Patients with central diabetes insipidus require MR imaging of the sellar region to rule out secondary causes. The posterior pituitary usually appears as a bright spot, corresponding to the presence of stored ADH. In patients with idiopathic diabetes insipidus such a bright spot is usually absent. However, the presence of a normal bright spot does not rule out the diagnosis of diabetes insipidus.

In contrast, nephrogenic diabetes insipidus is caused by kidney disorders in which the renal tubules do not respond normally to ADH. The condition can be familial or acquired through electrolyte derangements (e.g. hypokalemia, hypercalcemia), diseases of the renal interstitium that disrupt medullary concentrating mechanisms, or drugs that impair renal tubular function (e.g. lithium carbonate or demeclocycline). Familial nephrogenic diabetes insipidus can be transmitted as an X-linked character (due to defects in the ADH receptor gene) or, less frequently, autosomal recessive (due to defects in the gene encoding for the vasopressin-sensitive water channel aquaporin-2) (Bichet, 1998).

Differential diagnosis

Polyuria is not pathognomonic for diabetes insipidus, and the physician must consider other conditions when a patient presents with excessive urination. Polyuria can reflect primary renal diseases, diuretic therapy, and diabetes mellitus. The cause can also be compulsive water drinking, also known as 'psychogenic' or 'primary' polydipsia. Such chronic excessive water drinking can lead to temporary loss of renal medullary hypertonicity, which then impairs urine concentration even when the drinking is temporarily interrupted and plasma ADH levels rise, resembling nephrogenic diabetes insipidus. Primary polydipsia is usually diagnosed in young women with known psychiatric disease; in rare patients, the cause is a structural lesion in the hypothalamus. It needs to be suspected particularly in polyuric patients who have hyponatremia, never caused by diabetes insipidus.

The physician evaluating a patient with polyuria must first exclude an osmotic diuresis, such as the glycosuria of diabetes mellitus. The history and routine laboratory findings can generally exclude diabetes mellitus, primary renal diseases, drug effects, and electrolyte disturbances. The degree of polyuria can vary, up to 16–18 litres a day in case of total lack of ADH. Special tests are needed for certain systemic diseases that affect renal interstitial function, for example, sickle cell disease, amyloidosis, multiple myeloma, and Sjögren's syndrome. It is important to remember that lithium can cause a transient and a permanent form of nephrogenic diabetes insipidus. Therefore, lithium exposure needs to be considered as a possible etiology even if the medication has been discontinued.

Most patients need a water deprivation test to confirm diabetes insipidus and to distinguish central from nephrogenic diabetes insipidus. Fluids and food are withheld, starting in the morning to avoid dangerous nocturnal dehydration. Over the next 4–8 hours, hourly measurements of urine and plasma should show increasing osmolality and a two- to four-fold greater increase in urine osmolality than plasma osmolality. When plasma osmolality exceeds 295 mosm/l or urine osmolality stops rising, blood is drawn for ADH level and patients are given aqueous ADH or its analogue dDAVP. In normal people, endogenous ADH is already maximally stimulated, so exogenous ADH does not cause further urine concentration. Patients with complete central diabetes insipidus do not concentrate their urine despite a rising plasma osmolality, but do respond to exogenous ADH with a rise in urine concentration. Patients with nephrogenic diabetes insipidus also maintain dilute urines despite dehydration, and when they receive exogenous ADH, their urine osmolality does not rise above that of plasma. In selected cases with partial diabetes insipidus, a short administration of hypertonic saline may be needed to reach a serum osmolality of 295 mosm/l.

When central diabetes insipidus is diagnosed, patients should have a MRI scan to check the hypothalamic and pituitary regions for the presence of tumour or infiltrative diseases.

Patients with primary polydipsia may be difficult to identify with the water deprivation test because chronic dilution

Table 57.8. Distinguishing primary polydipsia from diabetes insipidus (DI)

Feature	Primary polydipsia	Diabetes insipidus
Onset of polyuria	Gradual	Sudden
Nocturia	Unusual	Common
Random plasma osmolality	Sometimes <285 mOsm/l	Normal or elevated
Morning plasma osmolality	Normal	Elevated
Morning urine osmolality	Normal	Inappropriately low
Plasma ADH concentration	Normal relative to plasma osmolality	Low relative to plasma osmolality (in neurogenic DI)

of their renal medullary osmolar gradient can prevent them from responding properly to either endogenous or exogenous ADH. However, other features may distinguish primary polydipsia from diabetes insipidus (Table 57.8). Polyuria usually begins gradually in primary polydipsia, but suddenly in diabetes insipidus. Patients with primary polydipsia may not have much nocturia, but most patients with diabetes insipidus have a constant urine output. Compulsive water drinkers do not share the high plasma osmolality and inappropriately low urine osmolality seen after overnight fasting in patients with central or nephrogenic diabetes insipidus. Most patients with primary polydipsia have at least one random plasma sample documenting an osmolality below 285 mosm/l (dilutional hyponatremia). Plasma ADH levels are normal relative to plasma osmolality in patients with primary polydipsia, but are low in patients with central diabetes insipidus.

Management

Patients with mild diabetes insipidus may not need drug treatment as long as they have an intact thirst mechanism and free access to water. However, patients with diabetes insipidus who are temporarily deprived of water can quickly develop circulatory collapse and hypertonic encephalopathy. Treatment is usually indicated when urine volumes exceed 5 l per day or when nocturia interferes with restful sleep.

DDAVP (Desmopressin^{R}), a long-acting synthetic analog of ADH, is the treatment of choice for central diabetes insipidus. The drug is usually given orally (0.1–0.2 mg once or twice a day) or by nasal insufflation (10 μg/spray, 1–2 spray a day). Subcutaneous injections (1 μg SQ 1–2 times a day) are available for situations in which oral or nasal administrations are not possible. The dose–effect equivalence between oral, intranasal and SQ administration is approximately 1/10/200. If patients with partial central diabetes insipidus require treatment, many can be successfully managed with chlorpropamide, which augments ADH release and potentiates its action on renal tubular cells. Most patients with normal glucose tolerance can take chlorpropamide in the low dose required, without developing symptomatic hypoglycemia. Clofibrate and carbamazepine can also augment ADH release. During pregnancy the dose requirement of DDAVP may increase, due to vasopressinase produced by the placenta.

There is no good treatment for nephrogenic Dl. Some patients show a partial response to high doses of DDAVP, but most are treated with volume contraction (thiazide diuretics) to decrease glomerular filtration rate.

Syndrome of inappropriate secretion of ADH (SIADH)

Differential diagnosis

Excessive secretion of ADH, termed the 'syndrome of inappropriate secretion of antidiuretic hormone' (SIADH), leads to excessive water retention and hyponatremia. SIADH is the most common cause of non-iatrogenic hyponatremia. The major causes of SIADH are ectopic secretion of ADH (e.g. by a small cell carcinoma), neurologic disorders, pulmonary diseases, and certain drugs (Table 57.9). Cardinal features of the syndrome are hyponatremia and serum hypo-osmolality resulting from an inappropriately concentrated urine.

Patients with mild SIADH may have few symptoms and signs, especially if hyponatremia develops slowly. But when the serum sodium falls below 130 meq/l, patients can become anorexic, lethargic, and confused, with nausea and muscle cramping. When the serum sodium falls below 115 meq/l, patients can become obtunded and develop seizures. The severity of symptoms generally corresponds to the degree of hypo-osmolality and the rate at which hyponatremia develops. Premenopausal women seem to be more sensitive to rapid fluxes in serum sodium than are men and postmenopausal women and have a higher risk of permanent neurologic damage following hyponatremic encephalopathy.

Table 57.9. Common causes of the syndrome of inappropriate secretion of antidiuretic hormone

1. Central nervous system diseases
Meningitis
Encephalitis
Brain abscess
Subarachnoid hemorrage
Postoperative (5–7 days after pituitary surgery)
2. Pulmonary diseases
Lung abscess
Pneumonia
Positive pressure ventilation
3. Tumours
Lung carcinoma (especially small cell)
Gastrointestinal malignancies
Prostate cancer
Thymoma
Lymphoma
4. Drugs
Vincristine
Chlorpropramide
Narcotics
Clofibrate
Carbamazepine
Nicotine
Phenothiazine
Cyclophosphamide

Hyponatremia is the most common form of electrolyte abnormality in hospitalized patients. Other causes of hyponatremia must be considered in the differential diagnosis of SIADH. Sodium may be falsely low ('pseudohyponatremia') in case of severe hypertriglyceridemia or marked increase in serum protein concentration. Hyperglycemia can cause hyponatremia by attracting free water in the extracellular space. Plasma glucose will generally decrease plasma sodium concentration by 1.6 meq/l for every 100 mg/dl increase in glucose above 100 mg/dl. The physician should determine clinically whether hyponatremic patients are euvolemic (normal water volume), hypervolemic, or hypovolemic. Although patients with SIADH do have modest volume expansion, they are not edematous. In patients with edema, the physician should consider the major causes of hypervolemic hyponatremia such as liver cirrhosis, heart failure, and kidney failure. Patients with glucocorticoid or thyroid hormone deficiencies can develop hyponatremia because these hormones are essential for normal renal tubular function and free water excretion by the kidney. Thus, the diagnosis of SIADH cannot be established until hypothyroidism has been excluded by measurement of the serum free T4 and TSH concentrations, adrenal insufficiency has been excluded, and kidney disease has been excluded by renal function tests. The physician should also seek a history of medications (chlorpropramide, carbamazepine, vincristin), neoplasia, pulmonary disease, and neurologic disorders known to be associated with SIADH.

In SIADH, urine sodium is generally above 20 meq/l, but it is usually below 20 meq/l in conditions with intravascular volume contraction or decreased effective plasma volume, for example, congestive heart failure, cirrhosis, and the nephrotic syndrome (Chung et al., 1987). The blood urea nitrogen and uric acid are low in SIADH but high in volume-contracted states. Lastly, in SIADH the urine is less than maximally dilute (50–100 mosm/kg) despite plasma hypo-osmolality. Occasionally the water load test helps the diagnosis of SIADH. After drinking 20 ml/kg of water, normal individuals reach maximally diluted urine ($<$100 mosm/kg) and eliminate 80–90% of the water load within 4 hours. This test should not be performed if serum sodium is $<$125 meq/l.

Management

The aims of treating SIADH are to correct hypo-osmolality and hyponatremia, and to diagnose and, when possible, treat the underlying disorder. It is important to understand that the brain can adapt to hyponatremia by releasing osmoles, provided that it develops slowly. Therefore, it is not unusual to find patients with marked hyponatremia who are absolutely asymptomatic. For the asymptomatic patient, water restriction to 500–1000 cc a day corrects hyponatremia at a rate of about 5 meq/l a day. Infusions of normal saline do not correct hyponatremia because the sodium is promptly excreted in the urine. Only symptomatic hyponatremia is treated with hypertonic saline (3% NaCl) until the serum sodium concentration reaches 125 meq/l (Verbalis & Martinez, 1991). An approximate way of calculating the rate (cc/hour) of hypertonic solution infusion is to multiply the ideal body weight by the desired hourly increase in serum sodium concentration. In a 70 kg patient, if an increase of 0.5 meq/l/hour is desired, the rate of infusion should be $70 \times 0.5 = 35$ cc/hour. Serum osmolarity should not be corrected faster than 12 meq/l in 24 hours, because of risk of potentially fatal central pontine myelolysis. Therefore, plasma sodium level should be monitored very closely during hypertonic solution infusion. Once a level of 125 is reached, hyptertonic solution should be discontinued and plasma osmolality is restored gradually by water restriction alone. For many patients with chronic SIADH in whom hyponatremia cannot be controlled with fluid restriction only, deme-

clocycline normalizes serum sodium by inhibiting ADH action in the kidney. Lithium carbonate acts similarly but is rarely used because it can be more toxic.

Fluid abnormalities after pituitary surgery

Manipulation of the pituitary gland during transphenoidal or transcranial pituitary surgery may cause transient or permanent abnormalities in ADH production, leading to diabetes insipidus or hyponatremia. Although a classical triphasic pattern is often reported when the posterior pituitary is permanently damaged (with transient diabetes insipidus followed by a SIADH phase and ultimately by permanent diabetes insipidus) the possible patterns are way more variable. In a large analysis of 1571 transphenoidal pituitary surgery done by Hensen et al. (1999) the classical triphasic pattern was observed only in 1.1% of patients. However, 8.4% developed hyponatremia (symptomatic in 2.1%) at some point during the first 10 postoperative days. Patients with Cushing's disease seem to have a particular high prevalence of polyuria and hyponatremia, and should be monitored particularly closely.

Part VII

Headache and pain

58

Peripheral nociception and genesis of persistent pain

Richard J. Mannion and Clifford J. Woolf

Neural Plasticity Research Group, Department of Anesthesia and Critical Care,
Massachusetts General Hospital and Harvard Medical School, Charlestown, Massachusetts, USA

Pain can be divided into two distinct categories, nociceptive and clinical. The detection of, or reaction to damaging or noxious stimuli, the phenomenon of nociception, is mediated in the periphery by highly specialized primary sensory neurons, the nociceptors. These have peripheral terminals that are activated only by high intensity mechanical, thermal and chemical stimuli. Nociceptive pain, the 'ouch' pain typically experienced on touching a hot object or stubbing a toe, is the readout from a protective system fundamental to maintaining bodily integrity in a potentially lethal environment. The key physiological role of this system is well illustrated by the tissue destruction produced both in the denervated (Charcot) joints and neuropathic ulcers in diabetic patients, or in the mutilating injuries seen in patients with congenital insensitivity to pain due to a loss of nociceptor sensory neurons during development, as a result of a mutation of the TrkA receptor (Indo et al., 1996). Nociceptive pain contributes to the pain associated with the onset of acute trauma and is amenable to a variety of therapies that directly target the nociceptor neuron. These include blocking input to the spinal cord with local anesthetic nerve blockade, epidural or spinal anesthesia or reducing transmission from the nociceptor to the CNS with high dose opioids.

Clinical pain has two general manifestations, that associated with tissue injury and inflammation, inflammatory pain, and that generated as a result of damage to the nervous system, neuropathic pain. Multiple distinct, but commonly coexisting pathophysiological mechanisms are responsible for the generation of clinical pain and these typically involve the recruitment of pain in response to sensory inputs other than just nociceptors (the pain is no longer purely nociceptive). Clinical pain, is moreover, the manifestation of profound alterations in sensory processing within the peripheral and central nervous systems, neuroplasticity. Two key features of clinical pain are that the pain may present in the absence of any obvious peripheral stimulus (spontaneous pain) and that there is typically an abnormal hypersensitivity to applied innocuous and noxious stimuli. Clinical pain can arise from insults to, or changes induced anywhere along, the somatosensory neuraxis from the peripheral innervation targets (as with osteo- or rheumatoid arthritis), in inflammatory pain, along peripheral nerves (postherpetic neuralgia and diabetic neuropathy), in the spinal cord (spinal cord injury) or the brain (stroke), for neuropathic pain. The aim of clinical pain treatment is the elimination of spontaneous pain and the normalization of sensibility, rather than the elimination of pain perception *per se*, but this can be achieved optimally only if the mechanisms responsible can be identified in individual patients and if treatments specific to each mechanism are available. At the moment, however, standard clinical techniques do not enable pain mechanisms to be unambiguously established, nor are there treatments suitable for each mechanism. Accelerating progress in the study of pain makes such a rational approach a realistic possibility for the near future, one that will require, however, considerable effort to translate molecular advances into new clinical diagnostic approaches and therapies. The aim of this chapter is to highlight the advances in our understanding of pain mechanisms and their clinical implications.

Primary sensory neurons and the dorsal horn

Sensory neurons are a heterogeneous group of neurons whose cell bodies are located within the dorsal root and trigeminal ganglia, and which have either myelinated A, or unmyelinated C, axons (Lawson, 1979). Making up approximately two-thirds of the population are the C-fibre neurons, the majority of which are nociceptors (some are

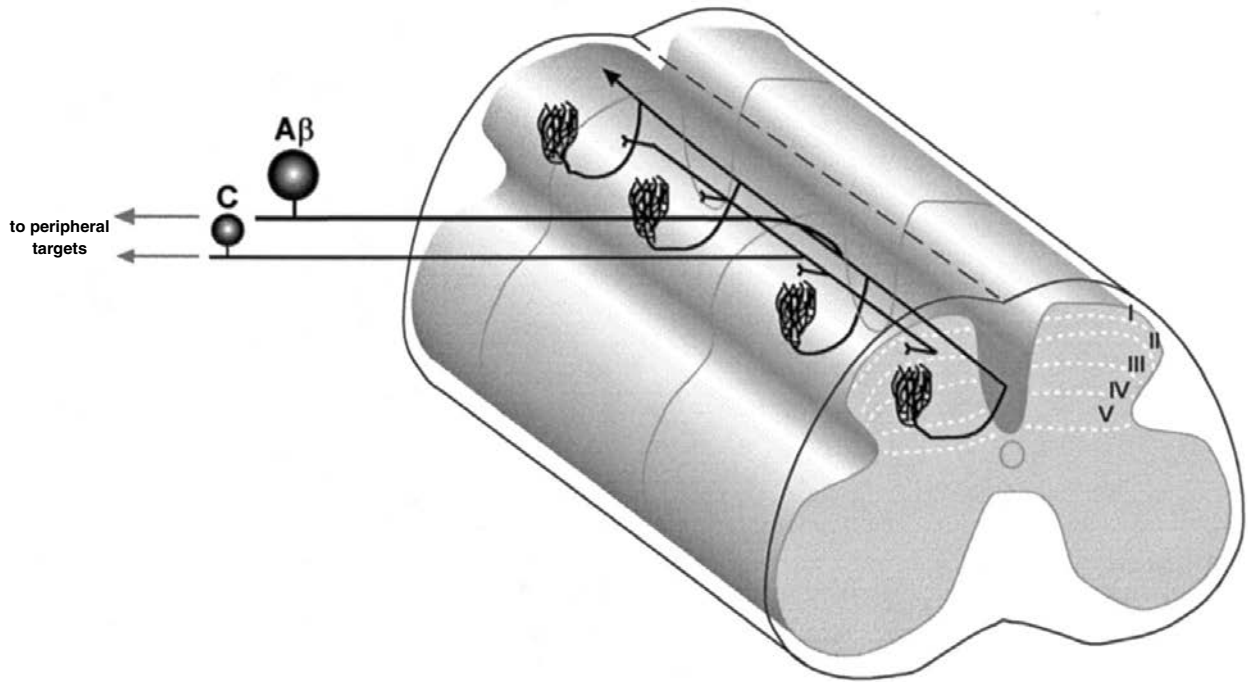

Fig. 58.1. Diagram showing Aβ- and C-fibre central axons entering the spinal cord. C-fibres synapse directly in the superficial dorsal horn. Aβ-fibre central axons enter the ipsilateral dorsal column pathway to travel up to the brain, synapsing in the dorsal column nuclei within the medulla. In addition, they give off multiple collateral axons that synapse within the deep dorsal horn over a few spinal segments.

innocuous warm receptors) (Willis & Coggeshall, 1991). Although some nociceptors are modality-specific, most are polymodal, responding to thermal, mechanical and chemical stimuli (Willis & Coggeshall, 1991). In addition, some are silent, unresponsive to all stimuli even at a very high intensities, but become active under pathological conditions, e.g. during inflammation (McMahon & Koltzenburg, 1990). The remaining sensory neurons (~30–40%) are the A-fibres, which are larger and are classified into three groups: the thinly myelinated Aδ fibres, which are predominantly nociceptive but include cool detectors; the myelinated Aβ fibres, many of which are cutaneous mechanoreceptors responsible for the detection of vibration, pressure and brush; and the large myelinated Aα fibres innervating muscle spindles and golgi-tendon organs, responsible for proprioceptive afferent input (Bonica, 1990).

The central terminal projections of primary sensory neurons in the dorsal horn of the spinal cord are highly ordered rostrocaudally, mediolaterally and dorsoventrally to form a somatotopic map of the body surface with minimal overlap between adjacent nerves (Willis & Coggeshall, 1991). C-fibres synapse directly onto second-order neurons in the ipsilateral dorsal horn either at the same spinal level that they enter the cord or within a few segments rostrocaudally. A-fibre central axons on entering the spinal cord via a dorsal root give off collateral axons to the dorsal horn before entering the dorsal column pathways and ascending to the brainstem (Fig. 58.1). Dorsoventrally, specific types of afferent innervate cytoarchitectonically distinct laminae in the dorsal horn. Aδ-fibres project to laminae I and V, Aβ-fibre collaterals project to the deeper dorsal horn laminae (III-V, with some input to lamina II inner (II_i)), while C-fibres project to lamina II. Lamina II outer (II_o), is therefore, innervated almost exclusively by C-fibres (Woolf, 1994) (Fig. 58.2(a), see colour plate section). In addition to producing excitation of pain projection pathways, afferent input also activates segmental inhibitory interneurons which feed back onto the projection neurons in a reciprocal arrangement to dampen down and functionally focus the effect of the input (Woolf, 1994) (Fig. 58.3(a)).

The spinal cord is the site of the first relay along the sensory neuraxis at which the transfer of sensory information can be controlled. The dorsal horn also receives descending innervation from brainstem regions like the periaqueductal grey via the raphe nuclei and locus ceruleus. These tonic and phasic inputs are both excitatory (e.g.

5HT) and inhibitory (e.g. NA and opioids) and act to modulate spinal transmission through the dorsal horn. In this way the amount and nature of sensory input transferred to the brain following a particular stimulus can be either facilitated or inhibited altering the relationship between peripheral stimulus and perceptual response. This form of sensory adaptability was a key feature of Melzack & Wall's gate control theory of pain (1965) and both increased facilitation and reduced inhibition have been implicated in persistent pain states.

Primary sensory neurons can be classified on the basis of their chemical phenotype (i.e. what genes they express). Sensory neuron phenotype is thought to be actively maintained by signalling molecules extrinsic to the neuron, such as growth factors expressed by cells in the peripheral targets and Schwann cells lining the axons (McMahon & Bennett, 1999), and molecules intrinsic to the neurons such as cell specific transcription factors (Wood et al., 1999). For unmyelinated C-fibres, one major phenotypic distinction made is that between peptidergic and non-peptidergic afferents, each forming approximately half of the population. The former express neuropeptide neuromodulators (e.g. SP, CGRP) while the latter do not. The former also express the high affinity NGF receptor TrkA, while the latter express the GDNF receptor binding complex and the $P2X_3$ purinoreceptor (McMahon & Bennett, 1999). The NGF and GDNF sensitive nociceptor populations terminate in laminae I / II_o and II_i respectively (Snider & McMahon, 1998) (Fig. 58.2(b), see colour plate section).

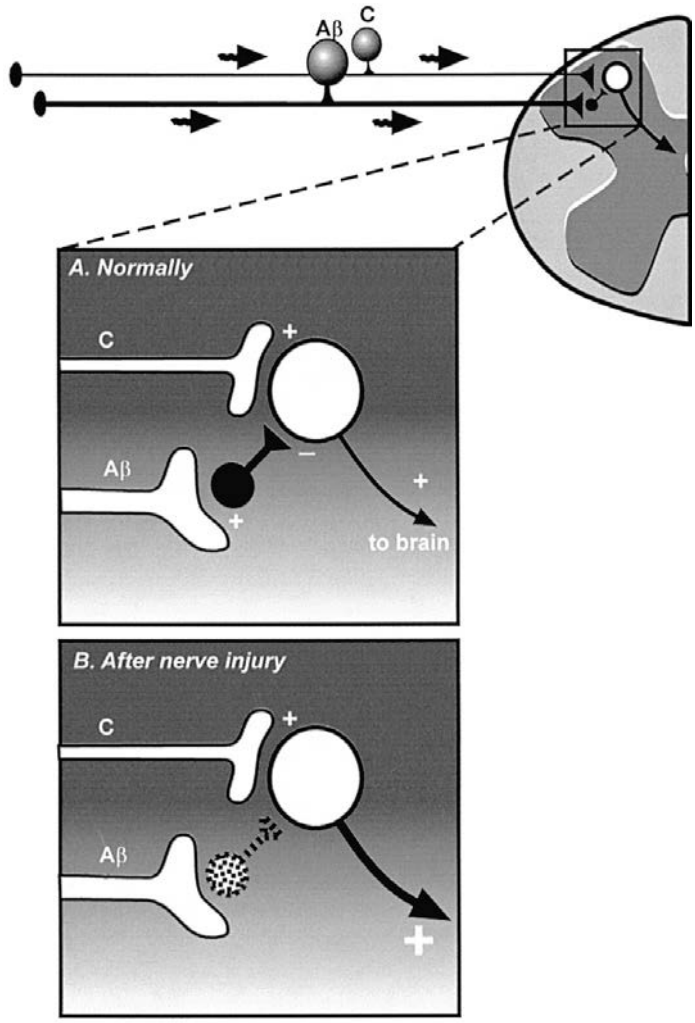

Fig. 58.3. (*a*) A noxious stimulus leads to the activation of both A- and C-fibres. C-fibres make monosynaptic connections with some spinal neurons that may also receive polysynaptic input from A-fibres that is relayed through an inhibitory interneuron (some Aβ input may also be relayed via excitatory interneurons). Thus, noxious input to spinal projection neurons through C-fibres is controlled to a certain extent by A-fibre activity. The inhibitory input acts to dampen down and functionally focus the effects of the C-fibre input. (*b*) Following nerve injury, many inhibitory interneurons in lamina II die leading to disinhibition of spinal projection neurons manifesting as increased excitation with a greater level of information being transferred to higher centres.

Activation: transduction, transmission and use-dependent augmentation

Primary nociceptor activation

For most of the time the 'protective pain system' lies quiescent, being activated only on exposure to damaging or potentially damaging events. The detection by nociceptors of noxious stimuli is the consequence of their selective expression of specialized transducer molecules, that when activated result in the opening of cation channels and the generation of inward currents at the peripheral terminal. Examples of these molecules are: the VR1 receptor for capsaicin (the active ingredient in chilli peppers), an ion channel that opens in response to heat (>42 °C); VRL1, another vanilloid receptor also activated by heat but at higher temperatures (>50 °C) (Caterina & Julius, 1999); chemosensitive molecules like $P2X_3$ purinoreceptors that detect ATP (released during tissue damage) and proton-gated ion channels like ASIC (acid-sensing ion channel) which respond to tissue acidosis (Wood et al., 1999); and molecules that transduce mechanical stimuli, candidates for which are the mDEG ion channels which are homologues of the degenerins, mechanotransducer proteins in the nematode *Caenorhabditis elegans* (Wood et al., 1999).

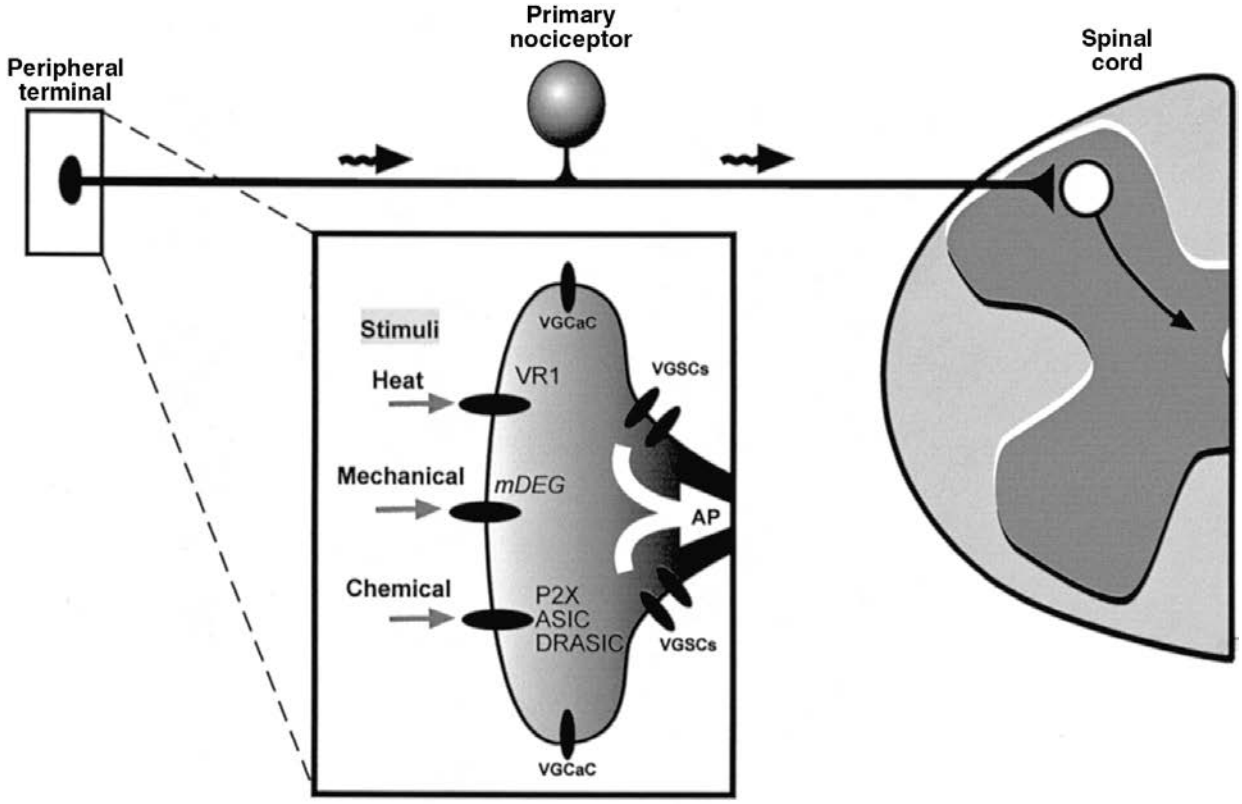

Fig. 58.4. Primary nociceptors responding to different stimulus modalities through the expression of specific transducer proteins on their peripheral terminal membranes. Activation of these proteins leads to the generation of inward currents that further activate voltage gated sodium channels (VGSCs). If stimulus intensity is sufficient to reach activation threshold, action potentials are generated and conducted orthodromically along the axon to the spinal cord. This represents pain normosensitivity.

Once specific transducer receptor/ion channels proteins are activated, depolarization of the nociceptor terminal by cation influx (the generator potential) activates voltage-gated sodium channels (VGSCs) in the terminal axon (Fig. 58.4). VGSCs are responsible for generating the upward phase of the action potential and in sensory neurons can be divided into two types based upon sensitivity to the puffer fish poison tetrodotoxin (TTX), either sensitive (TTXs) or resistant (TTXr) (Gold, 1999). TTXs sodium channels (there are up to six such channels in DRG neurons, most of which are expressed elsewhere in the CNS as well) play a major role in action potential conduction along the axon and are expressed by all sensory neurons. They are inserted into the membrane along unmyelinated axons or selectively at nodes of Ranvier along myelinated axons, mediating fast saltatory conduction (Waxman & Ritchie, 1993) (Fig. 58.5(a), see colour plate section). The TTXr channels, two of which have been cloned (SNS and SNS2) are however, expressed selectively by nociceptors and their electrophysiological properties are thought to mediate specific functional features of these neurons. For example, TTXr channels have higher activation and inactivation thresholds along with a rapid recovery when compared to TTXs channels, allowing them to remain active during sustained depolarization, a specific feature of nociceptor function (Bevan, 1999). The TTXr channels are likely to contribute both to the generator potential of nociceptors as well as to action potential conduction (Quasthoff et al., 1995).

The threshold of individual transducer proteins in the peripheral nociceptor terminal can be altered by prior activation, as with repetitive peripheral stimuli, an example of activation-dependent plasticity or autosensitization (Woolf & Salter, 2000). Such a lowering of threshold is observed in response to repeated thermal activation of the VR1 receptor producing a drop from 42 °C to about 38 °C and reverses rapidly. Similar thermal threshold changes for the VR1 receptor also occur after capsaicin or proton activation of the receptor. The increased sensitivity may be mediated either by conformational changes or by phos-

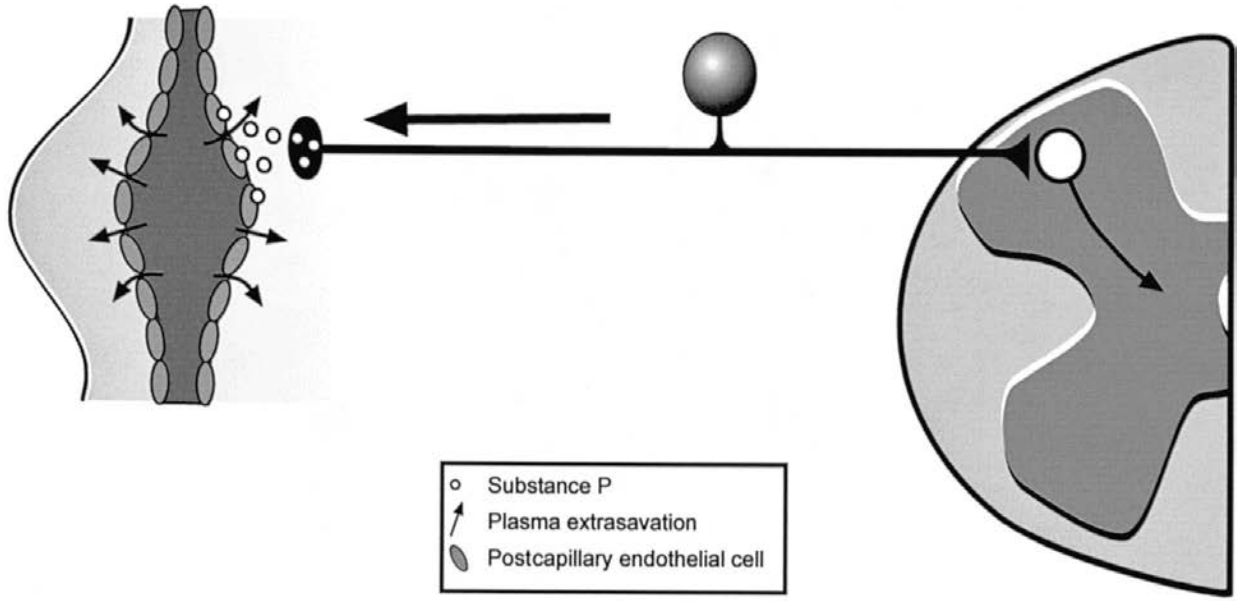

Fig. 58.6. Antidromic conduction of action potentials along nociceptor axons leads to the release of peptides such as CGRP and Substance P into the skin. These molecules bind to receptors on endothelial cells to cause vasodilatation and increase permeability leading to plasma extrasavation. This is known as neurogenic inflammation.

phorylation following calcium entry through the channel, which will activate intracellular kinases.

The selective expression of nociceptor-specific molecules such as VR1 has been exploited by clinicians for treatment targeted at the nociceptor. Topical capsaicin cream has been used to treat postherpetic neuralgia and painful diabetic neuropathy. Initially it results in nociceptor activation (through activation of the VR1 receptor), producing a burning sensation. However, with repeated application over days, the heightened pain is followed by a reduction in sensitivity, a consequence of nociceptor peripheral terminal degeneration that lasts for approximately 4–6 weeks and is thought to be due to prolonged calcium influx (Simone et al., 1998).

Local anesthetic nerve block produces a more rapid and reversible method of blocking primary nociceptor input, but sodium channel blockers such as lignocaine or bupivicaine are both non-selective (motor, sympathetic and proprioceptive sensory axons are also blocked) and limited by their cardiac and central nervous system side effects (they block all sodium channels in a use-dependent fashion). The recent identification of sensory neuron specific sodium channels offers the possibility for the development of highly selective nociceptor blockers/antagonists that will avoid unwanted side effects.

In addition to orthodromic action potentials moving from the peripheral terminal towards the spinal cord, C-fibres can conduct action potentials antidromically, i.e. from the spinal cord towards the periphery. This is important in producing neurogenic inflammation, where antidromic C-fibre activation causes the release of CGRP and SP from the peripheral terminals, acting on postcapillary venules to produce peripheral vasodilatation and increased capillary permeability respectively (Fig. 58.6). The exact role of neurogenic inflammation is controversial but it has been implicated in pain states, such as migraine, asthma, and arthritis as well as wound healing (Raja et al., 1999). It has also been suggested as a potential mechanism for the trophic skin and nail changes in Reflex Sympathetic Dystrophy (RSD)/Causalgia (Complex Regional Pain Syndrome type II) (Devor & Seltzer, 1999). It is not clear how this antidromic activation occurs; one possibility is that the central terminals of C-afferent fibres are depolarized by presynaptic axo-axonic synapses in the spinal cord, as part of presynaptic inhibition, and this can cause a backfiring of action potentials. Antidromic action potentials also occur as part of the axon reflex producing the flare response (Simone et al., 1998). This process is almost entirely absent in animals with a null mutation in genes for either Substance P or its receptor NK1, suggesting that this is a Substance P mediated phenonemon amenable to treatment with newly developed highly selective tachykinin antagonists (Woolf et al., 1998).

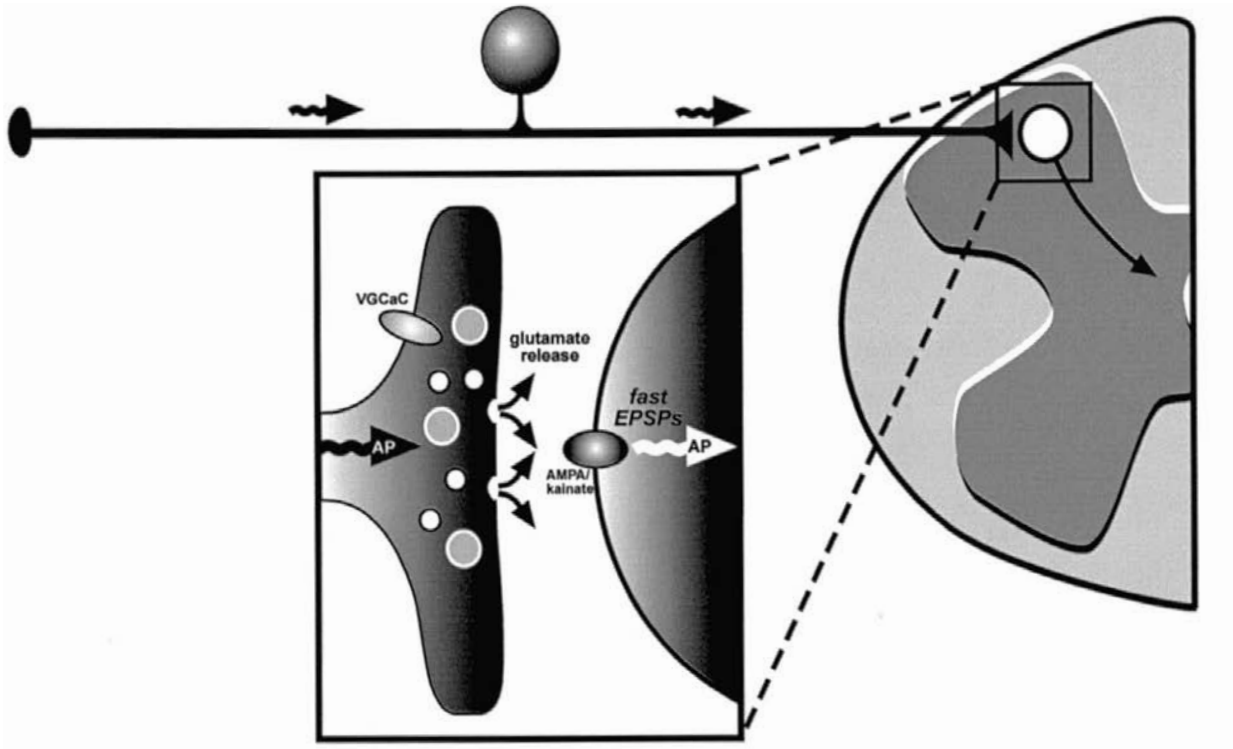

Fig. 58.7. Nociceptor activation leads to the release of glutamate, from primary afferent axon central terminals, that binds postsynaptically to AMPA receptors. If stimulus intensity is sufficient, action potential activation threshold is reached and the spinal projection neuron fires.

Activation of central pain pathways

Primary nociceptor activation leads to the propagation of action potentials to the spinal cord (the frequency of which codes for the intensity of the stimulus (Raja et al., 1999), where they invade central presynaptic terminals to elicit neurotransmitter release. Expressed upon the presynaptic terminal membrane are many different receptors for neurotransmitters/modulators whose activation (both as autoreceptors and from axo-axonic synapses) can alter intracellular calcium levels and the degree of transmitter release from the terminal, e.g. excitatory receptors such as the ionotropic glutamate receptors AMPA, kainate and NMDA, the metabotropic glutamate receptor mGluR, the NK1, P2X3, α_2-adrenoreceptors, 5-HT receptors, ACh_N receptors, EP (prostaglandin) receptors, and receptors which inhibit transmitter release, particularly those for GABA, adenosine and the opioids. A reduction in transmitter release is one of the major mechanisms underlying the analgesic actions of opioids.

Terminals of nociceptor neurons contain two types of synaptic vesicle, small clear glutaminergic vesicles, and large dense-core peptidergic vesicles (containing SP, BDNF, CGRP, etc). Terminal depolarization, with the influx of calcium through high threshold voltage dependent channels (e.g. N-type) results in the fusion of vesicles with the pre-synaptic membrane and the release of transmitters into the synaptic cleft. N-type calcium channels are inhibited by Ω-conopeptides which reduce inflammatory and neuropathic-related allodynia and hyperalgesia without affecting normal nociceptive responses (Vanegas & Schaible, 2000). The Ω-conopeptides have, however, a narrow therapeutic index and are associated with significant motor and sympatholytic side effects which limit their clinical use.

Following brief, noxious stimulation, spinal nociceptive transmission is mediated mainly, if not exclusively by glutamate released from small clear vesicles acting on AMPA and kainate receptors on postsynaptic dorsal horn neurons to produce fast excitatory post-synaptic potentials (EPSPs) (Yoshimura & Jessell, 1990). Much of this postsynaptic activity is subthreshold, but if stimulus intensity is sufficient, action potentials are generated and the spinal neuron fires at a discharge frequency that is linearly related to stimulus intensity (Fig. 58.7). It is this activity that signals the onset, intensity, and duration of transient

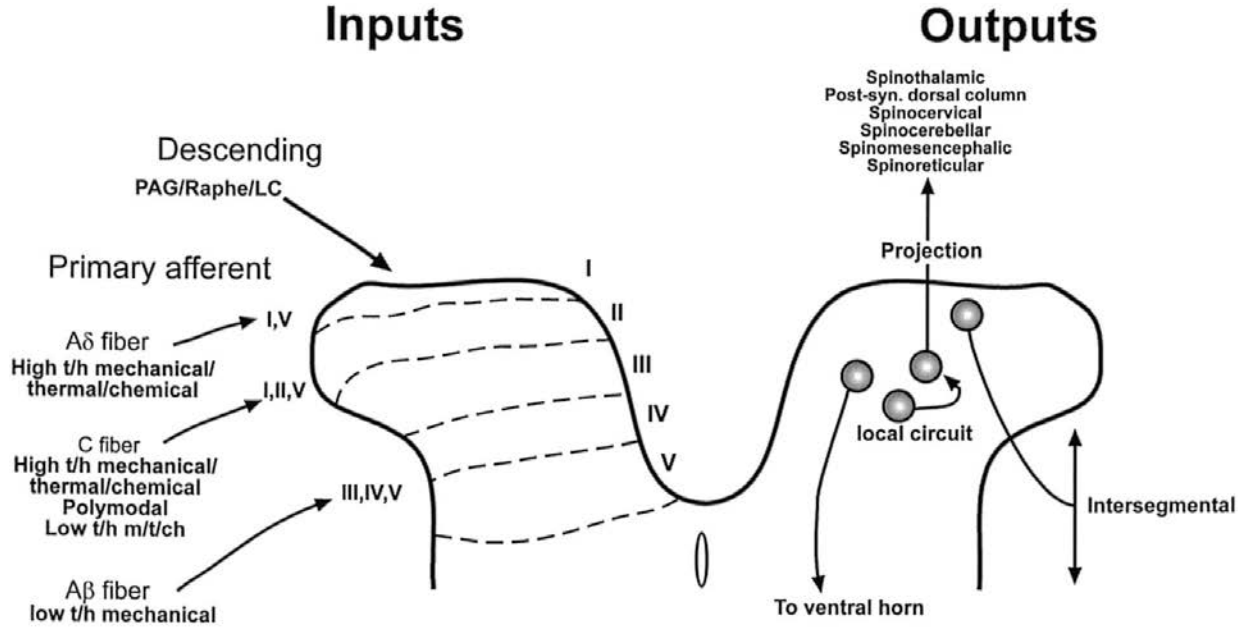

Fig. 58.8. A schematic diagram showing the major sources of inputs into and outputs from the dorsal horn.

noxious stimuli. Spinal neurons are a heterogeneous population often divided into those responding with an action potential output in response only to nociceptor input (nocispecific cells) situated predominantly within superficial regions of the dorsal horn, or those responding to C-, Aδ- and Aβ-fibre inputs, the non-nocispecific (also known as wide dynamic range) cells typically situated in deeper dorsal horn laminae. The electrophysiological properties of dorsal horn neurons are not fixed, however, and change dramatically under different situations such as after a sustained noxious stimulus, after nerve injury or in response to altered descending modulatory inputs. A nocispecific cell may, following a prolonged C-fibre input that induces increased membrane excitability and the recruitment of previously sub-threshold (e.g. Aβ) inputs, become a non-nociceptive specific cell. Similarly, a non-nociceptive cell may become unresponsive to Aβ input if descending modulatory inhibitory inputs increase following electrical stimulation of brain stem nuclei or pharmacologically with morphine (Fields & Basbaum, 1999).

Most neurons in the superficial dorsal horn that project to the thalamus via the spinothalamic tract express the NK1 (Substance P) receptor (Nichols et al., 1999). Neurons that project axons to the brain through the dorsal columns are implicated in visceral pain transmission. Some propriospinal neurons project a few segments along the spinal cord, allowing for the polysynaptic transfer of sensory input to the brain, a pathway implicated in somatosympathetic reflexes, and others project locally/segmentally, forming local excitatory and inhibitory networks (Fig. 58.8). Thus, although the anterolateral spinothalamic tract is sometimes referred to as the 'pain pathway', there actually exist multiple pathways by which primary nociceptor inputs are transferred to the brain. This is seen in patients suffering from chronic pain who, having been rendered 'analgesic' by an anterolateral cordotomy, commonly have their pain return after a period of months (Tasker, 1990). A 'twenty-first century' update of surgical anterolateral cordotomy, recently tested in animals, uses intrathecal infusion of a toxin conjugated to substance P. The substance P toxin conjugate, on binding to NK1 receptors on lamina I spinothalamic tract neurons, and following internalization, selectively kills only these cells (Nichols et al., 1999).

High frequency nociceptor activation following intense or prolonged noxious stimuli leads to the co-release, with glutamate, of neuromodulators such as SP, CGRP and BDNF, possibly controlled by intracellular calcium concentrations (Cao et al., 1998). The corelease of peptides/proteins results in the production of slow synaptic potentials due to activation of ionotropic (AMPA/kainate) and metabotropic (e.g. mGluR, NK1) receptors as well as the NMDA receptor (which at resting membrane potential is blocked by magnesium but opens during depolarization). These slow potentials last for seconds to minutes and have the potential to summate temporally, such that a repetitive noxious stimulation at $>$0.5 Hz produces a progressively

greater postsynaptic response (a cumulative depolarization), which is further augmented by the activation of postsynaptic voltage dependent calcium-activated cation channels. The increased action potential discharge that results is known as wind-up and is an example of spinal autosensitization and represents a short-lasting mechanism for boosting pain transmission. Psychophysical correlates of wind-up can be shown in humans both after repeated heat stimuli and in patients suffering from neuropathic pain (Arendt-Neilsen et al., 1995).

Modulation: reversible alterations in pain processing

The hypersensitivity that accompanies peripheral inflammatory disease or nervous system lesions arises as a consequence of alterations in sensory processing. These alterations can be divided into two mechanistic categories: modulation, a reversible alteration in primary and secondary nociceptor function, brought about by post-translational changes in specific signalling molecules (e.g. through phosphorylation) and modification, longer-term potentially irreversible changes in signalling within the sensory system, involving altered gene expression, neuronal and non-neuronal cell death and the structural reorganization of peripheral terminals and of interneuronal connectivity in the spinal cord (Woolf & Salter, 2000).

Modulating the sensitivity of primary nociceptors

The threshold at which nociceptors are activated determines basal pain sensitivity, the point at which neural activation may lead to the sensation of pain. Inflammatory pain is associated with an increase in nociceptor terminal membrane excitability, increasing basal sensitivity by reducing the activation threshold (enabling normally innocuous inputs to activate the terminal) and increasing suprathreshold responses of the nociceptor terminal to noxious stimuli (peripheral sensitization). This phenomenon accounts for the hypersensitivity to chemical and thermal stimuli at the site of tissue damage in inflammatory pain, but less so for mechanical hypersensitivity, which is largely a central phenomenon.

Peripheral sensitization occurs as a consequence of the local action of inflammatory mediators on the nociceptor terminal. Tissue injury results in the release of ATP and protons from damaged cells, 5-HT and histamine from mast cells, cytokines like TNF and IL-1 from macrophages, prostaglandins, bradykinin and growth factors like NGF and LIF (Woolf & Costigan, 1999) (Fig. 58.9). Some of these mediators (ATP, bradykinin) can directly activate the terminal eliciting pain, others (NGF, PGE_2) do not activate the terminal but sensitize it. The low levels of NGF produced normally in the target tissue maintain normal basal sensitivity to thermal stimuli (Bennett et al., 1998), but increased NGF increases pain sensitivity (Lewin & Mendell, 1993), which has limited its use as replacement therapy for neuropathies in humans. NGF does not directly depolarize the terminal but sensitizes it, on activation of its tyrosine kinase TrkA receptor, to subsequent thermal and chemical input, both through a short latency (seconds) effect on the VR1 receptor (Shu & Mendell, 1999) as well as slower onset changes (>6 hours) in the level of gene expression in the DRG following retrograde transport of the internalized NGF-TrkA complex to the cell body.

Other peripheral sensitizing agents include prostaglandins particularly PGE_2, 5-HT and adenosine, which activate protein kinase A (PKA), and noradrenaline and bradykinin, which activate PKC (Woolf & Costigan, 1999). The predominant mechanism responsible for peripheral sensitization is phosphorylation of membrane bound receptors and ion channels in the peripheral terminal by the kinases PKC and PKA. Activation of PKC results, for example, in phosphorylation of the TTXr sodium channel SNS/PN3, enhancing nociceptor excitability by increasing the inward current produced by any depolarizing stimulus (Gold, 1999). A similar phosphorylation of the VR1 receptor is likely. Although many PKC isoforms are expressed by primary nociceptors, the PKC′ isoform plays a pivotal role in bradykinin (BK), noradrenaline and heat-induced hypersensitivity without involvement in normal nociceptor activation (Cesare et al., 1999).

The molecules that contribute to the generation of this modulation of nociceptor terminal excitability represent potential targets for the development of antihypersensitivity/analgesic treatments for inflammatory pain which could be aimed at reducing the build up or action of inflammatory mediators (IL-1 / TNFα neutralizing antibodies or fusion proteins, NSAIDs, bradykinin antagonists, NGF antibodies/fusion proteins) or kinase inhibitors that block the phosphorylation of nociceptor signalling molecules. The use of cyclo-oxygenase (COX) inhibitors to treat inflammation by reducing prostaglandin synthesis is central to the current management of conditions like rheumatoid arthritis and the introduction of highly selective COX-2 inhibitors (the inducible cyclo-oxygenase isoform) designed to avoid the gastrointestinal and other side effects of COX-1 inhibitors (the constitutive isoform) has been a major advance.

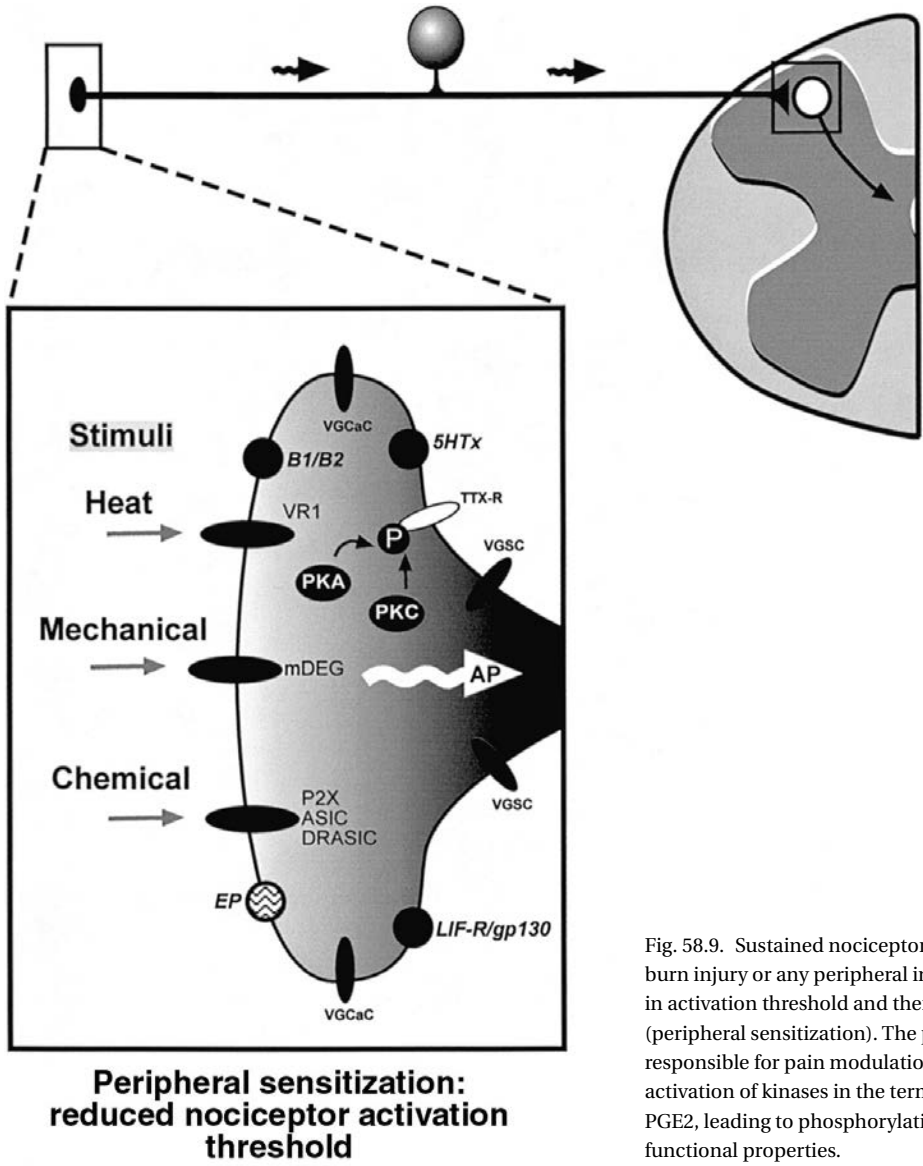

Fig. 58.9. Sustained nociceptor activation such as following a burn injury or any peripheral inflammation leads to a reduction in activation threshold and thereby to pain hypersensitivity (peripheral sensitization). The predominant mechanism responsible for pain modulation in primary nociceptors is activation of kinases in the terminal by sensitizing agents such as PGE2, leading to phosphorylation of ion channels, altering their functional properties.

Peripheral sensitization predominantly contributes to local hypersensitivity where there is local inflammation. In some patients with nerve lesions, however, an increased nociceptor terminal excitability has been detected clinically, particularly in a subgroup of patients with postherpetic neuralgia who can be identified by a reduction in thermal pain threshold at the site of their lesions (Fields et al., 1998). This has led to the recent development of lignocaine patches that can be applied directly to painful areas, limiting systemic action, and these have been used to treat that subtype of postherpetic neuralgia where 'irritable (overactive) nociceptors' are implicated (Fields et al., 1999).

Modulating central pain pathways:

If the intensity/duration of nociceptor input to the spinal cord increases beyond a critical threshold, in addition to the direct fast activation of the dorsal horn neurons during the input, a long-lasting facilitation of sensory transmission occurs in the spinal cord, which is known as central sensitization (Woolf, 1983). Central sensitization manifests as a reduction in the threshold of activation of the dorsal horn neurons, an increase in their receptive field size and an increased response to suprathreshold inputs and is due to a maintained increase in synaptic efficacy. This contributes,

with peripheral sensitization, to primary hyperalgesia but is exclusively responsible for the abnormal sensitivity to noxious and innocuous inputs to uninjured tissue adjacent to the site of injury, such as the production of pain on activation of low threshold Aβ fibres (tactile allodynia) and Aδ fibre mediated pin-prick hyperalgesia. In common with peripheral sensitization, this form of central modulation occurs as a consequence of the activation of specific intracellular signal transduction molecules that post-translationally modify receptors and ion channels, but in this case, on the postsynaptic membrane of dorsal horn neurons. This post-translational processing increases membrane excitability such that the stimulus–response relationship of the neuron is augmented, increasing the spinal response to both innocuous and noxious inputs.

The AMPA and NMDA glutamate receptors expressed on dorsal horn neurons are crucial to this functional synaptic plasticity, which may occur either at the activated synapse (homosynaptic facilitation) or spread to neighbouring synapses (heterosynaptic facilitation). Homosynaptic facilitation of spinal AMPA receptor-mediated responses to nociceptor inputs is thought to occur via a mechanism similar to long-term potentiation in CA1 hippocampal neurons. Brief high frequency (100 Hz) inputs lead to the summation of fast AMPA-mediated EPSPs that release the NMDA receptor magnesium block, increasing channel opening and intracellular calcium levels postsynaptically. Calcium-activated kinases, e.g. calcium/calmodulin dependent kinase II (CaMKII) or PKC can then phosphorylate the AMPA receptor on serine or threonine residues increasing AMPA mediated postsynaptic activity for a long period. These changes contribute to the facilitation of responses to subsequent inputs in the same nociceptors that initiated this form of synaptic plasticity. Heterosynaptic facilitation, in contrast, is initiated by much lower stimulation frequencies (1 Hz) in nociceptors and causes a spatially dispersed synaptic enhancement in dorsal horn neurons. This NMDA receptor-mediated increase in membrane excitability leads to the augmentation of the response to subsequent Aβ, Aδ and C-fibre inputs, the first of which leads to tactile allodynia, a major feature of inflammatory and neuropathic pain. This form of NMDA-mediated functional enhancement is the consequence of NK1, mGluR and TrkB receptor activation, secondary to the release from C-fibre terminals of substance P, glutamate and BDNF, followed by convergent activation of second messenger kinases (such as PKCγ) that in turn phosphorylate an intracellular tyrosine kinase src. Src when activated phosphorylates the NMDA receptor on tyrosine residues modifying its channel kinetics and voltage-dependent characteristics, increasing membrane excitability. Other postsynaptic kinase signalling cascades have also been implicated in central sensitization such as the mitogen-activated protein kinase (MAPK), whose activity is induced in the superficial dorsal horn by nociceptor activity and whose pharmacological inhibition reduces central sensitization experimentally (Ji et al., 1999). Not all the substrates of these kinases have been identified, nor have all the phosphatases involved in regulating their activity. Nitric oxide (NO) generated in dorsal horn neurons following calcium entry is also believed to facilitate NMDA-mediated central sensitization through a positive feedback onto the presynaptic membrane enhancing further transmitter release (Fig. 58.10).

