and chemical characteristics could produce the same adverse reaction. The low probability for a productive metabolic event could explain the long lag time for autoimmunity to unfold.

Incubation of procainamide with human or rat liver microsomes that contain the “mixed function oxidases” results in the formation of an unstable product, procainamide-hydroxylamine (PAHA) (272 ,273), and PAHA can be detected after the perfusion of rat liver with procainamide in a blood-free environment (274). Hydralazine and isoniazid are also susceptible to hepatic oxidative metabolism (275 ,276). PAHA enters RBCs, and oxyhemoglobin enhances its biologic activity (245 ,274), presumably by converting PAHA to nitro-procainamide (277 ,278). Hepatic metabolism of drugs to reactive products demonstrates that the chemistry exists for generation of potentially toxic compounds, but these products typically bind to microsomes or macromolecules near their site of formation and fail to exit the liver in reactive forms. Although rats treated with procainamide showed increased liver lipid peroxide levels and antioxidant activity (279), hepatotoxicity is generally not associated with drug-induced autoimmunity or lupus, making it unlikely that sufficient amounts of reactive metabolites of lupus-inducing drugs are generated in the liver to interact with resident lymphocytes or inflammatory cells. Although drug metabolites might bind to self-antigen in the liver, there is not

enough structural information in such small molecules to specifically interact with the chromatin-derived targets that characterize the autoimmune response in DIL.

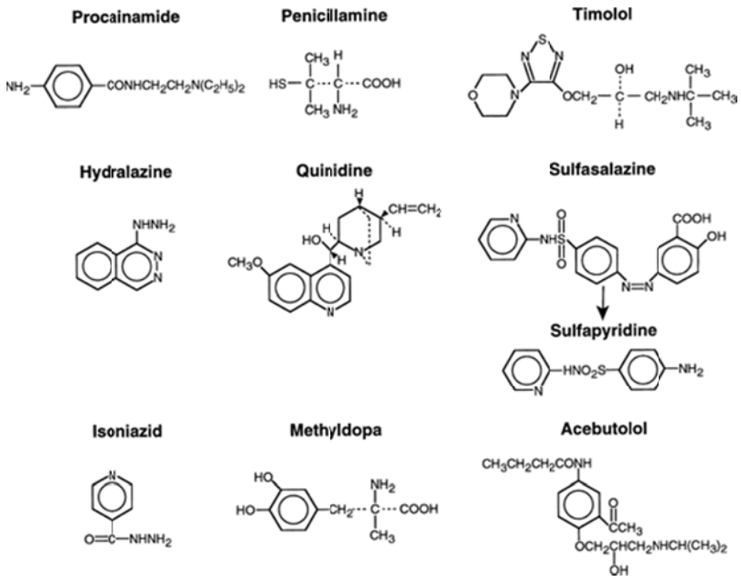

Figure 44-2. Structures of drugs reported to induce lupus and anti-[(H2A-H2B)-DNA] antibodies. Sulfasalazine undergoes hydrolysis in the intestine to 5-aminosalicylic acid and sulfapyridine, which is absorbed and the candidate agent for inducing lupus. However, cases of lupus induced by 5-aminosalicylic acid (mesalamine) have been reported (147). Although four drugs are aromatic amines (procainamide and sulfapyridine) or hydrazines (hydralazine and isoniazid), the chemical structures of drugs with capacity to induce lupus are highly diverse.

Phagocytic leukocytes including neutrophils, monocytes, macrophages, and skin Langerhans cells have drug metabolizing capacity because of the presence within these cells of various enzymes with promiscuous substrate properties such as myeloperoxidase, prostaglandin H synthase or, less commonly, the cytochrome P450s. Rubin et al. (280) showed that activated peripheral blood neutrophils have capacity to metabolize procainamide to PAHA in the extracellular milieu; the role of the respiratory burst and degranulation events associated with neutrophil and macrophage activation was confirmed (281) and analyzed in detail (282). Neutrophils are clearly the greatest drug-metabolizing engine outside the liver because of their preponderance in the circulation, apparently unlimited hematopoietic regenerative capacity, ability to freely circulate and populate essentially any organ or tissue including lymphoid tissue where autoimmunity presumably develops, and capacity to generate in response to stimulants a robust extracellular oxidizing machinery. It is this latter feature that is particularly important because generation of reactive drug metabolites outside a cell sets up a condition for delivering these agents some distance from their immediate site of formation.

Essentially all pharmacologic classes of lupus-inducing drugs (Table 44-1) but not their nonlupus-inducing analogues have been demonstrated to undergo oxidative metabolism by activated neutrophils including procainamide, hydralazine, phenytoin, quinidine, dapsone, propylthiouracil, penicillamine, chlorpromazine, INH, and carbamazepine (281 ,282 ,283 ,284 ,285 ,286 ,287 ,288 ,289 ,290 ,291 ,292 ,293 ,294). The general mechanism responsible for drug transformation is shown in Figure 44-3 . Activation of neutrophils by opsonized particles or certain soluble factors triggers the ectoenzyme NADPH oxidase to

produce superoxide anion (O_2^-) in the extracellular environment. O_2^- spontaneously dismutates to hydrogen peroxide (H_2O_2). Degranulation often follows, releasing myeloperoxidase (MPO). If a drug with an appropriate functional group is present, it will participate in electron transfer with the H_2O_2-MPO intermediate. Consequently, the functional group accepts an oxygen atom from H_2O_2, resulting in a new compound. Neutrophil-mediated drug metabolism by this mechanism requires the enzymatic action of MPO, as evidenced by the competitive inhibition of MPO activity by all lupus-inducing drugs tested and the correlation of this property with neutrophil-dependent drug cytotoxicity (Table 44-8) (293). The instability of these drug metabolites precludes their detection in vivo, but in vitro generated reactive oxidative intermediates of procainamide (277 ,278 ,295), hydralazine (290), chlorpromazine (291), and isoniazid (276) have been identified. Reactive intermediates of lupus-inducing drugs are strong candidates for triggering autoimmunity.

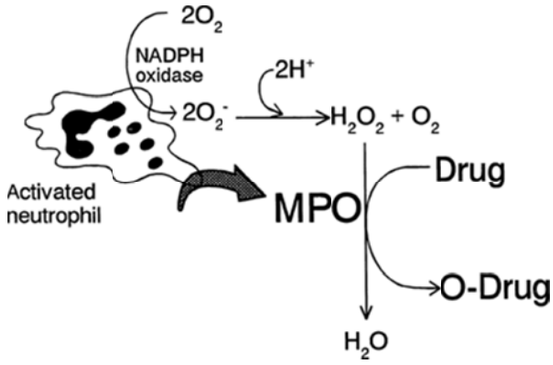

Figure 44-3. Mechanism for transformation of drugs by activated neutrophils (see text).

Table 44-8: Correlation Between Lupus-Inducing Propensity and Neutrophil-Dependent Drug Metabolism Mediated by Myeloperoxidase (MPO)*

Drug	Lupus-Inducing Incidence (%)	Neutrophil-Mediated Cytotoxicity (%)**	Inhibition of MPO Activity (%)**
Procainamide	15–20	76 ± 11	17 ± 5
N-Acetylprocainamide	0	-3 ± 3	3 ± 2
Hydralazine	5–10	37 ± 4	95 ± 5
Phthalazine	N.T.	-3 ± 1	2 ± 1
Quinidine	<1	26 ± 4	21 ± 7
Quinilone	N.T.	1 ± 1	0 ± 3
Chlorpromazine	<1	30 ± 7	29 ± 8
Promazine	N.T.	-5 ± 1	3 ± 5
Isoniazid	<1	24 ± 3	40 ± 5
Isonicotinamide	N.T.	1 ± 1	1 ± 3
Propylthiouracil	<1	63 ± 11	87 ± 1
Propyluracil	N.T.	-4 ± 2	0 ± 2

*Derived from Jiang X, Khursigara G, Rubin RL. Transformation of lupus-inducing drugs to cytotoxic products by activated neutrophils. *Science* 1994;266:810–813.

**Neutrophil-dependent drug cytotoxicity measures the capacity of the indicated drug in the presence of activated neutrophils to affect the viability of a target cell line and is expressed as the percent of cells killed by the drug metabolite. Inhibition of MPO activity measures the capacity of the drug to act as a competitive inhibitor of the enzymatic activity of MPO. Both in vitro assays were measured at a drug concentration of 10 μM. Drugs are grouped as pairs with the incidence of drug-induced lupus indicated for the upper drug, whereas the lower member being the an inactive analogue or metabolite.

N.T. = not tested.

Although it is difficult to prove that neutrophil-mediated bioactivation of drugs occurs in vivo, the frequent finding of anti-MPO antibodies in patients with lupus induced by hydralazine (125 ,235 ,236), propyylthiouracil (125 ,158), and minocycline (145) is consistent with an autoimmune reaction initiated by drug bioactivation mediated by neutrophil-derived MPO. Indirect evidence that neutrophil- mediated drug metabolism is required for induction of autoimmunity is suggested by the strong correlation between MPO-mediated oxidative drug transformation and propensity of the drug to induce lupus (Table 44-8). Nitro-procainamide, a further oxidation product of PAHA (277 ,278), has been detected in the urine of procainamide- treated patients (198 ,296). Urinary metabolites of hydralazine have also been described (233 ,297). Murine T cells sensitized to oxidative metabolites of procainamide (298), propylthiouracil, or gold(I) thiomalate (299 ,300)

displayed specific responses to lysates of phagocytic cells (which were derived from mice subjected to long-term treatment with the respective parent compound), but did not respond to the parent compound itself. These data suggest that lupus-inducing drugs undergo oxidative metabolism in vivo, implicating these products in the induction of autoimmunity. N-acetylation of hydralazine and procainamide competes with N-oxidation of these drugs, accounting for the lower probability for development of autoimmunity in people with the rapid acetylation phenotype.

Pathogenesis

Because symptoms and serologic features of DIL overlap with those of idiopathic SLE, it is presumed that similar pathogenic factors underlie both syndromes. However, immune complex formation and deposition in vital organs, one of the mechanisms believed to operate in SLE, have not been well-documented in DIL. Immune complexes have been reported in DIL (153 ,154 ,155), but their composition, correlation with disease activity, and pathogenic potential have not been evaluated. Evidence supporting the involvement of immune complexes in disease pathogenesis include the observations that complement breakdown products (e.g., C3d and C4d) were detected in DIL (37 ,161). C4d/C4 ratios were significantly elevated in five of six procainamide-induced lupus patients (37), and, in a prospective study, C4d gradually increased during the development of DIL and returned to normal 2.5 months after discontinuation of procainamide treatment (160). Immune complexes involving IgG anti-[(H2A-H2B)-DNA] and a chromatin-derived antigen would be a candidate mediator of complement activation and subsequent inflammatory reactions. This possibility is consistent with the finding that anti-[(H2A-H2B)-DNA] activity is predominantly IgG1 and IgG3 (301), immunoglobulin subclasses which are potent activators of the classical complement pathway when engaged by antigen. Detection of LE cells in procainamide-induced lupus (150) also suggests the presence of complement-fixing autoantibodies. However, in comparison to the complement fixing activity of autoantibodies in SLE, antihistone and antichromatin antibodies from patients with DIL displayed much lower capacity to activate the complement system using an indirect immunofluorescence assay involving cell nuclei (302 ,303 ,304 ,305). In addition to this weak complement-fixing activity, which may be related to the relative homogeneity of autoantibodies in DIL compared to SLE (305), overloading of the immune complex clearance machinery and pro-inflammatory signaling through complement and Fc receptors (306) may be necessary for the serious pathologic features that are typical of SLE (Chapter 12).

Hydralazine and INH inhibit C4, especially C4A, binding activity in vitro, and it has been suggested, therefore, that these drugs may interfere with immune complex clearance by inhibiting classical pathway activation (307 ,308). Although these effects were only observed at drug concentrations that were 10- to 100-fold higher than therapeutic plasma levels in humans, penicillamine inhibition of C4A binding may fall within therapeutically relevant concentrations (308). Of particular interest was the finding by Sim et al. (309) that PAHA inhibits C3 or C4 activity at concentrations 10-fold lower than that of procainamide. However, this effect still required concentrations of PAHA not pharmacologically obtainable, making it unlikely that an acquired C3 or C4 deficiency contributes to DIL.

Animal Models

Compared to human standards all strains of mice are slow acetylators (310) and, therefore, should be susceptible to autoantibody elicitation upon exposure to lupus-inducing drugs. On the other hand, drug clearance rates in mice are at least ten times faster than in humans (311), so at equivalent weight-adjusted oral doses, mice will have much lower steady-state blood levels of delivered drug. The measured elimination half-life for procainamide in 20 strains of mice varied from 23.5 to 54.7 minutes (312), compared to 180 to 300 minutes in humans (313). Use of excess drug concentrations in the drinking water is limited by the natural aversion of mice to higher oral doses.

Continuous oral administration of isoniazid or hydralazine for 6 to 8 months in C57BL/6 mice was reported by Cannat and Seligmann (314 ,315) to result in ANA induction in 34% to 46% of mice. TenVeen and Feltkamp (316 ,317) reported similar findings and extended positive results to procainamide and to two other mouse strains. Tannen and Weber (318 ,319) also were able to elicit ANA by procainamide in A/J mice, but, contrary to the earlier reports, observed suppression of spontaneous ANA appearance during 9 months of exposure of C57BL/6 mice to procainamide. Injection of procainamide three times per week for 30 weeks failed to elicit ANA in mice, rats, rabbits, or guinea pigs (320). Although provocative, the murine models in which a lupus-inducing drug is administered in the drinking water are impractical, because of the long duration required to develop even a partial response, the common spontaneous seroconversion of aging mice to ANA positivity and the inability to develop steady-state blood levels of the drug which are comparable to therapeutic doses in humans. Monoclonal antichromatin antibodies derived from mice receiving quinidine or penicillamine in their drinking water for 5 to 8 months were reported (321), but it is not certain that these autoantibodies were truly drug-induced. Uniform mean plasma levels of 2.1 ± 0.7 μg/ml (7.4 μM) procainamide, which is at the lower end of the human therapeutic level, were obtained by delivering the drug via implanted osmotic pumps, but the mice failed to develop autoantibodies during the 7 weeks of exposure that this protocol could be sustained (312 ,322).

Oral administration of propylthiouracil into mongrel cats for 2 months resulted in ANA, direct anti-RBC antibodies and lupus-like symptoms in approximately half the animals (323). Discontinuation of propylthiouracil or replacement with propyluracil caused resolution of symptoms and signs within 1 to 4 weeks (323), indicating that this was a bonafide drug-induced lupus-like syndrome. Induction of autoimmunity was drug dose–dependent, and, as in human DIL (see Rechallenge Studies), cats that had previously developed propylthiouracil-induced lupus followed by a 3-month washout period were not hyperresposive to challenge with propylthiouracil (i.e., they failed to redevelop disease at lower challenge doses) (324). Interestingly, the ANA was predominantly a result of antinative DNA antibodies; antihistone antibodies were not detected (324). Therefore, this syndrome has features of both drug-induced and idiopathic lupus and may be a unique feline animal model.

A lupus-like pathology including autoantibodies and glomerulonephritis has been produced in mice by injection of splenocytes treated with procainamide in vitro (325). For this effect to be manifested, splenocytes were activated by allogeneic stimulation and treated in vitro with procainamide prior to their adoptive transfer monthly for 6 months into syngeneic mice. A conalbumin-specific T cell clone treated with procainamide or hydralazine, but not their structural analogs, produced a similar in vivo pathology (326 ,327 ,328), suggesting that autoimmunity in this animal model was mediated by nonantigen specific activated T cells exposed to lupus-inducing drugs (see Mechanisms).

A number of lupus-inducing drugs (hydralazine, chlorpromazine, carbamazepine, phenylbutazone, and nitrofurantion) will cause significant enlargement of the draining popliteal lymph node when injected subcutaneously into the hind foot pad of mice (298 ,299 ,300 ,329). In this popliteal lymph node assay (PLNA) T cells apparently respond to drug-altered self proteins. Interestingly, procainamide, INH, and propylthiouracil were negative in this assay (298 ,329 ,330), unless oxidatively metabolized by rat liver microsomes (330) or peritoneal macrophage (298) or if the metabolite itself such as PAHA or propyluracil 2-sulfonate was injected (298). The requirement for a drug metabolite is in good agreement with the in vitro studies demonstrating neutrophil- or macrophage-mediated metabolism of the same drugs (see Oxidative Drug Metabolism). The possible significance of this animal model in the context of DIL is discussed under Mechanisms.

Injection of PAHA into the thymus of normal adult mice resulted in the delayed appearance and long-lasting production of IgG anti-[(H2A-H2B)-DNA] antibodies, similar to those found in patients with DIL (331). Transfer into naïve mice of autoreactive peripheral T cells derived from PAHA-injected animals elicited a similar autoantibody profile, indicating that autoreactive T cells that emigrated from the thymus to the periphery accounted for autoantibody production in this system (332). The cellular basis for autoantibody production in this mouse model is discussed below.

Mechanisms

Most of the older experimental studies on DIL explored the significance of the presumed capacity of lupus-inducing drugs to form stable complexes with self-macromolecules or to directly stimulate lymphocytes. The premise underlying much of this work was apparently based on previously described immune reactions to xenobiotics such as the penicillin-type of drug hypersensitivity (allergic) reaction mediated by antibodies or the delayed-type hypersensitivity reaction associated with allergic contact dermatitis mediated by T cells. Autoantibodies might develop if an immune response to the drug in the form of a hapten or to a self-antigen altered by the drug induces antibodies that cross-react with or cause spreading of the immune response to native self-macromolecules. For the most part these experiments have not been illuminating because nonpharmacologic concentrations of drugs or artificial drug-macromolecular complexes together with immunologic adjuvants were employed (reviewed in (182)). A more recent examination of the specificities of antibodies elicited in rabbits by immunization with drug-albumin complexes revealed no cross-reaction between denatured DNA or histones and antibodies to procainamide or its oxidative metabolites (211). However, several groups are pursuing variants of this hypothesis at the T cell level as discussed below.

Studies over the past decade attempting to determine which component(s) of the immune system are important in the initiation of drug-induced lupus and exactly how autoimmunity is triggered by drugs or drug metabolites are organized below into four general mechanistic hypotheses. The pros and cons of these ideas as well as the hypersensitivity mechanism are summarized in Table 44-9 .

- Drug Metabolites Act as Haptens for Drug-Specific T Cells.

  Immune responses require presentation of the antigen on the class II molecules of the MHC on antigen presenting cells, and most drugs are ignored by the immune system, in part because their molecular mass is too small to enter this machinery. However, if a drug or its metabolite can form a stable bond to self-molecules, it (as a hapten) or a combined epitope generated by the drug-self molecule complex may be recognized by antigen receptors on B and/or T cells. Such a phenomenon appears to be the basis of the immunoreactivity of many drugs in the PLNA reported by Gleichmann and others (298 ,299 ,300 ,329 ,330 ,333) (see Animal Models). Since monocytes, macrophages, and Langerhans cells can present antigens to T cells, they have received special attention as a potential source of both drug biotransformation producing drug conjugates as well as immune presentation of the conjugate to initiate an immune response (82). These professional antigen-presenting cells could also take up drug conjugates produced in their immediate microenvironment by other cells such as neutrophils. Oxidative metabolites of carbamazapine,

chlorpromazine, hydralazine, phenytoin, procainamide, and propylthiouracil have been demonstrated to form covalent bonds with cellular proteins. Alternatively, B cells within the microenvironment of a drug-specific T cell response might become activated by cytokine-mediated bystander mechanisms.

Table 44-9: Possible Mechanisms in Drug-Induced Lupus*

Mechanism	Pro	Con
Immune response to drug-modified self-macromolecule initiates autoimmunity	Precedent in allergic drug hypersensitivity and contact dermatitis	Antibodies to drug-altered antigens not cross-reactive with autoantibodies in DIL; Nature of the immune response in DIL dissimilar to that in drug hypersensitivity
Drug metabolite-specific T cell responses spread to autoantigens	Experimental elicitation of drug (metabolite)-specific T cells	Drug-specific T cells not associated with autoimmunity
Cytotoxic drug metabolites release self-macromolecules that initiate autoimmunity	Toxicity of many drug metabolites demonstrated in vitro	No evidence that drug-induced cytotoxicity enhances autoantibody production
Non-antigen-specific activation of lymphocytes by drug leads to autoimmunity	Prototypic lupus-inducing drugs can cause polyclonal T-cell activation, resulting in autoimmunity	Global inflammatory reactions dissimilar to specific autoimmune features of DIL
Drug metabolites disrupt immune tolerance machinery	Disruption of central T cell tolerance leads to autoantigen-specific T cells and DIL-like autoantibodies	No evidence for action of reactive drug metabolites in thymus

*see text for details

Unfortunately for this hypothesis, mice that developed enlarged lymph nodes in response to lupus-inducing drugs or their oxidative metabolites failed to develop autoreactive T cells or autoantibodies, indicating that drug-specific T cells do not typically lead to autoimmunity. Additionally, the autoantibodies that arise in people with DIL or drug-induced cytopenias are limited in specificity, a feature not consistent with a bystander activation scenario. However, if an incipient autoimmune response were independently underway and if the drug as a hapten becomes expressed on the MHC of autoreactive B cells, it is possible that drug-specific T cells could accelerate development of autoimmunity. Presentation of a drug on the MHC could occur after endocytosis and intracellular processing of the drug bound to the cognate self-antigen recognized by an autoreactive B cell or by binding directly to the MHC through a noncovalent association (334).

- Drug Metabolites Cause Cell Death.

Cytopenias associated with certain drugs (see Clinical and Laboratory Features) may be related to the capacity of various reactive drug metabolites to directly cause cell death in in vitro studies. This would be a nonimmune-mediated process. Demonstration that PAHA under certain in vitro conditions can directly kill a wide variety of cells at pharmacologically relevant concentrations (245 ,278 ,293 ,295) or enhance reactive oxygen species generation by murine macrophage (335) and human neutrophils (245) is consistent with this view. Apoptosis rather than necrotic cell death was mediated by sulphamethoxazole hydroxylamine (336) or by the nitrenium ion of clozapine (337). Cell death may be initiated by damage to the plasma or mitochondrial membrane or by covalent binding to critical intracellular molecules or may be a result of redox (reduction/oxidation) cycling with NADH/NADPH, depleting the cell of its energy stores as suggested by the correlation between cell-reducing potential and sensitivity to PAHA cytotoxicity (278). Cytotoxic drug metabolites generated by neutrophils in vitro have been demonstrated for amodiaquine, carbamazapine, chlorpromazine, clozapine, hydralazine, INH, procainamide, propylthiouracil, quinidine, vesnarinone (348) and sulfonamides at therapeutically feasible concentrations. Cytopenia could occur by killing of stem cells if reactive drug metabolites were produced by myeloperoxidase released from immature promyelocytes undergoing granulopoiesis or from activated neutrophils recirculating into the bone marrow (Fig. 44-3). Additionally, certain hematopoietic cell lineages sensitized by an immune-mediated mechanism because of drug binding to the cell surface could be destroyed by an otherwise subtoxic concentration of a reactive drug metabolite. Lymphocytes from patients with a history of agranulocytosis secondary to clozapine therapy were somewhat more sensitive to the cytotoxic effects of oxidative metabolites of clozapine than normals or patients who did not develop agranulocytosis (338 ,339), possibly related to differences in

drug bioinactivation by intracellular glutathione or cysteine (340).

Although it is possible that this type of direct cytotoxicity of drug metabolites could be an independent pathogenic mechanism, especially in certain susceptible populations, such a process can not explain the bulk of the immune abnormalities in DIL.

It is also formally possible that drug toxicity alters degradation, clearance or processing of self-materials by antigen-presenting cells, producing abnormal macromolecular forms or unusual peptides. These “cryptic” T cell autoepitopes may induce classical adaptive immune responses because immune tolerance to such unusual forms of self-materials was never established (see Chapter 20). Autoreactive B cells pre-existing in the immune repertoire could present such cryptic epitopes to T cells, resulting in B cell activation and autoantibody secretion. Alternatively, repetitive macromolecular structures released from dying cells could theoretically elicit T-independent autoimmune responses. This type of scenario has been proposed to account for autoantibodies associated with diverse medications, environmental agents, and viruses, but there remains little in the way of experimental support.

- Drugs Nonspecifically Activate Lymphocytes

A study of Adams et al. (245) suggested that PAHA at 2 μM had capacity to enhance pokeweed mitogen-mediated lymphocyte proliferation and increase the number of Ig plaque-forming cells, but these observations have not been verified. A more recent study reported an approximately twofold increase in poly(ADP-ribosylation) level in the lymphocyte Wil-2 cell line exposed to micromolar levels of procainamide or hydralazine (341). Mouse splenocytes exposed to procainamide or hydralazine while activated in vitro displayed an increased proliferative response to autologous antigen-presenting cells without the need for cognate antigen, killed autologous macrophage, and promoted B cell differentiation into antibody-secreting cells (342 ,343 ,344 ,345). Autoantibodies and glomerulonephritis were produced after adoptive transfer of such drug-treated cells into mice (325 ,326). The autoreactive nature of drug-treated cells was shown by Richardson et al. to be a result of decreased DNA methyltransferase activity in CD4+ T cells as a result of competitive inhibition by procainamide of DNA methyltransferase (346) or by hydralazine of the extracellular-regulated kinase (ERK) pathway resulting in lower expression of DNA methyltransferase (347). As a result, with each round of cell division undermethylation of deoxycytosine residues in CpG pairs occurs in the genomic DNA. Hypomethylation of promoter sequences is associated with enhanced gene transcription, and drug-treated T cells showed increased expression of lymphocyte function antigen-1 (328), an important adhesion molecule that helps stabilize the interaction between T cells and antigen-presenting cells, and enhanced CD70 expression (349), a costimulatory ligand for CD27 on T and B cells. Longer contact between T cells and antigen-presenting cells may promote T cell activation and/or stimulate IgG production in B cells.

One concern about these studies is that the immunopathologic features of this mouse model do not resemble DIL but are more like the global autoimmune characteristics of a graft-versus-host reaction when adoptively transferred semi-allogeneic T cells recognize histoincompatible MHC molecules in the host (350). This syndrome is similar to SLE, whereas DIL displays much more limited autoimmune features (Table 44-5). Additionally, since multiple exposures to large numbers of dividing lymphocytes were required to produce the in vivo phenomena, it is not clear what the natural counterpart of such a polyclonal T cell activation would be. Immune responses to infectious agents that might occur coincident with medication with a lupus-inducing drug would be expected to be associated with a much more limited, oligoclonal T cell activation. However, it is possible that in DIL autoreactive T cells developing through another mechanism become more aggressive because of such a drug-induced LFA-1 and/or CD70 overexpression process, thereby aggravating disease in DIL.

- Drug Metabolites Disrupt Immune Tolerance Machinery

Rather than stimulating mature T cells, drug metabolites when present during T cell development in the thymus may prevent the de novo acquisition of self-tolerance. T cells originate in the thymus, where they are selected to ensure that only cells that are nonresponsive to self are released into the periphery. The possibility that lupus-inducing drugs interfere in this process had been generally ignored, because it was widely assumed that there is no thymic function in the adult, but several studies have demonstrated that T cells are generated in the thymus at least up to the seventh decade of life in normals (351 ,352) and in patients with a history of DIL (352). Kretz-Rommel and Rubin showed that injection of PAHA into the thymus, but not into any part of the peripheral immune system, of normal adult mice resulted in the delayed appearance and long-lasting production of anti-[(H2A-H2B)-DNA] autoantibodies (331 ,332), similar to the autoantibodies that characterize patients with DIL. Observations in this animal model and in an in vitro model of T cell tolerance (353) indicated that PAHA did not reverse self-tolerance of the mature thymocyte and did not prevent deletion of high affinity autoreactive T cells in the thymus. Instead, PAHA apparently interfered with the establishment of tolerance to endogenous self-antigens that are normally presented by the MHC on thymic epithelial cells during the positive selection of thymocytes (354). As a result, mature T cells are produced that are capable of undergo spontaneous activation when

they encounter similar self-antigens in the periphery. These studies would imply that the restricted autoantibody production associated with DIL reflects a limited diversity in the selecting antigens encountered as T cells undergo positive selection in the thymus and that T cell tolerance to these antigens is compromised in the presence of reactive drug metabolites.

Currently, there is no evidence that reactive metabolites of procainamide can be produced in the thymus by circulating or resident phagocytic cells and that metabolites of other lupus-inducing drugs can also initiate autoimmunity by this mechanism. Ultimately, identification of the molecular target(s) in developing thymocytes that are compromised by reactive drug metabolites will be needed to make this a convincing story.

Chapter 45

Infections in Systemic Lupus Erythematosus

Ellen M Ginzler

Olga Dvorkina

Infection is a major source of morbidity and mortality in patients with systemic lupus erythematosus (SLE). The literature includes anecdotal reports of sepsis from common and unusual organisms, as well as compilations of infections in both small and large series. Although the most frequent infections continue to be attributed to pyogenic organisms such as *Staphylococcus* sp. and *Escherichia coli,* opportunistic pathogens such as uncommon bacteria, deep-seated fungal organisms, viruses, and protozoans have been well described, including infection at multiple sites and multiple organisms at a single site. Features of SLE itself, including many forms of immunologic dysfunction, appear to play a role in an increased susceptibility to infection, which may be further affected by treatment modalities, such as corticosteroids and other immunosuppressive agents. At times, the actions of microbial agents on the host are difficult to differentiate from those of a lupus flare and, by themselves, may aggravate the disease. This chapter reviews infections in SLE, discusses differential diagnosis, and describes the infectious agents that most frequently are found in these patients.

SLE Mortality from Infection

In 1987, Hellmann et al. (1) reviewed mortality studies from a 40-year period. Among the 3,175 patients included in their report, there were 641 deaths, 170 (27%) of which resulted from infection. A fairly constant death rate caused by infection has persisted since the pre-antibiotic era of the 1930s to 1940s, when Klemperer et al. (2) attributed 40% of the deaths in their patients with SLE to infection, generally with pyogenic organisms. Even with advances in treatment of the underlying disease, a large U.S. multicenter study of 1,103 patients with SLE found that 33% of the 222 deaths were directly caused by infection, and infection was a contributing cause in an additional 10% (3). When clinical and demographic features such as age, socioeconomic status, and race were considered, the leading cause of death in all groups in a study by Reveille et al. of 389 patients from 1975 to 1985 in Birmingham, Alabama, was infection; 35 of 89 deaths (39%) were from this cause (4). In developing countries, such as Jamaica, infection has been the major cause of death among patients with SLE, being directly responsible for the fatal course in 20 of 55 patients (36%) at the University Hospital of the West Indies from 1972 to 1985 (5). Nossent (6) observed that 50% of the 22 fatalities in his series of 68 Caribbean patients with SLE who were treated between 1980 and 1990 also resulted from sepsis; 25% of those with fatal infections had only mildly active SLE at the time of death. Similarly, a 1993 report from Thailand documented infection as the cause of death in 23 of 77 patients with SLE from a cohort of 537, with opportunistic organisms and other common bacterial pathogens being implicated equally (7). In European and Asian series reported in the late 1990s, despite wide ranges in overall case fatality rates of 4.5% to 24%, the proportion of deaths attributed to infection was similar, ranging from 20.5% to 32.5% (8 ,9 ,10 ,11).

Rates of Infection in SLE

The incidence of infection in SLE is a reflection of overall morbidity, and it has considerable prognostic significance. In a series of 223 patients followed at Downstate Medical Center in New York from 1966 to 1976, 150 patients had 384 infections diagnosed over 655 patient-years, for an overall infection rate of 59 per 100 patient-years (12). The bacterial infection rate was 25 per 100 patient-years. The rate of nonspecific viral infections was 28 per 100 patient-years. Twenty-eight opportunistic infections were identified in 23 patients. Twelve had oral candidiasis, and 3 other patients with oral thrush also had evidence of systemic infection. Two of 11 patients with deep-seated fungal infections had multiple organisms at a single site, 2 had coincident bacterial infection at the same site, and 1 had a single fungal organism at two sites. In a Swedish epidemiologic study reported in 1985, Nived et al.(13) found an overall infection rate of 142 per 100 patient-years of SLE. More than one-half of these infections were of suspected viral origin, and approximately 40% were bacterial. A high incidence of mucocutaneous infections was noted, often caused by *S. aureus*.

The 1974 report of hospitalized SLE patients by Staples et al. (14) identified an overall culture-verified infection rate of 1.22 per 100 hospital days. The most common infection site was the urinary tract. Nearly one half of the patients who developed infections had multiple episodes, with recurrent sites frequently involving the opportunistic organism *Candida albicans*. A 1991 review of infections in hospitalized patients at the University of Toronto found an infection rate of 1.94 per 100 hospital days (15). Nearly one half of these infections were deemed to be major, requiring intravenous antibiotics; sites included pneumonia, septic arthritis, bacteremia, pyelonephritis, abdominal abscesses, endometritis, and esophageal candidiasis. In the U.S. multicenter lupus study, infections were responsible for 29% of all but obstetric hospitalizations (3), whereas 14% of the 1989 and 1990 hospitalizations in the Hopkins Lupus Cohort resulted from infection (16).

Factors Influencing Susceptibility of Patients to Infection

Many investigators have examined the risk factors that predispose to infection in SLE patients. Most agree that treatment with corticosteroids, as well as some manifestations of active SLE itself, play an important role. Staples et al. (14) found that the infection rate in hospitalized patients increased from 0.43 to 1.63 per 100 hospital days with an increase in steroid dose from zero to more than 50 mg/day. In the Downstate study, a fivefold increase in the frequency of all infections was found, ranging from 35 to 179 per 100 patient-years as average prednisone dose increased from zero to greater than 40 mg/day (12). The same trend was observed with bacterial infections (10/100 patient-years, increasing to 87/100 patient-years) and opportunistic infections (range, 142/100 patient-years). Recently Noel reported follow-up data in 87 SLE patients followed from 1960 to 1997. Thirty-five of 87 had at least one episode of infection. Risk factors for infection by univariate analysis were severe flare, glomerulonephritis, corticosteroids, cyclophosphamide, and plasmapheresis (17).

The physiologic and pharmacologic actions of corticosteroids predispose to infection by affecting host responses to micro-organisms. These include a decreased inflammatory response, decreased effector cell response in cell-mediated immunity, lysis of lymphoid follicles, and decreased immunoglobulin synthesis (18). Frenkel (19) reviewed the role of corticosteroids as predisposing factors in fungal diseases and concluded that inhibition of cellular host responses, particularly impaired proliferation of epithelioid and giant cells as well as decreased digestive capability of these cells and macrophages, was responsible. The role of steroids in the development of opportunistic infections was examined in a case-control study of 797 SLE patients hospitalized at Bellevue/NYU Medical Center; 26 patients with a total of 32 opportunistic infections were compared to 26 patients without opportunistic infections (20). Prednisone was a major risk factor for the development of opportunistic infection, with the most common organisms including *Salmonella, Candida, Strongyloides,* and *Aspergillus* sp. The mortality rate was highest among patients who had both opportunistic infection and active disease. The need to aggressively investigate the possibility of occult opportunistic infection was underscored by Hellmann et al. (1), who reviewed 44 lupus-related deaths at Moffitt Hospital in San Francisco between 1969 and 1986, where opportunistic infections occurred in 15 patients (35%) and caused death in 10. Antemortem diagnosis was made in only 3 of these 15 patients; *Candida* and *Pneumocystis* sp. were the most common organisms.

Prolonged corticosteroid administration further increases the risk of infection by causing chronic changes in tissues, such as skin atrophy, which in turn allow increased access of micro-organisms into the circulation. A regimen of alternate-day steroid administration is believed to decrease the pharmacologic risk of infection; this was confirmed in a 1993 Spanish study that showed a significant decrease in infection rate ($P > 0.001$) among patients receiving an alternate-day dose compared with those on daily steroids (21).

Other immunosuppressive agents, especially azathioprine and cyclophosphamide, also have been implicated as risk factors for infection in patients with SLE, frequently in anecdotal reports and in the setting of aggressive treatment for disease exacerbations (7 ,22 ,23 ,24 ,25 ,26 ,27). When corrected for steroid dose, however, azathioprine use in the Downstate population was not associated with an increased risk of bacterial, opportunistic, or nonspecific viral infections (12). A French study of cytolytic therapy in rheumatic disease failed to find an increased risk of infection, with the exception of herpes virus, which was associated with a 10% to 20% incidence of infection compared with 2% in patients not treated with immunosuppressive agents (28). Similarly, a prospective study of infections in hospitalized patients with SLE in Singapore did not show an association of cytotoxic therapy and infection (29). On the other hand, Aringer et al. (30) observed that 7 of 9 patients treated with plasmapheresis in addition to intravenous cyclophosphamide had serious bacterial or viral infections, compared to only 2 of 12 patients with serious infections in the cyclophosphamide alone group. Recent clinical trials suggest that infections are less frequent in patient treated with mycophenolate mofetil, as compared to cyclophosphamide (31).

Clinical Features and Immunologic Dysfunction in SLE as Risks for Infection

Even in the absence of corticosteroid treatment, infections are common in patients with SLE. Ropes (32) used steroids sparingly and rarely, if ever, gave immunosuppressive agents, yet 108 of 137 patients (79%) had serious infections during their disease course. These infections usually were

associated with disease exacerbations. In the Downstate study, new exacerbations of disease were associated with increased infection rates, but the correction for steroid dose eliminated this effect (12). This study also found that specific renal measures, most notably active urinary sediment, were a significant predictor of infection, whereas presence of the nephrotic syndrome and uremia were associated with an increased, but not statistically significant, incidence of bacterial and opportunistic infections. Among renal parameters, including blood urea nitrogen (BUN), creatinine clearance, urine sediment, and 24-hour protein excretion, Staples et al. (14) found BUN to have the strongest association with infection, suggesting that poor renal function is more important than active renal inflammation. Studies of hospitalized patients have shown that overall disease activity, measured by either the SLE Disease Activity Index (SLEDAI) or the Lupus Activity Index (LAI), correlates well with the incidence of infection (15 ,16).

Even among patients with SLE in clinical remission, an increased tendency to develop bacterial and opportunistic infections has been documented. Staples et al. (14) compared infection rates in SLE to those in patients with rheumatoid arthritis (RA) and idiopathic nephrotic syndrome, controlling for steroid dose. Infections were 10 times more frequent among patients with SLE than in the other two groups. In the population-based study by Nived et al., which included many mild cases, a significant increase in bacterial infections was observed among patients with SLE as compared to an age- and gender-matched cohort of patients with RA and to a similarly matched cohort of normal controls (13). The incidence of fungal and viral infections was similar in patients with SLE and controls.

Among patients with end-stage renal failure receiving chronic maintenance hemodialysis, the incidence and severity of infections continue to be influenced by underlying SLE. Jarrett et al. (33) found that 4 of 14 patients with SLE undergoing long-term dialysis at Northwestern University died of infection, compared with only 1 infectious death in 62 non-SLE patients on hemodialysis.

Many abnormalities, including immunoglobulin deficiency, acquired and inherited complement deficiencies, defects in chemotaxis, phagocytic activity, and delayed hypersensitivity, may account for this susceptibility to infection. As the prototype immune complex disease, activation and consumption of complement have been well characterized in SLE, and the role of specific complement components has been defined (34). For example, fixation of C3 to bacterial cell walls is essential for phagocytosis and subsequent digestion of micro-organisms. C3b, which is an activation product of C3, is critical to the opsonization of bacteria before phagocytosis. C3-deficient individuals therefore are at risk for recurrent and/or disseminated bacterial infections (35 ,36). Hereditary deficiencies in the production of various complement components also have been described in patients with SLE or lupus-like syndromes. Autosomal recessive defects in C1q, C1r, and C2 production and homozygous deficiencies of C2 have been associated with repeated skin and upper airway infections, recurrent *Haemophilus influenzae* septicemia, and bacterial meningitis (37 ,38 ,39). Recurrent pulmonary infections in a family with lupus-like disease has been linked to an autosomal recessive, human leukocyte antigen (HLA)-associated total deficiency of C4 (40). Granulocyte phagocytic function was found to be normal in these family members; however, a serum defect, which was corrected by the addition of purified C4, appears to have been responsible for the abnormal phagocytosis and intracellular killing. Deficiency of complement components C5 through C9 (i.e., the membrane attack complex) make individuals especially prone to infections with encapsulated organisms such as *Neisseria* sp., for which phagocytosis tends to be normal but bacterial lysis is impaired (41 ,42). Recently, homozygosity for variant alleles in the coding portion of the mannose-binding lectin (MBL) gene in patients with SLE has been shown to be associated with increased susceptibility to infections (odds ratio 8.6) (43). MBL is a serum protein structurally similar to C1q, which binds to antibodies and protein structures on bacteria and viruses. Homozygosity for MBL variant alleles was observed in 7.7% of SLE patients compared to 2.8% of controls by Garret et al. (43). Among homozygotes with SLE, the time interval from SLE diagnosis to the first infection was shorter, and the annual number of infections was four times higher than in patients homozygous or heterozygous for the normal allele (43).

Acquired functional defects in complement components that are associated with disease activity also have been described. Perez et al. (44) observed an increased incidence of infections in patients with SLE in whom they identified a serum inhibitor of C5-derived chemotactic activity. When levels of this inhibitor decreased as disease activity lessened, the incidence of infection also fell. A National Institutes of Health (NIH) report also correlated a decrease in serum generation of chemotactic factors with infection in 23 patients with SLE (45).

Other studies have found impaired in vitro antibacterial activity from alveolar macrophages obtained at bronchioalveolar lavage (46), decreased *S. aureus* intracellular destruction capability (47), impaired opsonic capability (48 ,49), and defective degradation of bacterial deoxyribonucleic acid (DNA) by phagocytes in patients with both discoid and systemic lupus (50), independent of steroid therapy.

Handling of micro-organisms also may be influenced by abnormalities of reticulo-endothelial function. Saturation of Fc receptors on liver and spleen cells by circulating immune complexes may prevent the clearance of opsonized bacteria (51). Fries et al. (52) demonstrated, however, that Fc receptors on the cell surface of monocytes from patients with SLE actually are increased in number, suggesting that a primary defect in Fc receptor function exists. Such a mechanism might explain the observations of overwhelming pneumococcal bacteremia (53 ,54) and the chronic *Salmonella* carrier state in some patients with

SLE, leading to *Salmonella* arthritis and osteomyelitis (55 ,56). Functional asplenia (i.e., the complete absence of uptake of intravenously administered, radiolabeled sulfur colloid unrelated to splenic size) has been identified in 7 to 10 of screened series of patients with SLE, and it has been implicated in the development of pneumococcal and salmonella septicemia (57).

Abnormalities of cellular immunity in patients with SLE appear to contribute to the risk of opportunistic infections. The incidence of herpes zoster is increased in patients with SLE compared to normal individuals; the rate among Japanese patients with SLE is especially high. Nagasawa et al. (58) found a 43% overall incidence of herpes zoster in their patients, with an annual incidence of 9%. Despite significantly higher antibody titers against herpes zoster than those seen in non-SLE subjects, only 30% of the patients with SLE showed positive delayed hypersensitivity skin reactions to varicella-zoster antigen. In contrast, 100% of normal individuals had a positive skin reaction.

Specific Types of Infection

Bacterial Infections

The most frequent sites for bacterial infections in patients with SLE are similar to those in individuals without lupus, including the urinary and respiratory tracts and the skin (12 ,13 ,14 ,59). The organisms most often cultured include *S. aureus, E. coli, Klebsiella* sp., and *Pseudomonas* sp. (13 ,29). In general, gram-positive cocci and gram-negative bacilli are most often implicated as an infectious cause of death (5 ,60). Bacteremia is common, especially in hospitalized patients with SLE (7 ,24); other sites of infection also have been well described and may account for some of the difficulty in distinguishing sepsis from exacerbations of SLE. For example, anecdotal cases of septic bacterial arthritis continue to be reported (52 ,55 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70). Bacterial seeding resulting in septic discitis may put a patient at risk for serious neurologic deficit (71). Bursal abscesses also may mimic musculoskeletal problems such as sciatica (72 ,73). Hung reported 17 cases of CNS infection during a 20-year follow-up of 3,165 patients with SLE. Ten cases were a result of *Cryptococcus neoformans,* 4 *Listeria monocytogenes,* 2 *Streptococcus pneumoniae,* and 1 *Enterobacter aerogenes*. An active flare of lupus was present in 94% of the cases at the time of CNS infection (74).

Commonly diagnosed bacterial organisms, even among otherwise healthy individuals, appear to occur more frequently in unusual locations in patients with SLE. Purulent pericarditis is a rare phenomenon, yet it has been described in at least 14 patients with SLE, most often resulting from *Staphylococcus* sp. (75 ,76 ,77), and in one case which resulted in tamponade being caused by *N. gonorrhoeae* (60). Bacterial epiglottitis, facial cellulitis, and multiple soft-tissue abscesses have been described as well (78 ,79 ,80).

Opportunistic bacterial infections also occur with increased frequency in patients with SLE. Among the most common are *Salmonella* sp., especially *S. typhimurium* and *S. enteritidis* (55 ,56 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95). Occasionally *Salmonella* infection can coincide with the initial presentation of the disease, and aspects of the infection can mimic features of SLE (79 ,82). Hospitalized lupus versus nonlupus patients have an increased risk for *Salmonella* infections (80), which can manifest not only as diarrheal illnesses but also as gas-producing leg abscesses (84), septic arthritis (55 ,56 ,85) especially at sites of former avascular necrosis (95), osteomyelitis (85 ,86), and spondylodiscitis (87). Patients with glomerulonephritis may have an increased susceptibility to becoming *Salmonella* carriers (55).

Infection with *Listeria monocytogenes* is uncommon in healthy adults, occurring predominantly in young children, the aged, and immunocompromised individuals. In two series of seven and eight patients with SLE, listerial infection usually presented as meningitis or bacteremia without a known focus, and it most often was associated with active disease, high-dose prednisone with or without other immunosuppressive drugs, or renal failure (25 ,96). Despite aggressive antibiotic therapy, a fatal course is not uncommon (26).

Active tuberculosis can mimic the manifestations of SLE, thus delaying diagnosis and appropriate treatment. Feng and Tan (97) found tuberculosis in 16 of 311 patients with SLE (5%) who were followed in Singapore between 1963 and 1979. Presentation with miliary (98) and far-advanced pulmonary disease was common. Seven of the Singapore cases were fatal, five of which were attributed directly to mycobacterial infection. A recent study from Korea reported tuberculosis in 15 of 283 SLE patients, associated with a high incidence of extrapulmonary and miliary involvement (99). Mok et al. noted 91 episodes of TB among 76 patients in a cohort of 652 SLE patients; 39.6% of cases had extrapulmonary involvement. Isoniazid (INH) prophylaxis was given in 33 of the 76 patients. Those receiving INH prophylaxis had a slightly lower recurrence of active tuberculosis, but a higher rate of subsequent SLE flare (100). The role of INH prophylaxis remains controversial, especially in endemic areas. Gaitonde studied 95 patients with SLE, of whom 70 were able to continue INH for at least 2 years. The incidence of active tuberculosis in his cases decreased from 11 to 2%. There were no reported deaths as a result of active tuberculosis or toxic hepatitis (101).

Atypical mycobacterial infections have been reported rarely in patients with SLE and tend to be limited to the skin (102 ,103 ,104). The presentation may mimic lupus profundus, delaying appropriate diagnosis and treatment.

Other unusual bacterial infections reported in patients with SLE include five cases of Legionnaires disease (105 ,106 ,107 ,108), *Campylobacter endocarditis* (109), toxic shock syndrome (110), *Pseudomonas pseudomallei* meningitis (111), and a documented tick bite with high antibody levels against *Borrelia burgdorferi* that coincided with the initial presentation of lupus (112). A 1992 report suggested that genitourinary colonization with mycoplasma organisms is

common in women with SLE, documenting 22 of 49 urine specimens (63%) to be culture positive for *Ureaplasma urealyticum* or *Mycoplasma hominis* (113). It also should be remembered that althouugh false-positive serologic tests for syphilis are an expected feature of SLE, concomitant infection with *Treponema pallidum* may occur (114), sometimes with signs and symptoms that may mimic those of active SLE (115). Distinguishing false-positive from true-positive serologic tests for syphilis in SLE patients has been problematic in part because of interference with the presence of antiphospholipid antibodies; the fluorescent treponemal antibody absorption (FTA-ABS) test is not considered to be an accurate confirmatory test for syphilis in such patients. Murphy et al. have proposed the treponemal Western blot test as the gold standard, based on its combination of sensitivity and specificity (116).

Viral Infections

Herpes zoster is the most common specific viral infection that is diagnosed in patients with SLE. In Western countries, its reported incidence ranges from 3% to 21% (12 ,117 ,118 ,119 ,120), which is somewhat increased over that observed in the general population (22) but considerably less than the 43% incidence diagnosed among Japanese patients with SLE (58). Treatment with corticosteroids and cytotoxic agents significantly increases the risk of herpes zoster; however, 65% of zoster episodes in Kahl's 1994 series occurred during mild or inactive SLE (119). In each of two series, dissemination occurred in 11% (118 ,119). Two reports of CNS herpes zoster mimicking active lupus have appeared (120 ,121); in one, visual loss and an unusual pattern of retinitis developed. Endoretinal biopsy established the diagnosis of herpesvirus infection, and the patient was successfully treated with acyclovir (121). Herpes simplex also is common in SLE and is particularly associated with esophageal and perianal lesions (122 ,123). If untreated, disseminated infection may progress to hepatic necrosis, coma, and death (124). Even in the absence of clinical manifestations of infection, antibody titers indicative of herpesvirus-6 infection were found in 55% of 56 patients with SLE in a 1991 study (125).

Cytomegalovirus (CMV) is uncommon. The usual presentation is pulmonary infection, which may be fatal (126 ,127 ,128). CMV has been identified in active SLE in the absence of immunosuppressive therapy (129), and unusual presentations including cutaneous vasculitis have been reported (130).

The role of human papilloma virus (HPV), which has been implicated in causing clinical disease ranging from warts to malignancy, has been examined in SLE. HPV titers were elevated in 45% of patients with SLE (compared to 12% of controls), in a 1977 study (131). Although a high prevalence of cutaneous warts did not correlate with immunosuppressive treatment in a 1993 series (132), an increased risk of uterine cervical atypia in women with SLE receiving cytotoxic agents was observed (133), and this in turn has been linked to a predisposition to infection with HPV, which may induce oncogenic mutations (134).

The association of parvovirus B19 (HPV-B19) with SLE is controversial. Especially in the pediatric population, presentation of the two diseases may be strikingly similar. Moore et al. described 6 of 7 children with HPV-B19 infection who had malar rash (the classic “slapped cheek” erythema) and positive antinuclear antibodies in titers of 1:40 or greater; all had prolonged arthralgias and fatigue (135). Although the overall course was generally self-limited, some patients had symptoms for up to 120 weeks. Although it has been suggested that HPV-B19 infection may actually trigger SLE (136), Bengtsson et al. found no evidence that HPV-B19 infection was more prevalent among 99 SLE patients (88% of all new cases seen from 1981 to 1995 in a specific health care district in Sweden) compared to age- and sex-matched healthy controls (137). (See the differential diagnosis section in Chapter 51 for a discussion of infection with human immunodeficiency virus and SLE).

Fungal Infections

Candida infection is a common complication in patients with SLE, most often presenting with oral thrush (12). Extension to the esophagus with mucosal invasion occurs in association with steroid and cytotoxic therapy. Peripheral blood lymphocytes from patients who are receiving high doses of prednisone have been shown to have markedly depressed in vitro lymphocyte transformation to antigenic stimulation by *Candida* sp. (138). One half of the patients with esophageal moniliasis do not have oral lesions (139 ,140). Esophageal candidiasis may co-exist with herpes simplex (122).

The development of deep fungal infections in SLE patients is generally associated with corticosteroid and immunosuppressive therapy, and is most often a result of *Candida* sp. or cryptococcus (141), frequently with a fatal outcome. Reports of visceral candidiasis include pericarditis with tamponade (142) and hepatic involvement (143). Cryptococcal infection is not uncommon and usually produces a terminal meningitis, with or without pulmonary changes (144 ,145 ,146 ,147 ,148). An insidious onset of persistent headache often is the earliest manifestation. It may also present with hepatic (149) or cutaneous (150) involvement. Zygomycosis (formerly known as “mucormycosis”) is a severe infection that has been associated with CNS complications, thrombotic thrombocytopenic purpura, and a high mortality rate (151 ,152 ,153). Infection with *Aspergillus* sp. Most often involves the lungs (143 ,154 ,155), presenting with fever and cough in an immunosuppressed patient. The finding of hyphae in the sputum should be confirmed with a tissue diagnosis demonstrating budding hyphae; long-term therapy with amphotericin B and/or fluorocytosine or itraconazole may improve survival. Fatal aspergillus meningitis (156) and septicemia (22 ,157) also have been documented in patients with SLE. Coccidioidomycosis has

been reported in four patients as a complication of steroid-treated lupus (158 ,159 ,160 ,161). Other documented fungal infections in SLE include nocardia of subcutaneous tissues, pneumonitis, laryngitis, encephalitis, and meningitis (162 ,163 ,164 ,165 ,166 ,167 ,168 ,169), disseminated histoplasmosis (170), and maduromycosis (171).

Parasitic Infections

Hyperinfection with *Strongyloides stercoralis* may occur in immunosuppressed patients. The syndrome is characterized by profound malabsorption, diarrhea, electrolyte disturbance, gram-negative or opportunistic fungal sepsis, coma, and death. It can mimic an SLE flare, and eosinophilia may be absent as a result of steroid treatment (172 ,173). Visceral leishmaniasis has been reported in one SLE patient (174), as has paragonimiasis (175).

Protozoan Infections

Pneumocystis carinii pneumonia (PCP) has been reported in patients with SLE since the 1960s, almost exclusively in the setting of aggressive treatment of active disease with high-dose corticosteroids and cytotoxic drugs (1 ,12 ,14 ,27 ,126 ,176 ,177 ,178 ,179 ,180 ,181 ,182). Porges et al. found that an additional important risk factor for PCP was severe lymphopenia; four of six patients in their series had lymphocyte counts of less than 350/mL (27). This is consistent with a single reported case of PCP in an untreated patient with SLE and severe lymphopenia (183).

Toxoplasmosis has been found in neonates with SLE (178) and in both lymphopenic (184) and immunosuppressed (185) patients. It may be difficult to identify, because the symptoms of CNS infection mimic lupus cerebritis (186), whereas false-positive antibody titers can be seen in patients with SLE (187). Further, toxoplasma infection may enhance the production of autoantibodies, which may interfere with the standard dye test that is used for diagnosis (188).

Immunization and Antibiotics

See Chapter 61 .

A Practical Approach to Infection in SLE

Despite case series and anecdotal reports of unusual infections, each patient with SLE must be considered individually when infection is suspected. There is no “cookbook” approach to diagnosis and treatment; however, a number of important principles can provide guidance in determining a plan of action:

- Patients with SLE develop community-acquired infections just like individuals in the general population. Especially with classic or usual presentations, common bacterial and viral infections should be high on the list of differential diagnoses. Appropriate treatment of these common infections should help to avoid the risk of toxicity (often potentiated by renal or hematologic abnormalities resulting from active lupus) from unnecessary antimicrobial agents.
- Because the symptoms of SLE and of infection often are similar, a high index of suspicion is important; therefore, culture early and often. Advise the laboratory to hold specimens for fungal cultures, and freeze acute serum to match with convalescent serum in the event that antibody titers may be useful.
- Although corticosteroids and cytotoxic agents increase the risk of infection, it is equally true that sick patients with active lupus are far less likely to recover from serious infections. Once a patient has been placed on an appropriate regimen for the suspected or documented infection, treatment of the underlying SLE activity should proceed with vigor.
- In difficult or recalcitrant cases, especially with persistent fever or increasing organ dysfunction (e.g., hepatic abnormalities, pulmonary infiltrates), a tissue diagnosis may be essential. Percutaneous or endoscopic biopsy procedures may be sufficient, but open surgical procedures may be necessary. These may be guided by radiographic procedures (e.g., computed tomography, magnetic resonance imaging) or by nuclear imaging (e.g., bone scans for suspected osteomyelitis).

Summary

To summarize the major points of this chapter:

- Infections are a major source of morbidity and mortality in patients with SLE.
- Patients with SLE are susceptible to infection; treatment with corticosteroids increases this susceptibility in a dose-dependent fashion.
- The respiratory and urinary tracts are the most common sites of infection in outpatients.
- Patients on steroids are at a particularly increased risk for opportunistic infections. The most common organisms include herpes, Candida sp., Salmonella sp., Cryptococcus sp., and Toxoplasma sp.
- Presentations of SLE often are difficult to differentiate from those of infection. The most helpful clues to infection are the presence of shaking chills, leukocytosis (unless steroids are being given), and the absence of active SLE in multiple systems.

Chapter 46

Serum and Plasma Protein Abnormalities and Other Clinical Laboratory Determinations in Systemic Lupus Erythematosus

Daniel J. Wallace

The serum protein electrophoresis is an inexpensive test that can reveal increased or decreased levels of proteins in lupus patients, as well as screen for a variety of manifestations of the disease. The overwhelming majority of papers on this subject were published 30 to 40 years ago and the reader is referred to Chapter 44 of the 6th edition for a critical review of them. Table 46-1 lists the most important proteins germane to systemic lupus erythematosus (SLE). This chapter summarizes important abnormalities of clinical relevance and also reviews sedimentation rate, C-reactive protein, and blood viscosity, which are not covered elsewhere.

Hypoalbuminemia

Low serum albumins were first detected in SLE by Colburn and Moore in 1943 (1), and are present in 30% to 50% of patients (2 ,3 ,4 ,5 ,6 ,7). The most common cause is chronic disease, and the catabolic rate of albumin is increased in active SLE (8). Other associations include nephritic syndrome, protein-losing enteropathies, and malnutrition seen in lupus.

α Globulins

α_1 and α_2 globulins are acute phase reactants and are elevated with inflammation. These glycoproteins are made in the liver and defend against cellular injury. They are increased in 8% to 33% of lupus patients at any visit (4 ,5 ,6 ,9 ,10). Specific components include:

- α_1 acid glycoprotein—also known as orosomucoid is elevated in most lupus patients at some time in the course of their disease (11 ,12 ,13 ,14 ,15).
- α_1 Feto protein—increased in most pregnant women with SLE without associations with neural tube defects (16).
- α_1 Antitrypsin—the dominant protease inhibitor in plasma, and not associated with any phenotype in SLE. Studies suggest normal or slightly increased levels (13 ,17 ,18 ,19 ,20 ,21).
- α_1 Antichymotrypsin—one study suggests increased levels (13).
- Lactoferrin and neutrophil elastase—increase in one study (22).
- Ceruloplasmin—both an acute phase reactant and carrier protein, it was increased by 20% to 40% in lupus patients in a single study (11).
- Haptoglobin—decreased with hemolysis (see Chapter 41).
- α_2 Macroglobulin-Ha-glycoprotein—a protease inhibitor that is elevated in SLE (18 ,23 ,24).

β Globulins

Most β globulins relate to serum lipids, which are dysfunctional in SLE and influenced by corticosteroids. See Chapter 19 for a review of this subject. Complement is discussed in Chapter 13 and coagulation abnormalities in Chapter 27 . Transferrin, a beta globulin carrier molecule, is normal to decreased in lupus patients (11 ,17) and β_2 macroglycoprotein has been associated with SLE (25).

β_2 microglobulin is a single-chain polypeptide (molecular weight, 11,800 daltons) that is found on the surface of most nucleated cells, especially T and B lymphocytes. A normal constituent of serum that is catabolized by the kidney, it is associated with the light chains of class I human leukocyte antibody (HLA) antigens. Its serum values increase slightly with age and are elevated with decreased glomerular filtration rates and various rheumatic diseases. In SLE sera, anti-β_2-microglobulin antibodies inhibit in vitro mitogenic stimulation and lymphocyte proliferation (26). Eight well-designed studies have evaluated its clinical

importance in SLE (27 ,28 ,29 ,30 ,31 ,32 ,33 ,34), and all came to similar conclusions. Overall, it has a 64% sensitivity and 87% specificity for assessing disease activity when compared to healthy controls. β_2 microglobulin levels are increased with active disease, nephropathy, low C3 complement levels, elevated sedimentation rates, and anti-DNA. Its highest levels are seen in lupus nephritis, although azotemia with inactive disease also can result in larger values.

Table 46-1: Relevant Plasma Proteins in Systemic Lupus Erythematosus

Albumin
Globulin
α_1 Globulins
  α_1 Acid glycoprotein
  α_1 Fetoprotein
  α_1Antitrypsin
  α_1 Antichymotrypsin
  Neutrophil elastase
  Lactoferrin
α_2 Globulins
  Ceruloplasmin
  Haptoglobin
  α_2 Macroglobulin-Ha-glycoprotein
β_2 Globulins
  Transferrin
  β_2 Macroglycoprotein
  β Lipoproteins
  β_2 Microglobulin
  Complement components
  Prothrombin, fibrinogen, plasminogen, and other clotting factors
λ Globulin
  Paraproteins
  Cryoglobulins
  IgG
  IgM
  IgA
  IgD
  IgE

γ Globulins

A broad polyclonal elevation of the γ globulin fraction is a hallmark of autoimmune reactions, and if present should alert the clinician that the patient has an immune problem. It is seen in 8% to 77% of lupus patients, in our clinical practice a polyclonal gammopathy is present in 30% (4 ,6 ,9 ,10 ,35 ,36). Marked acquired hypogammaglobulinemia is present in less than 1% with SLE and is associated with recurrent infections (37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45); it can stem from marrow suppression, medication, or inflammation.

Serum Immunoglobulins

Immunoglobulin G and Its Subclasses

Mean serum levels of immunoglobulin (Ig)G are increased in patients with SLE compared to those in healthy controls (46). Evidence that this increase is polyclonal stems from the observation that isolated IgG elevation occurs in only 9% of patients with SLE (47). The IgG level tends to be elevated at diagnosis but normalizes with therapy. At any time, IgG was increased in 23% of 39 patients followed serially (48).

Levy (49) studied the mean survival half-life for IgG in patients with SLE. It averaged 8.2 days, compared with an average of 28 days in normal controls. An average of 10.1% of total-body IgG was catabolized daily, compared with a mean of 3.9% in normals. Despite normal serum IgG concentrations in patients with SLE, their synthetic rates were as much as four to five times normal, revealing far greater IgG antibody production in SLE than suggested merely by serum concentration. In a long-term serial study at the National Institutes of Health (NIH), 18 patients developed low IgG levels during the course of their disease, but it was transient in 110. Also, four developed recurrent infections. Excessive T-cell suppressor and decreased B-cell activity characterized this subset (50). Ward et al. (51) were unable to correlate IgG levels with age, sex, race, or duration of disease.

Several centers have evaluated patients with SLE for IgG subclasses. Among 20 children, significantly increased IgG1 and IgG3 subclasses were present, along with decreased IgG4; 48 adults with SLE had decreased IgG2 and IgG4 levels (52). Low IgG3 and IgG4 levels correlated with an increased rate of infection (53). Decreased IgG2 levels were found among 15 patients with SLE in Isenberg et al. (54), compared with 20 controls. In another report, an increased IgG1 level was associated with a subgroup of patients having high-titer rheumatoid factor, antinuclear antibody, and low levels of anti–double-stranded DNA (55).

Immunoglobulin M

Elevated mean IgM levels were found by Alarcon-Segovia and Fishbein (46) in 481 serum samples from 106 patients compared with those from 106 controls. Schoenfeld et al. (48) noted that the IgM level often was decreased at diagnosis but normalized later. In 39 patients followed serially, the IgM level was elevated at any time in 18%. Three other large-scale studies found that very low IgM levels (>2 standard deviations [SD] below the mean) could be found in 20% of over 200 patients with SLE (56 ,57 ,58). Low IgM levels tended to correlate with disease duration but not with activity (51). Survival studies of IgM in SLE show a normal half-life (49).

A 7S β-M-globulin occurs in SLE, RA, and in the cord blood of apparently normal infants, but it is absent in

normal human adult sera (59). This fraction was found by Rothfield (60) in 8 of 53 patients with SLE, 4 of whom were males, and in 32% of 31 men with SLE by Kaufman et al. (61). Low molecular weight IgM as a monomeric subunit probably comprises approximately 15% of the total IgM seen in patients with SLE (62).

In the hyper-IgM syndrome, patients have low IgG, IgA, and IgE with recurrent infections. The X-linked form is caused by mutations in the gene for CD40 ligand, and this has been reported in SLE patients (63).

Immunoglobulin A

IgA deficiency is found in from 1 in 400 to 1 in 3,800 adults. It has been observed in 3 of 72, 3 of 96, 0 of 181, 5 of 96, and 7 of 102 patients with SLE in five reports (64 ,65 ,66 ,67 ,68), which suggests an increased incidence of this uncommon finding. Men and those with antibodies to Sm and La may have an increased incidence of IgA deficiency in SLE (61), as may Afro-Caribbeans (67 ,68). Although the serum IgA level usually is normal or slightly elevated in SLE (46 ,47 ,57), elevations of IgA were found in 30% of patients during the course of disease in one study (48). Saliva γ A or secretory IgA levels may be reduced in patients with SLE and frequent attacks of respiratory disease (68). Blacks with SLE may have a higher IgA2 level than whites (69).

Immunoglobulin E

Increases in IgE levels may correlate roughly with disease activity in lupus erythematosus (LE) (70 ,71 ,72 ,73 ,74). Elevations of serum IgE are also associated with IgE isotype antinuclear antibody in those without signs of allergy and in males. IgE production is contributed to by DNA hypomethylation and enhanced by estrogens (74 ,75 ,76). Four cases of hyper-IgE syndrome, one following carbamazepine administration, have been reported in patients with SLE (77 ,78 ,79 ,80). A hyperimmunization phenomenon might by contributory to high IgE levels. (Chapter 67 reviews the relationship between IgE, lupus, and allergies.)

Monoclonal Gammopathies, Paraproteinemia, and Paraproteinuria

When ordering a serum protein electrophoresis, 2% to 4% of lupus patients will demonstrate a monoclonal gammopathy of unknown significance (MGUS). A long-term follow-up of 1,384 patients with MGUS at the Mayo Clinic suggested that 12% evolve myeloma, lymphoma, leukemia, amyloid, or macroglobulinemia over 10 years (81). Individuals with lupus and Sjögren syndrome should have a protein electrophoresis done every 6 to 12 months, since they have an increased risk of developing one of these complications. Cryoglobulinemia is reviewed in Chapter XX.

Of 415 patients with SLE followed in Toronto, nine (2.2%) had evidence of paraproteinemia (82). The monoclonal proteins were IgG (in 6 patients), IgA (in 2), and IgM (in 1). None had myeloma, and no consistent patterns could be discerned. Porcel et al. (83) noted a monoclonal gammopathy in 4 of 120 patients with SLE (3.3%). Approximately 30 cases have appeared in the literature (84). Characterized as transient, stable, or increasing, they are almost always benign. Kappa/lambda ratios for serum IgG, IgA, and IgM in 40 patients with SLE were not different from those in healthy controls (85).

Unbound free urinary light chains are increased in lupus nephritis and represent quantitative markers of concurrent in vivo immunoglobulin synthesis and secretion (86 ,87 ,88). Tsai et al. (89) observed free κ chains in 36% and free λ chains in 43% of 23 patients with active lupus nephritis but in none of the patients with inactive lupus nephritis.

Sedimentation Rate

Elevation of the sedimentation rate has been noted in 54% to 94% of lupus patients (7 ,9 ,90) and significantly associated with fevers, fatigue, alopecia, myalgias, and greater disease activity when elevated (7). Among 163 Italian SLE patients, the mean Westergren sedimentation rate was 37.26 ± 14.21 (1 SD) (91). Sedimentation rates can be high, with no obvious clinical activity, and normal with active disease. They usually are helpful in following the subset of patients for whom its rise and fall reflect other clinical and laboratory parameters. A recent study correlated sedimentation rate with disease activity and damage accrual among 450 patients (92). Occasionally, very high sedimentation rates in the absence of other findings lead to the performance of tests that ultimately result in the diagnosis of SLE (93).

The rapid sedimentation rate is partially attributable to the tendency of red cells to clump and form rouleaux, often because of the associated abnormal antibodies in SLE. When the Wintrobe method is used, rapid falling occasionally occurred, and the final value often was limited by the hematocrit. The Westergren method is more precise. (An excellent review of the subject can be found in Bedell and Bush (94)).

C-Reactive Protein

Why might C-reactive protein be important in lupus?

C-reactive protein (CRP) is a serum component that binds to pneumococcal C-polysaccharide. It is composed of five identical nonglycosylated polypeptide units of 187 amino acid residues (pentraxin proteins) each that are noncovalently associated in a disk-like configuration. CRP is synthesized by hepatic parenchymal cells, weighs 120,000

daltons, and circulates in the γ globulin fraction. It can act as an opsonin or agglutinin, and it mediates phagocytic activities while inhibiting immune responses. A putative evolutionary homology with immunoglobulin, complement, and human leukocyte antigen has been suggested (95). It activates complement inhibits cytokine production and generates T-suppressor cells, binds to phospholipids on damaged cell membranes, reacts with chromatin, and small nuclear ribonucleoprotein (snRNP) particles exposed in the setting of tissue injury with apoptosis. The latter might facilitate their same, nonimmunologic disposal and marks them for killing by phagocytes and complement. In mice expressing a human CRP transgene, CRP (in the presence of IL-10) protects against SLE by increasing blood and mesangial clearance of immune complexes (96 ,97 ,98 ,99 ,100 ,101 ,102).

Clinical Studies in SLE

First described as being elevated in patients with SLE and infection by Hill (103) in 1951, other reports using older methodologies of ascertainment suggested that it was an accurate test for active SLE (104 ,105 ,106 ,107). Enthusiasm peaked in 1980 when an editorial in the journal *Arthritis and Rheumatism* suggested that it might be a good American Rheumatism Association classification criterion for SLE (108). Other studies, however, found the CRP level to be useful for neither SLE nor infection (109 ,110). It soon became apparent that older methods for determining the CRP level were not accurate when rheumatoid factor also was present. Using the more reliable radioimmunodiffusion assay, Rothschild et al. (110) noted it to be elevated in 56% of 52 patients with SLE, with or without infection. It vaguely correlated with clinical activity but not with any organ system involvement, except for leukopenia. Bertouch et al. (111) observed elevated CRP levels in 55 of 70 patients with SLE; it was very high in 13, none of whom had infection. Morrow et al. (112) noted that CRP was present in 59% of 27 patients with SLE, especially in those with active disease. Zein et al. (113) found it in some patients without obvious explanation and observed numerous disease exacerbations in patients without any CRP changes. In another survey, only 9% of 34 patients with SLE had an elevated CRP level (114).

Pepys et al. (115) reviewed the subject at length, following sedimentation rates and CRP binding in 429 measurements involving 124 patients with inactive, mildly active, and active SLE, and in SLE with infection. It is clear that the mean CRP level is not elevated, or is only slightly elevated, in the first three categories, but it is high with infection. Mean CRP levels were significantly greater than sedimentation rates with infection but significantly less with active disease. The CRP levels in individual patients with active disease or infection, however, ranged from absent to high. In other words, CRP was not useful in individual cases, although the mean values in patient groups were significantly elevated. The only positive conclusion that can be reached is that if the CRP level is very high (>60 mg/L), the chances of infection are greater which has been confirmed by others (116 ,117 ,118 ,119), although Middleton et al. (120 ,121) have disputed this CRP values are high in those with RA and the seronegative spondyloarthropathies, but they are only modestly elevated in those with systemic vasculitis. Williams et al. found high levels with renal involvement (122).

Nearly half with SLE have autoantibodies to CRP, especially if anti DNA is present (123 ,124). High sensitivity CRP is only a rough guide to disease activity (125).

In conclusion, CRP is a misunderstood test of disease activity that is neither sensitive nor specific in SLE. It may be of some value, however, for ruling in infection and may be of future importance as an immune suppressive adjunct in the disease's management.

Viscosity

Viscosity is an important determinant of blood flow. Plasma viscosity can be increased by elevations of high molecular weight globulins, such as fibrinogen and immunoglobulin. Four studies have shown that patients with SLE have slightly increased levels when compared to control groups (34 ,114 ,126 ,127 ,128 ,129). Rosenson et al. correlated blood viscosity with a higher SLICC/ACR Damage Index (130). Rarely, complexes of IgG, and especially IgM rheumatoid factor, produce high levels of plasma viscosity and a clinical syndrome resembling that found in Waldenström macroglobulinemia. This so-called hyperviscosity syndrome has been observed infrequently in SLE, and it is an indication for emergency plasmapheresis and steroid therapy (131 ,132 ,133).

Miscellaneous Laboratory Abnormalities, Connective Tissue Components, and Trace Metals

Connective Tissue Components

SLE is characterized by striking changes in the amorphous ground substance of tissues. Consisting largely of hyaluronic acid and chondroitin sulfuric acid, hexosamine constitutes approximately 40% of each of these mucopolysaccharides, and human serum contains definite amounts of bound hexosamine as glucose and galactosamine. Serum levels of hexosamine were increased in active disease in one report that followed 19 patients serially (134). Free and bound glycosaminoglycans, which consist mostly of slow sulfated chondroitin 4-sulfate, also are elevated with active disease (135). Additionally, serum immunoreactive prolyl hydroxylase is an acute-phase reactant in SLE, and its increased levels may reflect greater connective tissue disease metabolism (136). On the other hand, serum sulfhydryl and serum histidine levels decrease in active disease (114 ,137). Urinary sialylated saccharides, serum sialic acid, and serum amyloid A protein may act as acute-phase reactants in SLE as well, but is disappointing (138 ,139 ,140). Serum laminin P1 is one of

the glycoproteins of basement membranes is found in high amounts with active disease (141 ,142). Calprotectin (L1), which is a granulocytic and monocyte cytosolic protein released during activation of these cells, is said to be elevated in SLE (143 ,144).

Trace Metals

Zinc and selenium levels are normal in SLE (145).

Other Putative Markers of Disease Activity

A marker for adenocarcinoma, CA 19.9, also can be increased with inflammatory joint disease (146), as can the ovarian cancer marker CA 125 (147 ,148 ,149). Several studies have suggested that serum thrombomodulin, a marker for endothelial cell injury, correlates with vasculitis and SLE activity (150 ,151 ,152 ,153 ,154 ,155 ,156). Nerve growth factor may be elevated in SLE as well as in RA (157 ,158). Serum levels of a cytoplasmic enzyme in the pyrimidine salvage pathway, cytidine deaminase, and the enzyme for purine nucleosides, adenosine deaminase, are increased with active lupus as well (159 ,160 ,161 ,162 ,163). Endothelin-1 is a vasoconstrictor peptide that is present in active SLE in the plasma in high concentrations and may correlate with vascular injury and/or pulmonary hypertension (164 ,165), as are serum levels of the lysosomal enzyme ß-glucuronidase (166) and the serine exoproteinase dipeptidyl peptidase IV (167). Single reports have claimed that cathepsin D activity (168) and plasma neopterin (169 ,170 ,171), ferritin (172 ,173 ,174), soluble vascular cell adhesion molecule-1 (VCAM-1) (175), tyrosine kinase receptor (176), matrix metalloproteinase-3 or 9 (177 ,178 ,179), serum levels of HLA class I antigen (180), katacalcin (181), serum leucine aminopeptidase (182), serum 3-nitrotyrosine (183), and plasma thrombospondin levels (184) are increased in SLE. Serum procalcitonin is increased in early infections in SLE (185) as is serum and urine nitrate and citrulline (186).

Summary

- Hypoalbuminemia occurs in patients with SLE and active disease, particularly nephrosis. Following serum albumin levels serially is of prognostic value.
- Both α_1- and α_2-globulins include acute-phase reactants that are increased and carrier proteins that are decreased in active SLE.
- The IgG level is elevated with disease activity in patients who are not on steroids or immunosuppressive drugs. Its turnover is greatly increased. No IgG subclass is characteristic, and the IgM level is consistently decreased in 20% of patients.
- Sedimentation rates are elevated with active SLE; disease activity thus can be followed in a subset of patients. In some patients, the sedimentation rate does not correlate with disease activity. The CRP level usually is normal or slightly elevated in SLE; high levels should raise suspicions of infection.
- $ß_2$-Microglobulin levels generally are increased in active SLE, especially if renal disease is present.
- Although plasma viscosity is slightly increased in SLE, hyperviscosity syndrome is an extreme rarity.

Chapter 47

Clinical Indices in the Assessment of Lupus

Jennifer Grossman

Caroline P. Gordon

Systemic lupus erythematosus (SLE) is a heterogeneous disease with waxing and waning manifestations. As such, the assessment of SLE is complicated and needs to encompass a variety of domains. In 1998, OMERACT (outcome measures in rheumatoid arthritis clinical trials) evaluated 21 different domains that were candidates for inclusion in clinical trials of SLE (1). They concluded that a minimum of four domains were necessary. Broadly the domains specific to lupus can be described as disease activity, damage, and quality of life. Disease activity is a measure of the reversible manifestations of the SLE, whereas damage represents irreversible changes. Quality of life represents the functional ability of the patient and includes a variety of domains including physical and social function. The fourth domain proposed by OMERACT is toxicity and adverse events. This chapter will focus on the development and characteristics of the instruments used to assess these different domains.

Disease Activity

More than 60 different instruments have been developed to assess disease activity in lupus. To date, there has been no agreement as to the “gold standard” in this field. The more commonly used measures, in order of date of publication, include the British Isles Lupus Assessment Group index (BILAG) (2), the Systemic Lupus Activity Measure (SLAM) (3), the Lupus Activity Index (LAI) (4), the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) (5), the European Consensus Lupus Activity Measure (ECLAM) (6). A key feature of all of these instruments in addition to the focus of active SLE as opposed to damage is the attribution of the manifestations to SLE. Although they are all valid, reliable, responsive indices that have been shown to correlate with each other (7), there are significant differences that will be reviewed.

British Lupus Isles Assessment Group index (BILAG)

BILAG was developed using a nominal consensus approach by a group of investigators from five centers in the United Kingdom and was first published in 1988 (2). The instrument scores the activity in eight organ-based systems occurring in the preceding month. It is based on an intent to treat principle and uses the following ratings:

- A—Action (severe disease that would warrant increased prednisone at more than 20 mg a day or the addition of other immunosuppressants)
- B—Beware (less active disease that would be treated with low-dose prednisone, nonsteroidal anti-inflammatories or antimalarials)
- C—Contentment (mild stable disease with no change in therapy or simple analgesics)
- D—(system unaffected)

The organ-based systems include general features, mucocutaneous, neurologic, musculoskeletal, cardiorespiratory, vasculopathy, renal, and hematologic. Immunologic abnormalities are not included in this index. Although not originally derived to be a global score, a weighted system where an A = 9, B = 4, C = 1, and D = 0, was devised to yield a total score of all the organ systems ranging from 0 to 72 (8). This was later revised to A = 9, B = 3, C = 1, D = 0, and E = 0 (version 3).

The initial BILAG has undergone a series of revisions. BILAG (version 2) included modifications of some features of the original BILAG that were found to have poor face validity such as small fluctuations in blood pressure. Liang et al. evaluated this version and found good reliability both within and between raters and good correlation with other measures of disease activity (3).

Hay et al. validated BILAG (version 3) (9). Modifications to this version included clarification of ambiguous terms, the addition of a glossary, definition of a time scale, the standardization of the calculation of the BILAG score, and the change of D to Discount (previously unaffected) and the addition of a category E, never affected. The positive predictive value (ppv) of a BILAG A, that is the likelihood that a patient with an A score would receive prednisone at greater than or equal to 20 mg a day or additional immunosuppressant therapy was excellent at 80%. The only individual systems that did not have at least an 80% ppv were the nervous system (ppv 30%) and hematologic (ppv 50%).

Stoll et al. used a cross-sectional study of 133 patients to further evaluate the validity of the BILAG in relationship to patients' and doctors' global assessments and the SF20+ (10). The BILAG organ systems of general, neurologic, musculoskeletal, and vasculitis correlated with the patient and physician global assessments. The same systems excluding vasculitis, but including the cardiorespiratory system correlated with the SF20+. The hematologic and renal components demonstrated an association with laboratory parameters of sedimentation rate and C3 level. Only the mucocutaneous system failed to demonstrate any significant associations with these measures. Importantly, the individual organ systems did not demonstrate significant correlation with each other. Also, disease activity was often very discordant among systems stressing the benefits of using an organ-system–based disease activity index as opposed to a global activity index.

Also using BILAG version 3, Gordon et al. evaluated whether treatment differed for BILAG A scores as compared with BILAG B scores in routine clinical practice at two different institutions (11). Two hundred and fifty patients seen regularly over a 12-month period were assessed with a BILAG score at each visit. A new A flare was seen in 10.4% of patients with 92% of these patients having an increase in their lupus-related therapies, consistent with the principles upon which the BILAG was derived. A new B score preceded by a D or E scores was seen in 26% and a B score preceded by a C score was seen in 25.2%. During the 1-year period, 38.4% of the patients did not have an A or B score. Of the B flares, 32% received some increase in steroid and/or cytotoxic therapy, whereas 59% did not receive any additional therapy for a variety of reasons ranging from recently starting therapy to allowing the disease to settle spontaneously.

A computerized program called the British Lupus Integrated Prospective System (BLIPS), which automatically calculates the A-B-C-D or E score has been developed using the BILAG version modified in 2000 (12). This program also includes a glossary for BILAG, SLAM-R, SELENA-SLEDAI, the SLICC/ACR Damage Index and SF-36 Health Survey. Figure 47-1 shows the BILAG worksheet for this. This sophisticated software should facilitate clinical research in SLE.

Although BILAG was originally developed for adult lupus patients, Brunner et al. adapted it and assessed its use in children (13). In 2004, BILAG was validated for use in childhood lupus using a prospective cohort of 21 patients under age 18 followed for a 1-year period (14).

Over time, members of the British Isles Lupus Assessment Group have found certain aspects of the BILAG index unsatisfactory and modifications have been made. As a result BILAG 2004 was developed (15). This version has nine organ-based systems rather than eight adding lupus-related ophthalmologic problems, re-organizing and expanding the gastrointestinal and hepatic manifestations into its own category and removing the vasculitis category and distributing its components to the appropriate organ system. Furthermore, BILAG 2004 deletes some items from the current BILAG that are really more damage than activity such as avascular necrosis. Also, BILAG 2004 states that an A score that is improving becomes a B score, rather than a C as it is currently measured to try to more accurately reflect change in activity. In two real patient exercises, the instrument demonstrated good reliability and agreement in all organ systems except musculoskeletal. Further improvement of the glossary as well as additional validation studies are underway. It is anticipated that BILAG 2004 will be the BILAG index used in the near future.

In a draft statement of guidelines for the development of drugs for the treatment of SLE put forward by the Food and Drug Administration (FDA), it is recommended that BILAG be used in randomized clinical trials, because it is based on the principle of intent to treat and a change in the score should be clinically meaningful (16). For this reason, this instrument will gain more widespread use in lupus trials. As such, it is imperative that investigators be trained properly on this instrument as it is more complicated and does have a subjective component that if not used consistently between different sites and studies will interfere with its utility.

Systemic Lupus Activity Measure

The SLAM was developed at the Brigham and Women's Hospital and published in 1989 (3). Like the SLEDAI, it is a global score assessing overall disease activity occurring in the month preceding the assessment with a score ranging from 0 to 84. It consists of 24 clinical and 7 laboratory manifestations of lupus. The manifestations are graded as active or inactive, with activity scores varying from mild to moderate to severe. A revised version, SLAM-R, which drops the pneumonitis and “other” manifestations and rewords some of the definitions has been more commonly used (17 ,18). Like SLEDAI, SLAM has been shown to be a valid, reliable measure that is sensitive to change in both adults and children (3 ,13 ,19 ,20). There are a few important differences between SLEDAI and SLAM. SLE manifestations in SLAM are not weighted giving equal importance to features, such as fatigue and urinary sediment. It does, however, allow for severity to be taken into account such that a severe rash scores more than a mild rash. It also captures subjective features in SLE such as fatigue and myalgias, which are not part of SLEDAI. This may be a problem in studies of disease activity as the SLAM scores fibromyalgia, which frequently does not correlate with active lupus.

Also, because it is a subjective index, it would be very difficult to use the instrument in multicenter studies, where reproducibility of an instrument between sites is critical.

The Lupus Activity Index

The LAI was developed at Johns Hopkins University and the University of California, San Francisco (4). It is a global scale with five parts that assesses disease activity occurring

up to 14 days before the visit. Part one is the physician's global assessment (PGA) scored on a 0 to 3 point Visual Analogue Scale (VAS) where 3 represents the most severe disease. Part two is an assessment of fatigue, rash, arthritis, and serositis again on a 0 to 3 VAS. Part three scores the activity of the neurologic, renal, pulmonary, and hematologic organ systems of a 0 to 3 VAS. Part four scores medications with higher doses of prednisone and cytotoxic agents receiving higher scores. Part five scores three laboratory parameters of urinary sediment, anti-DNA levels, and complement levels. The LAI summary score is calculated as the mean of part one score plus the mean of the four values in part 2 plus the maximum value in part 3 plus the mean of the scores in part 4 plus the mean of the three laboratory values. The summary score ranges from 0 to 3. The modified LAI (modified to exclude part 1, the PGA) correlated well with the PGA and with SLEDAI (4). It has also been shown to be sensitive to change (20).

SLEDAI-2K: DATA COLLECTION SHEET

Study No.: _____ Patient Name: _____ Visit Date: _____ _____ _____
d m yr

(Enter weight in SLEDAI-2K Score column if descriptor is present at the time of the visit or in the preceding 10 days.)

SLEDAI 2K Weight	SCORE	Descriptor	Definition
8	_____	Seizure	Recent onset, exclude metabolic, infectious or drug causes.
8	_____	Psychosis	Altered ability to function in normal activity due to severe disturbance in the perception of reality. Include hallucinations, incoherence, marked loose associations, impoverished thought content, marked illogical thinking, bizarre, disorganized, or catatonic behavior. Exclude uremia and drug causes
8	_____	Organic brain syndrome	Altered mental function with impaired orientation, memory, or other intellectual function, with rapid onset and fluctuating clinical features, inability to sustain attention to environment, plus at least 2 of the following: perceptual disturbance, incoherent speech, insomnia or daytime drowsiness, or increased or decreased psychomotor activity. Exclude metabolic, infectious, or drug causes
8	_____	Visual disturbance	Retinal changes of SLE. Include cytoid bodies, retinal hemorrhages, serous exudate or hemorrhages in the choroid or optic neuritis. Exclude hypertension, infection, or drug causes.
8	_____	Cranial nerve disorder	New onset of sensory or motor neuropathy involving cranial nerves.
8	_____	Lupus headache	Severe, persistent headache; may be migrainous but must be nonresponsive to narcotic analgesia.
8	_____	CVA	New onset of cerebrovascular accident(s). Exclude arteriosclerosis.
8	_____	Vasculitis	Ulceration, gangrene, tender finger nodules, periungual infarction, splinter hemorrhages, or biopsy or angiogram proof of vasculitis.
4	_____	Arthritis	≥ 2 joints with pain and signs of inflammation (ie., tenderness, swelling or effusion).
4	_____	Myositis	Proximal muscle aching/weakness, associated with elevated creatine phosphokinase/aldolase or electromyogram changes or a biopsy showing myositis.
4	_____	Urinary casts	Heme-granular or red blood cell casts.
4	_____	Hematuria	>5 red blood cells/high power field. Exclude stone, infection or other cause.
4	_____	Proteinuria	>0.5 gram/24 hours
4	_____	Pyuria	>5 white blood cells/high power field. Exclude infection.
2	_____	Rash	Inflammatory type rash.
2	_____	Alopecia	Abnormal, patchy or diffuse loss of hair.
2	_____	Mucosal ulcers	Oral or nasal ulcerations.
2	_____	Pleurisy	Pleuritic chest pain with pleural rub or effusion, or pleural thickening.
2	_____	Pericarditis	Pericardial pain with at least 1 of the following: rub, effusion, or electrocardiogram or echocardiogram confirmation.
2	_____	Low complement	Decrease in CH50, C3, or C4 below the lower limit of normal for testing laboratory
2	_____	Increased DNA binding	Increased DNA binding by Farr assay above normal range for testing laboratory.
1	_____	Fever	>38° C. Exclude infectious cause.
1	_____	Thrombocytopenia	<100,000 platelets / $x10^9$/L, exclude drug causes.
1	_____	Leukopenia	< 3,000 white blood cells / $x10^9$/L, exclude drug causes.
TOTAL SCORE	_____		

Figure 47-1. BILAG (version 3) worksheet. Most items of the worksheet are recorded (not scored), 1 = improving, 2 = same, 3 = worse, and 4 = new. Items not present are recorded (not scored) as zero. Laboratory values and blood pressure readings are entered as numeric values and a few items are recorded as Yes/No depending on whether they are present or absent. Scores of A, B and C for each system are determine based on which items have been present during the last 4 weeks and whether they are recorded as 1, 2, 3 or 4, yes or have abnormal numerical values. (ref 9, 12)

Systemic Lupus Erythematosus Disease Activity Index

The SLEDAI was developed at the University of Toronto in 1992 (5). It is a one-page weighted scale for 24 items. The weighting system was derived by multiple regression analysis from expert clinicians' judgment about the features' contribution to the overall disease activity. The manifestations felt to be most commonly contributing to disease activity are included and are scored based on presence or absence within 10 days of the evaluation and are more objective rather than subjective in nature. The score can range from 0 to 105 and is a global score reflecting all aspects of disease activity. The SLEDAI does include immunologic laboratory results. It has been shown to be a valid, reliable instrument that is sensitive to change (7 ,21 ,22). Its validity has also been demonstrated in the study of childhood SLE (13).

Since the publication of the original SLEDAI, several modifications of the SLEDAI have been made. These versions of the SLEDAI include the MEX-SLEDAI (23), the SELENA-SLEDAI (24), and SLEDAI-2K (25). MEX-SLEDAI was developed by Guzman et al. for use in countries where immunologic tests are not routinely available (23). The MEX-SLEDAI does not include complement levels, anti-DNA antibodies, visual disturbances, lupus headache, and pyuria. It does, however, include creatinine increases of more than 5 mg/dL, lymphopenia, fatigue, hemolysis, and peritonitis. In a prospective study of 39 patients seen for three consecutive visits, the MEX-SLEDAI, like the SLEDAI, was found to be reliable and showed good correlation with expert opinion and treatment changes. The MEX-SLEDAI was less expensive to administer. The MEX-SLEDAI was also evaluated in the LUpus in MInority populations: NAture vs. nurture (LUMINA) study and found to show good correlation with the SLEDAI-2K and the PGA (26) and again was less expensive than the SLEDAI-2K.

Another modification of the SLEDAI occurred for the Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA) trial (24). The SELENA-SLEDAI modification has several different definitions in an attempt to improve clarification and attribution for the individual items. The seizure descriptor in the SELENA-SLEDAI specifically excludes seizures that are caused by old, irreversible CNS damage. The visual disturbances item was expanded to include scleritis and episcleritis, and the cranial nerve descriptor was expanded to include vertigo. The cerebrovascular accident item was clarified to exclude hypertensive causes. The pleurisy and pericarditis item definitions were expanded to ensure attribution of the manifestations to lupus by added the phrase “severe and classic” to the definitions. The SELENA-SLEDAI also modified the proteinuria item by adding new-onset or recent increase to the definition of >0.5 g in 24 hours to try to better capture changes in disease activity.

In 2002, Gladman et al. published their updated version of the SLEDAI called the SLEDAI-2K (27) (Fig. 47-2). The modifications in this version were done in part to capture persistent active disease manifestations and not just new or recurrent ones. As in the SELENA-SLEDAI, the authors wanted to score ongoing rashes, proteinuria, alopecia, and mucous membrane lesions. However, they did not concur with all the modifications of the SELENA-SLEDAI, such as the inclusion of scleritis and episcleritis with a score of 8 points and were concerned about the lack of a rigorous validation of the new instrument. Using their Toronto cohort representing 18,636 visits, only 22% differed in the SLEDAI-2K versus SLEDAI score. Furthermore, 212 patients were assessed on a five-point scale as either inactive, mild activity, activity improved from the previous visit, persistent activity, or flare by an independent rheumatologist who was blinded to the SLEDAI score. They found that both SLEDAI and SLEDAI-2K scores were significantly different between the activity categories and that change in disease activity was similar for both SLEDAI and SLEDAI-2K. Thus, SLEDAI-2K, like SLEDAI, was a valid measure for disease activity in SLE. The authors propose to use this version in clinical trials to avoid the appearance of improvement when a score in the older version would decrease for persistent activity.

Gladman et al. have devised an adjusted mean SLEDAI (AMS) to capture disease activity over a period of time as assessed by SLEDAI-2K (28). This is calculated as an area under the curve over time divided by the observed time interval. In a cohort of 575 patients, higher scores have been associated with increased mortality. In a follow-up study, the authors further evaluated AMS SLEDAI-2K relationship to outcomes in addition to survival (29). Coronary artery disease (CAD) and the presence of damage defined by a score of ≥1 on the SLICC/ACR Damage Index was positively associated with the AMS-SLEDAI-2K, as was age, disease duration, and use of steroid or immunosuppressive agents. CAD was also associated with gender. These findings suggest that longitudinal studies in lupus

should consider using AMS-SLEDAI-2K to evaluate the relationship of disease activity with outcomes.

Item	Score
Ocular (either eye, by clinical assessment)	
Any cataract ever	1
Retinal change *or* optic atrophy	1
Neuropsychiatric	
Cognitive impairment (e.g., memory deficit, difficulty with calculation, poor concentration, difficulty in spoken or written language, impairec performance level) *or* major psychosis	1
Seizures requiring therapy for 6 months	1
Cerebrovascular accident ever (score 2 if >1)	1 (2)
Cranial or peripheral neuropathy (excluding optic)	1
Transverse myelitis	1
Renal	
Estimated or measured glomerular filtration rate <50%	1
Proteinuria ≥3.5 grn/24 hours *or*	1
End-stage renal disease (regardless of dialysis or transplantation)	3
Pulmonary	
Pulmonary hyperteasion (right ventricular prominence, or loud P2)	1
Pulmonary fibrosis (physical and radiograph)	1
Shrinking lung (radiograph)	1
Pleural fibrosis (radiograph)	1
Pulmonary infarction (radiograph)	1
Cardiovascular	
Angina *or* coronary artery bypass	1
Myocardial infarction ever (score 2 if >1)	1 (2)
Cardiomyopathy (ventricular dysfunction)	1
Valvular disease (diastolic murmur, or systolic murmur >3/6)	1
Pericarditis for 6 months, *or* pericardiectomy	1
Peripheral vascular	
Claudication for 6 months	1
Minor tissue loss (pulp space)	1
Significant tissue los ever (e.g., loss of digit or limb) (score 2 if >1 site)	1 (2)
Venous thrombosis with swelling, ulceration, *or* venous stasis	1
Gastrointestinal	
Infarction or resection of bowel below duodenum, spleen, liver, or gall bladder ever, for any cause (score 2 if >1 site)	1 (2)
Mesenteric insufficiency	1
Chronic peritonitis	1
Stricture *or* upper gastrointestinal tract surgery ever	1
Musculoskeletal	
Muscle atrophy or weakness	1
Deforming or erosive arthritis (including reducible deformities, excluding avascular necrosis)	1
Osteoporosis with fracture or vertebral collapse (excluding avascular necrosis)	1
Avascular necrosis (score 2 if >1)	1 (2)
Osteomyelitis	1
Skin	
Scarring chronic alopecia	1
Extensive scarring or panniculum other than scalp and pulp space	1
Skin ulceration (excluding thrombosis) for >6 months	1
Premature gonadal failure	1
Diabetes (regardless of treatment)	1
Malignancy (exclude dysplasia) (score 2 if >1 site)	1 (2)

Damage (nonreversible change, not related to active inflammation) occurring since onset of lupus, ascertained by clinical assessment and present for at least 6 months unless otherwise stated. Repeat episodes must occur at least 6 months apart to score 2. The same lesion cannot be scored twice.

Figure 47-2. The Systemic Lupus Erythematosus Disease Activity Index 2K. (From Bombardier C, Gladman DD, Urowitz MB, et al. Derivation of the SLEDAI. A disease activity index for lupus patients. The Committee for Prognosis Studies in SLE. *Arthritis Rheum* 1992;35:630–640, with permission.)

The SLEDAI is a disease activity that is brief, easy to administer and more objective in its scoring. It is relatively easy to train investigators to use this instrument. This theoretically should improve the correlation between observers. It does have limitations in that is rather heavily weighted for central nervous system manifestations, which are not that frequent. Furthermore, it is not as comprehensive as other indices as it does not score several life-threatening manifestations such as pulmonary hemorrhage, hemolytic anemia, and thrombotic thrombocytopenic purpura. Also, it does not take into account severity of manifestations. For example, a platelet count of 99,000/mm^3 scores the same 1 point as a platelet count of 5,000/mm^3. These benefits and deficiencies need to be taken into account when deciding which indices to use for any given study. In the draft of the guidance for industry for the development of drugs for lupus, it is proposed that if SLEDAI is used as an outcome measure of disease activity for a particular trial, that another disease activity measure also be used as what is considered a clinically meaningful change in a SLEDAI score is complicated (16).

The European Consensus Lupus Activity Measurement Index

The ECLAM was developed in 1992 from data on 704 actual SLE patients. Using the PGA as the gold standard of disease activity, univariate and multivariate analysis were performed to determine which features should be included and the weight to ascribe to each feature (6 ,30). Like the other instruments described, it is a global score. Nine clinical and three laboratory manifestations are scored based on their appearance within the preceding 1 month. Complement levels and sedimentation rates are included but autobody titers are not. The total score ranges from 0 to 10. Like SLEDAI, it does not provide any additional weight for some items such as more severe arthritis, but new or worsening features such as rashes and nephritis do get additional points. ECLAM has been shown to be a valid measure that is sensitive to change (6 ,20). Ward et al. found that ECLAM, along with LAI, was the instrument most sensitive to change as defined by the PGA. The correlation with LAI may be artificially elevated as the LAI included the PGA (20). ECLAM has also been shown to be sensitive to the change in disease activity for childhood SLE (31). A retrospective study of disease activity using ECLAM found good correlation between scores obtained from retrospective chart review compared with direct standard ascertainment of the score (32). Unlike retrospective studies of SLEDAI (33) and SLAM (34), there was no underestimation of disease activity. This suggests that, although not the ideal study design, ECLAM may be the best disease activity measure to use if scores need to be calculated retrospectively. However, retrospective assessment by any index will only be as good as the details in the clinical chart and may vary between centers.

Comparison of the Disease Indices

Although all the activity indices are valid measures, there are some differences that may make one instrument a more desirable tool to use in a particular situation. Table 47-1 summarizes these differences. For example, some instruments with a shorter review period may be better for studies with more frequent visits. Global scores, although convenient and perhaps quicker to calculate are problematic in that patients can have the same score whether they are improving, stable, or worsening. For instance, using SLEDAI, a rash can improve but still be present and will get the same score. Furthermore, one system can improve while another system worsens, which has been estimated to happen 10% of the time (35), and the score can be the same. Furthermore, global scores can have difficulty in differentiating patients with many mild features from patients with one or two severe features. Indices that are more subjective will require additional training for investigators to ensure some enhanced degree of uniformity to minimize the inherent error.

Sensitivity to Change

BILAG, SLEDAI, and SLAM were simultaneous assessed to compare the ability to assess changes in disease activity (7). All three were found to detect differences between patients, although in this study, SLEDAI was perhaps a little better determining changes between visits. Fortin et al. evaluated 96 patients monthly for 5 months using SLAM-R, SLEDAI, PGA, and a physician's transitional score of stable, improved, or the same at each visit (19). Both SLEDAI and SLAM-R were sensitive to change, but SLAM-R was more sensitive. Ward et al. evaluated 23 patients at 2-week intervals for up to 40 weeks with SLEDAI, ECLAM, BILAG, SLAM, and LAI at each visit (20). Using the PGA as the gold standard, all indices were sensitive to change, with LAI and ECLAM the most sensitive and SLEDAI the least sensitive. As evident, there is no consensus as to which disease activity measure is the most sensitive.

Disease Flare

Flare in SLE has been an important yet elusive concept. A variety of definitions have been proposed, but there is no uniform agreement of what constitutes a flare. Petri et al. have defined disease flare as an increase in PGA of 1.0 or greater (36). In a study of 185 patients with SLE, the incidence of flare was 0.65 flares per patient-year.

Table 47-1: Comparison of the Different Disease Activity Indices (68)

	SLEDAI	SLAM-R	LAI	ECLAM	BILAG
Number of Items	24	30	14	30	86
Number of organ systems	9	9	8	10	8
Review period	10 days	28 days	14 days	28 days	28 days
Scoring	Global score	Global score	Global score	Global score	Individual organ systems but also global score

Modified from Griffiths B, Mosca M, Gordon C. Assessment of patients with systemic lupus erythematosus and the use of lupus disease activity indices. *Best Pract Res Clin Rheumatol* 2005;19(5):685–708.

Using BILAG with its intent to treat premise, Gordon et al. defined a severe flare as a new BILAG A in any organ system from a previous B, C, D, or E. A moderate flare is a new BILAG B in any organ system from a previous C, D, or E (11). An important feature of the BILAG scoring system is the ability to assess each system separately. Thus, a flare data can be analyzed as a new A or B in a particular system, or as any new A or B from no A or B at all.

Gladman et al. compared SLEDAI scores to a 5-point scale of no activity, mild activity but no change in treatment, mild activity but improvement, persistent activity, and flare in a cohort of lupus patients (37). Their results suggested that an increase in a SLEDAI score of more than 3 was a flare, that a decrease in score of more than 3 was improvement, a SLEDAI score that was within 3 points of the previous score was persistent disease, and a SLEDAI score of 0 was remission.

Criteria for mild/moderate and severe flares were developed for use in the SELENA trial (24). Criteria for a mild/moderate flare included a change in the SLEDAI of 3 points or more, new or worse discoid rash, photosensitivity, lupus profundus, cutaneous vasculitis or bullous lesions, nasopharyngeal ulcers, pleuritis, pericarditis, arthritis, or fever attributable to lupus, the need to increase prednisone to less than 0.5 mg/kg/day, and an increase in the PGA of 1.0 to 2.5 (on a 0 to 3 VAS). A severe flare according to the study was a change in the SLEDAI score to greater than 12, or the following manifestations only if they required a doubling of the prednisone or an dose of prednisone greater than 0.5 mg/kg/day: new or worse CNS lupus, vasculitis, nephritis, myositis, thrombocytopenia of less than 60,000 per mL or hemolytic anemia with a hemoglobin level of less than 7 or a decrease in the hemoglobin greater than 3. A severe flare was also defined by need for hospitalization because of lupus activity, institution of new cytotoxic therapy, institution of prednisone to greater than 0.5 mg/kg/day or an increase in the PGA to a level greater than 2.5 (on a 0 to 3 VAS).

Abrahamowicz et al. evaluated the relationship between SLAM-R and SLEDAI in 30 paper patients (17). They found that 70% of physicians would initiate treatment at a score of 10 for both instruments.

Using a Dutch activity index, TerBorg et al. defined criteria for major and minor flares (38). A major flare consisted of severe manifestation of SLE with specific definitions that did not improve after 1 week of 30 mg/day of prednisolone. A minor flare included an increase in the activity index by at least two points to a score of at least three and the need to start at least 10 mg/day of prednisolone or increase the current prednisolone by at least 5 mg/day or start an antimalarial or immunosuppressant drug.

As clinical trials in lupus rapidly develop, the concept of flare will be further refined and defined.

Response in Lupus

Just as flare in SLE is an important idea, so is response. A priori definitions of response are critically important in lupus clinical trials. A variety of response definitions have

been proposed. Because the BILAG index is a transitional index, a variety of endpoints could be used. One possible response criteria is the time to remission defined as the loss of all initial A and B scores. Another response could be the proportion of patients that have lost all A and B scores at a predetermined time point. Responder Index for Lupus Erythematosus (RIFLE) has been developed and evaluated for this purpose (39). With this instrument, patients are characterized as complete responders, partial responders, and nonresponders.

The ACR set up an ad hoc committee to address the definition of response (35). This committee looked at the six most commonly used disease activity indices, the BILAG, SLEDAI, SLAM-R, ECLAM, SELENA-SLEDAI, and RIFLE, to define clinically meaningful improvement, no change, and worsening. To accomplish this task, they gathered data on 310 patients for paper vignettes. Then 88 lupus experts rated 5 common paper patient cases and an additional random 10 cases as to whether the patients were better, the same, or worse than the previous visit. The results were used to construct performance characteristic curves comparing the expert opinion with each of the different indices' scores. Using a 70% agreement of the expert physicians as the score at which a meaningful change could be determined, the following changes in score represented improvement: BILAG = 7, SLEDAI = 6, SLAM-R = 4, ECLAM = 3, SELENA-SLEDAI = 7, and RIFLE = 4. For a clinically meaningful worsening, the BILAG, SLEDAI, and SELENA-SLEDAI would need to increase by 8, the SLAM-R by 6, the ECLAM by 4, and RIFLE by 3. These findings may be useful in the design of clinical trials. However, it is not recommended to use BILAG as a global score. Whether these findings will hold true for all levels of disease activity deserves further evaluation as larger changes may need to be seen for those with already high levels of disease activity, whereas those with milder disease may need smaller degrees of change for significant improvement or worsening.

Damage Index

Damage is an important outcome for measurement in SLE. Although it is inherent in activity indices that all scoring must be attributable to active lupus, the same does not hold true for damage, which could be a result of the illness, side effects of medications, or comorbid conditions. In 1996, the Systemic Lupus International Collaborating Clinics developed the SLICC/ACR Damage Index (DI) (Fig. 47-3) (40). The DI was found to have reliability and validity when used by 10 physicians from five countries in the assessment of 10 actual patients with SLE (41). It has also been shown to have good agreement with prospective and retrospective measurement (42). The index is assessed from the onset of lupus and is irrespective of current disease activity, therapy, and disability in the patient. The index includes descriptors in 12 organ systems ranging from SLE-associated complications, such as renal with proteinuria, reduced glomerular filtration, and dialysis to those potentially related to complications of therapy, such as diabetes and premature gonadal failure to comorbid conditions associated with SLE, such as cardiovascular complications of angina and myocardial infarction. For the purposes of the SLICC/ACR DI, damage is considered only if present for at least 6 months. Some items such as cerebrovascular accidents and avascular necrosis can be scored twice if there is more than one occurrence. Also, once an item is scored, it will remain positive even if the manifestation resolves, such as could be seen with proteinuria, because the concept of damage argues against a score improving.

Damage is common in patients with lupus. In a study of 200 lupus patients from five centers, 61% were noted to have damage within 7 years of disease onset with a mean of 3.8 years (43). Furthermore, in a study of 1,297 patients from eight centers, the DI has been shown to increase over time (44). In a follow-up study from their own cohort, Gladman et al. also found that damage increased over time, and that a substantial portion of that increase was attributable to corticosteroid therapy (45).

The DI score has been associated with an increased mortality for those with high scores early in the course of the disease. Ninety-nine of the 1,297 patients had died and the DI was significantly higher early in those patients compared with those who survived (44). Two other studies have also found higher DI scores to be associated with an increased mortality (46 ,47).

Although there are few long-term longitudinal studies looking at what factors are associated with higher DI scores, intuitively, disease activity would be expected to correlate with damage. Gilboe et al. found that baseline disease activity did predict an increase in the DI score at 2 years (48). In a study of pediatric lupus, higher disease activity over time, as assessed by SLEDAI, was associated with more damage (49). More recently, in an adult lupus cohort of 141 patients followed prospectively for 5 years with serial DI and BILAG scores, damage and death were strongly associated with higher cumulative disease activity and a higher average number of A flares (50). Although there was no relationship between the SLEDAI and SLICC/DI score in the Toronto cohort (51), the adjusted mean in the SLEDAI, which assesses disease activity over time, did correlate with the DI (29).

In summary, the SLICC/ACR DI may be helpful in clinical practice to identify those with a poor prognosis. It may also be a useful instrument for stratification in trials of lupus, given its prognostic implications. Caution is advised, however, when using the DI in short-term clinical trials of up to 12 months' duration. If patients with long disease duration are included, damage may develop that reflects disease activity and therapy that predates the onset of the trial.

Item	Score
Ocular (either eye, by clinical assessment)	
Any cataract ever	1
Retinal change or optic atrophy	1
Neuropsychiatric	
Cognitive impairment (e.g., memory deficit, difficulty with calculation, poor concentration, difficulty in spoken or written language, impaired performance level) or major psychosis	1
Seizures requiring therapy for 6 months	1
Cerebrovascular accident ever (score 2 if >1)	1 (2)
Cranial or peripheral neuropathy (excluding optic)	1
Transverse myelitis	1
Renal	
Estimated or measured glomerular filtration rate <50%	1
Proteinuria ≥3.5 gm/24 hours	1
or	
End-stage renal disease (regardless of dialysis or transplantation)	3
Pulmonary	
Pulmonary hypertension (right ventricular prominence, or loud P2)	1
Pulmonary fibrosis (physical and radiograph)	1
Shrinking lung (radiograph)	1
Pleural fibrosis (radiograph)	1
Pulmonary infarction (radiograph)	1
Cardiovascular	
Angina or coronary artery bypass	1
Myocardial infarcton ever (score 2 if >1)	1 (2)
Cardiomyopathy (ventricular dysfunction)	1
Valvular disease (diastolic murmur, or systolic murmur >3/6)	1
Pericarditis for 6 months, or pericardiectomy	1
Peripheral vascular	
Claudication for 6 months	1
Minor tissue loss (pulp space)	1
Significant tissue loss ever (e.g., loss of digit or limb) (score 2 if >1 site)	1 (2)
Venous thrombosis with swelling, ulceration, or venous stasis	1
Gastrointestinal	
Infarction or resection of bowel below duodenum, spleen, liver, or gall bladder ever, for any cause (score 2 if >1 site)	1 (2)
Mesenteric insufficiency	1
Chronic peritonitis	1
Stricture or upper gastrointestinal tract surgery ever	1
Musculoskeletal	
Muscle atrophy or weakness	1
Deforming or erosive arthritis (including reducible deformities, excluding avascular necrosis)	1
Osteoporosis with fracture or vertebral collapse (excluding avascular necrosis)	1
Avascular necrosis (score 2 if >1)	1 (2)
Osteomyelitis	1
Skin	
Scarring chronic alopecia	1
Extensive scarring or panniculum other than scalp and pulp space	1
Skin ulceration (excluding thrombosis) for >6 months	1
Premature gonadal failure	1
Diabetes (regardless of treatment)	1
Malignancy (exclude dysplasia) (score 2 if >1 site)	1 (2)

Damage (nonrevensible change, not related to active inflammation) occurring since onset of lupus, ascertained by clinicl assessment and present for at least 6 months unless otherwise stated. Repeat episodes must occur at least 6 months apart to score 2. The same lesion cannot be scored twice.

Figure 47-3. The Systemic Lupus International Collaborating Clinics/American College of Rheumatology Damage Index for SLE. (From

Gladman DD, Ginzler E, Goldsmith C, et al. The development and initial validation of the Systemic Lupus International Collaborating Clinics/American College of Rheumatology Damage Index for Systemic Lupus Erythematosus. *Arthritis Rheum* 1996;39:363–369, with permission.)

Health Status

Health status refers to measurements of quality of life from a patient's perspective. This is a third important component in the assessment of patients with SLE. Gladman et al. compared five different health status instruments in lupus, the Health Assessment Questionnaire (HAQ), 1) Functional Ability Index, 2) the Fatigue Severity Scale (FSS), 3) the Disability Days Measure (DDM), 4) the Center for Epidemiological Studies Depression scale (CES-D) and 5) the Medical Outcomes Study Short Form Health Survey (MOS-SF-20) (52). They found that none of the instruments correlated with SLEDAI and that the MOS short form correlated with the other health status instruments, making it a valid, broad single instrument to use. Numerous other studies have shown poor correlation of the health status measures with damage and most aspects of disease activity demonstrating that these instruments capture an otherwise potentially unappreciated part of evaluating lupus (51 ,53 ,54). These findings are consistent with the discordant perspectives on disease activity that physicians and patients can have (55 ,56). Furthermore, recent work has demonstrated that psychosocial factors play an important role in determining health status (57 ,58 ,59).

Some studies, however, have shown some degree of correlation with disease activity and health related quality of life. In a cross-sectional analysis, Fortin et al. found that SLAM-R, but not SLEDAI, correlated with most subscales of the SF-36 (60). This may in part be related to the more subjective nature of SLAM-R and its inclusion of fibromyalgia symptoms. In a longitudinal analysis, both disease activity instruments were associated with changes in the SF-36. Sutcliffe et al. found that higher disease activity correlated with worse physical and emotional function, pain, and general health (61). Khanna et al. used the World Health Organization Quality of Life-Bref (WHOQOL-Bref) and Mex-SLEDAI to evaluate the relationship between disease activity and health status in the Indian subcontinent. The WHOQOL-Bref includes an environment domain, which the authors wanted to capture. They found that physical and psychological QOL are impaired with active lupus, whereas social and environmental QOL do not correlate with disease activity (62). To evaluate a cross-country comparison, Panopalis et al. evaluated the Short Form-36 General Health Survey (SF-36) scores done annually over 4 years in 231 patients from Canada, 269 from the United States, and 215 from the United Kingdom. They found that the physical and mental well-being components did not differ significantly between countries (63). Whether the equivocal results on the relationship with disease activity and quality of life measures will be resolved with more uniform use of activity and health status indices remains to be seen. Larger studies including cohorts from diverse geographic regions are also needed for comparisons to better understand lupus variability.

As illustrated above, a variety of general health status measures applicable to numerous different illnesses have been used in SLE. Although not specific to lupus, the SF-36 (see Appendix III) is an instrument that has been validated, is available in a number of languages, and is one of the most commonly used in lupus (64). It is a 36-item self-administered questionnaire that measures eight domains: physical function-role limitation, physical problems-role limitations, emotional problems, social function, mental health, general health perception, vitality, and pain. Scores range from 0 to 100, with higher scores representing better health. The SF-36 was chosen as the health status measure of choice at the SLICC workshop in 1995 (65). A study has shown that patients receiving LJP 394 reported stable or improved health-related quality of life measured by the SF-36 survey with active treatment following renal flares, compared with deterioration in placebo-treated patients. Bearing in mind the significant influence of psychosocial factors on health-related quality of life, it remains uncertain how much benefit in SF-36 scores can be expected in clinical trials designed to treat active inflammatory disease.

Although the SF-36 remains the most commonly used health status measure, other measures do exist and new ones are being developed that are specifically designed for SLE. This is felt to be necessary as the general health status measures are not comprehensive enough for lupus and focus more on physical rather than mental function. It is also felt that a disease specific QOL instrument may be more sensitive to change and therefore more useful in lupus trials. Recently, Leong et al. published their preliminary validation of a SLE-specific quality-of-life instrument (SLEQOL) (66). It contains 40 items scored from 0 to 7 for a maximum score of 280. As with other studies, there was poor correlation with disease activity and damage. There was only poor to fair correlation with the SF-36, which the authors attributed to fact that these instruments cover different domains. The SLEQOL was more sensitive to change than the SF-36. The authors currently recommend using both instruments in studies, becaise they can complement each other; the SLEQOL specifically addresses lupus issues, whereas the SF-36 captures comorbid conditions and provides generalizability to conditions other than lupus.