Central sensitization represents a major area for potential new analgesics, ones that could be targeted presynaptically to block neuromodulator release, or postsynaptically to block receptor activation or inhibit intracellular kinases. Since the NMDA receptor is downstream of most of the signalling activity that leads to central sensitization, NMDA receptor antagonists may also have a major role as antihypersensitivity agents. NMDA receptor antagonists, such as ketamine or dextromethorphan, have been found to reduce hypersensitivity in patients with inflammatory and neuropathic pain, but their use is limited by psychotropic side effects due to the widespread distribution of these receptors. Antagonists for the glycine site on the NMDA receptor or those directed at the NR2a NMDA receptor subunit may have a greater therapeutic index and could make a major contribution to normalizing centrally generated pain hypersensitivity.

Central sensitization has been shown to contribute to the generation of both postsurgical and neuropathic pain hypersensitivity (Dahl et al., 1992; Stubhaug et al., 1997; Koltzenburg, 1998). Recently, both peripheral and central sensitization have also been implicated in the pathogenesis of migraine. Early on, pain and associated hypersensitivity in migraine is lateralized on the head, often around or above the orbit, a feature thought to be mediated by peripherally sensitized primary nociceptors (Strassmann et al., 1996). Within hours, hypersensitivity spreads over a much wider area and this has been correlated with the induction of central sensitization within brainstem (Burstein et al., 2000). Treatment early in attack should be targeted, therefore, at preventing/reducing peripheral sensitization, which will then prevent the establishment of central sensitization. If an attack is not aborted early, treatment will have to be targeted at the established central sensitization.

An area where targeting central sensitization contributes to clinical management is use of pre-emptive anal-

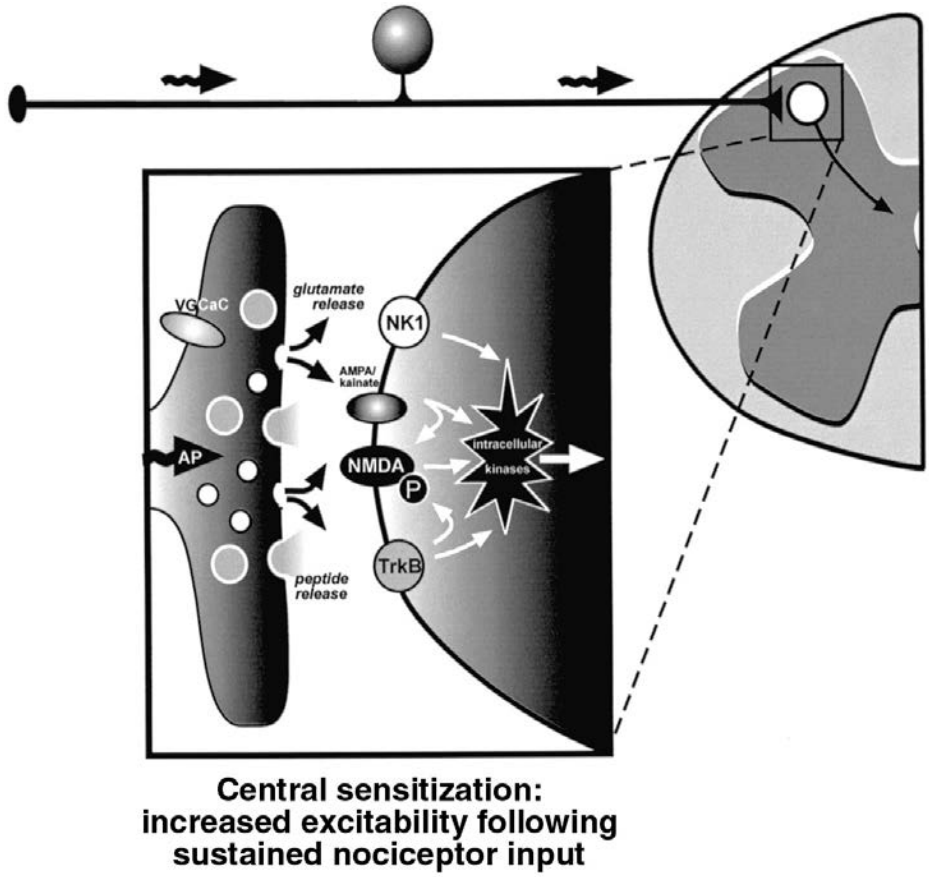

Fig. 58.10. Prolonged nociceptor input to the spinal cord leads to a use-dependent increase in neuronal membrane excitability that long outlasts the duration of the stimulus. A key molecule in this process, known as central sensitization, is the NMDA glutamate receptor. Other receptors such as the substance P receptor NK1 and the BDNF receptor TrkB are involved by means of activating many postsynaptic kinases, which then act to phosphorylate the NMDA and other receptor/ion channels.

gesia to reduce postoperative pain. The rationale is that by blocking C-fibre input to, or action on, the spinal cord before a surgical incision is made, the dorsal horn will remain in a state of normosensitivity and the patient will require less postoperative analgesia. Although this has been borne out in many carefully designed placebo controlled clinical trials using ketamine, opioids and regional anesthesia, this approach has not yet been fully optimized. One problem is that a sensory input sufficient to drive central sensitization will be generated both intraoperatively by surgically induced activation of nociceptors, and postoperatively by input arising from the injured and inflamed tissue. For this reason pre-emptive treatment administered preoperatively alone is insufficient, it needs to continue into the immediate postoperative period.

Modification: long-lasting alterations in pain processing

In addition to the reversible changes in nociceptor and dorsal horn neurons during peripheral and central sensitization, long-term and potentially irreversible changes can occur in these cells, which can be divided into two types: phenotypic and structural, including degeneration, cell death and sprouting and contribute to altered synaptic input, changes in synaptic connectivity as well as disinhibition.

Phenotypic modifications in the sensory system

Both peripheral inflammation and nerve injury can change the phenotype of primary sensory and dorsal horn

neurons. The raised levels of NGF at the site of the inflammation results in an increase in NGF-regulated peptide transmitters expressed by sensory neurons (substance P, CGRP and BDNF). This involves both an increase in those cells which normally express these synaptic neuromodulators, as well as novel expression in sensory neurons which normally do not contain them, such as neurons with myelinated axons, a switch from an A-fibre phenotype to a C-fibre phenotype (see Fig. 58.10). In addition to the retrograde transport of NGF, increased activity in sensory neurons appears to be sufficient to alter transcription (Mannion et al., 1999).

For nerve lesions, the disconnection of the neuronal body from its target cuts off the cell body from target-derived peripheral growth factor signals and introduces the neuron to novel signals (such as local inflammation at the site of injury, molecules produced by denervated Schwann cells and altered activity patterns) all of which can lead to a change in sensory neuron phenotype. Nerve injury results in increased excitability in the injured neurons as a consequence of transcriptionally and post-translationally mediated alterations in voltage gated sodium channel function as well as a reduction in potassium channel expression which may be sufficient to generate ectopic activity leading both to spontaneous burning pain and paresthesias (Waxman & Ritchie, 1993). Injured C-fibre afferents dramatically up-regulate a TTXs sodium channel, Brain III, normally only expressed by sensory neurons at high levels during development. This switch to a phenotype resembling developmental (embryonic) neurons is seen for many molecules including structural growth related proteins like growth associated protein-43 (GAP-43). A-fibre neurons distribute sodium channels differently following nerve injury and no longer are they found solely at Nodes of Ranvier (Waxman & Ritchie, 1993) (Fig. 58.5(*b*), (*c*), see colour plate section). In particular, sodium channels accumulate at the site of the neuroma and this alters the activation properties of cells and becomes a site for ectopic discharge, as can be demonstrated by tapping the neuroma site as in the Tinel sign in carpal tunnel syndrome. Peripheral nerve injury also results in the development of increased adrenoreceptivity, either due to increased local catecholamine levels following sympathetic axon sprouting into injured tissue and the DRG or following the up-regulation of α_2-adrenoreceptors by sensory neurons which may contribute to the development of sympathetically maintained pain (Devor & Seltzer, 1999).

Although the phenotypic changes in C-fibres after inflammation and nerve injury tend to be in opposite directions, remarkably, both nerve injury and inflammation induce substance P and BDNF expression *de novo* in those large A-fibre neurons normally involved in signalling low threshold innocuous stimuli (Fig. 58.11). A novel feature of both these clinical pain states is that contrary to the normal situation, where only C-fibre input can induce central sensitization, low threshold fibre stimulation can lead to central sensitization and in consequence a build up of pain hypersensitivity known as progressive tactile hypersensitivity (PTH) (Ma & Woolf, 1996). Apart from an increased synaptic drive by virtue of such phenotypic shifts, peripheral nerve injury also results in reduced inhibition as a result of the down-regulation of opioid receptors on injured primary afferents and this may contribute to the relative decrease in morphine sensitivity frequently found in patients with neuropathic pain.

Dorsal horn neurons also show phenotypic changes including up- and down- regulation of receptors such as NK1, TrkB and GABA-R. Alterations in dorsal horn transmitters also occur including increases in dynorphin, GABA and COX-2. These changes may be the result both of alterations in synaptic input as well as systemic signals from cytokines and they may contribute both to an alteration in responsiveness to primary afferent input as well as modifying intrinsic dorsal horn neuronal function.

Postinjury sensory neuron cell death and central sprouting

During development, primary sensory neurons are dependent for survival upon a limited supply of trophic factors expressed in peripheral targets, with around 50% of neurons undergoing apoptosis, known as programmed cell death. After experimental nerve injury in adult animals, although there are small increases in the number of cells undergoing apoptosis (Groves et al., 1998), there are no significant changes in DRG cell or axon number for up to 4 months (Coggeshall et al., 1996), suggesting that adult sensory neurons are independent of target-derived growth factors for survival. The cell death that does occur is predominantly in C-fibres leaving most A-fibre neurons intact. The degree and timing of cell death associated with other insults such as herpes zoster infection remains controversial (Oaklander, 1999) but there is a marked reduced innervation of the epidermis in many of these patients (Oaklander et al., 1998), which contributes to decreased thermal sensitivity and a loss of histamine-induced flare in such patients, while leaving A-fibre terminals in the dermis intact to signal tactile allodynia.

Although nerve injury does not at early time points result in neuronal cell death, it induces the transganglionic degeneration of C-fibre central terminals within the superficial dorsal horn (Doubell et al., 1999). Shortly after, Aβ-

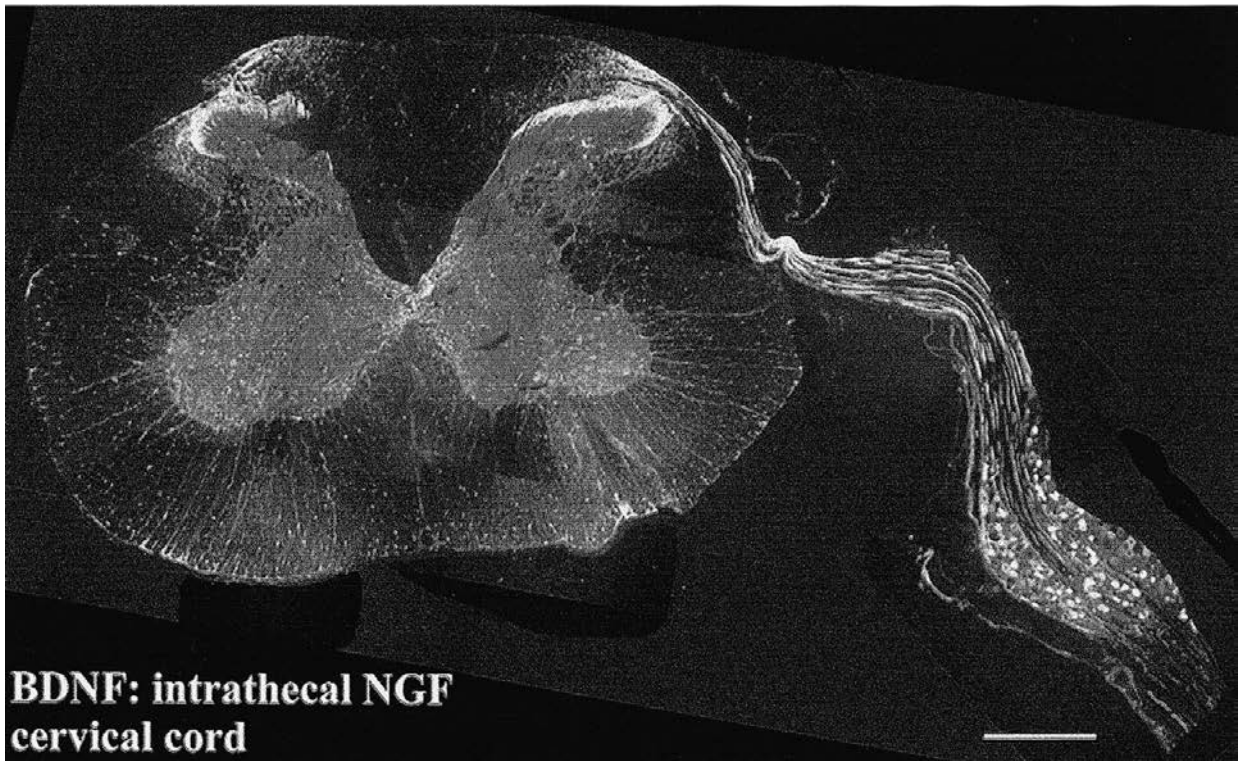

Fig. 58.11. BDNF is expressed by a subpopulation of sensory neurons in the DRG, predominantly those that express the NGF receptor TrkA. BDNF is synthesized in the cell body and transported centrally into the spinal cord where immunoreactivity can be seen in the superficial laminae of the dorsal horn. Following nerve injury and inflammation and intrathecal NGF administration, BDNF expression is increased and some A-fibres begin to express BDNF. (Printed with permission from Michael et al., 1997.)

fibre collateral central terminals sprout dorsally into superficial regions that normally are innervated specifically by C-fibre neurons (Woolf et al., 1992) (Fig. 58.12, see colour plate section). These sprouted collateral axons make novel synapses with dorsal horn neurons (Woolf et al., 1992; Kohama et al., 2000). Direct monosynaptic input to lamina II may result in the misinterpretation of A-fibre input as C-fibre input, an anatomical substrate for tactile allodynia (Koerber et al., 1999). The spinal A-fibre sprouting in animals is considered a consequence of C-fibre injury (Mannion et al., 1996) possibly as a consequence of peripherally derived growth factor deprivation as suggested by the prevention of the sprouting with intrathecal NGF or BDNF administration (McMahon & Bennett, 1999).

Tonic and phasic central inhibition of sensory transmission, a major part of normal sensory processing, is reduced in superficial laminae following nerve injury as a result of the decreased expression of inhibitory transmitters and receptors and direct cell death of local inhibitory interneurons in this region (Coggeshall et al., 1998; Fig. 58.3(b)). The novel presence of A-fibre terminals in lamina II after nerve injury may contribute to excitotoxic interneuron death in the superficial dorsal horn, manifesting as progressive disinhibition and worsening neuropathic pain. Such a disinhibition is functionally equivalent to an increase in excitation. In animal models, blocking glycine or GABA receptors locally in the spinal cord produces tactile allodynia. If similar changes occur in patients the issue then is how to prevent/treat this disinhibition. The former may be possible by blocking excitotoxic inhibitory interneuron loss soon after injury with NMDA receptor antagonists, the latter may require administration of GABAergic compounds.

In conclusion, the three functional states of the sensory system: activation, modulation and modification, are distinct but overlapping and will manifest in most patients with chronic pain, to a greater or lesser degree. Thus, successful treatment will never be achieved with single agents which act only on one state. Persistent pain is, therefore, a family of syndromes initiated by diverse etiological factors, the expression of which is a reflection of the activation of

diverse neurobiological mechanisms. These syndromes demand a multilayered management strategy targeting not just the mechanisms but also their evolution within the individual. The breakdown of complex symptoms into their cellular and molecular components is expanding our understanding of individual features of pain syndromes as well as identifying new targets to develop rational treatment plans. The key challenges for a rational mechanistically orientated treatment are to be able to identify individual mechanisms within patients using simple, reliable and reproducible clinical tests and to identify specific treatments that have the potential to treat individual mechanisms responsible for hypersensitivity, without the abolition or even reduction of pain normosensitivity. The challenge of conquering pain is enormous and will be difficult but the need is great, as are the opportunities.

Chronic pain is an immense unsolved clinical problem. Current approaches to this condition are limited by uncertainty about mechanisms of acute and chronic pain in man. Although much progress has been made toward understanding peripheral neural mechanisms of human nociception (Willis, 1985; Price & Dubner, 1977), we have a poor understanding of CNS pain mechanisms. Spinal mechanisms of pain processing are the subject of the previous chapter. The purpose of the present chapter is to review the anatomy and physiology of the ascending spinal pathways and supraspinal centres with pain-related activity. This chapter will focus on the primate nervous systems since there are significant differences between pain transmission in primates and other species such as cats and rats.

It is widely recognized that there are different components to the pain sensation (Melzack & Casey, 1968; Casey, 1978). The sensory–discriminative aspect of pain refers to the intensity of the sensory experience of pain. The motivational–affective aspect of pain refers to the unpleasantness of the pain and how likely it is that the pain will motivate the organism to escape the pain. Throughout this chapter we will refer to these different components of the pain sensation.

Ascending spinal pathways

The two main output somatosensory tracts from the spinal cord are the anterior–lateral and the dorsal column spinal systems. The anterior–lateral system terminates in the brainstem and thalamus while the dorsal column system terminates in the dorsal column nuclei (Willis, 1985).

The anterior–lateral spinal column

Anatomy

The cell bodies of origin for the anterior–lateral system are found in the spinal dorsal horn, particularly in lamina I, outer layers of lamina II and in laminae III to V; though some cells are also found in laminae VI to IX (Willis, 1985; Willis & Coggeshall, 1991). The spinal pathway from the spinal cord to the thalamus, the spinothalamic tract (STT) is partly located in the anterior lateral column. The STT system consists of two tracts, one positioned in the ventral lateral and the other in the dorsal lateral spinal funiculus (Cusick et al., 1989; Apkarian & Hodge, 1989b; Craig, 1997; Ralston & Ralston, 1992) and most commonly referred to as the 'ventral' and 'dorsal' STTs, respectively (Ralston & Ralston, 1992; Zhang et al., 2000). The axons of cells in the deeper spinal laminae project via the ventral tract while those from more superficial laminae project in the dorsal STT (Apkarian & Hodge, 1989a,b).

Axons and axon collaterals of the spinal projection neurons that ascend in the ventro-lateral spinal quadrant terminate in a number of nuclei of the medulla, midbrain and diencephalon (Mehler, 1962; Mehler et al., 1960). These include in ascending order, the medullary reticular formation (via the spino-reticular tract) (Kevetter et al., 1982; Menetrey et al., 1982), the mesencephalic periaqueductal grey and neighbouring area (spino-mesencephalic tract) (Bjorkeland & Boivie, 1984; Mehler et al., 1960; Menetrey et al., 1982), the parabrachial nucleus (spino-parabrachial tract) (Saper, 1995; Saper & Loewy, 1980; Slugg & Light, 1994), and the hypothalamus (spino-hypothalamic tract) (Burstein et al., 1987, 1990).

Anterior–lateral spinal columns

Physiology

Neuronal responses

Both non-nociceptive and nociceptive spinoreticular (Blair et al., 1984; Fields et al., 1977; Haber et al., 1982), spinomesencephalic (Hylden et al., 1986; Yezierski & Schwartz, 1986; Yezierski et al., 1987), spinohypothalamic (Burstein et al., 1991; Katter et al., 1996), spino-parabrachial (Bernard & Besson, 1990), and spinothalamic (Craig & Hunsley, 1991; Palecek et al., 1992a, b; Surmeier et al., 1988), neurons have been demonstrated in many animal species. The non-nociceptive projection cells are termed low-threshold or LT neurons. These are an infrequently observed cell group, usually comprising no more than about 10% of dorsal horn neurons (Dougherty et al., 1993, 1998, 1999). The two types of nociceptive spinal projection neurons identified in the spinal cord include wide dynamic range (WDR) and nociceptive specific (NS) neurons. WDR cells are the most frequently encountered cell group, comprising about 70% of the cells sampled in the dorsal horn. WDR cells are especially concentrated in the deeper laminae of the dorsal horn (III to V) where they receive input from both low-threshold and nociceptive afferent fibres and hence are activated by both innocuous and noxious stimuli. However, the responses of WDR cells to these stimuli are graded so that the noxious stimuli evoke a greater response than non-noxious stimuli. It has been suggested that these properties of WDR neurons account for the discrimination of noxious from non-noxious stimuli (Bushnell et al., 1984; Dubner et al., 1989; Maixner et al., 1989) (the sensory-discriminative aspect of pain). In contrast to WDR cells, NS projection cells respond only to noxious stimuli under physiological conditions. The majority of NS cells are found in the superficial laminae of the dorsal horn (I and outer II).

The dorsal spinal column system

Anatomy

The second set of somatosensory inputs to the brainstem include those primary afferent fibres which ascend in the dorsal (posterior) columns of the spinal cord to form their first synapse at the dorsal column nuclei. In addition, there is input to the dorsal column nuclei from at least two groups of dorsal horn projection neurons, the postsynaptic dorsal column pathway and the spino-cervical tract (Wall & Melzack, 1984; Willis, 1985; Willis & Coggeshall, 1991). Both groups of inputs are organized so that the fibres from the lower extremities are most medial in the nucleus gracilis, and inputs from the upper extremities are most lateral in the nucleus cuneatus. The trunk is represented in a region between these nuclei. Inputs from the most distal body regions are dorsal and the more proximal body regions are ventral. The axons of the second-order cells in the dorsal column nuclei cross the midline and gather into the medial lemniscus on the contralateral side of the brainstem. These fibres then ascend through the brainstem and midbrain toward their site of termination in the ventral posterior lateral (VPL) nucleus of the thalamus.

The dorsal spinal column system

Physiology

The cells of the dorsal column nuclei largely respond to innocuous stimuli alone. The lemniscal system in primates does not appear to encode painful stimuli. The information carried in this path is primarily from hair follicle receptors, pacinian corpuscles, and types I and II slowly adapting receptors (Willis, 1985; Willis & Coggeshall, 1991). In addition, the nucleus cuneatus (but not gracilis) shows responses to muscle afferents (spindles and Golgi tendon organs). However, there are several lines of evidence which suggest a role of the dorsal column nuclei in nociceptive transmission. For example, the dorsal columns might account for the recurrence of pain sensitivity and reference of pain to other regions of the body after lesion of the anterolateral spinal quadrant (Vierck et al., 1990; Vierch, Jr. & Luck, 1979; Nagaro et al., 1993). Neuropathic pains are largely conveyed by myelinated fibre inputs (Campbell et al., 1988), which are the majority of fibres afferent to the dorsal column pathway. In addition, non-myelinated afferents have been shown to project to the dorsal column nuclei (Conti et al., 1990; Fabri & Conti, 1990; Garrett et al., 1992; Patterson et al., 1989, 1990). A small number of nociceptive dorsal column neurons have been reported (Cliffer et al., 1992; Ferrington et al., 1988). Finally, the postsynaptic dorsal column pathway and the spino-cervical tract ascend to the dorsal column nuclei and are often nociceptive (Brown et al., 1983; Brown & Franz, 1969).

Supraspinal nociceptive centres

Brainstem centres

Nociceptive neurons have been shown within the reticular formation (Barbaro et al., 1989; Guilbaud et al., 1973; Haws

et al., 1989; Nyquist & Greenhoot, 1974; Villanueva et al., 1990), and the periaqueductal grey (PAG) (Casey, 1971b; Eickhoff et al., 1978). Microstimulation in these nuclei produces a wide spectrum of pain-related responses (Bowsher, 1976; Carstens et al., 1980; Casey, 1971a; Gerhart et al., 1984; Janss et al., 1987; Bandler & Depaulis, 1988; Bandler & Carrive, 1988; Delgado, 1955; Fardin et al., 1984; Lovick, 1993; Nashold, Jr. et al., 1969; Spiegel et al., 1954;Walker, 1938; Wolfle et al., 1971). Electrical or chemical stimulation of the PAG or hypothalamus in animals and humans produces a spectrum of responses from overt nocifensive behaviour and associated cardiopulmonary changes to analgesia. This spectrum of effects in PAG is due to the activation of one of two subdivisions of the PAG, the dorsolateral and ventrolateral columns. Activation of the dorsolateral column of the PAG produces a behavioural response of vocalization, grimacing, attack or escape and a parallel tachycardia and pressor response (Bandler & Shipley, 1994; Lovick, 1993), while activation of the ventrolateral column produces behavioural quiescence, bradycardia and hypotension (Depaulis et al., 1994; Keay et al., 1994). Both of these response profiles have been observed by stimulation within the PAG of humans (Nashold, Jr. et al., 1969; Young, 1989; Young et al., 1985).

Lateral thalamic nuclei

Nociceptive neurons in humans have been observed in the mesencephalon (Amano et al., 1978), hypothalamus (Sano, 1977b; Sano, 1979) and thalamus (Lenz et al., 1993b; Lee et al., 1999). The region of Vc where the majority of cells respond to innocuous cutaneous stimulation is termed the core. Below and behind the core is a less cellular region arbitrarily termed the posterior inferior region in our studies. Receptive field locations for the cells in Vc remain unchanged over distances of several millimetres in the anterior–posterior and dorsoventral directions, but change markedly over similar distances in the mediolateral direction (Lenz et al., 1988). From medial to lateral the sequence of neuronal cutaneous receptive fields progresses from intraoral through face, thumb, fingers (radial to ulnar), and arm to leg. Cells with deep receptive fields are usually located anterior and dorsal in the core but sometime posterior to those with cutaneous receptive fields.

Several lines of evidence demonstrate that the region of Vc is important in human pain-signalling pathways. Studies of patients at autopsy following lesions of the STT show the most dense STT termination in Vc (Mehler, 1962; Mehler, 1966; Bowsher, 1957; Walker, 1943). Additionally, terminations are observed posterior to Vc in the magnocellular medial geniculate (Mehler, 1962; Mehler, 1969), limitans, and Vc portae nuclei (Mehler, 1966) and inferior to Vc in Vcpc (Mehler, 1966). STT terminations are found in monkey VMpo, posterior to medial Vc, which appears, by immunohistochemistry, to have a human analogue (Craig et al., 1994). It has been suggested that VMpo and the posterior nuclear group are specifically innervated by the dorsal STT (Craig, 1997; Craig et al., 1994), though not all studies have been in agreement (Apkarian & Hodge, 1989a,b; Ralston & Ralston, 1992; Zhang et al., 2000).

The cortical projections of these nuclei in monkeys are as follows: VP (corresponding to human Vc (Hirai & Jones, 1989a)) to primary (S1) and secondary (S2) somatosensory cortices (Jones, 1985; Burton, 1986; Kenshalo, Jr. & Willis, 1991), VPI (corresponding to human Vcpc) to S2 and granular and dysgranular insular cortex (Friedman & Murray, 1986), medial and oral pulvinar (corresponding to human Vcpor) to inferior parietal lobule and outer parietal operculum (7b) plus granular and dysgranular insular cortex (Burton & Jones, 1976; Burton, 1986; Friedman & Murray, 1986), posterior nucleus (as in humans) to retro-, granular and dysgranular insular cortex and S2 (Burton & Jones, 1976; Burton, 1986; Friedman & Murray, 1986), supragenicculate and limitans (as in humans) to granular insular cortex (Burton & Jones, 1976; Burton, 1986) and magnocellular medial geniculate to granular and dysgranular insular cortex (Friedman & Murray, 1986).

Fig. 59.1 shows an example of a cell in Vc with a differential response to painful thermal and mechanical stimuli and with a response to innocuous cool and mechanical stimuli (Lee et al., 1999). Cells in the posterior inferior region have been identified with a significant selective response to noxious heat stimuli (Lenz et al., 1993b) and to cold stimuli (Davis et al., 1999). These reports extend to humans the results of numerous monkey studies in which cells within VP (Casey & Morrow, 1983; Chung et al., 1986; Gautron & Guilbaud, 1982; Apkarian et al., 1991; Casey, 1966; Bushnell et al., 1993; Apkarian & Shi, 1994; Kenshalo et al., 1980; Bushnell & Duncan, 1987) and posterior and inferior to VP respond to noxious stimuli (Apkarian et al., 1991; Casey, 1966; Apkarian & Shi, 1994; Craig et al., 1994).

Cells in the region of Vc that respond to noxious stimuli probably signal pain based on temporary lesioning and stimulation studies. Blockade of the activity in this region by injection of local anesthetic into monkey VP, corresponding to human Vc (Hirai & Jones, 1989a), significantly interferes with the monkey's ability to discriminate temperature in both the innocuous and noxious range (Duncan et al., 1993). Stimulation within Vc and posterior-

inferior to it can evoke the sensation of pain (Dostrovsky et al., 1991; Halliday & Logue, 1972; Hassler & Reichert, 1959; Lenz et al., 1993a) and thermal sensations (Lenz et al., 1993a; Davis et al., 1999). Thus, there is strong evidence that the region of Vc is involved in pain signalling pathways: i. it receives input from pain signalling pathways, ii. it contains cells that respond to noxious stimuli, iii. stimulation can evoke pain, and iv. temporary lesioning of monkey VP disables the discrimination of pain and temperature.

Medial and intralaminar thalamic nuclei

In the medial tier of human thalamic nuclei the most dense STT terminal pattern is found in intralaminar nucleus centralis lateralis (Bowsher, 1957; Mehler, 1962; Mehler, 1969) while a much less dense termination is found in other interlaminar nuclei central medial and parafascicularis (Mehler, 1962). These nuclei project to cortex diffusely (Le Gros Clark & Russell, 1940) and to striatum (Oppenheimer, 1967; Vogt & Vogt, 1941). STT terminations are also found in the medial dorsal nucleus (Mehler, 1969) which project to lateral prefrontal cortex (Meyer, 1947; Van Buren & Borke, 1972). An STT projection to human submedius has not been identified although regions of dense neurokinin staining in medial Vcpc (Hirai & Jones, 1989b) may correspond to monkey nucleus submedius (Burton & Craig, Jr., 1983). The nuclear pattern of STT terminations and projection patterns of these nuclei in humans is similar to that demonstrated in more precise anatomic studies in monkeys.

In monkeys, dense STT terminations are observed in central lateral (Mehler et al., 1960; Boivie, 1979; Mantyh, 1983; Berkley, 1980), while a light projection is found in central medial and parafascicularis (Mehler et al., 1960; Burton & Craig, Jr., 1983; Berkley, 1980; Apkarian & Hodge, 1989c; Kerr, 1975). These intralaminar nuclei project to caudate and putamen (Sadikot et al., 1990; Smith & Parent, 1986; Nakano et al., 1990; Kalil, 1978; Sadikot et al., 1992a,b) and diffusely to cortex (Macchi & Bentivoglio, 1986; Strick, 1975; Powell & Cowan, 1967). STT terminations are also found in monkey submedius (Apkarian & Hodge, 1989c), particularly the dorsal (Craig & Burton, 1981) and rostral (Mantyh, 1983; Craig, 1990) portion. The cortical projections of submedius have not been reported in monkey although projections to deep presylvian sulcus have been reported in cats (Craig et al., 1982). The medial dorsal nucleus receives STT input (Apkarian & Hodge, 1989c; Rothwell et al., 1983; Kerr, 1975) and projects to dorsolateral prefrontal cortex (Kievit & Kuypers, 1975; Tobias, 1975; Goldman-Rakic & Porrino, 1985). Therefore, the pattern of STT terminations in monkeys largely confirms that described in humans.

Nociceptive neurons have been identified in the human central medial nucleus (Ishijima et al., 1975; Jeanmonod et al., 1993, 1994; Rinaldi et al., 1991; Tsubokawa & Moriyasu, 1975). Ishijima et al. found that one-quarter (20/80) of the cells they recorded from the central medial/parafascicularis complex of man responded to noxious pinprick and two of these responded to application of noxious heat to the skin (Ishijima et al., 1975). None of these cells responded to non-noxious cutaneous stimuli. They identified nociceptive cells which responded at short latency to the application of stimuli, and terminated discharges shortly after discontinuation of the stimulus. A second group of cells responded with a long latency and showed prolonged after-discharges. Both types of cells had receptive fields that were large and often bilateral. The two types of cells were distributed in different areas of the central medial/parafascicularis, with the first type of cells in the medial basal parts of the nucleus, while the second type were scattered throughout the central medial and in the dorsal parts of parafascicularis. Tsubokawa and Moriyasu (Tsubokawa & Moriyasu, 1975) also found a relatively large number of nociceptive neurons which they localized to the central medial nucleus.

Studies by Rinaldi and coworkers ($n = 81$ cells (Rinaldi et al., 1991)) and Jeanmonod and coworkers ($n = 972$, (Jeanmonod et al., 1993, 1994)) in patients with deafferentation pain rarely found cells with receptive fields, in contrast to previous reports (Ishijima et al., 1975; Tsubokawa & Moriyasu, 1975). Instead cells with very high rates of spontaneous bursting discharge activity were reported ((Rinaldi et al., 1991; Jeanmonod et al., 1993, 1994), see below). The cells with receptive fields to tapping were found in two patients in whom bursting activity was absent (Rinaldi et al., 1991). The receptive fields were very large and often bilateral. Jeanmonod et al. (1993, 1994) found two cells with large, bilateral cutaneous receptive fields to innocuous and noxious stimuli. These cells were found in the medial dorsal nucleus.

Electrical stimulation of the medial regions of thalamus for localization prior to thalamotomy for pain (Amano et al., 1976; Choi & Umbach, 1977; Hithcock & Teixeria, 1981; Laitinen, 1988; Richardson, 1967; Rinaldi et al., 1991; Urabe & Tsubokawa, 1965; Voris & Whisler, 1975) evoked painful sensations (Sano, 1977a; Fairman & Llavallol, 1973; Fairman, 1966). Sano's group (Sano, 1977a, 1979) described two types of sensation evoked by stimulation in medial thalamus. The first type was a diffuse, burning pain

referred to the contralateral half of the body or on occasion the whole body. The sites at which these sensations were produced were usually concentrated near the posterior half of the internal medullary lamina, corresponding to the parvocellular regions of central medial, plus parafascicularis and limitans. The spontaneous pain of the patient was frequently exacerbated by macrostimulation at these sites. The other type of sensation produced by Sano and coworkers was a generalized 'unpleasant' sensation, not localized to a particular body part. The sites at which these sensations were produced were concentrated in the very medial and anterior regions, possibly the medial dorsal and periventricular nuclei. Rinaldi and coworkers have also produced sensations by microstimulation in the medial thalamus, but these were not considered painful (Rinaldi et al., 1991). Instead a sensation of 'pulling' was produced by stimulation in parafascicularis while throbbing was produced by stimulation in the central medial nucleus.

The medial or intralaminar thalamus has often been lesioned for treatment of chronic pain. A decrease in the level of pain was found in 73% of patients on average for these studies (Lenz & Dougherty, 1997). The sensation of pain evoked by an acute experimental paradigm was not altered. Therefore, it is assumed that the medial nuclei subserve the affective–motivational component of pain.

Cortex

Our understanding of cortical areas involved in pain perception has been dramatically altered by the results of functional imaging studies carried out during the application of painful stimuli (Jones et al., 1991; Talbot et al., 1991a; Casey, 1999; Casey & Bushnell, 2000). These studies have identified four areas metabolically activated by the application of painful stimuli. This section will review anatomy and physiology of each of these areas: primary somatosensory cortex (S1), secondary somatic sensory cortex (S2), insula, and cingulate cortex.

The primary somatosensory cortex (S1)

The S1 cortex located in post-central gyrus is the first cortical target of somesthetic information from the monkey VPL and VPM nuclei of the thalamus. Most of the thalamocortical neurons of VPL and VPM project to S1 cortex, including the fraction that receives input from the STT. Human studies suggest a similar picture, such that the ventral caudal nucleus (Vc; corresponding to monkey VP) projects to S1 (Van Buren & Borke, 1972). Multiple case reports describe lesions involving parietal cerebral cortex and underlying white matter, that are associated with hypalgesia (Marshall, 1951; Boivie et al., 1989). Lesions of S1 cortex in old world primates are reported to interfere with discrimination of stimuli into the noxious range (Kenshalo et al., 1991). These results suggest that S1 has a pain-related function.

Neurophysiological studies in primates have demonstrated the existence of nociresponsive neurons in the S1 cortex, although they appear to be a small fraction ($\geqslant$1%) of all somatosensory neurons in this area (Kenshalo, Jr. et al., 1988). Nociresponsive neurons in S1 demonstrate response magnitudes that are proportional to the intensity of noxious heat. Thus, these neurons have the capacity to encode the intensity of painful stimuli. This intensity encoding capacity is consistent with S1 being involved in the discriminative aspect of pain.

Fig. 59.1 *(Opposite).* Activity of cell (061093) in Vc responding to painful mechanical and thermal stimuli. (*a*) location of the cell (arrow) relative to the positions of trajectories, nuclear boundaries, and other recorded cells. The ACPC line is indicated by the horizontal line and the trajectories are shown by the oblique lines (left-anterior, up-dorsal). Nuclear location was approximated from the position of the ACPC line. Lateral location of the cell (in millimeters) is indicated above each map. Trajectories have been shifted along the ACPC line until the most posterior cell with a cutaneous RF is aligned with the posterior border of Vc. Since cells responding to innocuous sensory stimuli may be located posterior to Vc (Apkarian & Shi, 1994), this map represents a first approximation of nuclear location and dimensions. The locations of cells are indicated by ticks to the right of each trajectory. Cells with cutaneous RFs are indicated by long ticks, those without definable RFs by short ticks. Filled circles attached to the long ticks indicate that somatic sensory testing was carried out. The scale is as indicated. The shape of action potentials recorded at the beginning of the recording on this cell during application of the brush (upper) and at the end of the recording, during a 12 °C stimulus (lower). Data were collected from upgoing stroke of the action potential by using voltage threshold of 0.15 μV. The RF and PF for the natural, surface and deep, non-painful, tingling sensation evoked by TMIS at the recording site (threshold – 15 μA) are also shown.

(*b*) response to the brush, LC, MC, and SC. (*c*) the response of the neuron to progressive increase in pressure applied with the non-penetrating towel clip, indicated by the number of steps. (*d*) responses to heat stimuli at 42 °C, 45 °C, and 48 °C. (*e*) responses to cold stimuli at 12 °C, 18 °C, and 24 °C. The upper trace in each panel is a footswitch signal indicating the onset and duration of the stimulus in panels (*b*) and (*c*) and the thermode signal in panels (*d*) and (*e*). The scales for the axes for all histograms (binwidth 100 milliseconds) are indicated in each panel. (From Lee et al., 1999 with permission.)

S1 cortex is activated by either innocuous or noxious stimulation in humans, based on magnetoencephalography (MEG), evoked potentials, positron emission tomography (PET), and most recently, functional magnetic resonance imaging (fMRI; see review by Bushnell et al., 1999). Several laser evoked potential (LEP) studies have proposed that LEPs arise in part from generators localized to the contralateral S1 cortex (Tarkka & Treede, 1993). Recent studies have demonstrated that metabolic activation in S1 is significantly related to the magnitude of perceived pain evoked by stimuli of varying intensity (Coghill et al., 1999). Thus, there is clear evidence that S1 is involved in the discriminative dimension of pain.

The secondary somatosensory cortex (S2)

There are several regions in the posterior parietal operculum and posterior insula that show somesthetic responsive neurons in the non-human primate. A part of that area has been identified as S2 cortex, by nature of its connectivity to ventrobasal thalamus and the S1 cortex (Burton, 1986). It is located in the parietal operculum, immediately posterior to the most lateral aspect of S1 cortex. Surrounding S2 cortex are several other electophysiologically defined somatotopic maps, which have been identified as PV (parietal ventral – just anterior to S2 in the parietal operculum; (Krubitzer et al., 1995)), area 7b (lateral to S2), posterior insula (medial to S2), and retroinsula (in the lateral fissure posterior to the insula proper) (Burton, 1986). Together, these areas are referred to as parasylvian cortical areas. Neurophysiological studies in primates have identified cells responsive to painful stimuli in S2 and area 7b (Dong et al., 1989, 1994).

Human studies suggest that the subnuclei in and around Vc project to the posterior parietal operculum (including S2; (Van Buren & Borke, 1972)). Human LEP studies provide evidence of nociceptive inputs to this area. LEPs are the potentials evoked by cutaneous application of a laser which is a pure pain stimulus. Subdural studies demonstrate that LEPs arise from a generator between the sylvian and the central fissures anterior to auditory cortex and discrete from the generator for the P3 event-related potentials (Lenz et al., 1998b). This suggests that the positive component of the LEP is not a potential related to the P3, a potential related to the attention evoked by infrequent events (cf Zaslansky et al., 1996).

The maximum of the LEP is identified just above the sylvian fissure and just anterior to a generator of the AEP – the primary auditory cortex located in Heschl's transverse gyrus on the temporal operculum (Celesia & Puletti, 1969). The polarity of the AEP is opposite at recording sites on opposite sides of the sylvian fissure (Fig. 59.2), consistent with the known location of the AEP generator. If we assume a generator in S2 on the parietal operculum (Burton et al., 1993), facing the temporal operculum, the polarity of the LEP should be opposite on opposite sides of the sylvian fissure, by analogy to the AEP. However, LEPs recorded on opposite sides of the sylvian fissure have the same polarity (Fig. 59.2), suggesting that this generator of the LEP is not located in S2 (Kakigi et al., 1995; Tarkka & Treede, 1993). Comparisons of LEPs with auditory evoked potentials recorded through the same electrodes suggest that the LEP generator is not in S2 but in the dorsal insula at the level of the central sulcus (Lenz et al., 2000).

It has not been possible for PET studies to resolve those regions around the lateral sulcus which are activated by this painful stimulus. Recent fMRI studies have demonstrated multiple loci of activation on the parietal operculum–posterior insula region with both innocuous (Disbrow et al., 2000) and noxious stimuli (Moulton et al., 1999). Hypalgesia has been reported in patients with cerebral lesions involving the parietal operculum, posterior insula, and/or underlying white matter (thereby involving the S2 region), while apparently sparing S1 (Biemond, 1956; Greenspan & Winfield, 1992; Greenspan et al., 1999).

One major issue to be addressed is whether these somatosensory regions demonstrate intensity encoding capacity within the noxious range. Single-unit neurophysiological studies in primates show that some neurons in 7b (adjacent to S2) show responses that can encode for the intensity of noxious heat stimuli (Dong et al., 1994). One PET study reported that responses in the S2 regions (among other areas) were graded in relation to noxious heat intensity (Coghill et al., 1999). Thus there is strong evidence that nociceptive information reaches S2 cortex, and that the activity in this area is related to pain intensity.

The insular cortex

In monkey, portions of the insular cortex have neuroanatomical connectivity suggestive of a role in somatosensory information processing, including inputs from S1 and S2 (Mufson & Mesulam, 1982; Friedman et al., 1986). Additionally, the insula receives input from several thalamic nuclei, including VPI, the oral and medial pulvinar nuclei, the centromedian-parafasicular nuclei, the medial dorsal nucleus, and the VMpo portion of thalamus, which receive nociceptive input from the spinal cord (Burton & Jones, 1976; Jones & Burton, 1976; Friedman et al., 1980; Mesulam & Mufson, 1985; Friedman & Murray, 1986). Stimulation in human Vcpc can evoke previously experienced pain, and the emotional tone associated with that previously experi-

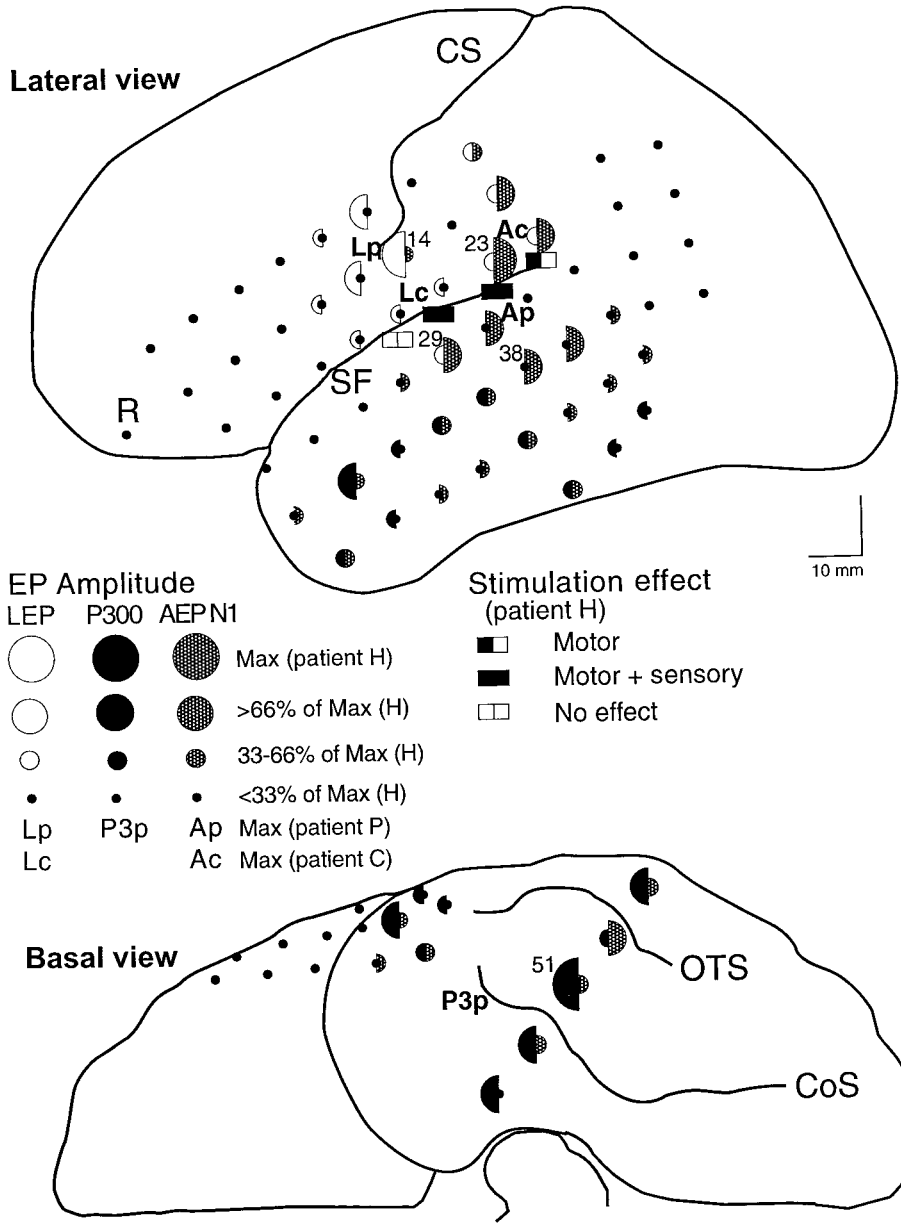

Fig. 59.2. Amplitude distribution of facial LEP P2, AEP, and P3 potentials in patient H and location of maximums for patients C and P. For patient H the LEP P2 amplitude was expressed as a percentage of the maximum (electrode 14) as indicated by the size of the circle. The same conventions were applied to circles for AEPs and P3s so that the location indicates electrode position, the size indicates amplitude as a percentage of the maximum, and the shading indicates the potential (LEP P2, AEP or P3) represented by the circle (Fig. 59.1, left inset). Amplitudes of greater than 33% of maximum were never found at the same electrode for both the LEP P2 and the auditory P3 so that the potentials not represented at any site were less than 33% of maximum.

In patient H, large LEP P2 potentials (>66% maximum) were seen over a restricted area adjacent to the inferior central sulcus, which was confirmed as facial sensorimotor area by stimulation mapping (right inset). LEP P2 maximums in patients C and P (Lc and Lp) were located close to that for patient H. AEPs were maximal posterior and superior to the maximum for LEPs. In patient H, large P3 potentials (>66% maximum) were widespread over basal, anterior, and lateral temporal areas with a maximum over the fusiform gyrus of the temporal base. CS, central sulcus; SF, sylvian fissure; OTS, occipital temporal sulcus; CoS, collateral sulcus. (From Lenz et al., 2000, with permission.)

enced pain. This finding suggests that nuclei in the posterior group may be connected to limbic structures (Lenz et al., 1994b, 1995), through insular connections to the medial temporal lobe (Mishkin, 1979). This suggestion is consistent with anatomic studies demonstrating that the granular portion of insula projects to limbic structures, including the amygdala and perirhinal cortex (Friedman et al., 1986).

There is also evidence that the insula plays a role in human somesthetic perception. Penfield and Faulk (Penfield & Faulk, Jr., 1955) documented somesthetic experiences evoked in patients by direct electrical stimulation of insular cortex. Berthier et al. (1987) described six patients with insular lesions who had reduced motivational–affective responses to pain, but normal sensory-–discriminative capacity. A recent report described the perceptual alterations in a group of people with lesions involving portions of the insula and the parietal operculum (Greenspan et al., 1999). Those individuals with lesions encompassing the posterior parietal operculum showed elevated pain thresholds contralaterally, regardless of whether the lesion involved the neighbouring insula. Those individuals with lesions involving the insula, but sparing the parietal operculum showed normal pain thresholds, but demonstrated greater pain tolerance contralaterally. This was interpreted to show that the parietal operculum (containing S2) has a role in the sensory–discriminative aspect of pain (evidenced by elevation of the pain threshold), while the insula has a role in the motivational–affective aspect of pain (evidenced by elevation of pain tolerance).

The insula's significance to thermal and nociceptive information processing has been highlighted by PET studies (Casey et al., 1994, 1996; Coghill et al., 1994; Craig et al., 1996). These reports describe significant activation of a mid/anterior region of insula, and a separate posterior region of insula, associated with noxious thermal stimuli. Both of these insular areas have been described as showing response levels proportional to stimulus and/or pain intensity (Coghill et al., 1999). It has been suggested that the more posterior region of insula, receiving thalamic input similar to S2 cortex, is more related to sensory discriminative functions.

The cingulate cortex

The anterior cingulate cortex (ACC) also appears to have a role in processing nociceptive input. Brodmann's area 24 in particular receives thalamic input from some of the nociresponsive medial thalamic nuclei and VPI (Craig, Jr. et al., 1982; Vogt et al., 1987; Musil & Olson, 1988; Yasui et al., 1988). Nociresponsive neurons have been recorded (Hutchison et al., 1999) in human ACC and LEPS have a maximum over this area (Lenz et al., 1998c). Surgical lesions have been made near the genu of the ACC in order to relieve chronic pain, and the effects are described as blunting the affective–motivational aspect of pain (Folz & White, 1962; Gybels & Sweet, 1989). Recently, two detailed psychophysical investigations reported sensory changes following cingulotomy or capsulotomy. In the first case pain intensity and unpleasantness was decreased postoperatively (Talbot et al., 1995); a more complex alteration in pain sensibility was observed in the second case who underwent both a capsulotomy and a cingulotomy (Davis et al., 1994).

Perhaps most compelling is the fact that the ACC is the region most consistently activated by noxious stimuli across all PET and fMRI studies (Casey, 1999; Casey & Bushnell, 2000), while innocuous tactile or thermal stimuli consistently fail to activate this region. It has been argued that the ACC activity associated with painful stimulation is not related to the pain experience *per se*, but rather is related to the attentional shift that occurs with an acute painful stimulus. However, the region of the ACC that is activated by painful stimulation is different from the region that is activated by directing attention to non-painful events (Davis et al., 1997). One PET study showed that hypnotic alteration of perceived unpleasantness of painful stimulation produced correlated changes in the ACC response, while producing no significant change in other cortical regions (Rainville et al., 1997). The part of ACC related to pain may be particularly involved in pain unpleasantness.

Central pain syndrome (CPS)

Although little is known of the fundamental pathophysiology of central pain (Boivie & Leijon, 1991), the condition is considered to involve a primary dysfunction of the somatosensory thalamus (Head & Holmes, 1912) that in turn involves cortical structures. The well-described relay of somatosensory information in the ventral posterior medial and lateral nuclei (VPM and VPL) (Guilbaud et al., 1980; Harris, 1980; Jasper & Bertrand, 1966; Jones, 1985; Mountcastle & Henneman, 1949) has historically been cited as evidence to implicate the thalamus in the paroxysmal pain evoked by acute peripheral stimuli in CPS patients (Head & Holmes, 1912). Consistent with this view, intraoperative studies have shown somatotopic rearrangement, abnormal responsiveness to peripheral stimuli, and abnormal spontaneous discharge patterns in thalamic neurons of CPS patients (Lenz et al., 1989, 1993a, 1998d; Radhakrishnan et al., 1999). Electrical stimulation in these zones of altered cellular activity, in lateral thalamus, provoked the sensation of pain at a higher frequency than

would be normally expected (Lenz et al., 1998a), and lesion in areas of altered activity in the medial thalamus successfully relieved CPS (Ishijima et al., 1975; Jeanmonod et al., 1993).

Psychophysical studies uniformly demonstrate that CPS is found in patients with impaired STT function (Boivie & Leijon, 1991; Vestergaard et al., 1997; Boivie et al., 1989; Beric et al., 1988) due to injuries to the STT and it's projections (Cassinari & Pagni, 1969). Acute lesion of the STT in humans produces insensitivity to pain but rarely produces pain (Boivie & Leijon, 1991; Bowsher, 1997; Casey, 1991; Cassinari & Pagni, 1969). However, chronic pain develops in an increasing percentage of patients with increasing length of survival following anterior lateral spinal lesion, so that the risk of CPS becomes a major limiting factor in use of cordotomy for pain relief with prolonged life expectancy (Beric et al., 1988; Casey, 1991). Unfortunately, the extent of spinal lesions was variable in the human neurophysiological studies and so, the specific contribution of STT damage to the observed changes in neurons of CPS patients could not be assessed. In monkeys, acute lesion of the STT reduced sensitivity to pain (Vierck, Jr. et al., 1971, 1983; Vierck, Jr., 1998; Vierck, Jr. & Luck, 1979; Willis, 1985). Over the next 6 months pain sensitivity returned for most in monkeys with STT lesions. In addition, one-third to one-half of all animals developed exaggerated responsiveness to nociceptive stimuli (Vierck et al., 1990). Therefore there is strong evidence that lesions of the STT can evoke features of the CPS.

Anatomic plasticity following peripheral neurological injury has been shown in the thalamus of several species (Albe-Fessard et al., 1983; Albe-Fessard & Rampin, 1991; Lombard & Larabi, 1983; Pollin & Albe-Fessard, 1979; Wall & Egger, 1971) (or for review, see Dougherty & Lenz, 1994). Anatomic rearrangements observed after cervical dorsal rhizotomy in non-human primates included loss of afferent terminals and decreased density of neurons (Rausell et al., 1992). Zones of parvalbumin and cytochrome oxidase staining, characteristic of lemniscal terminals, decreased in size while the calbindin positive zones, characteristic of the spinothalamic terminals, increased (Rausell et al., 1992). The affected areas also demonstrated a decrease in GABA-A receptors (GABA-B and -C receptors were not examined) without a decrease in the number of GABA positive interneurons. Marked changes in GABA synaptic morphology have also been shown following chronic dorsal column lesion (Ralston et al., 1996; Ralston & Ralston, 1994).

Thalamic neurons also show functional signs of plasticity after peripheral or central nervous system injury. Among these changes, receptive field reorganization (Kaas, 1991) and changes in the responses to mechanical and thermal stimuli are common (Koyama et al., 1993). Also, pain is evoked more commonly by stimulation in the region of Vc in patients with chronic pain than in patients with movement disorders (Lenz et al., 1998a). These changes may account for perceptual alterations which occur in patients with chronic pain secondary to peripheral deafferentation. For instance, changes in receptive and projected field organization could explain the telescoping of the limbs experienced by patients with amputations (Jensen & Rasmussen, 1994). Pain and hyperalgesia in patients with chronic pain could be explained by the increased likelihood of provoking pain by stimulation of the region of Vc.

An increase in the rate of action potential bursts has been widely reported in both the thalamus of humans (Jeanmonod et al., 1993; Lenz et al., 1989, 1994a) and in animals following lesion of the nervous system (Albe-Fessard et al., 1983, 1985; Lombard & Larabi, 1983; Rodin & Kruger, 1984). Particular significance has been assigned to the changes in spike train properties of thalamic neurons following deafferentation because the rate of neuronal spike bursts in pain patients is significantly higher in regions of the lateral thalamus (VPL/VPM) representing the painful part of the body (Lenz et al., 1994a). Microstimulation in areas of increased rates of neuronal bursting is more likely to produce pain in both post-amputation and post-stroke CPS patients than in other areas of VPL (Davis et al., 1996; Lenz, 1992; Lenz et al., 1998a). Lesions directed at medial thalamic regions of abnormal bursting have been used as a guide to relieve chronic pain surgically (Ishijima et al., 1975; Jeanmonod et al., 1993). The significance of these findings has been challenged by a study suggesting that the number of bursting cells is equal in patients with pain and in patients with movement disorders (Radhakrishnan et al., 1999). It is unclear how the two patient groups in that study would have compared if the rate of bursting in all cells (Lenz et al., 1994) rather than number of bursting cells were studied (Radhakrishnan et al., 1999).

A recently proposed mechanism of central pain proposes that central pain is the result of an imbalance between two ascending pathways. This hypothesis attempts to explain the burning pain and cold allodynia that can be observed in central pain syndromes. It is proposed that the burning pain of intense cold is mediated by the medial pathway from polymodal nociceptive lamina I spinothalamic neurons (HPC) in monkey lamina I to the cingulate gyrus via the ventral caudal portion of the medial dorsal nucleus (MDvc). It is further proposed that the medial pathway is inhibited by the lateral pathway from cold specific lamina I spinothalamic neurons (COLD) to

insula via the posterior portion of the ventral medial nucleus (VMpo) (Craig et al., 1996). Lesions of the lateral pathway are proposed to release inhibition of the medial pathway and so cause a burning pain similar to that evoked by intense cold. The site at which the lateral pathway may inhibit the medial pathway is unclear at present.

The idea that the ongoing pain of central pain syndromes resembles the burn of cold pain is the most basic tenet of this hypothesis. However, many patients with central poststroke pain (CPSP: 40–50%) do not experience a burning pain (Leijon et al., 1989; Bowsher, 1997). The cold allodynia which is predicted by this hypothesis is found in a minority of patients with CPSP (23% – 5/22) (Boivie et al., 1989). Thus, it is not clear that clinical features found in central pain syndromes are explained by this hypothesis done. Nevertheless, it is a useful construct for guiding research into central pain mechanisms.