A Dutch SLE-specific QOL measure called the SLE Symptom Checklist (SSC) has been developed that assesses 38 disease- and treatment-related symptoms (67). Reliability and reproducibility has been shown in a preliminary study of 115 stable lupus patients. It has been translated into English and further larger-scale studies are pending.

In future clinical trials, it may be advisable to include a generic health survey, such as the SF-36, and a disease specific quality of life measure, such as the SLEQOL, as secondary outcome measures. In the guidance document put forward by the FDA for the development of drugs in lupus, the measure of health-related quality of life should not worsen with a specific therapy, further emphasizing the importance of these measures in clinical trials. A drug that significantly improves the quality of life in the treated

group compared with those on placebo, in addition to controlling clinical manifestations of the disease, will be of great value to patients and physicians.

Summary

SLE is a complex illness. Studies of lupus pose many challenges given the heterogeneity of the disease. Although biomarkers for the illness are in development, no current blood tests exist that capture disease activity or correlate with damage. This further stresses the need for reliable, responsive activity and outcome indices for SLE in order to further the understanding of pathogenesis and improve treatment. A variety of disease activity and damage indices and health status measures have been described in this chapter. All have been shown to be valid, reliable, and sensitive to change in lupus. Although none of the indices were developed in particular for randomized clinical trials, the current culture of potential new therapies in lupus will enhanced their use and expand their importance. In a draft version of guidance for the development of new therapies for lupus by the FDA, the acceptance of claims for SLE will be based on one of four categories: (1) reduction in overall disease activity, (2) treatment of a organ specific manifestation of lupus such as nephritis, (3) complete clinical response/remission, and (4) reduction in flares (16). Currently, BILAG is the favored disease activity index as changes in scores are more interpretable, because they are based on the principle of intent to change therapy. If other indices are used, then at least two different ones should be chosen, because what is a meaningful change in the score remains controversial. Inclusion of HRQL indices and a damage index are also necessary components of a study. Just as these indices have evolved, they will continue to change as their strengths and weakness are further brought to light in the testing of promising new interventions.

Chapter 48

Clinical Application of Serologic Abnormalities in Systemic Lupus Erythematosus

Francisco P. Quismorio Jr.

One hallmark of systemic lupus erythematosus (SLE) is the wide array of serologic abnormalities, including a polyclonal increase in serum gamma globulins, the presence of antinuclear antibodies (ANAs) and various serum organ-specific and nonorgan-specific autoantibodies, circulating immune complexes, and serum complement changes. The presence of some of these abnormalities is important in corroborating the clinical diagnosis of SLE, whereas others are useful in monitoring disease activity. Each abnormality is discussed in a separate chapter. This chapter focuses on the clinical application of selected serologic abnormalities in establishing the diagnosis, in assessing disease activity, and in predicting specific organ-system involvement and overall prognosis of the patient. Only serologic tests that are generally available in most clinical laboratories as well as promising tests are discussed.

Serologic Tests

Diagnosis of Systemic Lupus Erythematosus

When the diagnosis of SLE is suspected or made on clinical grounds, the following serologic tests are considered to be helpful in corroborating the diagnosis (Table 48-1): fluorescent ANA test, ANA panel, serum-complement level, and Venereal Disease Research Laboratories (VDRL) or other comparable serologic test for syphilis. In certain situations, other serologic tests also are applicable, such as the Coombs test in a patient presenting with hemolytic anemia, lupus anticoagulant test, and anticardiolipin antibody test in a patient with a history of thrombosis or multiple fetal loss.

Virtually all patients with active and untreated SLE test positive for ANA. Nevertheless, ANA is prevalent in other rheumatic and nonrheumatic disorders as well, including some conditions that may mimic the clinical picture of SLE. ANA also is found in healthy children and adults (1). Thus, by itself, a positive ANA has a low diagnostic specificity for the disease, but its value increases when the patient meets the clinical criteria for SLE. The indirect immunofluorescent test is the most commonly used method for detecting ANA, and the choice of substrate in this test is important. Sections of rodent liver or kidney and tissue culture cell lines (Hep-2 or KB cells) are used in most clinical laboratories. Certain types of ANA, such as anti-Ro/SSa and anticentromere antibodies, can be detected with these cell lines but not with rodent tissues (2). A positive serum should be titered to give a semiquantitative value to the antibody level. The fluorescent staining pattern also should be included, but in the presence of multiple types of ANA, the staining pattern may change as the serum is titered.

Test for ANA is a useful screening test when there is a high index of suspicion of SLE or other systemic rheumatic conditions. However, it should be noted that ANA can be seen in a number of nonrheumatic conditions as well as in some healthy individuals (3 ,4 ,5). A study of the clinical utility of ANA testing in a large teaching hospital revealed a high sensitivity of a positive ANA for SLE; however, the predictive value was low for SLE and for other systemic rheumatic diseases (6). Malleson et al. (7) concluded in a study of a pediatric population that a positive ANA test is a poor predictor of SLE or mixed connective-tissue disease (MCTD). Many children with a positive ANA in their study did not have a rheumatic disease. The clinician should recognize the significant limitations of a positive ANA when the patient in question does not have clinical features suggestive of SLE or other connective-tissue disease. A study of diagnostic accuracy for SLE in a community setting revealed that many patients with a positive test for ANA are incorrectly given a diagnosis of SLE (8).

The ANA panel that is available in clinical laboratories includes ANA of defined specificity: anti-double-stranded DNA (anti-dsDNA), anti-Sm, anti-U1 RNP, anti-Ro/SSA, and anti-La/SSB. Some laboratories include antinucleoprotein, anticentromere, antihistone, and/or anti-single-stranded DNA (anti-ssDNA) in their panel. When the fluorescent ANA is positive in a patient who is suspected of having SLE, an ANA panel should be obtained. Anti-dsDNA and anti-Sm antibodies are considered to be highly diagnostic,

and their presence almost confirms the clinical diagnosis. The other types of ANA in the panel have lesser value as diagnostic markers for SLE, except in special situations such as the presence of anti-Ro/SSa antibody in a patient with subacute cutaneous LE (SCLE) (individual ANA types are discussed later) or ANA-negative lupus.

Table 48-1: Serologic Tests Useful in the Diagnosis of Systemic Lupus Erythematosus

2. ANA panel: anti-ds DNA*, anti-Sm, anti-U1RNP, anti-Ro/SSA, anti-La/SSB
3. Serum complement level
4. VDRL**
5. Anticardiolipin antibodies
6. Lupus anticoagulant
7. Coombs test

*dsDNA, double-stranded DNA
**VDRL, Venereal Disease Research Laboratories.

The serum complement level generally is measured as concentration of C3 or C4, or as CH850 or CH8100 hemolytic units. Although more commonly used in assessing disease activity, the presence of both hypocomplementemia and high titers of anti-dsDNA in a patient who is suspected of having SLE almost confirms diagnosis of the disease (9). Additionally, a genetic deficiency of C1q, C2, or C4 may present clinically with an LE-like syndrome, and the combination of a low or absent CH_{50} and normal C3 level should raise the possibility of this diagnosis (10). In patients with incomplete lupus erythematosus, i.e., those presenting with less than four of the American College of Rheumatology (ACR) classification criteria, the presence of low C4 was predictive of subsequent evolution into SLE (11).

A biologic false-positive test for syphilis is one of the four immunologic abnormalities that are included in the ACR criteria for the classification of SLE. Other antiphospholipid antibodies including the lupus anticoagulant and anticardiolipin antibodies are helpful in delineating a subset of patients who are prone to develop recurrent arterial or venous thrombosis and/or fetal loss (antiphospholipid syndrome).

Monitoring Disease Activity in Systemic Lupus Erythematosus

Serologic tests are widely used for assessing disease activity and predicting exacerbations (Table 48-2). Determinations of the serum titer of anti-dsDNA and of the complement level are the most common and, probably, the most useful serologic tests that are readily available to the clinician. Although applicable to most patients, both tests have important limitations. Anti-dsDNA antibodies and hypocomplementemia do not occur in all patients, and their correlation with disease activity is not absolute. A few patients can have persistently elevated anti-dsDNA antibody titers without developing evidence of clinical disease, even when followed for several months (12 ,13). Serial measurement of the serum titer of anti-Sm and anti-Ro/SSA antibodies can be useful, particularly in those who test negative for anti-dsDNA antibodies.

Table 48-2: Serologic Tests for Assessing Disease Activity in SLE

1. Anti-double-stranded DNA antibodies
2. Serum complement level: C3, C4, CH_{50}
3. Anti-Sm and other specific types of antinuclear antibody
4. Split products of complement
5. Serum cryoglobulins
6. Serum level of soluble cytokine receptors, adhesion molecules, thrombomodulin

In analyzing reports about the predictive value of various serologic tests in SLE, several points should be stressed. The selection of patients varies widely, and the clinical criteria that are used to define active SLE are not uniform. The effect of previous or current drug therapy frequently is not addressed. Most studies are cross-sectional, comparing groups of patients, and only a few are well-designed, long-term, prospective studies. Conclusions often are derived from a single serum determination rather than from multiple specimens over a period of time. Different test systems are used by various investigators to measure a given serologic parameter. Thus, comparison of the results of various studies is not always feasible or appropriate. The use of uniform activity indices (e.g., Systemic Lupus Activity Measurement [SLAM] and Systemic Lupus Erythematosus Disease Activity Index [SLEDAI] indices) in future prospective studies will help to correct these deficiencies.

Serologic abnormalities do not always occur before or during disease exacerbations, especially in clinically mild flare-ups. In a well-designed prospective cohort study of 185 patients with SLE, Petri et al. (14) demonstrated that lupus flare is quantifiable and that the incidence of a disease flare was approximately 0.65 per patient-year of follow-up. Most of the flares were minor, manifesting as fatigue, other constitutional symptoms, mucocutaneous lesions, and musculoskeletal complaints. Only 10% flares were associated with the new appearance of anti-dsDNA antibodies, and only 17% with an increase in antibody titer. Depression of C3 and C4 were observed in 44% and 41% of the disease flares, respectively.

We, and others, have found the concentration of serum cryoglobulins to be a useful parameter that correlates with disease activity, especially in those with nephritis (15 ,16 ,17 ,18). Although technically simple, it is labor-intensive. Measurement of cryoglobulins requires careful handling of

the specimen for proper interpretation of the results. Venous blood is allowed to clot at 37°C immediately after venipuncture. Following incubation at 4°C for 48 hours, the specimen is centrifuged in the cold and the precipitate saved. The precipitate is washed carefully with a low-ionic phosphate buffer, and the protein concentration is measured by standard methods.

The role of circulating immune complexes in monitoring disease activity in SLE remains unproven and has been abandoned (19 ,20). The lack of a widely accepted standardized test system, the heterogeneity of immune complexes in SLE sera (18 ,19), and the imprecise and inconsistent correlation with disease activity limit the application of circulating immune complexes in following the clinical course of the disease in individual patients. Of the numerous serologic tests for circulating immune complexes, the C1q solid-phase binding assay has been the most frequently used method in patients with SLE (20 ,21 ,22 ,23 ,24 ,25 ,26 ,27). Serologic tests with promising value are the measurements of products of complement activation and of soluble cytokine receptors (28 ,29).

Clinical Significance of the Anti-DNA Antibody

Diagnostic Value

Antibodies to DNA are classified according to their reactivity to native or dsDNA or to denatured or ssDNA. The presence of anti-dsDNA is highly characteristic of idiopathic SLE and rarely is seen in other rheumatic conditions, including drug-induced LE (30 ,31). One of the immunologic criteria for the classification of SLE by the ACR is the presence of anti-dsDNA. In contrast, anti-ssDNA antibodies, although prevalent in SLE, are less specific and can be seen in many other disorders, including rheumatic and nonrheumatic conditions (32). Thus, in the clinical laboratory, anti-dsDNA, but not anti-ssDNA antibodies, are tested routinely in the ANA panel.

In a large cohort prospective study, Weinstein et al. (9) found that high titers of anti-dsDNA and a low-serum C3 level are sensitive, and that each test had a high predictive value (94%) for the diagnosis of SLE when applied to a patient population in which the diagnosis was clinically suspected. Moreover, the predictive value was even higher when both serologic abnormalities were present in an individual patient.

Clinical Tests for Anti-DsDNA

The most commonly available tests for anti-dsDNA antibodies in the clinical laboratory are radioimmunoassay using either the Farr or the Millipore-filter binding technique, enzyme-linked immunosorbent assay (ELISA), and the *Crithidia luciliae* immunofluorescence test. The radioimmunoassay is a sensitive technique, and approximately 60% to 70% of patients with SLE test positive for anti-dsDNA by use of this method (30 ,31). False-positive results occasionally are seen with this test because of the contamination of the DNA substrate with single-stranded forms. False-positive results have been reported with commercial kits (31). The ELISA test for anti-dsDNA is technically easy to perform, and is the least labor intensive. The serum titer can be readily measured and, more important, both high- and low-avidity anti-dsDNA antibodies can be detected. False-positive ELISA results can be seen when impure DNA is used as a substrate (33). The immunofluorescence test uses fixed smears of *C. luciliae,* which is a nonpathogenic hemoflagellate containing a circular cytoplasmic organelle (called a kinetoplast) that consists of dsDNA. Serum anti-dsDNA, but not anti-ssDNA antibodies, bind to the kinetoplast. My own group has used this method to measure not only the titer of the antibody but also the immunoglobulin class and complement-fixing property of anti-dsDNA (34).

Qualitative properties of anti-dsDNA antibodies, including avidity, immunoglobulin class, and complement-fixing property, may affect the pathogenicity of the antibodies.

Because the available clinical tests for anti-dsDNA preferentially measure antibodies of different properties, some controversy has arisen as to which test yields the most useful information in assessing disease activity.

Ward et al. (35) compared the ELISA, *C. luciliae* immunofluorescence test, and filter-binding radioimmunoassay in patients with SLE who were followed over a period of time. They found that in most patients, the changes in anti-dsDNA antibody levels measured over time parallel each other, and that the anti-dsDNA titer as measured by each assay is inversely correlated to the serum C3 concentration. Data from this study indicate that the repertoire of anti-dsDNA antibodies detected in an individual patient remains relatively constant over time, confirming the observation that high- and low-avidity anti-DNA antibodies do not move independently in an individual patient but rise and fall in a parallel pattern (36).

Smeenk et al. (37) compared four methods for measuring anti-dsDNA antibodies in a defined population of patients with SLE. They found good correlation between the Farr assay, a commercial radioimmunoassay kit, polyethylene glycol test, and *C. luciliae* immunofluorescent test. As a diagnostic test, however, they recommend the Farr assay and *C. luciliae* as having the highest specificity for SLE. Werle et al. (38) suggest that ELISA is a sensitive test that is well suited to screening for anti-dsDNA. However, positive sera should be confirmed by either *C. luciliae* immunofluorescent test or by Farr assay, because they found positive ELISA in some patients with chronic liver disease, infections, and connective-tissue diseases other than SLE. Bootsma et al. (39) found the Farr assay have the highest specificity and sensitivity for the diagnosis of SLE when compared to the ELISA and *C. luciliae* test. Moreover, SLE sera with IgM-class anti-dsDNA as measured by the ELISA were positive when tested by the Farr

assay. In contrast, patients with other medical conditions who have IgM-class anti-dsDNA by the ELISA test were negative when tested with the Farr assay.

IgA anti-dsDNA antibodies have been reported to be associated with disease activity and a clinical subset of SLE patients with cutaneous vasculitis, acral necrosis, and erythema (40). In contrast, the presence and the serum level of IgM anti-dsDNA were not associated with disease activity or to particular clinical features of SLE (39). In a prospective study of 72 patients over a period of 19.6 months, Bootsma et al. (41) found that rises in the serum titer of the IgM anti-dsDNA, in contrast to rises of IgG anti-dsDNA, were not useful in predicting clinical relapses of SLE.

Telomeres are repetitive sequences of DNA at the end of eukaryotic chromosomes. Wallace et al. (42) evaluated an ELISA test for antitelomere antibodies as a diagnostic test for SLE. Antitelomere antibodies were found to be more sensitive than the Farr assay for anti-dsDNA (71% vs. 50%) in a cohort of SLE patients. When compared to commercially available ELISA test kits using calf thymus DNA, *C. luciliae* immunofluorescent test and Farr assay, Salonen et al. (43) found IgG antitelomere antibodies to have high sensitivity (60%) and specificity (91%) for SLE. Moreover, antitelomere antibodies correlated with lupus nephritis. Prospective studies of patients evaluated for SLE and other rheumatic conditions are needed to confirm the high sensitivity and specificity as well as its application in assessing lupus disease activity.

In summary, the most commonly available tests for anti-dsDNA antibodies yield comparable results over time in individual patients; however, as a diagnostic test, the Farr assay and *C. luciliae* are preferred (44). In clinical practice, any of these tests can be used to follow the antibody titer sequentially in most patients with SLE. The ELISA test and *C. luciliae* immunofluorescent test are commonly used for this purpose. If a patient with clinically active lupus has repeatedly low serum levels of anti-dsDNA antibodies with one test, use of a different test system should be considered.

Assessment of Disease Activity

A number of studies mostly retrospective, but a few prospective have examined the value of anti-dsDNA antibodies in predicting disease exacerbations and response to drug therapy. Table 48-3 summarizes the results of selected studies (21 ,38 ,45 ,46 ,47 ,48 ,49 ,50 ,51).

Retrospective Studies

Davis et al. (46) described a fairly good correlation between disease activity and anti-dsDNA antibodies as measured by a Millipore radioassay. Several patients in clinical remission, however, had a mild to moderate elevation of anti-dsDNA antibody levels. Swaak et al. (49) found a sharp drop in anti-dsDNA antibody titer, usually preceded by a rise that correlated with lupus nephritis and other major organ involvement. In contrast, a continuously high antibody titer was not predictive of disease flare. Isenberg et al. (47) reported that severe lupus nephritis, but not central nervous system (CNS) and other extrarenal involvement, correlated with anti-dsDNA antibodies, especially with antipoly (dT) antibodies. Measurement of antibodies to different synthetic polynucleotides did not significantly add to the routine determination of anti-dsDNA antibodies. Lloyd and Schur (24) observed that anti-dsDNA antibody as measured by the *C. luciliae* test correlates only fairly with disease activity. A rising antibody titer correlated with 75% of renal, 60% of extrarenal, and 30% to 50% of combined renal and extrarenal flares. In a study of patients with lupus nephritis who were treated with azathioprine and steroids, Adler et al. (45), using the Farr assay, found a persistently elevated anti-dsDNA to be predictive of a poor renal outcome.

Prospective Studies

A few long-term prospective studies have evaluated the clinical significance of anti-dsDNA antibodies both alone and in combination with serum complement level and other serologic parameters. Minter et al. (48) studied 70 patients longitudinally over 3 years. Only slightly more than one half of the active-disease episodes were associated with both a low CH_{50} and a high anti-dsDNA level as measured by the Farr assay. Many patients with clinically inactive disease had isolated elevated anti-dsDNA iters or low CH_{50} level. Active lupus nephritis was associated with complement-fixing anti-dsDNA or a low CH_{50}. In contrast, most episodes of CNS disease occurred without significant changes in CH_{50} level and anti-dsDNA antibody titer. Overall, the CH_{50} parameter correlated better than the anti-dsDNA antibodies with disease activity.

In a longitudinal study of 143 patients with SLE, Swaak et al. (50) found that a progressive rise followed by a sharp drop in anti-dsDNA titer as measured by the Farr assay preceded all 33 major disease flares. A drop in the serum C4 level followed by a decrease in the serum C1q and C3 levels occurred 20 to 25 weeks before the onset of lupus nephritis.

Ter Borg et al. (51) reported that 89% of all disease flares that occurred in 72 patients with SLE studied serially were preceded by a rise in anti-dsDNA titer by 8 to 10 weeks. The anti-dsDNA antibody titer was more sensitive than serum C3 or C4 levels in predicting exacerbations. The Farr assay was superior to the *C. luciliae* or ELISA test for the determination of anti-dsDNA antibodies. Based on these observations, a randomized, controlled trial was undertaken to determine if increasing the daily dose of prednisone after a rise in anti-dsDNA is detected can prevent relapses in SLE (52). A 25% increase in serum anti-dsDNA titer by the Farr method was considered to be significant. The cumulative risk of a major or minor relapse was significantly reduced in patients who received an additional dose of prednisolone.

Table 48-3: Association of Anti-Double-Stranded DNA and Disease Activity

Source	No. of Patients	Method Used	Results and Comments
Retrospective studies			
Davis, 1977 (46)	23	Radioassay	Good correlation between disease activity but positive tests were seen in several patients in remission.
Swaak, 1979 (49)	78	Farr assay	Sharp drop in antibody titer especially if combined with low C3 and C1q; predictive of nephritis or major organ flare. Persistently high titer was not predictive.
Isenberg, 1988 (47)	39	ELISA	Severe lupus nephritis but not extrarenal involvement correlated with anti-double-stranded (ds)DNA and especially with antipoly (dT).
Lloyd, 1981 (24)	27 with 47 flares	*C. luciliae*	Only fair association with disease activity. Rising titer of anti-dsDNA coincided with 75% of renal 60% of extrarenal, and 30% to 50% of combined renal and extrarenal.
Adler, 1975 (45)	21 diffuse lupus	Farr assay	Persistently high anti-dsDNA despite drug therapy correlated nephritis with poor renal outcome. An initial high titer had no prognostic value.
Esdaile, 1996 (55)	202 with 83 flares	Farr assay	Fluctuation in anti-dsDNA, C3, C4, and C1q binding were poor predictors of disease flares.
Prospective studies			
Swaak, 1986 (49)	143, with 33 flares	Farr assay	All 33 flares proceeded by a progressive rise and sharp drop of anti-dsDNA titer; 20 to 25 weeks prior to onset of nephritis; serum C4 decreased followed by C1q and C3.
ter Borg, 1990 (51)	72, with 27 flares	Farr assay, ELISA, *C. luciliae*	24 flares (89%) preceded by rise in anti-dsDNA by 8 to 10 weeks; anti-dsDNA was more predictive than C3 or C4. Farr assay was the most sensitive test.
Minter, 1979 (48)	40	Radioassay filter	Half of active episodes associated with low CH_{50} and high anti-dsDNA; isolated high anti-dsDNA or low CH_{50} seen in inactive disease; most central nervous system episodes occurred with normal CH_{50} and anti-dsDNA. Low CH_{50} correlated better than high anti-dsDNA.
Bootsma, 1995 (52)	156	Farr assay	A rise in anti-dsDNA titer was treated with an increase in prednisone dose. This reduced the risk of a clinical relapse.
Zonana-Nacach, 1995 (245)	53	Farr assay	Odds ratio of three for flare in asymptomatic patients with high anti-dsDNA and odds ratio of two for low C3.
Bootsma, 1997 (41)	34 with 18 flares	ELISA and Farr	Rise in IgG anti-dsDNA but not IgM anti-dsDNA was assay predictive of disease flare. ELISA, enzyme-linked immunosorbent assay.
Ho, 2001 (53)	53	ELISA, *C. luciliae*, IF test	Previous increase in anti-dsDNA occurred before flare As measured by SLEDAI and modified lupus activity I index; anti-dsDNA titer decreased during renal flares
Linnik, 2005 (54)	487 with nephritis	Farr assay	Changes in anti-dsDNA correlated with renal flares; inversely related with serum C3

In a prospective study of 53 SLE patients for up to a year, Ho et al. (53) reported that a previous increase in anti-dsDNA, measured by ELISA and *C. luciliae* assays, occurred before disease flares when measured by SLEDAI and a modified lupus activity index. On the other hand, at the time of the lupus flares including those patients with renal flares, the serum titer of anti-dsDNA often decreased. The authors suggested that decrease may represent deposition of immune complexes during the disease flare.

A multicenter study of 487 SLE patients with a history of lupus nephritis and a positive test for anti-dsDNA, found that changes in the titer of anti-dsDNA measured by a Farr assay, correlated with a risk of renal flare and was inversely correlated with serum C3 levels (54).

Other investigators have found that anti-dsDNA and other serologic tests are not very useful in predicting disease flares. Esdaile et al. (55) analyzed retrospectively clinical and laboratory data from 202 SLE patients who were followed prospectively for a median period of 86.5 months. Using a modified SLE disease activity index, they concluded that fluctuations in the laboratory test values including anti-dsDNA, C3, C4, and C1q binding assay for immune complexes are poor predictors of disease exacerbations in SLE. For the four serologic tests, the sensitivity approximated 50% and the sensitivity was less than 75% (56). In this study, anti-dsDNA and other laboratory data were obtained every 3 months. In contrast, in the prospective studies that found anti-dsDNA to be predictive of disease flares (51 ,52), laboratory values were obtained more frequently every 4 to 6 weeks.

Guidelines for Immunologic Laboratory Testing

The ACR guidelines on anti-dsDNA antibody (57) can be summarized as follows: A positive test for anti-dsDNA offers strong support for the diagnosis of SLE but a negative test result does not exclude the diagnosis. Anti-dsDNA antibodies do correlate with overall disease activity in SLE, however, the correlation is at best modest and test results must be interpreted in the clinical context. Anti-dsDNA antibodies correlate with lupus nephritis to a limited extent. High serum antibody titers have a stronger correlation with disease activity. In longitudinal assessment of patients, the presence of anti-dsDNA alone does not predict a disease flare. Increasing titers of anti-dsDNA in an individual patient may antedate or be associated with disease activity.

Summary

The quantitative determination of anti-dsDNA antibodies does not adequately predict disease flares in every patient. This is not unexpected considering the heterogeneity of the clinical disease and the anti-dsDNA antibodies. Several investigators have proposed that the qualitative properties of the anti-dsDNA antibodies, such as the complement-fixing property, avidity, dissociation constant, and immunoglobulin class, are more important determinants than the total antibody content in regard to pathogenicity and correlation with disease activity (56 ,57 ,58 ,59 ,60 ,61 ,62). Data from these studies are not readily available to the practicing clinician. Meanwhile, the anti-dsDNA antibody titer continues to be used widely as a serologic parameter for assessing disease activity. Combined with serum complement and other renal laboratory parameters, it is valuable in patients with lupus nephritis. In my experience, it is especially useful if the patient in question had a high anti-dsDNA and low serum complement in past exacerbations of the disease. Data from the few prospective studies suggest that anti-dsDNA should be measured at frequent intervals, every 4 to 6 weeks, and an increasing antibody titer may be predictive of disease flares. Considering the cost of laboratory testing, additional longitudinal studies are needed to confirm this finding.

Clinical Significance of the Anti-Sm Antibody

Anti-Sm antibody is present in only 30% of patients with SLE, but it has considerable diagnostic value as it is rarely found in other rheumatic diseases, such as MCTD, systemic sclerosis, and rheumatoid arthritis (RA) (63 ,64). Anti-Sm is included in the ACR criteria for the classification of SLE, and as an immunologic parameter, it carries the same weight as anti-dsDNA, positive LE-cell test, and false-positive serologic test for syphilis.

The anti-Sm antibody usually is measured in the clinical laboratory, by immunodiffusion, counterimmunoelectrophoresis (CIE), ELISA, and hemagglutination methods. The ELISA test, using highly purified antigens, is the most sensitive but less specific than the immunodiffusion and CIE (63 ,65). The lower specificity of the former is partly a result of the difficulty in preparing highly purified Sm antigen (66). The ELISA test is superior to other methods, however, in measuring the serum titer of the antibody. The use of recombinant Sm antigen and Sm polypeptides in ELISA is promising, but additional studies are needed to evaluate their clinical application (67 ,68 ,69).

When SLE was compared to healthy controls, anti-Sm has a weighted mean sensitivity of 24% and a sensitivity of 98%. On the other hand when SLE was compared to other rheumatic conditions, anti-Sm had a mean sensitivity of 30% and a specificity of 96% (70).

Prevalence

Studies have shown that the prevalence of anti-Sm antibody in SLE varies among the different ethnic groups. In the United States, Arnett et al. (65) found anti-Sm and anti-RNP antibodies to be more common in African Americans (25% and 40%, respectively) than in whites (10% and 24%, respectively). Antibodies to Ro/SSA and La/SSB, however, occurred with equal frequencies in the two racial groups. The higher prevalence of anti-Sm and anti-U1RNP in African Americans has been confirmed by others (71 ,72 ,73). The frequency of anti-Sm antibody in SLE appears to be lower in France than in the United States (74). Anti-Sm was present in 12% (by immunodiffusion) and in 17% (by immunoblotting) of French patients with SLE; in contrast, the prevalence among French West Indies patients was five times higher: 39% by immunodiffusion and 50% by immunoblotting. In a smaller study, Field et al. (66) found a higher frequency of the antibody among patients with SLE originally from West Africa, the Caribbean Islands, and Asia than among local whites in England. The prevalence of anti-Sm antibodies in a large number of European patients

with SLE (93% whites) was 10.3% (74). The prevalence of anti-Sm in Thailand was 44% (75); in Mexico, 39.2% (76); in India, 13.7% (77) and in Malaysia 15% (78).

The selection of SLE patients and of controls, the antigen that is used, and the laboratory procedure are variable, so prevalence of anti-Sm antibodies may not be comparable among the cited studies.

Association with Organ Involvement

Whether the presence of anti-Sm antibodies defines a clinical subset of patients with SLE or carries a prognostic value in SLE remains uncertain. Winfield (79) found a higher frequency of anti-Sm antibodies among patients with SLE and CNS dysfunction. Winn et al. (16) reported anti-Sm antibodies to be associated with milder CNS and renal disease.

Other investigators, however, could not confirm these associations (80 ,81). Gripenberg et al. (82) found Raynaud phenomenon to be more prevalent in patients with high titers of IgG anti-Sm antibodies. Yasuma et al. (74) found a positive correlation among serositis, interstitial pulmonary fibrosis, and IgG anti-Sm antibodies in a large cohort of Japanese patients. Huynh et al. (84) reported an increased frequency of anti-Sm antibodies in SLE patients with peripheral neuropathy. Alba et al. (85) found anti-Sm, anti-dsDNA and lupus anticoagulant to be associated with a higher risk of lupus nephritis among young Black patients.

The discrepancies in these results may be a result of variation in prevalence among various ethnic groups and differences in the sensitivity of the test system. More important, conclusions were often based on a single serum specimen rather than on a sequential determination of the anti-Sm antibody.

Antibody Titer and Disease Activity

Few longitudinal studies on the usefulness of anti-Sm antibody titers in monitoring disease activity in patients with SLE have been performed. A prospective study of 14 patients with SLE and anti-Sm antibodies, over a period of 7 to 30 months, showed fluctuations in serum titer. A fourfold rise in titer predicted disease flare in 50% of patients (but in only 28% of episodes) and correlated with exacerbation of the disease in 60%. The rise in titer occurred within 2 to 12 weeks preceding a major disease flare (nephritis and CNS disease), but not in milder flares (arthritis, rash, or serositis) (83). Another study of 17 patients with SLE who were followed for 6 to 120 months showed a correlation between anti-Sm antibody and disease activity (82).

Immunologic Testing Guidelines

The ACR recently published guidelines on the utility of anti-Sm antibody tests in laboratory testing in rheumatic diseases (86). The guidelines were developed based on an extensive and critical literature review. The presence of anti-Sm antibody is highly specific for SLE and it is valuable serologic marker for diagnosis. It should be tested in all patients who are suspected on clinical grounds of having SLE. It is not useful in the diagnosis of other systemic rheumatic diseases. Anti-Sm antibodies did not correlate with presence of lupus nephritis and were not useful in predicting renal flares. Anti-Sm do not appear to predict disease flares, however, there were few published prospective studies.

Further studies are needed, to evaluate the value of anti-Sm antibody titer in monitoring disease activity, to determine whether it adds to the measurement of anti-dsDNA antibodies and other serologic tests, and to ascertain whether it may be more useful in African Americans and other ethnic groups in whom the anti-Sm antibodies are more prevalent.

Significance of Anti-U1RNP Antibody in Systemic Lupus Erythematosus

Prevalence and Diagnostic Significance

Arnett et al. (65) found that the prevalence of anti-U1RNP antibodies measured by the immunodiffusion and CIE tests, is higher in black patients (40%) than in white patients with SLE (23%). Using immunoprecipitation and autoradiography, Williamson et al. (72) found a higher frequency of anti-Sm (34% vs. 15%) but not anti-U1RNP (36% vs. 27%) in black compared to white SLE patients. The ELISA test is a sensitive test for anti-U1RNP, showing a prevalence of the antibody as high as 55% in patients with SLE (63). Anti-U1RNP antibodies were found in 20.1% of a large number of European patients with SLE who were collected from 14 different countries (74). A high frequency of anti-U1RNP antibodies in SLE has been reported in Japanese patients (24%) (87) and in Malaysian patients (36%) (78).

Unlike anti-Sm antibodies, anti-U1RNP antibodies are not considered specific for SLE. They can be seen in patients with other systemic rheumatic conditions such as MCTD, RA, Sjögren syndrome, systemic sclerosis, and polymyositis.

Clinical Association of Anti-U1RNP Antibodies

The presence of high titers of anti-U1RNP antibodies is associated with MCTD, a clinical entity that is characterized by overlapping features of SLE, scleroderma, and polymyositis (30 ,31). Some investigators have proposed that in MCTD, anti-U1RNP should occur in the absence of other autoantibodies such as anti-Sm and anti-dsDNA (88), and that the occurrence of multiple types of ANA in a patient is more indicative of SLE. The issue of whether MCTD is a distinct rheumatic disease or merely a syndrome that may occur during the course of SLE or systemic sclerosis remains controversial. Some patients with MCTD eventually

evolve into a more distinct rheumatic disease, such as definite systemic sclerosis (89 ,90). A study of the isotype of anti-U1RNP antibodies in Greek patients revealed a predominance of IgM antibodies in SLE. In contrast, IgG anti-U1RNP without IgM antibodies were found in MCTD (91).

In 1972, Reichlin and Mattioli (92) found that anti-U1RNP antibody is prevalent in SLE and is associated with a more benign disease. A cross-sectional study of 49 patients with SLE revealed that those with anti-U1RNP and anti-Sm antibodies have a higher frequency of scleroderma-associated features, such as Raynaud phenomenon, sclerodactyly, interstitial changes in the chest radiograph, and nailfold capillary abnormalities (93 ,94). Vasculitis, deforming, nonerosive, Jaccoud-type arthropathy of the hands and Raynaud phenomenon also have been reported to be associated with anti-U1RNP in SLE by other investigators (76 ,78 ,95).

A prospective study of a large cohort of SLE patients, predominantly Caucasian, found no association between the presence of anti-U1RNP or anti-Sm antibodies with specific major organ damage including renal, CNS, cardiac, or pulmonary (96). In contrast, both anti-U1RNP and anti-dsDNA were reported to be significant predictors of lupus nephritis among Hispanic and African-American SLE patients (97).

Serum Antibody Titer

A few reports of longitudinal measurements of the serum titer of anti-U1RNP among patients with SLE have appeared. Nishikai et al. (98) showed that in some, but not all, patients with SLE, the anti-U1RNP titer appeared to fluctuate with disease activity. A prospective study of 71 patients with SLE and 40 separate clinical exacerbations showed that the measurement of antibodies to 70 kd and A polypeptides of the U1RNP complex was not useful in monitoring disease activity or predicting disease exacerbations (99). The presence of anti-U1RNP and/or anti-Sm did not appear to affect survivorship in SLE (100).

A prospective study of patients with anti-U1RNP antibodies showed that most patients with a persistently high serum titer evolve into a clinical picture of MCTD (101). A 10-year follow-up of a group of patients with rheumatic disease and anti-U1RNP antibodies showed clinical features of MCTD and a high frequency of erosive and deforming arthritis (102). A large proportion of patients with “undifferentiated connective tissue disease” who tested positive for anti-U1RNP subsequently developed MCTD (103).

ACR guidelines on immunologic laboratory testing assert that anti-U1RNP is not specific for SLE, but supports a diagnosis of MCTD. Anti-U1RNP does not support the diagnosis of SLE, RA, or systemic sclerosis. Testing for anti-U1RNP is not useful in assessing for lupus nephritis. However, further prospective studies are needed to evaluate the association between anti-U1RNP and other SLE features (86).

Summary

Anti-U1RNP and anti-Sm antibodies commonly are found together in the sera of patients with SLE. Anti-U1RNP antibodies are not considered to be diagnostic of SLE; when present alone in a patient with systemic rheumatic disease (especially in high titer); the possibility of MCTD should be considered. Although the serum titer of anti-U1RNP may fluctuate in some patients, the determination of anti-dsDNA and complement is more useful in monitoring disease activity in patients with SLE, especially in those with nephritis.

Anti-Ro/SSA and Anti-La/SSB Antibodies in SLE

Diagnostic Specificity

Anti-Ro/SSA antibodies are most commonly found in primary Sjögren syndrome and SLE, although they also occur in other systemic rheumatic diseases, including systemic sclerosis, RA, and polymyositis (30). In the clinical laboratory, anti-Ro/SSA antibodies are detected by immunodiffusion in agarose gels or by CIE. They are present in 30% to 40% of patients with SLE and in 40% to 70% of patients with primary Sjögren syndrome (31).

Immunoblotting, RNA precipitation, and ELISA have been developed to measure anti-Ro/SSA and anti-La/SSB antibodies. A comparative study of these methods (104 ,105) has shown that although the RNA precipitation has the highest sensitivity and specificity, the most convenient and practical clinical test is CIE for anti-Ro/SSA and immunoblotting for anti-La/SSB. ELISA tests using affinity-purified antigens and recombinant protein have become available (106 ,107). An indirect immunofluorescent test using transfected HEp-2 cells that over express the human 60kDa Ro/SSA antigen is a highly sensitive screening test (108 ,109). Other investigators recommend the use of a combination of two or more commercially available test systems for anti-Ro/SSA to improve sensitivity and specificity (110).

Like anti-Ro/SSA antibodies, anti-La/SSB antibodies are found in patients with primary Sjögren syndrome and SLE. Precipitating anti-La/SSB antibodies are found in 12% of unselected patients with SLE (111).

Using various test systems, anti-Ro/SSA antibodies have been reported to occur in low titers in 15% of healthy individuals, especially those who are HLA-DR3 positive, and anti-La/SSB have been detected in 7.5% of normal subjects (63 ,112 ,113 ,114).

Disease Associations

Although anti-Ro/SSA antibodies do not have a high diagnostic specificity for SLE, their presence is associated with a number of clinical conditions. These include SCLE, neonatal lupus syndrome, homozygous C2 and C4 deficiency with

SLE-like disease, ANA-negative SLE, photosensitivity in SLE, and interstitial pneumonitis.

SCLE is a distinct clinical subset of SLE. It is characterized by recurrent, erythematous, photosensitive, nonscarring skin lesions in a characteristic distribution involving the face, trunk, and arms, and by mild systemic disease. Anti-Ro/SSA antibodies are found in 63% to 90% of patients with SCLE (115 ,116 ,117). The major anti-Ro/SSA response in SCLE is directed against the native 60-kD Ro protein (118).

Neonatal lupus syndrome is an uncommon condition in infants born of SLE mothers. It is characterized by photosensitive, annular, discoid, or erythematous skin lesions of the face and trunk, which appear at or before 2 months of age and disappear by 6 to 12 months of age. Congenital heart block with or without structural cardiac defects is seen in 50 of patients. Almost all afflicted infants and their mothers have anti-Ro/SSA and/or anti-La/SSB antibodies (119 ,120 ,121). Buyon et al. (122) found that women with both antibodies, especially if the anti-Ro/SSA antibodies identify the 52-kd component, have an increased risk of giving birth to an infant with neonatal lupus syndrome. Unfortunately, most of the commercially available tests for anti-Ro/SSA antibodies do not distinguish between antibodies to the 52-kd and the 60-kd components. The frequency of anti-Ro/SSA antibodies is increased in mothers of male children with SLE and in mothers of children with SLE that develops before the age of 10 years (123).

Homozygous C2 deficiency is characterized by a lupus-like illness with photosensitive cutaneous lesions reminiscent of those of SCLE and arthralgia, but rare CNS and renal involvement. Anti-Ro/SSA antibodies are present in 50% to 75% of these patients (116 ,124 ,125). A genetic deficiency of C4, which may manifest clinically as SLE or a lupus-like syndrome, also is associated with anti-Ro/SSA antibodies (125). In one study, one of four patients with a genetic deficiency of C1q had anti-Ro/SSA antibodies (125).

ANA-negative SLE, first described by Fessel (126) and by Gladman et al. (127), refers to patients with clinical features that are compatible with those of SLE, except that their sera test negative for ANA by immunofluorescence using sections of rodent liver or kidney. In a study of 66 patients, Madison et al. (128) had SCLE. Precipitating anti-Ro/SSA antibodies were found in 41 patients, and anti-ssDNA antibodies were present in 18. Moreover, 66% of patients actually had a positive fluorescent ANA when KB epithelial tissue culture cells rather than mouse kidney sections were used as substrate. The Ro/SSA antigen appears to have a variable species distribution with significant amounts in certain cells, including a concentration in mouse, rat, and rabbit tissues (1).

Blomberg et al. (129) found that 25% of a group of patients suspected of having systemic rheumatic disease with anti-Ro/SSA antibodies by an ELISA test but with a negative standard ANA test had SLE or cutaneous SLE. Further characterization of the antibody revealed specificity for the Ro 52-kd protein (130). Using a sensitive ELISA test, Reichlin (131) found anti-Ro/SSA in all 66 patients with ANA negative SLE. Anti-La/SSB was detected in 46% and anti-U1RNP was present in 35%.

The presence of anti-Ro/SSA antibodies has been reported to correlate positively with photosensitivity in white patients with SLE (132). In contrast, among African Americans, anti-Ro/SSA antibodies appear to be inversely associated with photosensitivity (133). A probable relationship between anti-Ro/SSA antibodies and interstitial pneumonitis as well as “shrinking lung syndrome” in SLE have been described (134 ,135), and deforming arthropathy in SLE has been reported to be associated with anti-Ro/SSA (especially the 52-kd component) and with anti-La/SSB antibodies (136). Anti-Ro/SSA and anti-La/SSB were strongly associated with sicca symptoms in a large cohort of SLE patients (137 ,138).

SLE patients with anti-La/SSB antibodies usually have anti-Ro/SSA antibodies concomitantly, and they tend to be older at diagnosis (111 ,139 ,140 ,141). Although lupus nephritis is positively associated with anti-dsDNA, it is inversely related with anti-La/SSB antibodies (139).

Hamilton and associates (140) suggested two serologic genetic subsets of SLE in whites, but not in African Americans, with different ages of onset. White patients with SLE and anti-Ro/SSA antibodies alone differ from those with both anti-Ro/SSA and anti-La/SSB antibodies. Those in the former group have a lower titer of anti-Ro/SSA antibodies, a younger age of onset, a higher frequency of anti-dsDNA and significant renal disease, and they are strongly associated with DR2 and DQw1. In contrast, those in the latter group are associated with an older age of onset, sicca complex, less renal involvement, and HLA-B8, Dr3, Drw52, and DQW2. A study of SLE patients in Taiwan revealed no correlation between anti-Ro/SSA and anti-La/SSB and the occurrence of lupus nephritis (142).

Cavazzana et al. (143) reported that 24% of patients with “undifferentiated connective tissue disease” who test positive for anti-Ro/SSA antibodies progressed within a short period of time to either SLE or primary Sjogren syndrome.

Serial Measurement of Antibody Titer

Scopelitis et al. (144) reported fluctuating titers of anti-Ro/SSA antibodies in patients with SLE that appeared to correlate with disease activity and anti-dsDNA antibody levels. Moreover, some episodes of acute exacerbation were characterized by a rising titer in anti-Ro/SSA antibody in the absence of detectable anti-dsDNA antibodies. A longitudinal study of anti-Ro/SSA and anti-La/SSB in a lupus mother who gave birth to an infant with congenital heart block revealed fluctuations of serum antibody titers that were unrelated to disease activity or to immunosuppressive therapy (145). Additionally, frequent measurements of these autoantibodies during pregnancy did not predict occurrence of congenital heart block. A 2-year prospective study of anti-Ro/SSA antibody by CIE method in SLE

showed fluctuation in the serum antibody titer, however, there was no correlation with lupus disease activity (146). On the other hand, Wahren et al. (147), using a sensitive ELISA test in a small number of SLE patients, found correlation between disease activity and serum titer of anti-Ro/SSA and anti-La/SSB antibodies.

A retrospective longitudinal study of 130 SLE patients revealed that anti-ENA antibodies including anti-Ro/SSA and anti-La/SSB fluctuates frequently over time. For patients who tested negative at baseline, the frequency of positive seroconversion was 56% for anti-La/SSB and 15% for anti-Ro/SSA (148).

Summary

Anti-Ro/SSA antibodies are strongly correlated with the clinical subsets of SCLE, ANA-negative SLE, and lupus-like syndrome associated with a genetic deficiency of complement. Infants of SLE mothers with anti-Ro/SSA and anti-La/SSB antibodies have an increased risk of neonatal lupus syndrome, thus, pregnant patients with SLE should be tested for these antibodies. A sensitive ELISA test for anti-Ro/SSA antibodies is useful in the diagnosis of ANA negative SLE. Prospective studies are needed to evaluate the value of anti-Ro/SSA and anti-La/SSB antibodies in monitoring disease activity.

Anti-Histone Antibodies in Systemic Lupus Erythematosus

Prevalence and Diagnostic Specificity

Antihistone antibodies comprise a heterogeneous group of antibodies that are reactive with various subfractions or complexes. Although found mainly in patients with SLE, drug-induced LE, or RA, these antibodies have been described in those with other rheumatic conditions, malignancy, and liver disease (see Chapter 22). In SLE, these antibodies are directed against H1, H2B, H3, and H2A-H2B complex (149), although other specificities can occur. All isotypes of antihistone antibodies are common in SLE (150 ,151).

Several methods have been devised to measure antihistone antibodies, including ELISA, immunoblotting, complement fixation, and immunofluorescence (152). Depending on the method, substrate, and patient selection, the prevalence of antihistone antibodies in SLE has been reported to be from 21% to 90% (152).

Antihistone antibodies have limited diagnostic specificity for idiopathic SLE. The presence of these antibodies does not appear to be any more significant than that of anti-dsDNA or anti-Sm antibodies in corroborating the clinical diagnosis of the disease. Wallace et al. (153) found that antibodies to histone (H2A-H2B) DNA complex in the absence of anti-dsDNA antibodies are found more commonly in MCTD and scleroderma-related conditions than in SLE.

Clinical Association

Several published studies on the relationship between the presence of antihistone antibodies and the clinical features of SLE have reported inconsistent results. In a small number of patients with lupus, Fishbein et al. (154) found a significantly lower prevalence of CNS involvement among those with antihistone antibodies. Fritzler et al. (155) confirmed the lower frequency of neuropsychiatric disease and the lower prevalence of nephritis, alopecia, anemia, and hypocomplementemia in patients with SLE and antihistone antibodies, suggesting a milder form of the disease. In contrast, antihistone antibodies have been reported to be associated with diffuse proliferative lupus nephritis (156) and to with lupus arthritis (137). Other investigators have failed to find any positive or negative correlation with specific clinical manifestations of the disease (150 ,157 ,158).

Similarly, the available data on the association between antihistone antibodies and disease activity are few and inconclusive. Fishbein et al. (154) found a significant drop in the serum antibody titer within a month after the initiation of steroid therapy for active SLE. Gioud et al. (157) reported a higher frequency of antihistone antibodies in patients with active disease (87%) than in those who were in remission (18%). A serial study in a small number of patients showed a correlation with disease activity (159). In untreated patients with lupus nephritis, antibodies to H2B correlated with renal, histologic, and clinical activity of the disease (159). Other investigators, however, have found no correlation among antihistone antibodies, disease activity, or activity index in the renal biopsy (151 ,155 ,158 ,160 ,161 ,162).

The discrepancy in the results of the above studies may be a result of several factors including variation in patient selection, the test system used, histone preparation, and study design.

Association with Anti-DNA Antibodies

Antihistone antibodies have been shown to correlate with the presence of anti-DNA antibodies (156 ,157 ,158) and circulating immune complexes (159). Subiza et al. (163) have established that some of the antihistone activity that is measured in SLE sera results from complexes of dsDNA anti-dsDNA, which bind to the histone substrate used in the assay. Stockl et al. (164) found that glomerular deposits of histones may bind to fixed anionic sites in the glomerular capillary wall, acting as a planted antigen that can induce immune complex formation in situ. Deposits of histones and DNA have also been identified at the basement membrane of nonlesional skin in SLE patients (165).

Histone Binding with SLE IgG

The binding of IgG isolated from SLE sera to histone has been reported to be noncognate, i.e., it is not dependent on true antigen-specific Fab recognition. In contrast, the

binding of SLE IgG with dsDNA, Sm, and other nuclear antigens was cognate, i.e., true antigen-antibody reaction (166). Further studies have revealed that histones bind an “anomalous” monomeric IgG that is present in the sera of patients with SLE as well as drug-induced SLE. The binding was sensitive to pepsin digestion of the IgG and appeared to be mediated Fc binding (167). The nature of this “anomalous” IgG remains to be elucidated, however, these observations may in part account for the discrepancies in the results of studies of antihistone antibodies in SLE and other diseases.

Association with Lupus Erythematosus Cell Test

Schett et al. (168) have identified serum antibodies to H1 as the major group of antinuclear antibodies responsible for the LE cell phenomenon in SLE. They also found that SLE patients who have antihistone-1 antibodies had marked immune response to other histones and other nuclear proteins. Moreover, these patients tended to have more severe organ involvement with nephritis and CNS disease (169).

Summary

Antihistone antibodies are of limited value in corroborating the clinical diagnosis of SLE. Serial determinations of these antibodies do not add significantly to the measurement of anti-dsDNA and other serologic parameters for assessing disease activity in patients with SLE.

Further studies on the binding of histone with SLE IgG, circulating immune complexes are needed to understand fully the significance of antihistone antibodies including pathogenicity and assessment of disease activity.

Antinucleosome Antibodies in SLE

Using purified nucleosomes in an ELISA test, Bruns et al. (170) found IgG antinucleosome antibodies in 56% of 136 SLE patients and in only 3% of 309 patients with other diagnosis. When applied to the diagnosis, IgG antinucleosome antibodies had a specificity of 97% and a sensitivity of 56%. Other investigators have reported sensitivities ranging from 30% to 90% (171 ,172 ,173 ,174).

IgG antinucleosome antibodies may be of diagnostic value for SLE in patients who test negative for anti-dsDNA antibodies. In a large series of consecutive patients suspected of autoimmune diseases. IgG antinucleosome antibodies were found in 88% of 197 SLE patients with anti-dsDNA and in 51% of 43 patients with negative anti-dsDNA. However, in this study, IgG antinucleosome antibodies were also found in patients with systemic sclerosis (21%) and in mixed connective tissue disease (7%) (175). Simon et al. (174) reported a high prevalence (70%) of IgG antinucleosome antibodies in mixed connective tissue disease and was not useful in differentiating MCTD from SLE.

When compared with conventional ANA and anti-dsDNA, Julkunen et al. (173) found that antinucleosome antibodies did not provide additional information in the diagnosis of SLE. Servais et al. (176) reported that antinucleosome antibodies were inferior to anti-dsDNA in the diagnosis of SLE. In contrast, other investigators have reported that antinucleosome antibodies had higher sensitivity than anti-dsDNA in the diagnosis of SLE (170 ,177). The discrepancies in these studies are in part a result of variations in patient selection and test methodology, including antigen preparation and study design.

Antinucleosome antibodies have been reported to be associated with lupus disease activity including nephritis in several cross-sectional studies of SLE patients of different ethnicities (170 ,174 ,178 ,179 ,180). However, other investigators have reported lack of correlation with disease activity (181). A 2-year follow up study of 101 SLE patients found no correlation between antinucleosome antibodies and lupus disease activity, renal disease, and disease damage (182).

Summary

Antinucleosome antibodies are prevalent in SLE and high serum antibody titers maybe a useful aid in the diagnosis of SLE especially in patients who test negative for anti-dsDNA and anti-Sm antibodies. Antinucleosome antibodies may be seen in drug-induced lupus erythematosus, MCTD, and systemic sclerosis. Prospective well-designed studies are needed to investigate the utility of antinucleosome antibodies in individual SLE patients for assessing disease activity and following the response to therapy.

Serologic Parameters and Renal Biopsy Findings in Lupus Nephritis

A number of studies (Table 48-4) have examined the relationship between renal biopsy findings and the serologic data obtained at biopsy (161 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190). Could the histologic type of lupus nephritis, histologic activity, and chronicity indices be predicted by anti-dsDNA, C3, and/or serologic parameters? The results of various studies are not necessarily comparable because of differences in morphologic classification, parameters measured, and patient selection, including consideration of the effects of previous or current drug therapy. All studies except two (187 ,190) were based on a single kidney biopsy that was performed within a few months after onset of the renal abnormality.

Hill et al. (188) found an excellent correlation between serum levels of anti-dsDNA and C3 with the overall amount and distribution of immune deposits in the renal biopsy as assessed by immunofluorescence. In contrast, a poor association between the degree of epithelial proliferation and

the histologic type of lupus nephritis was noted using the Baldwin classification system (191).

Table 48-4: Correlation of Serologic Abnormalities and Renal Histology

Source	No. of Patients	Results and Comments
Hill, 1978 (188)	59 with 77 biopsies	Excellent correlation between anti-dsDNA and C3 with overall amount and distribution of immune deposits; rheumatoid factor found in those with milder lesions; cryoglobulins correlated with more severe changes.
Hossiau, 1990 (189)	50	High anti-dsDNA and low C3 correlated with nephrotic syndrome with or without renal failure; class IV nephritis patients had higher anti-dsDNA titer than those with class III or V nephritis.
Nossent, 1991 (161)	35	High histologic activity index correlated with IgM antinuclear antibody and IgM anti-dsDNA. No correlation between histologic type and serologic abnormalities.
Clough, 1980 (183)	11	IgM anti-dsDNA was higher than IgG anti-dsDNA in class IV nephritis. IgG anti-dsDNA was higher than IgM anti-dsDNA in class III nephritis.
Hashimoto, 1983 (186)	20	Histologically active lesions, especially class IV nephritis, correlated with high titer and complement fixing IgG anti-dsDNA. Glomerular C3 deposits correlated with complement fixing IgG anti-dsDNA.
Feldman, 1982 (185)	34	Renal activity index but not chronicity index correlated with anti-dsDNA (Farr assay) and IgG anti-dsDNA by ELISA.
Esdaile, 1989 (184)	87	Low C3 was predictive of renal insufficiency, renal death and total SLE death; high anti-dsDNA associated with renal death and inversely related with nonrenal death.
Hecht, 1976 (187)	31 with repeat biopsy	Persistently normal C3 was associated with stability or improvement of renal lesion of repeat biopsy in some but not all patients. Anti-dsDNA showed better correlation with clinical histologic improvement.
Pillemer, 1988 (190)	55 with repeat biopsy	Normalization of C3 correlated better than decrease in anti-dsDNA titer with activity index during repeat biopsy.
Okamura, 1993 (192)	40	IgG but not IgM anti-dsDNA by ELISA correlated with renal histologic activity score and amount of electron dense glomerular deposits.

Houssiau et al. (189) reported a good correlation among the anti-dsDNA titer and the serum C3 (but not C4) level with functional severity of the renal disease and the World Health Organization (WHO) histologic classification of lupus nephritis. Patients with nephrotic syndrome or renal failure had a higher anti-dsDNA titer and a lower C3 level than those presenting with proteinuria alone and a normal serum creatinine level. Patients with class IV nephritis had a higher anti-dsDNA level than those with class III or V nephritis. In contrast, the serum C3 level did not correlate with the histologic type. Considerable overlap in values among the various clinical or histologic groups was found, however, so these associations are not applicable to the individual patient.

Nossent et al. (161) observed no correlation among the WHO histologic classification and various serologic parameters (anti-dsDNA, other types of ANA, C3, C4, C1q, immune complexes, and anticardiolipin antibodies) in 35 patients with lupus nephritis. Conversely, using the National Institutes of Health (NIH) renal histology index, the activity index correlated with serum titers of IgM ANA and IgM anti-dsDNA. Glomerular proliferation showed the best overall correlation with serologic parameters. Clough and Valenzuela (183) described a similar correlation between IgM anti-dsDNA and diffuse lupus nephritis.

Hashimoto et al. (186) reported a good correlation between histologically active lesions, especially in diffuse lupus nephritis, and high titers of IgG complement-fixing anti-dsDNA. Feldman et al. (185) obtained similar results, and they noted a good correlation between anti-dsDNA using the Farr binding assay and IgG anti-dsDNA using ELISA and renal activity, but not with the chronicity index. IgG, but not IgM, anti-dsDNA antibodies as measured by ELISA were found to correlate with the histological activity score and the amount of electron-dense deposits in 40 patients with untreated SLE who underwent kidney biopsy (192). The serum titer of anti-dsDNA antibodies was

significantly higher in patients with class IV nephritis as compared to those with class I, II, or III (192).

In contrast to these studies, Pillemer et al. (190) correlated serologic tests and histologic changes over time in 55 patients who had both initial and repeat renal biopsies. All patients received various immunosuppressive drugs for nephritis during the interval. At the time of the second biopsy, the serum C3 level had improved in 78% and the anti-dsDNA level decreased in 85% of patients. Patients with a normal C3 level at the time of the second biopsy had a significantly lower activity index than those with a low C3 level. The activity index was not significantly affected by a decrease in anti-dsDNA antibody titer. The duration of hypocomplementemia, however, was less consistent as a prognostic indicator. Esdaile et al. (184) also found a low serum C3 level to be a valuable predictor of renal insufficiency, renal death, and total SLE death in a study of the long-term outcome of 87 patients with lupus nephritis. In a similar study of 31 patients with SLE and serial kidney biopsies, Hech et al. (187) showed that normalization of the serum C3 level and a drop in the anti-dsDNA titer following drug therapy are associated with stabilization or improvement of the renal disease.

A prospective study of 17 patients concluded that serum C3 levels are more sensitive and specific than serum C4 values for monitoring disease activity in lupus nephritis (193).