In conclusion, studies in humans have demonstrated involvement of both lateral and medial thalamus in pain processing. In lateral thalamus, cells responsive to painful stimuli are located in the core area and in the postero-inferior area. Stimulation in the postero-inferior area or at the posterior aspect of the core can evoke pain or visceral pain suggesting involvement of this area in the mechanisms of somatic and visceral pain. Injections of local anesthetic into monkey VP blocks the ability of monkeys to discriminate temperature differences in the noxious and non-noxious ranges. These findings and particularly the presence of sensory loss following lesions of lateral thalamus suggest that the region of Vc signals the sensory discriminative aspect of acute pain in humans. Anatomic studies are consistent with this area projecting to parietal and parasylvian cortex.

In medial and intralaminar thalamus, some cells responsive to noxious stimuli have been recorded. Pain has been reported by macrostimulation at some sites. STT terminates in the nuclei where these recording and stimulation results are reported. These results provide support for the involvement of medial thalamic nuclei in pain signalling pathways in man. These structures project to cingulate cortex and diffusely to a wide area of cortex.

Abnormalities in lateral thalamus in patients with chronic pain point to involvement of this area in chronic pain in humans. Somatotopic reorganization of Vc occurs in patients who have chronic pain secondary to deafferentation or spinal cord injury. A reorganization of modalities occurs in patients with chronic pain so that the number of sites where thermal sensations are normally evoked by thalamic stimulation is decreased by an amount equal to the increase in the number of sites where pain is evoked. Increased rate of bursting is observed in the deafferented areas of thalamus and is probably related to loss of STT inputs. This abnormal burst firing is most pronounced in the posterior – inferior area of the thalamus involved in signalling pain, suggesting that this firing is involved in the sensation of chronic pain.

Management of chronic pain

Russell K. Portenoy

Department of Pain Medicine and Palliative Care, Beth Israel Medical Center, New York, NY, USA

Pain is the most common reason that patients seek medical attention. Most community-based surveys indicate that at least 15% of the population have chronic pain associated with adverse consequences in varied domains of functioning (Smith et al., 2001). The aggregate cost of unrelieved pain for health care systems and national economies is staggering.

All clinicians encounter patients with chronic pain. An understanding of the nature of pain provides a foundation for comprehensive assessment. Assessment, in turn, guides the long-term therapeutic strategy for enhancing the comfort of these patients and addressing their pain-related disability.

Definition of pain

Pain has been defined by the International Association for the Study of Pain (IASP) as 'an unpleasant sensory and emotional experience which we primarily associate with tissue damage or describe in terms of such damage, or both (Mersky & Bogduk, 1994)'. This definition underscores the potential contribution of sensory, emotional, and cognitive processes in the experience of pain, and the complex relationship between tissue injury and pain perception. Although pain is typically perceived to be a primary indicator of tissue injury, the relationship between pain and tissue damage is neither uniform nor constant. Pain may occur in association with progressive or stable chronic disease, or may occur in the complete absence of an identifiable lesion.

This complexity highlights the need to distinguish the neural processes initiated by tissue injury from pain. The mechanisms induced in neural pathways by potentially tissue-damaging stimuli are termed 'nociception', and are neither necessary nor sufficient for the experience of pain. Pain is the perception of nociception, and like other perceptions, is inherently subjective and can be influenced by a variety of non-nociceptive factors. These factors may be organic, e.g. the aberrant processes in the nervous system that result in neuropathic pain, or psychologic.

Given the subjective nature of pain, pain specialists generally believe that the clinician is best served by assuming that the patient is reporting a true experience, even when a causative lesion cannot be demonstrated. Clinical discussion focused on whether or not a pain is 'real' usually obscures the important issues and is unhelpful. Malingering or factitious pain is rare in clinical practice and, in almost all cases, the clinician is better served by assuming that the pain is truly experienced and then thoughtfully inferring the range of factors – ongoing tissue injury, neuropathic processes and psychologic processes – that may be sustaining the pain.

Early definitions of chronic pain used only a temporal measure, specifically pain persisting longer than 3 months or 6 months. More recently, a broader definition has been preferred. Pain is chronic if it persists for a month beyond the usual course of an acute illness or a reasonable duration for an injury to heal, if it is associated with a chronic pathologic process, or if it recurs at intervals for months or years (Bonica, 1990).

Pain assessment

The complexity of chronic pain underscores the critical importance of a comprehensive assessment as a first step in successful management. This assessment includes characterization of the pain, clarification of the relationship between the symptom and underlying diseases, and evaluation of the various comorbidities that may become important ancillary targets of therapy.

Table 60.1. Pain characteristics

Characteristic	Elements
Temporal	Acute, recurrent or chronic Onset and duration Course Daily variation (including breakthrough pain)
Intensity	Pain 'on average,' Pain 'at its worst,' Pain 'right now' Pain 'at its least'
Location	Focal or multifocal Referred Superficial or deep
Quality	Varied descriptors e.g., aching, stabbing, or burning Familiar or unfamiliar
Exacerbating/ relieving factors	Volitional ('incident pain') vs. non-volitional

Source: Adapted from Portenoy & Kanner (1996).

Evaluation of pain characteristics

Like all symptoms, pain is evaluated by the verbal reports used by patients to describe the experience (Portenoy & Kanner, 1996) (Table 60.1). Temporal descriptors are essential and include the onset and duration of the pain, the occurrences of episodic pain, and the fluctuation during the day.

Measurement of pain severity can be performed using simple unidimensional scales or multidimensional questionnaires. The choice of one or another method in clinical practice is probably less important than its systematic application repeatedly over time (Au et al., 1994). Because measuring pain enhances its visibility to clinicians, measurement and documentation are major elements in the new standards of institutional pain care adopted by the United States Joint Commission on the Accreditation of Healthcare Organizations. In clinical practice, the clinician is usually best served by selecting a simple approach, e.g. a four-point verbal rating scale such as 'none', 'mild', 'moderate', or 'severe', or an eleven-point, '0–10' numeric scale, and incorporating it into the routine. The time frame, e.g. 'pain right now' or 'pain during the past day', and the clinical context, e.g. after a dose of pain medication, must be defined to adequately measure pain.

Other important characteristics include pain location, quality, and factors that exacerbate or relieve the pain (Table 60.1). The medical record of patients with chronic pain should document these characteristics so that they can be tracked over time.

Etiology, inferred pathophysiology, and syndromes

The pain assessment, combined with information from the physical examination and radiographic or laboratory evaluations, may identify a pain syndrome or an etiology for the pain, and allow inferences about the broad set of mechanisms that might be sustaining it. These understandings may suggest additional investigations and guide therapeutic decision making.

If a discrete etiology can be reasonably identified as a cause for the pain, this information may be helpful in clarifying the nature of an underlying disease, indicating prognosis (for the pain or the disease itself), or suggesting the use of specific primary therapies. For example, the identification of a neoplasm impinging on a nerve plexus may allow use of an antineoplastic treatment, such as radiotherapy.

Although the classification of pain according to inferences about the underlying mechanisms oversimplifies complex pathophysiological processes, the approach has utility in clinical practice. Based on the characteristics of the pain and its etiologies, pathophysiology can be labeled 'nociceptive', neuropathic', psychogenic', or 'mixed' (Table 60.2). If pain persists in the absence of an identifiable organic substrate (nociceptive or neuropathic) and there is no evidence of a substantial psychologic contribution, it is best to label the pain 'idiopathic' and reassess in the future.

These pathophysiologic constructs have important therapeutic implications. For example, the response to opioids appears to be relatively better during treatment of nociceptive pains than neuropathic pains (Portenoy et al., 1990). Numerous drugs are now targeted specifically to the treatment of neuropathic pain (see below).

The pain assessment also may identify a discrete pain syndrome, identification of which can guide additional evaluation, indicate the likely etiology, or suggest a therapeutic approach. A very large number of disease-related pain syndromes have been defined and varied systems of classification have been proposed. For example, neuropathic pain may be classified by the presumed site of the sustaining pathophysiology – peripheral vs. central (Table 60.3) (Caraceni & Portenoy, 1998) – or by some combination or neurologic findings and etiology (Table 60.4) (Portenoy, 1996a,b).

In some cases, syndromic labels are imprecise and must be applied cautiously. For example, the generic terms 'chronic pain syndrome', 'chronic non-malignant

Table 60.2. Inferred pathophysiologies

Descriptor	Presumed mechanism	Characteristics
Nociceptive pain	Ongoing activation of somatic or visceral nociceptors as a result of persistent tissue injury; nervous system is presumed to be intact	Quality usually aching, sharp, throbbing; described as 'familiar' pain; evaluation typically reveals a source of tissue injury perceived to be commensurate with the pain
Neuropathic pain	Related to aberrant somato-sensory processing in the peripheral or central nervous systems; presumed to be sustained by neural processes that become independent, in part, from areas of tissue injury	Quality may be like nociceptive pain, e.g. aching from radiculopathy, or may be dysesthetic (abnormal, unfamiliar) and described as burning, shooting, electrical; evaluation may or may not reveal neurologic findings
Psychogenic pain	Predominantly determined by psychologic factors	Quality and characteristics variable; psychiatric assessment allows classification by specific diagnoses, e.g. pain disorder, somatization disorder, etc.
Mixed syndromes	Multiple mechanisms	Varied
Idiopathic pain	Unable to infer	Varied

Table 60.3. Pathophysiologic classification of neuropathic pains

Presumed to be primarily sustained by central mechanisms
Complex regional pain syndrome Type I (reflex sympathetic dystrophy) and type II (causalgia)
Deafferentation pain syndromes
Central pain
Postherpetic neuralgia
Root avulsion pain
Phantom pain
Miscellaneous syndromes (anesthesia dolorosa)
Presumed to be primarily sustained by peripheral mechanisms
Painful polyneuropathies
Compressive mononeuropathies, e.g. discogenic radiculopathy
Infiltrative or ischemic mononeuropathies, e.g. malignant plexopathies
Traumatic mononeuropathies, e.g. postamputation neuroma
Presumed to be sustained by both peripheral and central mechanisms
Lancinating neuralgias, e.g. trigeminal neuralgia

Table 60.4. Etiologic classification in two types of neuropathic pain

	Possible etiologies
Central pain (lesion in cord, brainstem, or cerebrum)	Trauma
	Ischemia
	Neoplasm
	Syrinx formation
	Focal demyelination
	Infection
	Other
Painful polyneuropathy	Metabolic disorders
	Diabetes
	Hypovitaminosis
	Hypothyroidism
	Uremia
	Amyloid
	Drugs or toxins
	Neoplasm
	Hereditary painful polyneuropathy
	Others

pain syndrome' and 'chronic intractable pain syndrome' are often used but not well defined in the literature. Typically, these terms refer to patients who have pain that is perceived to be excessive for the identifiable organic substrate and is associated with a high level of disability and psychiatric comorbidity. Although the challenge that such patients pose – to enhance analgesia while addressing serious functional disturbances – is very real, these labels can be stigmatizing and divert attention from potentially treatable nociceptive or neuropathic processes. The same risk applies to some site-specific terms, such as atypical facial pain, failed low back surgery syndrome, chronic tension headache, and chronic pelvic pain of unknown etiology.

Evaluation of associated phenomena

The assessment of the medical condition, physical impairments, psychological and social functioning, and prior therapies is an integral part of the pain evaluation, and is essential in developing the therapeutic strategy. The evaluation of pain-related disability as part of this process is particularly important. In a broad sense, the goal is to first clarify the degree to which pain is accompanied by disability, and then to deconstruct the latter phenomenon and understand the various physical and psychosocial factors that may be sustaining it. This assessment will identify patients whose pain syndromes would be most appropriately managed using a multimodality approach that includes interventions that specifically address functional disturbances or impaired quality of life. Some patients will be identified whose disability is sufficient to justify referral to a multidisciplinary pain management program.

The psychological assessment should address the interaction among pain and a spectrum of psychological concerns, including coping and distress, personality, and both present and past psychiatric disorders. When a significant psychiatric disorder (i.e. major depression, anxiety disorder, panic disorder, somatization, or severe personality disorder) is suspected, referral for psychiatric evaluation and specialized treatment is warranted.

The psychologic assessment also should attempt to identify behavioural contingencies and secondary gains that may be sustaining the pain and disability. Although families can be a source of great support for patients who are attempting to cope with pain, the dynamics in some homes have maladaptive consequences. Behavioural contingencies may be identified that reinforce pain, or pain-related behaviours (such as strong encouragement to stay in bed), and could be directly addressed as part of the treatment plan developed by the physician.

The history of prior drug use is an essential part of the assessment. This history should address all types of drug use, including prescription drugs, over-the-counter remedies, and both licit and illicit recreational drugs. A history of substance abuse is extremely important and deliberate questioning may be required to obtain sufficient detail (Passik and Portenoy, 1998). The history should clarify the use of specific drugs (including alcohol) and determine whether this use is remote, recent or ongoing.

Pain management

A comprehensive assessment allows the development of a therapeutic strategy that combines appropriate interventions from a very large number of potential candidates (Table 60.5). In some cases, the therapeutic strategy can include a primary treatment directed against an etiology of the pain. In others, the strategy can attempt to address disability and various medical and psychosocial comorbidities, the overall goal of which is to improve function and quality of life in tandem with enhanced comfort. There are many interventions that could be offered in a multimodality approach to the pain itself, and the decision to emphasize one type, e.g. pharmacotherapy, over another, e.g. rehabilitative, or to combine them from the start, must be individualized based on the priorities identified by the assessment.

Table 60.5. Interventions for pain and pain-related disability

Category	Examples
Pharmacotherapy	
Non-opioid	numerous NSAIDs,
Opioid	various opioids,
Adjuvant analgesic	antidepressants, anticonvulsants, and many other classes
Rehabilitative	physical/occupational therapy, orthoses
Neurostimulatory	transcutaneous electrical nerve stimulation
Psychologic	cognitive/behavioural therapy
Anesthesiologic	neural blockade, neuraxial infusion
Neurosurgical	neuroma resection, CNS lesions, deep brain stimulation
Complementary and alternative	acupuncture, massage, chiropractic, mind-body approaches, herbal therapies
Lifestyle changes	weight loss, exercise

Pharmacologic therapies

Analgesic drugs can be divided into the non-opioid analgesics, the so-called adjuvant analgesics, and the opioid analgesics. The non-opioid analgesics refer to acetaminophen, dipyrone, and all the non-steroidal anti-inflammatory drugs (NSAIDs). The term 'adjuvant analgesic' can be applied to any drug that has a primary indication other than pain but is known to be analgesic in specific circumstances.

Non-opioid analgesics: NSAIDs

The NSAIDs comprise an extremely diverse group of drugs (Table 60.6). They all inhibit the enzyme cyclo-oxygenase

Table 60.6. Non-steroidal anti-inflammatory drugs

Chemical class	Drug	Recommended starting dose (mg/d)	Recommended maximum dose (mg/d)
Non-selective COX inhibitors			
Salicylates	aspirin	2600	6000
	diflunisal	1000×1	1500
	choline magnesium trisalicylate	1500×1 then 1000	4000
	salsalate	1500×1 then 1000	4000
Propionic acids	ibuprofen	1600	4200
	naproxen	500	1500
	naproxen sodium	550	1375
	fenoprofen	800	3200
	ketoprofen	100	300
	flurbiprofen	100	300
	oxaprozin	600	1800
Acetic acids	indomethacin	75	200
	tolmetin	600	2000
	sulindac	300	400
	diclofenac	75	200
	ketorolac (IM)	30 (loading)	60
	ketorolac (PO)	40	40
	etodolac	600	1200
Oxicams	piroxicam	20	40
	meloxicam	7.5	15
Naphthyl-alkanones	nabumetone	1000	2000
Fenamates	mefenamic acid	500×1	1000
	meclofenamic acid	150	400
Pyrazoles	phenylbutazone	300	400
Selective COX-2 inhibitors			
	celecoxib	200	400
	rofecoxib	12.5–25	25

(COX) and reduce the synthesis of prostaglandins. Prostaglandins are key inflammatory mediators and sensitize primary afferent nerves that respond to noxious stimuli in the periphery. Although inhibition of these peripheral processes can explain both the analgesic and anti-inflammatory effects of the NSAIDs, prostaglandin inhibition in the central nervous system probably also contributes to the analgesia produced by these drugs (Willer et al., 1989). A central mechanism predominates in the analgesia produced by acetaminophen and dipyrone, which have minimal to no peripheral anti-inflammatory effects, and also presumably accounts for he observed disparity between the anti-inflammatory and analgesic potencies of some NSAIDs (McCormack & Brune, 1999).

Cyclo-oxygenase is produced in two isoforms, COX-1 and COX-2. COX-1 is relatively more constitutive and is involved in physiologic processes, whereas COX-2 is generally more inducible and involved in the inflammatory cascade. Although the commercially available NSAIDs vary in the extent which they affect COX-1 and COX-2 (some, such as meloxicam and nambumetone are relatively COX-2 selective), all are considered to be non-selective COX-1 and COX-2 inhibitors. The inhibition of the constitutive isoform produced by these drugs is associated with their gastrointestinal toxicities.

COX-2 selective inhibitors are now commercially available and substantially reduce the gastrointestinal risks associated with NSAID therapy (Simon et al., 1999; Langman et al., 1999). These drugs do not have demonstrably lesser renal toxicity than the non-selective COX-1 and COX-2 inhibitors.

Although the maximal efficacy of the NSAIDs varies with the type of pain, these drugs are generally considered to be non-specific analgesics. Nonetheless, clinical observation

suggests that they have relatively better efficacy in pain related to a grossly inflammatory process and bone pain, and relatively poorer efficacy in neuropathic pains. Their dose–response relationships are characterized by a minimal effective dose, dose-dependent analgesic effects, and a ceiling dose for analgesia. The existence of a ceiling dose implies that these drugs have limited maximal efficacy and are usually considered first-line for pains that are mild to moderate in severity.

There is large individual variation in the effective dose range and the dose associated with toxicity. Moreover, the maximal efficacy of the NSAIDs varies across drugs in any individual patient. Although an explanation for this phenomenon is lacking, it has important clinical implications. Sequential trials may demonstrate striking differences in effectiveness.

The potential for toxicity during NSAID therapy influences the decision to initiate therapy, the selection of drugs, and the approach to dosing and monitoring. Clinically important adverse gastrointestinal (GI) symptoms occur in about 10% of patients treated with the non-selective COX-1 and COX-2 NSAIDS, and ulcers occur in about 2% (Loeb et al., 1992). Although some surveys suggest that the risk is limited to gastric ulceration, other data implicate both gastric and duodenal lesions. Nausea and abdominal pain are poor predictors of serious GI toxicity; as many as two-thirds of NSAID users have no symptoms before bleeding or perforation.

The factors that have been associated with an increased risk of ulceration include advanced age, higher NSAID dose, concomitant administration of a corticosteroid, and a history of either ulcer disease or previous GI complications from NSAIDs (Loeb et al., 1992). Heavy alcohol or cigarette consumption may also increase the risk. A role for infection with the bacterium, *Helicobacter pylori*, in NSAID-related gastropathy has been suggested but never proved.

There are differences in the potential for GI toxicity among the various NSAIDs. As noted, the COX-2 selective drugs significantly reduce the risk of both GI symptoms and ulcer formation (Simon et al., 1999; Langman et al., 1999). However, comparative epidemiologic data, for these drugs and others, are limited. It is generally accepted that some NSAIDs have a relatively lesser risk of serious GI toxicity (such as the non-acetylated salicylates, choline magnesium trisalicylate and salsalate; ibuprofen and several other proprionic acids; diclofenac, and nabumetone), whereas others have a relatively greater risk (such as ketorolac, piroxicam and the fenamates).

The risk of ulcer can be reduced by concurrent administration of gastroprotective therapy (La Corte et al., 1999). Misoprostol, a prostaglandin analogue, reduces the incidence of NSAID-induced ulcers without reversing anti-inflammatory and analgesic effects. Proton pump inhibitors, such as omeprazole and lansoprazole, also have established efficacy. Studies of H2 blockers have been mixed, but a trial of higher dose famotidine was positive (Taha et al., 1996). Other interventions, such as antacids and sulcrafate, may reduce symptoms but do not decrease ulcer risk.

At the present time, it is reasonable to consider first-line use of the COX-2 selective drugs for patients at relatively high risk for GI toxicity, such as the elderly. Alternatively, co-administration of a gastroprotective therapy could be considered. There are no data presently by which to judge the relative cost-effectiveness of these approaches. Although changing practice patterns suggest that many clinicians are positioning the COX-2 selective drugs ahead of others in all types of patients, studies that confirm the advantages of doing so are still lacking.

All NSAIDs can cause serious renal toxicity (Murray and Brater, 1993). They must be used cautiously in patients who have nephropathies or are likely to have subclinical disease as a result of advanced age, prior treatment with nephrotoxic therapy (such as platinum-based chemotherapy), or an underlying disease.

Although there are large drug-to-drug differences in the degree to which various NSAIDs affect platelet function, the safety of these drugs in patients predisposed to bleeding has not been established in the clinical setting. All these drugs should be used cautiously in patients with a bleeding diathesis. The COX-2 inhibitors do not affect platelets.

Long-term NSAID therapy should be monitored for adverse effects. This monitoring might include periodic testing for occult fecal blood and an evaluation of hemoglobin, renal function and hepatic function. Patients who are predisposed to adverse effects and those who are receiving relatively high doses should be monitored relatively more frequently.

Although studies of dosing protocols in different patient populations are limited, it is prudent to initiate NSAID therapy with gradual dose escalation from a relatively low starting dose when patients have mild to moderate pain or a relatively increased risk of NSAID toxicity. During therapy, dose escalation can be considered if pain is uncontrolled, side effects are not intolerable, and the conventional maximal dose has not yet been reached. Dose escalation will not yield increased effects if the patient is at the ceiling dose. If a ceiling dose or conventional maximal dose is reached without achieving satisfactory analgesia, an alternative NSAID trial should be considered.

Adjuvant analgesics

The adjuvant analgesics include numerous drugs in diverse classes (Table 60.7) (Portenoy, 1998). The term

Table 60.7. Adjuvant analgesics

Multipurpose analgesics	Examples
Antidepressants	
Tricyclic antidepressants	amitriptyline
	desipramine
SSRIs/SNRIs[a]	paroxetine
	venlafaxine
Others	maprotiline
	buproprion
Alpha-2 adrenergic agonists	clonidine
	tizanidine
Corticosteroids	dexamethasone
	prednisone
For neuropathic pain	
Anticonvulsants	gabapentin
	carbamazepine
	phenytoin
	valproate
	clonazepam
	lamotrigine
	topiramate
	tiagabine
	oxcarbazepine
	zonisamide
	levetiracetam
Oral local anesthetics	mexiletine
	tocainide
NMDA receptor antagonists	ketamine
	dextromethorphan
	amantadine
Miscellaneous	baclofen
	calcitonin
Drugs used for CRPS or suspected SMP[b]	calcitonin
	corticosteroids
	clonidine
	prazosin
	phenoxybenzamine
	nifedipine
Topical agents	capsaicin
	local anesthetics
	NSAIDs
For headache	calcium channel blockers
	beta blockers
	antidepressants
	anticonvulsants
	ergot derivatives
	triptans
	ACE inhibitors
For cancer-related bone pain	bisphosphonates, e.g. pamidronate
	calcitonin
	radiopharmaceuticals, e.g. strontium-89 and samarium-153
For painful bowel obstruction	scopolamine
	glycopyrrolate
	octreotide

Notes:

[a] SSRI = serotonin-selective reuptake inhibitor; SNRI = serotonin- and norepineprine-selective reuptake inhibitors.

[b] CRPS = complex regional pain syndrome; SMP = sympathetically maintained pain.

'adjuvant', which was coined in the context of cancer pain management, has become a misnomer as the role of these drugs has been expanded to the primary treatment of many pain syndromes.

Multipurpose adjuvant analgesics

With clinical trials demonstrating efficacy in diverse types of chronic pain, some drug classes are best considered multipurpose analgesics. In this sense, they are similar to the opioids and the NSAIDs.

Antidepressants

The analgesic efficacy of the tricyclic antidepressants (TCAs) has been established in many painful disorders, including headache, arthritis, low back pain, postherpetic neuralgia, painful polyneuropathy, and fibromyalgia (Monks & Merskey, 1999). Both the tertiary amine TCAs (such as amitriptyline, imipramine and doxepin) and the secondary amine compounds (such as desipramine and nortriptyline) have analgesic effects. The supporting evidence is best for amitriptyline and desipramine (Max et al., 1992). Controlled trials also have established the efficacy of some of the serotonin-selective reuptake inhibitors (such as paroxetine), the serotonin- and norepinephrine-selective reuptake inhibitors (such as venlafaxine), and other antidepressant classes. Together, the extant data suggest that all antidepressants have the potential to be analgesic, and that the TCAs are likely to have higher analgesic efficacy overall than the newer drugs.

The analgesia produced by antidepressant drugs is believed to be due to their actions on endogenous monoaminergic pain modulating systems, particularly those that use norepinephrine or serotonin. Although positive mood effects may be beneficial, they are not required for analgesic efficacy.

It is reasonable to consider a TCA as the first-line drug if pain is a primary indication and the patient is likely to tolerate the drug. A tertiary amine, such as amitriptyline,

might be considered first, but avoided if the patient is likely to experience troublesome sedative, anticholinergic, or cardiovascular toxicity. The secondary amine TCAs have fewer side effects and are often used instead. The newer antidepressants usually are better tolerated than the TCAs overall, and should be considered for those who cannot tolerate TCAs or are substantially predisposed to side effects.

Variability in the analgesic responses to antidepressant drugs is common and sequential trials are appropriate in an effort to identify an effective and well tolerated drug. When a TCA is used, the analgesic effect is typically obtained at doses lower than the antidepressant dose and the onset of analgesia is more rapid (within a week) than effects on mood.

Alpha-2 adrenergic agonists

Clonidine and tizanidine are alpha-2 adrenergic agonists with established analgesic effects in a variety of pain syndromes (headache, diabetic neuropathy pain, postoperative pain, postherpetic neuralgia, and cancer pain). A study of systemic clonidine in patients with postherpetic neuralgia supported the potential for analgesia, but suggested that a relatively small proportion of patients respond (Byas-Smith et al., 1995). Tizanidine appears to be better tolerated than clonidine. Somnolence is the most difficult side effect associated with both of these drugs. As a result, it is prudent to initiate a trial with a low dose, then gradually increase the dose if tolerated.

Corticosteroids

The corticosteroids have been shown to improve pain, appetite, nausea, malaise, and overall quality of life in populations with advanced medical illness (Tannock et al., 1989). Non-malignant pain syndromes, including neuropathic pains and pains associated with inflammatory diseases, also may respond. Because the risks associated with this therapy increase with both the dose and duration of use, long-term administration is usually considered only for patients with advanced medical illnesses, such as cancer, and those with chronic inflammatory disorders who are administered the drug as a primary, rather than symptomatic, treatment. Current data are inadequate to evaluate drug-selective differences, dose-response relationships for the various effects, predictors of efficacy, or the durability of effects.

Adjuvant analgesics for neuropathic pain

The advent of a more sophisticated pharmacotherapy for chronic neuropathic pain has been one of the major recent advances in pain management (Sindrup and Jensen, 2000). Although the empirical use of many drugs is occurring before confirmatory trials are done, the clinical experience has been positive and the options for patients with challenging neuropathic pain have never been greater.

Chronic neuropathic pain of any type may be a target of one of the multipurpose adjuvant analgesics. Traditionally, the antidepressants and alpha-2 adrenergic agonists are considered to be among the first drugs considered for neuropathic pain characterized by continuous dysesthesias. Although these drugs also may benefit syndromes characterized by lancinating paroxysmal pains (such as trigeminal neuralgia), they usually are considered after the anticonvulsants or baclofen in this circumstance.

Anticonvulsants

There is extensive experience in the use of anticonvulsant drugs in the treatment of neuropathic pains (Ross, 2000). Concurrent with this role, these drugs also have found an expanding utility in the management of headache and varied psychiatric syndromes.

Older anticonvulsant drugs that have been used for neuropathic pain include carbamazepine, phenytoin, valproate, and clonazepam. These drugs have established analgesic effects in many syndromes characterized by lancinating or paroxysmal neuropathic pains, most notably in trigeminal neuralgia. In recent years, however, they have been administered conventionally for all types of neuropathic pain.

There is now a large and favourable experience with gabapentin, and data from experimental and clinical studies support potential efficacy in any type of neuropathic pain (Sindrup and Jensen, 2000; Ross, 2000). A favourable clinical profile has encouraged its use and, at the present time, it is generally considered a first- or second-line drug for all types of neuropathic pain. The effective dose range for pain appears to be very large. Although some patients respond at a total daily dose of 600 mg, many do not benefit until the daily dose is increased to 3600 mg, and some patients appear to benefit at doses substantially higher.

Other anticonvulsants, including lamotrigine, topiramate, oxcarbazepine, zonisamide, tiagabine, and levetiracetam, have more limited support from clinical trials but are nonetheless used in the management of neuropathic pain. At the present time, the best supporting evidence has been obtained for lamotrigine, which has established efficacy in both trigeminal neuralgia and central pain (Zakrewska et al., 1997; Vestergaard et al., 2001).

In the absence of any contrary data, the administration of the anticonvulsants for pain mirrors the approaches used to manage seizures. To use these drugs optimally, the clinician must appreciate their risks and side effect profiles, and understand appropriate dosing methods and monitoring techniques.

Oral local anesthetics

Systemic administration of local anesthetic drugs may produce analgesia in diverse pain syndromes, including neuropathic pains (Deigard et al., 1988). The availability of oral local anesthetic drugs offers an acceptable approach for long-term therapy. In controlled clinical trials, these drugs have been effective in relieving both continuous and paroxysmal pains. Given the relatively limited experience with these drugs as analgesics, and their side effect profiles, they should be considered second-line approaches. In the United States, mexiletine has been the preferred oral local anesthetic for the treatment of pain, based on a relatively better therapeutic index for serious cardiac and neurological toxicity. Alternative drugs, such as tocainide and flecainide, are also used.

Brief intravenous local anesthetic infusions also are analgesic. This approach, which usually involves the administration of lidocaine in doses of 2–4 mg/kg over 20–30 minutes, may be used in an effort to relieve very severe or rapidly progressive pain, or provide a local anesthetic trial in those patients unable to tolerate the oral drugs. It may be possible to predict the effect of oral therapy with a brief infusion, but the validity of this technique has not yet been sufficiently established to apply it routinely.

Given the side effect and toxicity profiles, oral local anesthetic therapy is best initiated at a low starting dose. Gradual dose escalation should proceed until favourable effects occur, side effects become problematic, or the usual maximal daily dose is reached. The electrocardiogram should be monitored at higher doses and measurement of plasma drug concentrations may be informative.

NMDA receptor antagonists

Recent preclinical studies have established that binding of the excitatory amino acid glutamate at the N-methyl-D-aspartate (NMDA) receptor is involved in the mechanisms that may underlie some neuropathic pains. On the basis of these findings, NMDA receptor antagonists are undergoing intensive investigation as potential analgesics.

Three drugs commercially available in the United States, the antitussive dextromethorphan, the dissociative anesthetic ketamine, and the antiviral amantadine, act at this receptor and may be potentially useful in neuropathic pain (Persson et al., 1995; Nelson et al., 1997). A trial of dextromethorphan may be initiated using a commercially available product that contains neither alcohol nor guaifenasin. It is likely that the analgesic dose will be at least 250 mg per day. Ketamine has been used both via brief infusion and orally. The side effect profile of this drug, which includes nightmares, hallucinations and delirium, is problematic and its use is likely to be limited to patients with severe and refractory neuropathic pain. Experience with amantadine is yet very limited.

Other drugs for neuropathic pain

The GABA agonist baclofen has been shown to be effective in the treatment of trigeminal neuralgia and is now often administered for diverse types of neuropathic pain (Fromm et al., 1984). Similar to its use for spasticity, the usual effective dose range is very broad. Although most patients appear to respond at doses lower than 100 mg per day, some require more than twice this dose to achieve a favourable effect. A serious abstinence syndrome, which includes status epilepticus, can occur with abrupt discontinuation of this drug and the dose always should be tapered before treatment is stopped.

Calcitonin may be effective as a treatment for complex regional pain syndrome (reflex sympathetic dystrophy and causalgia) (Gobelet et al., 1992). Its mode of action in this disorder is unknown. Given the favourable safety profile of this drug, it is empirically considered for a trial in other types of neuropathic pain as well. There are no data by which to judge a dose-response or long-term efficacy.

Other drugs are sometimes used in the treatment of complex regional pain syndrome. Prednisone or some other corticosteroid may be administered on the basis of limited data from clinical trials. Other drugs, such as prazocin and phenoxybenzamine, have been tried based on the observation that sympathetic blockade can help a subset of these patients. Still other drugs, such as nifedipine, are used based on anecdotal observation only.

Topical therapies

The role of topical therapy for pain is enlarging. A lidocaine impregnated patch has now been approved by the U.S. Food and Drug Administration for the treatment of postherpetic neuralgia (Galer et al., 1999). It is being tried more generally for all types of neuropathic pain and other pain syndromes related to injury to skin. Patients with neuropathic pain due to peripheral nerve injury can also be considered for trials of topical local anesthetic creams and gels, which may begin with lidocaine in varied concentrations and extend to a trial of a commercially available eutectic mixture of lidocaine and prilocaine. The latter cream has the ability to produce cutaneous anesthesia with sufficient contact time (Ehrenstrom-Reiz & Reiz, 1982).

Despite equivocal findings in some studies, capsaicin, which depletes peptides in nociceptors and other small primary afferent neurons, continues to be used for both neuropathic and arthritic pain (McCleane, 2000). An adequate trial is generally believed to require three to four applications daily for one month. Musculoskeletal pains of

Table 60.8. Opioid analgesics used during long-term treatment of chronic pain

	Equianalgesic dose (mg)		Half-Life		
Drug	P.O.	I.M./I.V	(Hrs)	(Hrs)	Duration comment
Morphine	20–30[a]	10	2–3	2–4	Standard for comparison; although a single-dose study showed a P.O.: I.M. ratio of 6: 1, the ratio of 2–3: 1 is appropriate for chronic dosing
Morphine CR	20–30	10	2–3	8–12	Various formulations are not bioequivalent
Morphine SR	20–30	10	2–3	24	—
Oxycodone	20	—	2–3	3–4	
Oxycodone CR	20	—	2–3	8–12	
Hydromorphone	7.5	1.5	2–3	2–4	Potency may be greater, i.e. IV hydromorphone: IV Morphine = 3: 1 rather than 6.7: 1, during prolonged use.
Methadone	20	10	12–190	4–12	Although 1: 1 IV ratio with morphine was in single dose study, there is a change with chronic dosing and large dose reduction (75–90%) is needed when switching to methadone.
Fentanyl	—	—	7–12	—	Can be administered as a continuous IV or SQ infusion; based on clinical experience, 100 μg/hr is roughly equianalgesic to IV morphine 4 mg/h.
Fentanyl TTS	—	—	16–24	48–72	Based on clinical experience, 100μg/hr is roughly equianalgesic to IV morphine 4 mg/h. A ratio of oral morphine: transdermal fentanyl of 70: 1 may also be used clinically.

Notes:

[a] Although the PO: IM morphine ratio was 6: 1 in a single dose study, other observations indicate a ratio of 2–3: 1 with repeated administration.

Source: Adapted from Derby et al. (1998).

all types also are candidates for trials of topical NSAIDs, which can be commercially compounded in various formulations (Galer et al., 2000).

Topical opioids, antidepressants (McCleane, 2000), sodium channel blockers such as mexiletine, ketamine, and other drugs are being tried in challenging cases. The relatively low risk of side effects associated with topical therapy ensures that further efforts will be made to identify drugs that may be effective by this route. Studies are needed to establish the benefits and define appropriate therapeutic candidates.

Opioid analgesics

Opioids are mainstay analgesics for acute pain and chronic pain related to cancer, and the role of these drugs in the management of chronic non-malignant pain is rapidly evolving (Portenoy, 1996). Numerous pure mu agonists are available and are the preferred agents for the treatment of acute and chronic pain (Table 60.8).

Opioid drugs have no long-term major organ toxicity and no ceiling effect to analgesia. During dose titration, analgesia increases until unconsciousness or some other intolerable side effect imposes a practical limit. The goal of therapy is to identify a favourable balance between analgesia and side effects. Responsiveness varies with characteristics of the patient and pain syndrome, but there is no characteristic that imparts opioid resistance. Accordingly, any severe chronic pain is potentially a candidate for an opioid trial. Selection of a patient for a trial must be based on a careful assessment and is influenced by the pain syndrome and conventional practice (first-line therapy for moderate or severe cancer pain, but generally not first-line for non-malignant pains), availability of safe alternative therapies, the risk of side effects, and the likelihood that the patient is able to use the drug responsibly.

The most important opioid side effects are constipation, nausea, vomiting, sedation and mental clouding. Tolerance develops to many side effects, usually in the first

Table 60.9. Common strategies to manage opioid side effects

Constipation
– best managed with combination of cathartic and stool softener
– osmotic or lavage agents can be useful
– refractory constipation can be treated with a trial of oral naloxone
Nausea, Vomiting
– metoclopramide or other dopamine antagonists
– scopolamine or other anticholinergic drugs
– ondansetron or other 5-HT antagonists
– change route of administration
– switch opioid
Sedation
– methylphenidate or other psychostimulant
– switch opioid

Source: Adapted from Caraceni & Portenoy (1998).

weeks of therapy. There are numerous strategies for the treatment of common opioid side effects (Table 60.9) (Caraceni and Portenoy, 1998). Long-term opioid therapy is fully consistent with functional restoration. Cognitive impairment can usually be avoided and successful therapy is marked by the capacity to drive, work, enjoy social activities and avocations, and otherwise capitalize on analgesia to improve quality of life.

Opioid therapy may be compromised by confusion concerning the phenomena of tolerance, physical dependence and addiction (Portenoy & Payne, 1997). Tolerance refers to a process by which exposure to a drug at a constant dose results in a decreasing effect, or the need for a higher dose to maintain an effect. It is entirely distinct from addiction. In humans, tolerance to non-analgesic opioid effects, such as somnolence, is favourable and allows safe escalation of the opioid dose. Tolerance to analgesic effects is a concern, but large surveys have established that loss of analgesia rarely occurs in opioid-treated patients with stable pain syndromes.

Physical dependence is a physiological phenomenon characterized by the development of an abstinence syndrome following abrupt discontinuation of therapy, substantial dose reduction, or administration of an antagonist drug. It is distinct from addiction and the term 'addicted' should never be used to refer to the capacity for abstinence. If abstinence is avoided, physical dependence is clinically irrelevant.

A task force of the American Medical Association defined addiction as 'a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological or social harm to the user and continued use despite that harm' (Rinaldi et al., 1988). This statement emphasizes that addiction is a psychological and behavioural syndrome with several fundamental features: (i) loss of control over drug use, (ii) compulsive drug use, and (iii) continued use despite harm. The syndrome is characterized by a genetic predisposition, which interacts in complex ways with psychosocial factors, situational factors and access to abusable drugs. In treating pain patients, addiction is suggested by the development of aberrant drug-related behaviours consistent with these features (Portenoy & Payne, 1997).

Information about addiction liability derives from limited published surveys that report clinical experience in selected populations. In populations with acute pain and those with chronic cancer pain, iatrogenic addiction is rare. In populations with non-malignant pain, the likelihood of iatrogenic addiction is unknown and presumably relates to various risk factors, such as a prior history of drug abuse, a family history of drug abuse, major psychiatric pathology, and social disruption (Compton et al., 1998). Clinicians who are considering the use of an opioid must assess for these factors and monitor patients for the development of aberrant drug-related behaviours over time. Monitoring is particularly important if treatment is offered to patients with a prior or current history of substance abuse (Portenoy & Payne, 1997).

Guidelines for the long-term administration of opioid drugs are well accepted for populations with cancer pain (Jacox et al., 1994). Although additional guidelines should be considered when treating patients with non-malignant pain (Table 60.10) (Portenoy, 1994), the approach to optimizing pharmacologic outcomes is the same irrespective of the clinical population. The most important principle is individualization of therapy, which is accomplished through gradual dose titration. Doses should be increased until a favourable outcome is achieved or treatment-limiting side effects occur. The absolute dose is immaterial as long as there is a favourable balance between analgesia and side effects. The use of extended-release opioids or opioids of long half-life (particularly methadone) is preferred during chronic therapy.

Other analgesic therapies

Patients with chronic pain may be appropriate for any of a very large number of alternative analgesic therapies (Loeser, 2001). Many patients benefit from a multimodality strategy that combines systemic pharmacotherapy with other approaches (Table 60.5).

Psychological interventions and rehabilitative therapies may improve comfort and are essential elements in a

Table 60.10. Guidelines for opioid therapy in populations with non-malignant pain

1. Therapy is based on a comprehensive assessment, which should judge the nature and consequences of the pain, the availability of alternative therapeutic strategies, and the likelihood of opioid responsiveness and responsible drug use.
2. A history of substance abuse or other factors that may predispose to abuse or addiction suggest the need for a more detailed evaluation and the use of strategies during therapy to improve monitoring of drug-taking behaviour.
3. A single practitioner should take primary responsibility for treatment.
4. Patients should give informed consent before starting therapy; accurate information about addiction liability and the occurrence of physical dependence should be provided and the potential for cognitive impairment and constipation should be discussed.
5. After drug selection, doses should be given around-the-clock; several weeks should be agreed upon as the period of initial dose titration, and although improvement in function should be continually stressed, all should agree to at least partial analgesia as the appropriate goal of therapy.
6. Failure to achieve at least partial analgesia at relatively low initial doses in the non-tolerant patient raises questions about the potential treatability of the pain syndrome with opioids.
7. Emphasis should be given to capitalizing on improved analgesia by gains in physical and social function; opioid therapy should be considered complementary to other analgesic and rehabilitative approaches.
8. In addition to the daily dose determined initially, patients should be permitted to escalate dose transiently on days of increased pain; two methods are acceptable: a) prescription of additional 'rescue doses' of the same drug or an alternative short-acting opioid; b) instruction that one or two extra doses may be taken on any day, but must be followed by an equal reduction of dose on subsequent days.
9. Initially, patients must be seen and drugs prescribed at least monthly. When stable, less frequent visits may be acceptable.
10. Evidence of drug hoarding, acquisition of drugs from other physicians, uncontrolled dose escalation, or other aberrant behaviours must be carefully assessed. In some cases, tapering and discontinuation of opioid therapy will be necessary. Other patients may appropriately continue therapy within rigid guidelines. Consideration should be given to consultation with an addiction medicine specialist.
11. At each visit, assessment should specifically address (a) comfort (degree of analgesia), (b) opioid-related side effects, (c) functional status (physical and psychosocial), and (d) occurrence of aberrant drug-related behaviours; these four outcomes should be documented repeatedly in the medical record.

Source: Adapted from Portenoy (1994).

broader approach that addresses pain-related disability. There is strong evidence that the psychological approaches benefit patients with pain. Support for the various rehabilitative therapies derives from an extensive clinical experience. The psychological approaches usually include cognitive, e.g. relaxation training, biofeedback, hypnosis, and varied other techniques, and behavioural therapies. The rehabilitative interventions include therapeutic exercise, the use of orthoses, and various modalities such as heat and cold. Transcutaneous electrical nerve stimulation also is widely used and supported by abundant clinical experience.

Invasive therapies for pain are typically performed by anesthesiologists (sometimes others) with advanced training in pain management. These techniques include injection therapy, neural blockade, neuraxial analgesia techniques, and central nervous system stimulation approaches. Despite very limited data from controlled clinical trials, local anesthetic and corticosteroid injections are widely used to manage neuropathic pain, myofascial and joint pain, and spinal pain syndromes. There is an extensive experience with long-term intraspinal therapy and dorsal column stimulation, and the utility of both these approaches is expanding with improved technology and new drug development. The availability of these techniques to manage pain that has not responded to conservative therapies has relegated the use of chemical and surgical neuroablative interventions to rare patients.

Many patients with chronic pain seek complementary and alternative medicine approaches. Pain specialists, whose practice includes many conventional interventions supported only by clinical experience, are usually open to those modalities for which there is some limited evidence and a high likelihood of safety. Acupuncture, lumbar chiropractic manipulation, and therapeutic massage are widely used.

Conclusion

The past three decades have witnessed an extraordinary increase in knowledge concerning the neurobiology of pain and the potential of diverse types of analgesic interventions. All clinicians should be able to perform a comprehensive pain assessment that clarifies the nature of the pain and pain-related comorbidities, and facilitates a therapeutic strategy that may enhance comfort and function. The non-specialist can implement and monitor many components of this strategy. Patients with refractory pain, and those with pain associated with severe disability, should be considered for referral to specialists in pain management.

Migraine

Michael D. Ferrari[1] and Joost Haan[1,2]

[1] Department of Neurology, Leiden University Medical Centre, Leiden, The Netherlands
[2] Department of Neurology, Rijnland Hospital, Leiderdorp, The Netherlands

Migraine is a common, chronic, multifactorial, neurovascular disorder, typically characterized by attacks of severe headache, associated autonomic and neurological symptoms, and general malaise (Ferrari, 1998). The disease is beset by myths, including that it is mainly 'a psychological response to stress'. Despite that migraine is among the chronic diseases with the highest disability and socioeconomic impact (Menken et al., 2000), it also is among the most undertreated neurological conditions. More than two-thirds of patients either have never consulted a physician for their migraine, or have stopped doing so. Recent progress in the scientific basis of the diagnosis, epidemiology, pathophysiology, and pharmacology of migraine has, however, significantly improved the diagnostic and therapeutic options for this enigmatic brain disorder.

Clinical features and diagnosis

The International Headache Society (IHS, 1988) has considerably improved the diagnosis of migraine and other headache syndromes. Different types of headache, rather than patients, are diagnosed. Patients may have concurrent types of headache (e.g. migraine and tension-type headache), which should be treated separately. The two main types of migraine are migraine without aura (previously known as common migraine), occurring in 75% of migraineurs, and migraine with aura (previously classic migraine), occurring in one-third of patients (Table 61.1). Up to 33% of migraineurs experience both types of attacks during their lifetime (Russell et al., 1995).

Aura symptoms nearly always include visual (99% of patients), together with sensory (31%) or aphasic (18%) symptoms and, rarely, motor ones (6%) (Russel & Olesen, 1996). Aura symptoms typically progress over minutes, or different symptoms succeed one another. They usually occur at alternating body sides in different attacks, nearly always precede the headache and usually last between 5 and 60 minutes; motor symptoms may last longer. Up to 42% of patients may have attacks of migraine aura without headache. In patients with a typical history of migraine and an uneventful standard neurological examination, ancilliary investigations are redundant. The following 'alarm symptoms' may warrant a CT- or MRI-scan: aura symp-

Table 61.1. Simplified diagnostic criteria for migraine with and without aura

Migraine without aura
- Attacks lasting 4–72 hours[a]
- At least two of the following four headache characteristics:
  - unilateral
  - pulsating
  - moderate to severe[b]
  - aggravated by movement
- At least one associated symptom:
  - nausea or vomiting
  - photophobia
  - phonophobia

Migraine with aura[c]
- One or more transient focal neurological aura symptoms[d]
- Gradual development of aura symptom over >4 minutes, or several symptoms in succession
- The aura symptoms last 4–60 minutes
- Headache follows or accompanies aura within 60 minutes

Notes:
[a] duration applies to untreated or unsuccessfully treated attacks
[b] disturbing or precluding daily activities
[c] criteria for typical aura only; for atypical aura see IHS (1988)
[d] referring to focal cortical or brainstem dysfunction
Source: Adapted from IHS (1998).

toms always at the same body side or with acute onset without spread or either very brief (<5 min) or unusually long (> 60 min) duration; sudden change in migraine characteristics or a sudden, substantial increase in attack frequency; onset above age 50; aura without headache; or abnormal neurological examination. EEG is seldomly useful, except in the rare cases when epilepsy is suspected.

Differential diagnosis

Migraine may be difficult to differentiate from tension-type headache (previously known as stress-, tension-, or muscle contraction headache), and many patients have both headache types. The diagnostic criteria are opposite to those for migraine (IHS, 1988). Thus, tension-type headache has at least two of four characteristics: bilateral, non-pulsating, mild to moderate, and no aggravation by movement; there is no or only mild nausea or photophobia and phonophobia.

Overuse of antimigraine or analgesic drugs, especially those which also contain caffeine, frequently complicates migraine. The overuse syndrome is characterized by gradual increase of headache frequency and drug consumption, and a change of the headache characteristics. Ultimately, patients use 'painkillers' or other headache medication daily, to treat daily occurring atypical headaches, alternating with migraine-like aggravations. Anyone who has frequent headaches, should be specifically asked about their consumption of caffeine and analgesics, particularly those obtained without prescription (as these are usually not considered a medication by patients). The number of doses used, rather than the total weekly amount of drug, is important. Thus, daily use of a low dose is much riskier than a very large amount on one day a week. Frequent headache sufferers who regularly use headache drugs more often than 1 or 2 days per week should withdraw abruptly from all these drugs (and caffeine) (Hering & Steiner, 1991). After a few weeks of withdrawal symptoms, the severity and frequency of the headaches usually decrease and after 2 to 3 months the original headache characteristics return, enabling a correct diagnosis and treatment (see Chapter 64).

Epidemiology

Migraine patients are defined as individuals who have had at least two attacks with aura or at least five attacks without aura (IHS, 1988). One-year prevalence figures, i.e. migraine patients who have had at least one attack in the previous year, are remarkably similar across western countries and are primarily dependent on sex and age. Between age 10 and 19 there is a sharp but transient rise of the 1-year prevalence of migraine, with a peak around age 14–16 (Stewart et al., 1994); for women this is followed by a less abrupt second rise until age 40 (Stewart et al., 1994). Thus, overall 10–12% of the general population are active migraineurs. From age 16, migraine is 2–3 times more frequent in females than in males; females around age 40 have the highest prevalence (24%). The lifetime prevalence of migraine is at least 18% of the general population, but these figures are deflated by recall bias at older age (Russell et al., 1995). Onset of migraine may be at all ages, but is nearly always (90%) below age 50; the peak incidence is around puberty. The median attack frequency is 1.5 attacks per month; at least 10% of patients have weekly attacks (Stewart et al., 1994). The median attack duration is just under 1 day; one fifth of the patients have attacks lasting 2–3 days. Thus, more than 5% of the general population have at least 18 migraine days per year and more than 1% at least 54 days.

Pathophysiology

Anyone can have a migraine attack occasionally without necessarily being a migraine patient. It is not the attack but the repeated occurrence that is abnormal. Attacks seem to involve physiological mechanisms, initiated by migraine- and patient-specific triggers. Attacks recur only when the threshold for triggers is reduced or when the triggers are particularly strong and frequent. Genetic factors, most likely involving ion channel and receptor function, appear to set the individual threshold; internal and environmental factors such as hormonal fluctuations, fatigue, relaxation following stress, and substance misuse may modulate this set-point (Haan et al., 1996; Ferrari, 1998; Montagna, 2000).

Complex genetic factors are involved in migraine (Russell & Olesen, 1995; Haan et al., 1996; Montagna, 2000). The study of genetic factors in migraine has mainly focused on familial hemiplegic migraine (FHM), a rare, autosomal dominant subtype of migraine with aura, often misdiagnosed as epilepsy. Attacks are characterized by hemiparesis during the aura (IHS, 1988; Haan et al., 1996; Montagna, 2000). FHM is part of the migraine spectrum and can thus be used to identify candidate genes for migraine. In the majority of patients, FHM is caused by missense mutations in the so-called CACNA1A gene on chromosome 19p13, encoding the α_{1A} subunit of a P/Q type voltage-dependent calcium channel (Ophoff et al., 1996). These neuronal calcium channels are involved in cortical spreading

depression (see below) and release of neurotransmitters, including acetylcholine, neuroexcitatory aminoacids such as glutamate and aspartate, monoamines such as 5-HT, and calcitonin-gene-related-peptide (CGRP). Both clinical, genetic, and neurophsyiological evidence is accumulating that dysfunction of ion channels is involved in the pathophysiology of migraine (Ferrari, 1998).

Neurophysiological, magnetic resonance spectroscopy, biochemical, and epidemiological data suggest that migraineurs have an interictal state of cortical hyperexcitability, characterized by a reduced threshold and increased responses (Welch & Ramadan, 1995; Ferrari, 1998; Schoenen & Thomsen, 1999). The excitability level is proportional to the attack frequency. Its physiological basis may be defective mitochondrial oxidative phosphorylation, low intracellular magnesium, increased levels of neuroexcitatory amino acids, inherited dysfunction of calcium or other ionchannels, or a combination of these factors (Ferrari, 1998).

During attacks, PET studies have identified an area of increased cerebral blood flow in the upper brain stem (Weiler et al., 1995). This brainstem area may represent the 'migraine generator' involved in the initiation and maintenance of migraine attacks (Fig. 61.1, see colour plate section).

The migraine aura is most likely caused by 'cortical spreading depression' (CSD) (Lauritzen, 1994), a depolarization wave that propagates across the brain (mainly occipital) cortex at 2–3 mm/min and is associated with transient depression of spontaneous and evoked neuronal activity. The depression wave lasts several minutes and is preceded by a front of brief neuronal excitation and intense spike activity. During CSD there is dramatic failure of brain ion homeostasis and efflux of excitatory amino acids from nerve cells.

Activation of the trigeminovascular system (TVS; Fig. 61.1, see colour plate section) is pivotal to the pathogenesis of the migraine headache and associated symptoms. Afferent fibres, arising from the ophthalmic division of the trigeminal nerve and the upper cervical spinal cord segments, innervate the proximal parts of the large cerebral vessels, the pial vessels, large venous sinuses, and dura mater. These sensory fibres carry nociceptive information and project centrally, terminating within the trigeminal nucleus caudalis in the lower brain stem and upper cervical cord. The information is relayed further via the quintothalamic tract to the thalamus and cortical pain (perception) areas.

Depolarization of the trigeminal ganglion or its perivascular nerve terminals activates the TVS. This gives rise to central transmission of nociceptive information and retrograde release of powerful vasoactive neuropeptides from the perivascular nerve terminals. In animal experiments, these neuropeptides promote a sterile neurogenic inflammation response, consisting of two components: (i) dural vasodilation, mediated via release of CGRP from trigeminal A-delta-fibres; and (ii) dural plasma extravasation, mediated via release of neurokinin A and substance P from trigeminal C-fibres. Neurogenic inflammation has yet to be demonstrated in migraine.

Non-pharmacological treatment

Non-pharmacological treatments for migraine, including avoidance of putative migraine triggers, have no demonstrated efficacy, and are usually disappointing. Migraineurs have an inherited tendency to attacks, which may be triggered by a wide variety of factors. Complete avoidance seems impossible. There is no good evidence that specific diets ameliorate migraine. When overuse of analgesics and caffeine is present, stopping can reduce migraine attack frequency and severity.

Prophylactic drug-treatment

Preventive efficacy has been demonstrated for the β adrenoceptor-blockers propranolol and metoprolol (and probably also atenolol, timolol and nadolol), and the antiepileptic drug valproate (which has GABA-ergic and ion channel activity). Other β-blockers or antiepileptic drugs have no demonstrated efficacy. The 5-HT receptor antagonists pizotifen and methysergide, and the non-selective calcium-channel blocker flunarizine, are probably also effective, but formal evidence is limited (Goadsby, 1997a). The widespread use of amitriptyline is largely based on its efficacy in concurrent tension-type headaches, rather than on preventing migraine attacks. In North America such headaches are often referred to as 'minor migraines', which may explain the confusion. The calcium channel blockers nifedipine, nimodipine and verapamil, the α2-adrenoceptor agonist clonidine, some NSAIDs, the herbal drug feverfew, riboflavin, and hormonal manipulation, are often recommended, but evidence for preventive efficacy is lacking or unconvincing. Verapamil, however, is highly effective in preventing cluster headache attacks, and NSAIDs are effective symptomatic treatments of migraine.

The efficacy of the current migraine prophylactics is limited: at most 55% of patients will have a 50% or more reduction of the attack frequency (Ramadan et al., 1997; Goadsby, 1997b). The individual reponse is unpredictable

and must be determined by 'trial and error', taking into account individual (contra-)indications. Due to the non-specific pharmacology, there is a high risk of adverse events. Therefore, only patients with two attacks or more per month, which respond unsatisfactory to symptomatic treatment, should be considered for preventive treatment. There is a great need for better prophylactic agents.

Attack treatment

Specific and non-specific symptomatic antimigraine drugs treat the headache and associated symptoms only, not the aura. Non-specific drugs include analgesics such as aspirin and paracetamol, rapidly absorbable NSAIDs, prokinetic and antiemetic compounds such as metoclopramide and domperidone, and narcotics such as codeine, pethidine and morphine (Welch, 1993; Ferrari & Haan, 1997). The use of narcotics and barbiturates is highly controversial, not supported by scientific evidence, and is associated with prominent side effects and a high risk of abuse and dependency. Most patients who require narcotics are in fact overusing headache or migraine agents. After withdrawal, they rarely require narcotics anymore.

In migraine attacks, oral resorption is impaired because of vomiting or gastrointestinal stasis and dilatation, even in not nauseated patients. Thus, to optimize drug administration the parenteral route is usually preferred. However, most patients prefer tablets. Use of metoclopramide or domperidone 30 minutes prior to analgesics, improves their oral resorption and combats the nausea, but there is no evidence that analgesic efficacy is improved. The choice of drug, dose, and route of administration, depends on the characteristics and frequency of the attacks, and on the preferences of and contraindications for the patient. Not all attacks in a given patient are necessarily treated with the same drug or dose. Mild attacks may be treated with analgesics or NSAIDs, while severe, disabling ones usually respond better to specific antimigraine drugs. The Migraine Disability Assessment Scale (MIDAS) has proven to be a useful and easy to use clinical instrument to predict acute treatment needs (Lipton et al., 2000).

Ergot alkaloids

For decades ergots were the only drugs specifically for migraine. Most of our so-called knowledge is, however, based on 'authoritative reviews' and textbooks, largely summarizing uncontrolled studies and personal experiences. This surprising lack of scientific evidence contributes to the striking differences between countries in frequency of use, recommended dosing, formulations, and combinations with other compounds. Recent reviews conclude that ergot derivatives display a complex pharmacology and erratic pharmacokinetics, have poorly justified dose recommendations and only limited evidence for efficacy, and show potent and sustained generalized vasoconstrictor effects (Dahlöf, 1993; Tfelt-Hansen et al., 2000). As a result, their clinical use is complicated, results are unpredictable, and complications (including ischemia of organs and limbs, overuse syndromes, and rebound headaches) are frequent; ergot derivatives are strictly contraindicated in the presence of cardiovascular disease. The major reasons for prescribing ergots today seem to be that they have been around for a long time and are much cheaper than the newer drugs. The European Consensus Committee concluded that generally triptans (see below) are to be preferred but when patients have a satisfactory response to ergots it is not necessary to switch as long as there is no escalation of the use of ergots beyond 1–2 days per week.

Table 61.2. The triptans (5-$HT_{1B/1D}$ receptor agonists)

Triptan	Recommended oral doses (mg)	Company
In clinical use (year)		
Sumatriptan (1991)	25; 50; 100	GlaxoSK**
Zolmitriptan (1997)	2.5; 5	AstraZeneca
Naratriptan (1997)	2.5	GlaxoSK**
Rizatriptan (1998)	5; 10	Merck
Almotriptan (2001)	12.5	Almirall-Prodesfarma
Approved for registration		
Eletriptan (2001)	20; 40; 80	Pfizer
Frovatriptan (2001)	unknown	Vernalis

Triptans

Advances in the understanding of the neurobiology of migraine have resulted in the development of the novel class of selective 5-$HT_{1B/1D}$ (serotonin; 5-hydroxytryptamine$_{1B/1D}$) receptor agonists, known as the triptans (Table 61.2). It is likely that the 5-$HT_{1B/1D}$ agonist activity is the major basis for their therapeutic effects, although 5-HT_{1F} action may be involved as well. Triptans have three potential mechanisms of action, cranial vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second order neurons of the trigeminocervical complex (Ferrari 1998; Goadsby et al., 2002). The relative importance of each

of these mechanisms remains uncertain (Fig. 61.1, see colour plate section).

In comparison to ergot derivatives, triptans have a number of distinct advantages. These include selective pharmacology, simple and consistent pharmacokinetics, evidence-based prescribing instructions, established efficacy based on an enormous body of well-designed placebo-controlled and direct comparative clinical trials, modest side effects, and a well-established safety record; their most important disadvantage is the higher price (Goadsby et al., 2002; Ferrari et al., 2001). The triptans are now the leading class of acute migraine medications in many western countries. They have proven to be very effective and generally well-tolerated acute migraine treatments, which have made an enormous difference for many patients. However, although the triptans currently are the most effective antimigraine drugs available, they certainly are no wonder drugs.

Sumatriptan was the first triptan available and undoubtedly is the most extensively investigated antimigraine drug (Plosker & McTavish, 1994; Visser et al., 1996a,b,c; Goadsby et al., 2002; Ferrari et al., 2001). Since its launch, first as a 6 mg subcutaneous auto-injector and 100 and 50 mg oral formulations, and later as 20 mg nasal and 25 mg rectal formulations, six other triptans have been marketed all in oral formulations (Table 61.2). For the oral triptans, the following effects can be expected (Goadsby et al., 2002; Ferrari et al., 2001). Approximately 60% of migraine patients improve by 2 hours postdose and up to 40% are pain free at that time. Up to one-third of the responders may experience recurrence of the headache (relapse) within 24–48 hours; repeated drug administration is then usually effective. Prescribing physicians should explain this to their patients. The mechanism of headache relapse is unknown, but seems, contrary to earlier belief, unrelated to the drug plasma half-life. Adverse events (AEs) are frequent, but in the great majority very mild and of short duration. The most frequent AEs include tingling, paresthesias, and warm and hot sensations in head, neck, chest, and extremities; less frequent AEs are dizziness, flushing, and neck pain or stiffness. Of more relevance are the so-called 'chest symptoms' which mainly consist of short-lived heaviness or pressure in the arms and chest, shortness of breath, anxiety, palpitations, and, very rarely, chest pain (Visser et al., 1998a,b,c; Ferrari et al., 2001). When patients are warned about these events, they rarely cause problems. However, they sometimes closely mimic angina and cause alarm. Severe and sustaining sumatriptan-associated chest symptoms should be taken seriously and should prompt cardiovascular investigation.

The mechanism of triptan-induced chest symptoms is unknown. Triptans may cause constriction of the coronary arteries, which is usually short-lived and mild. In atherosclerotic arteries, however, the constrictor effect of triptans may clinically be more important. Furthermore, use of triptans has been associated with myocardial or cerebral ischemia in some individuals, although very few given the very substantial total human exposure to triptans and mainly with pre-existing coronary or cerebral artery disease (Wilkinson et al., 1995; Welch et al., 2000). Myocardial ischemia can thus not be excluded in some patients with chest symptoms, though it seems an unlikely mechanism in most. Other mechanisms such as esophageal spasms, pulmonary vasoconstriction, intercostal muscle spasm, or bronchospasm, seem more likely (Ferrari, 1998). Thus, when prescribed prudently, i.e. not in patients with cardio- or cerebrovascular disease or risk factors, the triptans are safe. The risk of triptan-induced myocardial ischemia in migraineurs without clinical evidence of cardiovascular disease appears no greater than the risk is of exercise-induced myocardial ischemia in sportsmen (Ferrari, 1998).

A large meta-analysis investigated the relative efficacy and tolerability of the oral triptans (Ferrari et al., 2001; Goadsby et al., 2002). Rizatriptan 10 mg (especially to rapidly and consistently achieve freedom of pain), eletriptan 80 mg (especially when high efficacy and low recurrence are favoured over tolerability) and almotriptan 12.5 mg (especially when very good tolerability in combination with good efficacy are favoured) offer the highest likelihood of success. The lower doses of rizatriptan (5 mg) and eletriptan (40 mg) may be good starting doses in many patients. Sumatriptan 100 mg and 50 mg provide good efficacy and tolerability and by far the longest clinical experience; the 50 mg dose has a slightly better efficacy/tolerability ratio but also a slightly lower consistency. In addition, sumatriptan offers the widest range of formulation options (oral, suppositories, nasal, and subcutaneous), allowing tailor-made treatments for individual patients. Naratriptan 2.5 mg offers very good tolerability coupled to a slower onset of improvement; this can be useful in patients with mild or moderate migraine. Zolmitriptan 2.5 mg and 5 mg are good alternatives in many patients; they offer no specific advantages but there are also no specific flaws. Frovatriptan cannot be fully judged in view of the lack of data but doesn't seem to offer any particular advantage; available efficacy data suggest inferior results compared to most of the other oral triptans.

Sumatriptan is also available in parenteral formulations (for review, see Goadsby et al., 2002). Of all triptans, subcutaneous sumatriptan has the best pharmacokinetic profile (Tmax = 10 min; bioavailability = 96%). It is unaffected by

gastro-intestinal disturbances during migraine attacks and has excellent clinical efficacy (response of 76% and pain free of 48% already at 1 hour post dose) and within-patient consistency over multiple attacks (up to 90% for headache response in two out of three treated attacks. The main disadvantages are that patients need to inject themselves, and that the incidence of AEs is higher and the intensity is generally greater than for oral triptans, although still usually acceptable and short-lived. This may be related, among other factors, to the fixed 6mg dose; a 3–4mg dose may suffice in many patients. Subcutaneous sumatriptan is also highly effective in the acute treatment of cluster headache attacks. The efficacy and tolerability profiles of rectal and intranasal sumatriptan are very similar to those of the oral formulation, although many users of the nasal formulation complain about the bitter taste. Both formulations may be useful in nauseated and vomiting patients. Intranasal sumatriptan 20 mg is so far the only triptan with at least some demonstrated efficacy in adolescents. A number of studies of oral triptans in adolescent migraine have failed, most likely because adolescent attacks usually are short lasting and associated with prominent gastrointestinal symptoms; spontaneous early remissions generate high placebo responses.

When selecting a triptan, it is important to realize that patients' characteristics and preferences vary and that response to and tolerability for a triptan cannot be predicted in individual patients. As a consequence, optimizing therapy involves trial-and-error: if the first triptan is not successful one may successfully switch to another. Physicians thus need more than one triptan in their repertoire to optimally treat migraine patients. Differences in efficacy and tolerability among the oral triptans at optimal doses are relatively small, but clinically relevant for individual patients.

In conclusion, migraine is a common, very disabling, multifactorial, neurovascular disorder. Prophylactic treatment to prevent attacks may prove highly effective in individual patients, but often provides rather disappointing results, associated with prominent adverse events. There is a great need for specific and better migraine prophylactic drugs. In contrast, acute attack treatment with the novel class of triptans has greatly improved the life of many patients. They often provide very good efficacy and tolerability. Highest likelihood of consistent success is offered by 6mg subcutaneous sumatriptan (highest efficacy with reasonable tolerability); 10 mg oral rizatriptan (very good efficacy and very good tolerability), 80 mg eletriptan (very good efficacy and good tolerability), and 12.5 mg almotriptan (good efficacy and excellent tolerability). Sumatriptan provides the longest clinical experience and widest range of formulations allowing tailor-made treatments for individual patients. Other triptans and dosages are also good alternatives in many patients. When prescribed prudently (i.e. not in patients with cardio- or cerebrovascular disease or major risk factors), triptans are safe.

Cluster headache, other trigeminal autonomic syndromes and the short-lived headaches

Peter J. Goadsby

Institute of Neurology, The National Hospital for Neurology and Neurosurgery, Queen Square, London UK

Of the primary headache syndromes, cluster headache and the related trigeminal autonomic cephalgias, as well as some of the short-lived headache syndromes (Table 62.1), stand out for their very well-defined phenotypes and considerable associated disability. The trigeminal autonomic cephalgias (Goadsby & Lipton, 1997) offer some exceptional physiological insights (see also Chapter 79 (Volume 2)) (May & Goadsby, 1999) and are very rewarding to treat. Books have been written on cluster headache (Kudrow, 1980; Olesen & Goadsby, 1999; Sjaastad, 1992), and readers are referred to these for greater detail. A further issue arises as to what is short-lived; in this context attacks that commonly are measured in minutes (Table 62.2) will fulfil that definition.

Table 62.1. Primary headache – cluster headache, other TACs and short-lasting headaches

Trigeminal autonomic cephalgias (TACS)	Other short-lasting headaches
Cluster headache	Primary stabbing headache[b]
Paroxysmal hemicrania	Benign cough headache
SUNCT[a] syndrome	Hypnic headache
Hemicrania continua	

Notes:

[a] Shortlasting unilateral neuralgiform headache with conjunctival injection and tearing.

[b] Currently known as idiopathic stabbing headache but due for change in the second edition of the International Headache Society classification.

Cluster headache

Cluster headache is a relatively rare very severe episodic primary headache with a population prevalence at about 0.1%. It has been recognized for many years with among the earliest known description appearing in Gerhard van Swieten's medical textbook (Isler, 1993):

A healthy robust man of middle age [was suffering from] troublesome pain which came on every day at the same hour at the same spot above the orbit of the left eye, where the nerve emerges from the opening of the frontal bone: after a short time the left eye began to redden, and to overflow with tears; then he felt as if his eye was slowly forced out of its orbit with so much pain, that he nearly went mad. After a few hours all these evils ceased, and nothing in the eye appeared at all changed.

This description fulfils the International Headache Society diagnostic criteria (Table 62.3) for cluster headache (Headache Classification Committee of The International Headache Society, 1988). Before the term cluster headache was widely used, the disease was known by a large number of names (Table 62.4), with perhaps the most remarkable understatement being that of Sir Charles Symons (1956b), who called it a particular variety of headache. It has been suggested for many years that cluster headache was a disorder of the carotid artery at the base of the skull (Moskowitz, 1988) on the basis of inflammation (Hardebo, 1994) and vascular change (Ekbom & Greitz, 1970; Waldenlind et al., 1993). However, neuroendocrine studies (Leone & Bussone, 1993) suggest hypothalamic dysfunction in pacemaker regions of the brain, the suprachiasmatic nucleus (Hofman et al., 1996). Recently, activation on functional imaging with positron emission tomography (PET) in the region of the posterior hypothalamic grey (May et al., 1998), as well as a structural difference in the brain of cluster headache patients when compared with controls (May et al.,1999a), confirms this region of the brain to be pivotal to the syndrome (Fig. 62.1,

Table 62.2. Differential diagnosis for short-lasting primary headaches

With autonomic features	Without autonomic features
Cluster headache	Idiopathic stabbing headache
Paroxysmal hemicrania	Trigeminal neuralgia
SUNCT[a] syndrome	Migraine
	Benign cough headache
	Hypnic headache

Notes:
[a] Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing.

Table 62.3. Diagnostic features of cluster headache modified from the International Headache Society

Headaches must have each of:

Severe unilateral orbital, supraorbital, temporal pain lasting 15 minutes to 3 hours;

Frequency: 1 every second day to 8 per day;

Associated with 1 of:
- lacrimation
- nasal congestion
- rhinorrhea
- forehead/facial sweating
- miosis
- ptosis
- eyelid edema
- conjunctival injection

Source: From Headache Classification Committee of The International Headache Society (1988).

see colour plate section). The physiology of the pain and cranial autonomic activation has been reviewed recently (May & Goadsby, 1999).

Clinical features and differential diagnosis (Table 62.5)

Cluster headache is characterized by intermittent, repeated, brief attacks of very severe unilateral pain that is most usually reported to occur over or behind one eye. There are usually associated autonomic features such as lacrimation, nasal congestion, conjunctival injection and a partial Horner's syndrome (Headache Classification Committee of The International Headache Society, 1988). By these criteria each attack may last from 15 minutes to 3 hours and the frequency of attacks varies from one every other day to eight per day. Clearly, these are arbitrary rules that human biology breaks from time to time and when broken may be a sign that a more refractory clinical problem is emerging. Most patients with cluster headache have them in a bout or cluster that may last from 6 weeks to several months and are thus designated episodic cluster headache. Some 10–15 of patients have no substantial breaks and are classified as chronic cluster headache. These can be the most challenging of cases being frequently resistant to simpler treatments.

Table 62.4. Older terms for cluster headache

Histaminic cephalagia
Sphenopalatine neuralgia
Petrosal neuralgia
Migrainous neuralgia
Hemicrania periodic neuralgiformis
Erythroprosopalgia of Bing
Horton's headache

Emerging clinical features

Two recent large cohorts of cluster headache (Bahra et al., 2002; Silberstein et al., 2000) have revealed clinical aspects of cluster headache that are noteworthy. The reported ratio of males to females has dropped over the last 15 years from 9:1 to 3.5:1, due probably to better case ascertainment with studies from non-clinic populations. While clearly a predominately male disorder, female cases are readily seen. A key feature of acute cluster headache that occurs in more than 90% of patients is restlessness or agitation, which contrasts with acute migraine where slightly more than 90% of patients report aggravation of pain with movement. While not perfect, this completely opposite behaviour is an extremely helpful differentiating factor in clinical practice. It has also become clear that migrainous symptoms, such as nausea, photophobia and phonophobia, which occur in 70–80% of migraineurs, can occur in about 50% of cluster headache sufferers. Lastly, typical migrainous aura can be seen in about 15% of patients with cluster headache and should not preclude the diagnosis of cluster headache.

It is important to differentiate cluster headache from similar conditions, which most often consist of shorter more frequent attacks (Goadsby & Lipton, 1997), and to be aware of the rare but recognized causes of secondary cluster headache (Table 62.5) as they guide logical investigation. It can be both diagnostically profitable and clinically reassuring to the patient to investigate or even

Note:
[a] SUNCT, Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing

reinvestigate the most refractory patients. It is certainly conceivable that they may harbour a secondary headache, since secondary cluster can respond to routine treatments (Cremer et al., 1995), and it certainly can be difficult to differentiate on clinical grounds.

Management of cluster headache

Many medical treatments in cluster headache can be used in both episodic and chronic cluster headache patients. In general, the acute medications may be used in both settings, although in chronic cluster headache long-term safety issues make the use of the medicines sometimes problematic. Key issues in difficult cluster headache include providing acute treatment when there are several attacks a day, particularly because of the limits on the use of injectable sumatriptan; finding a drug, or combinations of drugs, that are useful in preventing attacks and making decisions about the place and timing of surgery.

Preventative treatment

Preventative treatments in cluster headache can be used to either arrest a bout of episodic cluster headache or to ameliorate symptoms in patients with chronic cluster headache. Although each of the preventatives would probably be useful in either situation, certain practical limitations favour the clinical use of each drug. It is useful to think of preventatives as either being short term, limited usually by side effects and useful in episodic and less so in chronic cluster headache; and long term, usually used for longer bouts of episodic cluster headache or chronic cluster headache.

Short-term prevention: Oral ergotamine may be useful as a regular night-time dose to avoid nocturnal attacks (Ekbom, 1947) and at a dose of 1–2 mg nightly can be very useful. Ergotamine is at its best when given well before the attacks and is ideal for the patient with predictable nocturnal attacks and a short bout. It is problematic in patients with vascular disease although, in contrast to migraine sufferers, ergotamine-induced headache seems relatively uncommon in patients with cluster headache. Another useful strategy can be daily or even twice dihydroergotamine (1 mg) which can suppress attacks very effectively. The author has found both injectable dihydroergotamine and the dihydroergotamine nasal spray useful.

A short burst of oral corticosteroids has been recommended for some years (Jammes, 1975) and is certainly

effective. The problem of aspectic necrosis of the hip must be clearly explained to the patient. In this regard bony problems with steroid use have been reviewed by Mirzai and colleagues (Mirzai et al., 1999). The shortest course of prednisolone reported to be associated with osteonecrosis of the femoral head is a 30-day course of 16 mg/day (Fischer & Bickel, 1971). Furthermore, courses of adrenocorticotropic hormone (Good, 1974) have produced osteonecrosis after 16 days and dexamethasone at 16 mg per day after 7 days (Anderton & Helm, 1982). Thus a tapering course of prednisolone for 21 days is effective and seems prudent.

Methysergide can be an extremely effective anticluster agent and, because the bouts are usually short, the exposure can be limited. Patients may require up to 12 mg daily but usually respond reasonably quickly and in up to 70% of cases (Curran et al., 1967).

Longer-term prevention: The first-line treatment for longer-term prevention in cluster headache is verapamil. In an open trial employing large doses of 240–720 mg daily in episodic cluster and 120–1200 mg daily in chronic cluster headache, an improvement of more than 75% was noted in 69% of 48 patients treated with verapamil (Gabai & Spierings, 1989). Since this early report, verapamil has been established as among the most effective preventative agents in cluster headache. It is superior to placebo (Leone et al., 2000), and at least equal to lithium (Bussone et al., 1990). It is generally true that the regular verapamil preparation is more useful than the slow-release preparations and that the upper limit of dosing relates to side effects, particularly cardiac conduction problems. Although most patients will start on doses as low as 40 mg twice daily, doses up to 960 mg daily are now employed (Olesen & Goadsby, 1999). Side effects, such as constipation and leg swelling, can be a problem (Silberstein, 1994), but more difficult is the issue of cardiovascular safety.

Verapamil can cause heart block by slowing conduction in the atrioventricular node (Singh & Nademanee, 1987) as demonstrated by prolongation of the A–H interval (Naylor, 1988). Given that the PR interval on the ECG is made up of atrial conduction, A–H and His bundle conduction, it may be difficult to monitor subtle early effects as verapamil dose is increased. This question needs study in this group of patients but for the moment it seems appropriate to do a baseline ECG and then repeat the ECG at least 10 days after a dose change, usually 80 mg increments, when doses exceed 240 mg daily.

Lithium carbonate has been reported to be useful in up to 40% of patients (Carolis et al., 1988; Kudrow, 1977) and its use requires careful monitoring. Unfortunately, its most recent study was limited by practical problems and came to no clear conclusions on the drug's efficacy (Steiner et al., 1997). More recently, each of valproate (Hering & Kuritzky, 1989), gabapentin and topiramate (Wheeler & Carrazana, 1999) have been suggested to be useful. Blinded studies are required before these can be widely recommended.

Acute attacks of cluster headache

Perhaps the over-riding problem in acute cluster headache is that the attacks come on rapidly and reach a peak very quickly so that therapy to be of any value must be rapid in onset and thus oral preparations used in migraine may not be effective. Parenteral dihydroergotamine (1 mg intramuscularly) (Horton, 1952) and intranasal dihydroergotamine (Andersson & Jespersen, 1986) are effective for some but not all patients. Inhalation of 100% oxygen (10–12 l/min) for 15 minutes has been clearly shown to be of benefit in arresting attacks (Fogan, 1985; Kudrow, 1981). Other options include instillation of lidocaine nasal drops (4–6%) ipsilateral to the side of pain (Kitrelle et al., 1985; Robbins, 1995) or injection of the ipsilateral greater occipital nerve (Anthony, 1987). Sumatriptan, a 5-$HT_{1B/1D}$ receptor agonist developed for the treatment of migraine (Humphrey et al., 1991), has proved highly efficacious and rapid in onset of action (Hardebo, 1993) in the treatment of acute attacks of cluster headache (Ekbom & The Sumatriptan Cluster Headache Study Group, 1991). It has been shown that increasing the dose from 6 mg to 12 mg does not result in either more responders or a quicker effect (Ekbom et al., 1993). It is important clinically that the response is not diminished with time (Ekbom et al., 1992) and the side effect profile is modest as it is for migraine (Goadsby, 1994).

Pre-emptive treatment with sumatriptan in a regimen of 100 mg three times daily does not alter either the timing or frequency of headaches (Monstad et al., 1995). These data are in accordance with published data for migraine with aura that has shown pretreatment of patients prior to headache does not prevent headache (Bates et al., 1994). Rather, sumatriptan is only effective when headache has commenced even if the headache is mild (Aube, 1995; Lipton et al., 2000). Sumatriptan nasal spray has been studied in an open-label fashion and had modest effects (Hardebo & Dahlof, 1998). Recently, it was shown that zolmitriptan 5 mg and 10 mg were effective treatments of acute cluster headache but only in patients with the episodic form (Bahra et al., 2000).

Paroxysmal hemicrania (PH)

Sjaastad et al. first reported cases (Sjaastad & Dale, 1974), 7 of whom were female, of a frequent unilateral severe but short-lasting headache without remission coining the

term chronic paroxysmal hemicrania (CPH) (Sjaastad & Dale, 1976). The mean daily frequency of attacks varied from 7 to 22 with the pain persisting from 5 to 45 minutes on each occasion. The site and associated autonomic phenomena were similar to cluster headache, but the attacks of CPH were suppressed completely by indomethacin. A subsequent review of 84 cases showed a history of remission in 35 cases whereas 49 were chronic (Antonaci & Sjaastad, 1989). CPH usually begins in adulthood at the mean age of 34 years with a range of 6 to 81 years. Children with CPH have been reported (Broeske et al., 1993; Gladstein et al., 1994; Kudrow & Kudrow, 1989), although at least one case has been considered to be cluster headache (Solomon & Newman, 1995). The author has seen a 4-year child with an otherwise typical indomethacin-sensitive case. A typical case responding to acetazolamide has been reported (Warner et al., 1994).

By analogy with cluster headache the patients with remission have been referred to as episodic paroxysmal hemicrania (Kudrow et al., 1987). Pareja (1995) has recorded attacks which swap sides, just as is known for cluster headache, and attacks of autonomic features without pain. This has been observed in cluster headache after trigeminal nerve section, by this author and others, and is excellent evidence for a primarily CNS disorder. Event-related potentials which have been reported to be abnormal in migraine (Wang & Schoenen, 1998) are normal in CPH (Evers et al., 1997) as is cognitive processing (Evers et al., 1999).

Some recent cases have broadened our understanding of paroxysmal hemicrania. Boes and colleagues reported otalgia and an interesting sensation of fullness of the external auditory meatus responding to indomethacin (Boes et al., 1998). There has been some interesting speculation from Dodick about extra-trigeminal pain in episodic paroxysmal hemicrania (Dodick, 1998), and I doubt that the full clinical dimensions of these syndromes have been defined.

The essential features of paroxysmal hemicrania as it is now understood are:

- female preponderance;
- unilateral, usually fronto-temporal, very severe pain;
- short-lasting attacks (2–45 mins);
- very frequent attacks (usually more than 5 a day);
- marked autonomic features ipsilateral to the pain;
- robust, quick (less than 72 hours), excellent response to indomethacin, generally.

Other issues

The therapy of CPH has been discussed in relation to its responses to triptans. The issue is not clearly settled and may be both variable and dependent on the length of the attacks (Antonaci et al., 1998b; Dahlof, 1993; Pascual & Quijano, 1998). Greater occipital nerve injection is not useful in CPH (Antonaci et al., 1997). Piroxicam has been suggested to be helpful (Sjaastad & Antonaci, 1995), although again not as effective as indomethacin. By analogy with cluster headache verapamil has been used in CPH (Shabbir & McAbee, 1994), although the response is not spectacular and higher doses require exploration. An important and as yet unresolved issue is whether COX (cycloxygenase) II-selective blockers, such as celecoxib (Mathew et al., 2000) or rofecoxib, would be useful in CPH. An early impression is that some patients will benefit from these compounds.

CPH can coexist with trigeminal neuralgia (Caminero et al., 1998; Hannerz, 1993, 1998), just as does cluster headache (Pascual & Berciano, 1993; Watson & Evans, 1985). Both conditions must be treated to control the entire phenotype of the disorder. Similarly, secondary CPH has also been reported with a syndrome like Tolosa–Hunt (Foerderreuther et al., 1997) and in patients with a pituitary microadenoma and a maxillary cyst (Gatzonis et al., 1996), as well as as a first manifestation of cerebral metastasis of parotid epidermoid carcinoma (Mariano et al., 1998). Although extremely rare, a patient with CPH and typical migraine aura is reported.

Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) (Fig. 62.6)

This condition was first described by Sjaastad et al. (1989) and its basis has been the subject of speculation, although recently posterior hypothalamic activation with BOLD contrast fMRI has been observed (May et al., 1999b), suggesting a disorder of the central nervous system. The patients are mostly males (Pareja & Sjaastad, 1994) with a gender ratio of approximately 4 to 1 (Pareja & Sjaastad, 1997). The paroxysms of pain usually last between 5 and 250 seconds (Pareja et al., 1996b) although longer duller interictal pains have been recognized, as have attacks up to 2 hours in two patients (Pareja et al., 1996a). Patients may have up to 30 episodes an hour although more usually would have 5–6 per hour. The frequency may also vary in bouts. A systematic study of attack frequency demonstrated a mean of 28 attacks per day with a range of 6 to 77 (Pareja et al., 1996a). The conjunctival injection seen with SUNCT is often the most prominent autonomic feature and tearing may also be very obvious. Other less prominent autonomic symptoms include sweating of the forehead or

[b] Cranial autonomic activation may be seen in first division trigeminal neuralgia.

rhinorrhoea. The attacks may become bilateral but the most severe pain remains unilateral.

Secondary SUNCT and associations

There have been several reported patients with SUNCT syndromes secondary to homolateral cerebellopontine angle and brainstem arteriovenous malformations diagnosed on MRI (Bussone et al., 1991; De Benedittis, 1996). One patient had a cavernous hemangioma of the cerebellopontine angle seen only on MRI (Morales et al., 1994), so that MRI of the brain should be part of the investigation of this syndrome when it is recognized. Extratrigeminal pain typical of SUNCT is reported (Wingerchuk et al., 2000) and is a syndrome which bears some consideration.

Management

Unlike some of the other short-lasting headache syndromes, such as the paroxsymal hemicranias that are highly responsive to indomethacin, SUNCT is remarkably refractory to treatment, including indomethacin (Pareja et al., 1995). The relationship between trigeminal neuralgia and SUNCT remains unclear (Sjaastad et al., 1997). There is a single report of a patient with trigeminal neuralgia who developed a SUNCT syndrome (Bouhassira et al., 1994). SUNCT patients may respond to carbamazepine in a partial sense. Case reports of responses with gabapentin, lamotrigine and topiramate can be found; of these topiramate and lamotrigine seem most promising.

Hemicrania continua

Sjaastad and Spierings (1984) reported two patients, a woman aged 63 years and a man of 53, who developed unilateral headache without obvious cause. One of these patients noticed redness, lacrimation and sensitivity to light in the eye on the affected side and the other described superadded 'jabs and jolts'. Both patients were relieved completely by indomethacin while other NSAIDs were of little or no benefit. Newman and colleagues (1994) reviewed the 24 previously reported cases and added 10 of their own, some with pronounced autonomic features resembling cluster headache. They divided their case histories into remitting and unremitting forms. Of the 34 patients reviewed, 22 were women and 12 men with the age of onset ranging from 11 to 58 years. The symptoms were controlled by indomethacin 75–150 mg daily.

Goadsby and Lipton (1997) compared the clinical presentation of hemicrania continua with that of chronic and episodic paroxysmal hemicrania, cluster headache and the SUNCT syndrome, concluding that it is likely to best fit under the general heading of 'trigeminal-autonomic cephalgias' to respect some of the likely shared pathophysiology. Silberstein et al. (1996) proposed that patients with hemicrania continua be subdivided into those with and without medication overuse. Apart from this secondary cause, analgesic overuse (Warner, 1997), and a report in an HIV-infected patient (Brilla et al., 1998), the status of secondary hemicrania continua is unclear.

Treatment

Sjaastad and Antonaci (1995) regard responsiveness to indomethacin as being essential for the diagnosis. Antonaci et al. (1998a) proposed the 'indotest' by which the intramuscular injection of 50 mg of indomethacin could be used as a diagnostic tool. In hemicrania continua, pain was relieved in 73 ± 66 minutes and the pain-free period was 13 ± 8 hours. The time elapsed between the oral administration of 25–50 mg t.i.d. and relief varied from 30 minutes to 48 hours (Pareja & Staastad, 1996). In practice, intramuscular indomethacin can be easily done as a single-blind placebo-controlled crossover *n-of-*1 study to clarify the best clinical management. Some patients may also respond to piroxicam and other NSAIDs (Sjaastad & Antonaci, 1995). Acute treatment with sumatriptan has been employed and reported to be of no benefit (Antonaci et al., 1998b). A useful effect from the COX (cycloxygenase) II-selective blocker, rofecoxib, is reported (Peres & Zukerman, 2000).

Primary (idiopathic) stabbing headache

Short-lived jabs of pain, defined by the International Headache Society as idiopathic jabbing headache (Headache Classification Committee of The International Headache Society, 1988) to be known as primary stabbing headache after the next revision, are well documented in association with most types of primary headache. The essential clinical features are:

- pain confined to the head, although rarely is it facial;
- stabbing pain lasting for a fraction of a second and occurring as a single stab or a series of stabs;
- recurring at irregular intervals (hours to days).

Raskin and Schwartz (1980) first described sharp, jabbing pains about the head resembling a stab from an ice-pick, nail, or needle. They compared the prevalence of such pains in 100 migrainous patients and 100 headache-free controls and only three of the control subjects had experienced ice-pick pains compared with 42 of the migraine patients, of whom 60% had more than one attack per month. The pains affected the temple or orbit more often than the parietal and occipital areas and often occurred before or during migraine headaches. Drummond and Lance (1984) obtained a history of ice-pick pains in 200 of 530 patients with recurrent primary headache. The sites of the ice-pick pains were recorded for 92 patients and coincided with the site of the patients' habitual headache in 37.

Retroauricular and occipital region pains are well described and these respond promptly to indomethacin (Martins et al., 1995). Ice-pick pains have been described in conjunction with cluster headaches (Lance & Anthony, 1971), and generally are experienced in the same area as the cluster pain. Ekbom (1975) noted that ice-pick pains may become more frequent as the attack abates. Sjaastad described what he called 'jabs and jolts' lasting less than a minute in patients with chronic paroxysmal hemicrania (Sjaastad et al., 1979). These seem more the exception, since idiopathic stabbing headache is generally truly stabbing: it is likely that longer lasting pains are a part of this overall spectrum. It is of interest that jabbing pains generally are not accompanied by cranial autonomic symptoms and can be seen with each of the trigeminal-autonomic cephalgias described in this chapter. The response of idiopathic jabbing headache to indomethacin (25–50 mg twice to three times daily) is generally excellent (Matthew, 1981; Medina & Diamond, 1981). As a general rule the symptoms wax and wane, and after a period of control on indomethacin it is appropriate to withdraw treatment and observe the outcome.

Benign cough headache

The clinical features of benign cough headache as defined by the IHS are (Headache Classification Committee of The International Headache Society, 1988):

- bilateral headache of sudden onset, short-lasting (usually < 1 min, but may last 30 min) and precipitated by coughing;
- may be prevented by avoiding coughing;
- may be diagnosed only after structural lesions such as posterior fossa tumour have been excluded by neuroimaging.

The presence of an Arnold–Chiari malformation or any lesion causing obstruction of CSF pathways or displacing cerebral structures must be excluded before cough headache is assumed to be benign. Cerebral aneurysm (Smith & Messing, 1993), carotid stenosis (Britton & Guiloff, 1988; Rivera et al., 1991) and vertebrobasilar disease (Staikov & Mattle, 1994) may also present with cough or exertional headache as the initial symptom.

Sharp pain in the head on coughing, sneezing, straining, laughing, or stooping has long been regarded as a symptom of organic intracranial disease, commonly associated with obstruction of the CSF pathways. Symonds (1956a) presented the case histories of six patients in whom cough headache was a symptom of a space-occupying lesion in the posterior fossa or of basilar impression from Paget's disease. He then described 21 patients with the same symptom in whom no intracranial disease became apparent. Cough headache disappeared in nine patients and improved spontaneously in another six patients. Two patients died of heart disease, and four were

lost to follow-up. Symonds (1956a) concluded that there was a syndrome of benign cough headache, which he attributed to the stretching of a pain-producing structure in the posterior fossa, possibly the result of an adhesive arachnoiditis. Of Symonds' 21 patients, 18 were males, and ages ranged from 37 to 77 years, with an average age of 55 years (Symonds, 1956a).

Rooke (1968) considered cough headache as a variety of exertional headache and recorded his experienced with 103 patients who experienced transient headaches on running, bending, coughing, sneezing, lifting, or straining at stool in whom no intracranial disease could be detected and who were followed for 3 years or more. During the follow-up period, reinvestigation discovered structural lesions such as Arnold–Chiari malformations, platybasia, subdural hematoma, and cerebral or cerebellar tumour in 10 patients. Of the remaining 93, 30 were free of headache within 5 years, and 73 were improved or free of headache after 10 years. This type of headache was found in men more often than in women at a ratio of 4:1. Rooke observed that this form of headache may appear for the first time after a respiratory infection with cough and that some patients reported an abrupt recovery after the extraction of abscessed teeth, which had also been noted by Symonds (1956a).

Pathophysiology

Williams (1976) recorded cerebrospinal fluid (CSF) pressures from the cisterna magna and lumbar region during coughing. He found that there was a phase in which lumbar pressure exceeded cisternal pressure, followed by a phase in which the pressure gradient was reversed. He postulated that cough headache may be caused by a valve-like blockage at the foramen magnum, which interferes with the downward or rebound pulsation. Williams (1980) followed up this observation by studying two patients with cough headache whose cerebellar tonsils descended below the foramen magnum without any obvious obstruction and confirmed a severe craniospinal pressure dissociation during the rebound after a Valsalva manoeuvre. Decompression of the cerebellar tonsils relieved the headache and eliminated the steep pressure gradient on coughing. Williams (1980) commented that coughing increased intrathoracic and intra-abdominal pressure, which was transmitted to the epidural veins, causing a pressure wave and CSF to move rostrally. The headache was presumably caused by temporary impaction of the cerebellar tonsils when the subject relaxed and the pressure gradient then reversed. Whether this explanation applies to those patients without an Arnold–Chiari type I malformation remains uncertain.

The possibility of a sudden increase in venous pressure being sufficient by itself to cause headache must be considered. Lance (1991) reported the case of a man with a goitre sufficiently large to cause sudden headache when his arms were elevated and the jugular veins distended. Calendre et al. (1996) suggested the term 'Benign Valsalva's manoeuvre-related headache' to cover headaches provoked by coughing, straining or stooping but *cough headache* is more succinct and unlikely to be displaced.

Management

Mathew (1981) reported two patients with benign cough headache (one of whom had proved unresponsive to ergotamine, propranolol, and methysergide) who improved with indomethacin 50 mg three times daily. When this therapy was compared with placebo, the reduction in cough headache with the active drug was 95% in one case and 85% in the other, while the reductions on placebo medication were 0% and 18%, respectively. One patient who had particularly severe cough headaches unresponsive to indomethacin responded completely to the i.v. injection of dihydroergotamine (Hazelrigg, 1986). Raskin (1995) has reported that some patients with cough headache are relieved by lumbar puncture which is a simple option when compared to prolonged use of indomethacin. The mechanism of this response remains unclear.

Hypnic headache

This syndrome was first described by Raskin (1988) in patients aged from 67–84 who had headache of a moderately severe nature that typically came on a few hours after going to sleep. These headaches last from 15 to 30 minutes, are typically generalized, although may be unilateral (Gould & Silberstein, 1997; Morales-Asin et al., 1998), and can be throbbing (Newman et al., 1990). Patients may report falling back to sleep only to be awoken by a further attack a few hours later with up to three repetitions of this pattern over the night. In a large and very carefully presented series of Dodick's (1998) 19 patients, 16 (84%) were female and the mean age at onset was 61 ± 9 years. Headaches were bilateral in two-thirds and unilateral in one-third and in 80% of cases mild or moderate. Three patients reported similar headaches when falling asleep during the day. None had photophobia or phonophobia (Dodick et al., 1998).

Management

Patients with this form of headache generally respond to a bedtime dose of lithium carbonate (200–600 mg) (Newman et al., 1990; Raskin, 1988) and in those that do

not tolerate this verapamil or methysergide at bedtime may be alternative strategies. Two patients who responded to flunarizine 5 mg at night have now been reported (Morales-Asin et al., 1998). Dodick and colleagues (1998) reported that one to two cups of coffee or caffeine 60 mg orally at bedtime was helpful. This author has recently successfully controlled a patient poorly tolerant of lithium using verapamil at night (160 mg) and others have reported a case controlled by indomethacin (Ivanez et al., 1998). This is an important observation in the context of trigeminal autonomic cephalgias (Goadsby & Lipton, 1997). Other strategies are important since, in the age group affected by the condition, lithium may have significant side effects.

Orofacial pain

Steven B. Graff-Radford

Cedars–Sinai Medical Center, 444 South San Vicente # 1101, Los Angeles CA, USA

Orofacial pain presents clinicians with a daunting task. The most critical task in treating patients is to establish the correct diagnosis. Often with chronic pain, we are faced with limited understanding, resulting too often in patients being labelled psychogenic. Pain as defined by The International Association for the Study of Pain is 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (Mersky, 1986). This definition allows for the pain to be present without nociception (the recordable neural activity in Aδ and C-fibres). Thus the clinician is encouraged to consider assessing the associated suffering and pain behaviour in understanding and treating pain. Pain in the face is often referred, owing to the trigeminal nerves' complex distribution. It is suggested therefore, that an organ system classification may simplify the problem enabling a quick and accurate diagnosis.

Classification

The International Headache Society published a classification system that can be used to describe many orofacial pains (Olesen, 1988). This classification separates many conditions that may produce facial pain and classifies them independently. For this discussion Table 63.1 provides an organ-based classification system that simplifies differential diagnosis. The orofacial pains are divided into six categories and will be reviewed separately.

Extracranial

The eyes, ears, nose, throat, sinuses, teeth, lymph glands, salivary glands may produce pain when infectious, degenerative, edematous, neoplastic or destructive processes trigger noxious stimulation. While the musculoskeletal system is an extracranial structure, they are separated in the classification as they are considered as a very common pain condition worthy of special attention.

Table 63.1. Organ system classification for orofacial pain

Organ	Presence	Quality	
A	Extracranial	Continuous	Dull
B	Intracranial	Continuous	Variable
C	Psychogenic	Variable	Variable
D	Neurovascular	Intermittent	Throbbing
E	Neuropathic	Intermittent	Sharp, shooting, electric
		Continuous	Burning
F	Musculoskeletal	Continuous	Dull, aching

Eye

Pain in and around the eye usually is caused by local disease but may also be referred from the teeth, jaw or sinuses. In addition migraine and other neurovascular pains are often perceived in the eye. An inflammatory pseudotumour in the orbit associated with Tolosa–Hunt syndrome may produce eye pain. Pseudotumour cerebri, also called benign intracranial hypertension, or idiopathic intracranial hypertension, classically presents with headache, associated with papilledema and sometimes 6th nerve palsy. These patients are best followed by neurophthalmologists to ensure vision is not lost due to persistent papilledema. Eye pain may be differentiated into superficial or corneal pain, deep or inflammatory pains. Eye disease includes iritis, acute angle glaucoma. Other eye disease may involve optic neuritis, eye strain and enucleation. Pain quality is variable depending on the cause or

pathology location. It is suggested that localized eye pain be evaluated by an ophthalmologist.

Ear

Pain in the ear is often referred from musculoskeletal structures such as the temporomandibular joint or mastication muscles. Additionally, the teeth or temporomandibular joint may refer pain to the ear. In these cases the pain is described as a dull, achy, or stopped-up sensation. Because the ear is complexly innervated by cranial nerves V, VII, IX, X, and cervical roots C2–3, referred pain to the ear needs to be carefully considered. Ear pain may arise from the external ear canal as an acute inflammatory process, or due to an accumulation of wax producing pressure. Middle ear or mastoid problems are often due to infection of the mucous membranes causing otitis media. If inflammation spreads to the petrous bones, a petrositis may develop or meningitis. Acoustic neuroma, a benign tumour involving the neural sheath of cranial nerve VIII, is associated with hearing loss, a tingling sensation deep in the ear and, if there is trigeminal nerve involvement, pain in the ear or face.

Nose

Pain in the nose may also be refereed from the teeth, sinuses or other structures, but is more likely caused by inflammation or local tumour. When there is inflammation present, it is useful to differentiate inflammatory, allergic, vasomotor or atrophic rhinitis. Referral to an ear nose and throat specialist is recommended if dental etiology is ruled out.

Throat

Throat pain is most often a local inflammatory reaction secondary to infection. Certainly, other local problems such as tumor need be considered. Some neurological problems like glossopharyngeal neuralgia, stomatodynia (burning mouth syndrome) and Eagles syndrome will be discussed under neurogenous pains. Throat tumours may invade various structures and produce pain, often associated with neurological or functional change. Diagnosis requires imaging and careful tissue exploration.

Sinus and paranasal pain

It has been established that pain can emanate from nasal and paranasal structures. Wolff, using mechanical stimuli and faradic current at various sites, elicited an aching or sharp, burning sensation from nose and sinus mucosal linings. The referred pain, following stimulation, occurred in specific patterns. The referral patterns are summarized in Table 63.2.

Table 63.2. Pain referral from nasal and paranasal mucosa

Site stimulated	Site pain reported
Nasal floor and septum	Local, zygoma, towards ear, outer and inner eye canthus, eye
Nasal turbinates	Lateral wall inside nose, upper teeth, below eye
Maxillary sinus	Local, nasopharynx, posterior teeth, zygoma, temple
Frontal sinus	Local
Ethmoid sinus	Eye, deep in the inner eye canthus
Sphenoid sinus	Pharynx, deep in the head, maxillary teeth, vertex

Sinus inflammation may be acute or chronic. Acute sinusitis is characterized by symptoms indicating active nasal membrane and sinus inflammation. Symptoms including dull persistent pain, associated with a purulent discharge, usually into the nose or pharynx. Malaise and fever are also usually present. Inflammatory sinus disease commonly produces toothache. Usually the maxillary sinus is implicated and pain is felt in the maxillary teeth on the involved side. The pain presents as a continuous dull toothache, accompanied by a feeling that the tooth is extruded.

Chronic sinusitis is characterized by persistent sinus mucous membrane inflammation. Hypertrophy, may induce permanent changes to the nasal ciliary action and mucous glands. There is no evidence that these changes produce headache. Chronic sinusitis may relapse into acute inflammation and then may present with pain.

Sinus evaluation may include sinus transillumination, which often reveals pus in acute sinusitis. Plain radiographs may show fluid levels. Specific radiographic techniques may be needed to clearly identify each sinus, e.g. a Waters view is used for the maxillary sinus. A computerized tomogram (CT) scan or MRI may be helpful in differentiating cystic from solid lesions, but differentiating acute from chronic sinusitis requires the presence of clinical features. Treating acute sinusitis and the presenting orofacial pain is best accomplished with antibiotics and systemic or topical decongestants. Surgical drainage may be required.

Teeth

The most common orofacial pain involves the teeth and their supporting structures. Most frequently the pain is related to dental caries, presenting as a reversible pulpitis. The reversible pulpitis is characterized by poorly localized pain, often sensitive to hot or cold stimuli. The reaction to the noxious stimulus (hot or cold) disappears soon after its removal. Eventually when the carious lesion invades the pulp an irreversible pulpitis begins. This is characterized by a lingering reaction to noxious stimuli such as hot or cold. If the microorganisms and inflammatory products invade the area around the root apex (periapical) this is called a periodontitis and may present with toothache associated with chewing, touch and percussion sensitivity. Periapical pathology may be observed as an area of increased radiolucency on radiograms. The tooth may have an abnormal response to pulp testing where applying heat, cold or electrical stimulus is not perceived. In clinical practice differentiating reversible and irreversible pulpitis is difficult. In situations where the diagnosis is not obvious, careful observation over days or weeks is recommended. Too often endodontic therapy is performed when not indicated.

An intermittent pain that is triggered by biting on an offending tooth characterizes cracked tooth syndrome. Unfortunately the cracks are often difficult to find and don't show on all X-ray images. This pain is often confused with pulpitis or trigeminal neuralgia resulting in frustration and unnecessary treatment. Tomographic imaging 1 mm apart through the tooth's long axis may be beneficial in defining the crack. Further careful clinical examination including meticulous bite tests on each tooth cusp or staining may be useful. Graff-Radford and Gratt have studied cracked teeth with thermography and it appears there is a difference in the patients with cracked teeth and neuropathic facial pain. The cracked tooth patients have normal thermograms and the neuropathic pain patients display asymmetrical thermograms (Graff-Radford et al., 1995). Chronic toothache may be a referred phenomenon. Where no obvious local etiology is evident, neuropathic, muscular or vascular etiologies should be considered (Graff-Radford et al., 1995).

Burning mouth syndrome

Burning mouth syndrome (BMS) is characterized by a burning sensation in one or several oral structures (Tourne & Fricton, 1992). Although no obvious cause has been established, numerous possibilities exist. The pathogenesis may be summarized into local, systemic and psychological etiologies. Local factors include contact allergy, denture irritation, oral habits, infection, and possible reflux esophagitis. The systemic factors include menopause, vitamin and mineral deficiency, diabetes, oral infection and chemotherapy. Psychogenic factors have often been cited but are mostly anecdotal. An essential component to rule out is candida infection. Although this may not be obvious to the eye, swabbing the oral mucosa and culture for fungus often reveals an incipient infection. Patients with fungal infection respond quickly to antifungal preparations such as clotrimazole or fluconazole. The author's experience indicates approximately half the patients with BMS have a candida infection. This often follows steroid, antibiotic or chemotherapy. For those patients where no systemic or local pathology is identified, it is postulated that the cause is neuropathic. Topical clonazepam (0.5 –1.0 mg three times per day) has been effective in reducing a burning oral pain (Woda et al., 1998). Patients are instructed to suck a tablet for three minutes (and then spit out) 3 times per day for at least 10 days. Serum concentrations are minimal (3.3 ng/ml) 1 and 3 hours after application. Woda hypothesized clonazepam produced a peripheral not central action disrupting the neuropathologic mechanism. Additional treatments for BMS include medications ranging from tricyclic antidepressants, antiepileptic drugs, benzodiazepines, folic acid and oral rinses. Treatment outcome is varied.

Intracranial

Intracranial pathology presenting as orofacial pain is exceedingly rare. The pain is usually associated with additional neurological signs and symptoms. The meninges, cranial nerves and blood vessels are the pain sensitive structures intracranially. Traction, inflammation, distention or pressure on these structures produces pain referral to distant sites.

Thalamic pain is described as 'unilateral facial pain and dysesthesia attributed to a lesion of the quintothalamic pathway or thalamus. Symptoms may also involve the trunk and limbs of the affected side' (Mersky, 1986). Infarcts in the thalamus involving the primary sensory nuclei, or damage in other sensory pathways, may lead to thalamic pain syndrome. The pain quality is moderate to severe, burning or aching, and localized to the face contralateral to the infarct. The clinical presentation may include a hemiplegia and associated allodynia, hyperesthesia and hyperpathia. MRI or CT scans are used to confirm the diagnosis. Treatment is difficult, but patients respond best to the tricyclic antidepressants or membrane stabilizing

medications such as listed in Table 63.5. Stimulation produced analgesia such as acupuncture or TENS or even deep brain stimulation may be treatment considerations.

Intracranial neoplasms produce pain in approximately 60% of cases. This is typically a dull, non-pulsatile, persistent pain aggravated by exertion or postural changes (Bulitt & Tew, 1986). In the patient who presents with non-odontogenic face pain where other cranial nerve abnormalities are present, intracranial pathology must be considered. While certain intracranial tumours are more likely to produce neurological problems, all do not present with the same neurological signs (Rushton & Rooke, 1962). Tumours producing facial pain include meningiomas, schwannomas, neurofibromas, acoustic neuromas and cholesteatomas. Pituitary tumours may result in pain when they erode the sella or place pressure on the gasserian ganglion due to invasion of the cavernous sinus (Cueneo & Rand, 1952). It is suggested that tumours arising from the trigeminal ganglion produce pain, and those arising from the root do not (Schisano & Olivercrona, 1960).

Psychogenic

Labelling a disease process psychogenic without clear documented objective criteria is grossly unfair to the patient. Fordyce has pointed out that too often a patient's pain experiences are labelled 'psychogenic pain' when repeated failures using the biomedical model result in a lengthy medical history (Fordyce & Steger, 1978). Fordyce suggests it is the system that has not provided adequate diagnosis. Psychogenic pain may be interpreted in many ways. Some consider psychogenic pain when the pain behaviour is in excess or is discrepant from the physiological sensation or apparent nociceptive cause. A more useful manner in which the psychogenic pain label may be employed, is when the emotional and psychological factors are the pain's primary. The latter alternative requires positive inclusion criteria and Fordyce suggests these may be divided into four groups (i) somatic delusions, (ii) somatization disorder, (iii) conversion, (iv) depression. Fordyce points out that psychogenic diagnosis is a philosophical one. The fact that the International Association for the Study of Pain's (Mersky, 1986) definition of pain provides an emotional component, should not allow us to confuse the emotional overlay with a psychogenic etiology.

It would be better to label pain problems in which no obvious pathology can be determined as idiopathic rather than psychogenic or atypical. Further in-depth, systematic and objective study of these disorders needs to be carried out so as to understand their etiology. It has been reported that patients described as 'atypical' or 'idiopathic' all have an ascribable diagnosis if evaluated by someone with more experience (Fricton, 1999).

Severe unilateral neuralgiform headache with conjunctival injection and tearing, rhinorrhea and subclinical sweating (SUNCT)

Neurovascular

The problems discussed under the neurovascular organ system may not originate in this system but have the trigemino-vascular pathway as the nociceptive mediator (Moskowitz et al., 1988). Neurovascular pains are largely intermittent and involve a complex mechanism, which is still not fully understood. Table 63.3 lists the neurovascular pains that may present in the orofacial region.

Migraine

Although migraine is traditionally considered to present above the oculo-tragus line, facial migraine is documented well (Lovshin, 1960; Raskin & Prusiner, 1977). Migraine is discussed elsewhere in this text. Exertional migraine is described as 'migraine symptoms lasting minutes and presenting with the other associated symptoms attributed to migraine' (Rooke, 1968). The exertional migraine may also be subclassified into benign cough headache (BCH) and benign exertional headache. BCH is defined as an intermittent pain, usually bilateral, with severe bursting explosive pain brought on by coughing. The pain location is usually in the vertex, occipital, frontal or temporal regions, but has been described as presenting in the tooth (Symonds, 1956; Moncada & Graff-Radford, 1993). This pain is responsive to 25–225 mg / day indomethacin doses. Patients are required to maintain the treatment indefinitely. If decreased, the symptoms usually reoccur. When evaluating BCH, Symonds emphasizes the need to rule out intracranial pathology (Symonds, 1956).

Lovshin (Lovshin, 1960) was the first to describe migraine as a facial pain problem that could occur without headache. This has been further described by Raskin (1988). The pain is described as dull pain with superimposed throbbing occurring once to several times per week. Each attack lasting minutes to hours. In the facial migraine, Raskin describes ipsilatertal carotid tenderness, a finding also present when migraine presents in the head. This condition has also been refereed to as carotidynia (Raskin & Prusiner, 1977). Raskin feels that dental trauma may be a precipitant.

Cluster headache

Cluster headache is described as 'attacks of severe strictly unilateral pain orbitally, supraorbitally and/or temporally, lasting 15–180 minutes and occurring from once every other day to 8 times per day. The pains are associated with one or more of the following autonomic signs: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, meiosis, ptosis, eyelid edema. Attacks occur in series lasting for weeks or months (so-called cluster periods) separated by remission periods usually lasting months or years. About 10% of the patients have chronic symptoms' (Olesen, 1988).

Cluster headache has been described by Brooks as 'periodic migrainous neuralgia' when it presents as orofacial (Brooke, 1978). Brooke's facial cluster included 53% with toothache and 47% with jaw pain. Bittar and Graff-Radford described 42 cases of cluster headache where 42% received unnecessary dental procedures, provided as therapy (Bittar & Graff-Radford, 1992).

Cluster often presents in the orofacial region especially in the maxilla. Using sphenopalatine ganglion block with local anesthetic is useful as a temporary abortive therapy.

Chronic paroxysmal hemicrania (CPH) is described as 'attacks with largely the same characteristics of pain and associated symptoms and signs as cluster headache, but they are shorter lasting, more frequent, occur mostly in females, and there is absolute effectiveness of indomethacin' (Olesen, 1988). CPH may also present as face pain or involve the teeth. The clinical presentation is unchanged, as is the response to indomethacin (Delcanho & Graff-Radford, 1993).

SUNCT syndrome is described as a pain that is associated with short lasting unilateral neuralgiform headache attacks with conjunctival injection, tearing, rhinorrhea and subclinical sweating. Sjaastad and co-workers in 1978 first described SUNCT (Sjaastad et al., 1978). Most attacks are reported as moderate to severe, 30 to 120 second pain paroxysms. Pain is usually localized to the eye and may occur in a cluster fashion with some quiet periods. Attack frequency may be up to 30 per day or many per hour (Sjaastad et al., 1989; Sjaastad et al., 1991). Although SUNCT is clinically well identified it is poorly treated. Carbamazepine may be effective in controlling some symptomatology, but not consistently (Sjaastad et al., 1991). Gabapentin may also offer relief in some patients (Graff-Radford, 2000a).

Table 63.4. Neuropathic orofacial pain

Neuropathic

Neuropathic pain suggests there has been some tissue or nerve injury. With injury there is a permanent peripheral nerve and or central nervous system change. It is surprising that with all that the human endures; falls, scrapes, fractures, surgery, etc., that so few chronic pain patients develop. This is likely due to the brain's ability to inhibit or control the permanent changes seen following tissue injury.

We should start out by differentiating 'transient pain' from 'chronic pain'. Short-lived pain following a stimulus that is potentially tissue damaging, also referred to as acute pain is a protective mechanism. Acute pain resolves in an appropriate time period and then normal function is restored. What happens when the stimulus results in a chronic pain? Once the injury appears to have healed there is pain that is non-protective. It is postulated that this may be due to central and peripheral nervous system change (Ren & Dubner, 1999). These changes may include the presence of ongoing peripheral nociception, CNS sensitization or down-regulation of CNS inhibition.

Clinically neuropathic pain can be divided into continuous and intermittent and may present simultaneously or independently. Table 63.4 is a clinical classification for neuropathic facial pain.

Neuropathic pain presents clinically as an intermittent bright, stimulating, electric sharp or burning pain. This is

typically seen in trigeminal neuralgia, glossopharyngeal neuralgia, nervous intermedius neuralgia and occipital neuralgia. These intermittent neuralgias are triggerable, usually by non-noxious stimuli. Vascular nerve compression is the proposed etiology (Fromm & Sessel, 1991). Compression may also be secondary to other structures, including tumours and bony growths (e.g. Eagles syndrome) (Janetta, 1977; Massey & Massey, 1979).

Trigeminal neuralgia

Trigeminal neuralgia (TIC) is described as 'a painful unilateral affliction of the face, characterized by brief electric shock-like (lancinating) pain limited to the distribution of one or more divisions of the trigeminal nerve. Pain is commonly evoked by trivial stimuli including washing, shaving, smoking, talking and brushing the teeth, but may also occur spontaneously. The pain is abrupt in onset and termination may remit for varying periods' (Olesen, 1988). Symptomatic trigeminal neuralgia is described as 'pain indistinguishable from trigeminal neuralgia, caused by a demonstrable structural lesion'. This lesion is usually a tumour such as an acoustic neuroma, or may be due to demyelination as seen in multiple sclerosis. If there is tissue or nerve injury there may be an ensuing continuous trigeminal neuralgia, which is usually referred to as traumatic trigeminal neuralgia or trigeminal dysesthesia (TD) (Graff-Radford, 2000b).

TIC is usually unilateral and only occurs bilaterally in 4% of subjects. There is no genetic link to the disorder. The average age at onset is between the sixth and seventh decades, with women slightly more affected than men in a 3: 2 ratio. The bright stimulating pain perceived is short-lived lasting seconds to minutes. If not questioned carefully the patient may report the pain lasts all day as there is often a dull pain associated with TIC, or the sharp volleys come and go continuously. The author believes the persistent aching pain may be secondary to a reflex muscle splinting and can be controlled with stretching exercise and a vapocoolant spray. Mechanical manoeuvring the trigeminal sensory system usually triggers TIC pain. The area from which the pain is activated has been described as a trigger zone. Characteristically, trigger zones occur around the supraorbital, infraorbital foramina, the inner canthus of the eye, lateral to the ala and over the mental foramen. Trigger zones are also common intraorally. Pain is not elicited from the trigger zone if deep pressure is used or during a latency period between paroxysms. The second and third trigeminal nerve divisions are most commonly affected. The first division cases occur less frequently than 5% (Fromm & Sessel, 1991). Often there is ipsilateral reflex facial spasm hence the term 'tic douloureux' which has been used synonymously with TIC (Andre'N, 1756).

It is postulated that TIC may be due to a trigeminal nerve focal demyelination at any point along its course. Exploring the posterior cranial fossa reveals between 60 and 88% of cases have trigeminal nerve root vascular compression. The compression is present in the posterior cranial fossa as it exits the pons (Gardner, 1962). This has been postulated to set up a centrally mediated disinhibition of pain modulation and/or peripheral repetitive ectopic action potentials. Once there is sensitization there may be increased afferent fibre activity and enhanced tactile stimulation resulting in trigeminal nucleus interneuron discharge and trigeminothalamic neuron producing pain. Taarnhoj (1982) have described tumours as a possible cause in up to 6% of cases. These include acoustic neurinomas, cholesteatomas, meningiomas, osteomas and angiomas. Aneurysms and adhesions have also been implicated. Although the pain may be typical of TIC usually there are additional symptoms or cranial deficits present. When patients are in the 20–40-year age range and present with trigeminal neuralgia multiple sclerosis should be ruled out. Fromm suggests that all patients with trigeminal neuralgia obtain a brain MRI or CT scan, with particular attention paid to the posterior cranial fossa (Fromm & Sessel, 1991).