Serologic Parameters in Renal Relapse

A prospective study of 46 newly diagnosed lupus nephritis over a period of 5 years revealed that 37% experienced at least one renal relapse. Serological findings including rising anti-dsDNA titer and hypocomplementemia were less pronounced during the relapse than at baseline and were not particularly helpful in predicting renal relapse (194).

“Silent lupus nephritis” refers to patients with histolopathologic diagnosis of lupus nephritis on kidney biopsy, but without clinical evidence of renal disease including normal urinalysis, creatinine, BUN, and creatinine clearance. Wada et al. (195) reported that 8 of 31 (28.8%) of patients with silent lupus nephritis developed overt renal disease over a 60-month follow-up. Elevated anti-dsDNA and hypocomplementemia predicted the development of clinical nephritis.

Summary

Kidney biopsy is useful in the management of patients with lupus nephritis. The histologic type of lupus nephritis and severity of renal damage as assessed by the activity and chronicity of the lesions are predictive of the outcome of lupus nephritis in most patients. None of the serologic parameters at the time of biopsy, either singly or in combination, can adequately and satisfactorily predict the histologic type or severity of the renal lesion in an individual patient.

Complement and Activation Products in Systemic Lupus Erythematosus

The in vivo activation of the complement system by complexes of anti-DNA and DNA antigen and other autoantibodies is central to the pathogenesis of the glomerular injury and, possibly, to other tissue damage in patients with SLE. Acute exacerbations of the disease often are associated with hypocomplementemia. Serial measurements of C3 and C4 are routinely ordered in clinical practice while testing for total hemolytic activity (i.e., CH_{50}) or C1q is sometimes used to assess lupus disease activity.

A recent prospective study of 53 SLE patients studied monthly noted that a decrease in the serum level of C3 and C4 was not consistently associated with global measures of disease activity. However, decreasing serum complement over time was strongly associated with lupus nephritis and hematologic abnormalities (196). Other investigators have reported that measurements of C3 and C4 are not reliable marker or predictor of lupus disease activity or to separate patients with mild disease from those with severe disease (197 ,198 ,199). Several reasons are cited why serum complement levels are imperfectly associated with lupus disease activity. There is a wide variation of normal complement protein concentration among individuals partly because of genetic factors. The serum protein concentrations are controlled by the rate of protein synthesis and catabolism that vary between individual subjects. Complement components including C3 and C4 are acute phase reactants and synthesis may increase in response to inflammation. Serum levels of complement proteins do not reflect what is happening in the tissues. Autoantibodies to complement components such as anti-C1q antibodies may activate complement such that the degree of complement activation is associated with these autoantibodies rather than lupus disease activity (200).

Investigators have postulated that small-vessel injury in SLE may occur without evidence of immune complex mediation by the release of split products of complement activation, such as anaphylatoxins. These activation products, such as C3a, C5a, and SC5b-9 can activate and attract inflammatory cells. This can lead to cell aggregation and vascular adherence, resulting in an occlusive vasculopathy and ischemia (28).

Correlation with Disease Activity

A number of studies have shown that measurement of the plasma concentration of activation products of complement, including iC3b neoantigen, C3a, C4a, C3d, C4d, and the terminal complex, C5b-9, can be useful in assessing disease activity and predicting exacerbations (201 ,202 ,203 ,204 ,205 ,206 ,207 ,208)

(Table 48-5). The consensus of these various studies is that measurement of the activation products is superior to the determination of serum C3 or C4 values. Many patients with clinically active disease and normal serum C3 or C4 levels have elevated activation products of complement. Nevertheless, except for a few (201 ,203 ,209), most of these studies emphasized differences between patient groups (e.g., active vs. inactive) rather than longitudinal determinations in individual patients.

Table 48-5: Activation of Complement as a Measure of Disease Activity in SLE

Source	Activation product	No. of Patients	Results and Comments
Negoro, 1989 (205)	iC3b neoantigen	40 untreated	Plasma levels elevated in 83% of patients; highly correlated with disease activity and renal activity index.
Hopkins, 1988 (201)	C3a and C5a	40	C3a level increased in all patients; occurred 1 to 2 months prior to flare; marked elevation in cerebritis; C5a levels less sensitive.
Wild, 1990 (207)	C4a and C3a	24	C4a levels higher in patients with severe disease than in those with mild disease; C4a correlated with anti-dsDNA and C1q assay for immune complexes; C4a superior to C3a.
Senaldi, 1988 (206)	C4d and C3d	48	C4d correlated better than C3d with disease activity; C3 and C4 did not correlate with disease activity.
Horigome, 1987 (202)	Terminal C attack	54	TCC correlated with circulating immune complexes, CH_{50}, C4, C3, complex (TCC) C5, and alternate pathway activity.
Garwryl, 1988 (203)	Terminal C complex	22	Elevated TCC correlated with 89% of all flares.(C5b-9)
Kerr, 1989 (204)	Factor B activation (Ba)	51	51% of patients with high Ba had severe multisystem disease; associated with cutaneous vasculitis; Ba correlated better than C4a and C3d with disease severity.
Buyun, 1992 (209)	BaBb, C4d, SC5b-9	86	C4d most sensitive in 86% with major flares
Porcel, 1995 (210)	C3, C4, C3a, C4a, iC3b	39	SC5b-9 most useful with 77% sensitivity and 80% specificity.
Mollnes, 1999 (211)	C4bc, Bb, C3a, C3bc, C5a, SC5b-9	21	Only SC5b-9 correlated with disease activity scores.
Nagy, 2000 (197)	C1rs-C1inh, C3b(Bb)P, SC5b-9	65	C3b(Bb)P was highly specific and sensitive indictor of disease activity.

Three prospective studies examined the value of complement activation products and conventional measurements of complement in monitoring disease activity. Buyon et al. (209) reported that an elevated serum level of C4d had the most sensitivity, being found in 86% of patients who subsequently developed a major exacerbation. The specificity was low, however, such that 69% of the patients who did not flare during the study period had abnormally elevated C4d. Porcel et al. (210) found the terminal complement complex to be the most useful in monitoring disease activity, with 77% sensitivity and 80% specificity. Nagy et al. (194) compared the serum levels of C8H50, C4.C3 to the plasma levels of C1rs-C1inh, C3b(Bb)P, and SC5b-9 in 65 SLE patients. In a smaller number of patients studied serially, C3b(Bb)P, a complex formed during the activation of the alternative pathway, showed the highest difference between active and inactive disease and the best correlation with SLEDAI. Long-term study of a larger group of patients are needed to confirm these findings.

In the SLE patients without evidence of nephritis, Mollnes et al. (211) found that the routine measurement of complement including activation products is of limited importance in predicting disease flares. They measured conventional complement tests and plasma level of C1rs-C1inh, C4bc, Bb, C3a, C3bc, C5a, and SC5b-9. There were 27 flares in 21 patients but none developed nephritis during the study period. Only the plasma level of SC5b-9 correlated with disease activity at the time of the flare.

Measurement of C3d in the urine has been shown to be a sensitive indicator of complement activation and has been reported to be helpful in assessing disease activity in lupus nephritis (212 ,213).

Conventional measurements of complement and split products may be useful in evaluating disease flares during pregnancy and in differentiating a lupus flare from preeclampsia. The serum levels of CH_{50}, C3, and C4 rise during pregnancy. In patients without SLE but with

preeclampsia, the plasma concentration of complement split products, including Ba (i.e., activation product of the alternative pathway), C3a, C4d, and SC5b-9, is increased; however, CH50 generally remains normal. In pregnant patients with SLE and disease exacerbation, there is a reciprocal rise in complement split products and a drop in serum C3, C4, and CH_{50}. A high ratio of CH_50 to Ba has been suggested to differentiate patients with preeclampsia from those with active SLE (214 ,215 ,216).

Summary

Serial measurements of serum C3 and C4 are useful in following SLE patients with nephritis and possibly those with hematologic abnormalities. Additional prospective studies are needed to compare the relative value (including cost-effectiveness) of the various complement activation products in assessing disease activity, major organ involvement such as nephritis, and in determining the possible effects of comorbid conditions, especially infections. A minor drawback of these assays is the need for special handling of the plasma specimen to prevent spurious activation of complement in vitro. The measurement of activation products of complement may be particularly useful in patients with isolated CNS involvement, who frequently do not exhibit hypocomplementemia (201).

Table 48-6: Summary of Serologic Abnormalities in Systemic Lupus Erythematosus (SLE)

1. Anti-double-stranded (ds)DNA and anti-Sm antibodies are serologic markers of idiopathic SLE. Their presence in patients suspected of the disease on clinical grounds confirms the diagnosis.
2. Mixed connective-tissue disease (MCTD) should be considered in a patient with overlapping features of SLE, polymyositis, and scleroderma in the presence of a high titer of anti-U1RNP and the absence of anti-dsDNA and other specific types of antinuclear antibody (ANA).
3. Pregnant SLE patients should be tested for anti-Ro/SSA antibodies, because their presence indicates a risk for neonatal lupus syndrome.
4. Anti-Ro/SSA antibodies are associated with SCLE, photosensitivity, ANA-negative SLE, and genetic deficiency of complement with LE-like clinical features.
5. Antihistone antibodies have limited diagnostic value for idiopathic SLE but are considered characteristic of drug-induced LE.
6. No single serologic test is predictive of disease exacerbation in SLE. The most useful parameters for assessing disease activity are anti-dsDNA and serum complement levels.
7. Measurements of the activation products of complement and soluble receptors are promising serologic markers predictive of disease severity and exacerbation.

LE, lupus erythematosus; SCLE, subacute cutaneous lupus erythematosus.

Cytokines and Soluble Receptors in SLE

A recent analytical review of biomarkers in SLE identified four markers of disease activity that have promising clinical value: soluble IL-2 receptors, thrombomodulin, soluble VCAM-1, soluble TNFR and α interferon (217).

Soluble IL-2 Receptors in SLE

Following activation, resting T lymphocytes express receptors for IL-2 (IL-2R) on the cell surface, and a high-affinity IL-2R enables T lymphocytes to proliferate in response to the cytokine. The receptor can be shed or released in vitro, or physiologically in vivo, and can be detected in supernatants of cell cultures, in blood, and in body fluids. Elevated serum concentrations of soluble IL-2R (sIL-2R) have been found in patients with conditions that are characterized by immune-system activation, including SLE, RA, chronic infections, and malignancies.

Association with Disease Activity

We have found a positive correlation between serum levels of sIL-2R and immunologic markers of disease activity in SLE, including reduced serum C3 and high cryoglobulin levels (29). Sequential studies in patients with active SLE have revealed a decrease in serum sIL-2R levels concomitant with a clinical response to steroid therapy. Our findings have been confirmed and extended by other investigators (218 ,219 ,220 ,221 ,222 ,223).

A prospective study of 71 unselected patients with SLE by ter Borg et al. (218) showed an elevation of sIL-2R in 18 of 21 patients who developed clinical exacerbations, which correlated with changes in anti-dsDNA antibodies and with C3 and C4 values. Of these exacerbations, 75% were preceded by a rise in sIL-2R levels, but changes in anti-dsDNA and C3 levels tended to precede the increase in sIL-2R. The serum concentrations of sIL-2R in patients with inactive SLE were higher than those of healthy individuals, suggesting that an ongoing T cell activation process was occurring in SLE, even during periods of clinical quiescence. The sIL-2R level increased further before disease exacerbation.

In lupus nephritis, Laut et al. (223) reported a correlation between sIL-2R and histologic activity and chronicity indices, along with presence of IgG and C3 in the kidney biopsy specimen. The serum level did not correlate with serum creatinine, suggesting that the high sIL-2R was not the result of decreased renal clearance. Significant elevation of sIL-2R occurred during lupus nephritis flare and appeared to more sensitive than anti-dsDNA and CH_{50} as a serologic marker.

Elevation of sIL-2R can occur in infections and should be taken into consideration in patients with lupus. Wong and Wong (224) found markedly elevated sIL-2R in patients with lupus and either active or inactive SLE and concurrent infection. Chronic infections, especially tuberculosis and

candida infection, were associated with higher levels of sIL-2R than with pyogenic and herpes zoster infections.

Gilad et al. (225) reported elevated levels of sIL-2R in the cerebrospinal fluid (CSF) of patients with stroke as the initial manifestation of SLE. The levels were significantly higher than those seen in the CSF of nonlupus patients with ischemic strokes.

Soluble Tumor Necrosis Factor Receptor

In a prospective cohort study, Aderka et al. (226) found the serum level of sTNF p55 and p75 correlated with lupus disease activity than did anti-dsDNA antibodies. In a cross-sectional study of 40 SLE patients, Davas et al. (227) reported that the serum level of sTNF correlated with SLEDAI and European community lupus activity measure (ECLAM) disease activity scores. The elevated serum level of sTNFR in patients with lupus nephritis decreased significantly 6 months after drug therapy. Other investigators have reported similar findings that support the value of measuring soluble TNF receptor in assessing disease activity (228 ,229 ,230).

Serum Thrombomodulin

Thrombomodulin is a glycoprotein expressed on the luminal surface of vascular endothelium and acts as a thrombin receptor. Following endothelial damage, soluble thrombomodulin is detected in the plasma and urine and is considered a maker of microvascular endothelial cell injury. Elevated serum level of thrombomodulin has been reported in active SLE especially those with nephritis (231 ,232). Ho et al. (233) found plasma concentration of soluble thrombomodulin correlated with the level of vascular cell adhesion molecule-1 and both were correlated with serum creatinine and SLEDAI score. Plasma thrombomodulin remained persistently elevated in patients with history of lupus nephritis independent of disease activity and serum creatinine suggesting endothelial cell activation in the kidneys (234). Compared to other serologic parameters, including anti-dsDNA, complement, C-reactive protein, and soluble vascular endothelial adhesion molecules, Boehme et al. (235) found that (235) soluble thrombomodulin correlated the best with lupus disease activity measured by SLAM scores.

Circulating Adhesion Molecules

Elevated plasma levels of soluble vascular adhesion molecule-1 (sVCAM-1) and other cell adhesion molecules in SLE and other diseases are considered markers of leucocyte and endothelial cell activation or damage. Ikeda et al. (236) found soluble VCAM-1 to be significantly elevated in class III and IV lupus nephritis and the plasma level correlated with high SLEDAI score and decreasing during remission. Other investigators have also noted a significant association of sVCAM-1 levels with active lupus nephritis (233 ,237).

Serum levels of sVCAM-1 were found to be increased in patients with primary and secondary antiphospholipid syndrome associated with SLE, especially in those patients with severe and recurrent thromboses (238).

SLE patients presenting with demyelinating syndrome and patients with multiple sclerosis have been found to have elevated levels of sVCAM-1 in paried samples of serum and CSF. Intrathecal synthesis of sL-selectin but not sVCAM-1 was seen in SLE (239 ,240). To understand the significance of these findings, further studies on SLE patients presenting with other neuropsychiatric syndromes should be undertaken.

Summary

The measurement of sIL-2R, thrombomodulin, sTNF-R, and/or sVCAM-1 appears to be useful for assessing disease activity especially in lupus nephritis and may be particularly helpful in those patients who test negative for anti-dsDNA.

Additional prospective longitudinal studies are essential to determine whether serial measurements can predict disease exacerbation, provide additional information to conventional laboratory parameters in monitoring response to therapy, and to examine the effects of infections and other comorbid conditions in SLE patients.

Application of Multiple Serologic Measurements in Systemic Lupus Erythematosus

It is clear that no single serologic test can adequately assess or predict the clinical course of SLE in individual patients. A few studies have examined application of a panel of serologic reactions to improve sensitivity and correlation with disease activity.

In an early study, Schur and Sandson (241) concluded that a combination of complement-fixing anti-dsDNA and CH_{50} correlated better with active disease, especially lupus nephritis, than either of the serologic tests alone. In a more recent study, Lloyd and Schur (21) found that serial measurement of a combination of CH_{50}, C3, C4, and circulating immune complexes by C1q-binding assay appears to be the most useful. Anti-dsDNA antibodies did not significantly increase the usefulness of this panel (see Chapter 13 , Complement and Systemic Lupus Erythematosus).

In a prospective study of 48 unselected patients with SLE, Abrass et al. (23) found that circulating immune complexes, as determined by a solid-phase C1q-binding assay, correlate with active disease manifestations, particularly nephritis or arthritis, but not with skin or other organ involvement. A change in disease activity, prompting the physician to make a change in management, was predicted by the results of solid C1q-binding test. Neither C3 nor anti-dsDNA correlated with disease activity, and neither gave additional information when combined with use of the solid-phase C1q-binding test.

Using a battery of laboratory tests, Morrow et al. (242) failed to identify a single test that reliably distinguished between severely active, moderately active, and inactive disease groups of patients with SLE. Determination of circulating immune complexes by polyethylene glycol precipitation, platelet count, and erythrocyte sedimentation rate distinguished the active from the inactive disease group. Patients with severely active disease and involvement of three or more systems were different from the less active group by solid-phase C1q-binding assay for immune complexes, anti-dsDNA, CH_{50}, and lymphocyte count, but patients with neuropsychiatric involvement and those with thrombocytopenia were the most difficult to sort out. Only 44 of patients could be classified accordingly into clinical grades when combinations of four out of five laboratory tests were used. Isenberg et al. (243) were unable to find a correlation between clinical disease activity and multiple serologic reactions to dsDNA, ssDNA, RNA, synthetic polynucleotides, and cardiolipin. In a retrospective study of complement and circulating immune complexes (as tested by five different assays) in 33 patients, Valentijn et al. (25) concluded that although disease activity correlates with serum levels of CH_{50}, C3, or C1q (by binding assay), the sensitivity and predictive value of the serologic parameters are low. In 20 of patients, one or more parameters constantly was abnormal regardless of disease activity. On the other hand, in a small subset of patients, a patient-specific activity parameter could be identified.

In a cross-sectional study of 100 patients, Clough et al. (244) found that a combination of sIL-2R, Westergren sedimentation rate, and anti-dsDNA antibody by ELISA correlated best with disease activity as measured by SLAM index. In contrast, the serum levels of C4, iC3b, and Bb correlated poorly with disease activity.

A 12-month longitudinal study of 53 patients with lupus showed an incidence of disease flare of 0.69 per patient-year of follow-up and a good correlation with serologic abnormalities. Active nephritis was associated with high anti-dsDNA antibodies as measured by Farr method, low C3, and low C4. High anti-dsDNA level also was associated with musculoskeletal and cardiopulmonary involvement. The odds ratio for lupus flares in asymptomatic patients with high anti-dsDNA was three; for those with low serum C3, it was two (245).

Conclusions and Recommendations

Many reports evaluating the application of serologic tests in the assessment and prediction of disease activity have been rife with shortcomings. No uniform index of clinical disease activity has been used, and certain groups of patients (e.g., those with nephritis) were either over- or under-represented in the test populations. Conclusions often were based on a single test sample, and length of the follow-up period was not adequate. Serologic tests were not standardized, so comparison of the various studies is not feasible. Despite these obvious faults, it is clear that no single serologic test available today is ideal and applicable to all patients with lupus. Considering the heterogeneity of the clinical disease, it is unlikely that a single such test will be found. Serologic abnormalities in a patient with active lupus nephritis are not necessarily the same as those in another patient with skin rash, fever, hematologic changes, and/or serositis.

Newer serologic tests, such as determination of complement split products, sIL-2R and other soluble factors, are undergoing further evaluation, and a combination of anti-dsDNA and serum complement now is generally used in clinical practice. The ELISA test for anti-dsDNA probably is the most widely available test in clinical practice. The clinician should become familiar with the advantages and limitations of the particular assay that is used in the laboratory to which specimens are sent. In patients who continually do not have anti-dsDNA antibodies (even after using different assay methods), measuring the serum titer of some other ANA, such as anti-Sm or anti-Ro/SSa, may be useful (83). The serum C3 concentration is measured more frequently than CH_{50}, although the latter probably is more a more sensitive parameter (24 ,242). In my experience, serial measurement of serum cryoglobulins is a useful parameter, while tests for circulating immune complexes, such as the C1q solid-phase binding assay have limited value.

It must be remembered that there are some patients in clinical remission who have persistently abnormal serologic findings (12 ,13). Careful monitoring of specific organ functions, such as renal function, remains an important aspect in the assessment of disease activity and response to therapy (see Table 48-6).

Chapter 49

Differential Diagnosis and Disease Associations

Daniel J. Wallace

SLE's mimicry of other diseases was first reviewed in 1954 by Harvey (1), who listed 24 different diagnoses made on his patients during the early stages of their disease. Usually, the greatest difficulty is separation of SLE from closely related connective tissue disorders. Table 49-1 summarizes the clinical data in order to make these differences readily apparent. Presentations of diverse entities ranging from thyroiditis, gluten sensitivity, syphilis, and viral, as well as parasitic infections have all been misdiagnosed as lupus (2 ,3 ,4 ,5 ,6 ,7).

Is it Really Lupus?

In addition to obtaining a detailed history, attempting to correlate any past features that might have been manifestations of SLE with the current illness, the physician must perform a thorough physical examination (see Chapter 32) and make a careful laboratory survey. This should include determination of the presence of antinuclear antibody (ANA), rheumatoid factor (RF), anti-cyclic citrullinated peptide (anti-CCP), creatine phosphokinase (CPK), C3 complement, Westergren sedimentation rate, and also a complete blood count (with differential and platelet counts), blood-chemistry profile, Venereal Disease Research Laboratories (VDRL) test, partial thromboplastin time, urinalysis, chest radiography, and electrocardiography. If these tests are not diagnostic and SLE is strongly suspected, assays for anticardiolipin antibody, anti-Ro/SSA, anti-La/SSB, anti-DNA, anti-Sm, and antiribonucleoprotein (anti-RNP) should be done, as well as a serum-protein electrophoresis. The Mayo Clinic has advocated a cascade algorithm for screening positive ANAs (8). Along with a thorough clinical evaluation, a diagnosis can be derived 90% of the time.

Our group evaluated 44 patients with a positive ANA and no other abnormal commonly derived tests or autoantibodies (i.e., Sm, RNP, Ro, La, Scl-70, RF, C3, C4, CPK) who did not fulfill the ACR criteria for SLE and were referred for a rule-out-lupus consultation (9). At 6 months, 43% fulfilled criteria for SLE, 32% had fibromyalgia, and 9% had seronegative rheumatoid arthritis (RA). Obtaining a bone scan, lupus band test, serum-protein electrophoresis, and specific tests such as antineuronal antibodies, antibodies to histone-DNA complexes, or antiribosomal-P antibodies helped to make final determinations.

The differential diagnosis of connective-tissue disorders is complicated by the overlap of coexisting rheumatic syndromes. Two large clinics have reported that 25 and 33 of their patients, respectively, had features of two connective-tissue disorders (10 ,11). Co-existing SLE and scleroderma, as well as SLE and polymyositis, have been found in a number of patients. If a positive anti-RNP is present, the overlap syndrome may represent a distinct entity termed mixed connective-tissue disease (MCTD).

Complicating these issues is the recognition that autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, Sjögren syndrome, or Raynaud phenomenon can be isolated processes for years before evolving into an established connective-tissue disease. Thirty percent of Isenberg's 215 British lupus patients also had at least one other autoimmune disorder (12). As early as 1956, Talbott and Ferrandis (13) observed frequent transitional forms from one rheumatic disease to another. Some patients, who appear to have fulfilled all or most of the clinical criteria for a diagnosis of active RA, lose the exclusive features of this malady at some future time and manifest unmistakable SLE, polyarteritis, polymyositis, or scleroderma. Currently, it is not possible to determine whether the disorder was present from the beginning of symptoms and subsequently changed into another disorder.

Why is it necessary to differentiate among these conditions? Arriving at a specific diagnosis is necessary to understand the course and prognosis of the illness and treat it effectively. For example, if gold therapy had been instituted in a patient who was thought to have RA and urinary or hematologic abnormalities developed, it would be assumed that they were a reaction to the treatment. If ANA had been initially sought and found, however, gold therapy might not have been used, and the changes noted would have been recognized as being evidence for progression of the underlying disease.

Table 49-1: Differential Diagnosis of Connective Tissue Disorders

Parameter	SLE	RA	PSS	MCTD
Sex incidence	90% female	75% female	66% female	80% female
Age of majority	10–50 y	20–40 y	20–50 y	All ages
Family history	+ for LE or RA in 12% or more	Often +	0	Rarely +
Disease duration	Mo-y	Mo-y	Mo-y	Variable
First changes	Arthritis, rash	Arthritis	Skin	Arthritis, Raynaud's phenomenon
Cardiac involvement (clinical)	33%	65% at autopsy; clinically rare	+; perfusion and conduction abnormalities seen	Myocarditis in children (clinical)
Skin and mucous membranes	Alopecia, butterfly erythema, scaling erythematous papules, ulcers	Subcutaneous nodules	Tightness of skin of hands, face, neck; hyperpigmentation of involved skin	Rashes of SLE, PSS, and membranes dermatomyostitis
Ocular	Iritis, retinal vasculitis or infarcts; Sjögren's syndrome	Scleritis, Sjögren's syndrome	Sjögren's syndrome	Rare; Sjögren's sydrome
Adenopathy	Moderate	Minimal	0	Minimal
Pleurisy or lung disease	Most cases	Rare	Interstitial fibrosis common	30%
Pericarditis	30%	Clinically rare	Rare	25%
Generalized abdominal pain and tenderness	Often	0	Dysphagia common; bowel motility decreased	Dysphagia common
Hepatomegaly	Occasional	0	0	0
Splenomegaly	10%	Rare	0	0
Joints involved	All joints, esp. minor	All joints	Minor	Erosive arthritis in 30%
Arthritic deformity	Frequent, nonerosive	Often erosive	Often	20%
Myalgia	48%	Frequent	+20%	50%
Raynaud's phenomenon	26%	Occasional	Common	80%
CNS involvement	Personality changes, convulsions and localized deficits, fatigue	Rare	Rare	10%
Laboratory				
Urine abnormalities	46% at some time	0	Creatinuria	Lupus nephritis in 10–40%
WBC and differential	Leukopenia in 43%	Leukocytosis, acute phase	Normal	Leukopenia in 35%
Anemia	10% hemolytic; 56% < 11.0 g Hb	Normocytic	0	41%
Uremia	5–10%	0	Occasional	0
Hyperglobulinemia	Common	Frequent	40%	80%
LE cells	+in 75%	+9% only	+5%	14%
ANA	+95%	+25%	+50% speckled, CREST-centromere	+100% speckled
Muscle biopsy	Usually 0	Usually 0	Myositis uncommon	Often positive
Skin biopsy	Suggestive +	0	Diagnostic	+ lupus band test or PSS
Dermatomyostitis and Polymositis	**Polyarteritis Nodosa**	**Rheumatic Fever**	**Serum Sickness**	**Behçet's Syndrome**
66% female	40% female	Equal	Equal	Mostly female
10–50 y	All ages	2–19 y	All ages	10–50 y
0	0	0	0	0
Mo-y	Variable	Mo-y	Weeks	Mo-y
Myalgia, skin changes, or weakness	Asthma, polyneuritis, abdominal pain, or fever	Arthritis	Urticaria	Orogenital ulcers
Occasional	Occasional	Most in acute phase	0	0
Periorbital edema, dusky erythema, Gottron's nodes	Hives, necrotic ulcerations, cutaneous and subcutaneous nodules	Erythema marginata, subcutaneous nodule	Hives, angioneurotic edema	Recurrent aphthous stomatitis, cutaneous vasculitis
0	Rarely, retinal hemorrhages and exudates	0	0	Uveitis in 66%
Rare	Minimal	Minimal	Minimal	0
Rare	0	0	0	0
Rare	0	Often	0	0
0	Often	Occasionally	Occasionally	Inflammatory bowel disease, occasionally
0	20%	+ with failure	0	0
Occasional	0	Rare without subacute bacterial endocarditis	0	0
Rare	Major	Major	All	55%
0	0	0	0	Rare
Marked	Common	Frequent	Rare	0
Common	Rare	0	0	0
0	25%	Chorea	0	22%
Creatinuria	Hematuria and red cell casts	0	0	0
Normal; eosinophila occasionally	Leukocytosis, eosinophilia in 18%	Leukocytosis	Leukocytosis, eosinophilia	0
Uncommon	50%	Normocytic	?	0
0	Common	0	0	0
0	Occasionally	0	0	Occasional
0	0	0	0	0
+30%	+20%	0	0	0

The Misdiagnosis of Lupus

Many people who are told they have or might have SLE do not. Hochberg et al. noted that only one third of patients who were told they had lupus by a physician actually fulfilled the American College of Rheumatology (ACR) criteria for SLE (14). One hundred forty-nine patients were referred to the University of Alabama for management and/or consultation for suspected SLE; 37 (25%) probably had only fibromyalgia and 15% had an undifferentiated or incomplete autoimmune syndrome (15). Two hundred sixty-three patients referred to the University of Florida Autoimmune

Disease Clinic between 2001 and 2002 carried a presumptive diagnosis of SLE. The actual diagnosis could only be confirmed in 49% of them (16). Although many patients might have a cross-over syndrome or undifferentiated connective-tissue process, at least of half of those carrying a diagnosis of SLE that is unconfirmed do not have any inflammatory process. The misdiagnosis of lupus leads to unnecessary, toxic and expensive treatments, stigmatization of patients, pointless lifestyle and dietary restrictions, and upset family relationships and reproductive planning. Even more disturbing are the frequent feelings of anger toward the rheumatologist who tells the patient they do not have the disease. Although most of these patients have fibromyalgia (see Chapter 63), factitious disorders mimicking SLE also have to be considered (17).

Positive Antinuclear Antibody Testing: How Often Is It Lupus?

All too often, rheumatologists are referred patients who feel well or have vague symptoms and have a positive ANA to “rule out lupus.” A positive ANA often is found in patients with other disorders, even in seemingly healthy patients. A positive ANA had a 10% predictive value for SLE at a university medical center (18) and a 23% value in a large consultative rheumatology practice (19). A suburban Orange County, California rheumatology group studied 276 patients who were referred for a positive ANA without a diagnosis (20). After a comprehensive evaluation, 52 (18.8%) were diagnosed with SLE, 44 (15.9%) had an organ-specific autoimmune disease, 8.3% had an infectious disease, and 2.9% had neoplasia. No diagnosis was made in 13.4%. Of 1,010 ANA tests ordered during a 10-month period at the Beth Israel Hospital laboratory in Boston, 153 were positive. Seventeen patients turned out to have lupus, and other rheumatic diseases were identified in 22, for a predictive lupus value of 11% (21). On the other hand, 130 soldiers who donated sera while being inducted into the armed forces who ultimately developed lupus were studied (22). One hundred fifteen had at least one SLE autoantibody (78% had ANA), which presented a mean 3.3 years prior to diagnosis. Sixty-two ANA-positive Canadian patients were evaluated a mean 5.4 years later, only 3 had developed a connective tissue disease, and none were diagnosed with SLE (23).

Antinuclear Antibody-Negative Lupus

Positive ANA is only one of 11 criteria that are used to define SLE according to the ACR classification. As noted in Chapter 2 , 4 of the 11 criteria must be present to make a diagnosis, but the ANA is so central to current concepts of SLE that many rheumatologists find it inconceivable for SLE to be present without it.

Several reports have documented the delayed appearance of ANA in patients suspected of having SLE. In view of my own group's studies (24 ,25) documenting a mean of 3 to 4 years between onset of symptoms and time of diagnosis, this is not surprising. Cairns et al. (26) reported 11 patients with lupus nephritis in whom a negative ANA persisted for years before becoming positive. Bohan (27) and Enriquez et al. (28) presented several well-documented cases. Persillin and Takeuchi (29) found ANA in the urine and pleural fluid of a patient with diffuse proliferative nephritis and nephrotic syndrome for some time before serum ANA was present. Low antibody concentrations in the serum secondary to loss in body fluids can be present, as was noted by Ferreiro et al. (30).

Numerous reports in the 1960s and 1970s examined the ANA-negative lupus subgroup, but only animal substrates for ANA were considered to be reliable at the time (31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 ,43). Many patients actually had discoid lupus erythematosus (DLE) or subacute cutaneous lupus erythematosus (SCLE) and did not meet ACR (then ARA) criteria, but the remaining number of ANA-negative patients with lupus was larger than necessary. This became documented when human cell line ANA substrates were introduced. Provost's group evaluated 28 patients with SLE who had titers of 1:20 or less with a mouse liver substrate (31). Using a rat liver substrate, three (11%) had a positive ANA. With human spleen imprints, 16 (57%) were positive, 9 (32%) were positive on a KB cell-line substrate, and 8 (28%) were positive with an Hep-2 cell line. These results emphasize how a negative ANA can become positive merely by using another substrate, thereby converting ANA-negative lupus to ANA-positive lupus. Reichlin (44) has stated that with a KB or Hep-2 substrate, 98% of all patients with SLE are ANA-positive, because non-DNA–containing antigens such as Ro/SSA are better represented when these cell lines are studied. Unfortunately, human cell lines are less specific, although they are more sensitive. Larger numbers of healthy people have positive ANAs when human cell lines are used. Only 17 of 447 patients (3.8%) with idiopathic SLE who were tested between 1980 and 1989 on Hep-2 substrate were ANA-negative (45). They were evenly divided into three groups: (1) antiphospholipid syndrome, (2) renal biopsy documented lupus in patients who had received steroids and chemotherapy, and (3) skin biopsy positive patients who also fulfilled ARA criteria. Several reports also have documented patients with high-titer cardiolipin antibody, recurrent thromboses, and negative ANAs who fulfilled the ACR criteria for SLE (46 ,47). A 2004 literature review found 164 cases of ANA negative lupus published since 1976, or which 97% were described before 1987. Only 27 (16%) of the cases were tested on a suitable substrate (48).

Technical inaccuracy, prozone phenomenon, variations in microscope quality, ANA hidden within circulating immune complexes (CICs), in vivo binding of ANA by tissues, substrate specificity, low-cutoff dilutions, and use of monospecific antisera are other causes of negative ANAs in patients with SLE. Inadequate fixation of the substrate may lead to antigenic deficiency, allowing leaching of the pertinent antigens leading to negative ANA results. Occasionally, patients with positive LE-cell preparations

and negative ANAs have been observed (49 ,50 ,51). Wide variations in the reproducibility of ANA tests and difficulties in standardization also are problems that have not yet been overcome (52 ,53). Phenotyping B cells may help diagnose true SLE (54).

In summary, if a KB or Hep-2 cell-line substrate is used to detect ANA, 90% of the ANA-negative patients who meet ACR criteria can be shown to be ANA-positive. If these substrates are not available, specific tests for anti-Ro/SSA may be useful (55). Other ANA-negative patients with lupus may fulfill DLE, SCLE, or juvenile RA (JRA) definitions without fulfilling ARA criteria. ANA-negative patients with lupus usually fall into three categories: (1) antiphospholipid syndrome, (2) early disease, and (3) previously positive ANA made negative by steroids, cytotoxic drugs, or uremia (56). True ANA-negative lupus probably comprises less than two of all SLE cases. Many patients who claim to have ANA-negative lupus do not have SLE (57).

Undifferentiated Connective-Tissue Disease

Coined by LeRoy in 1980 (58), the term undifferentiated connective tissue disease (UCTD) has undergone many evolutions. Between 1982 and 1987, ten rheumatic disease centers enrolled 410 patients for a landmark study. All had symptoms for less than 1 year. Fifty-seven had RA, 57 SLE, 37 poly/dermatomyositis, 46 scleroderma, and 213 early “connective tissue disease.” The latter was defined as patients with isolated Raynaud phenomenon, unexplained polyarthritis, or isolated keratoconjunctivitis sicca, and at least three of the following: Raynaud, polyarthritis, sicca symptoms, myalgias, rash, pleurisy, pericarditis, central nervous system (CNS) symptoms, pulmonary symptoms, peripheral neuropathy, false-positive test for syphilis, and elevated sedimentation rate. These patients have been monitored for nearly 20 years and the following observations have been made (59 ,60 ,61 ,62 ,63):

- Twenty percent with unexplained polyarthritis developed RA; one of 67 developed SLE.
- Among 31 with isolated Raynauds, one developed SLE.
- Among 115 with UCTD, 33 were still UCTD, 12 developed SLE, four developed RA.
- UCTD had an 87% 10-year survival compared with 56% for scleroderma.
- Thirteen percent of the UCTD patients evolved SLE. They were more likely to be younger, African American, and have rashes autoantibodies.

In other words, at 10 years, approximately one third with UCTD had no disorder, one third remained UCTD, and one third evolved a defined rheumatic disorder. Six hundred sixty-five European UCTD patients were followed 5 years later (64). Two hundred thirty, or (34.5%) developed a defined connective-tissue disease, 12% remitted and 64.5% remained UCTD. From most to least frequent, the defined disorders were RA, Sjogren, SLE, MCTD, scleroderma, vasculitis, and inflammatory myositis.

Table 49-2: Practice Point: A Working Definition for UCTD

1. Mandatory: inflammatory arthritis in >1 joint or Raynaud or keratoconjunctivitis sicca
2. Mandatory: positive antinuclear antibody, rheumatoid factor or anti-CCP
3. Need three of the following: myalgias, autoimmune rash, serositis, persistent fever without infection, adenopathy, elevated sedimentation rate or CRP, antiphospholipid antibody

---

Must not fulfill ACR definitions or criteria for any other rheumatic process.

Smaller-scale related efforts came to similar conclusions (65 ,66 ,67 ,68) and one provides an excellent review of earlier studies (69). The presence of malar rash, oral ulcers, elevated anti-DNA, or low C4 complement made the evolution to lupus more likely (70). The reader is referred to two excellent reviews of the subject (69 ,71).

There are probably several UCTD patients for every individual who fulfills the ACR criteria for SLE. UCTD patients are responsive to antimalarials, methotrexate, and corticosteroids, but rarely have organ-threatening disease requiring aggressive management. Table 49-2 lists this writer's working diagnosis for UCTD, which updates definitions derived in the 1980s for the above-cited studies.

Incomplete Lupus

This misleading term has appeared in the literature to denote patients who are thought to have SLE but do not fulfill four ACR criteria. These individuals range from those with biopsy documented nephritis to idiopathic thrombocytopenic purpura with a positive ANA to fibromyalgia. Twenty-eight Swedish patients with “incomplete SLE” were followed for a median of 5.3 years. Fifty-seven evolved criteria fulfilling SLE (72). Swaak et al. managed 122 European incomplete lupus patients. Twenty-seven met full criteria shortly after study entry, but only 3 more did over the next 3 years (73). Nevertheless, 43% were taking corticosteroids 3 years later. Too many patients who carry this label undergo unnecessary treatments and become stigmatized and medicalized; hence, the term should not be used and replaced with those who meet definitions for UCTD.

RA and SLE

Clinical Differentiation

RA and SLE share many clinical and serologic features, an overlapping that was recognized in the 1950s and 1960s by the publication of hundreds of papers on “RA with LE cells.” (See pages 464 to 476 in, *Lupus Erythematosus* 2nd Ed. for an extensive review of these clinical and serologic

features.) RA and SLE usually can be distinguished easily from each other, especially if the former is ANA-negative or erosive. When RA displays extra-articular involvement or is ANA-positive, however, it occasionally is difficult to differentiate from SLE. When a patient presents with a new inflammatory arthritis that has overlapping features of both diseases, it may take 6 to 12 months of clinical observation before a definitive diagnosis can be made.

Extra-Articular Differentiation

Extra-articular RA may include serositis, Sjögren syndrome, subcutaneous nodules, cutaneous vasculitis, anemia, and other features that are observed in SLE. Ropes (74) compared 142 patients with SLE to a cohort of patients with RA. The latter had a 6% incidence of LE cells, a 1% incidence of sun sensitivity (vs. 34% in SLE), and a 4% incidence of alopecia (vs. 46% in SLE). The incidence of thyroid antibodies is increased in both disorders (75). Felty syndrome consists of a positive ANA, splenomegaly, arthritis, leukopenia, and an increased incidence of cutaneous vasculitis. Several patients of my acquaintance with Felty syndrome were misdiagnosed as having lupus. Felty syndrome is characterized by antigranulocyte (as opposed to antilymphocyte) antibodies and elevated complement levels (76). Close examination, however, reveals that the overwhelming majority of those with Felty syndrome are middle-aged men, that anti-DNA is never present, and that most have circulating cryoglobulins (77 ,78 ,79). CNS involvement and renal disease are absent. Another differentiating feature between RA and SLE is the lack of kidney involvement in those with RA. In what might be the definitive study, Davis et al. (80) reviewed the records of 5,232 patients with RA who were followed at UCLA between 1955 and 1977. Of these, 28 (0.5%) had renal disease of all types, only 4 of whom (0.1%) had glomerulonephritis. Also, 3 of the 4 met the ACR criteria for SLE, and 1 had MCTD. Davis et al.'s literature review of glomerulonephritis in RA (80) demonstrated that most of the cases could be accounted for by gold- or penicillamine-induced nephropathy, interstitial nephritis, amyloid, or diabetes.

Laboratory and Serologic Differentiation

RF was present in 15% of 166 patients with SLE who were studied by Ginzler's group in detail (81), in 18% of Wolfe et al.'s 124 patients with lupus, and in 22.7% of 365 patients tested with idiopathic SLE who were followed by Wallace (unpubl. observations). Its presence is associated with milder disease. The availability of anti-CCP has further helped differentiate SLE from RA. Among 231 patients in Isenberg's group tested for anti-CCP, only 3 (<1%) were positive. Two of the 3 had erosive arthritis (82 ,83). Four percent of 250 and of 365 patients with RA in each of two reports had reduced complement levels (84 ,85).

Numerous investigators have looked for ANA in RA, and its incidence has ranged from 3% to 88%, with an average of 25% (86 ,87 ,88). A subset of RF-negative, ANA-positive RA has been described (89 ,90). Many of these patients have JRA; most have erosive disease and a good prognosis. Chapter 28 discusses RF further.

Co-existence of Systemic Lupus Erythematosus and Rheumatoid Arthritis

Do SLE and RA co-exist? It has long been known that patients may start with a diagnosis of RA or SLE that becomes SLE or RA over a period of years. Assuming that MCTD is not present, however, the true co-existence of these conditions is rare. Despite the frequent clinical overlap between RA and SLE features, the combination of advanced, deforming, erosive RA and a significant degree of biopsy-proven SLE is an extremely unusual finding.

Occasional case reports have appeared documenting a true co-existence (91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103). Of my own group's 464 patients with idiopathic SLE, one had classic seropositive, erosive, nodular RA with biopsy-documented proliferative SLE nephritis and nephrotic syndrome. The concurrence of SCLE in patients with RA who are Ro/SSA-positive is more common (104 ,105). Cohen and Webb (106) reported the development of SLE in 11 Australian patients with typical RA who were observed over a 17-year period, but the total number of patients with RA followed was not stated. Brand et al. (107) presented 11 co-existing cases; most had class II genetic determinations of both disorders. Panush et al. (108) have identified a true co-existence in 6 of 7,000 patients with RA who were evaluated over an 11-year period. It was concluded that rhupus did not occur more frequently (0.09%) than expected from the chance concurrence of SLE and RA (1.2%). Van Vollenhoven's group at Stanford found “rhupus” in 13 patients among 1,507 with RA and 893 with SLE (109). Seven appeared to have transformed from SLE to RA. Among 22 “rhupus” patients in Mexico City an increased prevalence of HLA-DR1 and DR2 alleles were found (110).

Juvenile Rheumatoid Arthritis and Systemic Lupus Erythematosus

JRA has been classified into systemic (i.e., Still disease), oligo-articular, and polyarthritis subsets. Several large-scale studies have observed ANA in approximately 60% of patients with JRA, particularly oligo-articular disease in young girls with uveitis (111 ,112 ,113 ,114). One study has determined that ANA in this subset is directed against an RNP that requires both RNA and protein moieties for antigenic integrity (115). Despite the high frequency of ANA, other antibody systems, such as anti-RNP, anti-Sm, anti-Ro/SSA, anti-La/SSB, anti-nDNA, and anti-PM1, rarely are found.

Approximately 2.5% of patients with classic deforming polyarthritis originally diagnosed as JRA later develop multisystem lupus (116 ,117 ,118). In one study, two of 85 patients with JRA evolved into SLE both had anti-DNA while still carrying a JRA diagnosis (119). Of 509 referrals to a pediatric rheumatology unit, 110 had a positive ANA. Only

10 had SLE (120). These distinctions often are clouded by the high incidence of ANA and the relatively low incidence of RF in JRA (121). ANA-negative childhood SLE also has been reported (122).

Relationship of Systemic Lupus Erythematosus to Other Autoimmune and Rheumatic Diseases

Scleroderma and Other Fibrosing Syndromes

Although ANA is present in most patients with scleroderma, other serologies associated with SLE are observed in a small minority with scleroderma. These include LE-cell preparations (123), antiphospholipid antibodies (124 ,125), and other nuclear antigens (126). Anticentromere antibodies usually are associated with the calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia (CREST) syndrome but can be found in up to 5% of patients with pure SLE (127). In contrast to SLE, familial occurrence of scleroderma is rare. Clinically, sclerodactyly, telangiectasias, calcinosis, and malignant hypertension with acute renal failure are almost unheard of in patients with SLE. It is important to differentiate among SLE, MCTD, and scleroderma, because the latter rarely is responsive to steroids or cytotoxic agents. Conversely, one would not attempt to treat SLE or MCTD with penicillamine.

Features that are relatively unique to both scleroderma and SLE are infrequently observed in patients who do not have MCTD. Dubois et al. (123) reviewed 14 cases of co-existent scleroderma and SLE in detail in 1971 and summarized the literature to date. Unfortunately, their work was hampered by the lack of accepted criteria for scleroderma, SLE, or MCTD. Since then, case reports have appeared of autoimmune hemolytic anemia (128 ,129), high levels of anti-nDNA (130), lupus nephritis (131 ,132), and discoid lupus (133 ,134 ,135 ,136) occurring in patients with scleroderma. Patients with anti-Scl antibodies probably have lupus rather than scleroderma if anti-dsDNA is present (137). Scleroderma may evolve into SLE and vice versa (138); morphea (139) and linear scleroderma can be seen with SLE (136 ,140 ,141). One case of neonatal LE with morphea (142) and four of eosinophilic fasciitis with SLE have been presented (143 ,144 ,145 ,146).

The extreme rarity of retroperitoneal fibrosis in SLE has been noted (143 ,147 ,148 ,149). Dialysis associated nephrogenic fibrosing dermopathy has been reported in SLE (150).

Polymyositis and Dermatomyositis

In contrast to SLE, patients with polydermatomyositis are less often women and rarely have an autoimmune family history. Also, different skin lesions are present (i.e., Gottron nodules and heliotrope rashes), a co-existing malignancy may occur, serositis is rare, and nephritis, liver inflammation, and hematologic abnormalities are absent. Lupus can present as a focal, acute myositis (151). Rarely, MCTD may evolve into a pure poly/dermatomyositis. A low- grade myositis with muscle enzyme levels two to three times normal may be seen in lupus that responds to low doses of corticosteroids. (See Chapter 33 for a detailed discussion of lupus myopathy and its comparison with other inflammatory myopathies.)

Systemic Vasculitis

Although polyarteritis nodosa is relatively rare, it can be mistaken for SLE. In contrast to patients with SLE, those with polyarteritis nodosa usually are men and include all age groups equally. Cutaneous vasculitis may be more prominent, as may eosinophilia, wheezing, and nerve and bowel symptoms. The ANA often is negative; two cases of coexistence of these entities has been reported (152 ,153). Hypersensitivity angiitis and serum sickness may mimic SLE at first but, ultimately, can be distinguished by a self-limited course, an absence of ANA, and rarity of severe visceral involvement. Ordering an antineutrophilic cytoplasmic antibody often can differentiate lupus from microscopic polyangiitis and Wegener granulomatosis (154).

Behçet syndrome can mimic SLE with its uveitis, oral and genital ulcers, CNS involvement, and frank synovitis, but in Behçet syndrome, the ANA is negative and certain ethnic predispositions (i.e., Japanese and Turkish) as well as HLA predispositions (i.e., the B5 haplotypes) can be observed. There is little doubt that some ANA-negative patients with lupus actually have Behçet syndrome. The lack of any diagnostic test for Behçet syndrome further complicates the picture, and one case of co-existent disease has been reported (155). One case of SLE in a child with Kawasaki disease has been reported (156).

Large-Vessel Vasculitis

SLE is a disease of the small arteries and medium-sized arterioles, but it can rarely affect larger-caliber vessels. Large-vessel vasculitis is not associated with autoantibody formation. Elderly people more commonly develop polymyalgia rheumatica and giant-cell arteritis, however, and SLE occasionally is included in the differential diagnosis as musculoskeletal symptoms are present and an age-related positive ANA may be found (157 ,158). A true concurrence of giant-cell arteritis and SLE has been reported twice (159 ,160). Takayasu pulseless arteritis is found in young women, who mostly are Japanese, but also in other Asian and Hispanic women. One Japanese literature review described 10 cases of Takayasu arteritis with co-existent SLE (161). Saxe and Altman (162) reviewed 18 cases in the literature and concluded that co-existence of these diseases was coincidental. The co-existence of large-vessel vasculitis with SLE is coincidental, possible, and rare (163 ,164 ,165).

Crystal-Induced Arthropathies

Although 29% of patients with SLE are hyperuricemic (usually secondary to nephritis, diuretics, or chemotherapy), clinical gout is rare (166). This could result from the predominance of menstruating females among those with active SLE. Until 2000, fewer than 20 cases have been described in the literature (167 ,168 ,169 ,170 ,171 ,172 ,173 ,174); most were males taking diuretics. Recently, two groups examined the clinical features of 15 and 10 patients, respectively, with gout and SLE. Over 90% had nephritis, many had been transplanted, were on diuretics and cyclosporine, and the lupus was almost always inactive (175 ,176). Wallace et al. (177) reviewed the negative association between gout and RA. Only 3 of their 464 patients with idiopathic SLE had clinical gout, including a 25-year-old woman with nephritis who had tophaceous deposits. One report reviewed three young women with SLE and tophaceous deposits; all were underexcretors of uric acid (178). It has been proposed that patients with SLE (who often have decreased synovial fluid complement levels) have a natural barrier to gout, because urate requires the presence of near-normal synovial fluid complement levels to induce inflammation (168).

The rarity of pseudogout in patients with SLE has been reviewed by Rodriquez et al. (179).

Fibromyalgia

See Chapter 63 .

Dermatitis Herpetiformis

Thomas and Su (180) found nine patients with concomitant dermatitis herpetiformis and SLE who were followed at the Mayo Clinic from 1950 to 1981 and reviewed the literature. Five other reports have appeared, the most important of which are those of Aronson et al. (181) and Davies et al. (182).

Sarcoidosis

SLE and sarcoidosis share many immunologic features (183). Both manifest hyperglobulinemia, decreased skin test and lymphocyte responsiveness, lymphopenia, impaired antibody-dependent cellular cytotoxicity, and increased levels of circulating immune complexes (CICs). Cryoglobulins and antilymphocyte antibodies may be present in both disorders, and up to 32% of patients with sarcoidosis may have a positive ANA. Differential diagnosis can be a problem (184 ,185), but despite these similarities, only eleven cases of co-existence have been reported in the English-language literature (183 ,184 ,186 ,187 ,188 ,189 ,190 ,191 ,192).

Amyloid

It would be expected that patients with SLE have an increased incidence of amyloid, as do those with RA or ankylosing spondylitis. Cathcart and Scheinberg (193) enumerated many reasons why SLE and amyloid should co-exist. For example, both have a common pathogenetic pathway, and polyclonal B-cell proliferation is seen in both. Benson and Cohen (194) found serum levels of amyloid protein A to be elevated in 25 cases of active SLE (although these were one half the levels seen in an RA group). This α-globulin is a precursor of the major protein constituent of secondary amyloid fibrils. Serum-amyloid P component also can be deposited in lupus tissues without evidence of clinical amyloid (195 ,196), and may be protective against lupus (197 ,198). Despite this, fewer than 20 cases of the co-existence of SLE and amyloidosis have been reported (199 ,200 ,201 ,202 ,203 ,204 ,205 ,206 ,207 ,208 ,209 ,210 ,211 ,212 ,213 ,214 ,215 ,216 ,217 ,218).

Seronegative Spondyloarthropathies and Psoriasis

Nashel et al. (219) estimated that 500 concurrent cases of ankylosing spondylitis (AS) and SLE should be present in the United States, but this figure does not take into account the differences in catchment groups (AS–white males; SLE–females, especially nonwhites). They presented the first true case of co-existence and reviewed three cases reported earlier. None of these met both AS and SLE criteria, but one since has appeared (220). Kappes et al. (221) noted the difficulty in differential diagnosis, because patients with SLE may have sacroiliitis by bone scan and be HLA-B27 positive. Only one case of SLE and reactive arthritis and one case of discoid lupus in AS has been reported (222 ,223).

Several reviews have drawn attention to the co-existence of psoriasis and SLE (224 ,225 ,226 ,227 ,228). A 1980 report presented 23 cases of co-existence at the Mayo Clinic (10 met ACR criteria for SLE, and 13 had DLE) between 1950 and 1975 and reviewed 15 reports of 33 cases (11 of which antedated 1960) (226). Of these, 63% were female, SLE and psoriasis each appeared first one half of the time, and 80% had discoid lesions that usually were distinct from psoriatic patches (appearing and disappearing independently), but 7 of 27 biopsied lesions had pathologic features of both disorders. DLE can be misdiagnosed as psoriasis (229), may flare with ultraviolet B or psoralen ultraviolet A (PUVA) therapy (224 ,225), and SCLE can be induced during PUVA treatments in patients who are Ro/SSA positive (227 ,228). Despite the not uncommon concurrence of LE and psoriasis, only one case of psoriatic arthritis and SLE has been reported, and no HLA studies were cited in any of these reports (230).

Association of Systemic Lupus Erythematosus with Other Disorders

Several disorders have increased or decreased associations with SLE, and others can mimic its presentation and must be considered in the differential diagnosis. The relationship among Raynaud phenomenon, hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome, biliary

cirrhosis multiple sclerosis, myasthenia gravis, thyroiditis, inflammatory- bowel disease, syphilis, Klinefelter syndrome, sickle cell anemia, autoimmune hemolytic anemia, Sjögren syndrome, thrombocytopenic purpura, pemphigus, chronic active hepatitis, and SLE are discussed in other chapters (see the index for specific listings). Additional associations and differential diagnostic considerations are reviewed here. The reader is referred to an excellent discussion by Lorber et al. (230) regarding the rationale for such associations.

Porphyria

Both porphyria and SLE are characterized by fever, rash, sun sensitivity, leukopenia, anemia, arthralgias, and CNS abnormalities. Although almost 50 concurrent cases have been reported, many of these patients have not fulfilled the established criteria for SLE, and almost all of their symptoms could be explained by porphyria alone (231 ,232 ,233 ,234 ,235). Two comprehensive evaluations of 55 and 158 patients with porphyria cutanea tarda patients (233 ,234) found that none met the ACR criteria for SLE, although 12 were ANA positive. One review of 38 patients with porphyria (189) found that 8 of 15 with acute intermittent porphyria were ANA positive; one had SLE. Filotou reviewed 9 cases of acute intermittent porphyria in the literature; 8 had pre-existing SLE (236).Gibson and McEvoy found that 15 of 676 patients with porphyria had concurrent SLE. Nine had discoid lupus, 5 had SLE, and 1 had SCLE. Porphyria was precipitated by hydroxychloroquine therapy in 2 (237). Our group has had 2 concurrent cases among 2,000 lupus patients in 20 years. The ability of chloroquine to induce cutaneous porphyria further complicates the differential diagnosis.

Angioimmunoblastic Lymphadenopathy with Dysproteinemia and Autoimmune Proliferative Syndrome

Angio-immunoblastic lymphadenopathy with dysproteinemia (AILD) is a hyperimmune state that presents with rash, polyclonal gammopathy, Coombs-positive hemolytic anemia, hepatosplenomegaly, anergy, and decreased T-cell suppressor levels. It is fatal within months without treatment. AILD can resemble SLE (238 ,239 ,240 ,241 ,242) in that sicca syndrome, symmetric peripheral polyarthritis, and positive serologies can be observed (243 ,244). In their literature review, Rosenstein et al. (242) discussed several patients who followed the pattern of having an established autoimmune disease terminate with AILD, and they speculated that it represents a malignant transformation of immune-mediated disorders. Patients with autoimmune proliferative syndrome (e.g., ALS), characterized by a defect of the Fas-mediated apoptosis pathway, are usually children. Most have antinuclear and antiphospholipid antibodies (245 ,246).

Carcinoma

Chapter 69 discusses the occurrence of malignancies in those with SLE. The initial presentation of a patient with fevers, weight loss, adenopathy, and joint pains requires consideration of autoimmune and malignant disorders. Renal cell carcinomas can present with necrotizing vasculitis, Raynaud phenomenon, cryoglobulinemia, positive ANA, false-positive syphilis serologies, and elevated levels of CICs (247 ,248 ,249). Resection of the tumor usually reverses these findings. Mycosis fungoides can mimic chronic cutaneous lupus (250). A case of a woman with breast carcinoma and postradiation pneumonitis and serositis with a positive ANA and LE-cell preparation that disappeared after corticosteroid therapy also has been reported. Other malignancies are associated with ANAs (251). ANAs were detected in 27.7% of 274 Spanish patients with malignancies, but in only 6.4% of healthy subjects (252). Paraneoplastic rheumatic symptoms were seen more often in those who were ANA positive. For example, 31% of 204 patients with hepatocellular carcinoma had a positive ANA (253). Patients with immunoblastic sarcoma, lymphoma (254 ,255 ,256), Burkitt lymphoma (257), hairy-cell leukemia (258), ovarian carcinoma (259), adrenal adenoma (260), myelodysplastic syndromes (261 ,262), and Meigs syndrome (263) were thought to have SLE on initial presentation.

Tumor-associated antigen CA 19–9, which is a fairly specific marker for gastrointestinal adenocarcinomas, was positive in 6 of 19 patients with SLE in one report (264), and CA 125 in active SLE in another study (265).