Ratner and Roberts have proposed that bony cavities found in the alveolar bone may be the cause of trigeminal neuralgia and that repetitive curettage of these cavities is curative (Ratner et al., 1976, 1979; Roberts et al., 1984) Graff-Radford et al., have demonstrated, using 15-half-maxillae and 12 half-mandibles from cadavers, that cavities in bone larger than 2 mm in diameter occur throughout normal bone (Graff-Radford et al., 1988b). The cavities do not appear to be unique to trigeminal neuralgia patients. This sheds doubt on the bony cavity theory. Rather, it may be postulated that the curettage may be effective through central mechanisms or peripheral denervation.

TIC treatment may be divided into pharmacological and surgical. Table 63.5 outlines the drugs that may be used in TIC therapy.

The anticonvulsant action in pain management is not well understood. Some like carbamazepine block use dependent sodium channels, inhibiting sustained repetitive firing. There is also an effect in the spinal cord reducing post-tetanic synaptic transmission potentiation. There is also decreased synaptic transmission in the trigeminal nucleus, which may explain anticonvulsants effectiveness in facial pain. Valproic acid increases brain concentrations of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter in the central nervous system as well as affecting sodium channels. The action of phenobarbital is not at

Table 63.5. Common membrane stabilizing drugs used in neuralgia therapy

Generic	Trade name	Dosage (mg/day)	Blood level (ug/ml)	Serum half-life (h)
Lioresal	Baclofen	10–80	–	
Carbamazepine	Tegretol (XR) Carbitrol	100–2000	4–12	12–17
Phenytoin	Dilantin	200–600	10–20	18–24
Valproic acid	Depakote	125–2500	50–100	6–16
Gabapentin	Neurontin	100–5000	–	
Lamotragine	Lamictal	50–500	2–5	14–59
Klonopin	Clonazepam	0.5–8	–	22–33
Orap	Pimozide	2–12	–	55–154
Depakote	Valproic acid	125–2000	50–100	6–16
Topiramate	Topamax	50–400	–	21
Oxcarbazepine	Trileptal	200–2400	–	9

the trigeminal nucleus but rather in the brain. It is therefore not effective for TIC. Gabapentin may increase GABA by preventing its breakdown or may affect the NMDA receptor.

All drugs used in TIC have side effects and great care must be used in their administration. Baclofen perhaps has the least side effects, but also may be less effective than carbamazepine. Fromm has also described the baclofen L isomer are the effective component (Fromm et al., 1984). Therefore, non-response may be secondary to metabolizing the D isomer only. Baclofen is initiated at 10 mg per day and increased every 2 days to a maximum of 80 mg per day usually in four doses. Drowsiness and confusion are the major side effects and many patients will not tolerate it for this reason. Carbamazepine is without doubt the most effective drug. It is suggested that one begins at 100 mg per day and increases by 100 mg every two days to a maximum of 1200 mg. The side effect of aplastic anemia, although rare, needs to be monitored carefully with routine blood tests. Should there be no relief a carbamazepine blood level should be obtained to ensure a therapeutic blood concentration. A rough level should be obtained and is usually in the range of 5–10 μg/ml. The sustained preparations (Tegretol XR, Carbitrol) have improved compliance and reduced the sedating side effects. Gabapentin, although not formally studied has been useful in doses from 300 mg per day to 3000 mg per day. Phenytoin is a good alternative in doses ranging from 100 – 400 mg per day. Fromm (Fromm & Sessel, 1991) has suggested using some of these drugs in combination to either maximize effect or minimize side effects. Pimozide has been described as more effective than carbamazepine in a double blind cross over design using 48 subjects with trigeminal neuralgia refractory to medical treatment. Side effects were reported in 83% of subjects who received pimozide and included physical and mental retardation, hand tremors, memory impairment, involuntary movements during sleep and slight Parkinson's disease manifestations. None of the patients stopped treatment because of side effects. It is felt therefore by Lechin et al. (1989) that it is effective but because of the adverse effects it should be reserved for severe and intractable trigeminal neuralgia. A new preparation oxcarbazepine (Trileptal) has proven effective and has fewer side effects than carbamazepine.

The surgical treatments for TIC are summarized in Table 63.6. Less traditional treatments reported for trigeminal neuralgia include the curettage of the bony cavities described above. Ratner and Roberts report a long-term success of 80% (Ratner et al., 1976, 1979; Roberts et al., 1984). Sokolovic et al., have described the using peripheral streptomycin and lidocaine injections (Sokolovic et al., 1986). They studied 20 patients in whom five injections of 2% lidocaine and 1 g of streptomycin sulfate were deposited adjacent to peripheral nerves at one month intervals; 16 of the 20 patients remained pain free after 30 months. No side effects were reported and the authors report there was no loss of sensation after the local anesthetic wore off. Bittar and Graff-Radford completed a double-blind placebo-controlled cross-over study using streptomycin, and the results were not favourable. They also reported significant swelling associated with the injections (Bittar & Graff-Radford, 1993).

Although not suggested as a therapeutic modality for trigeminal dysesthesia, surgery is an excellent alternative for trigeminal neuralgia. The most effective surgical approach

Table 63.6. Surgical management of trigeminal neuralgia

Procedure	Effectiveness	Comment
Alcohol block	Excellent	relief is typically 8–16 months paresthesia or dysesthesia occur in 48%
Alcohol gangliolysis	88% at 4 years	corneal anesthesia occurs in 15% neuroparalitic keratitis in 4–7% postoperative paresthesia in 55% paresthesia in 38% herpetic outbreak in 26% transient masticatory muscle weakness in 45%
Neurectomy	Excellent	relief is typically 26–38 months anesthesia dolorosa and corneal anesthesia are rare
Glycerol gangliolysis	89–96%	7–10% have early recurrence 7–21% develop recurrence over extended follow-up facial hyperesthesia occurs in 24–80% corneal anesthesia occurs in 9% facial dysesthesia occurs in 8–29%
Radiofrequency gangliolysis	78–100%	1–17% early recurrence 4–32% develop recurrence over extended follow-up masseter weakness occurs in 7–23% trigeminal dysesthesia in 11–42% corneal hyperesthesia in 3–27% neuroparalytic keratitis in 1–5% anesthesia dolorosa in 1–4%
Microvascular compression	96–97%	16–29% develop recurrence over extended follow-compression mortality occurs in 1% morbidity occurs in 10–23%
Rhizotomy	85%	15% develop recurrence over extended follow-up mortality occurs in 0.5–1.6% facial weakness occurs in 7–8% paresthesia occurs as a minor complaint in 56% paresthesia occurs as a major complaint in 5% neuroparalytic keratitis occurs in 15%
Trigeminal Tractotomy		ipsilateral limb ataxia occurs in 10% contralateral limb sensory loss occurs in 14%
Gamma knife	80–95%	onset may be 6 weeks or longer facial numbness trigeminal dysesthesia rare

remains microvascular decompression (Janetta, 1996). Advances in microvascular decompression include the use of an endoscopic approach. This allows clearer observation and is less traumatic (Jarrahy & Shahinian, 2000). Gamma knife radiosurgery is a recent advance for trigeminal neuralgia (Young et al., 1997). This technique offers a relatively non-invasive means for lesioning the trigeminal nerve adjacent to the pons using a 4 mm collimator helmet. Complications are rare and to date the author has seen one case of trigeminal dysesthesia attributed to the procedure.

Pretrigeminal neuralgia

Sir Charles Symonds first described pretrigeminal neuralgia (PRE TIC)(Symonds, 1949). Mitchell later reviewed it (Mitchell, 1980). Fromm et al. (1990) have described a further 16 cases in which patients initially present with a dull continuous aching toothache in the upper or lower jaw and in whom the pain changed to classic trigeminal neuralgia. Further, they describe seven cases in which the continuous pain was successfully treated with traditional trigeminal neuralgia therapies. The diagnosis of pretri-

geminal neuralgia is based on the following criteria: (i) description of pain as dull toothache; (ii) normal neurological and dental examination; (iii) normal CT or MRI scan of the head. Of note is that the pain of pretrigeminal neuralgia can be interrupted with somatic anesthetic blockade. Merrill and Graff-Radford have described 61 patients treated for pretrigeminal or trigeminal neuralgia. Of these 61% were incorrectly diagnosed and treated with traditional dental therapies (Merrill & Graff-Radford, 1992). The clinician should be aware of PRE TIC prior to surgical intervention in orofacial pain where the etiology is unclear.

Glossopharyngeal neuralgia

This pain presents with similar quality and characteristics to trigeminal neuralgia, but in the distribution of the glossopharyngeal nerve. It may be confused with Eagles syndrome (Massey & Massey, 1979). This syndrome presents as described in glossopharyngeal neuralgia but is associated with an elongated stylohyoid process that irritates or compresses the glossopharyngeal nerve. Rotation of the head, swallowing, chewing are all triggering factors. Patients may complain of persistent sore throats. This pain can be decreased with neural blockade and confirmation of the diagnosis requires demonstration of the calcified stylohyoid ligament on radiogram. Treatment is best achieved with surgical resection of the ligament.

Nervous intermedius neuralgia

This pain is described as similar to trigeminal neuralgia but localized to the middle ear. Patients often complain of 'hot poker' in the ear (Walker, 1966). Treatment is usually similar to that for trigeminal neuralgia.

Occipital neuralgia

Occipital neuralgia is pain located in the distribution of the greater and lesser occipital nerves. Pain is described as paroxysmal, sharp electric-like. There is usually an associated trauma at the onset of pain. Graff-Radford et al., have described myofascial trigger points in the splenius cervicus and capitis muscles that may mimic occipital neuralgia and it is suggested that trigger point injections be used to help rule out this possibility (Graff-Radford et al., 1988a,b). Surgical neurectomy has been described for occipital neuralgia, but the results are often short lived.

The neuropathic pain following tissue or nerve injury in the trigeminal nerve distribution may be called a trigeminal dysesthesia (TD). TD is defined as a continuous pain following complete or partial damage to a peripheral nerve. The pain is described as a continuous, burning numbness and often pulling pain (see Table 63.7).

Table 63.7. Criteria for trigeminal dysesthesia

History of trauma
Continuous pain
Associated hyperalgesia and allodynia
Temperature change
Block effect (sympathetic vs. somatic)

In TD the initiating trauma is usually quite obvious, e.g. postwisdom tooth removal or postimplant placement, but may occur with minor traumas such as crown preparation or following viral infection such as herpes zoster. The discomfort can be self-limiting, depending on nerve regeneration. Campbell has described approximately 5% of patients undergoing root canal therapy have persistent pain (Campbell et al., 1990) which may be attributed to the nerve damage. Elies described 17% of patients with mandibular implants as developing persistent sensory change or pain (Ellies & Hawker, 1993; Ellies, 1992). Thermographic studies of TD reveal all patients have abnormal thermograms with some being hot in the pain distribution and some cold. None are normal. Graff-Radford et al. (1995) have described a hypothesis for these temperature changes that may be helpful in selecting a treatment.

There are three peripheral mechanism, which may be involved in chronic trigeminal neuropathic pain development. These are (i) nerve compression, (ii) nerve regeneration and (iii) sympathetically maintained pain.

Nerve compression

When a peripheral nerve is compressed or injured there is a sustained firing that may be persistent. The closer the damage is to the central nervous system, the longer is the spontaneous neural discharge. The pain following nerve compression can be temporarily relieved with local anesthetic blockade. Following neural trauma receptor sprouting occurs on the damaged nociceptor, on dorsal horn cells and peripheral blood vessels. These receptors may include alpha-receptors, NPY receptors and possibly others. There is also an increased release in trigeminal nucleus substance P, CGRP and other neurotransmitters, resulting in further neurogenic inflammation and chronic pain (Bennett & Xie, 1988). When neural inflammation occurs, a neuritis ensues. The pain presentation is a continuous dull, burning pain with associated allodynia and hyperalgesia. A neuritis involving the facial nerve (cranial nerve VII) may present as a Bell's palsy. There is no pain in Bell's palsy unless the herpes zoster involves the geniculate ganglion. Ramsy Hunt Syndrome requires a facial

palsy associated with herpes zoster eruption around the ear (Karnes, 1984).

Nerve regeneration

Neuroma formation is essentially created by nerve regeneration where the path for regrowth is obstructed. The nerve resprouting and the continuous nerve irritation may result in pain. As in nerve compression, receptor sprouting, and neurotransmitter presence will increase the pain. Injecting the neuroma with local anesthetic will temporarily block the pain. The sprouting axons fire spontaneously, develop abnormal sensitization to norepinepherine, cold and mechanical stimulation. This occurs in dorsal root ganglion cells as well as peripheral terminals. Clinically, the neuroma may only produce pain following mechanical stimulation. The pain is an aching, burning pain with associated sharp pain volleys.

Sympathetically maintained pain (SMP)

Campbell best summarizes this phenomenon (Campbell et al., 1992). He reports that the initial trauma to the peripheral nervous system activates nociceptors and produces a sprouting of alpha-adrenergic receptors on the nociceptors. Additionally, the initial sensory barrage sensitizes the CNS causing sympathetic afferent activation, and increased response to non-noxious stimulus. This causes peripheral norepinepherine release, which activates the peripheral nociceptors and keeps the cycle active. There is evidence that following neural injury the sympathetic innervation in the dorsal root ganglia increases with age (Roberts & Foglesong, 1988). It is not surprising that there is a higher incidence of neuropathic pain as we age. SMP is aggravated by non-noxious stimuli and interrupted temporarily by sympathetic block or alpha-adrenergic block with phentolamine.

Most orofacial trigeminal dysesthesia occurs in females usually in their 4th decade (Vickers et al., 1998; Solberg & Graff-Radford, 1988). There must be a lesion in the trigeminal nervous system, peripherally or centrally to cause the continuous dysesthesia (Vickers et al., 1998). Sex-based differences have been seen in many pain disorders. The relationship and role of sex hormones in the generation and perpetuation of central sensitization is not fully understood but is obviously important (Ren & Dubner, 1999). In a neuropathic pain model using partial sciatic nerve legation, female rats were more likely to develop allodynia (Coyle et al., 1995). In studies comparing female rats that have been ovariectomized, there is a greater chance that those with estrogen were more likely to develop allodynia after injury than those without estrogen (Coyle et al., 1996).

The therapy for trigeminal dysesthesia is aimed at reducing peripheral nociceptive inputs and simultaneously enhancing central nervous system pain inhibitory systems (Graff-Radford, 1995).

Topical applications

The use of topical therapies has not been well studied. There is some evidence that capsaicin (Zostrix) applied regularly will result in desensitization and pain relief (Scrivani et al., 1999). The recommended dose is five times per day for 5 days then three times per day for 3 weeks. If the patient cannot withstand the burning produced by the application, the addition of topical local anesthetic, either 4% lidocaine or EMLA is useful. A Lidoderm patch has been useful in postherpetic neuralgia and other neuralgias where it is convenient to apply the material to the skin. Clonadine can be applied to the hyperalgesic region by placing the proprietary subcutaneous delivery patch where it is most tender. Alternatively, a 4% gel can be compounded and delivered over a larger area. For local intraoral application a neurosensory stent has been conceived. After an oral impression, an acrylic stent is manufactured to cover the painful site (Graff-Radford, 1995). The topical agent is applied to the gingival surface and placed intraorally 24 hours per day.

Topical clonazepam (0.5 –1.0 mg three times per day) has been effective at reducing a burning oral pain (Woda et al., 1998). Patients were instructed to suck a tablet for three minutes (and then spit out) three times per day for at least 10 days. Serum concentrations were minimal (3.3 ng/ml) one and three hours after application. Woda hypothesized there was a peripheral not central action at disrupting the neuropathologic mechanism.

Procedures

Neural blockade is very effective in differentiating SMP from sympathetically independent pain. It may also be effective in controlling SMP if used repetitively. Stellate ganglion blocks, phentolamine infusion and sphenopalatine blocks have been described as useful in obtaining a chemical sympathetic block. The author has not had significant benefit using phentolamine infusion in facial pain. Scrivani who used 30 mg infusion without benefit (Scrivani et al., 1999) supports this.

Lidocaine infusion (200 mg over 1 hour) may be used therapeutically in various forms of neuropathic pain (Boas et al., 1982; Rowbotham et al., 1991). It is suggested that response to intravenous lidocaine may predict who responds to the lidocaine analogue mexilatine. Sinnott et

Table 63.8. Common antidepressants used in trigeminal dysesthesia

Medication trade name	Route	Dosage per day
Amitriptyline	PO	10–150
Desipramine	PO	10–150
Doxepin	PO	10–150
Imipramine	PO	10–150
Nortriptyline	PO	10–150
Trazedone	PO	50–300

al., used an animal model to demonstrate that there is a minimal lidocaine concentration (2.1μg/ml) to abolish allodynia (Sinnott et al., 1999). They also describe a ceiling effect. Many animals with experimentally induced allodynia did not obtain persistent relief. They suggest separate physiological mechanisms, with differing pharmacologies, may account for variability and postulate there are different aspects of neuropathic pain.

Pharmacology

Tricyclic antidepressants

It is well documented that tricyclic antidepressants are effective in many pain problems. Solberg and Graff-Radford have studied the response to amitriptyline in traumatic neuralgia. It is noted that the effective range is 10–150 mg per day usually taken in a single dose at bedtime (Solberg & Graff-Radford, 1988). Many antidepressants may be used, see Table 63.8.

Membrane stabilizers

These medications include the anticonvulsants, lidocaine derivatives and some muscle relaxants. They have been classically used in intermittent sharp electric pains (see Table 63.5).

Behavioural strategies

Prior to beginning therapy, it is common to perform a behavioural assessment with appropriate testing. Following the behavioural evaluation, management is directed at the factors which may impact treatment and determining the most appropriate interventions. Consideration should be given to the following factors: (i) behavioural or operant; (ii) emotional; (iii) characterlogical; (iv) cognitive; (v) side effects; (vi) medication use and (vii) compliance. Therapy such as cognitive and behavioural management techniques, relaxation, biofeedback and psychotherapeutic and psychopharmacological interventions may be useful.

Surgery

Although not suggested as a therapeutic modality for trigeminal dysesthesia, surgery is an excellent alternative for trigeminal neuralgia.

Postherpetic neuralgia

Postherpetic neuralgia (PHN) is a complex problem whose treatment has frustrated clinicians and patients (Loeser, 1986; Watson & Evans, 1986). Herpes zoster (HZ) is primarily a disease affecting older people with some predilection for males (67% males: 33% females to 53% males: 47% females) (Molin, 1969). The localization of HZ in the face is between 15% and 30% of reported cases, this includes involvement of the facial nerve (Molin, 1969). The duration of pain after outbreak of the vesicles varies, but with an increase in age of the subject the pain appears to last longer. The number of subjects who go on to having postherpetic neuralgia (PHN), defined as pain after the vesicles are healed, ranges from 14% of males to 25% of females but almost all are older than 60 years (Molin, 1969). No studies to date have suggested that the subset of HZ patients who go on to have PHN is predictable. The mechanism whereby the herpetic virus produces the neuralgia condition has not yet been determined, reports by Head (Head & Campbell, 1900), and Denny-Brown (Denny-Brown & Adams, 1944), reveal that changes occur in the skin and peripheral nerve endings producing anesthesia or dysesthesia in the dorsal root ganglion characteristic of hemorrhage and lymphocytic infiltration. The adjacent proximal nerves and sensory nerve roots show demyelination and rarely in the spinal cord is cell death evident. There are few controlled studies assessing treatment outcome in this relentless disease. Watson has described the use of amitriptyline, which has by and large been the treatment of choice (Watson & Evans, 1986). This was confirmed by Max who showed amitriptyline but not lorazepam was effective in treatment of PHN (Max et al., 1988). Phenothiazines have been suggested as helpful in the treatment of chronic pain, and in five case studies Taub reported the combination of amitriptyline and fluphenazine to be effective (Taub, 1973). In this report there was a mix of acute (active lesions) and chronic cases (pain lasting longer than 6 months). Graff-Radford has studied the effects of amitriptyline and fluphenazine using a double-blind protocol and found no significant benefit in combining amitriptyline with fluphenazine (Graff-Radford et al., 1986). Sympathetic nerve

block is considered by many to be effective in preventing PHN, when used in the first 3–6 months following the outbreak of zoster. It is suggested between 1 and 6 blocks be performed, depending on the effects. There is little purpose in doing more than 3 blocks if the pain relief is not outlasting the anesthetic effects. It may be more appropriate for this category to be in the autonomic nervous system category, but in some situations sympathetic block does not reduce the pain and this may suggest a sympathetically independent pain.

Musculoskeletal system

Musculoskeletal pain is the most common cause for chronic orofacial pain. Broadly speaking the disorders may be divided into arthrogenous and muscular referred to as temporomandibular disorders (TMD). The temporomandibular joint (TMJ) is different from other body joints. The most recognizable difference between the TMJ and other synovial joints is the non-innervated avascular fibrous connective tissue articular covering. This is not hyaline in nature, possibly to aid withstand twisting, turning and compressive forces. The fibroconnective tissue covering may also allow for significant remodelling to occur in the TMJ. Other significant differences include the diarthroidal structure. There is an intracapsular disc dividing the joint into upper and lower compartments providing for the complex hinge and gliding action. The mandible produces a reciprocal effect of one articulation on the other by joining the TMJ's. Also interacting in this system is the dental occlusion, which will result in altered forces on the system if not in equilibrium. The teeth provide a solid end point to joint movement unlike any other joint in which end range of motion is somewhat elastic. Due to the structure's nature, the intracapsular anatomy can remodel when subjected to extraneous forces. Such remodelling can be brought about through tooth loss, poor dental restoration, macro trauma and parafunctional habits such as tooth clenching and grinding. The remodelling may lead to dysfunction if the tissues are unable to compensate for the abnormal load. In addition, muscular hyperactivity may be initiated also as a compensation for the lack of equilibrium.

The joints hinge action allows for about a 25 mm interincisal opening, which occurs primarily in the lower joint space (condylar rotation). The next 20–25 mm requires the disc condyle complex to slide down the temporal eminence, with the disc moving posterior relative to the condyle (translation). Remodelling resulting in a deviation in articular form may interrupt this rhythmic function. The articular tissues are usually characterized by smooth rounded surfaces until subject to extraneous forces, which produce remodelling (Solberg et al., 1985). The mechanical interferences that are produced by the remodelling may cause noise as they move over each other. Remodelling is an ongoing process and results in a disease process continuum beginning with soft tissue change and progressing to involve the bony structures. One might view the process as a failure for the adaptive process to compensate for the extraneous forces exerted on the joint. If there is sufficient change the articular disc may become displaced. The usual direction for displacement is in an anteromedial direction (Ireland, 1953; Farrar, 1972) although displacement has been reported in a posterior direction (Blankestijn & Boering, 1985). The disc displacement may reduce if the individual can manipulate the condyle onto the disc, producing joint noise. This noise is usually heard after the initial 25 mm rotation in the opening movement and again just before the teeth occlude in the closing path. The closing noise is usually much quieter and may be produced by the relocation of the disc in the anterior position. Joint noise occurs in 20–30% of individuals over the age of 15 years (Egermark-Eriksson et al., 1981; Solberg et al., 1979). Pain associated with joint pathology is usually intermittent and associated with function. In order to confirm an articular TMD, patients should display at least three of the following four criteria: (i) limited range of motion $<$40 mm); (ii) joint noise (clicking, popping or crepitus); (iii) tenderness to palpation; (iv) functional pain. Continuous pain associated with an articular TMD is unusual and usually is produced by associated inflammation or secondary muscle pain. Pain emanating from the ligamentous attachments, the synovium and fibrous capsules is usually secondary to infection or trauma to these structures. The differences between synovitis and capsulitis is almost impossible to determine clinically (Bell, 1995).

Articular remodelling is a direct result of adaptive changes that help to establish a status quo between joint form and function (Moffett et al., 1964). Osteoarthrosis results when there is destruction of articular tissues secondary to excessive strain on the remodelling mechanism. The problem is therefore non-painful and usually only produces mechanical interference's. De Bont has suggested that the degenerative process is due to disruption of the collagen fibre network and fatty degeneration (De Bont et al., 1985). Inflammation of the articular tissue does not occur due to the unvascularized surface. For inflammation to occur a fundamental arthropathic change must occur such as the proliferation of inflamed synovial membrane into the articular tissue, or the exposure of innervated and vascularized osseous tissue (De Bont et al., 1985).

Osteoarthrosis is a common condition that seems to progress with age. It also appears to affect females more than males (Davis, 1981). Osteoarthrosis is insidious in onset, usually not associated with systemic disease, but perhaps initiated through repetitive loading or a variety of factors that occur over a lifetime. The inflammation that occurs in osteoarthritis requires an innervated and vascular surface. This suggests that the adaptive remodelling that continues has been overwhelmed and the tissues below the fibroconnective tissue surface are exposed allowing the inflammatory process to begin.

Muscle disorders

The disorders involving muscle may be independent of the articular problems but more often than not are involved when joint dysfunction exists. Their involvement may be mild and produce minimal dysfunction or severe and markedly disabling. When muscle pain problems occur, the treatment may differ depending on the subgroup defined below.

Myofascial pain syndromes, as classified by the International Association for the Study of Pain Subcommittee on Taxonomy (Mersky, 1986), may be found in any voluntary muscle, and are characterized by trigger points (TPs) which may cause referred pain and local and referred tenderness (Clark et al., 1981; Moller, 1981). When 'active', TPs are painful to palpation and spontaneously refer pain and autonomic symptoms to remote structures in reproducible patterns characteristic for each muscle (Travell & Simons, 1984). It is this referred pain that is usually the presenting complaint. When 'latent', TPs are still locally tender but do not produce referred phenomena. The pain quality is pressing, tightening, deep, aching, and often poorly circumscribed (Travell & Simons, 1984). It may be associated with sensations of swelling, numbness and stiffness. Pain, although usually constant, may fluctuate in intensity and shift anatomical site (Travell & Simons, 1984). Associated symptoms may include autonomic phenomena, most commonly reactive hyperemia or erythema, although photophobia and phonophobia are described (Butler et al., 1975).

The primary basis for myofascial pain is the referred pain. The referral patterns often do not make neurological sense. As an example, pain from a trigger point in the trapezius, innervated by cranial nerve 11, may refer to the forehead, innervated by cranial nerve 5. Despite the poor mechanistic understanding, clinically myofascial pain is widely accepted. It is imperative that we understand how this referral may take place.

Men described a hypothesis for muscle pain referral to other deep somatic tissues remote from the site of the original muscle stimulation or lesion (Mens, 1994). He criticizes the convergence: projection pain referral theory, by pointing out there is little convergence in the dorsal horns associated with deep tissues. Mens' hypothesis adds two new components to the convergence: projection theory. First, the convergent connections from deep tissues to dorsal horn neurons are opened only after nociceptive inputs from muscle are activated. The connections opened after muscle stimulus are called silent connections. Secondly, the referral to muscle outside the initially activated site is due to spread of central sensitization to adjacent spinal segment (Mens, 1994). The initiating stimulus requires a peripheral inflammatory stimulus. In the animal model described by Mens the noxious stimulus was bradykinin injected into the muscle. It is unclear what triggers the muscle referral in the clinical setting where there is usually no obvious inflammation-producing incident.

This Mens theory has been used by Simons to discuss a neurophysiological basis for trigger point pain (Simons, 1994). Simons hypothesizes that when the tender area in the muscle is palpated there are neurotransmitters released in the dorsal horn (trigeminal nucleus) resulting in nociceptive inputs, openings that were previously silent. This causes distant neurons to produce a retrograde referred pain (Simons, 1994). This model accounts for most of the clinical presentation and therapeutic options seen in myofascial pain, but does not account for what initiates the peripheral tenderness, that must be present to activate the silent connections.

Fields has described a means whereby the central nervous system may switch on nociception (Fields & Heinricher, 1989). He describes the presence of 'on' cells which when stimulated may produce activation of trigeminal nucleus nociceptors. Olesen has used Fields' model to describe a hypothesis for tension-type headache (Olesen, 1991). This model describes the interaction of three systems, the vascular, supraspinal and myogenic. The proposed hypothesis suggests that perceived headache pain is facilitated by the central nervous system depending on inputs from either muscle or blood vessel. In migraine the inputs are proposed as primarily vascular whereas in tension-type headache there are primarily muscular inputs. This model helps explain why the clinical presentation and therapeutic options in migraine and tension-type headache are often similar, as well as why there is temporary relief seen with peripheral treatments such as trigger point injections.

The resultant hyperalgesia or trigger point sensitivity may represent a peripheral sensitization related to serum levels on serotonin (5H-T). Ernberg et al. (1999) showed a significant correlation with serum 5H-T and allodynia associated with muscular face pain (Alstergen et al., 1999). In

rheumatoid temporomandibuar pain serum 5H-T concentrations correlated with pain. There was no correlation with circulating serum levels of neuropeptide Y (NPY) or interleukin–1B (Alstergen et al., 1999).

It is therefore proposed that patients presenting with facial pain where the etiology is not obvious may have myofascial pain. In these patients careful physical examination will allow the clinician to reproduce the pain by digitally palpating the muscles. Confirmation with trigger point injections is also helpful. It is suggested that the trigger point be injected with 1–2 cc of 1% procaine for best results.

The therapy for myofascial pain requires enhancing central inhibition through pharmacology or behavioural techniques and simultaneously reducing peripheral inputs through physical therapies including exercises and trigger point specific therapy (Travell & Simons, 1986; Graff-Radford et al., 1987; Davidoff, 1998). It is essential that patients are aware that the goals in therapy are to manage the pain and not to cure. It is important to stress the role patients' play in managing the perpetuating factors (Graff-Radford et al., 1987; Davidoff, 1998).

Discussion

Prior to making the diagnosis of orofacial pain, the evaluation must begin with an in-depth medical history which should include the chief complaint and a narrative history of the complaint, its progression and prior treatment. Not all chronic pain conditions require a psychological evaluation, but it should be kept in mind that all pain, no matter what the etiology, is subject to behavioural and emotional factors. These behavioural issues should be considered and, where there is any doubt as to their contribution, a psychological evaluation is suggested. The psychological evaluation is not done to determine weather the pain is psychogenic, rather, for the purpose of selecting specific cognitive and behavioural strategies useful in pain management. Once these data are gathered, a neurological screening examination, temporomandibular joint examination and myofascial palpation should be carried out. At this time, a differential diagnosis can be established and specific tests outlined above may be required to provide a definitive diagnosis. This process permits effective treatment, for an appropriate diagnosis.

Chronic daily headache

Stephen D. Silberstein[1] and Richard B. Lipton[2]

[1] Jefferson Headache Center, and Department of Neurology, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania
[2] Department of Neurology, Epidemiology, and Social Medicine, Albert Einstein College of Medicine, New York, NY, USA

There is no consensus on the classification of chronic daily headache (CDH). Some authors use the term CDH to refer to chronic or transformed migraine; others use it for any headache disorder that occurs on a daily or near-daily basis, regardless of cause. We use CDH to refer to the broad group of very frequent headaches (15 or more days a month) not related to a structural or systemic illness, but we include those headaches that are associated with medication overuse. Population-based studies in the United States, Europe, and Asia suggest that 4 to 5% of the general population has headache 15 or more days per month (Scher et al., 1998; Castillo et al., 1999; Wang et al., 2000) and that chronic tension-type headache (CTTH) is the leading cause (Rasmussen, 1992). CDH patients account for most consultations in headache subspecialty practices (Silberstein et al., 1994).

An approach to thinking about CDH is presented in Table 64.1. Once secondary headache has been excluded, we subdivide frequent headache sufferers into two groups, based on headache duration. When headache duration is less than 4 hours, the differential diagnosis includes cluster headache, chronic paroxysmal hemicrania, idiopathic stabbing headache, hypnic headache, and other miscellaneous headache disorders. When the headache duration is greater than 4 hours, the major primary disorders to consider are transformed migraine (TM), hemicrania continua (HC), CTTH, and new daily persistent headache (NDPH) (Silberstein et al., 1994).

In this chapter, we discuss the classification and treatment of primary CDH of long duration, highlighting the four categories outlined above. We propose revisions to the International Headache Society (IHS) system and offer criteria for TM, CTTH, NDPH, and HC (Silberstein et al., 1994). We also discuss the role of medication overuse in the development and treatment of these disorders, as well as their mechanisms and treatment.

Table 64.1. Chronic daily headache

Primary chronic daily headache
Headache duration >4 hours
Chronic migraine (transformed migraine)
Chronic tension-type headache
New daily persistent headache
Hemicrania continua
Headache duration <4 hours
Cluster headache
Paroxysmal hemicranias
Hypnic headache
Idiopathic stabbing headache
Secondary chronic daily headache
– Post-traumatic headache
– Cervical spine disorders
– Headache associated with vascular disorders (arteriovenous malformation, arteritis (including giant cell arteritis), dissection, and subdural hematoma)
– Headache associated with non-vascular intracranial disorders (intracranial hypertension, infection (EBV, HIV), neoplasm)
– Other (temporomandibular joint disorder; sinus infection)

Transformed (chronic) migraine

Transformed migraine has been variously called transformed or evolutive migraine, chronic migraine or mixed headache (Silberstein et al., 1995; Mathew, 1982; Mathew et al., 1982, 1987; Olesen et al., 1993; Saper, 1983). Patients with TM often have a history of episodic migraine that began in their teens or twenties (Silberstein et al., 1995). Most patients with this disorder are women, 90% of whom have a history of migraine without aura. Patients often report a process of transformation characterized by headaches that have grown more frequent over months to years

Table 64.2. Revised criteria for transformed migraine

1.8 Chronic migraine

A. Daily or almost daily (>15 days/month) head pain for >1 month
B. Average headache duration of >4 hours/day (if untreated)
C. At least one of the following:
   1) History of episodic migraine meeting any IHS criteria 1.1 to 1.6
   2) History of increasing headache frequency with decreasing average severity of migrainous features over at least 3 months.
   3) Headache at some time meets IHS criteria for migraine 1.1 to 1.6 other than duration
D. Does not meet criteria for new daily persistent headache (4.7) or hemicrania continua (4.8)
E. No evidence of organic disease.

Note:
The clinician should attempt to distinguish the coincidental occurrence of migraine and CTTH based on the pattern of headache evolution. If the patient cannot recall the pattern of evolution differentiating the coincidental occurrence of two disorders may be difficult.
Source: Modified from Silberstein et al. (1996).

Table 64.3. Proposed criteria for chronic tension-type headache

2.2 Chronic tension-type headache

Diagnostic criteria

A. Average headache frequency >15 days/month (180 days/year) with average duration of >4 hours/day (if untreated) for 6 months fulfilling criteria B-D listed below.
B. At least 2 of the following pain characteristics:
   1. Pressing/tightening quality
   2. Mild or moderate severity (may inhibit, but does not prohibit activities)
   3. Bilateral location
   4. No aggravation by walking upstairs or similar routine physical activity
C. History of episodic tension-type headache in the past (needs to be tested).
D. History of evolutive headaches which gradually increased in frequency over at least a 3 month period (needs to be tested).
E. Both of the following:
   1. No vomiting
   2. No more than one of nausea, photophobia, or phonophobia (needs to be tested).
F. Does not meet criteria for hemicrania continua (4.8), new daily persistent headache (4.7), or chronic migraine (1.8).
G. No evidence of organic disease.

Source: Modified from Silberstein et al. (1996).

while the associated symptoms of photophobia, phonophobia, and nausea have, on average, become less severe and less frequent (Mathew, 1982; Mathew et al., 1982; Mathew, 1987; Saper, 1983). Patients often develop (transform into) a pattern of daily or nearly daily headaches that resemble CTTH. That is, the pain is mild to moderate and not associated with photophobia, phonophobia, or gastrointestinal features. Other features of migraine, including aggravation by menstruation and other trigger factors, as well as unilaterality and gastrointestinal symptoms, may persist. Many patients have attacks of full-blown migraine superimposed on a background of less severe headaches. Migraine transformation most often develops when there is medication overuse, but transformation may occur without overuse (Mathew et al., 1982, 1990).

Eighty per cent of patients with TM have depression (Mathew, 1993; Saper, 1983) which often lifts when the pattern of medication overuse and daily headache is interrupted. We proposed criteria for TM (Table 64.2). We believe that TM is a form of migraine and that the diagnosis is best made in patients who have a past history of IHS migraine and a process of transformation (Silberstein et al., 1995). Our criteria provide three alternative diagnostic links to migraine: (i) a prior history of IHS migraine; (ii) a clear period of escalating headache frequency with decreasing severity of migrainous features (which were both required in the 1994 criteria); or (iii) current superimposed attacks of headaches that meet all the IHS criteria for migraine except duration. Pascual et al. pointed out that individuals with coincidental migraine and CTTH could meet criteria for TM. If a patient has episodic migraine and independent, coincidental CTTH, there is a risk that the headache may be misclassified as TM.

Chronic tension-type headache (Table 64.3)

Daily headaches may also develop in patients with a history of episodic tension-type headache (ETTH). These headaches are more often diffuse or bilateral, frequently involving the posterior aspect of the head and neck. Prior or coexistent episodic migraine is absent in patients with CTTH, as are most features of migraine. We proposed several modifications to the current classification of CTTH. CTTH (2.2) requires head pain on at least 15 days a month for at least 6 months. Although the pain criteria are identical to ETTH, the IHS classification allows nausea, but not

vomiting. The need to include any of these migrainous features in the IHS definition of CTTH may be a result of the practice of including TM under the rubric of CTTH. Coexistent migraine and CTTH might exist with the caveat that the non-migrainous headaches have no migrainous features. Guitera et al. (1999) have suggested, based on population-based epidemiologic data, that CTTH and migraine can coexist if, and only if, the current headache has no migrainous features and there is a remote history of migraine.

Calcitonin gene-related peptide (CGRP) is involved in the pathophysiology of migraine and cluster headache. Its role in CTTH is unknown. Ashina et al. (2000) found that plasma levels of CGRP are normal and unrelated to headache state in patients with CTTH. CGRP levels measured in the peripheral circulation of patients on days without headache, 63±5 pmol/l, tended to be higher than CGRP levels of controls, 53±3 pmol/l, but the difference was not statistically significant ($P=0.06$). No differences were found between CGRP levels assessed ictally and interictally in either the cranial ($P=0.91$) or the peripheral ($P=0.62$) circulation. Plasma CGRP was higher in the external jugular vein than in the antecubital vein on days without headache ($P=0.03$), but not on days with headache ($P=0.82$). Interictal plasma CGRP was increased in patients whose pain quality was pulsating. This study suggests that TTHs that fulfill IHS criteria may be related to migraine, if the headache has a pulsating quality.

Russell et al. (1999) evaluated CTTH in a family study of 122 probands and 377 first-degree relatives. Sensitivity, specificity, predictive values, and chance-corrected agreement rate for the diagnosis of CTTH were 68%, 86%, 53% (PVpos), 92% (PVneg), and 0.48, respectively. The low sensitivity for CTTH in a family member, assessed by a proband report, indicates that 32% of CTTH cases are missed using this method. They concluded that direct interviews of family members are necessary to determine case status, as was previously shown for migraine (Ottman & Lipton, 1994). Clinically interviewed parents, siblings, and children had a 2.1- to 3.9-fold increased risk of CTTH compared with the general population. The proband's gender did not influence the risk of CTTH among first-degree relatives. The significantly increased familial risk, with no increased risk found in spouses, suggests that genetic factors are involved in CTTH, although familial environmental factors are also possible.

New daily persistent headache (Table 64.4)

NDPH is characterized by the relatively abrupt onset of an unremitting CDH (Vanast, 1986); that is, a patient develops a headache that does not remit. NDPH is likely to be a heterogeneous disorder. Castillo et al. (1999) conducted a population study of over 2000 patients; they identified only two cases of this disorder, indicating that it is rare. Some cases may reflect a postviral syndrome (Vanast, 1986). The daily headache develops abruptly, over less than 3 days. Patients with NDPH are generally younger than those with TM (Vanast, 1986).

Table 64.4. Proposed criteria for new daily persistent headache

4.7 New daily persistent headache
A. Average headache frequency >15 days/month for >1 month
B. Average headache duration >4 hours/day (if untreated). Frequently constant without medication but may fluctuate.
C. No history of tension-type headache or migraine which increases in frequency and decreases in severity in association with the onset of NDPH (over 3 months).
D. Acute onset (developing over <3 days) of constant unremitting headache
E. Headache is constant in location? (Needs to be tested)
F. Does not meet criteria for hemicrania continua 4.8
G. No evidence of organic disease.

Source: Modified from Silberstein et al. (1994).

Since NDPH is not defined by the characteristics of the headache, this disorder overlaps with CTTH. The presence or absence of a past history of headache distinguishes the disorders. NDPH requires the relatively abrupt onset of near daily headache in the absence of a history of evolution from migraine or ETTH. Excluding all patients with a history of ETTH is problematic, as almost 70% of men and 90% of women have had a TTH in the past. We allow a diagnosis of NDPH in patients with migraine or ETTH if these disorders do not increase in frequency to give rise to NDPH. The constancy of location is uncertain and needs to be field-tested. NDPH may or may not be associated with medication overuse (4.7.1., 4.7.2.). A diagnosis of NDPH takes precedence over TM and CTTH.

Hemicrania continua (Table 64.5)

HC is a rare, indomethacin-responsive headache disorder characterized by a continuous, moderately severe, unilateral headache that varies in intensity, waxing and waning without disappearing completely (Newman et al., 1993). It rarely alternates sides (Bordini et al., 1991). HC is frequently associated with jabs and jolts (idiopathic stabbing headache). Exacerbations of pain are often associated with

Table 64.5. Proposed criteria for hemicrania continua

4.8 Hemicrania continua[a]
A. Headache present for at least 1 month
B. Strictly unilateral headache
C. Pain has all 3 of the following present:
1. Continuous but fluctuating
2. Moderate severity, at least some of the time
3. Lack of precipitating mechanisms
D. 1) Absolute response to indomethacin or
2) One of the following autonomic features with severe pain exacerbation
(a) Conjunctival infection
(b) Lacrimation
(c) Nasal congestion
(d) Rhinorrhea
(e) Ptosis
(f) Eyelid edema
E. May have associated stabbing headaches
F. No evidence of organic disease.

Notes:

[a] HC is usually non-remitting, but rare cases of remission have been reported.

Source: Modified from Goadsby and Lipton (1997).

autonomic disturbances, such as ptosis, miosis, tearing, and sweating. HC is not triggered by neck movements, but tender spots in the neck may be present (Table 64.5). Some patients have photophobia, phonophobia, and nausea.

Although HC almost invariably has a prompt and enduring response to indomethacin, the requirement of a therapeutic response as a diagnostic criterion is problematic. It effectively excludes the diagnosis of HC in patients who were never treated with indomethacin (perhaps because another agent helped) and in patients who failed to respond to indomethacin. Cases have been described that did not respond to indomethacin but meet the phenotype; for this reason a characteristic pattern or a response to indomethacin (Table 64.5) provides an alternative means of diagnosis.

HC exists in continuous and remitting forms. In the remitting variety, distinct headache phases last weeks to months, with prolonged pain-free remissions (Newman et al., 1993; Iordanidis & Sjaastad, 1989; Pareja et al., 1990). In the continuous variety, headaches occur on a daily, continuous basis, sometimes for years. A bilateral case and a patient whose attacks alternated sides (Newman et al., 1993) have been described. HC takes precedence over the diagnosis of other types of primary CDH. Many patients with this disorder overuse acute medication; it must be differentiated from TM.

The relative rarity of HC has made it difficult to study its pathophysiology. In a population study of nearly 2000 patients, no cases were identified (Castillo et al., 1999). Pain pressure thresholds are reduced in patients who have HC, as they are in those who have chronic paroxysmal hemicrania (Antonaci et al., 1994). In contrast, orbital phlebography is relatively normal compared with patients who have chronic paroxysmal hemicrania (Antonaci, 1994), although it should be observed that this area is controversial (Bovim et al., 1992). Pupillometric studies have shown no clear abnormality in HC (Antonaci et al., 1992), and studies of facial sweating have shown modest changes, similar to those seen in chronic paroxysmal hemicrania (Antonaci, 1991).

Espada et al.(1999) reported five men and four women who had HC (eight continuous, one remitting) that was diagnosed using proposed diagnostic criteria (Goadsby & Lipton, 1997). The mean age of onset was 53.3 years (range 29 to 69). All nine patients had initial relief with indomethacin (mean daily dose 94.4 mg, range 50 to 150). Follow-up was possible in eight patients. Indomethacin could be discontinued after 3, 7, and 15 months respectively, and patients remained pain free. Three patients discontinued treatment because of side effects and had headache recurrence; two had relief with aspirin. Two other patients continue to take indomethacin with partial relief.

Drug overuse and rebound headache

Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans (Katsarava et al., 1999). Medication overuse may be both a response to chronic pain and a cause of chronic pain. In headache-prone patients, medication overuse may produce drug-induced 'rebound headache' that is accompanied by dependence on symptomatic medication. In addition, medication overuse can make headaches refractory to prophylactic medication (Mathew et al., 1990; Mathew, 1990; Diamond & Dalessio, 1982; Wilkinson, 1988; Saper, 1987a, 1989). Although stopping the acute medication may result in the development of withdrawal symptoms and a period of increased headache, there is generally subsequent headache improvement (Saper, 1989; Andersson, 1988; Baumgartner et al., 1989; Rapoport et al., 1986; Saper & Jones, 1986).

In subspecialty centres, most patients with drug-induced headache have a history of episodic migraine that has been converted into TM as a result of medication overuse (Mathew et al., 1987, 1990; Mathew, 1990; Rapoport, 1988; Kudrow, 1982; Diener et al., 1984; Rasmussen et al., 1989).

Patients with TTH, HC, and NDPH may also overuse symptomatic medications.

In European headache centres, 5 to 10% of the patients have drug-induced headache. One series of 3000 consecutive headache patients reported that 4.3% had drug-induced headaches (Micieli et al., 1988). Experiences in the United Kingdom (Goadsby, P. personal communication) suggest that drug-associated headache is more common than the literature suggests. In American specialty headache clinics, as many as 80% of patients who presented with primary CDH used analgesics on a daily or near-daily basis (Rapoport, 1988; Solomon et al., 1992). In India, in contrast, medication overuse is less common (Ravishankar, 1997). Diener and Tfelt-Hansen (1993) summarized 29 studies, which included 2612 patients with chronic drug-induced headache. Migraine was the primary headache in 65%, TTH in 27%, and mixed or other headaches in 8% (for example, cluster headache). Women had more drug-induced headache than men (3.5 : 1; 1533 women, 442 men). The number of tablets or suppositories taken daily averaged 4.9 (range 0.25 to 25). Patients averaged 2.5 to 5.8 different pharmacologic components simultaneously (range 1 to 14) (Diener & Tfelt-Hansen, 1993).

Clinical features of rebound headache

Rebound headache has not been demonstrated in placebo-controlled trials. However, stopping daily low-dose caffeine frequently results in withdrawal headache (Silverman et al., 1992). In a controlled study of caffeine withdrawal, 64 normal adults (71% women) with low-to-moderate caffeine intake (the equivalent of about 2.5 cups of coffee a day) were given a two-day caffeine-free diet and either placebo or replacement caffeine. Under double-blind conditions, 50% of the patients who were given placebo had a headache by day two, compared to 6% of those given caffeine. Nausea, depression, and flu-like symptoms were common in the placebo group. This study is relevant since caffeine is frequently used by headache sufferers for pain relief, often in combination with analgesics or ergotamine. The study is a model for short-term caffeine withdrawal but does not demonstrate the long-term consequences of detoxification. In a community-based telephone survey of 11 112 subjects in Lincoln and Omaha, Nebraska, 61% reported daily caffeine consumption, and 11% of the caffeine consumers reported symptoms upon stopping coffee (Potter et al., 2000). A group of those who reported withdrawal were assigned to one of three regimes: abrupt caffeine withdrawal; gradual withdrawal; and no change. One-third of the abrupt-withdrawal group and an occasional member of the gradual-withdrawal group had symptoms that included headache and tiredness.

The actual dose limits and the time needed to develop rebound headaches have not been defined in rigorous studies, nor is the relationship of drug half-life to rebound development known. It is believed that overuse occurs when patients take three or more simple analgesics a day more often than 5 days a week, triptans or combination analgesics containing barbiturates, sedatives, or caffeine more often than 3 days a week, or opioids or ergotamine tartrate more often than 2 days a week (Mathew et al., 1990; Diamond & Dalessio, 1982; Mathew, 1990; Saper, 1987a; Wilkinson, 1988). Rebound headache can develop in patients taking as little as 0.5 to 1mg of ergotamine three times a week (Silberstein, 1993; Wilkinson, 1988; Saper, 1983, 1987b; Saper & Jones, 1986; Baumgartner et al., 1989).

The triptans are selective 5-HT_1 agonists that are effective in acute migraine treatment and all of them (sumatriptan, rizatriptan, naratriptan, and zolmitriptan) have been reported to induce rebound headache (Catarci et al., 1994; Diener et al., 1991; Gaist et al., 1996; Katsarava et al., 1999). The weekly dosages necessary to initiate drug-induced headache with the centrally penetrant triptans may be lower than with ergotamines or sumatriptan and the time of onset might be shorter. Increasing attack frequency can be the first sign that drug-induced headache is developing. We recommend limiting triptan use to 3 days a week.

Medication overuse may be responsible, in part, for the transformation of episodic migraine or ETTH into daily headache and for the perpetuation of the syndrome. However, medication overuse is not the sine qua non of TM or CTTH. Some patients develop TM or CTTH without overusing medication, and others continue to have daily headaches long after the overused medication has been discontinued. Medication overuse is usually motivated by a patient's desire to treat the headaches (Kaiser, 1999). However, some headache patients overuse combination analgesics to treat a mood disturbance. Medication overuse rarely represents a form of primary substance abuse.

In addition to exacerbating the headache disorder, drug overuse has other serious effects. The overuse of acute drugs may interfere with the effectiveness of preventive headache medications. Prolonged use of large amounts of medication may cause renal or hepatic toxicity in addition to tolerance, habituation, or dependence.

Psychiatric comorbidity

Anxiety, depression, panic disorder and bipolar disease are more frequent in migraineurs than in non-migraine

control subjects (Merikangas et al., 1990; Breslau & Davis, 1993). Since TM evolves from migraine, one would expect to find a similar profile of psychiatric comorbidity in TM. In clinic-based samples, depression occurs in 80% of TM patients. The Minnesota Multiphasic Personality Inventory was abnormal in 61% of primary CDH patients, compared with 12.2% of patients with episodic migraine. Zung and Beck Depression Scale scores were significantly higher in primary CDH patients than in migraine controls (Mathew, 1990, 1991; Mathew et al., 1990; Saper, 1987b). Comorbid depression often improves when the cycle of daily head pain is broken.

Mitsikostas and Thomas (1999) found that the average Hamilton rating scores for anxiety and depression were significantly higher in headache patients. Patients with CTTH, mixed headache, or drug abuse headache had the highest Hamilton rating scores for depression and anxiety. Verri et al. (1998) found current psychiatric comorbidity in 90% of primary CDH patients. Generalized anxiety occurred in 69.3% of patients and major depression in 25%.

Psychiatric comorbidity is a predictor of intractability. The Minnesota Multiphasic Personality Inventory was abnormal in 100% of CDH patients who failed to respond to aggressive management (31% of the primary CDH group), compared to 48% of the responders. Physical, emotional, or sexual abuse, parental alcohol abuse, and a positive dexamethasone suppression test also correlated highly with a poor response to aggressive management. Curioso et al. (1999) found that 31 of 69 (45%) CDH patients had an adjustment disorder, 16 (23%) had major depression, 12 (17%) were dysthymic, 6 (9%) had generalized anxiety disorder, 1 (2%) was bipolar, and 3 (4%) were normal. The risk of a bad outcome after treatment was significantly greater for patients with major depression than those without. CDH patients who have major depression or abnormal Beck Depression Inventory scores have worse outcomes at 3 to 6 months compared with patients who are not depressed.

Epidemiology

In population-based surveys, primary CDH occurs in 4.1% of Americans, 4.35% of Greeks, 3.9% of elderly Chinese, and 4.7% of Spaniards. Population-based estimates for the one-year period prevalence of CTTH are 1.7% in Ethiopia (Tekle Haimanot et al., 1995), 3% in Denmark (Rasmussen, 1995), 2.2% in Spain (Castillo et al., 1999), 2.7% in China (Wang et al., 2000), and 2.2% in the United States (Scher et al., 1998).

Scher et al. (1998) ascertained the prevalence of primary CDH in 13, 343 individuals aged 18 to 65 years in Baltimore County, Maryland. The overall prevalence of primary CDH was 4.1% (5.0% women, 2.8% men; 1.8: 1 women to men ratio). In both men and women, prevalence was highest in the lowest educational category. More than half (52% women, 56% men) met criteria for CTTH (2.2%), almost one-third (33% women, 25% men) met criteria for TM (1.3%), and the remainder (15% women, 19% men) were unclassified (0.6%). Overall, 30% of women and 25% of men who were frequent headache sufferers met IHS criteria for migraine (with or without aura). On the basis of chance, migraine and CTTH would co-occur in 0.22% of the population; the fact that TM occurred in 1.3% of this population would suggest that their co-occurrence is more than random.

Castillo et al. (1999) sampled 2252 subjects over 14 years of age in Cantabria, Spain. Overall 4.7% had CDH. Using the criteria of Silberstein et al. (1994), none had HC, 0.1% had NDPH, 2.2% had CTTH, and 2.4% had TM. Overuse of symptomatic medication occurred in 19% of CTTH and 31.1% of TM patients. Eight patients had a previous history of migraine without aura and now had primary CDH with only the characteristics of TTH. These headaches met the criteria of TM but could have been migraine and coincidental CTTH.

Wang et al. (2000) looked at the characteristics of primary CDH in a population of elderly Chinese (over 65 years of age) in two townships on Kinmen Island in August 1993. Person-to-person biannual follow-up of the primary CDH patients was done in June 1995 and August 1997. Sixty patients (3.9%) had CDH. Significantly more women than men had primary CDH (5.6% and 1.8%, $P<0.001$). Of the primary CDH patients, 42 (70%) had CTTH (2.7%), 15 (25%) had TM (1%), and 3 (5%) had other CDH. By multivariate logistic regression, the significant risk factors of primary CDH included analgesic overuse (OR = 79), a history of migraine (OR = 6.6), and a Geriatric Depression Scale-Short Form score of 8 or above (OR = 2.6). At follow-up in 1995 and 1997, approximately two-thirds of patients still had CDH. Compared with the patients in remission, the patients with persistent primary CDH in 1997 had a significantly higher frequency of analgesic overuse (33% vs. 0%, $P=0.03$) and major depression (38% vs. 0%, $P=0.04$).

Pathophysiology of chronic daily headache

The nucleus caudalis (NC) of the trigeminal complex, the major relay nucleus for head and face pain, receives nociceptive input from cephalic blood vessels and pericranial muscles, as well as inhibitory and facilitatory suprasegmental input. Recent evidence suggests that central pain

facilitatory neurons (on-cells) are present in the ventromedial medulla. In addition, neurons in the trigeminal NC can be sensitized as a result of intense neuronal stimulation. Chronic pain may be due to ongoing peripheral activation of nociceptors (for example, chronic inflammation), although it may occur in the absence of painful stimuli. Although the source of pain in primary CDH is unknown and may be dependent on the subtype of CDH, recent work suggests several mechanisms that could contribute to the process: (i) abnormal excitation of peripheral nociceptive afferent fibres (perhaps due to chronic neurogenic inflammation); (ii) enhanced responsiveness of the NC neurons (central sensitization); (iii) decreased pain modulation; (iv) spontaneous central pain; or (v) a combination of these.

Peripheral mechanisms

In migraine, trigeminal nerve activation is accompanied by the release of vasoactive neuropeptides, including calcitonin gene-related peptides, substance P (SP), and neurokinin A from the nerve terminals. These mediators produce mast cell activation, sensitization of the nerve terminals, and extravasation of fluid into the perivascular space around the dural blood vessels. Intense neuronal stimulation causes induction of c-fos (an immediate early gene product) in the trigeminal NC of the brainstem. Neurotropins such as nerve growth factor are synthesized locally and can also activate mast cells and sensitive nerve terminals. Prostaglandins and nitric oxide (a diffusible gas that acts as a neurotransmitter) (Edelman & Gally, 1992) are both endogenous mediators that can be produced locally and can sensitize nociceptors. Repeated episodes of neurogenic inflammation may chronically sensitize nociceptors and thus contribute to the development of daily headache.

Central sensitization is manifested by increased spontaneous impulse discharges, increased responsiveness to noxious and non-noxious peripheral stimuli, and expanded receptive fields of nociceptive neurons. Does central sensitization play a role in headache? Brief chemical irritation of the dura with a cocktail of four inflammatory mediators (histamine, serotonin, bradykinin, and prostaglandin E2) made meningeal perivascular neurons pain-sensitive for a period of one to two hours, becoming more sensitive to mechanical forces (>2 g) (Strassman et al., 1996). This can explain the intracranial hypersensitivity (i.e. the worsening pain during coughing, bending over, or any head movement) and the throbbing pain of migraine (Anthony & Rasmussen, 1993).

Brief dural chemical irritation may also result in temporary changes in the central trigeminal neurons that receive convergent input from the dura and the skin. Their threshold decreased and their excitability increased in response to brushing and heating (<42 °C) of the periorbital skin – stimuli to which they showed only minimal or no response prior to chemical stimulation (Burstein et al., 1998). Sensitization may be the basis of the extracranial tenderness that accompanies migraine. In addition, the threshold of cardiovascular responses to facial and intracranial stimuli is reduced (Yamamura et al., 1999). The enhanced neuronal responses represent a state of central sensitization and the enhanced cardiovascular responses represent a state of intracranial hypersensitivity and cutaneous allodynia.

Burstein et al. (1998) predicted that cutaneous allodynia is present in migraine patients during attacks. They examined the pain thresholds of patients during and between migraine attacks. Many patients had periorbital cutaneous allodynia ipsilateral to the headache. Patients with allodynia were significantly older than those without cutaneous allodynia, hinting at a possible correlation between age and sensitization. These findings provide a neural basis for the pathophysiology of migraine pain and suggest a basis for continued head pain.

Bendtsen et al. (1996b) found evidence for sensitization in CTTH patients. Pericranial myofascial tenderness, evaluated by manual palpation, was considerably higher in patients than in controls ($P<0.00001$). The stimulus–response function from highly tender muscle was qualitatively different than from normal muscle, suggesting that myofascial pain may be mediated by low-threshold mechanosensitive afferents projecting to sensitized dorsal horn neurons.

Lassen et al. (1997) discovered that nitroglycerin, a nitric oxide (NO) donor, can induce more headache in CTTH patients than in healthy volunteers. Ashina et al. (1999) found that a NO synthesis inhibitor (L-NMMA) reduced headache and muscle hardness in CTTH. CTTH patients may have sensitization of second-order neurons due to prolonged nociceptive input from myofascial tissues. The decrease in muscle hardness following treatment with L-NMMA may be caused by decreased central sensitization.