Infectious Diseases

Chapter 45 discusses the propensity of patients with SLE to develop infections, and specific infectious associations with the disease. Problems relating to differential diagnosis are presented here. Additionally, a variety of infections (e.g., toxoplasmosis, schistosomiasis, leishmaniasis) can present as SLE with autoantibodies (266 ,267 ,268 ,269).

Leprosy

Leprosy rarely occurs in association with SLE (270 ,271 ,272), but the presence of deforming arthritis, alopecia, rash, and neuropathy in both conditions can make the differential diagnosis confusing (273 ,274 ,275 ,276 ,277). A positive ANA or rheumatoid factor is found in 3% to 36% of leprosy cohorts, but other antibody systems are absent (273 ,274 ,275 ,276 ,277). Mackworth-Young et al. (278) have found a common idiotypic determinant that is shared by patients with SLE and lepromatous leprosy.

Tuberculosis

Tuberculosis and SLE have overlapping chest and CNS features, as well as symptoms of fever, malaise, and weight loss (279). Feng and Tan (280) found concurrent tuberculosis in

16 of 311 patients with SLE (5%) who were seen in Singapore between 1963 and 1979, Tan et al. in 11% of 526 Hong Kong and 3.6% of 556 Turkish patients (281 ,282 ,283). The coexistence of tuberculosis correlated with steroid dosing and renal involvement and was frequently extrapulmonary (283). Isoniazid prophylaxis is safe and effective (284 ,285).

Viral Infections

Viral infections may display overlapping features with those of lupus on initial presentation, including intense fatigue. The chronicity of certain viral infections, such as the Epstein-Barr virus (EBV), herpesvirus cytomegalovirus, and viral hepatitis in young women, as well as the tendency of patients with SLE to develop infections, makes this a complex issue (286 ,287). Infections with these viruses can induce a low-titer ANA, anticardiolipin antibody, RF, anti-DNA and cryoglobulin among others (288 ,289). Similarly, SLE may be associated with IgM antiviral antibodies (290 ,291 ,292).

Increased antibody titers to EBV capsid antigen, early antigen, and nuclear antigen and by PCR compared with those of controls have been noted in patients with SLE (293 ,294 ,295 ,296 ,297), and false-positive Monospot test results have been reported (298). Harley's group has suggested that EBV can induce lupus (299) and that nearly all lupus patients have seroconverted. Nearly all adults with SLE (195 of 196) in one study were exposed to EBV (300). $CD8^+$ T cells may defectively regulate viral loads in SLE (301). Fevers, fatigue, adenopathy, and leucopenia can represent EBV and/or SLE, especially in adolescents (302).

Surveys have shown that 5% to 69% with SLE are reactive to cytomegalovirus antibodies representing viral induction or activation of SLE, simultaneous disease, or an immune suppressive mediated viral illness (300 ,303 ,304 ,305). The high prevalence of varicella zoster in lupus is probably associated with reduced CD4 T cell responses to the virus (306). A study of 44 patients with parvovirus B19 infection demonstrated an association with a transient, subclinical autoimmune state, complete with expression of anti-nDNA and antilymphocyte antibodies in most patients (307). This can be confused with SLE or may co-exist or flare it (308 ,309 ,310 ,311 ,312 ,313 ,314 ,315 ,316 ,317 ,318 ,319 ,320 ,321 ,322).

Winfield's group reported that the IgM in sera from children with acute infectious mononucleosis and hepatitis A is reactive with different antibody epitopes than from those with SLE (323). The measles virus genome along with elevated antibody titers has been found in lupus nephritis patients (324). See Chapter 45 for a more complete discussion of infections in lupus.

Human Immunodeficiency Virus and AIDS

The presentation of human immunodeficiency virus (HIV) infection can mimic that of autoimmune phenomena (325 ,326). Fevers, lymphadenopathy, rash, renal dysfunction, neurologic and hematologic disorders, sicca syndrome, and polyarthralgias can be observed. HIV positivity is associated with the presence of the lupus circulating anticoagulant (although thrombosis does not occur), hemolytic anemia, ANA, RF, CICs, immune thrombocytopenia, polyclonal hyperglobulinemia, and leukopenia. Anti-Ro/SSA and anti-La/SSB are not seen (327 ,328 ,329 ,330 ,331).

Barthels and Wallace discussed two cases, reviewed the literature, and presented an algorithm for following SLE patients with false-positive AIDS testing (332). Approximately 40 cases of concurrent AIDS and SLE have been presented (326 ,333 ,334 ,335 ,336 ,337 ,338). Of the 30 cases that were reported prior to 2002 and reviewed by Palacios et al. and Daikh et al., only 18 fulfilled the ACR criteria for SLE (339 ,340). Interestingly, about half are males, have nephritis, are children (especially with congenital acquired immune deficiency syndrome [AIDS]), and are African American. In a fascinating report, Fox and Isenberg followed a lupus patient who was infected with HIV while under their care (341). Aggressive antiretroviral therapy can re-activate lupus (342 ,343), whereas cyclophosphamide can reactivate HIV (344). Stored sera showed the precise time of HIV seroconversion, which resulted in clinical improvement and the disappearance of autoantibodies. Kaye (345) hypothesized that SLE somehow may be protective of AIDS. Assuming that 500,000 Americans have SLE and that 150,000 have AIDS, at least 400 concurrent cases would be expected. This negative correlation becomes more impressive when one considers that if 10% of patients with SLE had autoimmune hemolytic anemia or other complications that required transfusions (e.g., uremia, surgery) between 1978 and 1983, when the U.S. blood supply was unsafe, up to 50,000 should have been at risk of becoming infected with HIV (345), but not a single report has stated that any converted to HIV seropositivity (346).

Approximately 10% to 20% of patients with SLE will have intederminant reactivity patterns against various glycoproteins that are associated with HIV-1, human T-cell lymphotropic virus (HTLV)-1, and HTLV-2 (347 ,348 ,349 ,350 ,351 ,352 ,353 ,354). Occasional reports of concurrent disease have appeared (355 ,356 ,357 ,358 ,359); lupus activity may be suppressed (360).

Interestingly, many patients with HIV infections have antibodies to RNP. It has been suggested that immunization with anti-U1 snRNP potentially can block HIV infectivity (361 ,362). High IL-16 levels associated with SLE also might be protective (363).

Miscellaneous Disorders

Skin lesions of chronic granulomatous disease can mimic those of DLE (364 ,365 ,366 ,367 ,368 ,369) and co-exist with SLE (370 ,371). Thallium poisoning can result in ANA formation and mimic SLE (372 ,373). Down syndrome is associated with an inflammatory arthropathy that sometimes resembles SLE (374 ,375 ,376 ,377) and can co-exist with it. Two cases of lysinuric protein intolerance (378 ,379), Moyamoya disease (380 ,381), and prolidase (382) with SLE have been reported. Cases of Hunter syndrome (383), Osler-Weber-Rendu (384),

amyotrophic lateral sclerosis (385), Fabry disease (386), Werner syndrome (387), Noonan syndrome, Wilson disease, Hermanky-Pudlak, osteopoikilosis, stiff person syndrome, hemophilia A, Rosai-Dorfman disease, autoimmune neuromyotonia, and multicentric reticulohistiocytosis (388 ,389 ,390 ,391 ,392 ,393 ,394 ,395 ,396 ,397 ,398) with SLE have appeared.

Chapter 50
Mixed Connective-Tissue Disease and Overlap Syndromes

Robert W. Hoffman

Mixed Connective Tissue Disease

Historical Perspective

The first full-length publication describing what the authors called “mixed connective-tissue disease” (MCTD) was reported by Sharp et al. in 1972 (1). The patients described by Sharp et al. were proposed to be distinct based upon the presence of high levels of antibodies against an extractable nuclear antigen (ENA) that was RNase- and trypsin-sensitive. Subsequently, it was shown that ENA contained both the RNase- and trypsin-sensitive ribonucleoprotein (RNP) antigen, and the RNase- and trypsin-resistant Smith (Sm) antigen (2 ,3). We now know that the RNP antigen consists of a complex containing a series of small nuclear ribonucleoproteins (snRNP) including three polypeptides (70kD, A, and C) that associate noncovalently with U1RNA as part of the spliceosome complex (4 ,5 ,6). The spliceosome is found in the nucleus of eukaryotic cells and has the physiologic function of assisting in the excision of introns and the processing of premessenger RNA to mature messenger RNA (5). The RNP antigen is also known by a variety of other names including nuclear RNP (nRNP), U1-snRNP and U1RNP (6).

Clinically, the patients initially reported by Sharp et al. from Stanford were described as having overlapping features of SLE, scleroderma, and polymyositis (1). The patients were felt to be distinctive based on the absence of serious renal or central nervous system (CNS) involvement, and their favorable clinical response to treatment with corticosteroids (1). The initial studies on MCTD that were begun at Stanford continued at the University of Missouri-Columbia by Sharp et al. beginning in 1969. Sharp's collaborative studies with other centers resulted in a seminal paper in 1976 describing MCTD patients identified from five academic medical centers, including the University of Missouri-Columbia, Stanford University, the Mayo Clinic, the University of Cincinnati, and Northwestern University (7). Numerous studies on MCTD by Sharp et al. followed in the ensuing decades from the University of Missouri-Columbia, including prospective longitudinal studies on a large cohort of patients, some of whom had been followed for as long as 30 years (7 ,8 ,9 ,10 ,11 ,12). Dr. Sharp has recently published a historical review describing the collective body of this work (13). It should also be acknowledged that a number of investigators from the United States, Japan, Mexico, and Europe have also made important contributions to defining and further characterizing MCTD. These include Drs. Donato Alarcon-Segovia, Robert Bennett, Evelyn Hess, Eva Hedfors, Halsted Holman, Mitsuo Homma, Reiji Kasukawa, Ingvar Pettersson, Morris Reichlin, Bernard Singsen, Eng Tan and their colleagues, to mention only a few (1 ,4 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23). The work of these individuals and others has substantially advanced our understanding of the clinical, immunologic, and genetic features of MCTD since its original description, now over three decades ago.

Definition

Four widely recognized criteria for classification of patients as MCTD have been published (22 ,23 ,24 ,25 ,26 ,27 ,28 ,29). Some authors currently favor the criteria proposed by Alarcon-Segovia and Villarreal, and later validated by Alarcon-Segovia and Cardiel, based on its simplicity and perceived general applicability (22 ,23). Table 50-1 shows this proposed classification algorithm. The other published classification criteria are substantially more cumbersome to apply outside of a clinical research setting. Unfortunately, there has been no international consensus conference that has addressed the topic of disease classification criteria in MCTD since the international conference on MCTD held in Japan in 1986 (18).

It is important to acknowledge that controversy does exist in the literature over nomenclature of MCTD (10 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38). Although most critics accept that a recognizable group of patients as those called “MCTD” exist, there is dispute over the nomenclature and whether MCTD should be considered a distinct disease rather than a syndrome on

the continuum of another rheumatic disease, such as SLE or scleroderma (30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38).

Table 50-1: Diagnostic Criteria for Mixed Connective Tissue Disease*

Serologic criteria
Anti-RNP antibody must be present at a moderate-high level in serum
AND
Clinical criteria
There must be at least three out of the five of the following clinical findings
Edema of the hand
Synovitis
Myositis
Raynaud
Acrosclerosis
AND this must include either synovitis or myositis

*Alarcon-Segovia and Villarreal
**Anti-RNP was defined in this study using hemagglutination. A titer equal to or greater than 1:1,600 was required in their study to be considered “moderate or high.”

Following the initial description of MCTD by Sharp et al., the concept of MCTD clearly has evolved based upon the work of Dr. Sharp and many other investigators (10). In the last two decades, considerable advances have been made in two areas that assist investigators in the classification of rheumatic disease patients; these are characterization of autoantibodies and genetic markers of the rheumatic diseases (39). Studies using these have been of paramount importance in advancing the classification of all systemic rheumatic diseases, including MCTD (39). In MCTD, for example, it has been shown that the frequency of HLA-DR4 is increased in patients compared to health controls in population- based studies done on several continents, including North American, South America, and Europe (10 ,40 ,41 ,42 ,43 ,44 ,45). It has been proposed that as newer classification criteria of MCTD are developed, these should take advantage of advances in serologic and genetic markers that might be particularly useful in the classification of MCTD. These might include serologic testing for antibodies reactive with the U1–70kD polypeptide of the RNP antigen and molecular genotyping for the presence of HLA haplotypes associated with MCTD (e.g., HLA-DR4 bearing haplotypes) (10 ,39 ,40 ,41 ,44 ,45).

Finally, recent studies on disease pathogenesis serve to refine and more clearly delineate our understanding of MCTD. For example, studies of autoantibodies in disease pathogenesis have advanced our understanding of MCTD and recent studies in an animal model support a direct role for immunity against the U1–70kD polypeptide of the RNP antigen in disease pathogenesis. Studies in murine models have demonstrated that a single immunization with autologous U1–70kD polypeptide of the RNP antigen plus U1RNA can induce anti-RNP immunity and autoimmune lung disease characteristic of MCTD (46 ,47). Disease pathogenesis and animal models are discussed in greater detail in the section that follows (see Pathogenesis).

Clinical Features

General Features

In the absence of a universally accepted classification criteria and with our understanding of MCTD having evolved over that past three decades, review of the literature on MCTD poses some challenges. This is particular true for rare complications of the disease described as case reports or small series of patients in the literature. Despite these challenges, there are now numerous well-characterized clinical series reporting on substantial numbers of patients from across the world that define the clinical features of MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Table 50-2 shows a summary of the most common clinical features of MCTD.

The primary clinical features of MCTD are Raynaud phenomenon, swollen fingers or hands, arthralgia, with or without associated arthritis, esophageal reflux or dysmotility, acrosclerosis (i.e., sclerodactyly), mild myositis, and pulmonary involvement of a variety of forms (see Table 50-2) (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Additional clinical features that have been commonly reported include: malar rash, alopecia, anemia, leucopenia, lymphadenopathy, and trigeminal neuralgia. The characteristic serologic findings are a high-titer FANA with a speckled pattern and the presence of antibodies to RNP at moderate to high levels in the serum; some authors require the absence of antibodies to Sm to classify patients as MCTD (10).

Table 50-2: Clinical Features of Mixed Connective Tissue Disease*

Clinical Findings	At Diagnosis (%)	Cumulative Feature (%)
Raynaud phenomenon	89	96
Arthralgia/arthritis	85	96
Swollen hands	60	66
Esophageal dysmotility	47	66
Pulmonary disease	43	66
Sclerodactyly	34	49
Pleuritis/pericarditis	34	43
Skin rash	30	53
Myositis	28	51
Renal disease	2	11
Neurologic disease	0	17

*Burdt et al. (9)

Prevalence

Currently, there is a paucity of epidemiologic data on MCTD. A nationwide multicenter collaborative survey on MCTD from Japan reported a prevalence of 2.7% (51). It has been reported by Sharp et al. that at a tertiary referral center known for expertise in MCTD, the disease was seen less frequently than SLE or rheumatoid arthritis (RA), but more commonly that polymyositis, dermatomyositis, or scleroderma (10).

Sex Distribution

MCTD is more common in females than it is in males. It appears to have a sex distribution similar to that seen in SLE (10). In a Japanese nationwide survey, MCTD was found to have a female to male ratio of 16:1 (51), whereas the longitudinal prospective clinical series of Burdt et al. reported an 11:1 ratio of women to men among patient from a tertiary referral center in the Midwestern United States (9). Lundberg and Hedfors reported a 4:1 ratio among patients selected for anti-RNP antibodies rather than MCTD per se who were studied at Huddinge University hospital in Stockholm, Sweden (15).

Skin

Raynaud phenomenon is one of the most common manifestations of MTCD in all clinical series. It has been reported to be present at diagnosis in 90% to 95% of patients (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). In some patients it may diminish in severity or resolve over time (9). There are a small number of patients who will have associated digital infarcts. Pathologic and radiographic studies have reported the presence of an obliterative vasculopathy in these patients (55). Digital infarcts appear to correlate with the presence of severe obliterative vasculopathy.

As in other organs, the vascular endothelium appears to be a major target of the pathologic process in MCTD (55).

Swollen fingers or swelling of the hand is very common in MCTD, particularly at the onset of disease (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Total hand edema can occur but is less common. Acrosclerosis (also known as sclerodactyly) occurs with or without proximal scleroderma and is typically a later manifestation of the disease. Nailfold vascular changes identified by unaided direct visual inspection or by one of several methods of capillary microscopy occur in MCTD. These are characterized by vascular dilatation and vessel loss or “drop out” (56). Skin rashes are present in 50% to 60% of patients (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). A malar rash similar to that typical of SLE has been reported to be common. Discoid lesions are also occasionally present. The scleroderma-like features of squared telangiectasis over the hands, and face, periungual telangiectasis and sclerodactyly with or without calcinosis cutis also occurs in some patients with MCTD. In contrast, truncal scleroderma is rare or absent in most series (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,57 ,58).

Gottron papules or a heliotrope rash, typical of dermatomyositis, are also seen in MCTD. Erythema nodosum, hyper- or hypopigmentation of the skin is uncommon but has been reported (10 ,59 ,60). Nodules appear to be uncommon despite the fact that arthritis and rheumatoid factor are common features of the disease.

The sicca complex has been found to be present in approximately one fourth to as high as one half of all patients with MCTD (11 ,61); these patients also frequently have anti-SS-A/Ro antibodies (61). Oral ulcers are reported to be present in patients with MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Genital ulcers and more severe lesions resulting in nasal septal perforation have been described (62).

Joints

Arthralgias, along with Raynaud phenomenon, are present in almost all patients with MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,63 ,64 ,65). Arthritis is also very common in MCTD. Arthritis ultimately develops in 50% to 60% of patients (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,63 ,64 ,65 ,66 ,67). Rheumatoid factor is also common in MCTD, occurring in 50% to 75% of patients. In fact, despite the fact that MCTD was initially observed among patients with overlapping features of SLE, scleroderma, and polymyositis, it is now recognized that MCTD patients have many features in common with RA. This includes increase in the frequency of the HLA-DR4 susceptibility gene and immune responses against serum immune globulin (i.e., rheumatoid factor) and immunity against heterogeneous nuclear ribonucleoprotein (hnRNP) in the form of antibodies and T cells (68 ,69 ,70). MCTD patients may fulfill the American College of Rheumatology (ACR) classification criteria for RA (10). In contrast to RA, however, most MCTD patients have no bony erosions or only small marginal erosions with well-demarcated edges (63 ,64 ,65 ,66 ,67). Occasionally, patients will develop RA-like deformities, including boutonniere deformities and swan neck deformities. More severe, erosive arthropathy has been reported to be associated with HLA-DR4 (44). A severe destructive arthritis including arthritis multilane has been reported in MCTD (65). A Jaccoud's-like arthropathy, similar to that seen in SLE with or without erosions, has also been reported (63 ,64 ,65 ,66 ,67).

Muscles

Myalgias are common in MCTD, being reported in 25% to 50% of patients. Myositis has been reported to be present in 20% to 70% of patients (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). The majority of MCTD patient, however, are not weak (9 ,59). Mild myositis with normal or modest elevation of muscle enzymes and normal electromyogram are the findings that are most common in MCTD; patients may be completely asymptomatic (9 ,10). In contrast, however, myositis can be severe in some patients and can be indistinguishable from dermatomyositis (10). Patients such as this may meet Bohan

and Peter's criteria for classification of myositis (71). Lundberg et al. have published findings of a longitudinal study comparing myositis patients with or without RNP antibodies (60). They found that patients with anti-RNP antibodies and myositis appeared to respond quickly to treatment with corticosteroids and that their myositis rarely relapsed after initial treatment (60). The pathologic muscle finding reported in MCTD include lymphocytic infiltrates, which may be either perivascular (within the endomysium vessel wall or perimysium) focal fiber necrosis, and occasionally perifascicular atrophy (59). Patients with MCTD may develop fibromyalgia and in a some patients this can be a clinically dominant aspect of the disease (72).

Pulmonary System

Pulmonary involvement can be a serious complication of MCTD and is the most common disease-related cause of death in MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Symptoms can include cough, dyspnea on exertion or at rest, and pleuritic chest pain. The physical examination may reveal basilar rales or cardiac finding compatible with pulmonary hypertension. Often, however, the physical examination of the lungs is normal. More sensitive testing may be required to detect early pulmonary disease, such as pulmonary function testing measuring lung diffusion capacity for carbon monoxide (DLco) (8 ,9).

Decreased DLco has been shown to be a sensitive measurement for detecting pulmonary involvement in MCTD and appears to be effective when used for periodic screening of patients as an approach to identify those with early pulmonary disease (8). Some patients may have an abnormal chest radiograph or abnormal pulmonary function testing result. The most common radiographic findings are small, irregular opacities of the basilar or less commonly the middle lung fields, although changes can include interstitial abnormalities, pleural effusions, infiltrative lesions, or pleural thickening. High resolution computerized tomography of the chest may reveal finding of fibrosis or alveolitis that may not be detectable using plain film radiography of the chest. Pathologic changes that may be found on biopsy or at autopsy include: interstitial fibrosing pneumonitis, obliterative vasculopathy of pulmonary vessels with intimal proliferation and medial hypertrophy of the pulmonary arteries and arterioles with minimal or no interstitial fibrosis, plexiform lesions, and vasculitis (8 ,9 ,10 ,18).

Pulmonary hypertension is the most common disease-related cause of death in MCTD (9). In the longitudinal study of Burdt et al. 13% (6/47) of the patients died of pulmonary hypertension (9). Additionally, there is evidence in MCTD that treatment of pulmonary hypertension can result in prolonged survival in some patients; therefore, early identification and proper treatment of pulmonary hypertension is very important (see Treatment section later in the chapter) (8 ,9 ,10 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80).

Rare pulmonary manifestations that have been reported in MCTD include pulmonary hemorrhage and diaphragm dysfunction (81 ,82 ,83).

Gastrointestinal System

Esophageal motility disorders with symptomatic esophageal reflux, including heart burn or regurgitation of food, is common in MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,84 ,85 ,86 ,87 ,88 ,89 ,90). Less commonly, patients may experience difficulty in swallowing or pain. Uncommon features of gastrointestinal involvement in MCTD that have been reported include: pseudodiverticula along the antimesenteric boarder (similar to that described in scleroderma), mesenteric vasculitis, pancreatitis, bacterial overgrowth syndrome, malabsorption, protein-loosing enteropathy, pseudo-obstruction, serositis, colonic perforation and gastrointestinal bleeding (84 ,85 ,86 ,87 ,88 ,89 ,90). There are reports in the literature of chronic active hepatitis, biliary cirrhosis and Budd-Chiari syndrome in patients with MCTD.

Cardiac System

When sought using methods such as electrocardiography or echocardiography, evidence of cardiac abnormalities are reported to be common in MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,91 ,92 ,93 ,94 ,95). Approximately 20% of patients will have abnormalities when examined by using either electrocardiography or echocardiography. As discussed above, pulmonary involvement is common in MCTD and may result in cardiopulmonary disease, such as pulmonary hypertension. Pulmonary hypertension can result in associated cardiac changes, such as right ventricular hypertrophy, right atrial enlargement, intraventricular and atrioventricular electrical conduction abnormalities. Pericarditis has been reported to occur in 10% to 30% of MCTD patients (91 ,92). Myocardial involvement may be found with severe myopathy or when pulmonary hypertension is present. Additional cardiac abnormalities that have been described have included: septal hypertrophy, various left ventricular abnormalities, mitral valve prolapse, intimal hyperplasia of the coronary arteries, and endocardial abnormalities. Although atherosclerotic heart disease has now been recognized as a significant complication of other rheumatic diseases, including SLE and RA, similar findings have not yet been reported in longitudinal studies on MCTD (9).

Nervous System

The presence of neuropsychiatry manifestations of MCTD were first emphasized by Bennett and colleagues (96 ,97 ,98). They reported that over half of the 20 patients that they studied with MCTD had neuropsychiatry findings, including aseptic meningitis, psychosis, seizures, peripheral neuropathy, trigeminal neuropathy, and cerebella ataxia (96 ,97 ,98).

Trigeminal neuralgia can rarely be the presenting feature of MCTD (99 ,100). Trigeminal neuralgia can manifest as neuralgic pain or as partial or complete anesthesia over the distribution of one or more branches of the trigeminal nerve (100). Vascular headaches have been frequently described in MCTD (101). Aseptic meningitis has been reported to be associated with the use of nonsteroidal anti-inflammatory agents particularly ibuprofen in MCTD. A peripheral, predominantly sensor polyneuropathy occurs in MCTD. Although MCTD was initially described to be notable for the absence of serious neurologic involvement, we now recognize that serious neurologic disease can occur in some MCTD patients (10 ,50 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103).

Cerebellar dysfunction, psychosis and seizure have been reported to occur in MCTD. Additionally, severe neurologic problems that have been rarely reported (most often in the form of case reports) in MCTD include: cauda equina, transverse myelitis, stroke, and cerebral hemorrhage. The precise relationship of these to MCTD has not been clearly established (102 ,103).

Renal Disease

Renal involvement is present in approximately 25% of patients with MCTD (104). In those patients with renal involvement, focal proliferative glomerulonephritis is more common than diffuse proliferative glomerulonephritis (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,104 ,105 ,106 , 107 ,108 ,109). Diffuse proliferative glomerulonephritis has been reported to occur but is uncommon in MCTD. Patients with diffuse renal involvement often initially have or subsequently develop anti-Sm and/or anti-double stranded DNA (anti-dsDNA) antibodies (10 ,110 ,111). It appears that the development of anti-Sm antibodies (particularly against the Sm-D peptide) occur when there is ongoing immune spreading and more severe disease (111).

In MCTD, membranous glomerulonephritis with or without nephrotic syndrome may rarely occur. Intimal proliferation within arteries and ischemic changes have been seen in MCTD. Scleroderma-like renal crisis has also been reported to occur in MCTD (10). Patients with MCTD and concomitant Sjögren syndrome may develop interstitial nephritis and can have associated finding such as renal tubular acidosis (11).

Hematologic Disorders

Hematologic abnormalities are common in MCTD (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,112 ,113 ,114 , 115). Mild lymphadenopathy occurs in approximately 25% to 50% of patients. Lymphadenopathy is often an initial feature of disease and tends to decrease over time; although it may re-appear with a flare of disease. The development of massive lymphadenopathy and pseudolymphoma has been observed.

Anemia, lymphopenia, and leukopenia are all common in MCTD, occurring 50% to 75% of patients. Antilymphocyte antibodies have been found to be common and have been reported to correlate with disease activity (10 ,112). Anemia of chronic disease is one of the most common finding in several series of MCTD. Coombs positive immune-mediated hemolytic anemia has been reported to be rare feature of MCTD (113).

Thrombocytopenia occurs in MCTD but appears less commonly that leucopenia or anemia (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Finally, there are case reports describing idiopathic thrombocytopenic purpura (ITP), red cell aplasia, and thrombotic thrombocytopenic purpura (TTP) in MCTD (114). Coagulation abnormalities appear to be rare but have been described.

Miscellaneous Systemic Features

Malaise and low-grade fever may occur in MCTD. The disease has been reported to present as fever of unknown origin (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Rarely, patients may have high-grade fever without an identifiable infectious agent as the cause of the fever. In these patients it has been inferred that MCTD was the cause of their fever, however, it is important to recognize that a careful search for infection should always be completed before fever is attributed to the underlying disease (116). Orofacial and ocular vascular involvement have been described in MCTD (117 ,118).

Sicca symptoms are common in MCTD and Sjögren syndrome is present in 25% to 50% of patients (11 ,61). Patients frequently will have antibodies to SSA/Ro and these may develop after the onset of MCTD. Anti-SSB/La is found in a small number of MCTD patients occurring in less than 5% (11). Photosensitivity and malar rash appear to be increased among MCTD patients who are positive for SSA/Ro antibody (11). Autoimmune thyroiditis and persistent hoarseness have also been described in MCTD.

Children

MCTD in a child was described within 1 year following the initial report of MCTD in adults (119). Early studies in children helped establish that the disease could occur in any age group and the examination of pathologic material from children who had died as a result of the disease provided some of the earliest insights into the vascular proliferative lesions that are fundamental to the immunopathologic process underlying MCTD (120 ,121). We have gained a more complete understanding of MCTD in children over the past three decades, as clinical series containing larger numbers of children with increasing length of follow-up have been published (120). Taken together, these studies demonstrate that MCTD can present at any age and that MCTD in children appears to have clinical manifestations of disease and disease outcome similar to that seen in adults (9 ,110 ,120).

The initial report of MCTD in a child was publishing in 1973 by Sanders et al. (119). Subsequently, Singsen et al.

published a seminal paper on MCTD describing the disease in 14 children (21). These children were characterized clinically as having arthritis, Raynaud phenomenon, sclerodermatous skin findings, fever, abnormal esophageal motility, and evidence of myositis (21). Serologically these children had high levels of antinuclear antibodies exhibiting a speckled patter and high levels of antibodies against ENA/RNP as measured by hemagglutination with their specificity against RNP confirmed using immunodiffusion (21).

These early clinical and serologic studies established that the newly recognized disease also occurred in children (21 ,49 ,119). In contrast to most of the outcome studies reported recently, these initial studies from Singsen et al. at the Los Angeles Children's Hospital found that renal involvement and thrombocytopenia appeared to be common, and that the prognosis was unfavorable in a significant number of the small group of children they had studied (21 ,49). Recent studies have challenged these initial observations that MCTD is different in children, although some studies from Japan have also reported that MCTD in that country may have a worse prognosis when the disease has its onset in childhood (9 ,110 ,120). Subsequent longitudinal studies from Europe and the United States, however, have found childhood MCTD to have the same core clinical manifestation as seen in adults, including Raynaud phenomenon, swollen hands, arthralgia, arthritis, mild myositis, telangiectasias, and sclerodactyly (9 ,110 ,120). These studies have also reported that MCTD in children has a relatively favorable outcome in approximate 70% of patients, with 5% to 20% having complete remission of their disease following treatment (9 ,110 ,120).

As in adults, pulmonary involvement appeared to be an important feature of the disease in children and the development of pulmonary hypertension has been reported in two series from the United States and in one series of patients from Japan (29). Thrombocytopenia, as initially reported by Singsen et al., has not been found to be clinically significant in other series (21 ,110 ,120). Infection complicating the disease has been reported as a major cause of death in MTCD (9 ,10 ,116). Coexisting sicca syndrome has been reported by some to be common in children with MCTD and there are rare patients reported with neurologic involvement in MCTD, which can be severe (61 ,120).

Pregnancy

A small number of published studies have examined the effects of MCTD on pregnancy (122 ,123 ,124). Lundberg and Hedfors have retrospectively examined pregnancy outcome in 40 pregnancies among 20 patients with high-titer RNP antibodies from Stockholm, Sweden (122). They found fetal and maternal outcome was excellent with no evidence of flares of disease during pregnancy or in the postpartum period (122). These finding were in contrast to somewhat less favorable outcome for pregnancy in MCTD reported by Kaufman and Kitridou from Los Angeles, where they found parity was decreased and fetal wastage was increased similarly among patients with either MCTD or SLE (123 ,124). Overall, the outcome of pregnancy in MCTD with careful clinical monitoring at centers with experience in managing MCTD appears highly favorable (122, Hoffman RW- personal observation).

Serologic and Immunology Studies

Antinuclear and Anti-RNP Antibodies

Patients with MCTD have antinuclear antibodies against a series of nuclear antigens. The presence of antibodies against U1RNP is required for the diagnosis by its original definition and subsequently proposed classification criteria (1 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,126 ,127 ,128 ,129). The typically MCTD patient will have high titers of fluorescent ANA exhibiting a speckled pattern of immunofluorescence with the commonly used HEp-2 cell line, as well as with other human or mouse tissue substrates (6). Patient will have antibodies against ENA and RNP, which typically will be present at high levels in untreated patients at the onset of disease. The development of anti-RNP antibodies occurs in close temporal relationship to the onset of clinical disease, with symptoms developing within 1 year after the appearance of this antibody in most patients (9 ,10 ,111 ,130). Although in active disease there is no close correlation between the level of anti-RNP and disease activity or severity, the level of anti-RNP antibodies may diminish or even disappear over time in some patients with treatment, particularly in those treated with cytotoxic drugs such as cyclophosphamide (9).

To fully understand the complex nature of autoantibodies found in MCTD and SLE, it is useful to review the structure of the spliceosome and its major components. The spliceosome contains a series of snRNP associated with a series of uridylic acid rich (U) RNAs. In the normal cell these are involved in the complex process of excising introns during the processing of premessenger RNA to the final mature messenger RNA molecules (5).

The primary antigenic components of the spliceosome include uridylic acid rich (U) RNAs (U1, U2, U4/6, and U5), which are associated with snRNP peptides. The snRNP complex contains both the Sm and RNP antigens (2 ,3). The RNP antigen consists of three polypeptides (70kD, A, and C) noncovalently associated with U1RNA; this is illustrated in Fig. 50-1 . The Sm antigen consists of 8 polypeptides (Sm-D1–3, B1–2, E, F, and G) that are noncovalently associated with U1, U2, U4/U6, and U5 RNA (4 ,131). The primary reactivity found in MCTD is with the U1–70kD polypeptide (previously called the 68kD polypeptide) (6 ,10 ,111), although patients sera may react with the U1-A or less commonly with the U1-C polypeptide of RNP (10 ,111). An individual patient's sera may react with some or all of the U1-associated polypeptides. At the onset of disease it has been reported that the most common reactivity is with the 70kD polypeptide or with the A polypeptide and that over time there is immune

spreading to other components of the complex (111). In longstanding disease, especially in patients who have received cytotoxic drug therapies such as cyclophosphamide, there may be so-called epitope contractions where antibody reactivity with one or more of these snRNP polypeptides deceases or disappears (9). There are a number of studies that have found that serologic reactivity with the U1–70kD polypeptide is closely associated with clinical finding of MCTD and is superior to measuring antibodies to RNP alone (10 ,40).

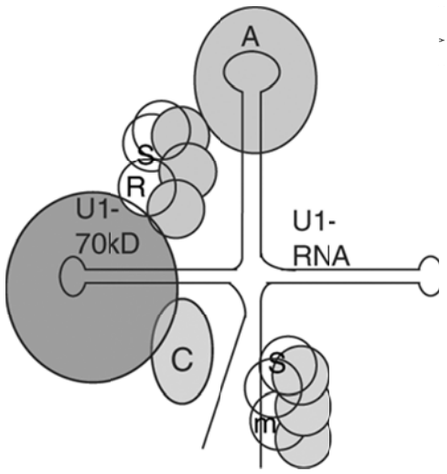

Figure 50-1. This illustration shows the 70kD polypeptide bound to U1-RNA. Also shown are the other U1-associated polypeptides, A & C which form the complex. The Sm polypeptides B, D, E, F, & G, which bind to U1, U2, U3, and U4/6 RNA, are also illustrated here. (Modified from Greidinger and Hoffman (148)).

In contrast to the reactivity with RNP typically found in MCTD, the snRNP antibody reactivity characteristically seen in patients with SLE is directed against the Sm antigen and its associated polypeptides. Approximately one third of patients classified as SLE will develop anti-Sm antibodies. The most prevalent antibodies found in sera that are reactive with the Sm antigen are directed against the Sm-B and Sm-D polypeptides, although reactivity with the other Sm polypeptides (Sm-E, F, and G) has been described (130). It appears that immune spreading to develop reactivity with the Sm-D polypeptides occurs later in the anti-snRNP immune response. The presence of anti-Sm-D antibodies is associated with the presence of renal disease and a worse clinical outcome (110).

There is a subset of patients with reactivity to the U1-specific polypeptides (including 70kD) as well as with the U1- to U6-associated Sm-B and Sm-D polypeptides at the time of initial presentation. Also, some patients that initially only have reactivity with the U1-specific polypeptides may have immune spreading and develop antibodies against the Sm-B and/or Sm-D polypeptides while under observation. As discussed above, such patients may develop more typical SLE-like clinical manifestations, have significant renal involvement and a worse prognosis (10 ,110).

There is a small group of patients that exhibit reactivity with both Sm and RNP at the time of diagnosis. Using some classification criteria the presence of antibodies against Sm disqualifies these patients as being classified as MCTD (10). One classification criteria proposed by Sharp et al. would eliminate any patient with significant levels of antibodies against Sm or dsDNA from being classified as MCTD (10). It appears that patients with anti-Sm antibodies are at increased risk for the development of renal involvement and may have a different major histocompatability genotype (HLA-DR2) than patients with isolated reactivity to RNP (HLA-DR4) (40 ,41 ,110).

Thus, there appear to be both genetic and clinical differences between patient that have immune reactivity limited to U1RNP (particularly U1–70kD) compare to those that exhibit immune spreading and develop immune reactivity against both U1RNP and Sm polypeptides.

Immune self-reactivity with U1RNA, rheumatoid factor, SSA/Ro, and viruses Antibodies against U1RNA are common in MCTD (12). Antibodies levels against U1RNA have been described as correlating with disease activity in at least one study, although others have not been able to confirm such a strong correlation between these (9 ,12 ,131). Interestingly, the RNA binding domain on the 70kD polypeptide has been identified as the dominant T-cell epitope recognized by MCTD patients; suggesting a link between B- and T-cell responses against U1RNA (132 ,133 ,134 ,135 ,136 ,137 ,138 ,139). It has been shown recently that U1RNA can activate murine and human cells through triggering innate immune receptors, including Toll-like receptor 3 (TLR3) and possibly others (140). These emerging studies support the broader concept that autoimmune diseases may have defects in both the acquired and innate arms of the immune system. Perhaps both are important in triggering and/or sustaining systemic autoimmune disease (140).

Rheumatoid factor is common in MCTD, occurring in 50% to 75% of patients (1 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 ,54). Antibodies to SSA/Ro are also common, occurring in one third of the 55 MCTD followed in a recent longitudinal study. In that study, anti-SSA/Ro was found in 33% of patients and SSB/La in 4% (11). Antibodies against phospholipids have been detected in MCTD, occurring in 15% of patients in one study (141 ,142). Unlike SLE, however, the presence of antiphospholipid antibodies was not found to be associated with an increased risk of clotting in MCTD (141). Many of these antiphospholipid antibodies in MCTD may be directed against $ß_2$ microglobulin (142). Although not associated with clotting, their presence has been reported to be associated with an increased risk for the development of pulmonary hypertension (9).

Antibodies against viruses or their products have been examined in MCTD. A cross-reactive epitope on 70kD and certain retroviral antigens has been reported, although there is no definitive evidence for retroviral triggering of MCTD (143). There has also been association between past infection or immunization against cytomegalovirus and the development of anti-RNP antibodies in some, but not all studies, where this has been examined (144 ,145 ,146).

T cells reactive with U1–70kD and U1-A snRNP polypeptides have been identified from the peripheral blood of patients with MCTD (133 ,134 ,135 ,136 ,137 ,138 ,139). T-cell clones reactive with U1–70kD and heterogeneous nuclear ribonucleoprotein

from the peripheral blood of MCTD patients have been extensively characterized. It has been shown ex vivo that such T cells can provide help to autoantibody producing B cells. Several features of the autoantibodies identified in MCTD are characteristic of a T-cell–dependent B-cell response suggesting a central role for T cells in disease (139). This is discussed further in the section on Pathogenesis below.

Immunopathology

Autopsy studies on children reported by Singsen et al. provided some of the earliest information on the histopathology of MCTD and supported the concept that MCTD was a distinct entity (49). They found that there were widespread proliferative vascular lesions, involving small, medium, and large vessels. They reported involvement of the coronary, renal, and pulmonary arteries, as well as the aorta with endothelial proliferation and an obliterative vasculopathy (49). They found that plasmacyte containing inflammatory infiltration of tissue was common and that vasculitis was also present. Subsequent studies have confirmed and extending these early findings (18 ,49 ,59 ,98 ,147).

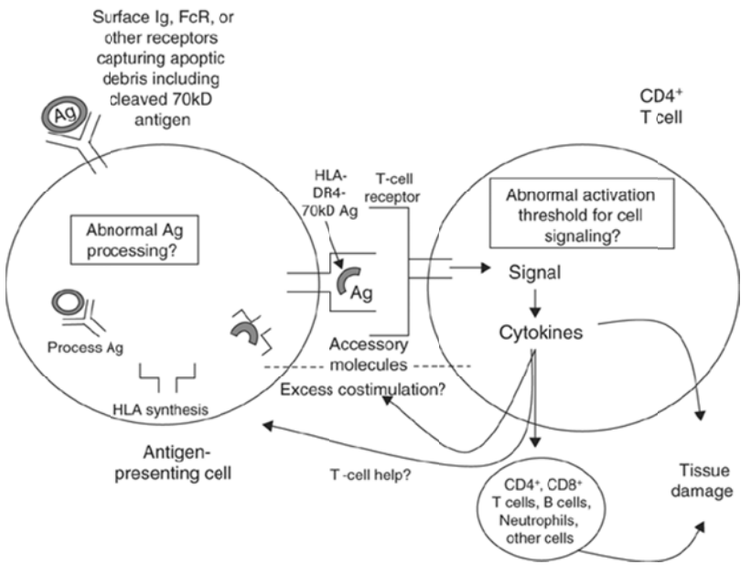

Figure 50-2. This illustrates one hypothetical model of the pathogenesis of MCTD. In this model, apoptotic material, including the 70kD polypeptide, are take up by an antigen-presenting cells (APC), processed and presented to an autoreactive T cells in the context of the major histocompatibility complex antigen HLA-DR4. CD4-positive T cells respond to antigen by producing cytokines that assist in the expansion of themselves in an autocrine fashion, as well as in the differentiation and proliferation of autoantibody producing cells. Tissue injury may be mediated directly by these cells or by soluble factors released from them. The autoreactive T cells may to have abnormal threshold for TCR triggering that renders them prone to autoimmunity. (Modified from Hoffman (139)).

Pathogenesis

An overarching model of disease pathogenesis in MCTD requires incorporation of a large amount of information on genetics, environmental influences, self-antigen modification, immune effector cells, and immunoregulation (139 ,148). Figure 50-2 shows a proposed model of disease pathogenesis in MCTD. Substantial knowledge has been gained from clinical observational studies and animal models have also helped to shape our current understanding of the pathogenesis of MCTD. Genetic factors and environmental factors contribute to susceptibility to MCTD. Immune effector mechanisms and abnormal immune regulation appear to be important features of the disease. Immune cells (T cells, B cells, antigen-presenting cells) and their products (cytokines, chemokines, antibodies) may all be important in pathogenesis. New experimental animal models are potentially instructive in identifying the molecular mechanisms of disease pathogenesis.

Genetic Factors

A useful model of genetic contributions to susceptibility to autoimmunity is the threshold liability model first proposed by Wright and as elegantly illustrated in studies dissecting the genetics of murine lupus in the New Zealand Mixed 2460 lupus-prone mice by Wakeland et al. (149 ,150 ,151). In this model, combinations of disease-susceptibility and disease-resistance genes interact with environmental factors; when a certain threshold is reached disease occurs. Environmental factors may lower the threshold for disease. In cases where the genetic burden is large enough (e.g., certain complete complement deficiencies such as C1q deficiency) an environmental trigger may not be necessary for the disease to develop (152). In MCTD major histocompatibility genes have been identified as having positive or negative associations with disease susceptibility; specifically, HLA-DR4 has been shown to be associated with anti-RNP antibody responses and with MCTD per se in a number of studies among several different populations, including patients from the United States, Mexico and Europe (10 ,39 ,40 ,41 ,42 ,43 ,44 ,45). HLA-DR2, DRw53, and DQw3 have also been reported to have positive association with MCTD (10). In contrast, the HLA class II phenotype/genotype most closely associated with scleroderma, HLA-DR5, and its subtypes, has been shown to have a negative association with MCTD (10). Regarding select immunoglobulin gene repertoire or regulation, immunoglobulin allotypes have been found to be associated with anti-RNP responses/MCTD in some but not all studies (10).

As for other multigenetic human diseases, the genetic contributions to the development of MCTD appear complex. Although the data are limited, reports of familial MCTD are rare (153). In longitudinal studies of families of affected individuals, the presence of anti-RNP antibodies was virtually never found among unaffected family members (9). These findings are also consistent with recent studies among military personnel where the development of anti-RNP antibodies was closely associated temporally with the development of clinical disease (129).

Environmental Factors

Several environmental factors that modify disease susceptibility or trigger disease have been proposed; most convincing among these is the influence of female sex hormones as suggested by the marked female-to-male ratio of the disease and other findings. There are also studies suggesting that in some patients Epstein Barr virus, retroviruses, or a newly identified virus may play a role in triggering disease (155 ,156). Cytomegalovirus has also been suggested as being able to elicit anti-RNP antibody response in the absence of disease (144 ,145 ,146). Vinyl chloride exposure has been associated with the development of MCTD-like syndrome (156).

B Cells in Pathogenesis

The presence of antibodies against RNP is required for the diagnosis of MCTD based upon the initial description by Sharp et al. and as defined by the currently proposed classification criteria (Table 50-1). The fact that anti-RNP antibodies are present in high levels in patients sera, have undergone isotype switch to the IgG class, and that anti-RNP producing B cells exhibit nucleotide substitutions typical of an antigen-driven immune response has all been presented as evidence that anti-RNP immunity in MCTD is an antigen-driven immune process. Anti-RNP antibodies may be reactive with the U1–70kD, A, or C polypeptides of the U1-snRNP complex (9). Patients may also have antibodies against the Sm-B peptide, which can be complexed to U1 or another member of the Sm-associated U1–6 RNA. IgG antibodies directed against U1–70kD appear to be those most closely linked to disease pathogenesis (9). The presence of antibodies against multiple individual components of the U1RNA/RNP snRNP macromolecular complex and the fact that immune spreading to different components of the complex occurs is supportive of the hypothesis that MCTD is an antigen-driven immune process (111 ,139).

Although anti-RNP antibodies are required for the diagnosis of MCTD and their development is closely linked chronologically to the onset of clinical symptoms, they have not been proven to directly mediate tissue injury. Studies in the recently developed animal model of MCTD may, however, allow for this to be examined definitively (see below) (46 ,47 ,148).

T Cells and APC in Pathogenesis

T cells are believed to play a central role in the pathogenesis of MCTD (132 ,133 ,134 ,135 ,136 ,137 ,138 ,139). As discussed above, autoantibody producing B cells produce high levels of IgG antibodies and exhibit features of T-cell–derived cytokines driven affinity maturation. Epitope mapping of anti-RNP antibodies reveal that epitope spreading typical of T-cell–dependent B-cell responses is identifiable (139). T cells may also produce cytokines or other soluble factors that recruit other cells to sites of inflammation or that directly mediate tissue injury.

Antigen-specific T cell may drive both T- and B-cell responses as illustrated in the model shown (Fig. 50-2). Autoantigen reactive human T cells have been identified and characterized from the peripheral blood of MCTD patients, including T cells reactive with U1–70kD, U1-A, and hnRNP A2 (136). These T cells have been linked to the presence of autoantibody production ex vivo and have been shown to be able to provide help for autoantibody production in vitro.

There is substantial evidence suggesting that in autoimmunity T cell hyperactivity and presentation of apoptotically modified self antigen presentation may be important in pathogenesis (Fig. 50-2). Rosen et al. were the first to show that snRNP antigens (including U1–70kD) undergo

site-specific cleavage during apoptosis and are found clustered in vesicles on the cell surface where they may be accessed by immune molecules (157 ,158). It has been proposed that structural modifications of the antigens, such as could occur during apoptosis, may render them more immunogenic and be important in breaking immune tolerance (157 ,158 ,159).

Tissue Injury and Innate Immune Signaling in Pathogenesis

A central feature to immunopathogenesis in MCTD may be local factors influencing tissue injury. We know based upon pathologic studies that one of the primary targets of tissue injury is the vascular endothelium. Clinically this is demonstrated by the almost uniform presence of Raynaud phenomenon and the potentially lethal development of pulmonary hypertension that remains as the primary disease-related caused of death (9). Although antiendothelial antibodies have been described, there is very little information on how tissue specific local responses may participate in the development of pathologic lesions. This important area awaits further investigation.

Very recently the potential importance of innate immune signaling through the TLR or other innate immune signaling pathways been recognized in autoimmunity (141 ,160 ,161). The finding that the dominant T-cell epitope on U1–70kD resides entirely within the RNA-binding domain of the RNP molecule, the fact that U1RNA antibodies are tightly linked to MCTD and finally the fact that U1RNA can activate human and murine cells through TLR3 and TLR7 all suggests that the innate immune signaling is of substantially potential importance in pathogenesis in MCTD (132 ,140). Although additional work is clearly needed, the schema shown in Fig. 50-2 illustrates how this information may be unified in a single model of disease.

Experimental Animal Model of MCTD

A variety of experimental murine models of autoimmunity and normal mice that have had single genes inactivated (so called “knock-out mice”) have substantially advanced our understanding of autoimmunity (162). Although murine models of SLE have been very informative, most of these have focused on the development of anti-DNA antibodies and renal disease and do not replicate MCTD. Recently, a model of MCTD has been described that has reactivity against RNP and develops pulmonary lesions characteristic of MCTD; rather than the renal lesions that are more typical of SLE. In this model, mice that are transgenic for the HLA-DR4 susceptibility gene that were immunized with U1–70kD polypeptide plus U1RNA or complete Freund adjuvant (containing a complex mixture of antigens including RNA). In that we know that MCTD and the overlap syndromes are characterized by immune responses against ribonucleoprotein antigens and typically lack renal involvement, this model may prove to be distinctively informative for advancing our understanding of disease pathogenesis.

Course and Prognosis

There can be an evolution of MCTD from mild to more severe disease developing over time (9). Patients typically exhibit Raynaud phenomenon, arthralgia, and swollen hand with or without polyarthritis at the outset of their disease. This often leads to a diagnosis of RA, another connective tissue disease or undifferentiated connective tissue disease (see Undifferentiated Connective Tissue Disease and Overlap Syndromes) at initial presentation. Prospective studies have shown that pulmonary or esophageal dysfunction may be detectable prior to the onset of clinical symptoms when sensitive diagnostics were used, such as pulmonary diffusion capacity for carbon monoxide and esophageal manometry) (8 ,9 ,87 ,88).

Long-term outcome studies by Burdt et al. found that with treatment certain features of the disease, including arthritis, swollen hands, serositis, myositis, erythematosus skin rash, Raynaud phenomenon, and esophageal hypomotility diminished (9). In contrast, sclerodactyly, diffuse sclerosis, pulmonary dysfunction, nervous system involvement, and pulmonary hypertension were less responsive to treatment and became the dominant residual features of the disease over time (9). In those unusual patients who develop serious renal involvement their prognosis was less favorable (9). The patients who develop pulmonary hypertension had the worst prognosis and this occurred in 23% of the 47 patients followed over a period of up to 30 years (8 ,11). In patients treated with corticosteroids or corticosteroid and cyclophosphamide, some had prolonged remission of their disease and some were able to discontinue all medications. Despite prolonged remission there were patients who later had recurrence of their disease, including those who developed membranoproliferative glomerulonephritis (9 ,10). Overall, however, the majority of patients were able to lead functionally normal lives.

Treatment

There are no large controlled clinical trials in MTCD and, therefore, management must be designed using data from controlled trials of other diseases and observational studies that typically include small numbers of patients (163 ,164 ,165 ,166 ,167 ,168 ,169 ,170). There are no drugs that have been approved in the United States by the Food and Drug Administration (FDA) specifically for the treatment of MCTD.

Arthralgia and mild synovitis can be treated with nonsteroidal anti-inflammatory agents and hydroxychloroquine (169 ,170). In patients where these measures are ineffective, disease-modifying antirheumatics can be used, similar to the approach used in the treatment of RA. There are some particular issues that should be considered, however.

Because MCTD can have associated lung disease, methotrexate therapy must be monitored closely, because, in theory, this could exacerbate MCTD lung disease. As in SLE, there are concerns that antitumor necrosis therapy could potentially exacerbate disease or affect the development of anti-dsDNA antibodies and induce renal disease or CNS disease in MCTD.

Raynaud phenomenon is treated with protective measures that maintain total body warmth and prevent peripheral cooling. The use of gloves should be encouraged and may assist patients (169 ,170). Calcium channel blockers are effective at reducing the severity and frequency of episodes of Raynaud phenomenon. Other approaches have been tried, such as regional sympathectomy, although it remains unclear how effective these may be. In patients with severe Raynaud phenomenon and complications such as digital infarctions, measures used in scleroderma, such as prostaglandin therapy, may be considered. Physical and occupational therapy may be helpful to maintain mobility and facilitate function.

Esophageal reflux symptoms can be effectively controlled in most patients with proton pump inhibitors. Many patients require chronic therapy to control symptoms. Evaluation for Barrett esophagitis should be done, although the timing of such evaluation has not been clearly defined. Dilatation of the esophagus may be of benefit for patients with strictures. There are case reports of severe, refractory esophageal involvement responding to aggressive immunotherapy with corticosteroids and with cyclophosphamide (168). Diarrhea in MCTD may be related to bacterial overgrowth syndrome and can result in malabsorption.

Clinically significant myopathy in MCTD can be treated in most patients with corticosteroids. The addition of methotrexate should be considered in more severe or refractory cases (169 ,170). In individuals with elevation of the serum creatinine, but without clinical weakness, low-dose corticosteroids or no treatment may be adequate with continued monitoring. Aggressive treatment, resulting in complete normalization of the serum creatinine, may not be readily achievable in patient with myositis nor required in patients without symptoms. Fibromyalgia may be the cause of muscle pain in MCTD patients. As in other rheumatic diseases, fibromyalgia may develop later during the course of the disease (72).

Pulmonary function should be monitored in MCTD as pulmonary disease is common and is the most frequent disease associate cause of death. Annual pulmonary function testing with DLco, plain film radiograph of the chest and two-dimensional echocardiogram have been empirically recommended. High-resolution computerized tomography of the chest may be indicated when abnormalities are found on the plain film radiographs or pulmonary function testing. Right heart catheterization may be required to evaluate pulmonary hypertension when significant abnormalities are detected by echocardiography or by pulmonary imaging studies. Intensive immunosuppressive therapy, including high-dose corticosteroids and intravenous cyclophosphamide, may benefit interstitial lung disease and pulmonary hypertension in MCTD (9 ,74 ,79 ,80 ,163 ,164). Although controlled clinical trial data is lacking, it appears rational to treat pulmonary hypertension in MCTD using similar agents to those used to treat primary pulmonary hypertension including the selective use of oxygen, anticoagulants, vasodilators, and prostacyclin (80). Although in MCTD the presence of antiphospholipid antibodies appears to be less clearly linked to clotting than in SLE, their presence has been associate with the development of pulmonary hypertension (9).

Thrombocytopenia may responds to corticosteroids, however, in patients who fail to respond, intravenous immune globulin and splenectomy may be beneficial. Patients may also respond to cytotoxic therapy with cyclophosphamide or other agents (169 ,170). Sicca symptoms are common and can be treated with supportive measures of ocular lubrications, preventative dental care, lubrication for dry skin, and vaginal lubrication for dyspareunia. A trial of pilocarpine therapy may be indicated in patients with more severe symptoms and those who fail to obtain adequate relief with supportive measures alone (11 ,168). Specific treatment is typically not required for mild anemia or leucopenia.

Erectile dysfunction and altered sexual response are now recognized to be common problems, particularly in chronically ill populations. The use of sildenafil and similar compounds may benefit such patients after they have had careful evaluation. There is also some evidence from studies of systemic sclerosis that nitric oxide inhibitors may benefit Raynaud phenomenon.

Pregnancy

Patients should be counseled regarding contraception to prevent unplanned pregnancy, especially when taking medications that could be harmful to the fetus. High-risk obstetrical evaluation and care should be provided to the mother prior to and during the planned pregnancy. Attention should be given to the identification of any additional risk factors that often occur in such patients, such as the presence of anti-SSA/Ro antibodies that have been associated with congenital cardiac disease, including heart block and antiphospholipid antibodies that have been associated with increased risk for fetal loss. Most drugs used to treat MCTD are not approved for use during pregnancy.

Undifferentiated Connective TIssue Disease and Overlap Syndromes

Undifferentiated connective tissue disease is said to be present when a patient lacks adequate clinical or diagnostic features to fit a recognizable clinical syndrome. Conceivably this may range from the presence of a single clinical or laboratory finding, such as a positive antinuclear antibody test or the presence of arthralgia, to a more

complete syndrome with presence of a number of clinical and/or serologic features. The term was first used by LeRoy et al. in 1980 to describe the early phase of connective tissue diseases when the findings were nonspecific and often indistinct (171). Subsequent authors have similarly used the term UCTD, although the criteria for inclusion in later studies have not been uniform (172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182). Additionally, studies that have been reported have not always included laboratory testing for complete serologic characterization of antinuclear antibody present in the patients sera. It should be emphasized that the term “UCTD” as applied by LeRoy et al. was not intended to describe “overlap” syndrome patients who have two or more distinctly recognizable rheumatic diseases (171). Until there is more complete understanding of the pathogenesis of the rheumatic diseases and better markers that accurately predict organ damage and disease outcome, there will continue to be controversy in the area of disease classification (10).

Table 50-3: Autoantibodies Associated with Overlap Syndromes

Autoantibody Specificity	Clinical Features
tRNA synthetase	Myositis with arthritis and pulmonary involvement
PM/Scl	Overlapping features polymyositis and limited scleroderma
Ku	Polymyositis and systemic sclerosis
RNA polymerase II	SLE overlap

Another approach to classification of rheumatic disease is the use of autoantibodies as disease markers. It has been proposed that manifestations of disease in a single patient reflects the constellation of autoantibodies specifically present and that these may evolve over time (9 ,11 ,39 ,129). If in fact the presence of specific autoantibodies is linked to select aspects of disease, the classification of disease primarily based upon the autoantibodies present may be useful (39). Studies on immune spreading of autoantibodies and on epitope contraction potentially provide one explanation on how evolving and even fluctuating clinical manifestations may be linked to autoantibody production (9 ,11 ,39 ,110 ,111 ,129). Table 50-3 summarized a number of uncommon antibodies that have been associated with systemic rheumatic diseases with protean and often overlapping clinical manifestations.

Undifferentiated Connective Tissue Disease

There may be evolution of disease in a patient initially classified as UCTD into a recognizable rheumatic disease over time or the patient may remain without adequate features for classification as a well-recognized rheumatic disease (171 ,172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181). Alarcon et al. have published a series of studies examining the evolution of UCTD and classification of the rheumatic diseases (172 ,173 ,174 ,175 ,176 ,177). Their work would indicate that the 90% to 100% of patients who present initially with a well-recognized diagnosis will retain that diagnosis over time and that a moderate percentage of patients with UCTD will evolve into a recognizable disease, although many will remain classified as UCTD. Bombaridieri et al. reported that the patients with UCTD they studied did not progress into distinctly recognizable rheumatic diseases, but remained classified as UCTD when observed over time (177 ,178 ,179). Thus, it would appear that UCTD is a common rheumatic syndrome that may remain stable over time and appears to have a favorable outcome (172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180).

UCTD is reviewed in more detail in Chapter 49 .

Overlap Syndromes

There are a number of so-called overlap syndromes that have been described (180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196). Many of these are identifiable by the presence of a specific antibody. Table 50-3 shows some examples of these syndromes and their associated antibodies.

Synthetase Syndromes

Synthetase syndromes are characterized immunologically by the presence of antibodies reactive with aminoacyl transfer-RNA synthetases. The first to be reported were characterized by the presence of antibodies against the Jo-1 antigen; we now know that these autoantibodies are directed against histidyl-tRNA synthetase (188 ,189 ,190). Clinically, the patient possessing anti-Jo-1 antibodies have inflammatory muscle disease plus the presence of additional widespread connective tissue disease signs and symptoms. Patients may have Raynaud phenomenon, arthralgia, arthritis, sicca symptoms, telangiectasias, dermatomyositis-like rashes, dysphagia, and pulmonary fibrosis (188 ,189 ,190).

PM/Scl

Patients with PM/Scl antibodies are characterized by having features of both polymyositis and scleroderma (191 ,192). Additionally, the illness may include Raynaud phenomenon, tendon inflammation, and concomitant pulmonary involvement. Although sclerodactyly or mild proximal scleroderma may be present, there is the absence of widespread sclerodermatous skin involvement. However, severe renal involvement with scleroderma-like kidney disease has been described to occur in these patients.

Ku

The patients first describe has having antibodies against the Ku antigen were found to have overlapping features of

polymyositis and systemic sclerosis (192). Patients with antibodies against Ku may also have a wide range of clinical manifestations including features of SLE, MCTD, Sjögren syndrome, and systemic sclerosis (193 ,194).

RNA Polymerase II

Patients with a number of clinical syndromes can have antibodies against one or more of three RNA polymerases, including RNA polymerase I, II, and III (195 ,196). A moderate number of patients with diffuse scleroderma or less commonly patients with limited scleroderma may have antibodies against RNA polymerase I and RNA polymerase III (195). Patients classified as SLE-overlap syndrome have been reported to have antibodies against RNA polymerase II in the absence of antibodies against RNA polymerase I and III (196). These patients have been reported to frequently have antibodies reactive with other specificities including Ku, RNP, and topoisomerase I, in addition to antibodies to RNA polymerase II (196). This finding is consistent with the concept of epitope spreading against multiple antigenic determinants that may develop over time in some patients, as discussed above.

Coexisting Rheumatic Diseases

A patient may simultaneously develop two coexisting rheumatic diseases where their coexistence is not causally related but rather is based upon a chance association. This is especially more likely for those diseases that are common, such as the coexistence of RA and fibromyalgia, or RA and Sjögren syndrome (181 ,182 ,183 ,184 ,185 ,186 ,187). Small clinical series of such patients have been described and the literature is replete with case reports of patients said to have overlapping features of different autoimmune diseases. The precise relationship of these to each other ultimately waits a more complete understanding of the genetics and pathogenesis of autoimmunity and of the connective tissue diseases (10).

Mixed Connective-Tissue Disease and Overlap Syndromes: Summary Points

- MCTD was described by Sharp et al. among a group of patients with clinically overlapping features of SLE, scleroderma, and polymyositis who had high levels of antibodies reactive with a novel antigen which is now known to be RNP.
- Primary clinical features of MCTD are Raynaud phenomenon, swollen fingers or hands, arthralgia, with or without associated arthritis, esophageal reflux or dysmotility, acrosclerosis (i.e., sclerodactyly), mild myositis, and pulmonary involvement of a variety of forms.
- Serologic hallmark of MCTD is the presence of high levels of antibodies against the RNP antigen.
- RNP antigen also known as nRNP, U1-snRNP or U1RNP.
- Several criteria for classification of MCTD have been published and include clinical and serologic criteria.
- Laboratory abnormalities common in MCTD are high titer antinuclear antibodies, rheumatoid factor, leukopenia, and anemia.
- U1–70kD polypeptide of RNP plays a key role in MCTD.
- Genetic studies have shown that there is an association between HLA-DR4 and MCTD in several populations.
- MCTD can be mild to severe with most patients able to lead functionally normal lives.
- Pulmonary hypertension is the main disease associate cause of death and has been found to be present in over one fifth of patients.
- Absence of controlled clinical trials in MCTD requires that rational treatment is based upon evidence-based approaches derived from other rheumatic diseases.
- Overlap syndromes are often incorrectly used as synonymous with MCTD.

There are a number of distinctive overlap syndromes that have been reported, such as those associated with antibodies against Jo-1, PM/Scl, Ku, and RNA polymerase II.

Chapter 51

The Mother in Systemic Lupus Erythematosus

George A. Karpouzas

Rodanthi C. Kitridou

Systemic lupus erythematosus (SLE) affects predominantly young women with normal fertility, who frequently get pregnant. In the past, pregnancy in lupus was often fraught with serious disease flares, fetal, and even maternal death. The course and outcomes of pregnancy in this disease has changed substantially in the last 55 years and pregnancy in lupus patients has now become commonplace.

A lot of insight has been recently gained on the immunobiology of both normal and lupus pregnancy. Moreover, much has been discovered on determining factors and biologic surrogate markers of a successful versus a failed pregnancy. The role of sex and pregnancy hormones on the maternal immune response and on the tolerance of a normal semiallogeneic fetus has been elucidated. A brief introduction will be given on the immunobiology of normal pregnancy and the role of sex hormones with direct reference to abnormalities seen in patients with SLE.

Immunobiology of Normal Pregnancy

Pregnancy is a physiologic condition characterized by a persistent local tolerance of the maternal immune system to the paternal human leukocyte antigens (HLA) expressed by the fetus. A normal semiallogeneic embryo is organized to evade hostile maternal cellular and humoral immune responses (1). This local immune tolerance is not associated with a reduced maternal immune response to exogenous stimuli, or with inability of the mother to produce antibodies against HLA (2). Several alterations occur in the normal immune system during pregnancy, both systemically and locally, that prevent fetal rejection.

The placenta represents the site of immune maternal-fetal interface. It has a maternal side, the decidua, which is the hypertrophic pregnant endometrium, and a fetal side, the trophoblast. The trophoblast has an inner layer of mononuclear cytotrophoblast and an outer layer of multinucleated syncytiotrophoblast, derived from fusion of cytotrophoblasts.

How is the maternal immune system alerted of the semiallogeneic trophoblastic cells invading the uterine wall and how does it respond?

The normal human endometrium hosts a significant number of leukocytes, the percentage and phenotype of which change during the menstrual cycle and pregnancy (3). Leukocytes account for 10% of stromal cells during the proliferative phase, 20% during the secretory phase, and 30% of endometrial stromal cells in early pregnancy decidua. Cells of the innate immune response, such as natural killer (NK) cells, represent about 70% of these leukocytes and are the largest leukocyte subset present in the decidua (3 ,4). Macrophages and dendritic cells (DC) are also diffusely distributed within the decidua, usually strictly adhering to extravillous trophoblast and close to the spiral arteries and endometrial glands (5). Cells of the adaptive immune response such as T and B cells, although a numeric minority, are critically important for normal pregnancy outcomes, as will be discussed later.

Endometrial leukocytes are derived from peripheral blood leukocytes that are locally chemotaxed and subsequently home in the decidua (6). During insemination, transforming growth factor beta-1 (TGF-ß1) found in seminal fluid stimulates production of granulocyte-macrophage colony-stimulating factor (GM-CSF) and results in recruitment of inflammatory cell infiltrates in the uterus (7). Uterine NK cells (uNK) derive from peripheral blood NK cells (8). Based on intensity of surface expression of CD56, an isoform of neural cell adhesion molecule (NCAM), peripheral blood NK cells are divided in two populations: CD56dim, representing 90% of the NK population and CD56bright, which is the remaining 10% (7). CD56dim cells express high levels of CD16 a low affinity receptor for IgG complexes (FcRIII) associated with their cytotoxic potential (9). CD56bright cells do not express CD16 and are the main source of NK cell-derived regulatory cytokines. $CD56^{bright}CD16^{-}$ cells represent the pool from which uNK cells derive. The uNK cell phenotype changes during the normal menstrual cycle and early pregnancy (10). During pregnancy, there is decreased expression of many activation markers, and almost all uNK have been found to express one or more inhibitory receptors. The most pertinent are CD94/NKG2A, KIR2DL4, and ILT-2 (LIR-1) (11). In addition, uNK selectively express CD9, galectin-1, and glycodelin, which are associated with immunomodulatory functions (12).

Although uNK represent the major immune cell type during early pregnancy, they do not persist throughout gestation.

Antigen-presenting cells (APCs), such as macrophages and DC are a stable population present throughout the tissue from implantation to parturition. Macrophages represent about 20% of the decidual leukocytes (13). Although activated in vivo, as indicated by expression of HLA class II, CD11c, and CD86, these macrophages exhibit a phenotype of alternative activation, associated with immune suppressive activity (14). This phenotype is characterized by surface expression of B7-H1, ILT3, DC-SIGN, MS-1, and factor 13. In addition, decidual macrophages spontaneously secrete anti-inflammatory cytokines, such as IL-10 and TGF-ß1, and are a major source of prostaglandin E2 (PGE2), responsible for the suppressive function of decidual cell mixtures demonstrated in early in vitro studies (15).

The DC present in the human decidua derive strictly from myeloid DC and exhibit a predominantly immature phenotype (CD83-) (16). When immature DC present antigens to T cells, this leads to antigen-specific T cell tolerance, whereas antigen presentation by mature DC causes activation of naïve or memory helper T cells, cytotoxic T cells, and B cells (17). Immature DC in the decidua could capture fetal antigens from the invading trophoblast and present peptides to local maternal T cells, thus inducing tolerance to those antigens (16 ,18). Moreover, macrophage-derived PGE2 greatly enhances the ability of the DC to produce IL-10 and decreases its ability to secrete IL-12, thus leading to the development of a tolerogenic DC (19).

Because the human conceptus represents a semiallograft to the maternal host, immunologic tolerance to the fetal allograft is essential for its maintenance. In humans, $CD4^+$CD25bright regulatory T cells (Treg) are known to play an important role in the development and maintenance of tolerance in peripheral tissues (20). These cells express high levels of CD152 (CTLA-4) and suppress effector T cell proliferation and action via direct cell contact. It was recently shown that absence of $CD4^+CD25^+$ Treg led to failure of gestation, because of immunologic rejection of the fetus in a mouse model, suggesting that $CD4^+CD25^+$ Treg cells mediate maternal tolerance to the fetus (21). The presence and action of $CD4^+$CD25bright Tregs was recently characterized in human pregnancy (22). $CD4^+$CD25bright Tregs represent about 6.5% of the total $CD4^+$ cells in the peripheral blood of nonpregnant women. In early pregnancy, there is a significant numeric expansion of these cells in the peripheral blood (8.5%, $p<0.05$). In human deciduas, 5% to 6% of decidual cells are $CD4^+$ cells. Early pregnancy deciduas from patients undergoing therapeutic abortion show tremendous enrichment of $CD4^+$CD25bright Tregs (21.8% of $CD4^+$) compared to those in patients with spontaneous abortion (7.1% of $CD4^+$, $p<0.0001$), indicating a potential role of these cells in maintenance of human pregnancy (22).

The extravillous trophoblast (EVT), which represents the fetal side of the maternal-fetal immune interface, has 50% genetic contribution from the father, and is thus an allogeneic normal tissue in the mother. However, unlike other situations in which allogeneic cells come into contact, as in transplantation, there are fundamental differences. The trophoblastic cell is not a normal somatic cell, but a normal extraembryonic cell. The highly polymorphic HLA class I (HLA-A and HLA-B) and class II molecules displayed by somatic cells, initiating recognition of the allograft and its subsequent rejection are not displayed by trophoblastic cells (23 ,24). Instead, EVT expresses an unusual combination of three HLA class I molecules: a less polymorphic HLA-C and two others, HLA-E and HLA-G, which are known to be dominant ligands for inhibitory receptors on maternal NK cells, macrophages, and DC (24). HLA-E is virtually monomorphic and would be perceived as “self” by maternal uNK cells expressing the inhibitory receptor CD94/NKG2A, thus preventing cytotoxicity (25). The quasimonomorphic HLA-G is recognized by the inhibitory uNK cell receptors KIR2DL4 and ILT2 (LIR-1), as well as by inhibitory receptors ILT-2 and ILT-4 (LIR-2) on macrophages and DC, and by ILT-2 on T cells (26). HLA-C allotypes are recognized by diverse inhibitory KIR2D receptors present on uNK cells (27). Given the stable presence of maternal macrophages and DC in the decidua throughout pregnancy, their exposure to trophoblastic antigens such as HLA-G, and their immunosuppressive phenotypes, HLA-G is a prime candidate potentially responsible for driving APC behavior beneficial to the maintenance of human pregnancy (16 ,28).

Another mechanism for protection of pregnancy against rejection is the abundant expression of Fas ligand (FasL) by maternal syncytiotrophoblast (29). Activated lymphocytes expressing Fas would be driven to apoptosis upon FasL engagement on the surface of such trophoblastic cells.

Complement activation and complement-mediated cytolysis could readily occur at the maternal-fetal interface jeopardizing the integrity of pregnancy (30). Complement regulators have been identified on the surface of all trophoblastic cells protecting them from complement-mediated cytolysis. Membrane regulators such as decay acceleration factor (DAF, CD55), acting as a C3-convertase inhibitor, and membrane cofactor protein (MCP, CD46), acting as a cofactor for C3b-inactivator, are expressed on the trophoblast in association with CD59 (31). This is an important complement regulator that inhibits the assembly of the cytolytic membrane attack complex on the surface of the trophoblast (32).

Another mechanism of fetal protection is the expression of indoleamine 2,3-dioxygenase (IDO) on fetal-derived syncytiotrophoblasts at the maternal-fetal interface, an enzyme that catabolizes tryptophan (33). Inhibition of IDO in mice resulted in fetal rejection by maternal lymphocytes (34).

The uterine decidua and the fetoplacental unit produce large numbers of cytokines, which contribute to a shift of the immune response from T helper-1 (Th1) to Th2: successful pregnancy has been considered akin to a Th2 type of response (35), where cytokines IL-10, IL-4, IL-5, IL-6, and IL-13 predominate. Recurrent spontaneous abortion of unknown cause (pregnancy rejection) is mediated by a Th1 response (36), where interferon-γ (IFN-γ), tumor necrosis factor-alpha and -beta (TNF-α, TNF-ß), IL-2, and IL-12 predominate.

The hormonal milieu dramatically changes during pregnancy. Pregnancy-associated hormones modulate the number,

surface phenotype, and the biological function of immune competent cells in maternal blood and decidua, ascertaining protection and growth of a normal fetus.

Progesterone, the hormone of pregnancy has long been considered the “nature's immunosuppressant” (37). In pregnancy, progesterone causes a decrease in the NK cell numbers, activation and cytotoxicity via several ways: 1. direct action on NK cells (38), 2. through promoting Th2 differentiation in $CD4^+$ T cells, and 3. via progesterone-induced blocking factor (PIBF) on γδ-T cells. Progesterone also facilitates NK cell homing to the endometrium via induction of expression of homing receptors and addressins on peripheral NK cells and endometrium respectively, and possibly through upregulation of vascular endothelial growth factor (VEGF) and macrophage inflammatory protein-1b (MIP-1b) expression by endometrium (39). Endometrial stromal cells under the influence of progesterone produce IL-15, prolactin (PRL), and likely other unidentified factors, which regulate uNK cell proliferation, differentiation, and production of cytokines and other molecules that support placental and trophoblast development and promote local immunomodulation (40).

In the presence of progesterone, peripheral lymphocytes from healthy pregnant women produce PIBF, a 34-KD mediator protein (41). PIBF has been shown to exert immunomodulatory functions both in vitro and in vivo. It predominantly inhibits NK cell function (42). Neutralization of endogenous PIBF activity in pregnant mice by anti-PIBF antibody results in a 70% reduction in the number of viable fetuses, and this is associated with an increased splenic NK cell activity (42). Ninety percent of pregnancy loss mediated by anti-PIBF administration is corrected by the treatment of the pregnant animals with anti-NK antibodies. The second main mechanism of action of PIBF is the induction of a Th2 dominant cytokine response (43 ,44). During normal pregnancy, the concentration of PIBF in biological samples continuously increases until the thirty-seventh gestational week and is followed by a sharp decrease over the forty-first week of gestation (45).

In pathologic pregnancies, urinary PIBF fails to increase. Thus determination of PIBF concentration in the urine has been proposed as a useful surrogate test for threatened premature pregnancy termination (45).

Work on the immunoregulatory properties of steroid sex hormones shows the following: 17β-estradiol (E2) significantly reduces neutrophil chemotaxis through a receptor-dependent mechanism (46); in mice, estradiol reduces NK cell cytotoxicity in a dose-dependent manner, and augments polyclonal B cell activation, probably through suppression of NK cells (47). In vitro experiments with adult male mononuclear cells under various stimuli (e.g., phytohemagglutinin (PHA), anti-CD3, IL-2) showed that estradiol and pituitary gonadotropins had a variety of effects on T cell subsets, depending on the stimulus used (48): E2 significantly decreased $CD4^+$ cells and increased $CD8^+$ cells; prolactin had no subset-specific effects, but enhanced proliferation of peripheral mononuclear blood cells (PMBCs), as did follicle-stimulating hormone (FSH) and luteinizing hormone (LH); FSH decreased $CD4^+$ cells and enhanced $CD8^+$ cells, especially $CD8^+CD28^+$; LH increased $CD4^+$ cells. Human chorionic gonadotropin and somatotropin appear to suppress in vitro T cell functions. Peripheral T-lymphocytes from pregnant women express human chorionic gonadotropin/LH receptor messenger RNA (mRNA) transcript and the receptor protein, suggesting that immunomodulatory effects are receptor-mediated (49). Some of the actions of progesterone were detailed earlier. Cortisol is present at a fourfold concentration in the third trimester, and the free cortisol index is elevated (50). This fact might have been responsible for some of the clinical amelioration seen in lupus pregnancy.

It would appear, then, that various immunomodulatory events occur during pregnancy, especially at the maternal-fetal interface, which regulate the maternal immune response and result in tolerance, survival, and growth of the embryo.

Summary

- The fetoplacental unit is immunologically privileged by expressing (a) unique HLA antigens; (b) Fas ligand, which protects it from Fas-expressing lymphocytes; and (c) complement regulatory proteins, which protect it from complement lysis action.
- Successful pregnancy shows a shift to a Th2 response, with IL-10 playing a prominent role. Recurrent spontaneous abortion of unknown etiology is associated with a shift to Th1 response.
- Progesterone at the maternal-fetal interface, through PIBF, inhibits the function of uterine NK cells, and promotes a Th2 dominant cytokine response.
- Expression of IDO on fetal-derived syncytiotrophoblasts at the maternal-fetal interface catabolizes tryptophan and inhibits fetal rejection by maternal lymphocytes.
- Greatly increased levels of hormones such as progesterone, estrogen, cortisol, chorionic gonadotropin, and somatotropin modulate cellular immunity at the maternal-fetal interface.

Sex Hormones and Systemic Lupus Erythematosus

SLE is a chronic autoimmune disease known for its female proclivity and peak incidence during reproductive years (9:1 ratio of females to males). Early reports of SLE flares corresponding to the menstrual cycle (51), focused an era of investigations on the potential contributions of estrogens, androgens, and prolactin to the development of this disease (52). Sex hormonal factors play an important role in regulating disease onset, severity, and progression (53).

Observations suggesting hormonal disease modulation include reports of SLE flares precipitated by estrogen (54), oral contraceptives containing estrogen (55), and ovulation induction regimens (56). Conversely, ovarian failure has been associated with decreased risk of lupus flares (57). An association of lupus with Klinefelter syndrome, and its amelioration following testosterone administration, also imply that sex hormones modulate the prevalence and

expression of SLE (58). Clinical investigations of sex hormones in lupus have yielded confounding results because of small patient numbers, ethnic differences, long periods of reporting, and insufficient power to test respective hypotheses. A recent meta-analysis of all available studies enrolling nonpregnant female and male patients with SLE, and matched controls, with sex hormone measurements in the serum yielded enlightening results (53):

- Estradiol (17β-estradiol, the most potent and predominant estrogen in serum) was significantly higher in adult SLE patients compared to controls when all studies (20 studies) and female-only studies (8 studies) were considered. No significant differences in serum estradiol levels could be demonstrated between male-only lupus patients and healthy controls (12 studies).
- Serum testosterone levels were significantly suppressed in SLE patients compared to controls when all studies (19 studies) and female-only studies (8 studies) were considered. This was not observed in male-only studies (11 studies). Possible explanations include increased activity of aromatic hydroxylase or increased production of LH driving testosterone aromatization in women.
- Serum dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) levels were significantly lower in adults with SLE compared to controls when all studies were considered (14 studies). The paucity of studies precluded sex subset classification for DHEAS, or of common estimators for DHEA.
- Serum PRL concentrations were significantly higher in SLE adults when all studies were considered (14 studies). PRL levels were also significantly higher when female-only studies (10 studies) or male-only studies (4 studies) were considered separately. Summation of studies suggested that 21% of all SLE patients were hyperprolactinemic, compared to 3% of healthy matched controls.

To our knowledge, no genotypic variations in the enzymes of gonadal steroid synthesis have been identified in SLE patients. However, abnormal metabolism of estrogen and testosterone has been reported: women and men with lupus, and their first-degree relatives, have a higher rate of C16[α] hydroxylation of estradiol to estrone and estriol, which retain estrogenic activity (59). In addition, there is decreased C2 hydroxylation of estrogen, and increased C17 oxidation of testosterone, resulting in inactive metabolites (60).

Because a hallmark of SLE is B cell hyperactivity with production of multiple pathogenic and/or disease specific autoantibodies, it was hypothesized that female sex hormones modulate autoreactive B cells (61). Treatment with estrogen induces a lupus-like syndrome in BALB/c mice transgenic for the H-chain of a nephritogenic anti-DNA antibody (62). In untreated mice, high affinity anti-DNA B cells are rendered tolerant and SLE does not develop. Upon estrogen administration, autoreactive B cell tolerance is broken. Estrogen upregulates antiapoptotic Bcl-2 and inhibitory BCR signaling molecules CD22 and SHP-1. The resulting impaired apoptosis of autoreactive B cells allows for their expansion, high titers of serum anti-DNA, and nephritis with extensive glomerular IgG deposition.

In humans, estrogen increases IgG and anti-DNA production by SLE peripheral blood mononuclear cells (PBMCs) (63). In addition, it induces CD40L expression on B cells that in turn upregulates anti-apoptotic molecules and prevents BCR-mediated apoptosis (64).

Treatment of lupus-prone (NZBX NZW)F1 mice with PRL leads to elevated serum IgG and circulating immune complexes, early proteinuria, and premature death at 28 weeks from immune complex-mediated nephritis (61). PRL also breaks self-tolerance of autoreactive B cells in transgenic BALB/c mice leading to a lupus-like disease (65).

Prolactin levels correlated with clinical and serologic disease activity in humans (66). During lupus pregnancy, PRL was significantly higher than in control pregnant women, with highest levels late in pregnancy (67). Male SLE patients also had elevated serum PRL (68). Two double-blind, placebo-controlled studies of the prolactin antagonist bromocriptine in SLE patients showed decreased PRL levels, Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) score, and flare rates per patient/month (69). Of interest is that 33 women with increased PRL and no diagnosis of a rheumatic disease had increased prevalence of autoantibodies, including anti-double-stranded DNA (dsDNA), anti-Sm, and anti-Ro/SSA, compared to PRL-normal controls (70). Chapter 16 discusses sex hormones in SLE.

Definition of Terms

The following terms are used in this and Chapter 52 (71 ,72 ,73 ,74):

- Fertility rate: Average number of pregnancies per pregnant woman.
- Parity rate: Average number of viable infants per pregnant woman.
- Adjusted fertility or parity rate: Corrected for years at risk for pregnancy (10-year intervals).
- Spontaneous abortion: Spontaneous termination of pregnancy prior to 20 weeks' gestation.
- Elective or induced (“therapeutic”) abortion: Voluntarily induced termination of pregnancy.
- Stillbirth or intrauterine fetal death (IUFD or fetal death): The death of the fetus after the 20th week of gestation. The rate is approximately 5 per 1,000 in the general population.
- Neonatal death is defined as death occurring in the first 28 days after birth. The background rate is 5 per 1,000.
- Perinatal death is the sum of stillbirth and neonatal death. Perinatal death is approximately 10/1,000 in the general population.
- Pregnancy loss or fetal loss is the sum of spontaneous abortions and perinatal deaths.
- Recurrent spontaneous abortion; recurrent fetal loss: Three or more (75), or two or more (76), consecutive spontaneous abortions or intrauterine fetal deaths, respectively.
- Recurrent spontaneous aborter: A woman with recurrent spontaneous abortions, or recurrent fetal loss.

- Intrauterine growth restriction (IUGR): Formerly intrauterine growth retardation; the newborn weight is below the 10th percentile for gestational age. Synonyms: small newborn for gestational age, intrauterine malnutrition.
- Preterm premature rupture of membranes (PPROM) is the spontaneous rupture of membranes (amniorrhexis) before the onset of labor and before 37 weeks' gestation
- Premature rupture of membranes (PROM) refers to the spontaneous rupture of membranes before labor after 37 weeks' gestation.
- Premature or preterm birth: Spontaneous termination of pregnancy with a live birth between 21 and 37 weeks of gestation.
- Full-term or term birth: Spontaneous termination of pregnancy with a live birth between 38 and 40 weeks of gestation.
- Pregnancy-induced hypertension (PIH): Presence of blood pressure ≥140/90 mm Hg on at least two occasions, 6 or more hours apart, during the second half of pregnancy in a previously normotensive woman (77 ,78 ,79).
- Preeclampsia: PIH with proteinuria of >0.3 g/L in the absence of urinary tract infection (77), or abrupt onset of hypertension and proteinuria, usually after 24 weeks of gestation (78 ,79).
- Severe preeclampsia: Characterized by one or more of the following: blood pressure of at least 160 mm Hg systolic, or 110 mm Hg diastolic on two readings 6 hours apart; proteinuria >5 g/24 hours, oliguria (<400 mL/24 hours), cerebral or visual disturbances, pulmonary edema, or cyanosis (80).
- HELLP syndrome: is a form of severe preeclampsia characterized by Hemolysis, Elevated Liver enzymes, Low Platelets (80).
- Eclampsia: Severe preeclampsia with malignant hypertension, seizures, and renal failure.

Table 51-1: Course of Systemic Lupus Erythematosus (SLE) in Pregnancy

Pregnancy and Lupus Activity—Controversy or Consensus?

The relationship of pregnancy and SLE activity has been controversial and contradictory, especially in the earliest studies. The subject is fascinating, and there has been a virtual explosion in the number of studies addressing lupus pregnancy, both by rheumatologists and by obstetricians.

Reports from the 1950s recommended against pregnancy, and implied that it was not advisable and that termination should be offered (81 ,82). The numerous studies that followed, especially in the last 20 to 25 years, indicate that pregnancy in lupus patients often has a successful outcome, if well timed and managed. Although there is general agreement about successful pregnancy outcomes, there are still variations in study results, arising from differences in study design, variability of SLE severity, the lack of uniformity in the definition of flares, and cultural and socioeconomic factors.

- Study design: The majority of studies from the 1950s through the 1980s were uncontrolled and retrospective (72 ,81 ,82 ,83 ,84 ,85 ,86 ,87 ,88 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109), with the exception of three controlled studies (110 ,111 ,112). Since 1984, prospective and/or controlled studies have appeared, three in the 1980s (75 ,113 ,114), and 11 (115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,127) of the 19 published in the 1990s (115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129 ,130 ,131 ,132). Of the 17 studies published in 2000–2005 (133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149), 4 are controlled (134 ,140 ,148 ,149), 4 are prospective (133 ,137 ,138 ,143), and 9 are retrospective (135 ,136 ,139 ,141 ,142 ,144 ,145 ,146 ,147) (Table 51-1). All studies except 1 (149) utilized the American College of Rheumatology (ACR, formerly ARA) classification criteria for SLE (150).
- The great variability of SLE severity can skew study outcomes. For example, it has been well established that SLE

nephritis is more severe and has a worse outcome in African-American and African-Caribbean patients (151 ,152).

- The definition of flare has not been uniform, even in the last 5 years: it ranges from the use of clinical indices of signs and symptoms, the patient's opinion, to complicated analysis of laboratory data, the physician's global assessment, or the physician's decision to increase prednisone dosage. The availability of lupus activity indices allows for a standardized approach (153 ,154). Several indices (SLEDAI, Lupus Activity Index [LAI], Systemic Lupus Activity Measure [SLAM], and European Consensus Lupus Activity Measure [ECLAM]) have been adapted for use in pregnancy, as Systemic Lupus Erythematosus Pregnancy Disease Activity Index (SLEPDAI), Lupus Activity Index in Pregnancy (LAI-P), and modified Systemic Lupus Activity Measure (m-SLAM) (155 ,156 ,157). Modifications in the activity measures have been developed in recognition of differential diagnostic dilemmas between active SLE versus preeclampsia, which share certain symptoms and findings (headache, hypertension, proteinuria, seizures, red blood cells [RBCs] in urine), and versus pregnancy-associated problems (fatigue, edema, alopecia). Definitions of flare include a change in the physician's global assessment equal to, or greater than 1, an increase of 3 in SLEDAI, or of 0.26 in LAI (158). LAI has been successfully compared to the “gold standard,” the physician's global assessment (157). For further details on activity indices, please see Chapter 47 .
- SLE patient populations vary greatly in terms of cultural diversity and educational-socioeconomic background, which influence their perception of disease severity, their compliance with prescribed medications, and the site of their health care, ranging from private offices for patients of affluent background to university, tertiary hospitals for economically disadvantaged patients (159).
- Greater diagnostic uniformity in patient selection has been achieved by the use of the SLE classification criteria (preliminary since 1971 (161), revised in 1982 (150), and updated in 1997 (160). The availability of sophisticated and standardized laboratory tests (antinuclear antibody [ANA], complement C3 and C4, and antiphospholipid antibodies [APL]) has allowed confirmation of diagnosis and subsetting of patients, further contributing to uniformity of patient selection and clinical follow-up. In addition, 55 years of experience with the treatment of SLE patients in the poststeroid era have resulted in increased patient survival, a large patient population with controlled SLE, and, indeed, a modification of the natural history of the disease (162 ,163 ,164).

SLE Activity during Pregnancy

Pregnancy in SLE patients is common, the prognosis has greatly improved with proper management, and patients function well within society and their families (105). Their fertility is normal, at 2 to 2.4 pregnancies per patient, not only in quiescent periods of the disease, but also during active episodes when approximately 10% of total reported pregnancies occur (72 ,91 ,93 ,110 ,129 ,165).

In the presteroid era, exacerbations and remissions occurred almost equally during pregnancy, but severe postpartum flares were seen in virtually all patients (91). The course of pregnancy tended to be smoother in patients who conceived during a period of inactive lupus (83), and the value of steroid therapy in decreasing flares during pregnancy and postpartum was recognized in 1962 (111). A sizable proportion of patients developed preeclampsia (1.8% to 20%) (84 ,86 ,99). The debate whether hypertension alone or with proteinuria during pregnancy represents pregnancy-induced hypertension, preeclampsia, or active lupus nephritis has been longstanding (112 ,113 ,165), but differentiation is possible (166 ,167). The more acute the lupus, and the earlier the report, the worse was the outcome, with maternal death occurring in 10% to 25% of patients (81 ,86) (Table 51-1). In 1970, McGee and Makowski advocated steroids for 6 weeks after delivery (100).

In the mid-1960s to mid-1970s, three major studies, from New York, Mexico City, and Los Angeles, respectively, were published: Estes and Larson reported 79 pregnancies in 36 patients (83), Fraga et al. reported 225 pregnancies in 53 patients (110), and Dubois reported 217 pregnancies in 112 patients (84). The appropriate use of corticosteroids seemed to decrease pregnancy and postpartum flares to half of those in the 1950s (from 50%–75% to 24%–27%), and maternal mortality was very rare. The study by Fraga et al. from Mexico City was followed up by a prospective study by Mintz et al. (75).

Table 51-1 summarizes lupus pregnancy data over the last 55 years categorized by decade, and in greater detail for the 1980s, 1990s, and the years 2000 through 2005. The most striking change is a dramatic decrease in maternal mortality from 17% in the 1950s to 0.26% in the 1990s and a slight rise to 0.65% in the 2000s. Lupus flares during pregnancy range from 17% to 60%; however, in later reports the majority are mild and mostly musculoskeletal and cutaneous (75 ,116 ,129), with the exception of patients in whom disease began during pregnancy or postpartum. A good example are the studies of Cortes-Hernandez (138) and Chakravarty (135), where all flares were 33% and 67.7% respectively, but severe flares were seen in 10.7% of the former, and in 29% of the latter study. One third to one half of flares were seen in the postpartum period, and the rest are equally divided among trimesters. Throughout the last 55 years it is abundantly clear that patients whose SLE is inactive at conception have a lesser likelihood of disease flares, whereas active SLE at conception has been a very important factor for pregnancy flares during pregnancy and postpartum (95 ,98 ,135 ,136 ,137 ,138 ,143 ,144 ,145 ,168).

SLE onset during pregnancy is described in 12.5% of the pregnancies in the 1980s, in 0.19% during the 1990s (115), and in 4.5% of pregnancies in the 2000s (135 ,136 ,137 ,138) and is also associated with severe lupus activity during pregnancy. In addition, active SLE during pregnancy affects fetal outcome with greater perinatal loss, small infants (IUGR), more preterm births, and less live births (see Chapter 52).

Nine studies, spanning from 1962 to 2002, have examined the question of whether lupus flares are more frequent in pregnancy (75 ,111 ,112 ,113 ,122 ,125 ,138 ,168 ,169). Three studies used the patients as their own controls (111 ,112 ,138) and six used nonpregnant controls (75 ,113 ,122 ,125 ,169) (Table 51-2).

Table 51-2: Flares of SLE in Pregnant and Nonpregnant Patients

Study	Per 100 Weeks at Risk	Per Patient-Month	
Garsenstein et al. (111)			
32 weeks before pregnancy	0.91	0.04	
0–20 weeks of pregnancy	3.04	0.13	
21–40 weeks of pregnancy	1.62	0.07	
0–8 weeks postpartum	6.31	0.27	
9–40 weeks postpartum	0.84	0.04	
Study	**Flares/Pregnancies (%)**		
Zulman et al. (112)			
6 months before pregnancy	4		
1st trimester	13		
2nd trimester	14		
3rd trimester	55		
6 months postpartum	23		
Study		**Per Patient-Month**	
Wong et al. (125)			
Pregnant:	13 in 155 patient-months	0.08	$p<0.02$
Nonpregnant:	218 in 5202 patient-months	0.04	
Petri et al. (169)			
Pregnant:	1.6337/patient-year	0.14	$p<0.0001$
After delivery:	0.6392/patient-year	0.05	
Nonpregnant:	0.6518/patient-year	0.05	
Mintz et al. (75)			
Pregnant:	55 in 909 patient-months	0.06	p = NS
Nonpregnant:	19 in 468 patient-months	0.04	
Ruiz-Irastorza et al. (122)			
Pregnant:		0.08	$p<0.001$
Nonpregnant:		0.04	
Pregnant vs.:		0.09	p = 0.0015
themselves after puerperium		0.05	
Lockshin et al. (113)			
Similar in 28 pregnant and 21 nonpregnant patients			
Greater thrombocytopenia in pregnant patients			
Urowitz et al. (168)			
Flares similar in 79 pregnant and in nonpregnant control patients			
Flares were twice as frequent if SLE was active at conception (82%) versus inactive at conception (41%)			
Cortes-Hernandez et al. (138)			
Before pregnancy in 60 patients	0.4 flares per person-year		
During pregnancy, in 60 patients with 103 pregnancies	1.2 flares per person-year		$p<0.0001$

Garsenstein et al. noted a clear-cut increase in flares during the first half of pregnancy (3.04/100 weeks at risk versus 0.91/100 weeks for the 32 weeks before pregnancy), a small increase during the second half of pregnancy (1.62/100 weeks), a sevenfold increase during the 2 months postpartum

(6.31/100 weeks), and a return to baseline in the 9 to 40 weeks postpartum (111).

Zulman et al. reported the percentage of flares per number of pregnancies during the 6 months preceding pregnancy (4%), each trimester (13%, 14%, and 55%, respectively), and during 6 months postpartum (23%) (112). The flare rate during the third trimester and postpartum appears excessive.

Lockshin et al. reported similar flares in 28 pregnant and 21 nonpregnant patients, with the exception of greater thrombocytopenia in the pregnant patients (113).

Mintz et al. reported 55 flares in 909 months in their at-risk pregnant patients, not significantly different from the 19 flares in 468 months of their nonpregnant patients (p = NS). It is of note that all pregnant patients in this study, even without active lupus, were given 10 mg of prednisone daily (75).

Wong et al., however, found the rate of flares in their pregnant patients to be twice that of their nonpregnant patients ($p<0.02$) (125).

In a prospective study of 40 pregnancies in 37 women, Petri et al. defined flare as a change of over 1.0 in the physician's global assessment (scale of 0 to 3) since the preceding visit or during the previous 3 months (169). They noted 27 flares in 24 of 40 pregnancies, or 60%. The intrapregnancy flare rate of 1.6337 ± 0.30087 per person-year was significantly greater than the flare rate after delivery (0.6392, $p<0.001$), and the rate in nonpregnant patients (0.6518, $p<0.0001$). The majority of the flares were moderate (59%), or mild (30%), and only 11% were severe.

In a prospective, controlled study from the University of Toronto of 79 lupus pregnancies, flares were similar in pregnant and nonpregnant women, but were twice as frequent in women with active SLE at conception (82%) than in women with inactive SLE at conception (41%); inactive SLE at conception was deemed protective against flares in pregnancy (168).

A prospective, controlled study of 78 pregnancies in 68 SLE patients by Ruiz-Irastorza et al. found that 65% of pregnant patients flared, versus 42% of the 50 nonpregnant SLE controls (p = 0.015) (122). A flare was defined as an increase of ≥0.26 in the LAI. Flare rates per patient/month were 0.082 in the pregnant and 0.039 in the nonpregnant patients (p = 0.0015). A subset of 43 patients had higher flare rates during pregnancy versus the postpartum period, when SLE was controlled (0.093 vs. 0.049). Serious flares, affecting the kidneys and central nervous system (CNS), were equally distributed in the two groups.

A prospective study of 103 pregnancies in 60 patients by Cortes-Hernandez et al. showed that the prepregnancy flare rate of 0.4 per person-year, increased to 1.2 per person-year during pregnancy (138). Flare was defined as any clinical disease activity event that required a change in therapy, and patients were assessed with SLEDAI.

Summary

- There has been lack of uniformity in the definition of flare, but there are attempts at consensus.
- Six studies have found increased flares during pregnancy and postpartum, and three studies found a similar risk of flare regardless of pregnancy status.
- Flare rates are remarkably constant in the nonpregnant patients: when the data in the Garsenstein et al. (111), Mintz et al. (75), Petri et al. (169), Wong et al. (125), Ruiz-Irastorza et al. (122), and Cortes-Hernandez et al. studies (138) are expressed as flares per patient-month, these rates are 0.03 to 0.05 (0.039565, 0.040598, 0.054316, 0.041907, 0.039, and 0.03333 respectively), about one flare for every 2 years (Table 51-2). This suggests, however, that over four decades, the rate of flare in SLE has not changed materially.
- Most studies show that the proportion of severe flares has lessened.
- The differences in flares during pregnancy in these nine studies may be explained by differences in patient populations, flare definition, and evolving therapeutic strategies since the introduction of corticosteroids.

Course of Lupus in Pregnancy—Studies in the 1980s (Table 51-1)

Studies with a minimum of 10 lupus pregnancies are reviewed here, and Chapter 52 reviews fetal effects. Of 13 studies in the 1980s, 10 are retrospective (89 ,90 ,93 ,94 ,95 ,96 ,97 ,101 ,107 ,108 ,112) and three are prospective with control groups (75 ,113 ,114). Maternal flares ranged from 21% to 60%, with a mean of 33%. The definition of flares was not uniform: Gimovsky et al. (93) defined as flare that which required hospitalization, whereas Mintz et al. (75), in their prospective study, accounted for even mild mucocutaneous and articular flares. Postpartum flares occurred in 2% to 42% of pregnancies, with a mean of 17%. It is of interest that only two series claimed that there was a spontaneous remission of SLE in pregnancy (95 ,107), and there was no statement of remission in subsequent time periods. Maternal deaths were few, primarily noted in a study of patients with SLE nephritis (97), and ranged from 0% to 11%, with a mean of 1.7%, well below that of the 1950s and 1960s. Onset of lupus during pregnancy or postpartum was noted in 0% to 37%, with a mean of 12.5%.

Prospective Studies

Three prospective studies on lupus pregnancy appeared in the 1980s (75 ,113 ,114). In 1984, Lockshin et al. compared 33 pregnancies to nonpregnant patients (113). A flare was defined as new signs from a previously inactive organ system, or an increase in corticosteroid dosage, or the treating physician's statement that a flare was present. Five of 8 instances of thrombocytopenia were attributed to SLE (24%), 4 patients developed new proteinuria that subsided after delivery, and corticosteroid dosage was increased in 7 patients. There were no significant differences in flares between pregnant and nonpregnant groups, laboratory values, dosage, and number of patients treated with prednisone. These patients and controls seemed to have mild SLE, as 40% did not require steroids during the observation period.

In a 9-year prospective, controlled study from Mexico City, Mintz et al. reported 102 consecutive pregnancies in 75 patients (75), who were followed closely by a team of rheumatologists, obstetricians, and neonatologists. There were no elective abortions, and all patients received a minimum of 10 mg of prednisone daily from diagnosis of pregnancy to the end of postpartum. Of the 102 pregnancies, 10 started with active maternal disease, and in the remaining 92, a 60% flare rate was noted; 54% of flares occurred in the first trimester and 20% in the postpartum or post–spontaneous abortion periods. A matched group of women with SLE served as controls in this study and in a study of progestogens as contraceptives during the same 9 years (170). The pregnant patients had 55 flares in 909 patient-months and the controls had 19 in 468 patient-months, which is not statistically different (0.06 vs. 0.04 per patient/month). Most flares were mucocutaneous and articular, with mild fever and serositis, controlled by increasing prednisone to 15 to 45 mg/day. Severe flares included nephritis in 9 patients, CNS manifestations in 8, profound cytopenias in 1 and multisystem flare with vasculitis in 1. Most severe flares were treated with 60 mg/day, and two with 200 mg and 300 mg of prednisone per day, respectively. No maternal deaths occurred in this study of seriously ill patients.

In 1989, Lockshin (114) reported on 80 pregnancies, including 16 of the 33 in the 1984 study, without a control group. One third of the patients were on steroids at the time of pregnancy, which defines them as having mild disease, and, by global criteria, 26% had clinical evidence of active SLE during pregnancy.

Lupus Pregnancy Studies in the 1990s

The continued interest in SLE pregnancy produced 26 studies with 21 to 634 pregnancies each in the 1990s (115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,127 ,128 ,129 ,130 ,131 ,132 ,162 ,171 ,172 ,173 ,174 ,175 ,176 ,177), for a total of 2,275 pregnancies in more than 1,200 women. In several studies (127 ,162 ,172 ,173 ,174), there is no information on maternal flares, and five studies (171 ,172 ,175 ,176 ,177) are considered under nephritis. Seventeen studies report on maternal flares and are included in Table 51-1 (115 ,116 ,117 ,118 ,119 ,120 ,121 ,122 ,123 ,124 ,125 ,126 ,128 ,129 ,130 ,131 ,132). Eight studies were prospective (115 ,116 ,117 ,118 ,121 ,122 ,123 ,125), two were controlled (122 ,124), three were both prospective and controlled (120 ,122 ,125), and nine were retrospective (126 ,127 ,128 ,129 ,130 ,131 ,132 ,162 ,172) (Table 51-1). In 4 studies, the majority of pregnancies were conceived during inactive lupus at the prompting of the investigators: 100% (118), 95% (128), 94% (132), and 90% (115). Flares were seen in 43.6% of pregnancies, with a range of 2% to 95%. In the 2 months postpartum, flares ranged from 0% to 63%, with four studies reporting no postpartum flares (116 ,123 ,125 ,130). All of these patients were well cared for, and the great majority was in remission at pregnancy onset. In the 4 studies with SLE inactivity at conception, flares were 27.3% on average (20.7% to 33%), and postpartum flares were 4.9% to 9.4% (115 ,118 ,128 ,132). In the remaining 13 studies, flares occurred in 49.4% on average. Two patients were reported with SLE onset in pregnancy, 3.3% of 60 pregnancies (115), or 0.19% of 1,056 pregnancies in the 1990s.

There were only two maternal deaths in these 17 series of 765 women, for the very low maternal death prevalence of 0.26%. However, if we account for all publications of lupus pregnancies reported in the 1990s, including those without information on maternal flares, the prevalence of maternal death is the lowest ever, 0.17%, or 2 deaths in over 1,200 women.

Prospective and Controlled Studies

Wong et al. reported from Hong Kong on 29 pregnancies in 22 patients (125). Flares in 58% of patients included nephritis (*n* = 6), arthritis (*n* = 5), and vasculitis (*n* = 2). At the 30th week of pregnancy, steroid dose was increased to 10, 20, or 30 mg if the patients were taking less than 10 mg, 10 mg, or more than 10 mg daily, respectively. If a higher dose was required, it was maintained until 4 weeks after delivery. No postpartum flares or maternal deaths occurred. The flare rate during pregnancy was significantly higher than that of the nonpregnant patients (Table 51-2).

Petri et al. defined flare by the use of a visual analogue scale, graded from 0 to 3 (physician's global assessment) (120): of the 27 flares seen in 74 pregnancies (36%), 30% were mild, 59% were moderate, and 11% were severe, necessitating a prednisone increase of 43 ± 25 mg per day.

Tincani et al. (123) assessed SLE activity by the SLAM score(153) in 25 pregnancies and found 4 renal flares out of 11, with skin, joint, thrombocytopenia, and neuropsychiatric events accounting for the remainder. Most flares were treated with prednisone and azathioprine.

Derksen et al. used the SLEDAI to assess lupus activity every month, from 6 months before pregnancy to 6 months postpartum (116). Flares occurred in 6 of 35 pregnancies (17%), necessitating prednisone treatment in three patients with polymyositis, thrombocytopenia, and a combination of severe synovitis, vasculitis, and proteinuria. Increasing or new proteinuria without urine sediment abnormalities in an additional 5 patients was considered to be PIH and not treated.

In a multicenter study from France, Huong et al. observed flares in 34 of 75 patients with inactive lupus at conception (45%), with 9% of flares in postpartum and 2 deaths from opportunistic infection in mothers treated with steroids for nephrotic syndrome (117).

Lima et al. reported 108 pregnancies in 90 SLE patients, with 74 flares in 62 pregnancies (57%) (119). Most flares occurred in the second trimester (38%) and postpartum (35%). One in 5 flares (20%) was severe, 24% moderate, and 56% mild. Ten patients (9%) had active lupus at pregnancy onset and 2 had elective abortion. Active (*n* = 12) or prior nephritis (*n* = 2) in 14 pregnancies was present in 5 of 6 preeclampsia episodes. The patients were 79% white, and in 65%, SLE manifestations were cutaneous and articular, with nephritis, hematologic, and neuropsychiatric lupus in only 16%, 10%, and 9%, respectively. The patients were on prednisolone, azathioprine, and hydroxychloroquine, and flares were treated with dose modifications of these drugs.

The controlled study by Ruiz-Irastorza (122) was mentioned above (see SLE Activity During Pregnancy) and is

from the same lupus research unit in London as the study by Lima et al. (119). We are unaware of any patient duplication in these studies.

Tomer et al. (124) reported from Israel on 54 pregnancies of 46 SLE patients and 70 non-SLE pregnant controls, with only 14.5% flares during pregnancy, and the postpartum period was excluded from follow-up. The authors attributed the low flare rate to prophylactic prednisone that patients received; however, similar regimens did not prevent flares in the Mintz (75) and Tincani studies (123).

Huong et al. (117) reported 62 planned pregnancies in 38 women, who conceived after SLE inactivity for a year on ≤20 mg prednisone per day (118). Prednisone was maintained at ≥10 mg/day upon diagnosis of pregnancy and flares occurred in 27%, with 6% in postpartum. Flares were moderate, except for a patient with class IV nephritis. Preterm birth and cesarean section were common.

Rahman et al. from the University of Toronto studied 141 pregnancies in 73 lupus patients and defined active lupus as SLEDAI ≥1 (121). Flares were present in 63% of pregnancies, and renal flares were predictive of fetal loss. Patients were most commonly treated with steroids, antimalarials, and azathioprine.

Carmona et al. from the University of Barcelona reported 60 pregnancies in 46 SLE patients, with inactive SLE at conception in 54 of 60 (90%) (115). There were mostly moderate flares in 25% during pregnancy (0.044/patient/month), and 9.4% in postpartum. Hypertension and smaller gestational age at delivery were significantly associated with lupus nephritis in 10 pregnancies (50% vs. 11.6% and 35.9 vs. 37.3 weeks). This is the only study in the 1990s that reports SLE diagnosed in 2 patients during pregnancy, or 3.3%. The authors used prednisone prophylaxis in the last month of pregnancy and first month of postpartum from 1985 to 1994 and stopped in 1995.

Retrospective Studies

Six retrospective studies in the 1990s reported on 868 pregnancies in 470 women (126 ,128 ,129 ,131 ,132 ,162). The largest was by Pistiner et al. on 634 pregnancies in 307 women (162). Flares in the six studies were mostly mild and ranged from 20.7% to 95% (mean, 57.3%, with only two studies reporting postpartum flares (128 ,129). There was no SLE onset during pregnancy or maternal deaths in these series. Patients from a large private practice (Dr. Wallace) had well-controlled lupus (162), with less nephritis (28%) and neuropsychiatric disease (11%), whereas the indigent SLE population at Los Angeles County- University of Southern California Medical Center in the same metropolitan area had more than 50% prevalence of nephritis (159).

Studies in 2000 to 2005

Of the 20 studies published in 2000 to 2005 (133 ,134 ,135 ,136 ,137 ,138 ,139 ,140 ,141 ,142 ,143 ,144 ,145 ,146 ,147 ,148 ,149 ,157 ,178 ,179), four are controlled (134 ,140 ,148 ,149), 1 is controlled and prospective (133), 4 are prospective (137 ,138 ,143 ,157), and 11 are retrospective (135 ,136 ,139 ,141 ,142 ,144 ,145 ,146 ,147 ,178 ,179) (Table 51-1). All studies except 1 (149) utilized the ACR (formerly ARA) classification criteria for SLE (150). The 6 studies that address SLE nephritis and pregnancy and a study on pregnancy outcome of SLE women with kidney transplants (179) will be discussed in the nephritis section, and Chapter 52 discusses two studies that deal primarily with fetal outcome (149 ,178).

Georgiou et al. from the University of Ioannina, Greece reported 59 pregnancies in 47 SLE patients, with 59 nonpregnant SLE controls and 59 healthy pregnant women (140). Flares are described in 8 of 59 pregnancies (13.6%), and 6 of 8 had nephritis. The authors noted, however, clinical features of SLE during the first trimester in 57%, the second and third trimester in 13% each, and after delivery in 19%. The majority of patients were treated with ≤10 mg of prednisone/day, azathioprine, and hydroxychloroquine, and flares were treated with ≤60 mg of prednisone/day. There was one maternal death in a patient with severe nephritis.

De Bandt et al. from Paris reported 59 pregnancies in 31 women, with 55 (93%) of pregnancies during “inactive” SLE (SLEDAI ≤4) and on ≤10 mg of prednisone/day (139). These patients would not be considered inactive by the Toronto group (121). There were 12 flares (20.3%), 6 severe during pregnancy (4/6 in active patients), and 6 mild in postpartum.

Brucato et al. from the University of Milan reported on 147 pregnancies in 111 lupus patients, in a study designed to assess anti-Ro effects on pregnancy outcome (133). There were 26 major flares in 147 pregnancies (17.7%), and no postpartum flares or maternal deaths. In 100 pregnancies of anti-Ro positive women there were 2 infants with congenital heart block.

Cortes-Hernandez et al. from Barcelona examined predictors of fetal and maternal outcome in 60 SLE patients with 103 pregnancies (138). Of the flares in 33% of the pregnancies, 10.7% were severe, with the majority, 19.4%, in the postpartum period. Most flares were musculoskeletal and cutaneous, 4 were renal, and 1, thrombocytopenia. Onset of SLE in pregnancy was seen in 2 of 60 patients (3.3%), or 2 of 103 pregnancies (1.9%). SLE was active at conception in 6.8% of pregnancies (12% of patients). Cesarean section was required in 20% of deliveries. Preeclampsia occurred in 2, PIH in 5 (4.9%), gestational proteinuria in 12 (11.7%), and thrombotic events in 4 patients with APL antibodies, in spite of heparin treatment. Increased SLE activity in pregnancy was noted, with 1.2 flares per person-year during and 0.4 before pregnancy. Predictors of flare were more than 3 flares before gestation with a SLEDAI of ≥5, a higher SLEDAI during SLE evolution, and prior chloroquine treatment.

Tan et al. from Singapore reported 27 pregnancies in 18 Asian women (147). SLE was in remission at pregnancy onset in 26 of 27 (96.3%), renal impairment was present in 7 pregnancies/6 women, 2 of whom were on chronic dialysis. Flares were seen in 7.4% of pregnancies, all in postpartum. Preeclampsia (18.5%) occurred in 5 of 6 pregnancies with pre-existing hypertension.

Ruiz-Irastorza et al. found 26.3% flares in 38 women during pregnancy, in their evaluation of the LAI (157).

Chandran et al. in a retrospective study from India, examined 52 pregnancies in 31 women, 31 with inactive, and 21 with active SLE, including 12 patients with nephritis and 6 with neuropsychiatric (CNS) SLE (136). Flares were defined as any SLE activity that needed a change in therapy, or as a SLEDAI increase of >5, in contrast to definitions of >1 or >3 (121). There were no flares, maternal deaths, or SLE onset in the inactive SLE group, whereas the active group had 14.3% flares, 9.5% in the postpartum, and 3 patients with SLE onset in pregnancy (14.3%), 1 of whom died of severe flare with pulmonary hemorrhage (1.9% of 52 pregnancies).

Molad et al. reported 20 patients with 29 pregnancies from Israel and defined mild SLE activity as SLEDAI of 2, active SLE as SLEDAI ≥4 at the onset of pregnancy, and postpartum SLE flare as onset of new signs of SLE in a previously normal organ with or without abnormal laboratory studies, an increase of serum anti-dsDNA or a decrease in serum C3 and C4 (143). High pregestational activity by SLEDAI, and laboratory data compatible with active SLE were predictive of postpartum flares (20.7%).

Clowse et al. from Johns Hopkins University studied the impact of increased SLE activity in 267 pregnancies in 203 women over a 16-year period, and focused on moderate and severe flares (137). SLE activity was quantitated by a variation of the physician's global assessment, the Physician's Estimate of Activity (PEA), graded from 0 to 3. Lupus activity was considered high with scores of ≥2, and low ≤2. High activity was seen in 57 of 267 pregnancies (21%), was distributed evenly throughout the three trimesters, and was more common before 1995, in African-American women, and in women with SLE nephritis. High activity during the 6 months prior to conception was followed by high activity during pregnancy in 58% of 12 patients, and in only 8% of 84 women with low activity before pregnancy, the difference being highly significant. This study corroborates very well the results of prior studies (98 ,138 ,168), and the recommendation to plan conception after SLE remission of 6 months. In addition, fetal loss was 42% in high activity pregnancies, and only 11% in low activity pregnancies. There were 36 patients diagnosed with SLE during pregnancy (13.5%), and 3 maternal deaths (1.1%). The majority of patients were treated with prednisone (62% with low, 95% with high activity), one third with hydroxychloroquine, and 25% of high activity patients received azathioprine. The impact on fetal outcomes was substantial: pregnancy loss was threefold in high-activity pregnancies, full-term births were reduced (26% vs. 61% in pregnancies with no or mild activity), and live births were less (77% vs. 88%).

Chakravarty et al. from Stanford University reported 63 pregnancies in 48 women with SLE, 35% of whom had prior renal disease and 10% had previous CNS SLE (135). Active SLE at conception was defined as the use of ≥10 mg of prednisone per day, the use of any immunosuppressive drug, or a SLEDAI ≥2. Flares were defined as in the SELENA study (Safety of Estrogen in Lupus Erythematosus National Assessment) (180) and distinguished into mild/moderate and severe. There were 67.7% flares, 29% of them severe, all noted during pregnancy. Preeclampsia developed in 12/63 pregnancies (19%), and was severe in 7, with most of the patients having prepregnancy nephritis. The 4 of 48 women (8.3%) who developed SLE during 63 pregnancies (6.3%) had severe flares, with preeclampsia in 2 of 4. Two patients had HELLP syndrome, and 1 of them died later (1.6%). Thrombocytopenia was associated with a relative risk of 3.2 for preeclampsia, but the finding was not significant when the first pregnancy only was considered.