Pain modulation

The mammalian nervous system contains networks that modulate nociceptive transmission. In the rostroventromedial medulla are so-called off-cells that inhibit, and on-cells that facilitate nociception (Fields et al., 1991). Increased on-cell activity could enhance the response to both painful and non-painful stimuli. Opiate withdrawal

results in increased firing of the on-cells, decreased firing of the off-cells, and enhanced nociception (Fields et al., 1991). A similar mechanism may occur during drug-induced headaches. Primary CDH may result, in part, from enhanced neuronal activity in the NC as a result of enhanced on-cell or decreased off-cell activity.

Jensen and Olesen (1996) used sustained teeth-clenching to trigger TTH in 58 patients with frequent CTTH or ETTH and 58 matched controls. Within 24 hours, 69% of patients (more than would be expected) and 17% of controls developed TTH. Shortly after clenching, electromyography (EMG) amplitude was significantly increased in the trapezius but not in the temporal muscle, and tenderness (which was increased at baseline in the headache patients) was further increased only in the patients who subsequently developed headache. Mechanical pain thresholds remained unchanged in the group that developed headache but increased in the group that did not develop headache. Pain tolerance decreased in the patients who developed headache, was unchanged in the remaining patients, and increased in controls, suggesting that headache patients do not effectively activate their antinociceptive system. This study clearly shows that peripheral mechanisms alone cannot explain TTH, but they could act as a trigger for a central process. Tenderness, not muscle contraction, correlates to headache development.

Exteroceptive suppression (ES) is the inhibition of voluntary EMG activity of the temporalis muscle induced by trigeminal nerve stimulation (Schoenen et al., 1987). There are two successive periods of ES (ES1 and ES2) (silent periods). ES2, a multisynaptic reflex subject to limbic and other modulation, was originally reported to be absent in 40% of patients with CTTH and reduced in duration in 87%, whereas ES1, an oligosynaptic reflex, was normal (Paulus et al., 1992; Makashima & Takahashi, 1991; Pritchard, 1989). More recent studies have not confirmed these findings. Zwart and Sand found normal ES2 values in a small blinded study of 11 patients with CTTH (Zwart & Sand, 1995). Bendtsen et al. (1996a) and Lipchick et al. (1996, 1997) did not find abnormalities in ES2 in blinded studies of patients with CTTH. Measures of ES2 duration depend on tricky methodologic variables. ES2 may be absent in headache-prone patients (Paulus et al., 1992; Nakashima & Takahashi, 1991).

Schoenen et al. (1987) measured the ES2, pain threshold, EMG activity, anxiety scores, and response to biofeedback in 32 women with CTTH, and found an abnormal EMG in 62.5% of the patients if three different muscles and three states were tested. The EMG was abnormal in only 40% if only one muscle and one state were tested. A decreased pain threshold was found in half the patients tested in one of three muscles but in only 34% if only one muscle was tested. ES2 duration was reduced in 87% of patients

Schepelmann et al. (1998) found that the duration of ES2 (+SD) in fibromyalgia syndrome patients was 30.6 + 7.5 ms and was not significantly different from the control group (33.1 + 7.8 ms), whereas it was significantly shortened in CTTH patients (22.9 + 11.5 ms). Lipchik et al. (1996) evaluated masseter ES2 suppression and tenderness in the pericranial muscles of young adults with CTTH, ETTH, migraine without aura, migraine with aura, and controls. Pericranial muscle tenderness better distinguished diagnostic subgroups and better distinguished recurrent headache sufferers from controls than did masseter ES2. CTTH sufferers had the highest pericranial muscle tenderness and controls exhibited the lowest tenderness ($P<0.01$). The association between pericranial muscle tenderness and CTTH was independent of the intensity, frequency, or chronicity of headaches. Pericranial muscle tenderness may be present early in the development of tension headache, while ES2 suppression may only emerge later.

Reduced Achilles tendon pain thresholds were found in half of CTTH patients when compared with headache-free controls (Schoenen et al., 1991). Biofeedback moderately but significantly increased the pain threshold, perhaps by normalizing limbic input to the brainstem pain modulating system. Increased EMG activity or decreased pain thresholds were found in 72% of the patients (Schoenen et al., 1991), consistent with a diagnosis of 'CTTH associated with disorder of pericranial muscles', but these findings were not present in the remaining 28% of patients, consistent with a diagnosis of 'CTTH unassociated with such disorder'. Headache severity, anxiety, ES2, and response to biofeedback did not differ between these two groups, suggesting that their separation may be artificial or a consequence of the headache.

Spontaneous central pain activation

Post and Silberstein (1994) suggested the kindling model for epilepsy as a model for non-epileptic, progressive disorders such as mania. Post and Silberstein (1994) suggested that spontaneous recurrent migraine headaches might be analogous to the low levels of electrical stimulation in the kindling model in the process of headache transformation. Preventive migraine treatment could provide a dual benefit by preventing the occurrence of episodes and blocking the sensitization process that could lead to syndrome progression.

In primary CDH, hypersensitivity of neurons in the trigeminal NC may exist as a result of supraspinal facilitation. The vascular nociceptor may be hypersensitive in TM; in

CTTH associated with a disorder of the pericranial muscles, the myofascial nociceptor may be hypersensitive. In CTTH not associated with a disorder of the pericranial muscles, there may be less myofascial nociceptor hypersensitivity and a general increase in nociception. CTTH and TM may result from a defective interaction between endogenous nociceptive brainstem activity and peripheral input. Physical or psychologic stress or non-physiologic working positions can increase nociception from strained muscles that could trigger or sustain an attack and produce CTTH in an individual with altered pain modulation. Emotional mechanisms may also reduce endogenous antinociception. Long-term potentiation of nociceptive neurons and decreased activity in the antinociceptive system could cause primary CDH. Sensitization of the trigeminal NC neurons can result in normally non-painful stimuli becoming painful, production spots, an overlap in the symptoms of migraine and TTH, and activation of the trigeminal vascular system.

Drug-induced headache mechanisms

Overuse of analgesics, opioids, barbiturates, ergotamine-containing compounds, or triptans may contribute to the transformation of episodic into transformed migraine. Formulations of drugs that maintain sustained, non-fluctuating levels might avoid the development of drug-induced headache (Post & Silberstein, 1994). Continued high fluctuating doses of ergots, analgesics, opioids, or triptans could result in resetting the pain control mechanisms in susceptible individuals, perhaps by enhancing on-cell activity, enhancing central sensitization through NMDA receptors, or blocking adaptive antinociceptive changes.

Cerebral blood flow increases in the brainstem and cortex of patients with migraine without aura. During the headache, the increased cerebral blood flow in the cortex (but not the brainstem) is reversed by sumatriptan, as is the headache. This area of the brainstem is rich in opioids and includes the pain control centres. Dihydroergotamine (DHE) and centrally penetrant triptans selectively bind to this area of the brainstem, while sumatriptan may not. Perhaps this area of the brainstem integrates the phenomenon we call migraine, or it could be activated as a result of the migraine attack. If the first explanation is correct, ongoing activity in this area of the brainstem could produce recurrent or daily headache. If this area is responsible for controlling pain, then its failure to activate could explain ongoing headache activity. Acute migraine medications may induce daily headache by preventing the development of adaptive changes and perhaps by maintaining brainstem activation (Weiller et al., 1995).

Treatment

Overview

Patients suffering from CDH can be difficult to treat, especially when the disorder is complicated by medication overuse, comorbid psychiatric disease, low frustration tolerance, and physical and emotional dependency (Mathew et al., 1987; Saper, 1987b). The following steps should be taken. First, exclude secondary headache disorders; secondly, diagnose the specific primary headache disorder (i.e. TM, HC); and thirdly, identify comorbid medical and psychiatric conditions, as well as exacerbating factors, especially medication overuse. Limit all symptomatic medications (with the possible exception of the long-acting non-steroidal anti-inflammatory drugs (NSAIDs)). Start the patient on a programme of preventive medication (to decrease reliance on symptomatic medication), with the explicit understanding that the drugs may not become fully effective until medication overuse has been eliminated and detoxification completed (Silberstein & Saper, 1993). Outpatient detoxification options, including outpatient infusion in an ambulatory infusion unit, are available. If outpatient detoxification proves difficult or is dangerous, hospitalization may be required. We have proposed guidelines for hospitalization (Table 64.6). Patients need education and continuous support during this process.

Patients who overuse acute medication may not become fully responsive to acute and preventive treatment for 3 to 8 weeks after overuse is eliminated. Withdrawal symptoms include severely exacerbated headaches accompanied by nausea, vomiting, agitation, restlessness, sleep disorder, and (rarely) seizures. Barbiturates and benzodiazepines must be tapered gradually to avoid a serious withdrawal syndrome (Silberstein et al., 1990; Mathew et al., 1990; Baumgartner et al., 1989; Raskin, 1986).

Psychophysiologic therapy involves reassurance, counselling, stress management, relaxation therapy, and biofeedback. Physical therapy consists of modality treatments (heat, cold packs, ultrasound, and electrical stimulation), improvement of posture through stretching, exercise, and traction, trigger point injections, occipital nerve blocks, and a programme of regular exercise, stretching, balanced meals, and adequate sleep (Silberstein, 1984). It has been our experience that treating painful trigger areas in the neck can result in improvement of intractable primary CDH.

Acute pharmacotherapy

Choice of acute pharmacotherapy depends upon the diagnosis. Transformed migraine patients who do not overuse

Table 64.6. Criteria for hospitalization

I. Emergency or urgent admission

A. Certain migraine variants (e.g. hemiplegic migraine, suspected migrainous infarction, basilar migraine with serious neurologic symptoms such as syncope, confusional migraine, etc.)
   1. When a diagnosis has not been established during a previous similar occurrence
   2. When a patient's established outpatient treatment plan has failed.

B. Diagnostic suspicion of infectious disorder involving CNS (e.g. brain abscess, meningitis) with initiation of appropriate diagnostic testing.

C. Diagnostic suspicion of acute vascular compromise (e.g. aneurysm, subarachnoid hemorrhage, carotid dissection) with initiation of appropriate diagnostic testing.

D. Diagnostic suspicion of a structural disorder causing symptoms requiring an acute setting (e.g. brain tumour, increased intracranial pressure) with initiation of appropriate diagnostic testing.

E. Low cerebrospinal fluid headache when an outpatient blood patch has failed and an outpatient treatment plan has failed or there is no obvious cause.

F. Medical emergency presenting with a severe headache.

G. Severe headache associated with intractable nausea and vomiting producing dehydration or postural hypotension, or unable to retain oral medication, and unable to be controlled in an outpatient setting or with admission to observation status.

H. Failed outpatient treatment of an exacerbation of episodic headache disorder with:
   1. Failure to respond to 'rescue' or backup medications or
   2. Failure to respond to outpatient treatment with IV DHE on a schedule of a minimum of twice daily.

II. Non-emergent admission:

A. Coexistent psychiatric disease documented by psychologic or psychiatric evaluation with sufficient severity of illness such that failure to admit could pose a health risk to the patient or impair the implementation of outpatient treatment.

B. Coexistent or risk of disease (e.g. unstable angina, unstable diabetes, recent transient ischemic attack, myocardial infarction in the past 6 months, renal failure, hypertension, age >65) necessitating monitoring for treatment of headache significant enough to warrant admission.

C. Severe chronic daily headaches involving chronic medication overuse when there is:
   1. Daily use of potent opioids and/or barbiturates
   2. Daily use of triptans, simple analgesics, or ergotamine in a patient with a documented failed trial of withdrawal of these medications.

D. Impaired daily functioning (e.g. threatened relationships, many lost days at work or school due to headache), with a failure to respond to 2 days of outpatient treatment with i.v./DHE, i.v. neuroleptics, or i.v. corticosteroids on a schedule of a minimum of twice daily or equivalent treatment.

symptomatic medication can treat acute migrainous headache exacerbations with triptans, DHE, and NSAIDs. These drugs must be strictly limited to prevent superimposed rebound headache that will complicate treatment and require detoxification. The risk of rebound is much lower for DHE and triptans than for analgesics, opioids, and ergotamine. CTTH and NPDH can be treated with nonspecific headache medications, and HC can be treated with supplemental doses of indomethacin.

Preventive pharmacotherapy

Patients with very frequent headaches should be treated primarily with preventive medications, with the explicit understanding that their medications may not become fully effective until the overused medication has been eliminated. It may take 3 to 6 weeks for treatment effects to develop. The following principles guide the use of preventive treatment: (i) from among the first-line drugs, choose preventive agents based on their side effect profiles, comorbid conditions, and specific indications (for example, indomethacin for HC); (ii) start at a low dose; (iii) gradually increase the dose until you achieve efficacy, until the patient develops side effects, or until the ceiling dose for the drug in question is reached; (iv) treatment effects develop over weeks and treatment may not become fully effective until rebound is eliminated; (v) if one agent fails, choose an agent from another therapeutic class; (vi) prefer monotherapy, but be willing to use combination therapy; (vii) communicate realistic expectations (Silberstein & Lipton, 1994).

Table 64.7. Summary of preventive drugs for use in transformed migraine

Drug	Clinical efficacy	Side effects	Clinical evidence[a]
Antidepressants			
Amitriptyline	+++	++	+++
Doxepin	+++	++	++
Fluoxetine	++	+	+++
Anticonvulsants			
Divalproex	+++	++	++
Topiramate	+++	++	++
Beta-blockers			
Propranolol, Nadolol, etc.	++	+	+
Calcium channel blockers			
Verapamil	++	+	+
Miscellaneous			
Methysergide	+++	+++	+

Notes:
All categories are rated from + to ++++ based on a combination of published literature and clinical experience.
[a] Ratings of +++ for clinical evidence indicate at least one double-blind, placebo-controlled study. A rating of ++ indicates open well-designed studies and + indicates ratings based on clinical experience. A rating of ++++ requires at least two double-blind placebo-controlled trials.
Source: Modified from Tfelt-Hansen and Welch (2000).

Most preventive agents used for primary CDH have not been examined in well-designed double-blind studies. Table 64.7 summarizes an assessment of the efficacy, safety, and evidence for a number of agents (Silberstein & Saper, 1993).

Antidepressants are attractive agents for use in TM, CTTH, and NDPH, since many patients have comorbid depression and anxiety. The most widely used tricyclic antidepressants are nortriptyline (Aventyl, Pamelor), doxepin (Sinequan) (Morland et al., 1979), and amitriptyline (Elavil), which has been effective in many but not all studies (Bussone et al., 1991; Couch et al., 1976; Diamond & Baltes, 1971; Holland et al., 1983; Lance & Curran, 1964; Pluvinage, 1994; Pfaffenrath et al., 1986, 1994; Holroyd et al., 1991; Gobel et al., 1994; Cerbo et al., 1998; Mitsikostas et al., 1997; Bonuccelli et al., 1996). In an open-label study in 82 non-depressed patients with either ETTH or CTTH, Cerbo et al. (1998) found that amitriptyline (25mg a day) significantly reduced ($P<0.05$) analgesic consumption and the frequency and duration of headache in CTTH but not in ETTH.

Fluoxetine (Prozac), a selective serotonin reuptake inhibitor, is coming into wider use for daily headaches; evidence from a double-blind study demonstrates its efficacy in primary CDH (Bussone et al., 1991; Saper et al., 1994). Fluvoxamine appears to be effective (Manna et al., 1994) and may have analgesic properties (Palmer & Benfield, 1994). Other selective serotonin reuptake inhibitors including paroxetine (Foster & Bafaloukos, 1994) and monoamine oxidase inhibitors may have a therapeutic role, but this has not been proven to date (Langemark & Olesen, 1994).

Beta-blockers (propranolol, nadolol) remain a mainstay of therapy for migraine (Silberstein & Saper, 1993) and are used for primary CDH (Pfaffenrath et al., 1986; Mathew, 1981). Clinicians fear that beta-blockers may exacerbate depression; however, this issue is controversial (Bright & Everitt, 1992). Beta-blockers are relatively contraindicated in patients who have asthma and Raynaud's disease.

Calcium channel blockers are very well tolerated (Silberstein & Saper, 1993); anecdotal evidence supports their use for TM. Verapamil (Calan) is the most widely prescribed agent in this family. Diltiazem (Cardizem) and nifedipine (Procardia) may also be considered. Flunarizine (Silberstein & Saper, 1993; Lake et al., 1993) is widely used in Canada and Europe but is not available in the United States.

The anticonvulsant divalproex sodium (Depakote) (Jensen et al., 1994) is an important drug in migraine prophylaxis, even for patients who have failed other agents. Four double-blind placebo-controlled studies have demonstrated its efficacy in migraine (Jensen et al., 1994; Mathew et al., 1995; Hering & Kuritzky, 1998; Klapper, 1995). Smaller open studies support its utility in TM (Mathew & Ali, 1991). Doses lower than those used for epilepsy (250 mg twice a day) may be sufficient. In an open-label study, Edwards et al. (1999) assessed the possible benefit of sodium valproate in 20 consecutive CDH patients who were refractory to multiple standard treatments. Eleven (55%) had a response (mild or no headaches within one to four weeks). The doses ranged from 375 mgs to 1500 mg a day. Two patients (10%) discontinued medication due to side effects (nausea and difficulty thinking).

Topiramate is a new antiepileptic agent that has GABA-agonist properties and few side effects when used in low doses. Its chronic use has been associated with weight loss, not weight gain. In an open-label study, Shuaib et al. (1999) used topiramate (25 to 100 mg per day) to treat 37 patients who had more than ten migraine headaches a month. Most patients had CDH in addition to migraine; all had failed previous preventive treatment. Over a 3- to 9-month follow-up, 11 patients had an excellent result (headache

frequency decreased by over 60%); 11 patients had a good result (headaches frequency decreased 40% to 60%); three patients discontinued therapy due to side effects; and eight patients had no improvement. This uncontrolled study suggests that topiramate may be useful for TM.

The NSAIDs can be used for both symptomatic and preventive headache treatment. Naproxen sodium is effective for prevention at a dose of one or two 275 mg tablets twice a day (Miller et al., 1987). Other NSAIDs found to be effective include tolfenamic acid, ketoprofen, mefenamic acid, fenoprofen, and ibuprofen (Johnson & Tfelt-Hansen, 1993; Mylecharane & Tfelt-Hansen, 1993). Aspirin was found to be effective in one study (Kangasniemi et al., 1983) and equal to placebo in another (Scholz et al., 1987). We believe that the short-acting NSAIDs such as ibuprofen and aspirin cause rebound and their use should be limited. The rebound potential of the other NSAIDs is uncertain. Indomethacin is the drug of choice for HC, and the response to this medication defines the disorder. We give indomethacin a therapeutic trial to rule out HC, but otherwise limit the use of NSAIDs.

Although monotherapy is preferred, it is sometimes necessary to combine preventive medications. Antidepressants are often used with beta-blockers or calcium channel blockers and divalproex sodium may be used in combination with any of these medications.

Other treatments

Open and small placebo-controlled trials have suggested that CTTH may improve following injection with botulinum toxin A (Botox® (BTX-A)); whether this is due to paralysis of muscles or to unknown mechanisms is uncertain. Botulinum toxin has been shown to be effective in decreasing the frequency of migraine attacks (Gobel et al., 1999).

Porta et al. (1999), in a randomized, single-blind trial, compared BTX-A to methylprednisolone. Injections were given in the tender points of cranial muscles, which were determined using pressure pain threshold measurements with an electronic algometer. Inclusion criteria included a diagnosis of IHS ETTH or CTTH, age between 18 and 70 years, and no preventive treatment. At 30 and 60 days postinjection, both treatment groups had a significant reduction in pain scores (using a visual analogue scale) compared with baseline. At 60 days postinjection, the reduction in pain scores was statistically significantly greater in BTX-A-treated patients compared with those who received steroid.

Smuts et al. (1999) conducted a double-blind, placebo-controlled, randomized study of 40 CTTH patients (29 women, 11 men) who had previously been unsuccessfully treated with either amitriptyline or sodium valproate. Patients received intramuscular injections of either BTX-A (100U in 2 ml saline) or placebo (2 ml saline) at predefined areas in the neck and temporal muscles. The number of headache-free days was significantly increased in the BTX-A group 3 months following treatment compared with controls. A clear shift toward the lower headache score counts for the BTX-A group was retained throughout the study period. A statistically significant reduction in the average pain score was achieved for the BTX-A group compared with the placebo group over the 3-month period. No serious adverse events were reported.

In a double-blind trial, Gobel et al. (1999) treated ten CTTH patients with either 10 i.u. Botox® injected into the frontal muscle and the auricular muscle on each side and 20 i.u. injected into the splenius capitis muscle on each side, or the corresponding quantity of NaCl as placebo. No significant change in headache intensity, headache hours per day, or frequency of analgesic intake was observed between the treatment groups. Relja and Korsic (1999) reported a significant and rather long-lasting decrease in headache intensity in 16 CTTH patients in a double-blind, placebo-controlled study. Botox® and/or placebo (saline) were injected into the most tender pericranial muscle. Botulinum toxin A treatment resulted in a significant decrease of the total tenderness score, obtained by the palpation method, two weeks, four weeks, and eight weeks after injections. Placebo had no effect. According to patients' diaries, the severity and the duration of the attacks decreased significantly during the BTX-A treatment period (Relja & Korsic, 1999).

Outpatient treatment of medication overuse

Two general outpatient strategies are employed. One approach is to taper the overused medication, gradually substituting a long-acting NSAID as effective preventive therapy is established. The alternative strategy is to abruptly discontinue the overused drug, substitute a transitional medication to replace the overused drug, and subsequently taper the transitional drug. Drugs used for this purpose include NSAIDs, DHE, corticosteroids and triptans (Diener et al., 1991; Bonuccelli et al., 1996; Drucker & Tepper, 1998). Serious withdrawal syndromes that can be produced by the overused drug must be prevented. For example, if high doses of a butalbital-containing analgesic combination are abruptly discontinued, phenobarbital should be used to prevent barbiturate withdrawal syndrome. Similarly, benzodiazepines must be gradually tapered. Outpatient treatment is preferred for motivated patients, but is not always safe or effective.

Patients who do not need hospital-level care but cannot be safely or adequately treated as outpatients can be considered for ambulatory infusion treatment. Outpatient ambulatory infusion must be done in a hospital or a supervised medical setting where the patient can be monitored frequently (as often as every 15 minutes). Under these circumstances, repetitive i.v. treatment can be given twice a day for several days in a row. Although ambulatory infusion is better for many patients than outpatient treatment, major concerns still exist. Contraindications to outpatient ambulatory infusion include the likelihood of withdrawal symptoms at night when patients are withdrawn from long-acting or potent drugs; psychiatric disorders that interfere with treatment (these patients cannot be treated aggressively as outpatients); and comorbid medical illness that requires prolonged monitoring. No long-term observation is available, and many problems manifest themselves in an intensely monitored interactive environment.

Inpatient treatment of medication overuse

If outpatient treatment fails or is not safe, or if there is significant medical or psychiatric comorbidity present, inpatient treatment may be needed (Silberstein & Saper, 1993). The goals of inpatient headache treatment include: (i) medication withdrawal and rehydration; (ii) pain control with parenteral therapy; (iii) establishment of effective preventive treatment; (iv) interruption of the pain cycle; (v) patient education; and (vi) establishment of outpatient methods of pain control. The detoxification process can be enhanced and shortened and the patient's symptoms made more tolerable by the use of repetitive i.v. DHE coadministered with metoclopramide (Raskin, 1986), which helps control nausea and is an effective antimigraine drug in its own right. Following 10 mg of IV metoclopramide, 0.5 mg of DEH is administered i.v. Subsequent doses are adjusted based on pain relief and side effects. Patients who are not candidates for DHE or do not respond to this medication can be given repetitive i.v. neuroleptics, such as chlorpromazine, droperidol, and prochlorperazine, and/or corticosteroids. These agents may also supplement repetitive i.v. DHE in refractory patients (Silberstein et al., 1990). Hospitalization is also used as a time for patient education, for introducing behavioural methods of pain control, and for adjusting an outpatient programme of preventive and acute therapy.

Silberstein et al. (1990) showed that repetitive i.v. DHE is a safe and effective means of rapidly controlling intractable headache. Of 214 patients suffering from daily headache with rebound, 92% became headache free, usually within 2 to 3 days, with an average hospital stay of 7.3 days. With more aggressive treatment, the average length of stay is now 3 days. Pringsheim and Howse (1998) reported similar but less robust results.

Prognosis

The 'natural history' of primary CDH, and rebound headache in particular, has never been studied and probably never will be for ethical and technical reasons. Recognition of the rebound process probably is itself therapeutic and could affect the patient's behaviour or the physician's approach. Retrospective analysis suggests that there may be periods of stable drug consumption and periods of accelerated medication use. Patients who are treated aggressively generally improve. There are no literature reports of spontaneous improvement of rebound headache, although this may happen. Silberstein and Silberstein (1992) performed follow-up evaluations on 50 hospitalized primary CDH drug overuse patients who were treated with repetitive i.v. DHE and became headache free. Once detoxified, treated and discharged, most patients did not resume daily analgesic or ergotamine use. Seventy-two per cent continued to show significant improvement at 3 months, and 87% continued to show significant improvement after 2 years. This would suggest at least a 70% improvement at 2 years in the initial group (35/50), allowing for patients lost to follow-up.

Silberstein and Silberstein (1992) reported a 2-year success rate of 87%, consistent with other reports. In a series of 22 papers (Hering & Steiner, 1991; Andersson, 1975, 1988; Tfelt-Hansen & Krabbe, 1981; Schoenen et al., 1989; Isler, 1982; Dichgans et al., 1984; Granella et al., 1998; Baumgartner et al., 1989; Mathew, 1990; Mathew et al., 1990; Rapoport et al., 1986; Lake et al., 1990; Henry et al., 1984; Diener et al., 1988, 1989, 1992; Silberstein & Silberstein, 1992; Pini et al., 1996; Schnider et al., 1996; Pringsheim & Howse, 1998; Monzon & Lainez, 1998; Suhr et al., 1999) published between 1975 and 1991, the success rate of withdrawal therapy (often accompanied by pharmacologic and/or behavioural intervention) in patients overusing analgesics, ergotamine, or both, ranged from 48% to 91%; success rates of 77% or higher were reported in ten papers (45%).

Why treatment fails (Table 64.8)

When patients fail to respond to therapy or announce at the first consultation that they have already tried everything and nothing will work, it is important to try to identify the reason or reasons that treatment has failed. The

Table 64.8. Why treatment fails

The diagnosis is incomplete or incorrect
An undiagnosed secondary headache disorder is present
A primary headache disorder is misdiagnosed
Two or more different headache disorders are present
Important exacerbating factors may have been missed
Medication overuse (including over-the-counter)
Caffeine overuse
Dietary or lifestyle triggers
Hormonal triggers
Psychosocial factors
Other medications that trigger headaches
Pharmacotherapy has been inadequate
Ineffective drug
Excessive initial doses
Inadequate final doses
Inadequate duration of treatment
Other factors
Unrealistic expectations
Comorbid conditions complicate therapy
Inpatient treatment required

Source: Modified from Lipton et al. (2000).

cause of treatment failure may be an incomplete or incorrect diagnosis (Lipton et al., 2000). For example: (i) an undiagnosed secondary headache disorder is the major source of the head pain; (ii) a primary headache disorder has been misdiagnosed (i.e. HC is mistaken for TM, episodic paroxysmal hemicrania or hypnic headache is mistaken for cluster); or (iii) two or more different headache disorders are present. In addition, pharmacotherapy may have been inadequate or important exacerbating factors such as medication overuse may have been missed.

Pathophysiology of nerve and root disorders

Jonathan D. Glass

Departments of Neurology and Pathology, Neuromuscular Program, Emory University School of Medicine, Atlanta, GA, USA

The peripheral nervous system (PNS) represents the final common anatomical pathway linking the brain with the outside world. This chapter deals with the pathological basis of disorders of the PNS, including symptoms and signs related to abnormalities of peripheral nerves, spinal roots, and sensory and autonomic ganglia. Specific neurological disorders are discussed here only in the context of their representative value in understanding PNS dysfunction. Readers are directed to other chapters within this section and the section on Degenerative Disorders for more complete discussions of PNS diseases.

Anatomical organization

The neuronal cell bodies for the PNS are located within the dorsal root ganglia (primary sensory neurons), the cranial and spinal sympathetic and parasympathetic ganglia, and the anterior horn of the spinal cord (motor neurons). The perikaryal organization reflects the enormous synthetic requirements for maintaining the axonal and dendritic processes that may represent many times the volume of the perikaryon itself. Prominent within the perikaryal cytoplasm are mitochondria which are responsible for the production of ATP, and the Nissl substance which is made up of free and membrane-bound ribosomes (rough endoplasmic reticulum). The pattern of Nissl staining seems to reflect the metabolic state of the neuron, and changes in the staining pattern are associated with injury to the neuron. The classic example of these changes is chromatolysis (Fig. 65.1), where axonal injury leads to swelling of the cell body, eccentric displacement of the nucleus, and margination of the Nissl substance (for review see Peters et al., 1991). These changes are not necessarily associated with the death of the neuron; to the contrary they frequently reflect a reparative and regenerative stage after neuronal injury (Bodian & Mellors, 1945). Chromatolytic changes are stimulated by a variety of injuries including root avulsion, axonal transection, and even peripheral neuropathy.

Neurons communicate with one another and with their effector organs by transmitting chemical and electrical signals via dendrites and axons. Dendrites and axons may be distinguished by a variety of structural and functional characteristics (Table 65.1), however a practical distinction is that dendrites are responsible for input to and axons are responsible for output from the cell body.

In clinical neurology, few disorders are defined neuropathologically as diseases of dendrites. Diseases of axons, however, are recognized as the neuropathological substrate for neurological dysfunction in a large array of CNS and PNS disorders. This holds true for primary disorders of axons as well as for demyelinating diseases where secondary axonal degeneration correlates with the chronic loss of sensory and motor functions.

The axon

The axon emerges from the cell body as a unique structure that can be distinguished from the perikaryon on the basis of both morphological and functional features (Berthold & Rydmark, 1995). Within the axon, neurofilaments and microtubules are organized in parallel arrays along the axis of the nerve fibre, in contrast to the complex cytoskeletal structure of the cell body. Other organelles found within the axoplasm are mitochondria, smooth endoplasmic reticulum, and a variety of vesiculotubular and membranous structures. Axons are devoid of the machinery for protein synthesis (ribosomes and granular endoplasmic reticulum), and must depend on transport mechanisms for replenishment of proteins. (For an alternative view, see Alvarez et al., 2000.) Functionally, the axon is the wire that connects the cell body with its targets, and the intimate

Table 65.1. General features of axons and dendrites

	Number	Cytoskeletal elements	Function	Electrical activity	Presence of ribosomes	Protein markers
Axon	Single (except DRG)	Neurofilament rich (except in small axons)	Output from cell body	Saltatory in myelinated fibres	No[a]	Tau
Dendrite	Multiple	Microtubule rich	Input to cell body	Cable	Yes	MAP-2

Note:

[a] Ribosomes and local protein synthesis in axons are controversial topics; however, both have been described (Alvarez et al., 2000).

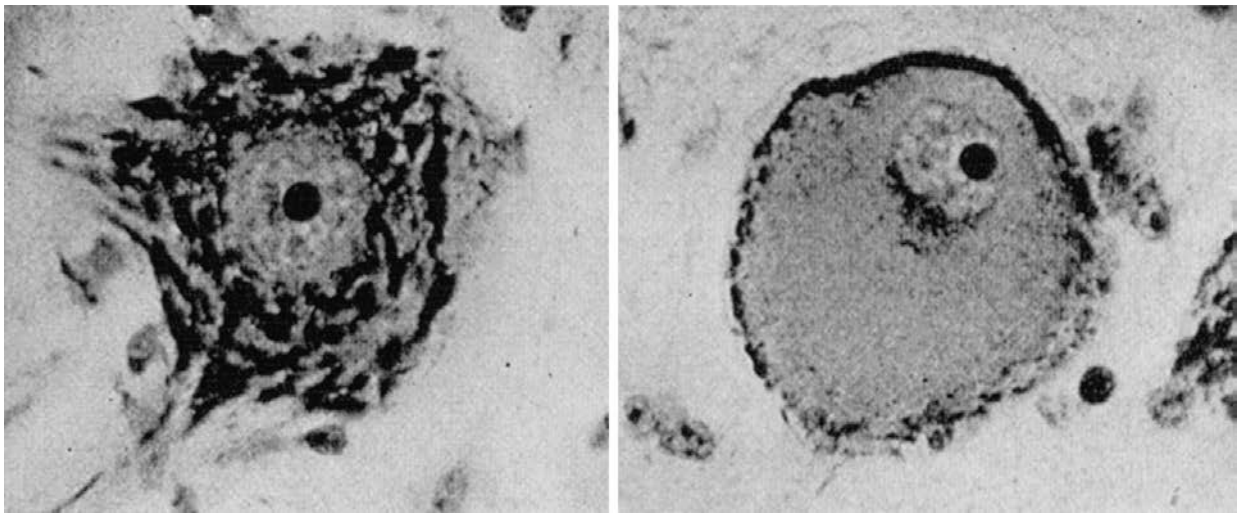

Fig. 65.1. Chromatolysis in motor neurons. As compared to the normal neuron on the left, the neuron on the right shows typical chromatolytic changes in response to axonal transection, including swelling, margination of the Nissl substance, and eccentric displacement of the nucleus. (From Bodian & Mellors, 1945.)

relationship between the axon and Schwann cell (in the PNS) allows for rapid electrochemical communication along that wire. The relationship with the Schwann cell also has major influences on the underlying axonal structure, including axonal calibre and degree of phosphorylation of neurofilaments (see below).

Axonal transport

The enormous volume of axoplasm in relation to perikaryal size, a feature particularly prominent in PNS axons, requires that proteins be transported over long distances for effective axonal and synaptic maintenance. For this purpose, axonal transport systems have evolved for shuttling proteins to and from the perikaryon (for reviews, see Vallee & Bloom, 1991; Goldstein & Yang, 2000). Axonal transport can be viewed metaphorically as a rail system, complete with tracks (axonal cytoskeleton), trains (vesicles), and engines (kinesin and cytoplasmic dynein), operating with express and local schedules (fast and slow transport). Passengers (proteins) board the rail system at both ends of the line. Axons and their presynaptic terminals are completely dependent on this transport system for the delivery of neurotransmitter-related enzymes and other proteins from the cell body. The cell body relies on retrograde transport for growth factors originating within muscle and skin, and the recycling of membrane constituents. Disruptions in either the slow or fast components of axonal transport are likely to underlie a variety of disorders including toxic and nutritional peripheral neuropathies (Griffin & Watson, 1988), and possibly some motor neuron diseases (Lee et al., 1994). A summary of axonal transport systems and their relationship to disease is outlined in Table 65.2.

The Schwann cell and organization of the myelinated nerve fibre

The Schwann cell is the glial cell of the PNS. Like the oligodendrocyte of the CNS, Schwann cells provide the myelin sheath that insulates large calibre axons and allows for the

Table 65.2. Axonal transport systems

	Fast transport	Slow transport
Direction	Bidirectional	Anterograde[a]
Rate of transport	Anterograde 100–400 mm/ day Retrograde: ≃300 mm/day	Component A: 0.2–2 mm/day Component B: 1–5 mm/day
Motors	Anterograde: kinesin Retrograde: dynein (MAP 1C)	Unknown
Components	Anterograde: smooth ER, vesicles, synaptic proteins, membrane components Retrograde: lysosomes, multivesicular bodies, synaptic ligands (e.g. – NGF)	Component A: neurofilament (NF) subunits, tubulins Component B: tubulins
Representative disorders	Delivery to perikaryon of toxins and infectious agents via retrograde transport: tetanus, poliovirus, rabies virus	Altered NF transport resulting in axonal swelling and distal axonal atrophy: hexacarbon, IDPN intoxication ?motor neuron diseases

Note:

[a] retrograde slow transport in special pathological preparations (Glass & Griffin, 1994).

phenomenon of saltatory conduction of action potentials (see below). Schwann cells and oligodendrocytes are clearly separate populations of cells that have structural, morphological and functional distinctions (Peters et al., 1991).

Axons and Schwann cells maintain a complex and interactive structure/function relationship both during development and within the adult PNS. There is a tight mathematical correlation between axonal calibre, myelin thickness, and internodal length (Friede & Samorajski, 1971; Friede & Bischhausen, 1982; Friede & Beuche, 1985; Berthold & Rydmark, 1995). A change in any of these features may influence the physiological characteristics of the fibre, including rate of axonal transport (Hoffman et al., 1984, 1985) and conduction velocity (Ritchie, 1995). Overall control of this relationship was, until recently, believed to rest with the axon, where calibre, as determined by neurofilament number and degree of phosphorylation, regulated myelination (Griffin & Hoffman, 1993; Griffin et al., 1981, 1988). Recent data, however, demonstrate that there is a major influence of Schwann cells, and specifically myelination, on axonal structure and function. In the normal PNS, examples of this relationship are found at the nodes of Ranvier and at proximal sites of dorsal root ganglion axons. In these regions, lack of myelination is correlated with reduction of axonal calibre, tighter packing of neurofilaments, and reduced neurofilament phosphorylation (Mata et al., 1992; Hsieh et al., 1994). Axons can also be modified in response to local demyelination, as has been demonstrated in xenograft studies using the Trembler mouse (de Waegh et al., 1992) and human sural nerves from patients with type-1 Charcot–Marie–Tooth disease (Sahenk, 1999). In both of these studies, axons from the recipient mouse regenerated through grafts containing the mutant Schwann cells. Axons in these regions, as compared to the regions containing normal host Schwann cells, showed reduced calibre, tighter neurofilament packing, and reduced phosphorylation of neurofilaments.

From a functional standpoint, the structural relationship between axons and Schwann cells is important for the very existence of large mammals. In mammals, neurological function depends on the rapid and efficient conduction of action potentials over long distances (sometimes many metres). The phenomenon of saltatory conduction has evolved to provide for rapid conduction of action potentials. This evolution includes the tight mathematical relationship between axonal calibre, myelin thickness, and internodal length which, taken together, are the determinants of conduction velocity in myelinated fibres.

Clinical nerve disorders demonstrate that the relationship between axons and Schwann cells is even more complex. Primary disorders of myelin or Schwann cells invariably result in some degree of axonal degeneration. A clear example is found in patients with type-1 (demyelinating) Charcot–Marie–Tooth disease (CMT). Children in these families frequently are asymptomatic even though their nerve conduction velocities are as slow as those in their symptomatic parents (Gutmann et al., 1983; Garcia et al., 1998). Symptoms of CMT, that is sensory loss and weakness, are correlated not with degree of demyelination or

conduction slowing, but with axonal degeneration that progresses over time in a distal to proximal fashion (Krajewski et al., 2000). An example in the CNS is multiple sclerosis, a primary demyelinating disorder in which the long term clinical deficits are best correlated with underlying degeneration of axons (Trapp et al., 1998).

Experimentally, primary disorders of Schwann cells frequently result in degeneration of underlying axons. In animal models of CMT, including the P-zero knockout mouse (CMT 1B) (Giese et al., 1992; Martini et al., 1995; Shy et al., 1997) the PMP-22 overexpressing rat (CMT 1A) (Sereda et al., 1996), the PMP-22 null mouse (CMT 1A) (Sancho et al., 1999), and the PMP-22 deficient mouse (HNPP) (Adlkofer et al., 1995), axonal degeneration is found, as it is in humans, in older mice. Similarly, mice deficient in the gene for myelin-associated glycoprotein (MAG) demonstrate age-related axonal degeneration (Fruttiger et al., 1995; Sheikh et al., 1999), and also show reduction in axonal calibre and degree of neurofilament phosphorylation. These experimental and clinical observations emphasize the importance of the axon–Schwann cell relationship for normal axonal maintenance.

Deficits due to primary demyelination without axonal degeneration are often either short term or easily reversible. Here, loss of function is due to the physiological disconnection between the cell body and effector organ by the phenomenon of conduction block. Conduction block occurs when the membrane potential at the node of Ranvier cannot reach threshold to generate an action potential, resulting in the loss of electrical propagation along the axon. This may occur because of a structural alteration of the internode (e.g. segmental demyelination or nodal expansion, Fig. 65.2), or through a block of ion channels at the node. Normally, the properties of myelin allow for propagation of the membrane potential from node to node with little loss of amplitude (saltatory conduction), so that each node easily reaches 'threshold' for the regeneration of the action potential. Demyelinated or inadequately myelinated internodes lose their capacity for saltatory conduction and must depend on the propagation of action potentials along the formerly myelinated internode, a process which is inefficient and slow (Felts et al., 1997). Conduction failure is due to insufficient sodium current density to offset the leak and capacitative currents along the demyelinated internode. This results in a dwindling of the membrane potential over distance to below the threshold for generation of an action potential (see Waxman et al., 1995). Remyelination, which may occur over days to weeks, re-establishes the anatomical structure of the internode, thus physiologically reconnecting the cell body with its target.

Biological toxins such as tetrodotoxin or saxitoxin cause the reversible blockade of sodium channels at the node of Ranvier, resulting in loss of propagation of action potentials along the axon (Brown & Ironton, 1977; Oda et al., 1989). This form of conduction block occurs in the absence of structural changes in myelin, and is practically reversible within minutes of the removal of the toxin.

Examples of conduction block are encountered frequently in clinical practice. Patients with immune-mediated demyelinating neuropathies, such as Guillain–Barré Syndrome and CIDP (Brown & Feasby, 1984), frequently demonstrate rapid loss and recovery of neurologic function which correlates well with the electrodiagnostic findings of conduction block. There are also many cases in the literature documenting patients with long-standing weakness, sometimes lasting many years, who show recovery after only a few days of immunomodulatory therapy. This pattern of disease and recovery, with electrodiagnostic demonstration of conduction block and reversal has been seen in patients with multifocal motor neuropathy (MMN) (Pestronk et al., 1988; Chaudhry et al., 1993). The rapidity of recovery, perhaps too rapid for the process of remyelination, probably reflects the unblocking of ion channels at the nodes. The mechanism of blocking and unblocking has not yet been delineated, however the binding of immunoglobulin at the node of Ranvier is suspected.

Axonal degeneration

Wallerian degeneration

Axonal degeneration is the most common pathological finding in patients with nerve and root disorders. Even though primary disorders of Schwann cells may lead to

Fig. 65.2. Neuropathological features of demyelination in human sural nerve biopsies. (*a*) Teased nerve fibre demonstrating a demyelinated and thinly remyelinated internode. Note that the internodal length is shorter than the adjacent normal internode. (*b*) Mild and severe paranodal demyelination in centre and right panels, respectively. Normal node shown in left panel. Measurement bar for panels (*a*) and (*b*). (*c*)–(*e*) Electron micrographs showing features of demyelination and remyelination. In (*c*), a thinly remyelinated fibre is shown next to normally myelinated fibres of similar calibres. In (*d*), a 'naked' axon is shown with surrounding Schwann cell cytoplasm. The Schwann cell basal lamina is depicted by the arrowheads. In (*e*) a well-formed 'onion bulb' created by multiple layers of Schwann cell cytoplasm surrounds a thinly myelinated axon. The cell on the right without a basal lamina is likely an inflammatory cell.

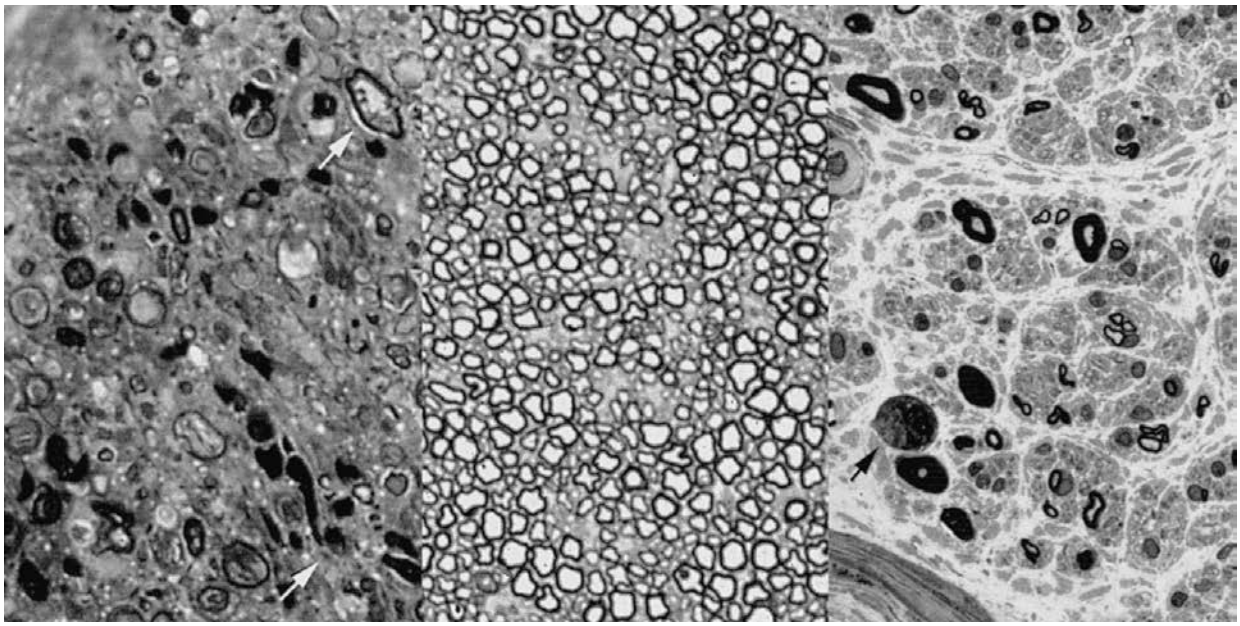

Fig. 65.3. Comparison of Wallerian degeneration in an axotomized rat nerve(left) and Wallerian-like nerve degeneration from a patient with diabetic neuropathy(right). Axonal loss and myelin ovoids are seen in both (arrows), but are more prominent in the rapidly progressing lesion due to axotomy. A normal rat sciatic nerve is demonstrated in the center panel (all 1 µm plastic sections stained with toluidine blue).

axonal degeneration, as described above, in the majority of cases axonal degeneration results from diseases of the axon or perikaryon. The simplest model of axonal degeneration is Wallerian degeneration (Waller, 1850) which results from physical separation of the axon from its cell body. After axotomy, Wallerian degeneration begins with a latency period during which the separated distal stump is relatively quiescent, showing only minor pathological changes. This latency period lasts from 1–7 days in mammals, roughly directly corresponding to the size of the organism (i.e. 1–2 days in mice, and 5–7 days in humans). The latency period ends with explosive degradation of the axonal cytoskeleton, triggering a sequence of events which includes myelin degradation and digestion, Schwann cell proliferation (in the PNS), and remodelling of the distal stump in preparation for regeneration (for review see Chaudhry et al., 1992). Axonal transection, and thus Wallerian degeneration, is not an uncommon factor in neurological diseases, including traumatic, ischemic, and inflammatory injuries. However, the importance of understanding the pathophysiology of Wallerian degeneration is markedly amplified by the apparent similarities between the rapid degeneration occurring after axotomy and the slowly evolving degeneration seen in neurodegenerative disorders (Wang et al., 2000a,b,c). Neuropathologists have long recognized these similarities, describing the changes seen in a wide spectrum of CNS and PNS disorders as 'Wallerian-like' in nature (Fig. 65.3).

Until recently, Wallerian degeneration was believed to represent the inevitable consequence of interruption of communication between the axon and perikaryon. The prevailing hypothesis was that the axon died passively due to starvation for 'trophic' substances from the cell body (Ramon y Cajal, 1928). Examples of prolonged survival of transected axons (weeks to months) were unknown in mammals, although were seen in invertebrates and poikilotherms (Bittner, 1991). In 1989, however, a spontaneous mouse mutant was discovered that demonstrates prolonged axonal survival after nerve injury (Lunn et al., 1989). In this mouse mutant, named Wld^S for 'slow Wallerian degeneration', the entire sequence of Wallerian degeneration is delayed, including macrophage recruitment, myelin clearance, and Schwann cell proliferation. Once axonal degeneration occurs, however, Wallerian degeneration progresses at a normal rate (Glass & Griffin, 1991; Hall, 1993). The phenotype of the Wld^S can thus be considered one of prolongation of the latency period after injury. Transected axons from the PNS or CNS of this remarkable animal remain structurally intact for up to 4 weeks (Glass & Griffin, 1991; Ludwin & Bisby, 1991; Crawford et al., 1995), support action potentials for at least 2 weeks, and will continue anterograde and retrograde transport of pro-

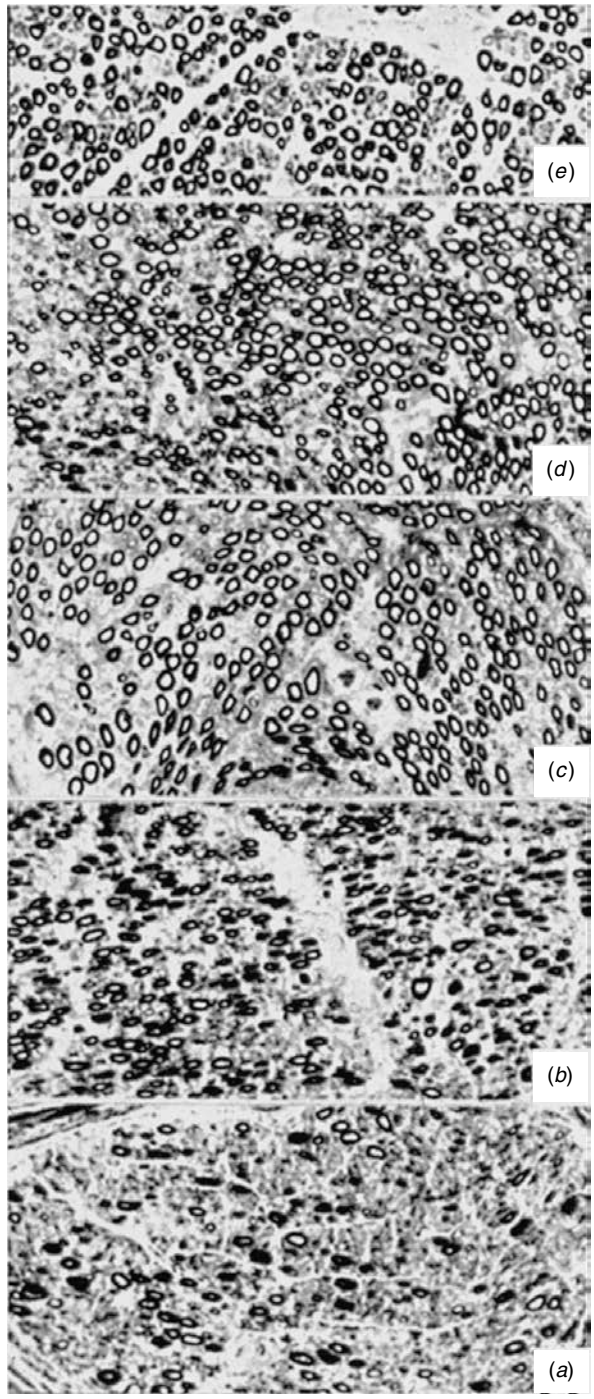

Fig. 65.4. Distal axonal degeneration ('dying-back' neuropathy). These sections of nerves were taken from an autopsy of a patient dying with AIDS complicated by peripheral neuropathy. Sections (*a*)–(*e*) were taken from progressively more proximal sites and demonstrate the distal predominence of pathological changes, correlating well with clinical symptoms and signs: (*a*) sural at ankle; (*b*) peroneal at fibular head; (*c*) peroneal at mid thigh; (*d*) lumbosacral plexus; (*e*) L5 root. 1 μm plastic sections stained with toluidine blue.

teins for similar amounts of time (Smith & Bisby, 1993; Glass & Griffin, 1994). The phenotype is carried as an autosomal dominant trait (Perry et al., 1990a), and the 'defect' which allows for prolonged survival of transected axons is inherent to the nervous system (Perry et al., 1990b; Glass et al., 1993). Remarkably, no other phenotypic markers of this mutation have been identified. The mutation lies within an 85 kB DNA triplication on chromosome 4 (Lyon et al., 1993; Coleman et al., 1998) which creates a new gene by splicing portions of two normally non-contiguous genes, *Ufd2* and *NMNAT* (Conforti et al., 2000). The existence of this gene, and its novel protein product, impart protection against axonal degeneration (Wang et al., 2001b). At the time of this writing, the mechanism of protection is unknown.

The existence of the Wld^s mutant reinforces the concept that axonal biology is more complex than previously believed, and has re-energized research interest in the mechanisms of axonal degeneration. The prolonged survival of anucleate axons suggests that axonal degeneration is not a passive process, but is a 'programmed' response to injury. This concept, that neuronal and axonal degeneration are independent processes, is supported by experimental studies on cultured sympathetic neurons from Wld^s mice (Deckwerth & Johnson, 1994). In these preparations, neuronal cell bodies deprived of nerve growth factor (NGF) die by the process of apoptosis, as expected for normal sympathetic neurons. Axons, however, remain intact long after their cell bodies have disappeared.

Mechanisms of axonal degeneration

Calcium entry into neurons is a common feature of experimental models of acute and chronic neurologic diseases (Choi, 1993; Nixon et al., 1994; Nixon, 1989; Caner et al., 1993; Meldrum & Garthwaite, 1990; LoPachin et al., 1990). There are data in both the CNS and PNS that calcium entry and elevated intracellular calcium levels are required for axonal degeneration. In a model of hypoxia/ischemia of rat optic nerve axons, Waxman and colleagues demonstrated that requirements for axonal injury (degradation) are the presence of calcium, and entry of calcium into the

intra-axonal space (Waxman et al., 1991, 1993; Stys et al., 1990, 1991; Lehning et al., 1996). Similarly, Schlaepfer and colleagues showed that calcium is required for degeneration of peripheral nerve fibres, and that calcium entry is associated with the structural and biochemical degradation of axonal neurofilaments (Schlaepfer, 1971, 1977; Schlaepfer & Hasler, 1979; Schlaepfer & Micko, 1979). Given that calcium is an essential component in the process of axonal degeneration, important considerations are how and when calcium enters an injured axon, and what role calcium plays in cytoskeletal degradation.

Elevation of intracellular calcium likely occurs by a variety of mechanisms that are both tissue and injury dependent. For example, in the model of optic nerve hypoxia/ischemia calcium enters as a result of energy failure, resulting in the reverse operation of a calcium pump (sodium–calcium exchanger) which under normal conditions works to keep intracellular calcium levels low. In an axotomy model of PNS axons, calcium entry proceeds through L-type calcium channels and not via energy dependent mechanisms (George et al., 1995). A third model of axonal degeneration caused by closed head trauma showed that increases in intracellular calcium levels may occur as a delayed phenomenon due to release of bound calcium from internal stores (calcium binding proteins, cytoskeletal proteins, and mitochondria) (Maxwell et al., 1997; Okonkwo & Povlishock, 1999).

Therapeutic intervention by reduction of extracellular calcium levels successfully prevents axonal degeneration in all of these models, but this strategy is only practical in in vitro situations. More important for designing rational preventative therapies is understanding the mechanism(s) by which elevated intracellular calcium leads to cell death. A current hypothesis is that elevated calcium levels in injured cells leads to pathologic activation of calpains (for review see Bartus, 1997).

Calpains are ubiquitous neutral cysteine proteases that are implicated in both physiological and pathological cellular processes (for review see Croall & DeMartino, 1991). The two major forms, μ-calpain (calpain I) and m-calpain (calpain II) are activated by micromolar and millimolar calcium concentrations, respectively (Melloni & Pontremoli, 1989; Sorimachi et al., 1994). Cytoskeletal proteins, and specifically neurofilaments, are excellent calpain substrates (Bernier et al., 1999; Castejon et al., 1999). It is likely that calpains act as the executors of cytoskeletal degradation during axonal degeneration. Experimental models of Wallerian degeneration (Kamakura et al., 1983), toxic peripheral neuropathy(Wang et al., 2000), ischemic stroke (Bartus et al., 1995), spinal cord injury (Li et al., 1995), and traumatic brain injury (Saatman et al., 1996), support a role for calpains in cellular degradation, and suggest that calpain inhibitors may be protective against axonal and neuronal death. Clinical applications of calpain inhibitors, as of this writing, have not been tested.

Calpains may not be the only proteases involved in axonal degeneration, and there is a growing interest in the presence and activity of the caspases in axons. Caspases are typically thought of as important in the process of apoptosis, which occurs within cell bodies. Axons, however, contain caspases (specifically caspase-3), which become active after brain trauma (Buki et al., 2000). Wallerian degeneration, however, may not require caspase activation (Finn et al., 2000). Interactions between calpains and caspases have been demonstrated, and may be important in some forms of axonal degeneration (Wang, 2000).

Distal axonal degeneration ('dying back')

The majority of slowly evolving axonal degenerations progress in a distal to proximal pattern, affecting the longest nerve fibres first (Fig. 65.4) (Cavanagh, 1964). Examples of this phenomenon are seen in a variety of peripheral and central disorders, including diabetic polyneuropathy in the PNS (Dyck & Giannini, 1996), and spinocerebellar degeneration in the CNS (Greenfield, 1954). Bipolar neurons in the dorsal root ganglion may show simultaneous distal degeneration of their peripheral and central processes, as demonstrated experimentally by Spencer and Schaumburg (for review see Spencer & Schaumburg, 1976), and termed 'central–peripheral distal axonopathy'. Clinically this pattern is seen in a number of toxic neuropathies and in the gracile tract degeneration of AIDS (Rance et al., 1988). This pattern of progression underlies the typical 'stocking and glove' clinical presentation and early loss of ankle reflexes in patients with peripheral neuropathies.

The pathophysiology of distal axonal degeneration is not understood in any disorder. Conceptually, the most satisfying explanation for length-dependent vulnerability is the 'distal watering' hypothesis (see Spencer et al., 1979). In this model, the highest metabolic demand for 'watering' the distal regions of the axon exists within the longest and largest calibre nerve fibres. During disease, alteration in the metabolic capabilities of the perikaryon, or inadequate function of the axonal transport system leads to undernourishment of the most distal regions, just as low water pressure leads to lack of irrigation of the most distant flower-bed. Experimental data supporting this model of distal axonal degeneration exists for acrylamide neuropathy, where pathologic alterations in the cell body are seen

early after exposure (Sterman, 1983; Cavanagh & Gysbers, 1983), and for 2, 5 hexanedione, where abnormalities of axonal transport are seen exclusively within the distal axon (Sahenk & Mendell, 1981; Watson et al., 1991). Perhaps the most compelling data supporting this hypothesis are those from experimental pyridoxine intoxication (Xu et al., 1989). In these studies, large single doses of pyridoxine caused acute neuronal death, whereas chronic low-dose exposure resulted in axonal atrophy along peripheral nerves. Large neurons with the longest processes were preferentially affected, creating the picture of a distally predominant neuropathy. These findings suggest that sublethal disruption of neuronal metabolism may underlie some distal axonopathies.