Pregnancy with pulmonary hypertension during SLE or antiphospholipid syndrome (APS) is an uncommon event with high maternal mortality, up to 56% (181 ,182). Most deaths occur within 3 days of delivery from acute cor pulmonale, because of high maternal blood volume and high pulmonary vascular resistance. Hopefully, the prognosis will improve with the introduction of pulmonary vasodilators (epoprostenol, bosentan, sildenafil).

CNS lupus during pregnancy can be accompanied by severe fetal prematurity and IUGR and poor maternal outcome (183).

Summary

Conclusions about SLE activity during pregnancy can be summarized as follows:

- Fertility in women with lupus is normal, except for amenorrhea and infertility during periods of severe disease activity.
- Despite the variability of definition and assessment of disease activity and disease severity, flare assessment is increasingly done with standardized methods, the majority of patients have inactive or well-controlled disease at the onset of pregnancy, and therapy is prompt and decisive.
- The average probability of flare during SLE pregnancy and postpartum has decreased substantially over the last 55 years, from 60% in the presteroid era, to 23.3% in the beginning of the 21st century. In contrast with studies of the 1950s, 1960s, and 1970s, most flares after 1980 are minor, with arthritis and cutaneous manifestations. Severe flares occur in approximately 10% to 29% of pregnancies and, for this reason, SLE pregnancy should still be handled as a high-risk pregnancy.
- Risk factors for flares include SLE activity during the 6 months preceding conception, and pre-existing renal disease (see also below). Conversely, conception during quiescence or remission is associated with a lesser risk for flare (8% to 15%). Mild lupus without vital organ involvement rarely exacerbates during pregnancy.
- Most studies avoid corticosteroid treatment for prevention of flares, and instead watch the patient very carefully and raise steroid dose at the slightest indication of flare.
- Most pregnant women in the 2000s were treated with steroids, hydroxychloroquine, and azathioprine.
- There is a greater prevalence of preeclampsia and PIH in lupus patients, especially with prior nephritis and antiphospholipid antibodies (see below).
- Onset of SLE during pregnancy or the postpartum period was seen in approximately 20% of patients (13% to 50%) in

older reports (95 ,97 ,110 ,184), and in 0% to 13.5% in recent reports (135 ,136 ,137 ,138): it can be a severe, catastrophic illness, with dire maternal and fetal outcome. A high index of suspicion for SLE should prevail when, during pregnancy or the early postpartum period, a young woman has unexplained rashes, arthritis, alopecia, proteinuria with active urine sediment, psychosis, chorea, pleuropericarditis, or vasculitis, alone or in combination. Delay in diagnosis and management can be lethal, whereas prompt, aggressive treatment is lifesaving.

Course of Lupus Nephritis during Pregnancy

Reports on lupus pregnancy from the 1950s and 1960s mention nephritis in the context of severe flare, increasing proteinuria, azotemia, or acute anuric renal failure, hypertension, preeclampsia, onset of nephritis during pregnancy, and even maternal death (83 ,91 ,103 ,111). Active nephritis at conception, often not detected early nor treated aggressively, can put the mother and fetus at grave risk.

On the other hand, in the late 1960s, 1970s, and 1980s, several papers reported an uneventful pregnancy course and better prognosis when renal function is normal and lupus nephritis has been inactive for 3 to 6 months before conception (75 ,83 ,89 ,90 ,95 ,97 ,98 ,107). This finding has been proven true through the 1990s and the 2000s.

Table 51-3 summarizes available data from 25 series published from 1978 to 2005 that address lupus nephritis and pregnancy (75 ,85 ,89 ,90 ,93 ,95 ,96 ,97 ,98 ,106 ,112 ,115 ,123 ,125 ,130 ,134 ,141 ,144 ,145 ,146 ,148 ,171 ,172 ,175 ,176 ,177). Although it is not a common practice, percutaneous needle biopsy can be performed during pregnancy under ultrasonic guidance (185).

In all, 918 pregnancies were reported in over 523 women with lupus nephritis. The prevalence of focal or diffuse proliferative nephritis was 40% to 100% (average, 64.6%), and nephrotic syndrome was present in 0% to 69.2% (average, 18%). The rate of flares in pregnancy was from 7.4% to 100% (average, 30.2%). Preeclampsia or severe PIH ranged from 0% to 50%, and hypertension was very common. Transient renal insufficiency occurred in 0% to 37% (up to 50% in active nephritis), and irreversible renal failure in 0% to 21% of patients (Table 51-3).

Flare rates in 115 pregnancies with lupus nephritis activity at conception or during pregnancy, were 48% to 100% (average, 57.9%) (89 ,95 ,96 ,98 ,144 ,145); flares in 256 pregnancies with inactive nephritis at conception were from 7.4% to 32% (average, 15.1%) (75 ,89 ,95 ,96 ,98 ,115 ,144 ,145 ,171).

Similar differences are seen in prevalence of nephrotic syndrome, preeclampsia, transient renal insufficiency, and renal failure in active versus inactive nephritis, with 38.1%, 38.3%, 32.7%, and 8% versus 8.8%, 13.2%, 5%, and 4.1%, respectively (Table 51-3).

Generally, studies of the 1990s and 2000s on SLE nephritis show a trend for planned pregnancies after several months of quiescence or remission, which should eventually improve the maternal and fetal outcome of these pregnancies.

Some of the most notable studies with the most patients are reviewed here.

Devoe and Taylor (85) reported 13 pregnancies in eight women, five with biopsy-proven nephritis and two with severe flares with decreased renal function and preeclampsia. The authors credited serum complement C3 and C4 levels with prognostication of SLE flare. In a subsequent report of 18 pregnancies in 15 women with SLE and renal biopsies prior to conception, decreased renal function, rather than severity of renal biopsy class correlated with abnormal fetal outcome (186).

Lupus Nephritis and Pregnancy in the 1980s

In Houser's report of 18 pregnancies in 11 patients with SLE nephritis, 10 pregnancies in 5 patients with inactive SLE were uneventful, whereas 8 pregnancies in 6 women with active disease included 3 with preeclampsia, severe in 2, and disease flare in a patient who developed class III lupus nephritis (96). All patients were receiving prednisone, and no maternal deaths occurred.

Hayslett and Lynn's questionnaire study of 13 nephrology centers and individual nephrologists reported 47 patients with 65 pregnancies, with focal or diffuse proliferative nephritis in 77% (95). In 9 instances, SLE began during pregnancy (14%), nephritis preceded conception in 80%, and nephritis worsened in 39% of the mothers. Of 25 pregnancies with active renal disease at conception, 12% improved, 48% worsened, and 40% remained unchanged. Pregnancy in patients with active SLE had a hectic course, successful outcome was reduced by 25%, and only 9 of 16 patients with nephrotic syndrome had successful deliveries. When the serum creatinine level was lower than 1.5 mg/dL, 9 of 10 pregnancies resulted in live births, but in 10 pregnancies with serum creatinine above 1.5 mg/dL, fetal loss was 50%. In 4 patients, however, with serum creatinine of 4 mg/dL or higher, pregnancies resulted in live births, indicating that a successful outcome is still possible despite severe renal failure.

Of 16 patients with prior nephritis reported by Zulman et al., 10 (62.5%) had flares during pregnancy (112). In 25% of patients, differentiation of acute presentation of lupus nephritis from toxemia was necessary, and the authors suggested that preeclampsia was a result of lupus nephritis.

Nearly one third of pregnancies reported by Fine et al. (12 of 37) resulted in worse renal function, 5 of them irreversibly (90). No conception occurred in patients with even moderate renal insufficiency. The authors recommended hemodialysis for pregnant patients with a blood urea nitrogen (BUN) of 50 mg/dL or greater and maintenance under that level. Volume removal should be done through isolated ultrafiltration, blood pressure should be supported with albumin, the dialysate should contain glucose and bicarbonate, low-dose heparin should be used, and progesterone should be administered, because the endogenous progesterone is lost in the dialysate.

Jungers et al. reported a retrospective study of 36 patients with 104 pregnancies seen between 1962 and 1980 (98).

Onset of SLE and nephritis occurred during pregnancy or postpartum in 25% of patients. All patients had clinical renal disease, and biopsies showed 5 with mesangial or minimal disease (World Health Organization [WHO] class II and I), 8 with focal proliferative (WHO class III), 6 with diffuse proliferative nephritis (WHO class IV), and two with membranous nephropathy (WHO class V). Flares occurred in 46%, and 8% progressed to irreversible renal failure. A full 66% of patients with active nephritis at conception had a flare; in contrast, only 9% of patients with inactive disease during the 5 months before conception had a flare.

Gimovsky et al. at the University of Southern California reported retrospectively on 39 patients, 19 with SLE nephritis, confirmed by renal biopsy in 15 (79%) (93). The 19 patients had 46 pregnancies, with lupus onset in pregnancy or postpartum in 8 of 39 patients (21%). Hospitalization was required because of flare in 9%, 8%, 14%, and 4% of patients during the three trimesters and postpartum, respectively. Preeclampsia occurred in 10 patients, 6 with nephritis. Of 19 patients, 4 (21%) developed decreased renal function within 2 years of delivery, and 3 required chronic hemodialysis (16%). The nephritis group had a fetal loss of 55%, with 18 of 40 pregnancies resulting in live births.

Imbasciati et al. from the University of Milan, Italy, reported 19 SLE nephritis patients with 26 pregnancies, class IV nephritis in 58%, and nephrotic syndrome in 42% (97). Transient renal insufficiency was seen in 37%, and renal failure in 21%. Four women developed anuric renal failure, 3 among 7 with SLE and nephritis onset during pregnancy, and 2 died, 7.7%. In all but two pregnancies, SLE was active, and by current standards, steroid dosage was low or of short duration, with inadequate control of maternal disease. In 7 flaring patients, mainly postpartum, high-dose steroid (≥50 mg prednisone/day) controlled SLE activity. This study is valuable, as multiple renal biopsies performed in 7 patients showed that 4 patients had progression of a minimal, focal proliferative, or membranous lesion to a diffuse proliferative nephritis, and 2 patients had regression of diffuse proliferative nephritis to focal proliferative in 1 and to minimal lesion in the other patient. Fetal outcome was poor, with 61% live births.

In 1987, Bobrie et al. (89) from Paris added 32 more pregnancies to their previous report (98). Of the 73 pregnancies reported, 14 had SLE onset during pregnancy, postpartum, or postabortion periods (18.4%). Half of these 14 patients had nephrotic syndrome with increased serum creatinine, and all had proliferative glomerulonephritis, diffuse in 11; high-dose steroid therapy improved all but 1 patient, who progressed to renal failure in 2 years. In 53 pregnancies after onset of SLE, nephritis flares occurred in 34% during pregnancy (*n* = 10) or postpartum (*n* = 8), and were more frequent with active SLE at conception (61.5%), than with stable remissions (7.4%). Four patients (11.4%) rapidly progressed to end-stage renal failure despite corticosteroid therapy.

In the prospective study from Mexico City, 58 of 102 pregnancies occurred in patients with known, inactive SLE nephritis, and all but three had previous renal biopsies (75 ,187). Proliferative glomerulonephritis was present in 23 (40%), treated with 30 to 60 mg of prednisone daily (75 ,187). In the 58 pregnancies with SLE nephritis, 6 flares occurred (10.3%) in patients with inactive renal disease for 2 to 5 years, and all responded to increases in prednisone dose. On long-term follow-up of 75 total patients for up to 5 years, renal function deteriorated in 3 of 15 patients with proliferative nephritis, with 1 of 5 deaths from renal disease, 49 months after pregnancy. Of the 44 pregnancies without previous kidney disease, nephritis appeared in 3 patients during pregnancy (6.8%); biopsies showed two with class II and one with class IV glomerulonephritis. All patients were treated with at least 10 mg of prednisone daily during the entire pregnancy. Pregnancy outcome was not different for patients with or without nephritis, and the authors attributed a better fetal outcome to inactive, well-controlled SLE, rather than to the absence of kidney disease.

Lupus Nephritis and Pregnancy in the 1990s

In the prospective study from Hong Kong (125), 6 nephritis flares occurred in 13 patients, with increasing proteinuria and nephrotic syndrome in 3 each. Two of the nephrotic patients remitted within 4 weeks after elective abortion and increased steroids, and the other 4 remitted with only increased doses of prednisone. Eight women with a history of preexisting diffuse proliferative nephritis had successful pregnancies, because of appropriate prednisone therapy per the authors.

In the 25 women with lupus nephritis reported by Oviasu et al. (130), a flare was seen in only 1 of 53 pregnancies, although 6 patients each had increased proteinuria and decreased creatinine clearance, and 9 patients had more than trivial cutaneous lupus. Hypertension was present and controlled in 17 of 47 pregnancies (36%), excluding elective abortions. No one developed renal failure, and cesarean section was necessary in 44% of the 39 completed pregnancies. 11 of the 17 cesarean sections (64.7%) were performed as emergencies). Preterm deliveries were seen in 28%.

Among 64 pregnancies in 41 women with lupus nephritis reported by Packham et al. from Australia (172), proteinuria was stable in 16%, increased in 48% of pregnancies, with nephrotic syndrome in 17%, and was irreversible postpartum in 5% (3 patients). Hypertension was present in 44%, was severe in 13%, and irreversible in 9 patients (14%). Eclampsia occurred in 3 women (5%). Transient renal insufficiency was seen in 19% and renal failure in 1 patient (2%). Prematurity occurred in 19 of 43 live births (44%).

Of 25 pregnancies reported by Tincani et al. (123), 9 occurred in seven women with nephritis. There were three nephritis flares in these patients and de novo nephritis in a fourth.

Julkunen et al. reported 26 pregnancies in 16 patients with lupus nephritis, 42% with focal or diffuse proliferative nephritis, all clinically inactive with normal renal function (171). Two patients flared (8%), one with nephrotic syndrome (4%), 7 of the 23 completed pregnancies were complicated by preeclampsia (30%), and 7 of 23 births (30%) were premature. There was no compromise of renal function.

Carmona et al. from Barcelona reported 10 pregnancies in 9 patients with lupus nephritis, compared to 50 pregnancies in 37 SLE patients without nephritis (115). Flares occurred in 30% of pregnancies, hypertension and preeclampsia were more prevalent in the nephritis patients (50% vs. 11.6%), cesarean sections were more frequent (60% vs. 18%), and neonates were of lower gestational age and birth weight.

Huong Du et al. (176) from Paris reported 25 pregnancies in 16 women with biopsy-proven SLE nephritis, proliferative in 76%. There was proteinuria in 32%, nephrotic syndrome in 12%, flares in 32%, preeclampsia in 16%, transient renal insufficiency in 8%, 1 maternal death (4%), and 15 premature births (60%). A second maternal death occurred 4 years after delivery. Treatment included prednisone, mean 22 mg/day, aspirin and heparin for antiphospholipid syndrome, azathioprine, and, after delivery, cyclophosphamide in 2 patients with renal flares.

Ramos et al. (177) from Mexico City reported 21 pregnant patients with lupus nephritis, proliferative in 67% (mostly class IV), assessed by SLEDAI. Renal flare occurred in 42.9% (first and second trimester), preeclampsia in 14.3%, and fetal loss in 14.3%. No progression of renal disease was noted. Treatment included prednisone (mean 20 mg/day), aspirin, and heparin for antiphospholipid syndrome.

The outcome of SLE nephritis and pregnancy in the 1990s is far better than that of previous decades.

Lupus Nephritis and Pregnancy in 2000 to 2005 (Table 51-3)

Although all articles in this time period include patients with SLE nephritis in pregnancy, one gives adequate details (138) and six series specifically address the subject (134 ,144 ,145 ,146 ,148 ,188).

The above studies addressed 333 pregnancies in 226 women. Fifty-four pregnancies in 54 women without nephritis were used as controls in Carmona et al.'s study (134). In 240 pregnancies proliferative classes of nephritis (WHO III and IV) were most common, 72.8%, ranging from 57.9% to 100%. As would be expected, flares, nephrotic syndrome, preeclampsia, transient renal insufficiency, and irreversible renal failure were more common in pregnancies with active nephritis at conception, or during pregnancy (Table 51-3). Maternal deaths occurred in three studies (141 ,144 ,145). The simultaneous presence of APL further complicated outcomes. The impact on fetal outcome was very substantial, with perinatal (fetal) loss, prematurity, and IUGR/SGA being very prevalent, and more so with active nephritis. Live births ranged from 42.1% to 94%, (average, 71.5%), fetal loss ranged from 6% to 57.9%, prematurity from 31.7% to 77.8%, and IUGR from 4.8% to 37.5%.

In the majority of patients lupus was inactive or quiescent at pregnancy onset, and these patients had a better pregnancy course with fewer flares, less proteinuria, preeclampsia, and a better fetal outcome. With better guidelines to distinguish renal flare from PIH and preeclampsia, there is a clearer picture conveyed by these publications.

Among 103 pregnancies in the series by Cortes-Hernandez, 20 pregnancies occurred in 12 lupus nephritis patients (138). The majority had proliferative nephritis (83.3%), none had nephrotic syndrome, there were 40% flares, and PIH in 25%. In 1 of the 5 pregnancies with hypertension, it was a result of a renal flare. There was transient renal insufficiency in 1 pregnancy (5%), and permanent worsening of renal function in 3 patients (15%), 2 of whom had prior renal insufficiency. The live birth rate was 42% in the nephritis pregnancies, and almost double (76%) without nephritis.

Of 32 pregnancies in the study by Huong (141), 25 were planned; 18 pregnancies were previously reported (117). Almost two thirds had proliferative classes of nephritis (62.5%), 15.6% had nephrotic syndrome, most of the flares were renal flares (15.6% and 12.5%), preeclampsia with features of HELLP syndrome was present in 15.6%, transient renal insufficiency in 3.1% and 1 patient died (3.1%). Flares in this study were halved, compared to their previous report (176). Most patients were treated with prednisone and hydroxychloroquine, and low molecular weight heparin (LMWH) was given to 9 women with prior history of thrombosis or miscarriages.

Moroni et al. reported on 48 women with 70 pregnancies, 57 pregnancies in 38 women with known SLE nephritis, and 13 pregnancies with nephritis developing in pregnancy, group A (144). Some of the patients were previously reported (97). Three quarters of biopsied group A patients (9/12) had proliferative lesions (7 class IV, two class III). In the group with active nephritis there was strikingly greater prevalence of nephrotic syndrome (12.3% vs. 69.2%), flares (26.3% vs. 100%), preeclampsia (9.8% vs. 38.5%), and transient and irreversible renal failure. Of three patients from group A who developed acute renal failure postpartum, 2 were treated with prednisone and azathioprine and 1 with methylprednisolone pulse and oral cyclophosphamide; 2 patients recovered after weeks of peritoneal dialysis and the third developed end-stage renal failure. The only predictor of favorable maternal outcome was quiescence of renal disease. Poor fetal outcome predictors were proteinuria, hypertension, and positive APL.

In a nested case-control study, Tandon et al. from the University of Toronto compared 78 pregnancies in 53 women to 78 nonpregnant patients, with SLE nephritis in both groups (148). The objective of the study was to assess the effect of pregnancy on SLE nephritis. The prevalence of nephritis activity during pregnancy was similar to that of controls (44.6% vs. 41.9%), and similar proportions of pregnant and nonpregnant patients showed a 20% increase in serum creatinine (17.3% vs. 24%).

Mok et al. from Hong Kong published a brief retrospective report on 91 pregnancies in 66 lupus patients (142). These included 33 pregnancies in 27 SLE patients with prior nephritis. Renal disease was quiescent at conception and no information is given about maternal problems. The fetal outcome was excellent with 94% live births, 6% fetal loss, 12.9% prematurity, and 19.4% IUGR.

Soubassi et al. from the University of Athens, Greece, reported 24 pregnancies in 22 patients with SLE nephritis

(146). There were flares with proteinuria in 50%, hypertension in 42%, and preeclampsia in 25%. Fetal outcome included live births in 75%, perinatal loss of 25%, and prematurity in 77.8%. No information is given about the proportion of proliferative nephritis or of nephrotic syndrome.

Rahman et al. from London and Saudi Arabia reported 55 pregnancies in 24 patients, 36 pregnancies during quiescent nephritis (16 patients), and 19 pregnancies with active SLE nephritis at conception (8 patients) (145). Proliferative nephritis was present in 58.3% of the entire group. Most rheumatologists would argue with the authors' definition of active clinical renal disease as serum creatinine of >3 mg/dL and glomerular filtration rate of <65 mL/min/1.73m^2. Pregnancies with active nephritis had more than twofold flares (21.1% vs. 8.3%), more than threefold PIH (46.2% vs. 13.9%), renal failure occurred in 5.3% versus 0%, and 2 mothers died.

Carmona et al. from Barcelona, Spain, published an excellent study on pregnancy in proliferative SLE nephritis (classes III and IV) and compared it to SLE pregnancies with mesangial and membranous nephritis (classes II or V), and with SLE pregnancies without nephritis (134) (Table 51-3): there were 42 pregnancies in 35 women with class III or IV, 12 pregnancies in 10 women with class II or V, and 54 pregnancies in as many women without nephritis. SLE was active at conception in 21.4% of the first, 33.3% of the second, and 11.1% of the third group. Flare rates were similar in the three groups (19%, 33.3%, and 27.8%), and renal flares were 9.5% in the proliferative group and 8.3% in the mesangial-membranous group. Proteinuria increased significantly in conjunction with the renal flares in proliferative nephritis (mean, 3 g/day), moderately, up to 1.5 g/day in the second group, and remained stable at about 0.7 g/day in the group without nephritis. Renal flares were treated with increased prednisone and with azathioprine. Hypertension and preeclampsia were almost exclusively seen in the proliferative group (37.5% and 28.1%) (Table 51-3). Cesarean section was required more frequently in the nephritis groups, 43.7% and 33.3% versus 18.6%. Preterm birth was not different between groups, but birthweight was significantly less in the proliferative nephritis group. The authors concluded that class III and IV lupus nephritis are risk factors for hypertensive disease in pregnancy.

The outcome of 60 pregnancies in 38 SLE patients with kidney transplants was published in a retrospective study by McGrory et al. (179). SLE pregnancies were compared to 374 pregnancies in 247 patients transplanted for other reasons. Most SLE patients were on cyclosporine A (*n* = 39) or azathioprine (*n* = 21) for transplant maintenance. Mycophenolate mofetil (MMF) was discontinued in one patient upon diagnosis of pregnancy. Drug-treated hypertension (45%), and Cesarean section (30%), were significantly less common in the SLE pregnancies, whereas preeclampsia (17%), rejection (5%), and infections (15%) were similar in the non-SLE pregnancies. No maternal SLE flares were reported. Live births were seen in 73%, with 43% preterm births, low birth weight in 53%, and 1 neonatal death, The results of this study are very encouraging for SLE patients with kidney transplants. Of 25 SLE patients with kidney transplants and antiphospholipid antibodies, 15 had clinical thrombotic events, including 3 with late fetal loss (189).

Preeclampsia in Lupus Pregnancy

Preeclampsia, defined as the abrupt onset of hypertension and proteinuria after 24 weeks of gestation, is found in 0.5% to 10% of all pregnancies, and is far more common in the primigravida (190). The clinical manifestations of severe preeclampsia are a result of the presence of systemic endothelial dysfunction and microangiopathy, in which the target organ may be the brain (seizures or eclampsia), the liver (with microangiopathic hemolysis, elevated liver tests, and low platelets; HELLP syndrome), or the kidney (glomerular endotheliosis and proteinuria). It can also be associated with pulmonary edema, intrauterine growth restriction, and oligohydramnios. The risk of preeclampsia is higher in SLE pregnancy (12% to 32%) (88), compared to healthy women (191). Our understanding of the pathophysiology and the risk factors contributing to the development of preeclampsia has dramatically advanced over the past few years. Controlled cohort studies showed that risk factors for preeclampsia and the respective (relative risk values (RR) are, a previous history of preeclampsia (7.19), antiphospholipid antibodies (9.72), preexisting diabetes (3.56), multiple (twin) pregnancy (2.93), nulliparity (2.91), family history (2.90), hypertension (diastolic >80 mm Hg) (1.38), increased body mass index before pregnancy (2.47) or at the first prenatal visit (1.55), and maternal age >40 (1.96, for multiparous women) (192). Individual studies show that risk is also increased with an interval of 10 years or more since a previous pregnancy, autoimmune disease, renal disease, and chronic hypertension.

Although not classically considered a genetic disease, genetic factors contribute to the susceptibility to preeclampsia. Genome-wide scanning of Icelandic families revealed a significant locus on chromosome 2p13 (LOD 4.7) (193). The same locus was recently confirmed in a study of patients from New Zealand and Australia (194). Linkage to HELLP syndrome has been reported with a locus on chromosome 12q (195). Moreover, women with trisomy 13 fetuses have a higher incidence of preeclampsia (196).

Generalized vascular constriction is universally present in preeclampsia and is likely a result of endothelial dysfunction:

- Women with a history of preeclampsia have impaired endothelial-dependent vasorelaxation as measured by brachial artery flow-mediated vasodilatation for up to 3 years after delivery, implying these changes in the maternal circulation maybe more than transient.
- The production of prostacyclin (PGI2, a circulating vasodilator produced by endothelial cells) is decreased in preeclampsia compared to normal pregnancy. Endothelial cells incubated with serum from preeclamptic women produce less prostacyclin in vitro, suggesting the presence of a circulating inhibitory factor.

- Production and urinary excretion of thromboxane A2 (TXA2, a potent vasoconstrictor) and its metabolites is reported to be increased in preeclampsia by some investigators, with decrease in the ratio of prostacyclin to TXA2 metabolites. Low-dose ASA had a favorable effect on the prostanoid ratio (197). TXA2 production also appears to parallel the severity of preeclampsia.
- Studies in human pregnancy have reported decreased nitric oxide production in the setting of preeclampsia.
- Endothelin-1 (ET-1) concentration is increased in sera of patients with preeclampsia and endothelial cells cultured in the presence of plasma from preeclamptic patients show enhanced ET-1 production.

The placenta in preeclampsia is usually abnormal with evidence of hypoperfusion and ischemia, which occurs as a result of defective placental vascular remodeling. During early normal placental development cytotrophoblastic cells of fetal origin attach to the uterine decidua with anchoring villi, that are bathed in maternal blood from the spiral arteries filling the intervillous spaces. These extravillous trophoblasts invade the decidual part of the spiral arteries and replace their endothelial lining. As they do so, they switch their surface phenotype from epithelial cell origin (trophoblastic) into endothelial cell phenotype. As a result, the original small resistance-type vessel spiral arteries are transformed into flaccid, high-caliber capacitance vessels allowing the increase in the placental blood flow that is needed to sustain the fetus throughout the pregnancy. In preeclampsia, this phenotype switch does not occur, and the characteristic placental lesion in severe preeclampsia is diminished endovascular invasion by cytotrophoblasts and failure of uterine spiral arteriolar remodeling. Preeclampsia occurs only in the presence of the placenta, even when there is no fetus (hydatidiform mole) and remits dramatically postpartum when the placenta is evacuated. Recently, gene expression profiling was used to search for candidate factors produced in the placenta that might be responsible for the clinical expression of preeclampsia. Using this approach, it was shown that placental sFlt-1 mRNA (soluble fms-like tyrosine kinase-1) is upregulated in preeclampsia. sFlt-1 is a splice variant of the vascular endothelial growth factor (VEGF) receptor Flt-1 that lacks the cytosolic and transmembrane domains. sFlt-1 acts as a potent VEGF and PlGF (placental growth factor) antagonist by binding these molecules in the circulation. It was recently shown that there is marked rise in circulating sFlt-1 concentration beginning 5 to 6 weeks before the onset of clinical preeclampsia and accompanied by decreases in the circulating VEGF and PlGF. In addition, decreased urinary concentrations of free PlGF during midgestation predict the subsequent development of clinical preeclampsia. The possibility that antagonism of VEGF and PlGF might play a role in preeclampsia has sound physiologic underpinnings. Other than a potent promoter of angiogenesis, VEGF is also known to induce nitric oxide and vasodilatory prostacyclins in endothelial cells. Moreover, exogenous VEGF and PlGF can reverse the antiangiogenic properties of preeclamptic serum as assessed by in vitro angiogenesis assays.

As mentioned, the prevalence of preeclampsia in lupus pregnancies is significantly higher compared to healthy women (8% to 38% vs. 3% to 5%). Preeclampsia is more likely to occur in patients with active lupus (29% vs. 6.4% for inactive disease, $p<0.05$), with lupus nephritis, especially if active (RR, 3) (93 ,96 ,112 ,144 ,145), (Table 51-3), with SLE onset during pregnancy (50%), and with the antiphospholipid syndrome, in the presence or absence of SLE (198 ,199 ,200 ,201). Patients with class III and IV SLE nephritis have a significantly higher prevalence of preeclampsia (28% to 38%) compared to class II or V (11.1%, $p<0.05$) or to lupus controls without nephritis (4.6%, $p<0.05$) (134). Thrombocytopenia at the onset of pregnancy is strongly associated with increased risk of preeclampsia (RR, 3.2), except when the first pregnancy only is considered (135). In addition, preeclampsia in SLE and in antiphospholipid syndrome tends to be severe and of early onset. In a prospective study of 317 women with prior preeclampsia but without SLE or antiphospholipid syndrome, of five antiphospholipid antibodies tested, only antiphosphatidylserine was associated with severe preeclampsia (202). Abnormal uterine artery vascular resistance, as detected by Doppler flow velocity waveform at the 18th week of pregnancy, was associated with significant increase in preeclampsia, compared with normal resistance (11% versus 4%), and with adverse pregnancy outcome (45% versus 28%) (203).

A predictor of development of preeclampsia or IUGR in subjects with APS, particularly with LAC, is bilateral notching of the uterine artery on Doppler examination at around 20 weeks gestation: bilateral notching is associated with a 12- to 14-fold increased likelihood, whereas normal flow is associated with an 80% decreased likelihood of preeclampsia or IUGR (204).

About 25% of lupus patients will develop hypertension and proteinuria in the second half of pregnancy. In case of prior nephritis of any type, hypertension develops in 41% of patients during pregnancy (205).

It is important to distinguish lupus nephritis flares from preeclampsia or PIH because of drastically different therapeutic management. However, in many cases a clear-cut diagnosis remains elusive and the two conditions may also coexist. The following clinical and laboratory findings are useful in distinguishing the two entities:

- Lupus flares are associated with active urine sediment, not just with proteinuria. Active sediment is rarely present in preeclampsia.
- Hypocomplementemia, high titers of anti-DNA antibodies and anti-C1q antibodies are frequently associated with renal flares and are usually normal or elevated in preeclampsia (166 ,167).
- Thrombocytopenia, elevated liver enzymes, and hyperuricemia are more common with preeclampsia.
- Renal flares are frequently associated with other clinical symptoms and signs of SLE.
- After delivery, proteinuria rapidly decreases in preeclampsia, whereas it persists or increases in SLE.

A further cause for potential confusion of preeclampsia with lupus exacerbation is the HELLP syndrome, which may

complicate the course of severe preeclampsia in a minority of patients (80). Hemolysis and thrombocytopenia are a result of disseminated intravascular coagulation (DIC) with microangiopathic hemolytic anemia, rather than autoimmune hemolytic anemia. HELLP syndrome patients have characteristic blood smears with burr cells and schistocytes, elevated liver enzymes in all, and an increased bilirubin level in about half of the patients. The liver dysfunction is attributed to fibrin deposition with obstruction of the hepatic sinusoids, resulting in liver distention, subcapsular hematomas, infarction (11 of 24 pregnancies), and even rupture (147 ,188 ,206). At times the diagnosis of antiphospholipid syndrome was unknown prior to HELLP (188). Treatment of preeclampsia and prompt delivery by Cesarean section is necessary because of grave danger to the mother and fetus (perinatal mortality, 9% to 60%).

The effectiveness of low-dose aspirin (75 to 81 mg/day) in the prevention preeclampsia is controversial, however, a Cochrane database review of 39 randomized trials (30,000 women), and a metaanalysis of 14 studies with over 12,000 high risk women concluded that such therapy is effective in patients at high risk (207 ,306). There was a 15% reduction in preeclampsia, a 14% risk reduction for fetal or neonatal death, and an 8% reduction in preterm birth. In addition, this therapy poses no added risk of bleeding to the mother and fetus.

When assessing proteinuria in lupus pregnancy the possibility of renal vein thrombosis should always be investigated. Proteinuria with severe flank pain and hematuria, especially in the presence of membranous nephropathy, a history of deep vein thrombosis, and positive antiphospholipid antibodies, should raise the possibility of acute renal vein thrombosis, that is easily detected by Doppler ultrasound examination. Chronic renal vein thrombosis has indolent symptoms (chronic flank pain) and no hematuria.

Summary—Lupus Nephritis and Pregnancy

The interrelationship of pregnancy and lupus nephritis can be summarized as follows:

- The need to plan pregnancy after a 6-month period of remission in patients with SLE nephritis cannot be overemphasized: flares and preeclampsia are far less in inactive nephritis.
- Nephritis flares during pregnancy and postpartum can be very severe, with anuric renal failure and even maternal death, or chronic renal failure. Vigilance for early detection and vigorous treatment of flares is required.
- No definitive relationship between the histologic class of lupus nephritis and the severity of flare during pregnancy has been established, but there is a tendency for more severe exacerbations in patients with proliferative nephritis, WHO classes IV and III. Limited information on kidney biopsies before and after SLE pregnancy has shown progression in some patients and regression in others.
- Women with lupus nephritis are prone to preeclampsia, with greater prevalence than in normal pregnancy. This clinical picture should be differentiated from a nephritis flare, because of the possibility of acute anuric or chronic renal failure that may follow a flare, and of the distinctly different therapeutic management indicated.
- Preexisting hypertension is the most common predisposing factor to preeclampsia. Antiphospholipid antibodies also appear important as predisposing factors.
- In the setting of lupus nephritis and prior hypertension, with or without antiphospholipid antibodies, preventive treatment with low-dose aspirin should be initiated at the 10th to 14th week of pregnancy.
- The onset of lupus with nephritis during pregnancy is often associated with a stormy course and acute anuric renal failure, and should be suspected in any young woman with a multisystem presentation that includes rashes, arthritis, and alopecia.
- Renal vein thrombosis should be suspected, detected, and treated, especially in patients with antiphospholipid antibodies and/or membranous nephropathy.
- Hemodialysis should be instituted during lupus pregnancy in patients with BUN levels of 50 mg/dL or greater. Several chronic dialysis patients have been able to conceive and deliver live infants.
- In the presence of active lupus nephritis, especially diffuse proliferative, nephrotic syndrome, moderate to severe hypertension, and a serum creatinine level of 2 mg/dL or greater, pregnancy is possible, but potentially problematic and high-risk.
- Pregnancy in women with SLE and kidney transplants has been successful, although hypertension, preeclampsia, prematurity, and IUGR are not uncommon.

Bottom line: pregnancy with lupus nephritis, even inactive, should be handled as a high-risk pregnancy.

Laboratory Findings, Serologic Markers, and Antiphospholipid Antibodies

When used judiciously and in the context of the patient's clinical picture, certain laboratory tests in lupus pregnancy are useful in predicting disease flare, or potential fetal problems. Monitoring of disease activity is achieved by the serial determination of complement levels, anti-dsDNA antibodies, circulating immune complexes, and urinalysis with microscopic exam. Fetal loss is high in patients with antiphospholipid antibodies, and neonatal lupus erythematosus is associated with anti-Ro/SSA, anti-La/SSB and, rarely, with anti-U1 ribonucleoprotein (RNP) antibodies.

Pregnancy Tests

Urine pregnancy test by radioimmunoassay may be false positive in SLE patients with nephrotic syndrome (208). False-positive urine pregnancy tests occurred in 14 of 140 (10%) nonpregnant lupus patients, including 1 male: 11 of 14 had

renal disease, 8 with nephrotic syndrome and heavy proteinuria, 4 with amenorrhea, and 1 was actually pregnant (209). The false-positive test presents as an atypical ring pattern and reflects a nonimmunologic interference by urine gamma globulins in concentrations of 1.7 to 16.6 mg/mL. Serum radioimmunoassay for beta human chorionic gonadotropin (*beta* HCG) gives false-positive results in only 1 in 10^3 to 1 in 10^4.

Tests for maternal serum alpha-fetoprotein (MSAFP) and hCG are used by obstetricians. High AFP or hCG, whether associated with SLE or not, are followed with serial ultrasound examination for fetal growth and antepartum testing after 34 weeks, because they are predictive of preeclampsia and IUGR (210). These are presumed to be markers of a “leaky” placenta in which the fetal-maternal barrier is damaged by intervillous, decidual, or villous thrombosis.

Pregnancy-Induced Laboratory Test Changes

The sedimentation rate (ESR) increases in normal pregnancy and cannot be relied on for predicting disease activity (109). Average ESR by the Westergren method are 29 mm/hour in the first, 42 mm/hour in the second, and 36 mm/hour in the third trimester. Friedman and Rutherford (91) reported a high incidence of postpartum flares in lupus patients with Westergren ESR ≥100 mm/hour. In addition, creatinine clearance increases, immunoglobulin levels decrease, but are still within normal limits (211), and the hemoglobin decreases; the latter two are attributed to hemodilution.

Complement

Several studies have shown that the C3 complement level rises in normal pregnancy by a mean of 30%, but little, if at all, in SLE (109 ,166 ,212). Failure of C3 to rise, or declining levels in pregnancy have been associated with SLE flare (109 ,112). The C3 level rose by 25% in a control group of normal pregnant women, whereas it only increased by 10% in a group of pregnant SLE patients (212). These findings were confirmed with a larger series; 87 of SLE patients who had a flat or declining C3 level had a significant increase in maternal problems, and in fetal morbidity and mortality (213). Devoe et al. also noted association of a falling C3 level with increased SLE activity in the mother and an increased risk of abortions (85 ,214).

The alternate complement pathway is also activated during lupus flares in pregnancy, with elevated level of Ba (activation product of the alternate pathway) and low hemolytic complement (CH_{50}); the ratio of CH_{50} to Ba was significantly lower in lupus flares than in preeclampsia without SLE (215).

There are further implications of the role of complement activation in antiphospholipid-related fetal loss, to be discussed under Antiphospholipid Antibodies.

Lupus-Induced Laboratory Changes

Antinuclear Antibodies

Antinuclear antibody (ANA) tests have no specificity for disease activity in lupus. Studies of ANA in normal pregnant women have shown a similar prevalence as in the general population, between 1% and 5% (mean, 2.3%) (216 ,217 ,218). A prospective study compared 214 normal pregnant women with 50 age-matched nonpregnant controls and found 11% and 2% ANA positivity, respectively, which was significantly higher in pregnancy (p <0.05) (219). Most positive ANAs were found in the third trimester. None of the ANA-positive subjects were symptomatic or took lupus-inducing drugs, and only two had anti-dsDNA. In an interesting study from Mexico, Garcia-de la Torre et al. (167) found a positive ANA in 6 of 20 women with recurrent fetal loss (30%), in 6 of 40 toxemic patients (15%), and in 2 of 30 normal pregnant women (6.7%). Of the two ANA-positive habitual aborters with anti-dsDNA, one fulfilled four criteria for SLE and three more in this group had one to three criteria. Of the 6 preeclamptic patients with a positive ANA, 3 patients had one, and 1 patient had two SLE criteria. The authors concluded that the high prevalence of ANA in women with recurrent abortion can help identify patients who will eventually develop lupus. We concur that ANA does not appear in pregnancy unless the patient is developing lupus.

Anti-dsDNA, especially the complement-fixing variety, has been recognized as a helpful marker for assessing the activity of lupus and lupus nephritis (220 ,221 ,222) and increasing anti-dsDNA levels or titers predict disease flare (223). IgG-class anti-dsDNA, when present in the mother's plasma, may cross the placenta: Grennan et al. followed four SLE patients with anti-dsDNA through pregnancy and found anti-dsDNA in the cord blood of the neonate whose mother had the highest DNA binding (224). In this baby, the DNA binding capacity fell from 96% to 52% at 2 weeks and to 9% (negative) at 8 weeks of age, which suggests transplacental passage of the autoantibody. Zulman et al. (112), however, did not detect anti-dsDNA in the cord blood of six neonates whose mothers had it. The appearance of complement-fixing anti-dsDNA, or an increase during pregnancy, should alert the physician to the possibility of new onset, or flare of lupus nephritis.

The determination of anti-Ro/SSA and anti-La/SSB antibodies in the pregnant lupus patient is highly recommended because of their link to the neonatal lupus erythematosus syndrome (NLE) (225 ,226) (see Chapter 53). Anti-Ro/SSA is found in 25% to 40% of lupus patients and anti-La/SSB in 10% to 15%. In a prospective study of 100 women positive for anti-Ro with 122 pregnancies, the proportion of children with neonatal lupus was 2 in 122 pregnancies (1.6%) (133). Anti-U1RNP antibody is detected in 40% to 45% of lupus patients and is rarely associated with neonatal lupus (227).

Cryoglobulins

It has been well established that cold-insoluble complexes (mixed cryoglobulins) are present in up to 30% of lupus patients' sera, and represent immune complexes. They are associated with decreased serum complement levels and with evidence of active lupus, especially nephritis (228). We have also found that increased levels of cryoglobulins correlate with disease activity.

Antiphospholipid Antibodies

One of the most important laboratory tests in lupus pregnancy is the determination of antiphospholipid antibodies (APL), the most common of which are anticardiolipin antibody (ACL), lupus anticoagulant (LA or LAC) and anti-ß$_2$-glycoprotein I (anti-ß$_2$GPI) (76 ,229 ,230). Although separate and distinct, these antibodies to negatively charged membrane phospholipids frequently coexist. Recently, anti-ß$_2$GPI has generated a lot of clinical interest, and in terms of mechanisms of fetal loss (231 ,232 ,233). Other antibodies of potential significance for intravascular clotting include anti-thrombin III, anti-protein S, and so on. The literature on APL is voluminous and at times contradictory.

Anticardiolipin antibodies (ACL) react with phospholipids (cardiolipin, phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, and others) bound to proteins such as ß$_2$GPI, prothrombin, or annexin V. ACLs can be detected by enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (229). (See also Chapter 27).

Lupus anticoagulants (LAC) are antibodies directed against plasma proteins bound to anionic phospholipids (ß$_2$GPI, prothrombin, or annexin V). LAC blocks in vitro assembly of the prothrombinase complex, resulting in prolongation of in vitro clotting assays: the activated partial thromboplastin time (aPTT), the dilute Russell viper venom time (dRVVT), the kaolin plasma clotting time (KCT, Exner test), and rarely the prothrombin time. dRVVT and Exner are preferred tests (234 ,235 ,236).

Antibodies to ß$_2$GPI, a phospholipid-binding inhibitor of coagulation, are found in a large percentage of patients with primary or secondary antiphospholipid syndrome (APS), along with LAC and/or ACL. Antibodies to ß$_2$GPI were the sole antiphospholipid antibody in 20.3% of 133 SLE patients, one fifth of whom had APS features (237), and in 1% to 10% of patients with APS (232 ,238).

Antiphospholipid antibodies have been linked to intravascular clotting, arterial or venous, recurrent fetal loss, livedo reticularis, immune thrombocytopenia, Coombs-positive autoimmune hemolytic anemia, and false-positive tests for syphilis (229 ,235). In a review of 21 studies comprising over 1,000 lupus patients, anticardiolipin antibody was found in 44% (21% to 63%) and LAC in 34% (7% to 73%) (76).

In a recent study of 311 individuals (25 APS, 89 SLE, of whom 23 had thrombotic episodes [SLE/APS], 77 women with unexplained recurrent pregnancy loss, and 120 healthy controls), the SLE patients had 37% positive ACL, 35% anti-ß$_2$GPI, 45% antiprothrombin and 13% antiannexin V (239). The 23 SLE/APS patients were 70% positive for ACL, 57% for anti-ß$_2$GPI, 87% for antiprothrombin and 4% for antiannexin V. Of 56 SLE patients without clotting episodes who were ACL- negative, 5% were positive for anti-ß$_2$GPI, 23% for antiprothrombin, and 9% for antiannexin V. The respective values for 25 APS patients were, 100%, 80%, 60%, and 24%. In a study of 90 SLE and 100 APS patients, anti-ß$_2$GPI and antiphosphatidylserine were the strongest predictors for APS and for arterial thrombosis (240). Antiprotein S antibodies were found in 57 of 184 SLE patients (31%), and were associated with thrombosis and pregnancy morbidity (241).

In addition to the association of APL with recurrent spontaneous abortion, fetal loss, and fetal distress in women with and without lupus, preeclampsia, IUGR, and prematurity have been associated with APL (199 ,200 ,201). Although a study of 424 women asserted that testing for anti-ß$_2$GPI did not identify additional patients at risk for recurrent abortion or fetal loss (241a), there is ample recent evidence that anti-ß$_2$GPI is an important factor in RPL (231 ,232 ,242). Thrombotic events have also been described with a functional or quantitative deficiency of protein C or protein S in association with antiphospholipid antibodies (243).

In 15 retrospective studies of 1,249 pregnancies in SLE and SLE-like illness, there was a mean fetal loss of 37% (14% to 68%) in 479 APL-positive pregnancies. and of 18% (3% to 43%) in 770 APL-negative pregnancies, not a statistically significant difference (127 ,229 ,244 ,245 ,246 ,247 ,248 ,249 ,250 ,251 ,252 ,253 ,254 ,255). In seven prospective studies of 892 lupus pregnancies, however, mean fetal loss was 48% (4% to 100%) in 301 APL-positive pregnancies, and 9% (0% to 20%) in 591 APL-negative pregnancies, a statistically significant difference (256 ,257 ,258 ,259 ,260 ,261 ,262). SLE patients with persistently positive ACL regardless of SLE activity had significantly higher ACL, more thromboses (33% vs. 3%), spontaneous abortions (41% vs. 7%), and lupus anticoagulant (45% vs. 8%), than patients with positive ACL only during active lupus (250).

APL were also reported in a segment of women with RPL but without lupus (4% to 31%) (263), in infertile women (10% to 17%), and in women who resort to assisted reproductive therapy (ART, 14% to 30%) (264 ,265 ,266).

Aside from intravascular clotting, that results in a small placenta with infarcts (258), there are important events triggered by APL. Recent progress in the elucidation of pathogenetic mechanisms in APL-induced fetal loss can be summarized as follows:

In an in vitro system of trophoblast cells that develop into syncytia as manifested by the cytoplasmic presence of hCG, and exhibit invasiveness, trophoblasts express cell membrane anionic phospholipids that bind ß$_2$GPI, the main cationic phospholipid binding protein recognized by the antiphospholipid antibodies. ß$_2$GPI binds to trophoblast in vitro through its fifth domain, as reported for endothelial cells, and can be recognized by anti-ß$_2$GPI antibodies (233). The highest binding occurs when cells show the greatest amount of syncytium formation. Both polyclonal and monoclonal APL, including IgM anti-ß$_2$GPI significantly downregulate hCG secretion and trophoblast invasiveness (267). APL binding to the trophoblast alters the expression of trophoblast adhesion molecules (integrins and cadherins), which can result in inadequate trophoblastic invasion (268). Anti-ß$_2$GPI inhibits in vitro trophoblast differentiation into multinuclear giant cells and IL-3 restores placental functions (269). Low molecular weight heparin significantly reduced the binding of APS IgG to trophoblast cells and restored in vitro placental invasiveness and differentiation (270).

In a mouse model of APL-induced fetal loss, inhibition of the complement cascade in vivo blocked fetal loss and growth retardation, and mice deficient in C3 were resistant to APL-induced fetal injury (271). The same group determined that heparin, low molecular weight or unfractionated, prevented APL-induced fetal loss by inhibiting complement activation in vivo and in vitro (272). They further demonstrated that APL binding to the trophoblast triggers complement activation, followed by rapid increase in decidual and systemic TNF-α, which may become a therapeutic target for APL-induced fetal loss (273).

The above effects of APL, complement and TNF-α on trophoblast cell maturation, differentiation and invasiveness may well interfere with implantation, placentation, and normal vascular perfusion of the developing embryo.

Other Tests

Thrombocytopenia during lupus pregnancy may be the result of association with antiphospholipid antibodies (274), and may signify lupus flare. Thrombocytopenia in the presence of preeclampsia, however, should prompt investigations for the HELLP syndrome (80), which needs to be differentiated from lupus flare. Hyperuricemia should alert clinicians to the possibility of preeclampsia.

Laboratory Monitoring in SLE Pregnancy

Recommendations for laboratory monitoring in SLE pregnancy can be summarized as follows:

- Initial laboratory assessment at diagnosis of pregnancy should include:
  - Complete blood count (CBC) with differential, including platelets
  - Urinalysis with microscopic examination
  - Chemistry panel inclusive of BUN, creatinine, and blood glucose
  - Coombs test
  - Venereal Disease Research Laboratory (VDRL) test, activated partial thromboplastin time (APTT), anticardiolipin, anti-$ß_2$GPI, if available
  - Anti-dsDNA, anti-Ro/SSA, anti-La/SSB, anti-U1RNP
  - Complement C3 and C4
  - 24-hour urine for protein and creatinine, in the event of nephritis

    A positive screening APTT should be followed by appropriate investigations for the lupus anticoagulant. Highly positive levels of antiphospholipid antibodies should alert the rheumatologist and obstetrician to the possibility of spontaneous abortion or stillbirth, fetal distress, or preeclampsia, and preventive therapy should be initiated Positive anti-Ro/SSA and/or anti-La/SSB and, to a lesser extent, a positive anti-U1RNP should alert the physicians to the possibility of neonatal lupus erythematosus. If the patient is nephrotic or on corticosteroids, serum lipid tests are also indicated. Patients with known nephritis should have frequent monitoring of blood pressure and an initial 24-hour urine collection for protein, creatinine, and creatinine clearance. At the University of Southern California we also obtain quantitative serum cryoglobulin levels as an indicator of circulatting immune complexes.

- Monthly laboratory assessment should include CBC with differential, platelets, urinalysis, chemistry panel (as above), anti-dsDNA, C3, C4, and cryoglobulins or other measures of immune complexes. Patients with known lupus nephritis should also have 24-hour urine collections for protein, creatinine, and creatinine clearance.
- In the event of a hematocrit decrease, Coombs test should be repeated and the peripheral smear reviewed.
- Increasing antibodies to dsDNA, especially if they are complement-fixing, decreasing complement C3 and C4, and increasing immune complexes, indicate active lupus or impending flare in over 80% of patients.

Management during Pregnancy, Delivery, and Postpartum Period

General Principles

The SLE patient should consider strongly planning her pregnancies after a remission of at least 6 months. Once pregnant, she requires special attention by a team of a rheumatologist and a obstetrician-perinatologist, who should have experience in SLE and high-risk pregnancy management, respectively. At the onset of pregnancy, a thorough assessment of system involvement and disease severity and activity should be made. The pregnant woman, her husband or mate, and other family members should be counseled with regard to the pregnancy (see below). During the first half of pregnancy, the woman with SLE under control should be followed every month, with increased frequency of visits during the second half (every 2 to 3 weeks). Aside from laboratory evaluation and monitoring as recommended above, blood pressure should be monitored at every visit, and at home, in patients with known nephritis. Women with nephritis, with or without a history of hypertension, should be considered for low-dose daily aspirin from the 10th or 14th week to week 36 of gestation, for prevention of preeclampsia. Follow-up should be geared toward early detection and aggressive therapy of lupus flares during pregnancy and the postpartum period.

Follow-up of fetal development includes repeated ultrasound evaluation and the modified biophysical profile (275 ,276) (see Chapter 52).

Patients with high levels of antiphospholipid antibodies, and especially those with recurrent pregnancy loss or prior thrombosis, should be considered for heparin treatment protocols that enhance the possibility of live birth (see below). Cytotoxic drugs should be avoided during the first trimester and full doses of prostaglandin inhibitors should be used very sparingly. Steroid preparation for the stress of delivery is needed for patients on steroids for the 2 previous years. Cesarean section should be considered for certain maternal

or fetal indications, such as preeclampsia, HELLP syndrome, maternal avascular necrosis (osteonecrosis) of the hips with inadequate hip abduction, fetal distress, abnormal nonstress test, and the usual obstetric indications (e.g., cephalopelvic disproportion, transverse presentation). A neonatologist should be available at delivery.

During the immediate postpartum period and for the next 2 months, the mother should be watched carefully for disease flare and development of infection at the site of episiotomy or cesarean incision, endometritis, urinary tract infection, or pneumonia. Infection and flare should be treated promptly and aggressively.

Use of Medications during Pregnancy (Table 51-4)

The major drugs used to treat lupus are corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs, including salicylates), antimalarials, immunosuppressives/cytotoxics, and, in the case of associated antiphospholipid syndrome, anticoagulants. There is a justifiable tendency to use as few drugs as possible during gestation, but a smooth course for mother and fetus might dictate their use. The major concerns about medication use in pregnancy are the pharmacologic effects on the mother and fetus, effects on the length of gestation and labor, and developmental effects on the fetus (intrauterine growth, malformations, and survival). A valuable textbook on the use of drugs in pregnancy and lactation is available (277).

Table 51-4: Medication Use in Lupus Pregnancy and Lactation

Medications Used in Lupus	FDA Category	Lactation Permitted Maternal Dose
Corticosteroids	B	Yes, up to 20 mg/day
Azathioprine	D	No, no data
Cyclophosphamide	D	No, cytopenia in infant
Methotrexate	X	No
Cyclosporine	C	No
Mycophenolate mofetil	C	No data
Leflunomide	X	No
Rituximab	C	No data—Not recommended
Chlorambucil (rarely)	D	No
Antimalarial ([hydroxy]chloroquine)	C	Yes per AAP
Low-dose aspirin	C	Probably yes
Heparin, enoxaparin	B	Yes
Warfarin	D, X_M	Yes
Intravenous immunoglobulin	C_M	Yes
NSAIDs	B, D*	Yes—short-acting NSAIDs
COX-2 inhibitors	C	No data
Misoprostol	X_M	No
Antihypertensive Drugs Allowed in Pregnancy		
Methyldopa	C	Yes
Labetalol	C_M	Yes
Nifedipine	C	Yes

AAP, American Academy of Pediatrics; FDA, Food and Drug Administration; NSAIDs, nonsteroidal anti-inflammatory drugs.
*In third trimester. $_{M,}$ Category per manufacturer.

The Food and Drug Administration (FDA) has categorized drugs in terms of fetal risk:

- Category A: Controlled studies in women fail to show risk to the fetus in the first trimester or later. Possibility of fetal harm seems remote.
- Category B: No controlled studies in pregnant women and no fetal risk in animal studies, or animal studies show adverse effect, not confirmed in controlled studies in women in first trimester and later.
- Category C: Animal studies show teratogenic, embryocidal, or other fetal effects and there are no controlled studies in women, or there are no studies in women and animals. Category C drugs should be given only if benefit outweighs the potential fetal risk.
- Category D: There is evidence of human fetal risk, but benefit from use in pregnant women may be acceptable in spite of risk (i.e., in life-threatening situations or serious disease).
- Category X: Animal or human studies show fetal abnormalities, or there is evidence of fetal risk in humans, or both, AND the risk outweighs any possible benefit.

- Subscript M: The manufacturer has assigned the fetal risk category.
- A website is available, http://www.motherisk.org/, of the Hospital for Sick Children in Toronto, Canada.

Corticosteroids Category B

Despite the lack of controlled or randomized studies, corticosteroids have been established as the mainstay of SLE treatment in acute situations. Active lupus or flares during pregnancy or postpartum should be controlled with aggressive steroid therapy (75 ,120 ,125 ,187). Dose selection depends on the extent and severity of system involvement. Nephritis of the more severe types (diffuse and focal proliferative), neuropsychiatric manifestations, autoimmune hemolytic anemia, thrombocytopenia, and extensive severe vasculitis, cutaneous or visceral, require doses greater than or equal to 1 mg/kg/day of prednisone, and at times, intravenous methylprednisolone pulses of 250 to 1,000 mg per day. Life-threatening lupus manifestations, such as acute pneumonitis or pulmonary hemorrhage, justify intravenous pulse methylprednisolone at 500 to 1,000 mg per day for 3 to 5 days. Pleuropericarditis usually requires 0.5 to 0.8 mg/kg/day, whereas skin rashes and arthritis require 5 to 20 mg of prednisone daily, and/or antimalarials and NSAIDs.

Although Mintz et al. (75) and Wong et al. (125) put their pregnant patients on “prophylactic” steroids, and that may have prevented postpartum flares and maternal deaths, there is no hard evidence to prove that, and there is a tendency away from this practice (115).

Any woman treated with systemic steroids within 2 years of the anticipated delivery should be considered as potentially adrenal-insufficient, and should be given steroid stress coverage (steroid prep) during delivery. The most usual form consists of 100 mg hydrocortisone IV just prior to onset of delivery, and every 8 hours for the first day. During the next day the dose can be reduced to 50 mg every 8 hours and then adjusted to the patient's previous oral dose. If the patient is receiving more than 75 mg of prednisone daily, the appropriate hydrocortisone equivalent should be used in the first 2 days, and then the patient's steroid dose resumed.

Cortisol (278), prednisone (279), prednisolone (279), methylprednisolone (280), betamethasone (281), and dexamethasone (282 ,283) can cross the placenta. With maternal administration of prednisone or prednisolone, fetal blood levels are approximately 10% of the mother's level; with methylprednisolone hemisuccinate, cord levels are 18% to 45% of the mother's, with a large standard deviation; with betamethasone, cord levels are approximately 33% and, with dexamethasone, are similar to the maternal level. Therefore, the use of prednisone or prednisolone to treat the mother is least likely to affect the fetus, methylprednisolone is intermediate and, if steroid therapy of the fetus is indicated, dexamethasone is the appropriate choice (284). There is evidence that placental oxidative enzymes (placental 11ß-hydroxysteroid dehydrogenase type 2 (11ß-HSD2) inactivate in vitro cortisol and prednisolone, but not betamethasone or dexamethasone (278 ,279 ,285 ,286).