This 'neurocentric' model of distal axonal degeneration does not easily account for other experimental and clinical observations. For example, Spencer and Schaumburg (for review see Spencer & Schaumburg, 1976) studied ultrastructurally the spatio-temporal progression of a number of toxic neuropathies and made the important observations that: (i) the longest and largest calibre fibres are not always the earliest to degenerate, and (ii) in several neurotoxic disorders the preterminal region of the axon degenerates before the terminal. A clinical observation that is not easily explained by the 'watering' hypothesis is the distal to proximal progression of neuropathy in primary demyelinating disorders, the most prominent of which is type-1 CMT (Krajewski et al., 2000). Patients with CMT 1 typically show symptoms and signs first in the feet and toes, even though demyelinating physiology can be demonstrated throughout the PNS. All of these observations suggest that the distal axon is a highly vulnerable region of the nerve fibre, and is susceptible to insults either from systemic toxins or even from some nourishing effect of the Schwann cell.

Relationship between Wallerian and Wallerian-like degenerations

Although it seems likely that the same or similar pathogenetic mechanisms are involved in true Wallerian degeneration and slowly evolving Wallerian-like degeneration, the evidence is mostly indirect. As described above, there are distinct pathological similarities between the two, and a distal to proximal pattern of axonal loss has been demonstrated in some models of Wallerian degeneration (Weddell & Glees, 1941; Miledi & Slater, 1970; Lunn et al., 1990), but not in others (Lubinska, 1982; George & Griffin, 1994). The best evidence linking the mechanisms of Wallerian and Wallerian-like degeneration come from therapeutic models and the Wld^S mouse. In a dorsal root ganglion model of Wallerian degeneration and vincristine neuropathy, calpain inhibitors are protective against both types of injury (Wang et al., 2000) (Fig. 65.5). Similarly, the Wld^S mouse which shows delayed Wallerian degeneration also shows delayed axonal degeneration after vincristine exposure, demonstrating that a genetic mutation has a similar affect on axonal degeneration seen in these two distinct types of injuries (Wang et al., 2001a). It appears clear that Waller's conclusion from his original axotomy remains true*: 'It is impossible not to anticipate important results from the application of this inquiry . . . with reference to nervous diseases . . .'* (Waller, 1850).

Symptoms and signs

The symptoms of nerve and root disorders are directly related to the loss of normal functional connectivity between the CNS and PNS and are conveniently divided into positive and negative symptoms. Positive symptoms are typically sensory in nature and include spontaneous pain or disturbed sensory phenomena including paresthesia, hyperesthesia and allodynia. Negative symptoms are sensory loss and weakness. Physiologically, negative symptoms result from complete disconnection of the cell body from its target, as may occur in axonal degeneration, demyelination or with conduction block.

Positive motor symptoms may have their origins in muscle, nerve, or within the CNS, and include cramps, fasciculations, and myokymia. A few rare disorders such as neuromyotonia ('Isaacs syndrome'), continuous motor unit activity ('stiff person syndrome'), and tetanus, demonstrate positive motor symptoms as their major manifestation. In neuromyotonia (for review see Newsom-Davis & Mills, 1993), motor unit activity is eliminated after administration of curare but is not affected by centrally-acting inhibitory agents or epidural block, suggesting a peripheral nerve origin for ectopic discharges. Neuromyotonia is frequently associated with antibodies to voltage-gated potassium channels occurring either in isolation or as a paraneoplastic process. It is hypothesized that antibody-mediated destruction of voltage-gated potassium channels, which are responsible for repolarization of the nerve following the action potential, may result in repetitive firing at the motor end plate due to incomplete repolarization of the axonal membrane (Vincent, 2000). The positive motor symptoms in Stiff Person syndrome (Moersch & Woltman, 1956) originate in the CNS. In these patients, stiffness is likely to be associated with systemic autoimmune abnormalities including diabetes mellitus, adrenal insufficiency, thyroiditis, and pernicious anemia.

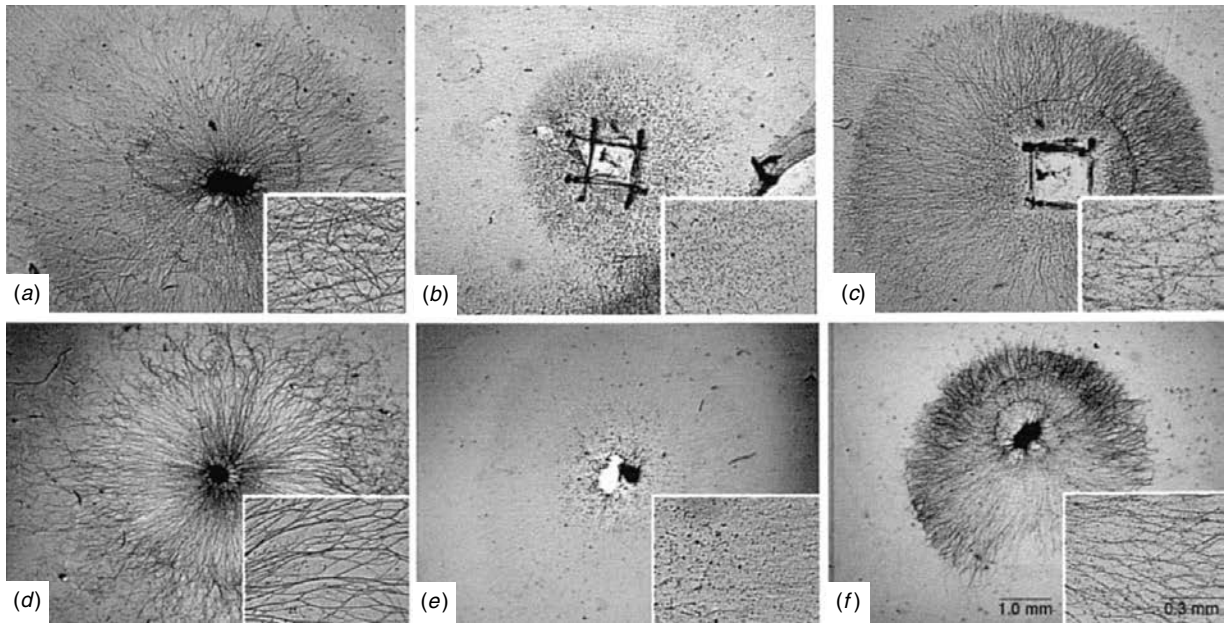

Fig. 65.5. Demonstration of protective effect of calpain inhibition against axonal degeneration after axotomy (*a*)–(*c*) and after exposure to the neurotoxin vincristine (*d*)–(*f*). Uninjured dorsal root ganglion cultures are shown in (*a*) and (*d*). Axonal degeneration 5 days after axotomy (*b*) or after 6 days exposure to 0.01 μM vincristine (*e*). Axonal degeneration is significantly prevented when injured axons exposed to 50 μM AK295, an experimental calpain inhibitor ((*c*) and (*f*)). (From Wang et al., 2000a,b,c with permission.)

Circulating antibodies to glutamic acid decarboxylase, found in about 70% of cases, are believed to target GABAergic neurons or their terminals, releasing motor neurons from the normal inhibitory tone through suppression of spinal inhibitory circuits (Floeter et al., 1998). Immunosuppressive and immunomodulatory therapies are effective in a subset of these patients.

Positive sensory symptoms are possibly the most frequent motivation for neurological consultation. In the PNS they are associated with the same types of pathologic processes as negative symptoms, but require a degree of intact communication between the cell body and the nerve terminal. Painful or disturbed sensory phenomena are typically associated with underlying axonal degeneration, although it is not clear why some patients with axonal neuropathies experience pain while others describe only numbness. Experimental studies have shown that action potentials that are normally generated at sensory terminals, may arise spontaneously along the axis of diseased nerve fibres (Rasminsky, 1987). There may also be 'cross-talk' (ephaptic transmission) between adjacent nerve fibres so that a normally non-painful stimulus may elicit activity in fibres destined for neurons perceiving pain (Granit et al., 1944). Physical stimulation of otherwise normal nerve fibres, as may occur in compression neuropathies or in compressive radiculopathies will generate ectopic discharges perceived as sensory symptoms ranging from tingling to severe pain. Common clinical examples are Tinel's sign in carpal tunnel syndrome and Lasegue's sign in lumbar radiculopathy. Similarly, inflammatory or neoplastic processes that infiltrate peripheral nerves or roots may generate pain through compression of fibres or destruction of the axon or myelin sheath (Fig. 65.6).

It is clear that the generators of abnormal or painful sensory symptoms in patients with nerve and root disorders may lie outside of the peripheral nerve or even within the CNS. Dorsal root ganglion cells or central sensory neurons may become 'sensitized' after nerve injury, potentially overreacting to incoming stimuli or displaying spontaneous discharge (Wall & Devor, 1983). Complex regional pain syndromes (CRPS) categorized under the headings of 'causalgia' (CRPS type 2) or 'reflex sympathetic dystrophy' (CRPS type 1) (Stanton-Hicks et al., 1995) combine pain with symptoms and signs of vasomotor instability. A role for sympathetic nerve fibres in the pathophysiology of these disorders has been demonstrated, with some patients responding to pharmacological sympathetic blockade or surgical sympathectomy (Jadad et al., 1995; Ramamurthy & Hoffman, 1995). A number of hypotheses describing the mechanism of sympathetically maintained

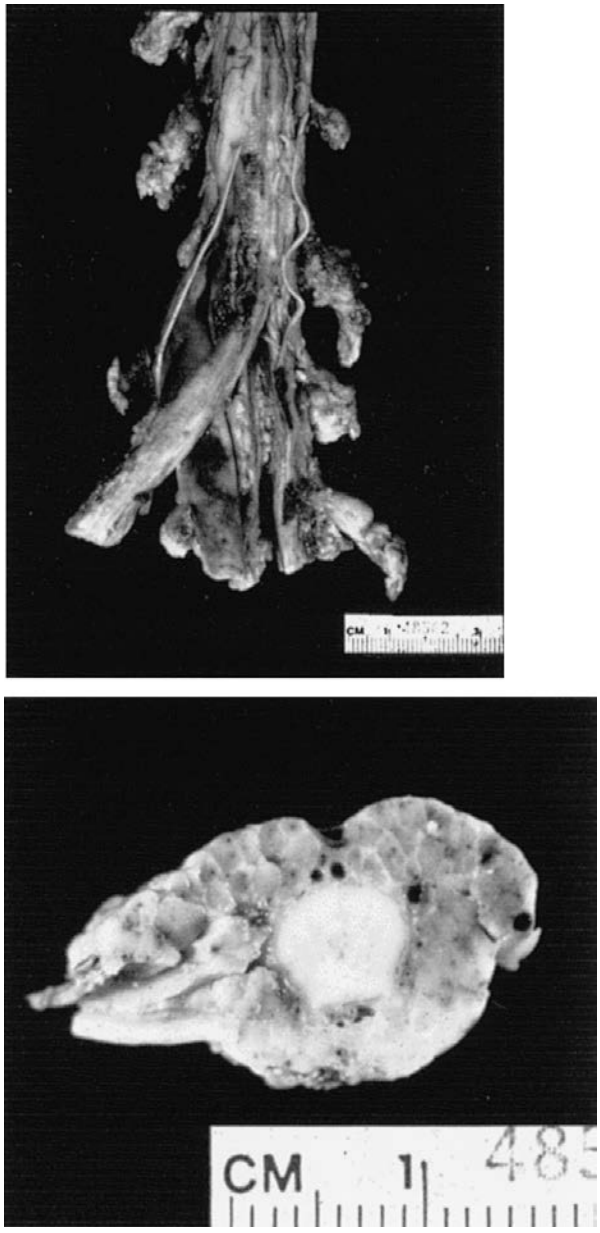

Fig. 65.6. Infiltrative and compressive radiculopathy caused by infection with cytomegalovirus (CMV polyradiculitis). This patient dying with AIDS had urinary retention and painful dysesthesias in the lower extremities, accompanied by reflex loss. He progressed to paraplegia.

pain are currently being investigated (Treede et al., 1992; McLachlan et al., 1993), and some controversy exists regarding the peripheral vs. central etiology of these disorders (Verdugo et al., 1994; Verdugo & Ochoa, 1994). The lack of satisfactory treatments for these patients speaks to the complexity of the disorder.

Primary disorders of neuronal cell bodies cause symptoms and signs that are distinguished from diseases affecting the nerve or root by their pure motor or pure sensory characteristics, and their irreversibility. Sensory neuronopathies are mediated by an immune attack as part of a systemic connective tissue disease (Griffin et al., 1990) or a paraneoplastic syndrome (Denny-Brown, 1948; Dalmau et al., 1999), as a toxic effect of antibiotics (Asbury, 1987), antineoplastic agents (Thompson et al., 1984; Verdu et al., 1999) or pyridoxine (Schaumburg et al., 1983; Windebank et al., 1985; Xu et al., 1989), or as part of heritable degenerative diseases such as Friedreich's Ataxia (Mott, 1907). In distinction to peripheral nerve disorders, the acquired sensory neuronopathies frequently demonstrate a rapid onset of days to weeks and may affect proximal and distal sites simultaneously. Sensory neurons are susceptible to immune attack because of the presence of specific antigens, including Hu in the case of paraneoplastic neuronopathy, and extractable nuclear antigens in the case of neuronopathy associated with Sjögren's syndrome. Motor neuronopathies are most commonly associated with sporadic and heritable degenerative disorders (spinal muscular atrophies and ALS), the pathophysiology of which is covered in other chapters. Poliovirus and other enteroviruses cause motor neuron destruction through their recognition of specific viral receptors on motor neurons (Ren & Racaniello, 1992; Racaniello & Ren, 1996). Paraneoplastic and HIV-related motor neuronopathies have also been described (Schold et al., 1979; Moulignier et al., 2001).

Areflexia and ataxia

Sensory receptors within muscle (spindle afferents and Golgi tendon organs) are a rich source of kinesthetic information important for normal proprioceptive function and balance. Neuropathies frequently result in disconnection of these receptors from the CNS ('sensory deafferentation') resulting in areflexia and ataxia. Both axonal and demyelinating neuropathies cause areflexia and ataxia, however the nature of demyelination makes these signs a more prominent feature of demyelinating neuropathies.

Axonal neuropathies are typically characterized as distal axonal degenerations. Deafferentation of proprioceptors occurs through distal axonal loss, which is noticed first as loss of the ankle jerk since it is the most distal, clinically tested reflex. For example, in vincristine neuropathy the ankle jerk is lost before loss of the H-reflex, which anatomically is only slightly more proximal (Guiheneuc et al., 1980). As axonal degeneration progresses, more proximal reflexes may be lost as well. Sensory ataxia is rarely a major

problem in peripheral axonal neuropathies, except in sensory neuronopathies where deafferentation occurs both proximally and distally. Axonal neuropathies preferentially affecting small myelinated and unmyelinated fibres, such as the small fibre sensory neuropathies or amyloid neuropathies, may not show reflex loss until late in the course of disease.

Demyelinating disorders preferentially affect the large calibre afferent nerve fibres, causing temporal dispersion of the nerve impulse or conduction block. Since demyelination typically occurs all along the nerve or root, reflexes are lost both proximally and distally. The physiological explanation for reflex loss in demyelinating neuropathies is that the afferent limb of the reflex arc cannot provide the necessary stimulus to fire the corresponding motor neurons. Temporal dispersion and conduction block degenerate the normally synchronized volley of action potentials into an impulse with insufficient amplitude and duration to fire the corresponding motor neurons. Compressive or infiltrative disorders of nerve roots that block electrical impulses destined for the spinal cord similarly cause loss of tendon jerks. Electrodiagnostically these types of lesions are recognized as prolongation or loss of the F-wave and H-reflex.

Ataxia in demyelinating neuropathies is also a manifestation of loss of proprioceptive input from large myelinated fibre populations through conduction abnormalities. Since proprioceptors are affected at all levels, sensory ataxia is a much more prominent feature in demyelinating neuropathies.

Muscle atrophy

In patients with peripheral neuropathies, the presence or absence of muscle atrophy and electrical changes of denervation are used as criteria to distinguish between axonal and demyelinating pathologies. Experimental denervation of muscle fibres leads to muscle atrophy and changes in the properties of the muscle fibre membrane such as partial loss of resting membrane potential and generation of spontaneous action potentials (fibrillations). Changes in muscle gene expression include an increase in acetylcholine receptors throughout the muscle with development of extrajunctional receptors (Purves & Lichtman, 1985), and re-expression of the embryonic type voltage-dependent sodium channels causing decreased sensitivity to the blocking action of tetrodotoxin (Kallen et al., 1990; Yang et al., 1991). These changes in gene expression are at least partially driven by increases in the levels of transcription factors in the MyoD family which are crucial for normal development but are present at low levels in adult muscle (Arnold & Braun, 1996). Changes in MyoD recapitulate the embryonic programme, and may be important for successful reinnervation.

There has been some controversy concerning the mechanism of denervation-induced changes in muscle. Several lines of evidence, however, suggest that loss of muscle activity and not physical separation of the terminal from the end-plate is the most significant factor. Blockade of impulse conduction alone is enough to stimulate denervation changes in muscle (Eftimie et al., 1991; Buonanno et al., 1992), and direct stimulation of muscle following denervation prevents changes in muscle gene expression (Lomo & Rosenthal, 1972; Lomo & Westgaard, 1975). How atrophy relates to this sequence of events is unknown, and whether inhibition of denervation programs in muscle will also prevent atrophy remains to be investigated.

Autonomic dysfunction

Autonomic function is served in the PNS by the small calibre myelinated and unmyelinated fibre populations (Groups B and C). Autonomic symptoms, which include abnormal bowel and bladder function, abnormal reflex control of blood pressure and heart rate, and abnormalities of sweating, occur in many neuropathies. Diseases such as familial and acquired amyloid neuropathies affect these fibre populations disproportionately, and autonomic neuropathy may be a presenting feature and a major factor in morbidity. Demyelinating disorders which typically affect large calibre fibres, such as Guillain–Barré syndrome, may cause autonomic dysfunction by demyelination of small myelinated fibres. Clinical symptoms, which are usually transient, may be tachycardia and hypertension or urinary retention. The populations of nerve fibres responsible for autonomic function show significant overlap with those serving sensory, and particularly pain, function. Patients with diabetic neuropathy may show either clinical or electrophysiological evidence of autonomic dysfunction as a major feature of their disease. In patients with small fibre sensory neuropathy without diabetes, where standard nerve conduction studies are typically normal, tests of autonomic function may be the only objective evidence for the presence of peripheral neuropathy.

Toxic and metabolic neuropathies

Shawn J. Bird and Arthur K. Asbury

Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Peripheral neuropathies caused by exogenous toxins or dysmetabolic states are relatively common. Most present as motor–sensory polyneuropathy, usually axonal in type. The underlying pathophysiology of such polyneuropathies is discussed in the previous chapter (Chapter 65).

Clinical features

First noticeable symptoms tend to be sensory and consist of tingling, prickling, burning, or band-like dysesthesias in the balls of the feet, in the tips of the toes, or generally over the soles. Symmetry of symptoms and findings in a distal graded fashion is the rule, but occasionally dysesthesias appear in the sole of one foot a brief time before the other one, or perhaps are more pronounced in one foot at first. Care must be used to avoid confusion with a mononeurothapy multiplex, in which initial sensory symptoms tend to appear in the distributions of individual digital nerves, usually asymmetrically, and in either a hand or a foot.

As a polyneuropathy worsens, both weakness and usually pansensory deficit and loss of tendon jerks spread more or less concurrently in a centripetal and symmetrical fashion, and if severe enough, involve even the torso and the axial parts of the body as well as the limbs. Numbness and imbalance are the main sensory features and are usually accompanied by positive symptoms, dysesthesias and pain. As a rule, pain in polyneuropathy is dysesthetic in character and is most prominent distally, but there is often an accompanying nerve trunk component. The character of this is deep aching pain and is generally experienced more proximally than the dysesthetic pain (Asbury, 1990; Asbury & Fields, 1984).

When sensory disturbance is severe and ascends to midthigh in the legs and to the elbows, a tent-shaped area of hypesthesia on the lower abdomen may be demonstrated. This grows broader and the apex extends rosterally toward the sternum or higher as the neuropathy worsens. This tent-shaped sensory disturbance on the anterior torso is nerve-length dependent and in this case involves dying back of the segmental truncal nerves. It can be mistaken for sensory deficit of spinal cord origin if care is not taken to check for a sensory level posteriorly on the back and to outline with care the precise area of deficit.

Variations on the pattern and sequence of progressive polyneuropathies are diverse and virtually endless. Variables are the rate of evolution of symptoms; the symmetry of signs and symptoms; their distribution in terms of proximal vs. distal, arms vs. legs, and motor vs. sensory; the relative proportion of sensory dysfunction attributable to either large nerve fibre deficits or to small nerve fibre deficits; and the determination, principally by electrodiagnostic examination, of the relative contributions of axonal vs. demyelinating processes.

Evaluation of patients with neuropathy

Clues to the diagnosis of toxic and metabolic neuropathies may be subtle, and even forgotten in the weeks or months before the onset of symptoms. Inquiries should be made about recently prescribed or self-prescribed medications, systemic symptoms that accompany the neuropathic symptoms, potential toxic exposures to solvents, pesticides, or heavy metals; the concurrence of similar symptoms in coworkers or family members; habits concerning alcohol ingestion; the presence of known underlying medical disorders. It is always useful to ask patients if they would otherwise feel well if free of their neuropathic symptoms to determine the presence or absence of underlying systemic features.

Axonal polyneuropathies of toxic or metabolic origin tend to evolve over several weeks to a year or perhaps even longer. Exceptions are diabetic polyneuropathy and para-

proteinemic neuropathies in which the progress may be insidious for five to ten years, and in which most of the manifestations are sensory. Rate of progression of demyelinating neuropathies is highly variable, depending upon the basis. Relatively few toxic and metabolic neuropathies are demyelinating, although paraproteinemic neuropathies are an exception. If major fluctuations occur in the course of the neuropathy, two possibilities come to mind: the first is a relapsing form of neuropathy, usually immune mediated, but not always. For instance, porphyric neuropathy may be relapsing in type. Also, repeated toxic exposures can give the appearance of a relapsing-type neuropathy and should be kept in mind. Slow fluctuation in symptoms taking place over weeks to months, reflecting changes in the activity of a particular neuropathy, should not be confused with the more commonplace variability from day to day or diurnal undulation of symptoms. The latter are common to all neuropathic disorders.

In most toxic or metabolic polyneuropathies, the legs are more severely affected than the arms and distal muscles more than the proximal ones. There are exceptions, as in lead neuropathy, in which manifestations of bilateral wrist drop may occur early and dominate the clinical picture.

Electrodiagnosis

Electrodiagnosis is a key part of the evaluation of any neuropathy. It allows one to be certain about the presence or absence of sensory deficit when this is unclear from clinical examination alone. It provides information about the distribution of subclinical findings thus sharpening the diagnostic focus. More general issues, more fully discussed elsewhere (Asbury, 1980), may be raised by the clinician and posed to the electrodiagnostician, including the following:

(i) The distinction between disorders primary to nerve or to muscle.
(ii) The distinction between root involvement and more distal nerve trunk involvement.
(iii) The distinction between generalized polyneuropathic processes and widespread multifocal nerve trunk involvement.
(iv) The confirmation of a clinical impression that a particular neuropathic disorder is purely motor or purely sensory which often suggests that the primary process is a neuronopathy.
(v) The distinction between upper and lower motor neuron weakness.
(vi) The distinction, in a given generalized polyneuropathic process, between a primary demyelinating neuropathy and an axonal degeneration.
(vii) The assessment, in both primary axonal and demyelinating neuropathies, of many factors bearing on the nature, activity, and likely prognosis of the neuropathy.
(viii) The assessment, in mononeuropathies, of the site of the lesion and its major effect on nerve fibres, especially the distinction between conduction block and wallerian degeneration.
(ix) The characterization of disorders of the neuromuscular junction.
(x) The identification, often in muscle of normal bulk and strength, of chronic partial denervation, fasciculation, and myotonia.

Pure motor or sensory presentations

In pure lower motor neuron syndromes, the diagnostic possibilities are relatively few, and even fewer of these are of toxic or metabolic causation. Neuropathies associated with lead intoxication or dapsone toxicity tend to be purely motor in presentation. Disorders of presynaptic neuromuscular transmission, such as the Lambert–Eaton myasthenic syndrome, tick paralysis, and organophosphate intoxication may be confused clinically on occasion with motor neuropathies, but these can be distinguished electrodiagnostically.

Pure sensory neuropathy or neuronopathy are much more frequently associated with toxic and metabolic disorders. The predominant nerve fibre type involved (large or small diameter) may be helpful in identifying the underlying disorder (see Tables 66.1, 66.2, and 66.3). Selected damage to small sensory fibres, with diminished pain–temperature sensation and frequently autonomic dysfunction, occurs with certain axonal neuropathies, most commonly in those associated with diabetes mellitus. An almost equally frequent type of small fibre sensory neuropathy is the idiopathic variety (Wolfe & Barohn, 1998), but this usually does not have an autonomic component. Other possibilities include amyloid polyneuropathy, sensory perineuritis (which is multifocal), sensory neuropathy associated with hyperlipidemia or primary biliary cirrhosis, and the chronic sensory neuropathy associated with acquired immunodeficiency syndrome (AIDS), which is inflammatory in nature. Neuropathy caused by ciguatera toxin (reef fish poisoning) and chronic metronidazole or misonidazole administration may also present as a primarily cutaneous, small fibre, sensory neuropathy. There are relatively few causes of large fibre sensory neuropathy (manifesting by proprioceptive loss and ataxia) that are toxic or dysmetabolic in origin. Certain dysproteinemic neuropathies

Table 66.1. Polyneuropathy associated with systemic diseases

		Axonal[a]			Demyelinating[a]					
Systemic Disease	Occurrence[b]	Ac	Sub	Chr	Ac	Sub	Chr	Sensory vs. Motor[c]	Autonomic	Comment
Diabetes mellitus	C	–	±	+	–	±	+	S, SM, rarely, M	± to +	See text
Uremia	S'	±	+	+	–	–	–	SM	±	Controllable with proper dialysis; curable with successful renal transplant; see Ch. 124
Porphyria (three types)	R	+	±	–	–	–	–	M	± to +	May be proximal, distal and may have atypical proximal sensory deficits
Hypoglycemia	R	±	+	+	–	–	–	M	–	Usually with insulinoma; arms often > legs
Vitamin deficiency, excluding B_{12}	S'	–	+	+	–	–	–	SM	±	Involves thiamine, pyridoxine, folate, pantothenic acid; probably others
Vitamin B_{12} deficiency	S'	–	±	+	–	–	–	S	–	Neuropathy overshadowed by myelopathy
Chronic liver disease	S'	–	–	–	–	–	+	S or SM	–	Usually mild or subclinical
Primary biliary cirrhosis	R	–	±	–	–	–	–	S	–	Intraneural xanthomas; dysesthesias
Hypothyroidism	R	–	–	–	–	±	+	S	–	May respond to thyroid replacement
Chronic obstructive pulmonary disease	S'	–	±	+	–	–	–	S or SM	–	Often subclinical; severe pulmonary insufficiency
Acromegaly	R	–	–	+	–	–	–	S	–	Carpal tunnel syndrome also frequent
Malabsorption (sprue, celiac disease)	S'	–	±	+	–	–	–	S or SM	±	Basis for neuropathy unclear; deficiency suspected
Carcinoma (sensory)	R	–	+	+	–	–	–	Pure S	–	Due to ganglionitis; mostly small cell lung and breast cancer
Carcinoma (sensorimotor)	S'	–	+	+	–	–	–	SM	±	Sensorimotor axonal neuropathy; mostly with lung cancer
Carcinoma (late)	C	–	+	+	–		–	S > M	±	Mild, probably related to weight loss and wasting
Carcinoma (demyelinating)	S'	–	–	–	+	+	±	SM	–	Acute or relapsing demyelinating neuropathy
Lymphoma, including Hodgkin's	S'	–	+	+	+	+	±	See earlier	±	Same as carcinomatous types
Polycythemia vera	R	–	±	+	–	–	–	S	–	Also CNS manifestations; often shooting pains in limbs
Multiple myeloma, lytic type	S	–	±	+	–	–	–	S, M or SM	±	Symptomatic neuropathy uncommon, subclinical neuropathy more frequent
Osteosclerotic myeloma	S	–	–	±	–	±	+	SM		Significant nerve conduction velocity slowing
MGUS	S									
IgA		–	±	+	–	–	–	SM	–	IgM binds to myelin-associated glycoprotein in half
IgG		–	±	+	–	–	±	SM	–	
IgM		–	–	–	–	±	+	SM	–

γ- diketone hexacarbons (solvents)	–	±	+	–	–	+	SM	±	+	Neurofilamentous swellings of axons; these solvents in restricted use
Dimethylamino-propionitrile (industrial)	–	–	+	–	–	–	S>M	+	–	Small-fibre neuropathy with prominent bladder symptoms and impotence in males
Diphtheria toxin	–	–	–	+	+	–	SM	–	–	Clinically rare; can be confused with GBS
Inorganic lead	–	–	+	–	–	–	M>S	–	±	Selective motor neuropathy with prominent wristdrop
Organophosphates	–	±	+	–	–	–	SM	–	+	Brain and spinal cord are also affected, the latter irreversibly
Thallium (rat poison)	–	+	+	–	–	–	SM		+	Also alopecia, Mees' lines in nails; painful

Notes:

[a] +, usually; ±, sometimes; -, rare, if ever.

[b] S, sensory; M, motor; SM, sensorimotor.

The following drugs and environmental toxins are also neurotoxic, mainly to the peripheral nervous system:
Drugs: amitriptyline, chloramphenicol, colchicine, ethambutol, nitrous oxide, perhexiline maleate, sodium cyanate, L-tryptophan
Environmental toxins: allyl chloride, buckthorn berry, carbon disulfide, dimethylaminoproprionitrile (DMAPN), ethylene oxide, metallic mercury, methyl bromide, polychlorinated biphenyls, styrene, trichloroethylene, vacor.

(antimyelin-associated glycoprotein (MAG) antibody associated) may present as a relatively pure large fibre sensory neuropathy.

Sensory neuronopathies are usually distinctive and recognizable. They may be associated with malignancies as a paraneoplastic disorder (see Chapter 90). Usually, they present as symmetrical, acral, or body-wide sensory loss and areflexia in contradistinction to the length-dependent changes seen in most motor–sensory polyneuropathies. Unlike the case with sensory axonal neuropathies, there is little likelihood of recovery. This is because of irreplaceable loss of sensory nerve cell bodies in the dorsal root ganglia, and trigeminal ganglia when affected. The type of sensory disturbance reflects the size of the sensory nerve cell bodies involved.

The rate of progression of sensory neuronopathies varies greatly, from acute to chronic, and the rate at which sensory disturbance evolves is quite helpful in arriving at the appropriate diagnosis (Asbury & Brown, 1990). Acute sensory neuronopathies evolve dramatically over days and in some cases may be related to the use of semisynthetic penicillins (Sterman et al., 1980). In other cases no apparent cause is found. Subacute sensory neuronopathies are associated with the remote malignancies as paraneoplastic syndromes, or are associated with Sjogren's syndrome or are idiopathic. Certain neurotoxins (see Table 66.2) affect primarily the sensory system and in high doses result in subacute neuronopathy. These include cisplatin, pyridoxine (vitamin B6), and taxol. Chronic sensory neuronopathies are usually either idiopathic or hereditary in nature (Table 66.3).

Table 66.3. Sensory neuropathies and neuronopathies

Cause or association	Course	Nerve fibre size affected: Small	Nerve fibre size affected: Large	Neuronopathy	Comment
Toxins/drugs					
Cisplatin (antineoplastic)	Sub/Chr	+	++	+	Dose related
Pyridoxine (vitamin, in megadose amounts)	Sub/Chr	+	++	±	Dose related
Taxol (antineoplastic)	Acu/Sub	++	+	−	NGF may be protective
Systemic diseases					
Paraneoplastic	Sub	+	++	++	Most SCLC and breast
Sjögren's syndrome	Sub/Chr	±	+	++	Variable presentation
Dysproteinemia (mainly IgM_k)	Chr	+	++	−	Demyelinating; may bind to MAG and other myelin glycoproteins
Idiopathic					
Acute sensory neuronopathy	Acu	±	++	++	Poor recovery; persistent deficit
Chronic ataxic neuropathy	Chr	±	++	Prob.	Gradual progression
Hereditary					
Many varieties (see Chapter 68)	Chr	Variable		Some	Progressive

Metabolic neuropathies

Diabetic neuropathies

Polyneuropathies

Classification of the neuropathies of diabetes have been put forward (Brown & Asbury, 1984; Thomas & Tomlinson, 1993; Bird & Brown, 1996) (For a thorough monograph devoted to diabetic neuropathy, see Dyck & Thomas, 1999). The classification in Table 66.4 is a variation of these schemes. Diabetes affects the peripheral nervous system in several distinctive patterns, the most common being the chronic primarily sensory polyneuropathy. Its occurrence appears to be mainly a function of the duration of diabetes. There are rare forms of acute diabetic polyneuropathy in which rapid (weeks) onset of severe burning pain and small fibre-type sensory loss predominates. This is often in the setting of weight loss or changing glycemic control, for example, starting insulin therapy. Proximal diabetic neuropathy (diabetic amyotrophy) is a distinctive motor syndrome with asymmetrical proximal leg weakness, usually preceded by weight loss and leg pain. Diabetics may develop acute cranial, truncal or limb mononeuropa-

Table 66.4. Classification of diabetic neuropathies

- Chronic diabetic polyneuropathy (diabetic polyneuropathy)
  - Mixed sensory-autonomic-motor polyneuropathy
  - Other patterns of chronic polyneuropathy
    - Predominantly sensory
      - Small fibre (painful)
      - Large fibre (ataxic)
    - Predominantly autonomic
    - Subclinical polyneuropathy
- Acute diabetic polyneuropathy
  - With worsening diabetic control (diabetic neuropathic cachexia)
  - With improved control (insulin neuritis)
- Proximal diabetic neuropathy (diabetic amyotrophy)
- Diabetic mononeuropathies and radiculopathies
  - Cranial neuropathies
  - Truncal neuropathies
  - Limb mononeuropathies
- Focal compression neuropathies associated with diabetes
  - Carpal tunnel syndrome
  - Other focal neuropathies

thies. Finally, patients with diabetic polyneuropathy are particularly susceptible to carpal tunnel syndrome and possibly other focal compression neuropathies. Some patients have a combination of these neuropathies.

Clinically overt polyneuropathy will develop in over half of all diabetic patients during the course of their disease. Even more have polyneuropathy if asymptomatic individuals with diabetes are screened with a careful neurological examination, nerve conduction studies (NCS), or quantitative sensory tests (QST) (Vinik et al., 2000). Diabetic polyneuropathy is a progressive predominantly sensory neuropathy that usually develops and progresses slowly after years of hyperglycemia. A varying combination of sensory and reflex loss and some weakness begins distally and slowly ascends as the neuropathy worsens. Autonomic dysfunction may become increasingly important as the neuropathy progresses, with erectile dysfunction, gastroparesis, and orthostatic hypotension. If a diabetic has an axonal polyneuropathy, it is important to consider whether the severity of the neuropathy is consistent with the likely duration of diabetes. Since diabetes is common, neuropathy may occur coincidentally, so other causes of polyneuropathy must be considered. Electrophysiologic tests can determine whether the neuropathy has multifocal or demyelinating features, either of which would suggest another diagnosis.

The pathogenesis of diabetic polyneuropathy is a subject of controversy. Pathologic studies of distal nerve show loss of both large and small-calibre axons (Giannini & Dyck, 1999), and endoneurial capillaries are often thickened. Microvascular occlusions and infarct-like lesions have been observed in the proximal nerves of patients with diabetic polyneuropathy (Johnson et al., 1986; Dyck et al., 1986) suggesting that in some cases endoneurial vascular factors play a role. Studies in experimental diabetic animals, summarized in recent reviews (Dyck & Thomas, 1999; Vinik et al., 2000), have pointed to several potential mechanisms. Metabolic alterations, or even elevated blood glucose itself, may be toxic to peripheral nerves. Glucose may bind non-enzymatically to endoneurial structures, with a deleterious effect on nerve function (Brownlee, 1999). Chronic hyperglycemia leads to reduced nerve blood flow and endoneurial hypoxia (Zochodne, 1999). As a result of altered glucose metabolism there is an increase in nerve polyols, such as sorbitol, and reduced myoinositol (Greene et al., 1987, 2000). Nerve growth factors are suppressed after hyperglycemia, and could contribute to the distal axonal degeneration of diabetic polyneuropathy. How and whether all of these factors converge to damage peripheral nerve insidiously in diabetes remains uncertain.

The best evidence that polyneuropathy is the result of chronic hyperglycemia was shown by two landmark diabetes trials (DCCT, 1993; UKPDS, 1998). In the Diabetes Control and Complications Trial, 1440 type 1 diabetics were followed for 5 or more years. They demonstrated that intensive treatment substantially reduced the incidence of polyneuropathy, as well as retinopathy and nephropathy. The incidence of neuropathy was reduced from 10% to 3% (a 69% risk reduction). To date, the only treatment proven to slow the course of diabetic neuropathy is rigorous control of blood glucose.

Acute diabetic polyneuropathy

Acute axonal polyneuropathy occurs in two settings. One form, acute painful diabetic neuropathy or 'diabetic neuropathic cachexia', generally follows a period of unintentional weight loss and is heralded by severe, cutaneous pain. The clinical sensory loss and nerve conduction abnormalities are mild. Weight gain usually precedes, and may be necessary for, recovery. The other form, 'insulin neuritis', starts coincident with the initiation of improved glycemic control. There is intense burning pain that is difficult to control, with mild objective signs of neuropathy. The painful period generally passes after 6 months or so, but the underlying mild polyneuropathy remains.

Proximal diabetic neuropathy (diabetic amyotrophy)

This disorder is much less common than diabetic polyneuropathy. Garland and Taverner (1953) characterized it as a distinct clinical entity seen in the setting of diabetes and manifested by asymmetric pain and proximal leg weakness, with little demonstrable sensory loss. Garland was uncertain of the underlying pathology so he termed this entity diabetic amyotrophy (Garland, 1955). Since the initial reports, other names have been proposed emphasizing different aspects of the presentation and possible localization (Goodman, 1954; Skanse, 1956; Raff & Asbury, 1968; Raff et al., 1968; Asbury, 1977; Bastron & Thomas, 1981; Chokroverty, 1982; Barohn et al., 1991). One suggestion is that diabetic amyotrophy be discarded in favour of the term proximal diabetic neuropathy, highlighting the presence of proximal leg weakness without implying a localization or pathogenesis (Asbury, 1977).

Proximal diabetic neuropathy (PDN) is a disorder of older adults with Type 2 diabetes (Coppack & Watkins, 1991; Chokroverty et al., 1977; Casey & Harrison, 1992). Substantial weight loss occurs before or during the progressive phase of the neuropathy, with a mean weight loss of 18 kg in one study (Pascoe et al., 1997). The characteristic presentation is one of severe thigh pain, followed within weeks by mild to severe hip girdle and thigh muscle weak-

ness. The muscles most often affected are the iliopsoas, quadriceps, and thigh adductors, and less so the hip extensors and hamstrings. Distal muscles, particularly peroneal-innervated ones, may be involved. However, proximal muscles are affected more than distal ones, the reverse of the usual pattern with polyneuropathy. Cutaneous sensory loss over the thigh may be demonstrated in half of patients and distal sensory loss may be seen if there is coexistent polyneuropathy. The majority of patients with PDN have clinical signs of a distal symmetric polyneuropathy as well (Said et al., 1994; Subramony & Wilbourn, 1982). Pain is often severe, requiring treatment with long-acting oral narcotics. The progressive phase of weakness may develop over a few days or more slowly, over months. Some authors report patients with a relatively symmetric, slowly progressive disorder (Chokroverty, 1982; Williams & Mayer, 1976), but this presentation is much less common in practice (Said & Thomas, 1999). It has been suggested that there is a rapid phase associated with pain followed by a slower phase of weakness that progresses over weeks or months (Barohn et al., 1991). Electrophysiologic studies are helpful in confirming the diagnosis or distinguishing it from another disorder that may mimic PDN and present with proximal leg weakness in the setting of diabetes, such as chronic inflammatory demyelinating polyneuropathy, polymyositis, or motor neuron disease.

Electrophysiologic evidence of a distal neuropathy is found in the majority of those patients who present with PDN (Subramony & Wilbourn, 1982). There is no convincing evidence of a difference in the distal electrophysiologic features of those with distal polyneuropathy with or without PDN. In the first few months, there are needle EMG signs of acute denervation (fibrillation potentials and positive sharp waves). The abnormalities are typically most prominent in the quadriceps, iliopsoas, and thigh adductor muscles, but may also involve the hamstrings, glutei and lumbar paraspinal muscles. Electrodiagnostic involvement of clinically uninvolved contralateral proximal muscles is variable.

The pathogenesis of this disorder has been controversial, but recent evidence supports the role of an inflammatory vasculopathy. An autopsy study of a diabetic with acutely developing leg weakness by Raff and colleagues described microinfarcts and an epineurial inflammatory cell infiltrate in the nerve to affected muscles (Raff et al., 1968b), but the most convincing evidence of an inflammatory vasculopathy comes from recent work of Said and colleagues (Said et al., 1994, 1997). They performed biopsies of the intermediate cutaneous nerve of the thigh in patients with PDN and found inflammation and vasonecrosis, perivascular inflammatory infiltrates and nerve lesions felt to be consistent with ischemia. The presence of inflammatory cell infiltrates or vasculitis in this disorder has been reported by others (Younger et al., 1996; Llewelyn et al., 1998; Kelkar et al., 2000).

Proximal diabetic neuropathy has an initial phase of progression, followed by improvement. The mean time to the beginning of recovery has been reported to be 3 months (range 1–12 months), and improvement ceases after 18 months (Coppack & Watkins, 1991). There are anecdotal reports that patients who regain a portion of the lost weight seem to improve faster than those who remain cachectic. Intravenous immunoglobulin (IVIG) therapy has been reported as effective in uncontrolled studies, but at this time there is no established role for immunotherapy.

Diabetic mononeuropathies

Diabetes is associated with the development of acute cranial mononeuropathies and often coexist with diabetic polyneuropathy. The cranial nerves most frequently affected are III, IV, VI, and VII. Ocular motor neuropathies appear suddenly, over hours or a few days, with ocular pain or unilateral headache in more than half of patients. Third nerve palsies manifest with ptosis and paresis of third nerve-supplied extraocular muscles. Pupillary function is typically spared. The usual explanation is that the pupillary fibres lie on the surface of the third nerve and therefore are less susceptible to ischemia. Pupillary sparing helps to differentiate this from a compressive lesion such as a cerebral aneurysm or tumour, but alternatively, pupil function may be partially spared in the presence of a compressive lesion in up to 20% of cases. The prognosis for vasculopathic ocular motor mononeuropathies is excellent. The majority recover completely or partially in 4 to 6 weeks, with a mean time to recovery of 2.5 months (Richards et al., 1992; Goldstein & Cogan, 1960). There is pathological evidence to support acute focal peripheral nerve ischemia as the cause of acute diabetic ophthalmoplegia. In a postmortem histopathologic study of a patient with diabetic third nerve palsy, findings supportive of nerve ischemia and centrofascicular fibre loss in the mid-cavernous portion of the nerve, were identified (Asbury et al., 1970).

Idiopathic facial neuropathy (Bell's palsy) appears to be more common in older diabetics than in non-diabetics in the same age groups (Aminoff & Miller, 1972; Adour et al., 1975). The clinical and electrophysiologic features are that of any other case of idiopathic facial palsy, with an acute onset of facial weakness that may progress further over several days. A disturbance of taste is seen in 14% of those with diabetes compared to 83% of those with no diabetes (Pecket & Schattner, 1982), suggesting that the lesion in diabetic patients is most often distal to the chorda

tympani. The prognosis for recovery is more variable than with the ocular motor mononeuropathies and depends on the degree of axonal loss.

Diabetic patients and others with chronic polyneuropathy are considered more susceptible to conventional compression neuropathies than persons with neither of these conditions. Such mononeuropathies are clinically and electrophysiologically similar to those occurring in the absence of diabetes. The best evidence for increased susceptibility to the development of compressive neuropathy exists for carpal tunnel syndrome (CTS) where the overall prevalence in persons with diabetes is about 30%, but only about 10% are symptomatic (Dyck et al., 1993; Albers et al., 1996). Ulnar neuropathy at the elbow, although much less common than CTS, also occurs more frequently in diabetics. Peroneal neuropathy at the fibular head is infrequent enough that it may be a coincidental occurrence with diabetic polyneuropathy. The limbs must be carefully examined clinically and electrophysiologically to determine the extent of coexistent polyneuropathy.

Truncal neuropathies

Acute truncal radiculoneuropathy, also called thoracic polyradiculopathy, truncal neuropathy, or diabetic thoracoabdominal neuropathy, is a distinctive complication of diabetes and often occurs in the setting of weight loss (Sun & Streib, 1981). It presents with pain, cutaneous hypersensitivity, sensory loss and sometimes weakness in the distribution of one or more thoracic or abdominal nerves or roots. The pain location may incorrectly suggest a myocardial infarction, acute cholecystitis, or acute appendicitis. The affected segments usually are contiguous and can be bilateral (Stewart, 1989). Focal abdominal wall weakness may produce a local bulge, simulating an abdominal hernia (Parry & Floberg, 1989). Cutaneous skin biopsies in diabetic truncal radiculoneuropathy show a loss of intraepidermal nerve fibres with a return of the fibres after clinical recovery, suggesting a lesion distal to the dorsal root ganglion (Lauria et al., 1998). The lesion in this disorder is likely at the level of the thoracic roots and the intercostal or abdominal nerve in varying combinations.

Chronic renal failure

A subacute or chronic motor–sensory polyneuropathy is seen in up to 70% of patients who require therapy for long-standing renal failure. It has been extensively and critically reviewed (Bolton & Young, 1990; Burn & Bates, 1998; see also Chapter 124). The degree of motor nerve conduction velocity slowing parallels the fall in creatinine clearance, even when the neuropathy is subclinical (Nielsen, 1974). Pathologically, the neuropathy is marked by axonal atrophy, secondary demyelination, and eventual axonal degeneration in a centripetal pattern (Asbury et al., 1963; Dyck et al., 1971; Thomas et al., 1971). There is pathophysiologic evidence of axolemma dysfunction (decreased resting membrane potential, sodium channel abnormality, and slowing impulse propagation) (Nielsen, 1974). This neuropathy is not seen with acute renal failure, and chronically does not develop if the glomerular filtration rate remains above 12 ml/min. The polyneuropathy can be stabilized, even improved, by adequate hemodialysis or continuous ambulatory peritoneal dialysis (CAPD) unless the neuropathy is already advanced (Burn & Bates, 1998; Laaksonen et al., 2000). This has implicated several possible dialyzable 'middle molecular weight' neurotoxins, as well as guanidino compounds, polyamines, myoinositol, and parathyroid hormone, although there is no clear correlation between neuropathy and any one of these. Successful renal transplantation usually reverses uremic neuropathy, often with complete recovery (Bolton et al., 1971).

Hepatic and gastrointestinal disorders

Four different conditions are known in which a hepatic disorder may have a neuropathic consequence (Asbury, 1993). These are a mild polyneuropathy that seems to occur in chronic hepatic failure of many causes (Chari et al., 1977; Kardel & Nielson, 1974; Knill-Jones et al., 1972; Seneviratne & Peiris, 1970). Chaudhry and colleagues found evidence of neuropathy in 71% of patients with end-stage liver disease of various causes, although it was subclinical or mild in almost all patients (Chaudhry et al., 1999). The electrophysiological features indicate a predominantly sensory axonal neuropathy. Half also had evidence of autonomic neuropathy. Autonomic neuropathy occurs in association with liver disease of any cause and is thus not necessarily a toxic effect of alcohol (Thuluvath & Triger, 1989; Szalay et al., 1998; Fleisher et al., 2000).

Less commonly, other forms of neuropathy are seen, such as acute demyelinating polyneuropathies of the Guillain–Barré type that may occur during the course of acute or chronic viral hepatitis (Berger et al., 1981; Tsukada et al., 1987). In the setting of primary biliary cirrhosis, two distinctive neuropathies occur. One is a patchy cutaneous sensory neuropathy in cases of far advanced primary biliary cirrhosis (Thomas & Walker, 1965), in whom xanthomatous deposits in cutaneous nerves may be demonstrated. The other syndrome has been described in women with primary biliary cirrhosis and no cutaneous nerve xanthomata (Charron et al., 1980; Illa et al., 1989). Rather, a

widespread sensory neuronopathy with severe large fibre sensory deficits dominates the clinical picture. Finally, large-fibre sensory neuropathies with axonal lesions of the posterior columns in the spinal cord can be seen in children with cholestatic liver disease and secondary vitamin E deficiency (Rosenblum et al., 1981; Sokol et al., 1985a; Traber et al., 1987). Vitamin E replacement can cause neurologic stabilization or improvement (Sokol et al., 1985b).

Peripheral neuropathy may be seen in association with inflammatory bowel disease, mostly with ulcerative colitis (Pfeifer, 1996; Lossos et al., 1995). It has been reported in the setting of Crohn's disease as well (Nemni et al., 1987; Humbert et al., 1989). Most cases are mild sensory axonal polyneuropathies, but on occasion a mononeuropathy multiplex-like presentation is seen. In one patient the neuropathy appeared to wax and wane with the clinical course of the inflammatory bowel disorder (Nemni et al., 1987).

Chronic respiratory insufficiency

A mild distal polyneuropathy may accompany chronic respiratory insufficiency, primarily with advanced chronic obstructive pulmonary disease (COPD) (Appenzeller et al., 1968; Kinsman et al., 1983; Malik et al., 1990). About 10% of these patients are symptomatic, usually with mild distal sensory loss (Faden et al., 1981; Stoebner et al., 1989; Malik et al., 1990; Jann et al., 1998). Electrophysiologically the changes are consistent with an axonal neuropathy, as are the sural nerve biopsy specimens examined (Appenzeller et al., 1968; Paramelle et al., 1986). Autonomic dysfunction can be demonstrated as well (Stewart et al., 1991, 1994). The peripheral neuropathy associated with COPD is typically far overshadowed by the pulmonary dysfunction. However, this minor polyneuropathy may interact with potentially neurotoxic agents, in an additive or synergistic fashion.

Microangiopathy of the endoneurial vessels in patients with hypoxic COPD has been recently reported. This includes thickening of the basement membrane and perineurium, endothelial cell hyperplasia and hypertrophy, and narrowing of the endoneurial capillary lumens (Stoebner et al., 1989; Malik et al., 1990). These endoneurial microvascular changes may accelerate injury to nerves that are already hypoxic.

Critical illness polyneuropathy

Two distinct syndromes, critical illness polyneuropathy and critical illness myopathy, develop in critically ill patients as a consequence of the illness and/or its treatment. A sensorimotor axonal polyneuropathy that develops in association with sepsis and critical illness was first described by Bolton and colleagues (Bolton et al., 1984). They described five patients who developed a severe sensorimotor polyneuropathy in the setting of sepsis and multiorgan failure. Using serial nerve conduction studies, they were able to characterize this as a distal sensorimotor axonal polyneuropathy, eventually termed critical illness polyneuropathy (CIP). Subsequently, the clinical, electrophysiologic and pathologic features of this disorder have been characterized by many observers (Bolton et al., 1986; Bolton, 1987; Williams et al., 1986; Witt et al., 1991; Zochodne et al., 1985, 1987; Zifko et al., 1998).

Patients may develop CIP in the setting of the systemic inflammatory response syndrome (SIRS), which is a response that occurs in the wake of infection or burns or trauma (Tran et al., 1990). When SIRS occurs in the setting of infection, this is termed sepsis. The major risk factor for the development of critical illness polyneuropathy is sepsis. Witt and coworkers (1991) prospectively evaluated 43 patients with sepsis and multiorgan failure. These patients were all noted to be encephalopathic and 70% had electrophysiologic evidence of axonal polyneuropathy when evaluated at a mean of 28 days (range 5–89). Half of the patients with electrophysiologic signs of neuropathy had clinical findings consistent with polyneuropathy as well. These latter clinical signs were defined as distal weakness and hyporeflexia or difficulty weaning from mechanical respiration. The severity of the neuropathy correlated with the length of time in the intensive care unit setting. For survivors of the period of critical illness (almost half), the degree of neurologic recovery correlated with the severity of the axonal loss. Over the past decade, critical illness myopathy has also been better delineated and distinguished from CIP (Bird & Rich, 2000). A recent study by Lacomis and coworkers (1998) of 92 patients in the ICU determined that myopathy was the more common cause (42%), but neuropathy was frequently found and was the cause of weakness in 13%.

The electrophysiological and pathological studies of CIP indicate an axonal basis (Bolton et al., 1984, 1986; Bolton, 1987; Witt et al., 1991; Zochodne et al., 1987). Nerve conduction studies demonstrate reduced or absent sensory responses and some degree of reduction in the motor responses. There are no features of demyelination (conduction block or significant conduction velocity slowing) and CIP is easily distinguished from the Guillain–Barré syndrome. Repetitive nerve stimulation studies of neuromuscular transmission are unremarkable, unless there is persistent pharmacological neuromuscular blockade.

Needle EMG examination of limb muscles is often notable for spontaneous activity (fibrillation potentials and positive sharp wave) in distal muscles at rest. With voluntary activation, there may be an excess of polyphasic and motor unit action potentials with abnormal recruitment. These features are consistent with acute denervation, but often are difficult to assess in patients with little voluntary movement due to encephalopathy and/or sedation. Phrenic nerve conduction studies as well as needle EMG of the diaphragm may demonstrate phrenic nerve involvement (Bolton, 1993). These can be helpful in confirming the neuromuscular basis for failure to wean from mechanical respiration in patients.

Nerve biopsy, as well as autopsy studies, have demonstrated axonal changes in CIP. Axonal degeneration is observed in both sensory and motor nerves without evidence of significant inflammation or demyelination (Bolton et al., 1984; Zochodne et al., 1987).

The pathogenesis of critical illness polyneuropathy is uncertain. Evidence is lacking to show that drugs, toxins, nutritional deficiencies, autoimmune disorders, or specific infectious agents are causative. Speculation has been advanced that the systemic inflammatory response syndrome produces a humoral product that disturbs the microcirculation of brain and nerve (Glauser et al., 1991).

Toxic neuropathies

Many of these disorders are summarized in Table 66.2, and are well described in recent reviews (Schaumburg & Kaplan, 1995; Spencer & Schaumburg, 2000).

Drugs and vitamins

Amiodarone

Amiodarone is an antiarrythmic drug that produces a sensory–motor polyneuropathy, often associated with tremor and ataxia (Charness et al., 1984). It generally occurs at doses at, or above, 400 mg/day and after 6 to 36 months of use, but it may occur earlier and at lower doses (Martinez-Arizala et al., 1983). An unusual feature for a toxic neuropathy is that amiodarone may produce electrophysiologic features of demyelination, as well as axonal loss (Fraser et al., 1985). If the neuropathy is not too severe, it may resolve following discontinuation of medication or even reduction of dose.

Cisplatin (platinum)

Cisplatin is a chemotherapeutic agent that produces a cumulative dose-dependent sensory neuropathy. Neuropathy develops in 50% of patients at a cumulative dose of 900 mg and in all by 1200 mg (Riggs et al., 1988). Newer cisplatin congeners are considerably less neurotoxic. The neuropathy is large-fibre selective with sparing of motor axons, even at higher doses. This produces loss of reflexes distally with prominent abnormalities in proprioception and vibratory sensation with locomotor ataxia (Krarup-Hansen et al., 1993). Pain and thermal sensation are relatively spared (Roelofs et al., 1984). A 'coasting effect', with worsening for a few weeks after drug discontinuation, has been described. When severe, the deficits may be irreversible, suggesting that this is a sensory neuronopathy at higher doses, much like pyridoxine excess (see below).

Colchicine

A polyneuropathy and myopathy may develop in those taking colchicine at standard doses, particularly if there is renal dysfunction (Kuncl et al., 1987). Colchicine is primarily a myotoxin; clinical myopathy is generally more severe than the neuropathic component. The combination of proximal weakness, distal paresthesias and mild sensory loss, and an elevated serum CK, although confusing, may be produced by colchicine. Electrophysiologically, there is evidence of a myopathy often with mildly reduced sensory nerve action potential amplitudes. It has been suggested that this drug exerts its toxic effect by the mechanism proposed for vincristine neuropathy, namely impaired microtubule assembly resulting in defective axonal transport (Kuncl et al., 1987).

Dapsone

Dapsone is used for leprosy and certain dermatologic conditions. It is an unusual neurotoxin in that it produces a pure motor neuropathy manifesting particularly by distal arm weakness (Gutmann et al., 1976). This may be mistaken for motor neuron disease clinically and electrophysiologically. The mechanism is unknown.

Disulfuram

Disulfiram is an agent used to treat alcoholism. A sensory–motor polyneuropathy may develop after many months at standard doses. The neuropathy may be hard to distinguish from that due to chronic alcoholism and other nutritional comorbidities. The electrophysiologic and pathologic features are those of an axonal neuropathy (Moddel et al., 1978; Mokri et al., 1981).

Isoniazid

Isoniazid (INH) is used to treat tuberculosis including prophylaxis for a positive PPD test. INH can cause a sensory–motor polyneuropathy in a dose-dependent

fashion. Distal sensory symptoms appear first from 1 to 6 months after starting therapy and progress if the drug is continued. INH is deactivated by acetylation, so slow acetylators are particularly at risk for the development of this neuropathy (Paulson & Nilsson, 1985). Neuropathy is due to the inhibition of pyridoxal phosphokinase by INH, thus acting as a pyridoxine inhibitor. The neuropathy can be prevented by the addition of 100 mg daily of pyridoxine (Ochoa, 1970). Hydralazine, an antihypertensive drug, may on occasion be associated with a mild neuropathy presumably due to a similar pyridoxine-inhibitor effect.

Metronidazole and misonidazole

Metronidazole is a commonly used antimicrobial agent used in the treatment of gram-negative infections. It is not a problem when used for short courses (e.g. 2 weeks), but when used for a chronic infection or Crohn's disease for weeks or longer it may produce neuropathy. This is particularly the case for total cumulative doses of 30 grams or more. The neuropathy is primarily a sensory axonal neuropathy affecting both large and small-diameter fibres (Bradley et al., 1977; Hahn & Feasby, 1989). Misonidazole is a cell sensitizer used in radiation therapy and a congener of metronidazole. It also produces a distal sensory axonopathy that is dose related, and this is the dose-limiting side effect of the drug (Urtasun et al., 1978).

Nitrofurantoin

This antibiotic is often used chronically for the suppression of recurrent urinary tract infections. The neurotoxic effect is dose related and tends to occur more readily in the presence of renal failure, presumably due to higher serum levels (Toole et al., 1968). The sensory–motor polyneuropathy is generally mild, although cases of more severe and subacute onset have been reported. Studies of human sural nerve biopsies and experimental animals given this agent are consistent with a distal axonopathy (Yiannikas et al., 1981).