In a European database of 11,150 malformed infants, a slight association was observed between first trimester exposure to systemic corticosteroids and the occurrence of cleft lip, or cleft palate, or a combination of the two (OR, 2.59) (287). There was a decreasing trend over time, from 1990 to 2002; the authors expressed concern about dioxin potentiation of steroid effects, as in seen in mice. There are two reports of fetal adrenal failure after maternal steroid treatment, one fatal (288 ,289). Intrauterine growth restriction (IUGR) and low birth weight have been reported with maternal steroid therapy (290). In the large prospective study by Mintz et al. (75), however, it seemed that IUGR was more a function of active maternal SLE than of steroid dose. Several studies have described prematurity in newborns of steroid-treated women, starting in 1967: Hodgman et al. reported 23 infants whose 19 mothers received 7.5 to 22.5 mg of prednisone/day during pregnancy because of SLE (*n* = 16) and rheumatoid arthritis (*n* = 3) (291). There was excessive prematurity in 20 children with first-trimester exposure, with birth weight below the 50th percentile in 73.7% and SGA in 26%. Follow-up at 6 months to 8 years showed normal height, weight, and developmental progress for 22 of 23. Preterm delivery, preterm premature rupture of membranes, and premature rupture of membranes are common in SLE and seem to be multifactorial: disease activity, prednisone use at ≥10 mg/day and ACL are incriminated (178 ,292). On the other hand, dexamethasone or betamethasone therapy for lung maturation has contributed greatly to the survival of small premature infants (293).

Induction or aggravation of maternal diabetes mellitus and hypertension are known risks of steroid therapy. Overall, corticosteroid therapy is the major factor in improved maternal survival in SLE in recent decades, with substantial decrease in maternal mortality.

Salicylates and Other NSAIDs Category B, D (in Third Trimester)

COX-2 Inhibitors Category C

Salicylates and NSAIDs have in common the capacity to interfere with prostaglandin formation through variable inhibition of cyclooxygenases. This inhibition includes prostaglandin action anywhere in the body, including uterine, platelet, and renal, and other prostaglandins. Aspirin and NSAIDs inhibit uterine contractility and prolong labor and gestation (294). Aspirin irreversibly inhibits platelet aggregation, whereas the other NSAIDs have a reversible effect, and both can cause bleeding during delivery (295). Given the immaturity of hepatic enzyme systems in the fetus and newborn, transplacentally delivered drugs may persist much longer. No human teratogenicity exists, at least with low-dose aspirin (277). Of 50,282 mother-child pairs, 35,418 pairs had not taken aspirin, 9,736 had intermediate exposure, and 5,128 had heavy exposure during the first 16 weeks of pregnancy (296). The observed and expected numbers of malformations were similar in the three groups.

Other NSAIDs have, to varying degrees, similar effects to those of aspirin in pregnancy. They readily cross the placenta, potentiate vasoconstriction under conditions of hypoxia, raise systemic vascular resistance, and have profound effects on fetal and neonatal circulation (297). Maternal aspirin intake during pregnancy can cause in utero closure of the fetal ductus arteriosus, with severe heart failure, tricuspid insufficiency, and acidosis, all of which disappeared the day after birth (298). COX-2 inhibitors cause constriction of the fetal lamb ductus arteriosus in vitro and in vivo (299). Maternal indomethacin therapy was considered the cause of primary pulmonary hypertension in a newborn (300). Transient neonatal renal failure and oligohydramnios have also been described (301). Full dose salicylates (almost never used lately), NSAIDs and COX-2 inhibitors should be discontinued 6 to 8 weeks prior to delivery for the reasons outlined above.

Other Indications for Salicylates and Other NSAIDs

The pharmacologic actions of prostaglandin inhibitors can be used to therapeutic advantage. Indomethacin has been successfully used to inhibit premature labor (302), and for postnatal closure of patent ductus arteriosus (303).

Prevention of Preeclampsia

The capacity of low aspirin (ASA) doses (50 to 81 mg/day) to inhibit thromboxane synthesis by platelets, while prostacyclin production by endothelium is unaffected (304), has promising applications in the prevention of preeclampsia, where exaggerated placental production of thromboxane A2 has been invoked (197 ,305). The effectiveness of low-dose aspirin (75 to 81 mg/day) in the prevention of preeclampsia has been controversial. Nonetheless, patients at high risk for preeclampsia, including SLE patients, especially with preexisting nephritis and hypertension and/or APL, benefit from low-dose aspirin: a Cochrane database review of 39 randomized trials (over 30,000 women) concluded that ASA therapy during pregnancy is effective, with 15% reduction in preeclampsia, 14% risk reduction for fetal or neonatal death, and 8% reduction in preterm birth (207). Another metaanalysis od women at high risk for preeclampsia led to similar conclusions (306). In addition, this therapy poses no added risk of bleeding to the mother and fetus.

Intrauterine Growth Restriction

Lu et al. reviewed the evidence for IUGR prevention by low-dose ASA treatment during pregnancy (307). Although a metaanalysis of 13 studies between 1985 and 1994 found an 18% reduction of IUGR in >13,000 pregnancies treated with low-dose ASA, one multicenter trial among healthy, nulliparous women and two large trials among women at increased risk for IUGR and preeclampsia failed to demonstrate any benefit of ASA treatment in preventing IUGR. Nonetheless, there is a trend for decrease in IUGR since 1980: from 31% in the 1980s, to 18.2% in the 1990s, to 18.1% in the 2000s, whereas live births have increased from 72.5% in the 1980s to 82.1 in the 2000s (see Chapter 52 , The Fetus in SLE).

Summary: Salicylates

Large, anti-inflammatory doses of aspirin and NSAIDs are not generally used in lupus patients and should be avoided during the last 2 to 4 weeks of pregnancy for fear of prolonging gestation and labor, increased maternal and fetal bleeding during delivery, and possible premature closure of ductus arteriosus. In susceptible SLE patients, however, low-dose aspirin therapy assists in prevention of preeclampsia, and, in conjunction with heparin, in the prevention of pregnancy loss from APL (308).

Prevention of Fetal Loss with Antiphospholipid Antibodies (Table 51-5)

Overall fetal loss in SLE has been steadily decreasing over the last 55 years, with live births from 72.5% in the 1950s, to 82.1% in the first 5 years of the 2000s (See Chapter 52 , The Fetus). Similar conclusions were reached by Clark et al. in their analysis of papers in the last 40 years (309). A substantial portion of fetal loss in SLE is a result of the presence of antiphospholipid antibodies. Prevention of APL-related recurrent fetal loss has stimulated tremendous interest with numerous investigations and voluminous literature over the last 20 years (262 ,310 ,311 ,312 ,313 ,314 ,315 ,316 ,317 ,318 ,319 ,320 ,321 ,322 ,323 ,324 ,325 ,326 ,327 ,328 ,329 ,330 ,331 ,332 ,333 ,334 ,335 ,336 ,337 ,338 ,339 ,340 ,341 ,342 ,343 ,344). Of the 33 studies on Table 51-5 , 14 were controlled and compared 2 or more therapeutic regimens (310 ,313 ,316 ,318 ,322 ,323 ,325 ,326 ,331 ,333 ,334 ,341 ,342), and most were prospective.

Aspirin alone does not prevent fetal loss (322 ,334). It is now well established that heparin and low-dose aspirin is the treatment of choice (318 ,322 ,326 ,334 ,335). The controlled study of aspirin 81 mg per day versus aspirin plus heparin high dose (up to 30,000 IU per day) showed a definitive advantage of the combination, 44% live births versus 80% (322), and similar benefit was shown by moderate dose of UFH plus ASA versus ASA alone (71% and 42% live births) (334). Comparison of aspirin plus heparin low dose (up to 12,000 IU/day) versus aspirin plus heparin high dose (up to 30,000 IU per day) showed no advantage of the latter (76% vs. 80% live births) (323). Low molecular weight heparin can be given once a day, and showed a decided advantage over historic placebo controls (83.9 vs. 55.9 live births) (326 ,344).

A recent prospective, multicenter, controlled pilot study compared LMWH versus unfractionated heparin (UFH), with aspirin in both arms, and showed that both types of heparin were equally effective, with 84% and 80% live births (331).

Before the establishment of heparin with low-dose aspirin as the definitive treatment, a variety of therapeutic regimens were used, including low-dose aspirin alone (75, 81, or 150 mg/day), combinations of aspirin and 20 to 60 mg/day of prednisone, aspirin plus prednisone plus

platelet antiaggregants, heparin in high or low dose, alone, or with prednisone, or with aspirin, fish oil (eicosapentaenoic acid and docosahexanoic acid), and intravenous gamma globulin (IVIG) alone, with ASA, or with ASA and heparin (313 ,321 ,339 ,341 ,342). Only low-dose aspirin was used (75 mg/day in Europe, 81 mg/day in the United States).

Table 51-5: Outcome of Treatment in Antiphospholipid-Associated Fetal Loss

		No. of Pregnancies		Live Births (%)	
First Author	Therapy Used, mg/d U/d	Before Therapy	After Therapy	Before Therapy	After Therapy
Lubbe (327,328)	Aspirin 75 + prednisone 40-60	28	6	10.7	85.7
Branch (312)	Aspirin 81 + prednisone 40-60	31	8	3.2	62.5
Gatenby (319)	Aspirin 75-150 + prednisone 30-50 or 10-60	145	27	17.2	63
Ordi (332)	Aspirin 50 + prednisone 20	18	9	0	78
Carp (315)	Aspirin 100-300 + Prednisone 10-40 ± heparin 10,000 ± dipyridamole 225	71	27	7	48
Semprini (337)	Heparin + prednisone	27	14	3.7	64
Rosove (335)	Heparin 24,700	29	15	3.4	93.3
Silveira (338)	Aspirin 81 + prednisone 40	32	12	15.6	100
Buchanan (314)	Aspirin 75, or ASA + heparin 10,000	101	87	18.7	63.2
Cowchock (318)	ASA 80 + heparin 20,000	≥2/pt*	12	0	75
	vs. ASA 80 + prednisone 40	≥2 pt*	8	0	75
Out (262)	Prednisone ≥40 ± ASA 40 ± heparin, or ASA or heparin	≥3/pt*	30	NS	73.3
Landy (324)	Prednisone 5-60 + ASA or + heparin, or single drug	126	33	23.8	90.9
Many (330)	ASA ± prednisone 30 + dipyridamole + heparin	102	52 23 23	6.8	51.9 43.5 69.1
Stuart (340)	ASA + prednisone 10-30	24	7	4.2	28.6
Caruso (317)	ASA + prednisone 40	63	28	11.1	82.1
Al Momen (310)	ASA 100	33	9	9.1	55.6
	vs. ASA + prednisone 40-60	80	13	13.8	53.8
	vs. ASA + prednisone + IVIG (failed ASA + prednisone)	44 5	7 0	4.5	57.1
Balasch (311)	ASA + prednisone 15-30	49	21	6.1	90.5
Rossi (336)	Fish oil (EPA + DHA 5.1 g)	≥3/pt*	22	NS	95.5
Carta (316)	low-dose ASA (LDA)	≥2/pt*	15	NS	80
	vs. fish oil	≥2/pt*	15	NS	73.3 p >0.05
Kaaja (321)	IVIg 1 g/kg + ASA 75	14	4	7.1	100
Spinnato (339)	IVIg 0.4 g/kg ± ASA ± heparin	17	5	0	100
Harger (320)	ASA 81 + prednisone 10-60 Individualized, tapered	69	28	8.7	72.0
Kutteh (322)	ASA 81	≥3/pt*	25	NS	44.0
	ys. ASA 81 + heparin 10,000-30,000	≥3/pt*	25	NS	80.0

	vs. placebo	≥3/pt*	20	NS	85.0

*Fetal losses/patient; NS, not specified

These studies have reported an overall increase in live births (Table 51-5). Fetal loss in the over 1,100 untreated pregnancies was 76.2% to 100%, with only 7.9% mean live births (range, 0% to 23.8%). All treatments have resulted in increase of live births, to a mean of 72.3% (range, 28.6% to 100%).

Most of the studies with prednisone in doses of 40 to 60 mg per day showed effectiveness, but were fraught with steroid complications, including cushingoid features, hypertension, and gestational diabetes. Prednisone has been abandoned as a preventive treatment for recurrent pregnancy loss because of APL.

The suggestion that fish oil was effective in RPL prevention was dispelled by a study of 30 women, 15 each randomized to fish oil, or to low-dose aspirin: there was no significant difference in live births (73.3% vs. 80%, p >0.05) (316). Of five studies on the effectiveness of IVIG, two used patients as their own controls and showed reduction of pregnancy loss, but the number of pregnancies was very small (321 ,339). The three recent studies were controlled: IVIG plus heparin and aspirin compared to heparin plus aspirin plus albumin (313), IVIG versus aspirin plus prednisone (342), and IVIG versus ASA plus LMWH (341). None of these studies proved any superiority of IVIG in pregnancy outcomes (Table 51-5).

The 7th conference of the American College of Chest Physicians on Antithrombotic and Thrombolytic Therapy (345) and the 10th International Congress on Antiphos-pholipid Antibodies (APLA) (308) have developed detailed therapeutic recommendations during pregnancy in APL-positive women, as seen in Table 51-6 . See also definitions of heparin doses in Table 51-6 . The majority of the recommendations are similar:

- With a history of multiple pregnancy losses (two or more early, or one or more late), or pregnancy complications (preeclampsia, IUGR, or abruption), ACCP suggests administration of antepartum minidose, or moderate-dose UFH, or prophylactic LMWH plus low-dose aspirin. The APLA Congress consensus recommends starting treatment as soon as there is a positive pregnancy test, recommends low-dose aspirin plus a slightly higher UFH dose, 7,500 to 10,000 U q12h, and cessation of treatment on the day of, or 6 to 24 hours before, delivery. Heparin is resumed 6 to 8 hours after delivery for 6 to 8 weeks.
- With a history of venous thrombosis, with or without pregnancy loss or complications, patients are usually receiving long-term oral anticoagulation therapy because of the high risk of recurrence. During pregnancy, ACCP recommends low-dose aspirin plus adjusted-dose LMWH or UFH therapy and resumption of long-term oral anticoagulation therapy postpartum. As the half-life of LMWH is shorter in pregnancy, twice daily dosing is preferable, at least in the initial treatment phase. The APLA Congress also recommends ASA, weight-adjusted LMWH q 12h, even higher doses with history of prior arterial thrombosis, stopping therapy on the day of delivery (6 to 24 hours before). Resumption of oral anticoagulants is recommended 6 to 8 hours after delivery, or LMWH for 1 to 12 weeks postpartum. With history of severe thromboembolism or thrombotic strokes, warfarin may be used from gestational week 14 to 34 (after organogenesis is complete).
- Women with persistent APLs and no prior venous thromboembolism or pregnancy loss, should be considered at increased risk for the development of venous thrombosis and, perhaps, pregnancy loss. ACCP suggests one of the following approaches for these women: surveillance, minidose heparin, prophylactic LMWH, and/or low-dose aspirin, 75 to 162 mg/day. The APL Congress suggests low-dose aspirin or surveillance.

Table 51-6: Treatment Recommendations in Antiphospholipid-Positive Pregnant Women for Prevention of Fetal Loss and Thrombosis

Clinical Situation	American College of Chest Physicians 7th Conference (345)	10th International APLA Congress Consensus Conference (308)
A. Previous pregnancy losses (≥2 early, or ≥1 late) or complications (preeclampsia, IUGR, abruption)	Low-dose aspirin plus Minidose unfractionated heparin (5000 U q12h), or moderate dose UFH, or prophylactic LMWH	Low-dose aspirin plus LMWH-enoxaparin 1 mg/kg/day, or dalteparin 5000 U/day or nadroparin Ca++ 3800 U/day, or UFH 7,500–10,000 U q12h Stop 6–24 hours before delivery, resume heparin 6–8 hours after delivery for 6–8 weeks
B. Previous intravascular thrombosis (with or without pregnancy loss or complications)	Low-dose aspirin plus adjusted dose LMWH or UFH and resumption of oral anticoagulation postpartum	Low-dose aspirin plus LMWH-enoxaparin 1 mg/kg/q12h, or dalteparin 5,000 U q12h, or nadroparin Ca++ 3800 U q12h Stop 6–24 hours before delivery. Resume oral anticoagulation 6–8 hours after delivery, or continue LMWH in postpartum, for 1–12 weeks UFH for emergencies, higher doses for history of severe/arterial thrombosis, warfarin at 14–34 wks.
C. Persistent positive APL without thrombosis or pregnancy loss or complications	Surveillance, or minidose UFH, or prophylactic LMWH and/or low-dose aspirin	Low-dose aspirin or surveillance
D. Persistent positive APL with (ovulation induction and) in vitro fertilization	Not addressed	LMWH or UFH during “high estrogen levels” (ovulation induction) Stop heparin during ovum pick up No consensus during pregnancy: Low-dose aspirin +/- LMWH for 10+ weeks

UFH: Unfractionated heparin; U=Units; SC: Subcutaneously; q: Every; h, hours.
LMWH: Low molecular weight heparin
Minidose UFH: UFH 5,000 U SC q12 hours
Moderate-dose UFH: UFH SC q12 hours in doses adjusted to target an anti-Xa level of 0.1 to 0.3 U/ml
Adjusted-dose UFH: UFH SC q12 hours in doses adjusted to target a mid-interval aPTT into the therapeutic range
Prophylactic LMWH: e.g., dalteparin 5,000 U SC q24h, or enoxaparin 40 mg q24h (or 1 mg/kg q24 h)
Intermediate dose LMWH: e.g., dalteparin 5,000 U q12h, or enoxaparin 40 mg SC q12h
Adjusted dose LMWH: weight-adjusted, full-treatment doses of LMWH once or twice daily (e.g., dalteparin 200 U/kg, or tinzaparin 175 U/kg, or dalteparin 100 U/kg q12h.

- A topic addressed by the APL Congress, but not by the ACCP, is the group of infertile women with persistent APL who resort to assisted reproductive therapy (ART) with ovulation induction, and in vitro fertilization (308). Some of these women develop SLE, or APS or thromboembolism during the ART. The APL Congress recommends LMWH or UFH after gonadotropin stimulation, during high estrogen levels, and discontinuation when ova are harvested, so as to avoid hemorrhage. There is no definitive recommendation during pregnancy, with some patients treated with low-dose aspirin and others with addition of LMWH for at least 10 weeks.

Women with positive APL, hypertension, and lupus nephritis should be given low-dose aspirin, even without previous pregnancy losses, because of heightened probability of preeclampsia.

Unfractionated heparin and the LMWHs are category B drugs, do not cross the placenta, and are not harmful to the fetus. Both, however, can cause osteoporosis and thrombocytopenia in the pregnant woman. There is evidence that LMWHs have a lower risk for development of spinal osteoporotic fractures than UFH (3% vs. 15%) (346). In a randomized trial, bone mineral density was significantly lower in women receiving UFH, whereas women on dalteparin did not differ from controls (347). The need for concomitant steroid therapy can further increase the chance of developing osteoporosis. Calcium intake of 1.5 g/day and exercise against gravity are recommended as preventive measures against

osteoporosis. Heparin-induced thrombocytopenia (HIT) is IgG-mediated and occurs in 3% of nonpregnant women 5 to 15 days after starting UFH. LMWHs cause less HIT (348). The heparinoid danaparoid sodium can be used if LMWH also causes HIT (349). LMW heparins are costlier than UFH.

Although warfarin has been used after organogenesis in mothers with prior thrombosis and recurrent fetal loss, it may be associated with malformations and fetal warfarin syndrome (277). Warfarin is FDA category D, XM (Table 51-4).

In a longitudinal study of SLE and APS women, in 9/15 with APS and prior fetal loss, ACL became negative during pregnancy and the women had live births (350). It should be noted that not all pregnancies in mothers with antiphospholipid antibodies are doomed; 4 patients had uncomplicated pregnancies and delivered at term (351).

Summary: Prevention of Fetal Loss Due to Antiphospholipid Antibodies

- Women with prior fetal losses and pregnancy complications related to antiphospholipid antibodies can be treated effectively, with substantial reduction in fetal loss.
- Guidelines for treatment are improving and categories of patients better delineated.
- Heparin with low-dose ASA are the mainstay of therapy and should begin when the urine pregnancy test becomes positive, should be continued until delivery, and sometimes into the postpartum period.
- LMW heparins show superiority over unfractionated heparin in terms of avoidance of osteoporosis, have less HIT, and lesser frequency of administration, but are costlier.
- Corticosteroids should only be given for lupus activity, not to suppress APL (318 ,325).

Antimalarial Drugs: FDA Category C

Antimalarial drugs have been used by pregnant women for years as prophylaxis in large-scale malaria eradication programs in Africa and Asia, with a good safety record (352). Even if the patient discontinues antimalarials early in pregnancy, there are deposits in the liver and other organs from which the drug is slowly excreted (353), with a half-life of 2 months. Hydroxychloroquine (HCQ) is the major antimalarial drug used in rheumatic diseases in countries where available. HCQ crosses the placenta with cord blood concentration nearly identical to the mother's (354).

There is a single report of retinal degeneration in two infants after malaria prophylaxis in the mother (355). No fetal malformations specific to HCQ per se have been reported. Most of the admonitions against the use of antimalarials during pregnancy cite a report of a woman with discoid lupus who intermittently took 500 mg of chloroquine daily, a dose over twice that recommended (356). Four of her seven pregnancies, conceived while on chloroquine, resulted in three children with congenital anomalies and one spontaneous abortion.

Discontinuation of HCQ carries a risk for flare: in a randomized, double-blind study, lupus patients on. placebo had a 2.5-fold risk for flare compared to HCQ patients, and the risk for a severe flare was 6.1-fold (357).

A total of 492 lupus pregnancies have been reported in mothers on HCQ, at times during the first trimester, without any fetal malformations in excess of the rate for the general population (358 ,359 ,360 ,361 ,362 ,363 ,364).

In 36 pregnancies among 33 women with SLE who continued hydroxychloroquine during pregnancy, there were no teratogenic effects (358). In 21 pregnancies where mothers took antimalarials for a mean of 32 months before pregnancy, there were no congenital malformations or developmental problems in the children through a mean follow-up of 5.3 years (361). The same authors reviewed 215 pregnancies with first-trimester antimalarial exposure, with only 7 cases of congenital malformations (3.3%), which is similar to the general population. In a double-blind, randomized, placebo-controlled study of 20 pregnant lupus patients, flares and toxemia occurred only in the placebo group (3 each), and there were no congenital abnormalities in the infants (362). Sixteen more lupus patients on HCQ throughout pregnancy delivered children without any ocular or aural deficits (364). A controlled study of 133 pregnancies on HCQ for at least 6 months before pregnancy was reported from a University center in Paris (359). Of the 90 mothers, 69 had SLE, and 20 of them SLE/APS. In 122 of the pregnancies the maternal dose of HCQ was 400 mg per day, in 11 pregnancies, 200 mg per day, and additional medications included prednisone and aspirin 100 mg in over 80%, heparin (26%) and azathioprine (2%). Of the 117 live births in mothers on HCQ, were present in 3 (2.6%) and in 4 of 70 control pregnancies (5.7%). The mean malformation rate in the European registry is 2.3%. Follow-up of the children until 26 months of age failed to show any vision, hearing, or developmental problems. Of 40 babies born to mothers on HCQ, 24, including 13 who were breastfed, were followed up during early infancy and had normal visual function and neurodevelopmental outcome (363). Similarly, 21 children with 7.2 months' gestational exposure to HCQ or chloroquine, had no ophthalmic abnormalities on follow-up (360). A survey of 52 lupus experts from North America and the United Kingdom showed that 69% continue antimalarial treatment sometimes, often, or always in pregnancy, and 63% continue HCQ in the postpartum period and advise breastfeeding (365). The physicians' recommendation to continue antimalarials increased with the number of pregnant lupus patients seen, and no fetal toxicity was observed.

Patients should be informed about the antimalarial deposits in the liver, the safety record of HCQ, and the paucity of congenital anomalies, when deciding about its use during pregnancy. In our experience, most patients opt to discontinue as many medications as possible during gestation.

Immunosuppressive-Cytotoxic Drugs (Table 51-4)

The most commonly used immunosuppressive drugs in SLE are azathioprine, cyclophosphamide, methotrexate (all three are FDA category D), mycophenolate mofetil (FDA category C), and cyclosporine (FDA category C). Nitrogen

mustard (FDA category D) and chlorambucil (FDA category D) are rarely, if ever, used. The first three are known to induce fetal malformations in animals and have shown potential for human teratogenesis (277). Use of these drugs during fetal organogenesis (the first trimester) has the greatest potential for causing fetal demise or malformation.

Among lupus, vasculitis, and rheumatoid arthritis patients on cytotoxic drugs, there is very little occurrence of fetal malformations. As a rule, patients are counseled to use effective contraception prior to starting immunosuppressive medication. A textbook and several excellent reviews on the subject have been published (277 ,366 ,367 ,368 ,369). Very often newborns have IUGR, low birthweight, and prematurity.

Azathioprine Category D

Azathioprine crosses the placenta, but the fetus lacks the enzyme inosinate phosphorylase, which converts azathioprine to active metabolites (mercaptopurine); hence, only traces of mercaptopurine are found in cord blood (370). The drug may cause decrease in thymic shadow size, lymphocyte count, and IgG and IgM in the neonate (371), and neonatal chromosomal abnormalities persisting for up to a year.

Of 974 pregnancies reviewed by Polifka and Friedman, 799 concerned mothers with renal transplants, 53 with SLE, 1 with mixed connective-tissue disease, and 121 with other transplants and other diseases (367). Fetal malformations were seen in 35 of 974, 3.6%, not unlike the general population prevalence of 3% to 4%, and there was no specific pattern. Prematurity was seen in 16.7% and IUGR was relatively common. In their review, Prevot et al. note prematurity of 40% to 52% and IUGR of 19% to 40% (368). Pregnancies in women with renal transplants, however, are high-risk pregnancies, often complicated by hypertension and fetal morbidity (372 ,373). Congenital anomalies were noted in 9 of 273 (3.3%) and 2 of 42 (4.8%) infants fathered by men on azathioprine for renal and cardiac transplants respectively (374 ,375).

Several additional reports of normal neonates born to lupus and renal transplant patients who received azathioprine and prednisone have appeared (90 ,95 ,101 ,376 ,377).

Ramsey-Goldman et al. reported on 23 lupus pregnancies on azathioprine, cyclophosphamide, or methotrexate (376). Adverse pregnancy outcomes and neonatal complications were no different in 519 pregnancies before SLE, 117 pregnancies after SLE on no immunosuppressives, and 23 pregnancies on immunosuppressive therapy.

Azathioprine interacts with warfarin. Either they should not be used concomitantly, or be used together with extreme caution (378). In summary, azathioprine is relatively safe during pregnancy, but the dose should be reduced to half in the third trimester, otherwise the neonate develops hypogammaglobulinemia.

Cyclophosphamide Category D

Cyclophosphamide (CTX) with prednisone or methylprednisolone has been the accepted therapeutic standard for severe SLE nephritis since the 1980s (379). CTX is highly teratogenic in experimental animals and can induce malformations in the human fetus. In addition, it can induce gonadal failure in men and women. Daily oral cyclophosphamide causes amenorrhea within a year, usually with permanent ovarian failure (71%), and monthly intravenous “pulse” cyclophosphamide can also cause amenorrhea (45%), depending on the dose (380). The risk of amenorrhea depends on the patient's age and total dose: in a National Institutes of Health (NIH) study of 39 women, amenorrhea was greatest in women older than 31 years of age, 62%, versus 12% in women younger than 25 years of age, and 27% at 26 to 30 years of age (381). Patients receiving seven doses of IV cyclophosphamide had a 12% chance of amenorrhea, versus 39% in patients on long-term therapy (15 or more doses) (381). Similar findings were reported in three more studies, from Greece, France, and Korea: of 67 women on long-term IV CTX (1.5 years total) 31.3% developed amenorrhea, the major factor being age ≥ 32. Important risk factors in younger women were SLE duration over 5 years, and the presence of anti-Ro and anti-U1RNP antibodies (382). Of 84 women treated with IV CTX for SLE (n = 56) and other diseases, mainly vasculitis (n = 28), 27.3% developed amenorrhea, which was sustained in 22.6%, with age being the major factor (383). Of 67 women with proliferative SLE nephritis treated with IV CTX, amenorrhea occurred in 37.3%, and became sustained in 14.9%. Age, high damage index, and high cumulative dose of cyclophosphamide were risk factors for permanent ovarian failure (384). The last two studies reported pregnancies after IV CTX. It has been suggested that the administration of monthly IV cyclophosphamide be timed during menses, when the ovarian follicles are quiescent. Preservation of ovarian function during CTX therapy has been achieved by treating concurrently with monthly injections of 3.75 mg gonadotropin-releasing agonist (GnRH-a, Lupron) (385). This treatment was successfully used in women with lymphoma. Of 75 patients with lymphoma, leukemia, or SLE undergoing chemotherapy, 93.3% maintained ovarian function, whereas only 46.3% of 82 patients on chemotherapy alone did (386).

First trimester exposure to cyclophosphamide has resulted in a fetal malformation complex termed cyclophosphamide embryopathy: it consists of growth deficiency, hypoplasia of calvarium and facial bones, hypotelorism, short palpebral fissures, supraorbital ridge hypoplasia, flat nasal bridge, microtia (small ears), cleft palate, and hypoplastic or absent thumb, radius and toes, variously present in the 8 newborns reported (387 ,388). Five of 8 newborns survived, 1 died, 1 pregnancy was terminated, and the fate of 1 was unknown. One pregnancy with cyclophosphamide late in the first trimester, and 4 pregnancies with chemotherapy including cyclophosphamide beyond the first trimester had a normal outcome (389). At the Los Angeles County University of Southern California Medical Center, three of our lupus patients on monthly IV cyclophosphamide for SLE nephritis became pregnant; cyclophosphamide was immediately stopped on all. One woman proceeded with a normal pregnancy and had a normal infant at term. The

second patient had a first-trimester spontaneous abortion, but conceived two more times, after cessation of cyclophosphamide therapy, and, despite a mild exacerbation during both pregnancies, carried to term and had two healthy infants. At this time, 17 and 15 years later, the children have developed normally and are healthy. The third patient received IV CTX inadvertently, had a normal newborn who is healthy and developing well to date, 1 year later. It is virtually impossible to foretell any risk of oncogenesis among such children. I have recommended IV pulse CTX during two pregnancies after the first trimester for a colleague's patient who developed acute oliguric/anuric renal failure, with improvement in the mother and without ill effects to the children so far. A primigravida with SLE nephritis unresponsive to steroids was given cyclophosphamide without apparent problems in the newborn (390). Cyclophosphamide was also given during pregnancy to four patients with severe SLE: in two, CTX was given inadvertently in the first trimester and both miscarried. The other two patients were treated for severe nephritis and thrombocytopenia with microangiopathic anemia at week 20 and 22, and both had fetal demise, 1 day and 7 days after CTX (391). In summary, IV CTX should only be given during pregnancy if the mother's life is endangered by severe SLE.

Mycophenolate Mofetil Category C

Mycophenolate mofetil (MMF) (FDA category C) is an inosine monophosphate dehydrogenase inhibitor that inhibits purine synthesis and is getting established as an effective therapy for lupus nephritis (392). Three instances of fetal malformations have been reported with MMF: of 14 pregnancies in 10 women with kidney transplants, there were 6 spontaneous abortions and 8 live births (393). A newborn with exposure to MMF, tacrolimus, and prednisone since the 7th week of gestation, had hypoplastic finger- and toenails and shortened fifth fingers bilaterally (394). Another newborn, conceived while the mother was on the same drugs, had cleft lip and palate and an ear deformity. A third case was reported from Paris, with first trimester exposure to MMF (500 mg/day), tacrolimus and prednisone (395). At 13 weeks the pregnancy was diagnosed and azathioprine 50 mg/day substituted for MMF. Major malformations were detected and the pregnancy was terminated at 22 weeks. The fetus had a large cleft lip and palate, hypertelorism, micrognathia, microtia, atresia of the external auditory canal, agenesis of the corpus callosum, and a left pelvic ectopic kidney. In a subsequent pregnancy, the patient was treated with azathioprine, tacrolimus, and prednisone and delivered a normal premature infant. Effective contraception is imperative in patients undergoing MMF therapy.

Methotrexate (MTX) Category X

Methotrexate, a methyl-derivative of aminopterin, reversibly inhibits dihydrofolate reductase, thus interfering with purine synthesis, and also has anti-inflammatory effects. It is used in rheumatoid arthritis as a first-line disease modifying drug in low weekly doses (7.5 to 25 mg), and also in SLE, poly/dermatolmyositis and other systemic rheumatic diseases. It has also been used as an abortifacient. Methotrexate induces multiple animal and human malformations, especially with exposure from the 4th to 12th week of gestation. The MTX-induced malformations are known collectively as “aminopterin syndrome” and consist of CNS and skeletal abnormalities (spina bifida, mental retardation, hydrocephalus, anencephaly, synostosis of lambdoid sutures, micrognathia, high or cleft palate, short extremities, hypertelorism, syndactyly, absent digits, club foot, large fontanelles, wide-set nasal bridge, and dextrocardia) (396). It has been suggested that there may be a common mechanism through apoptosis for the fetal malformations seen with CTX, MTX, and cytarabine (388). In the review by Lloyd, of 71 fetal exposures to MTX, 42 were in the first trimester and 10 of these (23.8%) resulted in physical malformations, with 4 from mothers on <20 mg MTX per week (396). Two children had later developmental abnormalities after third trimester exposure. Because MTX is found in the liver up to 116 days after the last dose, it is highly recommended that no conception be attempted before 5 months have elapsed from discontinuation, and that folinic acid, 10 mg per week, rather than folic acid, be taken throughout pregnancy in women exposed to MTX. Fertility after MTX therapy is unimpaired, with 97% conception rate 1 year after cessation of MTX. Of ten pregnancies in eight women with rheumatoid arthritis who conceived while on 7.5 mg MTX per week, three had spontaneous and two, elective abortions (397). All except one stopped methotrexate within the first trimester, and most received folate supplements. The five remaining pregnancies resulted in full-term normal infants.

Cyclosporine A Category C

Cyclosporine A (CSA) is a calcineurin inhibitor and has been widely used to prevent rejection in organ transplantation; it can cross the placenta, and is excreted in milk. Knowledge about cyclosporine in pregnancy is derived mostly from renal transplant recipients. By 1998, in 405 pregnancies under cyclosporine treatment, there were no excessive fetal malformations, or any specific pattern in those observed (398). On follow-up of 175 children of 133 women with renal transplants maintained on CSA through pregnancy, developmental delay was found in 0.5% of 20 children 1 year of age, in 6.3% of 84 children 1 to 5 years old, and in 9.7% of 71 children 5 to 12 years old (399). Overall, 16% of the children had delays or needed educational support. Given the high prevalence of prematurity and IUGR in this group (at times exceeding 50%), developmental delays may not be a result of CSA.

Nitrogen mustard has been used for the treatment of lupus nephritis in the past. In a report of 250 patients with nephritis, 18 of 44 women who had at least one course of nitrogen mustard had 11 successful pregnancies (159).

The decision to continue cytotoxic drugs during pregnancy depends on the need for disease control, and should be made jointly with the patient while weighing the potential

risks versus benefits. If continuation of pregnancy under cytotoxic therapy is desired, it is wise to have an amniocentesis done and the karyotype determined.

Leflunomide Category X

Leflunomide is only occasionally used in SLE (400), is a competitive inhibitor of dihydroorotate dehydrogenase, an enzyme necessary for pyrimidine synthesis, and has a very long half-life because of enterohepatic circulation, approximately 14 to 15 days. It is a known embryotoxic drug, and, because of its long half-life, pregnancy should not be attempted just after discontinuation. The manufacturer recommends cholestyramine treatment, 8 g three times a day for 11 days, with confirmation of blood levels less than 0.02 mg/L after treatment and 2 weeks later (401).

Rituximab Category C

Rituximab is a chimeric monoclonal antibody against CD20, which is expressed by B lymphocytes from the pre-beta cell to the mature B cell stage. It can effect long term B cell depletion, has been used successfully in lymphomas and in phase I/II studies of severe lupus, including nephritis, with or without cyclophosphamide (402 ,403). There are two case reports of pregnant women treated with rituximab during pregnancy for non-Hodgkin's lymphoma (404 ,405). The first had aggressive $CD20^+$ lymphoma and was treated with rituximab 375 mg/m^2, doxorubicin, vincristine, and prednisone for 4 cycles, starting in the 21st week of pregnancy. In the 35th week, she delivered by Cesarean section. Her child had normal B cell counts and CD19/20 by 4 months of age (404). The second patient, also with non-Hodgkin's lymphoma, conceived after the first dose of rituximab and decided to continue the pregnancy. She delivered vaginally at the 40th week. The child had granulocytopenia until 4 months, initially low IgM and IgA, but immunoglobulins, immune function, and development were normal by 18 months of age (405).

Miscellaneous Therapeutic Measures

Plasmapheresis

Plasmapheresis can be safely performed during pregnancy and has been used successfully in severe preeclampsia/eclampsia, with refractory HELLP syndrome that does not improve after delivery in women with APS and/or SLE (406 ,407 ,408 ,409 ,410), in severe lupus during pregnancy (411 ,412 ,413 ,414), for prevention of recurrent fetal loss in women with APL (415 ,416 ,417 ,418), and for prevention of congenital heart block due to anti-Ro and anti-La (419 ,420 ,421 ,422 ,423). Severe lupus manifestations improved with plasmapheresis (and steroid) include vasculitis, with decreased steroid requirement (412), extremely severe flare with myositis (414), and diffuse alveolar hemorrhage with oliguric renal failure (2 patients), in combination with continuous venovenous hemofiltration, steroids, and cyclophosphamide in 1 woman (411). In 1 patient, plasmapheresis failed to reverse thrombocytopenia, with subsequent fetal demise (413). Two patients with recurrent pregnancy loss and APL were given plasmapheresis. In 1 patient, dramatic reduction of APL was associated with successful pregnancy outcome (415). In the other, who had a multisystem disease with myositis, plasmapheresis was given because of fetal distress. The authors believed that they gained 2 more weeks of gestation, during which further fetal maturation occurred, which allowed fetal survival after Cesarean section at 29 weeks (416). Immunoadsorbent plasmapheresis with dextran sulfate, low-dose prednisone and low-dose aspirin in 9 pregnancies decreased lupus anticoagulant and anticardiolipin antibodies, with successful delivery in eight of nine lupus pregnancies (417 ,418). Prevention of congenital heart block because of anti-Ro and or anti-La was accomplished in 6 pregnancies by plasmapheresis, dexamethasone or prednisone (419 ,420 ,423), plus azathioprine (421 ,422). Plasmapheresis was started as early as the 15th week of gestation, and dexamethasone from the 7th or 10th week (422 ,423). An excellent review on plasmapheresis in pregnancy has been published (424).

Intravenous Immunoglobulin Therapy Category CM

Ten papers have reported 34 women with four to nine fetal losses each, positive anticardiolipin antibodies, lupus anticoagulant, and preeclampsia in three (310 ,321 ,425 ,426 ,427 ,428 ,429 ,430 ,431 ,432). Treatment with intravenous immunoglobulin (IVIg), at times with the addition of low-dose aspirin, heparin, and steroids, resulted in live births. Immunoglobulin was given at 400 to 1,000 mg/kg/day for 2 to 5 days per month. IVIg suppressed APL levels after each infusion (428). In an in vitro study, IVIg neutralized lupus anticoagulant activity in 10 of 11 patient sera (433). The mechanism of IVIg action is probably a result of anti-idiotypic antibodies against antiphospholipid antibodies (434) and other autoantibodies. In addition, IVIg has been used in severe clinical SLE manifestations (severe thrombocytopenia, pulmonary alveolar hemorrhage, transverse myelitis, and perhaps anuric renal failure) refractory to high-dose steroids. Three recent controlled studies in women with APL and recurrent pregnancy loss compared IVIg plus heparin and aspirin to heparin plus aspirin plus albumin (313), IVIg versus aspirin plus prednisone (342) and IVIg versus ASA plus LMWH (341). None of these studies proved any superiority of IVIg in pregnancy outcomes, as noted previously. However, this expensive treatment is worth considering in severe, life-threatening SLE, as noted above.

Herbs and Alternative "Medicines"

We all live in societies of great cultural diversity and should be keenly aware that our patients may be taking substances that may be harmful to themselves and their fetus, although patients are often convinced that "herbs are harmless." Some examples are: Ginger, used for morning sickness, may cause abortion, mutations of the fetus, or increased risk of bleeding. Blue cohosh tea causes uterine contractions and is used

to help induce labor, but it has been associated with myocardial infarction of the fetus. Species of birthwort are also used in pregnancy, even though they contain known nephrotoxins and mutagens. Hellebore is used for nausea and to regulate menstruation, hemlock as a sedative or for cramps and spasms, and tragacanth for immune stimulation, yet all are known teratogens in animals. These and other supplements should generally be avoided in pregnant patients.

In recent years, the potential dangers of herbs have become apparent with thousands of adverse events reported by users of ephedra supplements for weight loss, liver problems from kava use, and renal failure in African folk medicine users. For further information, see http://www.naturalstandard.com/.

Recommendations for Therapy in Lupus Pregnancy

- The best assurance for a successful pregnancy is control of the mother's lupus. Maternal disease should be assessed carefully for activity and severity months before and at the onset of pregnancy, which should ideally be planned after several (approximately 6) months of remission. The mother should be watched carefully for flares.
- Maternal flares should be diagnosed early and treated aggressively with appropriate steroid dose. Unless there is a dire emergency, i.e., acute anuric renal failure, or pulmonary alveolar hemorrhage, cytotoxic drugs such as cyclophosphamide, MMF, and methotrexate should be avoided during the first trimester. Azathioprine in reduced doses, or cyclosporine, can be used during pregnancy. Mothers with nephritis at risk for hypertension and preeclampsia should be treated with low-dose aspirin (60 to 81 mg/day) until the 36th week of gestation.
- The mother's status in terms of antiphospholipid antibody and anti-Ro/SSA, anti-La/SSB positivity should be known: the former, because of predisposition to fetal loss, IUGR and preeclampsia, and the latter two because of the small risk for congenital heart block in the child (see also Chapters 52 and 53).
- Joint follow-up by the rheumatologist and high-risk obstetrician should be done every month for the first half of pregnancy, and more frequently thereafter (every 1 to 3 weeks), with blood pressure check, careful exam, repeat of CBC, urine, chemistry, quantitation of proteinuria in patients with nephritis, complement C3 and C4 levels, anti-dsDNA, and a measure of circulating immune complexes on a monthly basis. Patients with known prior problem pregnancies should be followed more often.
- In the event of highly positive antiphospholipid antibodies (positive LAC, high IgG ACL, LAC plus IgG ACL, anti-β_2GPI), with a history of intravascular thrombosis or prior fetal loss, the patient should be enrolled in an effective antithrombotic protocol (LMWH with low-dose aspirin). Unless there is concomitant lupus activity, high-dose prednisone for APL alone is not indicated.

Breastfeeding (Table 51-4)

All drugs are excreted in human milk, usually in trace but variable amounts (352,435–437a). Factors influencing drug concentrations derived from milk in the infant have been delineated by Brooks and Needs (435). Maternal factors include milk fat and protein concentrations, milk pH, mammary blood flow, and maternal drug metabolism (e.g., absorption, protein binding, and plasma clearance). Drug-related factors include molecular weight, lipid solubility, pKa, elimination half-life, pharmacokinetics, dose amount, and interval. Infant factors include volume of milk consumed, feeding intervals relative to maternal drug intake, absorption, and metabolic and deconjugating ability of the infant.

An index has been proposed to calculate infant exposure to drugs in breast milk, which takes into account milk to maternal plasma drug concentration and drug clearance in the infant (438).

After a single dose of 5 mg of prednisolone, 0.07% to 0.23% of the dose was found in maternal milk (437a). With a maternal dose of 7.5 mg per day, a child drinking 1 L of milk daily would receive 0.028 mg of prednisolone (0.33%) (436). Long-term treatment of the mother with 10 to 80 mg/day of prednisolone produces milk concentrations 5% to 25% of those in serum (437 ,439). The milk/plasma ratio increases with increasing serum concentrations and it has been calculated that, at a maternal dose of 80 mg/day, the infant would be exposed to less than 0.1% of the maternal dose (437 ,440). The peak plasma level after oral intake is attained at 1.1 ± 0.7 hours; therefore, the exposure of the infant can be minimized by appropriate timing of nursing. No untoward effects in nursing infants have been reported (437 ,441), and maternal doses of up to 30 mg/day are probably safe.

Cyclophosphamide is found in substantial concentrations in human breast milk (442) and neutropenia and leukopenia were reported in two infants whose mothers used cyclophosphamide while breastfeeding; thus, nursing is contraindicated in a mother who requires CTX. The milk level of methotrexate in a woman with choriocarcinoma of the uterus was 8% of the plasma level (443). With small weekly doses, such as those used in rheumatic diseases, there may be a greater measure of safety, but data are lacking. Only small amounts of azathioprine have been detected in breast milk (444). Encouraging data are available for cyclosporine: in seven lactating transplanted mothers on cyclosporine, drug concentration in breast milk was similar to maternal trough level, but was below the detection limit in the infants, and their creatinine levels were normal (445).

Overall, a great deal of good judgment and caution should be exercised. Until data such as those on cyclosporine are available, the need for maternal cytotoxic drug therapy would preclude breast-feeding.

Antimalarials are also found in small amounts in human milk (446 ,447). Nation et al. (446) have calculated that the infant would be exposed to about 2% of the maternal daily dose of hydroxychloroquine. Although there are very few

problems with malaria prophylaxis in nursing mothers, doses used in lupus could expose the child to the risk of retinopathy.

In general, NSAIDs are weak acids and achieve low concentrations in the acidic pH of milk. After a single aspirin dose of 450 to 650 mg, 0.1% to 21% reaches the infant over a 24-hour period (448). Peak salicylate concentrations in milk occur about 2 hours after peak serum levels (449). However, if the mother takes anti-inflammatory doses, in view of the immature neonatal metabolic processes, the infant may develop acidosis and bleeding diathesis. Furthermore, the infant can absorb free salicylic acid from the cleavage of salicylphenolic glucuronide in the milk (450). Trace amounts of naproxen, piroxicam, ibuprofen, and diclofenac have been reported in milk. Some of the NSAIDs have enterohepatic circulation (e.g., indomethacin, sulindac), and are not recommended during lactation. With a maternal daily dose of 200 mg celecoxib, the infant's daily dose would be approximately 0.3% of the mother's, deemed to be unlikely to cause untoward effects (451). For the position of the American Academy of Pediatrics on drugs in milk, see (452).

Contraception

Uncontrolled and anecdotal reports have suggested that older oral contraceptives (OC) containing larger doses of estrogens cause SLE flares (50 ,453). In a study of 20 women with SLE nephritis by Jungers et al., the use of preparations containing 30 or 50 µg of ethinyl estradiol was associated with SLE flares in 43% within 3 months of beginning oral contraceptives, whereas 11 patients on progestational oral contraceptives did not flare during a 30-month period (98). Nevertheless, many patients tolerate small-dose estrogen OC (“mini-pills”) without adverse effects (454). In retrospective studies by Julkunen et al. (455 ,456) and Buyon (457), substantial numbers of lupus patients are able to tolerate modern-day OC or hormone replacement, with flares in 8% and 13% respectively and no thromboembolism. Newer OC contain <35 µg of ethinyl estradiol, and are preferable to 50 µg in the older preparations. Exceptions are women with antiphospholipid syndrome and prior thromboembolic episodes, or severe migraines, because thromboembolic phenomena have been associated with estrogen contraceptives (458).

Two important studies were recently published: in a prospective double-blind randomized placebo-controlled multicenter study, 183 women with inactive (76%) or stable-active (24%) SLE were assigned to either combination OC or placebo (OC-SELENA study). Rates of severe flare were similar, 7.7% in OC patients versus 7.6% in placebo patients (459). The 12-month rates of severe flare (0.084, OC group, and 0.087, placebo group) and of mild or moderate flares (1.40, OC and 1.44, placebo) were also similar, There were two clotting episodes in the OC group and three in the placebo group.

In a single-blind study from Mexico City, 162 women with SLE were randomly assigned to combined OC, a progestin-only pill, or a copper intrauterine device (IUD) for 1 year (460). Disease activity remained mild and stable in all groups throughout the trial, and there were no significant differences in global or maximum disease activity, incidence or probability of flares, or medication use. Flare rates and severe flare rates per patient-year were similar in the three groups: 0.86 and 0.049 in the combined OC group, 1.14 and 0.114 in the progestin group, 0.91 and 0.046 in the IUD group. There were two thrombotic events in each of the hormone groups. The conclusion from these seminal studies is that combination OC can be well tolerated in women with inactive or stable active SLE.

In a controlled study with progestogens, using either oral levonorgestrel 0.03 mg daily or norethisterone enanthate 200 mg IM every 3 months, there was no increase in flare rate compared to controls (6/122 patient/months and 4/48 patient/months respectively) (170). Menstrual irregularity and spotting were common complaints among the patients. Commercially available progestational agents include oral norethindrone (norethisterone), norgestrel, levonorgestrel, ethynodiol diacetate, and lynestrenol (461). Intramuscular depot medroxyprogesterone acetate (Depo-Provera), given every 12 weeks, is effective and does not confer increased risk of thrombosis, but may cause irregular bleeding, weight gain, and decreased bone density with protracted use. If long-term contraception (up to 5 years) is desired, a subdermal progestin implant (levonorgestrel) may be considered, as long as the implantation site is carefully watched for infection (462). Menstrual irregularity for 6 to 12 months from onset of use is common, and bleeding, amenorrhea, and, rarely, ectopic pregnancy may occur.

Mechanical barrier methods, such as the diaphragm, cervical cap, female condom, and male condom with spermicide cream or jelly, although considered cumbersome by some, are safe and effective. Male condoms are not very reliable and may rupture. Intrauterine devices are associated with dysmenorrhea, more frequent local infections (84 ,460), risk of menorrhagia, endometritis, and perforation, and should be used with caution. The copper IUD lasts for 10 years. An IUD with levonorgestrel (Mirena) is available and lasts for 5 years.

Hormone Replacement Therapy (HRT)

An important multicenter double-blind randomized placebo-controlled study of hormone replacement during menopause (SELENA study) was recently published: 351 postmenopausal women with inactive (81.5%) or stable-active SLE (18.5%) were randomized to combination HRT (0.625 mg estrogen plus 5mg progesterone for 12 days per month) or placebo for 1 year (463). The risk for severe flares was similar in the HRT and placebo groups, 7.5% and 4.5% respectively (12-month incidence rates 0.081 and 0.049). Mild and moderate flares were increased in the HRT group, with a significantly greater incidence rate: 1.14 flares/person-year for HRT versus 0.86 for placebo. There was one death, one stroke, and three clotting episodes in the HRT group, and one thrombotic episode in the placebo group. Women with positive APL antibodies or history of thrombosis were excluded from this trial. Although HRT has been discredited as cardioprotective (464 ,465), there are potential indications for premature

menopause management in SLE patients, and short-term treatment of postmenopausal bone loss.

Lupus and Assisted Reproduction

Ovulation induction (OI) is the first phase in assisted reproductive therapy (ART), followed by in vitro fertilization (IVF) and embryo transfer (ET) in the uterus. Stimulation of ovulation is done with a variety of hormonal or nonhormonal manipulations and results in tremendously high plasma estradiol levels. Several types of problems related to OI have been described: flares in patients with known lupus, de novo development of lupus, development of APS, and thrombotic episodes in patients with or without APS. To further complicate matters, ovarian hyperstimulation syndrome (OHSS), which may occur in 1.4% to 2.3% of women undergoing ART (466), can mimic a lupus flare. OHSS appears to be mediated by a variety of cytokines, including VEGF, and is distinguished into three grades: grade 1 consists of ovarian enlargement to 5 cm; grade 2, of ovarian size of 5 to 12 cm, nausea, vomiting, diarrhea, and abdominal distention; and grade 3, of massive ovarian size (>12 cm), ascites, pleural effusions, edema, hypotension, electrolyte imbalance, and hypercoagulability with phlebothrombosis (467). Thrombotic episodes often occur in the upper extremities and jugular veins (468).

The prevalence of SLE in 136 women undergoing OI-IVF was determined as 1.5% by questionnaire, ANA, anti-dsDNA and clinical assessment (469).

A total of 8 patients without prior SLE (1 with Raynaud phenomenon) developed lupus, 2 with SLE and APS, after OI (470 ,471 ,472 ,473). The development of SLE occurred after 1 to 27 cycles of OI. One of the patients developed rapidly progressive glomerulonephritis (470).

In 12 patients, 11 with known SLE and 1 with discoid LE, flares developed, ranging from arthritis, malar rash, alopecia, and myalgia, to myositis, pericarditis, vasculitis, seizures, and transverse myelitis with death (56 ,474 ,475). The last patient had also APS and died after a second attempt at conception with OI (56). One of the patients with SLE developed superior vena cava and left renal vein thrombosis (474). Of 7 SLE patients reported from New York, 3 had flares and 2 OHSS (475). The same paper reported 10 patients with APL syndrome and 2 with APL positivity undergoing OI while on antithrombotic therapy: 1 patient developed osteopenia secondary to heparin, but no thrombosis.

New diagnosis of APS was made in 8 patients undergoing OI, with femoropopliteal thrombosis and pulmonary embolus in 1 of 5 patients from Paris (472), and 1 each with middle cerebral artery stroke and OHSS (476), intracardiac thrombosis (477), and catastrophic APS (478).

Wechsler et al. (479) proposed the following guidelines for SLE patients desirous of ART:

- SLE remission without need for aggressive therapy for at least 12 months.
- Absence of systemic hypertension, significant renal failure, pulmonary hypertension, frank heart valve disease, or major vascular past history.
- Antiestrogens should be used (clomiphene and tamoxifen), followed by pulsatile GnRH, if the above fails. Gonadotropins have the greatest risk for OHSS.

The same group reported on 21 women, 19 of whom fulfilled 4, and two fulfilled 3 criteria for SLE, and 9 had concomitant APS (472). Of 18 pregnancies accomplished, 9 resulted in live births. Planned OI procedures resulted in 6 live births of 7 pregnancies, whereas 75% of pregnancies ended with fetal loss when the diagnosis was unknown to the gynecologists. Pregnancy rates (25%) and SLE flares (27%) were higher with gonadotropin or GNRHa treatment, and lower with clomiphene (4% and 6% respectively). There was no OHSS in this report.

A protocol for the prevention of OHSS has been proposed (480).

Although APL have been found with greater frequency among women failing IVF, and some have been treated with heparin and aspirin, the Practice Committee of the American Society for Reproductive Medicine has examined seven prospective studies and concluded that there was no association between APL and IVF failure, that testing for APL is not indicated, and that treatment is not justified (481).

Family Planning and Counseling

The patient with SLE and her partner must be assured that she is just as fertile and capable of having children as any other woman; however, she has an increased likelihood of a high-risk pregnancy. She should ideally plan her pregnancy after a sustained remission of several months. She, her partner, and the physician should assess her functional limitations and explore her emotional motivation prior to undertaking pregnancy and the responsibilities of raising a child. Her socioeconomic setting and husband/mate relationship are no less important. The rheumatologist and obstetrician should counsel the patient and family about chances of flare, fetal loss, prematurity, and IUGR, and prepare her to cooperate with the rigorous follow-up necessary. Only in the event of severe renal, myocardial, or pulmonary compromise should elective abortion be considered. The patient and husband should be cautioned, however, about the possibility of flare after elective abortion.

Couples should be made aware of the following points:

- Women with lupus have normal fertility, therefore, there is a need for family planning, just as in individuals without lupus.
- The best time to plan a pregnancy is after a 6- to 12-month remission or at least quiescence of SLE, even though there is no guarantee that the disease will remain inactive. With conception after remission, the chance of a flare is 10% or less.
- The probability of a flare varies and depends on the severity and activity of disease. The milder the disease, and the less active, the lesser the chance of a flare during pregnancy.
- Hypertension and preeclampsia are more common in SLE with nephritis, with antiphospholipid antibodies, and particularly in patients conceiving with active disease.

- Increased pregnancy loss, especially with active lupus, nephritis, and antiphospholipid antibodies can usually be prevented with heparin and low-dose aspirin. Details and side effects of this treatment should be explained.
- The methods for monitoring fetal growth and cardiac health need to be clearly explained (see also Chapters 52 and 53).
- The potential necessity of and indications for cesarean section should be outlined beforehand (preeclampsia, fetal distress, abnormal nonstress test, maternal aseptic necrosis of the hips with inadequate hip abduction, and usual obstetric indications, including cephalopelvic disproportion, transverse presentation, and others).
- Prematurity may be as high as 60% in women with active SLE, and intrauterine growth restriction may reach 30% of premature deliveries. The need for proper care of the newborn in adequate intensive care units and afterward should be stressed.
- Women positive for anti-Ro/SSA and/or anti-La/SSB should be aware of the small risk (about 1.6–2%) of congenital heart block in the child, the need for early detection, and for in utero treatment.
- Prednisone treatment may increase prematurity and has a small risk of cleft lip and palate, whereas cytotoxic drugs during the first trimester, should they be needed for severe flares, carry a risk of congenital malformations
- With close monitoring and aggressive treatment during pregnancy and the postpartum period, no long-term worsening of SLE should occur.

In the poststeroid era, the early diagnosis and appropriate therapy of lupus have led to tremendously increased survival rates of SLE patients—up to 97% for 5 years, 93% for 10 years, and 83% for 15 years (162). Similarly, with increased awareness of the potential problems for the mother and fetus, meticulous multidisciplinary follow-up, and effective disease control, most women with lupus can and do achieve motherhood.