Nucleoside analogues (ddC, ddI, d4T)

These agents, zalcitabine (dideoxycytidine, or ddC), didanosine (dideoxyinosine, or ddI), and stavudine (d4T) are antiretroviral agents used in HIV-infected patients (Hirsch & D'Aquila, 1993; Berger et al., 1993). At currently used doses, fewer than 10% of patients develop toxic neuropathy. The axonal sensory neuropathy secondary to nucleoside analogues may be difficult to differentiate from the painful, sensory neuropathy seen in late HIV infection. Both present early with distal paresthesias, pain and small-fibre sensory loss. They may be distinguished by the speed of onset and improvement after withdrawal of the drug. When these drugs are withdrawn, the neuropathy generally improves. A delay of a few weeks (a 'coasting-effect') is frequent, and may erroneously suggest that drug discontinuation was not beneficial. The degree of recovery after drug withdrawal depends on the severity of the neuropathy and whether there is coexistent HIV sensory neuropathy. The pathogenesis of nucleoside analogue neuropathy is uncertain.

Phenytoin

Neuropathy due to this anticonvulsant agent is uncommon, and generally does not occur until after 20 to 30 years of use. A sensory–motor axonal polyneuropathy insidiously develops and only slowly worsens. Recovery can follow drug discontinuation (Lovelace & Horowitz, 1968).

Pyridoxine (vitamin B6)

Vitamin B6 (pyridoxine) can produce a dose-dependent sensory neuropathy that at high doses is a neuronopathy. The severity and reversibility of the neuropathy is dose dependent (Schaumburg et al., 1983). Neuropathy has been reported at doses of 1000 mg per day in a few months or at 200 mg per day over a longer time period (Berger et al., 1992; Parry & Bredesen, 1985). Massive intravenous doses have been noted to produce a profound sensory neuronopathy with irreversible proprioceptive loss and ataxia (Albin et al., 1987). Pyridoxine has a preferential toxic effect on large-fibre sensory modalities. On electrophysiologic examination, sensory nerve action potential amplitudes are reduced or absent, with normal motor findings.

Pyridoxine, cisplatin (see above), and taxol are important examples of neurotoxins that produce a selective involvement of large sensory neurons (sensory neuronopathy). Dose–response studies using pyridoxine (Xue et al., 1989) demonstrated that the pyridoxine given to rats can cause a neuronopathy in large doses but an indolent distal sensory axonopathy in smaller doses. Megadose pyridoxine given to rats produced a neuronopathy with necrosis of dorsal root ganglion cells, whereas lower doses produced reversible neuropathy with perikaryal and axonal atrophy.

Statins

Statins are widely used cholesterol-lowering medications that act by inhibiting hydroxymethylglutaryl coenzyme A (HMG–CoA) and are now widely used. Recent reports suggest that these drugs may result in an axonal sensory polyneuropathy (Phan et al., 1995; Jacobs, 1994; Jeppesen et al., 1999; Ziajka & Wehmeier, 1998). In most case reports the neuropathy is mild and predominantly sensory, and reverses after drug withdrawal. One patient had recurrence of neuropathic symptoms after the drug was reintroduced

(Jacobs, 1994). It is probably an uncommon side effect since it was not observed in several large clinical trials of these agents. It is difficult in an individual patient to differentiate a possible toxic effect of these drugs from idiopathic sensory polyneuropathy. A reasonably long trial of drug withdrawal, 6 months or more, may be necessary to answer the question.

Taxol (paclitaxel)

Taxol is a chemotherapeutic agent used to treat several solid tumours. Neuropathy has been the limiting side effect and is dose related. Neuropathy tends to occur above 200 mg/m^2 total dose and is more severe when used with cisplatin (Kaplan et al., 1993a; Chaudhry et al., 1994). The neuropathy, like cisplatin and pyridoxine, is a selective for sensory fibres. Sensory symptoms and distal sensory and reflex loss predominate. Nerve conduction studies show loss of sensory nerve action potentials without demyelination. Taxol promotes increased microtubule assembly after binding to tubulin. In tissue culture, this results in abnormal bundles of microtubules. This presumably interferes with axoplasmic transport and thus results in an axonopathy (Lipton et al., 1989).

Thalidomide

Thalidomide is used in certain dermatological conditions, as well as Behcet's disease, and when used chronically, produces neuropathy. The initial symptoms are sensory, but as neuropathy worsens distal motor involvement appears. Neuropathy generally occurs at doses of 25–50 mg per day for a year or longer. The electrophysiological findings are those of an axonal sensory–motor polyneuropathy (Fullerton & O'Sullivan, 1968; Chaudhry et al., 1996).

Vincristine

Vincristine is a chemotherapeutic agent used to treat many malignancies. Toxic neuropathy begins with sensory symptoms in the distal limbs, often first or more prominently in the hands (Casey et al., 1973). The length-related pattern of sensory loss is evident on examination by the early loss of ankle reflexes and sensory deficit in the toes. As the neuropathy worsens, distal weakness develops. More severe neuropathy can be accompanied by autonomic involvement, with gastroparesis and urinary dysfunction. The neuropathy is axonal and may be reversible if not too severe (Bradley et al., 1970). Vincristine binds to tubulin and inhibits microtubule assembly, the opposite effect of taxol which promotes microtubule assembly. Both mechanisms disrupt fast axonal transport (Sahenk et al., 1987) and produce neuropathy.

Other

A number of other drugs have been associated with neuropathy (see Spencer & Schaumburg, 2000). These include amitriptyline, chloramphenicol, chloroquine, doxorubicin, hydralazine, nitrous oxide, perhexiline maleate, sodium cyanate, suramin and L-tryptophan.

Environmental toxins

The toxic effects of lead (inorganic), mercury, and other metals are discussed in Chapter 112 and alcohol in Chapter 113.

Acrylamide

The monomer of acrylamide is a grouting agent and may be neurotoxic. Polyacrylamide is not neurotoxic. Neuropathy may occur following absorption through the skin and be preceded by palmar desquamation. Acrylamide produces mainly a large-fibre sensory neuropathy (Spencer & Schaumburg, 2000). Distal reflex and proprioceptive loss, and ataxia, may be followed later by distal weakness. Recovery following removal from exposure is often incomplete and may reflect a central–peripheral process. Electrophysiologic studies are consistent with a distal sensory–motor axonopathy (Sumner & Asbury, 1975).

Arsenic

The neurotoxic effects occur usually after the ingestion of inorganic arsenic in a suicide or murder attempt. Acute ingestion of a massive dose produces nausea, vomiting, and hypotension. This is followed 1 to 3 weeks later by the development of a subacute axonal sensory–motor polyneuropathy (Spencer & Schaumberg, 2000; LeQuesne & McLeod, 1977). Neuropathy can be quite severe, and the ascending quadripareis may be confused with the Guillain–Barré syndrome (Donofrio et al., 1987). Chronic or repeated exposure results in a more indolent axonal sensory–motor polyneuropathy. Other effects are characteristic white lines in the fingernails and toenails (Mees' lines) and a pigmented dermatitis. Recovery from arsenical neuropathy depends on the severity of the axonal loss at its peak. The diagnosis may be confirmed by laboratory evaluation of the urine during acute exposure, but this rapidly normalizes. With chronic exposure or later after an acute one, an assay of hair is best since arsenic binds to keratin. The use of chelating agents to treat an acute exposure has been suggested but no clear role has been established.

Hexacarbons

Hexacabons (n-hexane and methyl n-butyl ketone (MBK)) can produce neuropathy. n-Hexane is a solvent widely

used in glues and thinners; methyl n-butyl ketone is now a rarely used industrial solvent. Chronic industrial exposure produces a length-related, sensory–motor polyneuropathy (Allen et al., 1975; Altenkirch et al., 1977). The pace and completeness of recovery, as with most toxic neuropathies, depends on the severity of the axonal loss. Central nervous system involvement may be seen with hyperreflexia and abnormal evoked potential studies of central conduction (Oge et al., 1994). The neuropathy may be also be seen as a result of inhalation abuse (glue sniffing). The inhalation, called huffing, may produce a subacute, severe neuropathy (Prockop et al., 1974; Smith & Albers, 1997). This presentation, with nerve conduction studies showing significant slowing and even conduction block (see below), may be confused with the Guillain–Barré syndrome or CIDP. Coasting, with progression for a few weeks, is commonly seen after exposure ceases.

The pathogenesis is uncertain, but one thought is that the γ-diketone form of these drugs causes cross-linking of neurofilaments. Pathologically, there is focal axonal enlargement due to neurofilament accumulation. These areas of giant axonal swelling result in multifocal myelin thinning and underlies the electrophysiologic findings consistent with demyelination (motor conduction velocity slowing and conduction block).

Organophosphates

Organophosphorus esters (OPs) are acetylcholinesterase inhibitors that are used as pesticides. Acute poisoning produces a picture of cholinergic excess with prominent muscarinic and nicotinic symptoms, due to the action as an inhibitor of acetylcholinesterase. Muscarinic effects include increased secretions, gastrointestinal cramps and diarrhea, and miosis. Neuromuscular weakness, and even diaphragm paralysis, can occur as part of the nicotinic effects.

These OPs also produce a delayed central and peripheral axonopathy, generally 2 to 3 weeks after acute exposure (Namba et al., 1971; Senenayake & Johnson, 1982; Gutmann & Besser, 1990; Kaplan et al., 1993b). The course is acute with a peak deficit at 14 days. The neuropathy is a sensory–motor disorder, but there are signs of myelopathy as well. The neuropathy generally recovers, whereas the disability due to the myelopathy does not. As a result there may be residual proprioceptive loss and spasticity. Drugs used to counteract the acute poisoning, such as atropine, have no effect on this late sequela once it has developed.

Other toxins

Other environmental toxins that are toxic to peripheral nerve (Spencer & Schaumburg, 2000) include allyl chloride, buckthorn berry, carbon disulfide, dimethylaminopropionitrile (DMAPN), ethylene oxide, methyl bromide, polychlorinated biphenyls (PCBs), styrene, thallium, trichlorethylene, and vacor (PNU).

Guillain–Barré syndrome (GBS)

John D. Pollard and Judith M. Spies

Department of Medicine, University of Sydney, New South Wales, Australia

With the eradication of polio, GBS is now the commonest cause of acute flaccid paralysis. GBS is an acute immune mediated polyradiculoneuropathy with an incidence of 1–1.5 per 100 000 per year. It occurs in all age groups, with peaks in young adulthood and in late life where a gradual increase in incidence is seen with advancing age (Kennedy et al., 1978; Hankey, 1987; Rees et al., 1998).

Criteria for diagnosis

GBS is an acute, monophasic, predominantly motor polyneuropathy. The currently accepted criteria for the diagnosis of Guillain–Barré syndrome (Asbury et al., 1978) include the following.

Features required for diagnosis

- Progressive motor weakness of more than one limb
- Areflexia which is usually universal but distal areflexia with more proximal hyporeflexia is adequate if other features are consistent

Features strongly supportive of the diagnosis

- Rapid progression of weakness which has ceased by 4 weeks
- Relative symmetry of involvement
- Mild sensory involvement, cranial nerve involvement, autonomic involvement
- Recovery usually beginning 2 to 4 weeks after progression stops

Features that rule out the diagnosis

- A diagnosis of botulism, toxic neuropathy or poliomyelitis
- Abnormal porphyrin metabolism
- Recent diphtheric infection

Antecedent events

This immune-mediated polyradiculoneuropathy often follows an acute infective illness. One-half to two-thirds of GBS patients report symptoms of a respiratory tract or gastrointestinal infection within the month preceding neurological symptoms (Winer et al., 1988a; Jacobs et al., 1998). The most commonly identified organism is *Campylobacter jejuni*; recent infection being detected by bacteriologic or serologic techniques in 26–40% of patients (Kaldor & Speed 1984; Rees et al., 1995). Other identified antecedent infections include Cytomegalovirus (CMV), Epstein–Barr virus, *Mycoplasma pneumoniae* and *Haemophilus influenza* (Winer et al., 1988a; Jacobs et al., 1998; Mori et al., 2000). GBS may be an early manifestation of HIV infection, presenting at the time of seroconversion or in the immunocompetent phase of the disease. A small proportion of GBS cases follow surgery by an interval of 1 to 4 weeks, in the absence of identifiable infection.

An increased incidence of GBS was reported with the no longer used rabies vaccines containing neural tissue (Arnason & Soliven 1993), with swine influenza vaccination in the United States in 1976 (Schonberger et al., 1979) and with oral poliovirus vaccine (Kinnunen et al., 1989). However, more recent large studies have failed to demonstrate an increased incidence after any currently administered vaccines, including influenza, measles, measles/rubella, oral polio, or tetanus toxoid containing vaccines (Roscelli et al., 1991; Hughes et al., 1996a; da Silveira et al., 1997; Tuttle et al., 1997; Lasky et al., 1998; Kinnunen et al., 1998; Ropper & Victor, 1998; Salisbury, 1998). Whether vaccination is associated with relapse of GBS remains uncertain, but it would seem reasonable to follow the recent advice of Hughes and avoid vaccination in the first 12 months after an episode of GBS (Hughes et al., 1996b).

Variants

In the past, the terms GBS and acute inflammatory demyelinating polyradiculoneuropathy (AIDP) have been used synonymously. However, in recent years it has become increasingly clear that GBS is not a single pathophysiological entity. The acute demyelinating form remains the most common type in Europe, North America and the rest of the developed world, accounting for 85–90% of patients. An axonal form, first described by Feasby et al. (1986) is now widely recognized (Yuki et al., 1990; McKhann et al., 1993). A pure motor axonal subtype (acute motor axonal neuropathy or AMAN) has been extensively characterized in Northern China (McKhann et al., 1993) and is more common in developing countries, although it may represent 10–15% of cases of GBS in the developed world (Visser et al., 1995). AMAN is strongly linked to preceding *Campylobacter* infection (Ho et al., 1995, Visser et al., 1995). The motor–sensory axonal type is a more severe form with less complete recovery (Feasby et al., 1986). The Miller Fisher variant of GBS (MFS), which represents approximately 5% of cases, has been recognized for many years (Fisher, 1956). In pure MFS, patients present with ataxia, ophthalmoplegia and areflexia without significant weakness, although overlap forms, with bulbar, facial and/or generalized weakness are also seen.

Clinical features

The most common initial symptom is weakness, usually beginning in the lower limbs and characteristically involving both proximal and distal muscles. The time from onset to nadir of neurological deficit varies from hours to weeks, but most patients develop maximal deficit within 14 days and over 90% reach a nadir by 4 weeks (Winer et al., 1988b). This is followed by a plateau phase, characteristically of 1 to 2 weeks, and then recovery. Pain, particularly low back, buttock or thigh pain, is an early symptom in approximately 50% of patients. Complete areflexia is found in over 80% of patients, and some reflexes are lost in virtually all. Numbness and paresthesiae are frequently reported, but abnormalities on sensory examination are often minimal, with reduced light touch or pinprick sensation evident in only one quarter of cases and some loss of vibration sensation in 60%. Cranial nerve involvement is seen in two-thirds of cases, most commonly facial weakness, ophthalmoplegia, difficulty swallowing or altered taste. Facial weakness occurs in just over one-half of cases and is usually bilateral. Ophthalmoplegia is evident in 10–15% of patients (Winer et al., 1988b; Hankey, 1987). Autonomic nervous system involvement is present in 30% of patients, and can be manifest as reduced sinus arrhythmia, sinus tachycardia, arrhythmias, hypertension, labile blood pressure, orthostatic hypotension, abnormal sweating or pupillary abnormalities (Tuck & McLeod, 1981; Fuller et al., 1992).

Investigations

Cerebrospinal fluid

The characteristic finding on examination of the CSF is increased protein without a significant increase in cells (cytoalbuminemic dissociation). CSF protein is increased in 80–90% of cases (Winer et al., 1988b; Hankey, 1987) and is more likely to be abnormal if the spinal tap is performed more than seven days after the onset of neurological symptoms. A mild increase in white cells in the CSF is evident in approximately 10% of patients. The CSF findings are not predictive of disease severity or outcome.

Electrodiagnostic studies

Nerve conduction studies may be normal early, particularly within the first week. The characteristic findings in AIDP are those of a demyelinating neuropathy, with prolonged distal motor latencies, slowing of motor conduction velocity and often evidence of conduction block or dispersion of the compound muscle action potential (CMAP) (Cornblath, 1990). F waves, which enable assessment of conduction in the more proximal segments of nerves and in the spinal motor roots, are the most sensitive parameter in the early stages of the disease, with abnormal lower limb latencies evident in 90% of patients (Winer et al., 1988b; Kimura, 1978). Sensory abnormalities are variable, but reduced or absent sensory nerve action potentials and slowing of sensory conduction velocity are common.

In AIDP, a reduction in the amplitude of the distal CMAP to 20% or less of the lower limit of normal is the most powerful electrodiagnostic predictor of protracted recovery and poor eventual outcome (Cornblath et al., 1988; Miller et al., 1988), and usually indicates significant axonal degeneration. However, cases of GBS with decreased distal CMAP amplitude, very distal demyelination and rapid recovery are recognized (Hall et al., 1992). Electromyography is helpful in determining the extent of acute denervation in cases where axonal degeneration is suspected and the presence of abundant fibrillation potentials is associated with a poor prognosis (McLeod, 1981). In the primary axonal forms of the disease, motor (AMAN) or motor and sensory (AMSAN) responses are absent or reduced in amplitude, with normal distal motor latencies and normal or only mildly reduced conduction velocities. Inexcitable nerves can be seen in severe demyelinating or

axonal forms. A gradual return of nerve conduction studies to normal is seen in most patients, however residual conduction abnormalities sometimes persist even in the absence of clinical disability (McLeod et al., 1976).

Clinical course

Approximately one-fifth of patients remain ambulant throughout, one-half become chair- or bed-bound, one-third require intensive care admission and one-quarter mechanical ventilation (Winer et al., 1988b; Sheth et al., 1996; Rees et al., 1998; Hankey, 1987). The severity of disease increases with increasing age (Sheth et al., 1996) and antecedent infection with either *Campylobacter* (Winer et al., 1988a; Kaldor & Speed, 1984) or CMV (Visser et al., 1996) is also associated with more severe disease.

Complete functional recovery is seen in two-thirds of patients, but 20–30% are left with significant disability and approximately 10% are unable to walk unaided. With modern intensive care facilities, the mortality rate has been significantly reduced, but remains 3–8% in recent series with most deaths a result of cardiac arrest (attributed to autonomic disturbance), respiratory failure or infection, or pulmonary embolism (Winer et al., 1988b; Rees et al., 1998; Guillain–Barré Study Group, 1985).

A number of factors have been associated with poor outcome, including a short interval from onset to being bedbound, the need for mechanical ventilation, age >40 and small ($\leq 20\%$ of normal) or absent distal CMAPs (Winer et al., 1988b; McKhann et al., 1988). The outcome is better in children (Delanoe et al., 1998; Bradshaw & Jones, 1992), and the presence of decreased CMAP amplitudes and denervation potentials may not predict poor outcome in this group, though a prolonged interval to commencement of recovery does correlate with a poor outcome (Eberle et al., 1975).

GBS recurs in 1–10% of untreated patients. Recurrent episodes have been reported 4 months to 8 years after the initial presentation in association with varying antecedent infections, pregnancy and the early post-partum period, and vaccination with tetanus toxoid (Grand'Maison et al., 1992; Pollard & Selby, 1978). Treament related fluctuations are noted in the acute phase of the disease in 5–10% of patients treated with either plasmapheresis or intravenous immunoglobulin (see treatment below) (Visser et al., 1998).

Pathology

In AIDP the primary abnormality is segmental demyelination. Perivascular lymphocytic infiltrates and endoneurial edema are evident early in the disease, and areas of vesicular myelin breakdown and phagocytosis correspond to the areas of inflammatory cell infiltrate (Fig. 67.1) (Asbury et al., 1969; Prineas, 1972; Carpenter, 1972). The earliest myelin lesion is retraction of myelin at the nodes of Ranvier (paranodal demyelination) which evolves to loss of myelin over complete internodes (segmental demyelination) (Asbury et al., 1969). Demyelination is macrophage mediated (Fig. 67.1) (Prineas, 1972; Carpenter, 1972). Axonal degeneration may be present, especially in cases with more intense inflammatory changes. All levels of the peripheral nervous system are involved, with multiple foci of inflammation scattered from spinal roots and ganglia to the terminal motor nerves and also involving cranial nerves and sympathetic chains and ganglia. Recent immunohistochemical studies on autopsy specimens from patients dying early in the disease have demonstrated dep-

Fig. 67.1. Vesicular demyelination in GBS. An electron micrograph of a sural nerve biopsy specimen showing vesicular dissolution of the myelin sheath (v) surrounding an axon (a). A macrophage (m) containing myelin debris is replacing effete Schwann cell cytoplasm within the Schwann cell basal lamina (arrows). Bar = 5 μm

osition of immunoglobulin and complement activation products on the Schwann cell surface, suggesting that the Schwann cell plasmalemma is the site of primary immune attack in this form of GBS (Hafer-Macko et al., 1996).

In AMAN, there is axonal degeneration of motor fibres in the spinal roots and peripheral nerves, but little lymphocytic inflammation or demyelination (Griffin et al., 1995). The earliest and mildest changes are lengthening of the nodes of Ranvier, with distortion and sometimes breakdown of the paranodal myelin. Macrophages are evident overlying the nodes, extending processes through the Schwann cell basal lamina to the axolemma, entering the periaxonal space and ultimately surrounding the axon (Griffin et al., 1996). The final stage is Wallerian degeneration of the axon. In the ventral roots of early fatal cases, immunoglobulin and complement activation markers are deposited on the axolemma suggesting that the axon is the site of primary immune attack in this form.

Pathogenesis

In AIDP, there is evidence that both humoral immune responses and T-cell activation are important in pathogenesis. Complement fixing antibodies directed against peripheral nerve myelin are detected in the serum of GBS patients (Koski et al., 1986) and immunoglobulin and complement deposition is evident on the Schwann cell surface consistent with a primary immune attack directed against the Schwann cell or myelin (Hafer-Macko et al., 1996).

Lymphocytic infiltration is evident in AIDP nerve, and there is systemic evidence of T-cell activation (Hartung et al., 1990). The pro-inflammatory cytokine TNF-α is up-regulated in AIDP and levels correlate with disease severity and electrophysiological evidence of demyelination (Sharief et al., 1993, 1997). Other inflammatory markers are also up-regulated, including vascular adhesion molecules, matrix metalloproteinases and B-7 costimulatory molecule (Créange et al., 1999; Kiefer et al., 2000).

In AMAN, lymphocyte infiltration of nerve is minimal, but there is deposition of immunoglobulin and complement on the axolemma, consistent with the axon being the site of primary immune attack. Given the lack of lymphocytic infiltration, humoral factors may be relatively more important in AMAN but this remains to be fully determined.

Molecular mimicry and antiganglioside antibodies

Recent evidence suggests that the heterogeneity of the clinical picture in GBS may reflect different antecedent infections and consequent immune responses. The concept of molecular mimicry is best established for *Campylobacter*-associated GBS. The lipopolysaccharide component of *Campylobacter* contains ganglioside-like epitopes, and antibodies directed against these bacterial epitopes can cross react with ganglioside epitopes on peripheral nerve (Yuki et al., 1993a; Sheikh et al., 1998). If a similar mechanism exists for other preceding infections, the antigenic specificities of the resultant antibodies and the distribution of specific ganglioside epitopes in the peripheral nervous system may, at least in part, determine the variable clinical features of the disease.

One-quarter to one-third of patients with GBS have high serum titers of anti-ganglioside antibodies, usually IgG. The occurrence of GBS, with high levels of antiganglioside antibodies, after parenteral therapy with gangliosides (Illa et al., 1995) adds weight to the hypothesis that these anti-ganglioside antibodies are pathogenic but their precise significance remains to be determined. There are a number of associations between different clinical variants of GBS, and antibodies to particular gangliosides. The strongest association is that of anti-GQ1b antibodies with Miller Fisher syndrome and GBS with ophthalmoplegia (Willison et al., 1993) and these antibodies have been shown to block neuromuscular transmission (Plomp et al., 1999). There is also a strong association between anti-GM1 antibodies and antecedent infection with *C. jejuni*, pure motor GBS and axonal involvement (Yuki et al., 1990; Rees et al., 1995). On the other hand, preceding CMV infection is associated with more marked sensory involvement and antibodies against GM2 ganglioside (Visser et al., 1996; Jacobs et al., 1997b). Some antiganglioside antibodies have also been associated with more severe disease (Yuki et al., 1993b) but at this stage the antiganglioside profile of individual patients is not helpful in making treatment decisions. The role of these antibodies is the subject of intense research that will probably yield further insights into the immunopathogenesis and treatment of the Guillain–Barré syndromes.

Treatment

Patients with GBS require admission to hospital as weakness can progress rapidly, and up to one-third of patients will require ICU admission for ventilatory support or as a result of hemodynamic instability secondary to autonomic dysfunction. Both plasmapheresis (Guillain–Barré Study Group, 1985; French Cooperative Group on Plasma Exchange in Guillain–Barré Syndrome, 1987) and intravenous immunoglobulin (IVIg) (van der Meché et al., 1992; Plasma Exchange/Sandoglobulin Guillain–Barré Syndrome Trial Group, 1997) are effective therapy if started within the

first two weeks of neurological symptoms. Both treatments improve the time to onset of recovery and outcome. No benefit has been demonstrated for either treatment over the other and no benefit is derived from combined therapy (Plasma Exchange/Sandoglobulin Gullain–Barré Syndrome Trial Group, 1997). High dose corticosteroids are ineffective in the treatment of GBS (Gullain–Barré syndrome Steroid Trial Group, 1993).

Standard plasmapheresis schedules involve a total of 200–250 ml/kg of plasma being exchanged in 4 to 5 sessions over 7 to 14 days. The dose of IVIg used in the treatment trials was 0.4 g/kg/day for 5 days although the same total dose (2 g/kg) is now given over two days in some centres. Treatment related fluctuations are seen in 5–10% of patients treated with either plasmapheresis or IVIg, with no significant differences between treatment modalities (French Cooperative Group on Plasma Exchange in Guillain–Barré Syndrome, 1987; Dutch Guillain–Barré Study Group, 1998). Retreatment with the original modality is the usual approach in patients who have improved and then relapsed. Those patients who fail to improve after an initial course of IVIg may respond to a second course (Farcas et al., 1997).

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)

Diagnosis and definition

CIDP, as the name implies, is a chronic demyelinating neuropathy affecting particularly nerve roots and plexuses as well as distal nerves, the onset of which in most cases evolves over a period of more than 4 weeks. The diagnosis is usually considered in patients who present with an appropriate history (progression over more than 4 weeks) and in whom the electrodiagnostic studies show changes consistent with an acquired demyelinating pathology when other causes of demyelination (drugs, paraproteins, etc.) have been excluded.

In considering the differential diagnosis, hereditary demyelinating neuropathies may not be easily distinguished on clinical grounds when no family history is available. Demyelinating neuropathy may occur in association with malignancy, in carcinoma, lymphoma and myeloma including POEMS Syndrome. Neuropathies associated with paraproteinemia, particularly IgM, need to be excluded by immunofixation or gel electrophoresis. Electrophysiological and histological features of demyelination may occur in diabetes and other metabolic disorders, including uremia, hypothyroidism and acromegaly and drug-induced causes include amiodorone, perhexilene, n-hexane and 2.5 hexanedione (glue sniffing neuropathy). HIV infection may be associated with demyelinating neuropathy (usually accompanied by CSF pleocytosis) as may Lyme disease and it may occur in graft vs. host disease. When CIDP presents in a multifocal fashion, it needs to be differentiated from multifocal motor neuropathy with persistent conduction block.

Clinical features

Most patients present with a mixed motor and sensory neuropathy with proximal and distal weakness, although motor and sensory signs may be mostly distal.

Occasional patients present with an ataxic sensory or purely motor neuropathy (McCombe et al., 1987a; Barohn et al., 1989). CIDP may also present with limb or back pain (Gorson et al., 1997; Bouchard et al., 1999). Postural or action tremor may occur even when power or sensation remains intact. Cranial nerve involvement occurs less commonly than in the Guillain–Barré syndrome. Hypertrophy of peripheral nerves (including cranial nerves), nerve roots or plexus is relatively common in CIDP particularly after a long time course and massive hypertrophy of nerve may be evident clinically and cause nerve root or limb pain (Duggins et al., 1999). Disturbances of micturition (urgency, difficulty voiding) occur in about 25% of cases (Sakakibara et al., 1998). Rarely CIDP may be associated with a multifocal central demyelinating disorder resembling multiple sclerosis. Patients fulfilling diagnostic criteria for CIDP may occasionally be shown to have an IgG and or IgA paraprotein (Bleasel et al., 1993). However, patients with IgM-associated neuropathies usually differ in clinical, electrophysiological and pathological features and in response to treatment (Yeung et al., 1991; Maisonobe et al., 1996).

Prevalence, course and prognosis

The prevalence of CIDP is between 1 and 2 per 100 000 whereas the incidence has been estimated to be 0.15 per 100 000 (Lunn et al., 1999; McLeod et al., 1999).

CIDP follows either a relapsing and remitting or progressive course whilst occasional patients experience a subacute monophasic illness although a chronic progressive course is more common (Dyck et al. 1993). Relapses may occur related to changes in therapy or intercurrent illness. A majority of patients present with a gradual onset of symptoms but some present acutely as GBS and CIDP is diagnosed retrospectively because of their subsequent relapsing or progressive course (McCombe et al., 1987b). Given appropriate treatment the prognosis for recovery is

excellent in most patients but is better in those with relapsing than with progressive disease (McCombe et al., 1987b; Bouchard et al., 1999). A major long-term prognostic factor in CIDP is axonal loss in sural nerve biopsy (Bouchard et al., 1999).

Electrodiagnostic studies

These studies provide the cornerstone of diagnosis in CIDP, since it is the finding of electrodiagnostic features of demyelination that, in practice, suggests the diagnosis. Electrophysiological criteria for the diagnosis of CIDP have been described by several authors (Lewis et al., 1982; Albers & Kelly, 1989; Ad hoc Sub Committee, 1991; Sumner, 1994). These include:

(i) motor conduction velocity less than 75% of the lower limit of normal/or less than 40 m/s in median and ulnar nerves and less than 30 m/s in common peroneal nerves;
(ii) terminal motor latencies greater than 140% of normal (or greater than 7 ms in median and ulnar nerves or 10 ms in common peroneal nerve);
(iii) conduction block and/or temporal dispersion of the compound muscle action potential;
(iv) F wave latency increased to greater than 120% of normal.

It is important to exercise care in the diagnosis of conduction block since severe conduction slowing and temporal dispersion may result in phase cancellation of action potentials of different motor units causing 'pseudoblock' (Rhee et al., 1990). Short segment stimulation to determine whether block occurs abruptly over a limited distance of nerve is a useful technique to facilitate the diagnosis of conduction block (Krarup et al., 1990). Moreover, since the pathological changes in inflammatory neuropathy have a predilection for proximal regions (nerve roots, plexuses, proximal nerve trunks) it is important to examine for proximal conduction block and conduction abnormalities within this region of the PNS despite the technical difficulties involved (Fig. 67.2) (Menkes et al., 1998). Assessment of F wave responses and spinal evoked potentials may reveal proximal demyelinating lesions in motor or sensory fibres respectively.

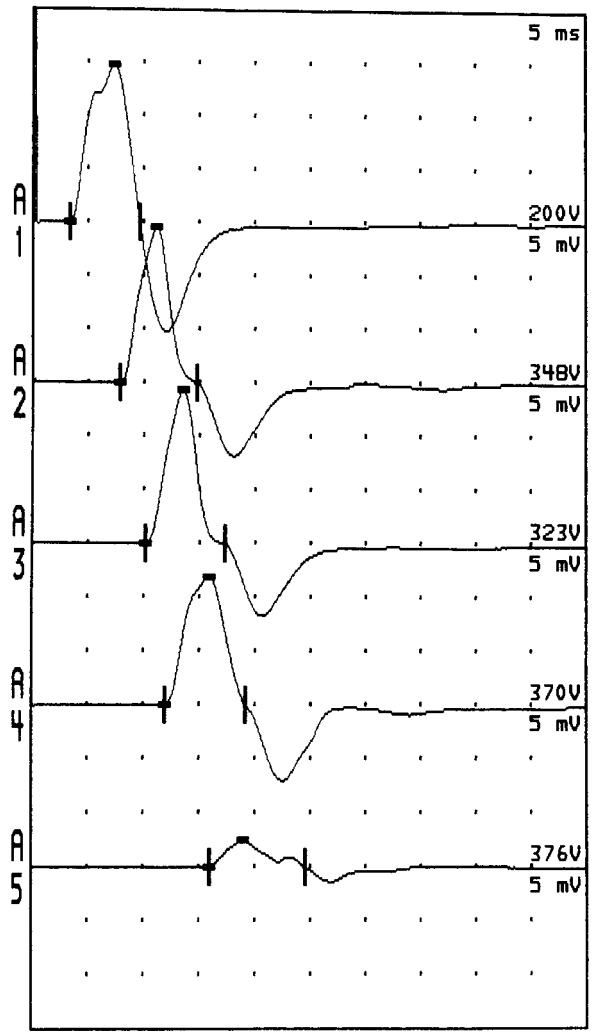

Fig. 67.2. Proximal conduction block in CIDP. Compound muscle action potentials (CMAPs) recorded from the ADM muscle following stimulation of the ulnar nerve at increasing proximal sites. A_1 = wrist, A_2 = below elbow, A_3 = above elbow, A_4 = axilla, A_5 = Erb's point. Note that amplitude and area are maintained until the most proximal stimulation site is reached. This patient who was quadriplegic had near normal routine conduction studies.

Pathology

The lesions of CIDP consist of patchy regions of edema and demyelination associated with a variable inflammatory infiltrate of T-cells and macrophages, occurring mainly within spinal nerve roots, plexuses and proximal nerve trunks (Prineas & McLeod, 1976). In sural nerve biopsy studies the findings may include endoneurial edema, thinly myelinated or demyelinated fibres, active demyelination (myelin stripping or vesicular dissolution in the presence of mononuclear phagocytes) onion bulb formation, varying degrees of axonal degeneration, and mononuclear cell infiltrates (Figs 67.3, 67.4) (Pollard, 1994). Analysis of nerve fibres teased from sural nerve biopsies showed demyelinating changes in 71%, mixed axonal and demyelinating in 21%, and purely axonal in 5% (Bouchard et al., 1999).

Fig. 67.3. Onion bulb formation in CIDP. An electron micrograph of a sural nerve biopsy specimen showing marked onion bulb formation in a CIDP. Note the variability of myelination of central axons, unlike CMT1a. Bar = 2.5 μm.

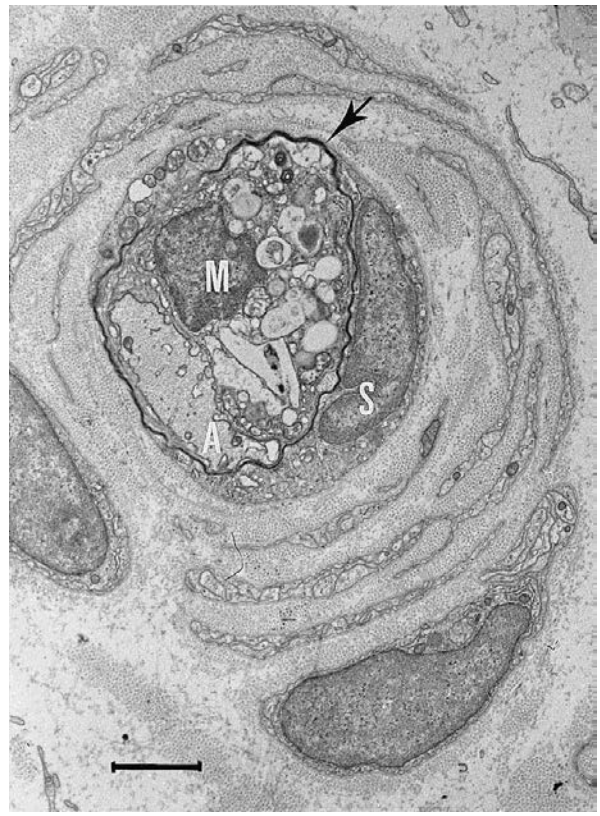

Fig. 67.4. Demyelination within an onion bulb. An electron micrograph of a sural nerve biopsy showing active demyelination within an onion bulb in a CIDP patient who was biopsied during a relapse. Arrow head points to myelin that has been lifted away from the axon (A) by a macrophage (M). The Schwann cell (S) has been pushed to the right side. Bar = 2 μm.

Immunopathological studies have shown deposition of C_3d or immunoglobulin (IgG or IgM) on myelinated fibres in a small percentage of patients and up-regulation of major histocompatibility antigens Class I and II (Yan et al., 2000; Rizzuto et al., 1998). Activation markers are found on endoneurial macrophages in CIDP but not in hereditary or other neuropathies (Kiefer et al., 1998).

Pathogenesis

An association with preceding illness and the presence of antiganglioside antibodies is less evident than with GBS (McCombe et al., 1987a,b). Nevertheless since a majority of CIDP patients respond to plasma exchange or intravenous immunoglobulin, an important role for humoral mediators such as antibody has long been suspected in CIDP. Antiglycolipid antibodies have been reported in CIDP in only small numbers of cases and pathogenicity has not been demonstrated (Melandez & Vasquez et al., 1997; Yuki et al., 1996). Anti GM-1 antibodies however are clearly associated with the related disorder multifocal motor neuropathy with persistent conduction block (MMN).

Recent evidence of a role for antimyelin protein antibodies has been shown by passive transfer studies using purified IgG from a select group of patients responsive to plasma exchange (Yan et al., 2000). IgG purified from patients whose serum bound to normal myelinated nerve fibres by indirect immunofluorescence, caused conduction block and demyelination in rat sciatic nerve in the presence of complement. The antigenic target of these antibodies was the P zero (P0) protein of peripheral myelin (Yan et al., 2001), which is largely responsible for compaction of the myelin sheath.

CIDP is a heterogeneous disease and it is likely that other target antigens and pathogenic pathways will be defined. For instance whereas some patients are easily maintained by regular plasma exchange or intravenous immunoglobulin infusion others respond only to high dose immunosuppressive therapy. In the animal model experimental autoimmune neuritis (EAN) and its chronic counterpart (CEAN) a role for both T- and B-cell mechanisms is evident. Even when antimyelin antibodies can be demonstrated, the involvement of T-cells, macrophages and mast cells is necessary for the production and regulation of cytokines, toxic mediators, proteinases and metalloproteinases that are implicated in vascular (blood–nerve barrier) and Schwann cell damage (Hartung et al., 1998; Mathey et al., 1999).

Although the etiology and pathogenesis of CIDP remains obscure, these findings provide early insight into why, for most patients, effective therapy can be provided. It may be that in patients readily responsive to plasma exchange antibody or other circulating mediators play a major role whereas T-cell mechanisms are dominant in those patients needing intense immunosuppression with cyclosporin or cyclophosphamide.

Treatment

Intravenous immunoglobulin (IVIg)

IVIG is effective, as shown by a randomized, double-blind, placebo-controlled study. In many centres it is first-line therapy since it is easy to administer, has few contra-indications or serious side effects and improvement has been reported in 62–63% of cases (Hahn et al., 1996a,b; Van Doorn et al., 1991). Although maintenance therapy is required for most patients, some chronic progressive cases have a prolonged remission following a single course. The recommended but empirical dose is 0.4 g/kg body weight daily for 5 days. Maintenance therapy may be given as a single dose of 0.4 g/kg every 2–3 weeks or at less frequent intervals as clinically indicated. IVIg has clear advantages over plasma exchange in small children, patients with venous access difficulties and cardiovascular instability and in patients in remote areas.

Plasma exchange (PE)

The efficacy of PE has also been shown by randomized controlled studies (Dyck et al., 1986; Hahn et al., 1996a,b). It is safe therapy in centres experienced in its use, but is time consuming and unsuitable for small children. In one randomized controlled study (Hahn et al., 1996a,b) 80% of patients responded but the majority required long-term immunosuppression (steroids ± azathioprine) for stabilization. PE may be given two to three times weekly until improvement is established and then the frequency tapered over several months until an appropriate maintenance program is established, usually one exchange every 3 to 4 weeks. Patients may be maintained with PE alone, but concomitant immunosuppression may allow the interexchange interval to be increased.

Corticosteroids

Steroids are efficacious (Dyck et al., 1982), cheap and convenient, but their well-known side effects have led to a significant reduction in their use for CIDP. They are useful when expensive and complicated therapies are unavailable, to induce remissions in relapsing and subacute cases and in combination with immunosuppressive agents when first line therapies prove ineffective. High dose intravenous methylprednisone (1 g daily for 3–5 days) or dexamethasone 40 mg daily for 4 days given monthly for 6 months has been reported to be beneficial in anecdotal cases (Molenaar et al., 1997).

Immunosuppressive agents

There is no class one evidence available for the use of immunosuppressive agents in CIDP. Azathioprine is nevertheless widely used, often in combination with steroids, in a starting dose of 2.5 mg/kg. Cyclophosphamide (Good et al., 1998) may be administered orally (2–3 mg/kg) or intravenously as pulse therapy 3–5 mg/kg twice weekly or 10–15 mg/kg every 7–10 days, but adverse side effects are considerable and include hemorrhagic cystitis, alopecia, sterility, mucosal ulceration, interstitial fibrosis and cancer.

Cyclosporin (CsA) has been used successfully in resistant CIDP (Barnett et al., 1998). It may be given in a starting dose of 5 mg/kg with a gradual dose reduction to a maintenance level of 2 mg/kg. Nephrotoxicity is the most serious side effect and is dose dependent. Whole blood CsA levels, creatinine clearance and serum creatinine should be monitored.

Interferons

Interferon beta has been reported in anecdotal cases only although a multicentre trial is currently in progress. Interferon 2A was given to 16 patients in an open prospective study in which 50% of patients improved (Gorson et al., 1998).

Recommended approach

Treatment should be initiated with IVIg or PE if available. These have high efficacy and few side effects. If one of these is ineffective the other should be tried. If PE is effective but

needed too frequently, an immunosuppressive regime such as azathioprine and steroid may allow an increase in the interexchange interval. Failing these measures immunosuppression with cyclosporin or cyclophosphamide may be used. Occasional patients need intense immunosuppression, i.e. CAA, azathioprine and steroids (in an organ transplant-like regime) before improvement is seen.

Multifocal motor neuropathy (MMN)

A chronic multifocal neuropathy with persistent conduction block was first described by Lewis and Sumner (Lewis et al., 1982). Parry and Clarke (1985) later reported a group of patients with a purely motor syndrome who had been diagnosed as motor neuron disease but were shown to have a pure motor neuropathy with motor conduction block. Other workers later pointed out a relationship between anti GM-1 antibodies and patients with motor neuropathies with persistent conduction block (Nordelli et al., 1988; Pestronk et al., 1988). Differences in clinical, electrophysiological and antibody profiles suggest that MMN can be differentiated from CIDP.

Clinical features

MMN is characterized by slowly progressive asymmetric limb weakness with muscle wasting often accompanied by cramps and fasciculations. Weakness often begins in the arms and prominent changes are seen in the forearms. There is a predilection for young adults. Reflexes may be preserved in normal or mildly weak muscles. Some muscles of normal bulk may be very weak. The clinical picture of muscle wasting, fasciculations and cramps with preserved reflexes often suggests the diagnosis of motor neuron disease. However, clinical examination may show that the pattern of muscle weakness follows the distribution of individual nerves rather than a spinal segmental pattern, particularly in the early stages (Parry, 1993).

Diagnosis

Electrophysiological studies

The hallmark of this disorder is persistent localized motor conduction block. However the diagnosis of conduction block in these chronic neuropathies needs to be made with care as described under CIDP (Parry, 1993).

Conduction block in MMN is confined to motor axons and may occur at any level of the peripheral nervous system although proximal segments are frequently affected (Kaji et al., 1993). Conduction velocity through the blocked segments is usually markedly slowed and the proximal CMAP markedly dispersed. The distal motor latency is usually normal and the region of slowing within the nerve confined to a short segment (Krarup, 1990). Frequent, asynchronous fasciculations can often be recorded in affected muscles and signs of chronic partial denervation may be found in clinically unaffected muscles.

Antiganglioside antibodies

High levels of IgM anti GM-1 antibodies have been reported in 18–84% of patients in various series (Pestronk, 1991; Kornberg et al., 1994; Bouche et al., 1995). Most antibodies are polyclonal and recognize the Gal(beta 1–3)GalNac epitope shared by GM-1 and GD1b. However the role of these antibodies remains uncertain. Although GM-1 and other Gal(beta 1–3)GalNac bearing glycoproteins are located in the vicinity of the node of Ranvier, the application of GM-1 antibodies from humans or experimental animals to single ventral root nerve fibres in the rat did not cause conduction block or blockade of sodium channels (Hirota et al., 1997). This finding is contrary to previous studies in which human and rabbit sera containing GM-1 antibodies were injected intraneurally (Santoro et al., 1992; Arasaki et al., 1993).

Histology

Pathological examination of nerve biopsied from identified sites of conduction block showed thinly myelinated and demyelinated axons and small onion bulb formations (Auer et al., 1989; Kaji et al., 1993).

Therapy

No placebo-controlled trials of therapy in MMN have been published. However this disorder is a progressive one, and many open studies have shown benefit from intravenous immunoglobulin and cyclophosphamide. Patients do not benefit from plasma exchange or prednisone and may worsen when so treated. Intravenous immunoglobulin has been repeatedly shown to be beneficial although maintenance therapy is necessary. Initial therapy is 0.4 g/kg for 5 consecutive days. A maintenance dose of 0.4 g/kg should be given as necessary to maintain the improvement, but optimal frequency has not been determined (Nobile-Orazio et al., 1993; Chaudry et al., 1993; Van den Berg, 1995).

Cyclophosphamide may be given orally or intravenously, alone or following plasma exchange (Pestronk et

al., 1994). In a recent study of six patients treated with both cyclophosphamide and IVIg all patients improved and improvement was associated with reduction of antibody level and lessening of conduction block (Meucci et al., 1997). Patients required periodic immunoglobulin to maintain improvement, but after 3–7 months of cyclophosphamide (1–3 mg/kg/day) the interval between immunoglobulin doses could be progressively increased. Thus intravenous immunoglobulin can induce and maintain remission but does not eradicate the disease whereas cyclophosphamide may help to induce a sustained remission. Because of the significant side effects of cyclophosphamide it should be reserved for patients who require frequent immunoglobulin or are severely disabled.

Most recently Levine and Pestronk (1999) reported improvement in a small group of patients following the use of a B-cell (anti-CD 20) monoclonal antibody (Rituximab). Clinical improvement correlated with reduced levels of serum antibodies.

Neuropathies associated with monoclonal gammopathy

This group of neuropathies is characterized by the presence of monoclonal serum proteins, some of which react with components of the myelin sheath or axolemma. Although usually they are associated with monoclonal gammopathy of uncertain significance (MGUS) they may accompany or precede certain systemic malignancies including multiple myeloma, osteosclerotic myeloma, Waldenstrom's macroglobulinemia, Castlemann's disease, POEMS Syndrome, primary amyloidosis, cryoglobulinemia and lymphoma.

Peripheral neuropathy associated with MGUS

IgG paraproteins are considerably more common than IgM or IgA, but peripheral neuropathy is more frequently seen in IgM paraproteinemia (Gosselin et al., 1991). M proteins have been reported to occur with an incidence of 10% among patients with idiopathic neuropathy (Kelly et al., 1981); 6% of these patients had MGUS, 2.5% primary amyloid and 1.1% multiple myeloma and there was one patient each with Waldenstrom's macroglobulinemia and heavy chain disease.

Neuropathy associated with IgM paraproteinemia

Clinical features

Most cases present with a slowly progressive distal sensorimotor neuropathy that predominantly affects men in the sixth or seventh decade. The signs are those of a distal and symmetrical sensorimotor neuropathy in the majority although a purely sensory neuropathy is occasionally seen and a multifocal neuropathy has rarely been described. An upper limb postural tremor resembling essential tremor and ataxia are prominent features (Smith et al., 1983; Gosselin et al., 1991, Yeung et al., 1991). Relatively few patients become severely disabled. In a prospective study of 18 patients followed for up to 14 years only 2 were unable to walk within 10 years of symptom onset (Smith, 1994).

Laboratory investigations

The CSF protein level is often raised and monoclonal IgM and anti MAG antibodies may be found. The M protein is shown by serum electrophoresis or immunofixation. Antibodies reacting with myelin associated glycoprotein MAG (and associated epitopes) are found in about 50% of patients with IgM monoclonal gammopathy and about 70% of those with IgM MGUS (Nobile-Orazio, 1998). The IgM reactivity is directed to a carbohydrate moiety in MAG that is shared by other glycoconjugates in nerve including P0 and PMP22 glycoproteins, and the glycosphingolipids, sulphoglucuronyl lactosaminyl paragloboside (SGLPG) and sulphoglucuronyl paragloboside (SGPG). The epitope is closely related to the HNK-1 epitope expressed on human natural killer cells. Anti MAG antibodies are detected by ELISA or immunoblot (Nobile-Orazio, 1998).

Electrophysiology

Slowing of motor conduction velocity is found in most patients and characteristically there is a marked prolongation of distal latencies representing a pronounced distal accentuation of conduction slowing (Kaku et al., 1994).

Pathology

Sural nerve studies show nerve fibre loss without inflammatory infiltrates. On teased fibre examination segmental demyelination is prominent and tomacula may be found (Sanders et al., 2000). On electron microscopy widened myelin lamellae, most pronounced in the outer lamellae, may be evident (Fig. 67.5). This change presumably results from deposition of the M protein since it is particularly pronounced in paranodal regions and Schmidt/Lantermann incisures where the target antigen MAG is located (Trapp & Quarles, 1982). Direct immunofluorescence shows binding of IgM and complement to surviving myelin sheaths (Fig. 67.6).

The mechanism by which anti MAG antibodies cause demyelination has not been clearly defined but there is strong evidence for their pathogenicity. The antibodies are deposited where MAG is located; intraneural injection of

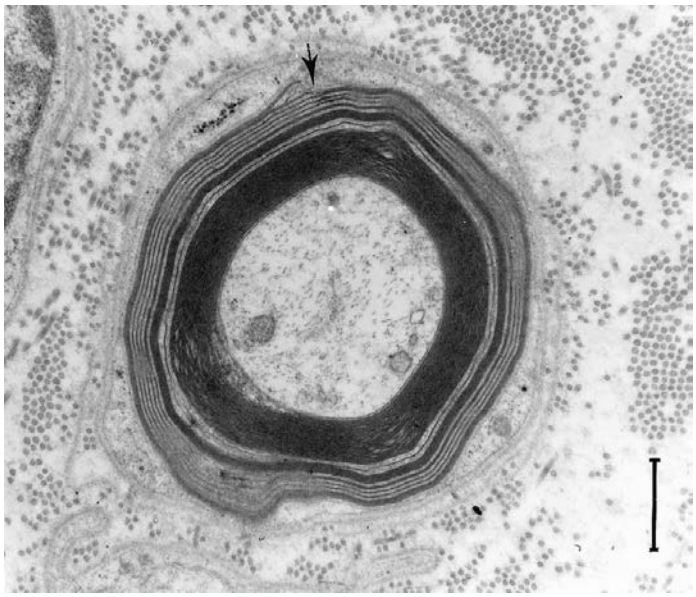

Fig. 67.5. Widened myelin lamellae in IgM paraprotein-associated neuropathy. An electron micrograph from a sural nerve biopsy specimen taken from a patient with high titre anti MAG antibodies. Note outer lamellae of myelin are widened (arrow). Bar = 5 μm.

the antibody causes focal demyelination. Passive transfer in the new born chick, in which blood–nerve barrier is defective has produced the electrophysiological and pathological features of the disease (Tatum, 1993).

Neuropathy associated with IgM paraproteins of non-MAG specificity

Less common paraproteins (polyclonal and monoclonal) react with GM-1 gangliosides causing a purely motor syndrome, multifocal motor neuropathy, discussed above. These antibodies mostly react with the terminal Gal (β1–3) GalNac structure. Other patients have antibodies with specificity for disialosyl groups on gangliosides GD1b, GT1b, GQ1b and related molecules and present with a chronic and progressive ataxic neuropathy. A subgroup of these patients develop ophthalmoplegia and the syndrome has been designated CANOMAD (chronic ataxic neuropathy, ophthalmoplegia, M protein, agglutination and disialosyl antibodies). Purified antibody from such a patient bound to human dorsal roots and dorsal root ganglia and to femoral and oculomotor nerves (Jacobs et al., 1997b). GQ1b antibodies as found in the Miller Fisher syndrome may be responsible for sensory symptoms by virtue of their cross reactivity with other disialosyl moieties (O'Leary & Willison, 1997).

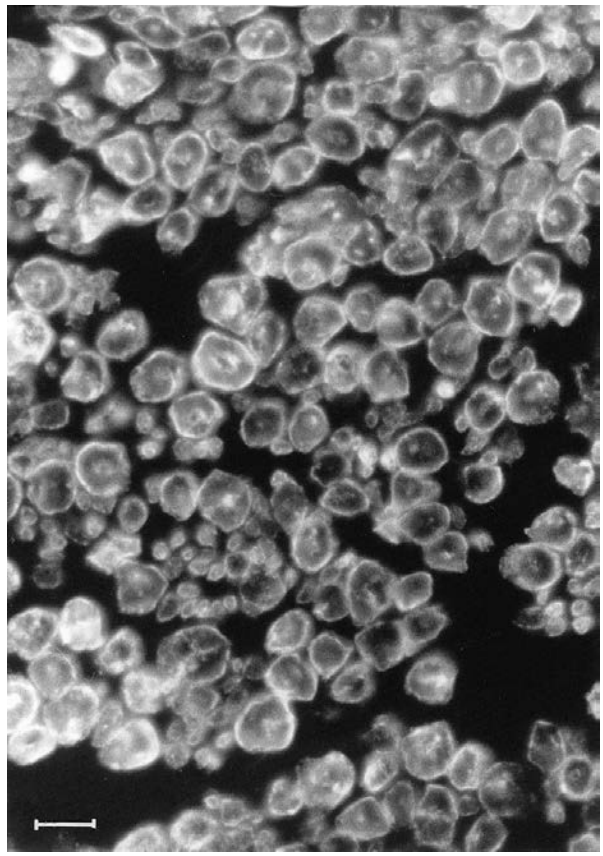

Fig. 67.6. Direct immunofluorescence showing binding of IgM to surviving myelin sheaths (arrow). Transverse section of sural nerve from a patient with IgM paraproteinemia. IgM is also evident within the perineurium (arrowhead). Bar = 20 μm.

In occasional patients paraproteins reacting with sulphatide and chondroitin sulphate are found. These patients have a chronic sensory neuropathy characterized by axonal degeneration (Sherman et al., 1983; Pestronk et al., 1991).

Neuropathy associated with IgG and IgA paraproteins

Neuropathy associated with IgG paraproteins is usually a sensorimotor neuropathy that may follow a progressive or relapsing course. Five cases described by Bleasel et al. (1993) were, in all respects apart from the paraprotein, similar to patients with CIDP. Mainly sensory neuropathies have been described (Gosselin et al., 1991; Yeung et al., 1991). Evidence for reactivity of the M protein to defined antigens is lacking in this group of patients. IgG reactivity to a neurofilament determinant was reported in

three patients with sensorimotor axonal neuropathy (Fazio et al., 1992).

Few cases of IgA paraprotein associated neuropathy have been reported and their clinical features have been similar to patients with IgG paraproteinemic neuropathy (Gosselin, 1991).

Treatment

Patients with IgG or IgA neuropathy respond to similar treatment regimes as used in CIDP; intravenous immunoglobulin, plasma exchange or immunosuppressive therapy (steroids with or without azathioprine, cyclosporin, cyclophosphamide) (Yeung et al., 1991; Pollard & Young, 1997). Treatment of IgM paraprotein-associated neuropathy is controversial. Improvement following plasma exchange has been reported in several uncontrolled trials, but not in one controlled trial (Yeung et al., 1991; Dyck et al., 1991; Kyle & Dyck, 1997; Gorson et al., 1998). Several uncontrolled studies have shown improvement when the IgM level is decreased by 50% but since IgM levels rapidly rise following plasma exchange, it needs to be accompanied by some form of immunosuppression. Chlorambucil and cyclophosphamide have been used successfully in open studies (Nobile-Orazio, 1998) and more recently fludarabine (Sherman et al., 1994) and rituximab, a monoclonal antibody directed against the B-cell surface marker CD20 (Levine & Pestronk, 1999).

Neuropathies associated with malignant plasma cell dyscrasias

There is no general agreement as to whether these neuropathies are autoimmune. Peripheral neuropathy occurs uncommonly in multiple myeloma. It is usually sensorimotor in type but purely sensory forms have been reported and relapsing and remitting forms occur. The presence of autonomic features in such patients may indicate the presence of systemic amyloidosis (Ropper & Gorson, 1998; Pollard & Young, 1997).

In patients with macroglobulinemia a sensorimotor neuropathy is frequently seen with features very similar to those described above for neuropathy with IgM paraproteinemia.

In contradistinction to the rarity of neuropathy complicating myeloma of the common osteolytic variety, in osteosclerotic myeloma a mainly motor demyelinating neuropathy is seen in almost half the patients. The neuropathy may be part of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein and skin changes). In addition to neuropathy, peripheral edema, hyperpigmentation and hypertrichosis are common. Gynecomastia, amenorrhea, impotence, testicular atrophy and finger clubbing may occur and ascites or pleural effusion are seen occasionally. Early weight loss is characteristic and facial lipoatrophy may be striking (Gherardi et al., 1994).

Reactivity of the M protein with myelin has not been firmly established in these patients. Increased serum levels of TNF-α have been reported in patients with POEMS and may be related to the weight loss (Gherardi et al., 1994). In addition IL-1 and IL-6 are increased and since both TNF-α and IL-1 have been implicated in increased vascular permeability within nerve, they may contribute to the neuropathy.

Stabilization or improvement of the neuropathy may be seen in half the patients who are treated. Treatment includes resection of solitary bone lesions, focused radiation or chemotherapy in patients with widespread lesions. Prednisone and melphalan or prednisone and cyclophosphamide have been shown to improve the neuropathy of some patients with POEMS (Nakanishi et al., 1984).

Vasculitic neuropathy

Vasculitic neuropathy results from ischemic nerve injury secondary to inflammatory cell infiltration of blood vessel walls and subsequent occlusion of those vessels. It occurs in association with systemic vasculitis or, less commonly, as an isolated vasculitis of peripheral nerve. In biopsy series of vasculitic neuropathy, the three most common diagnoses are polyarteritis nodosa, rheumatoid arthritis and isolated peripheral nerve vasculitis (Said et al., 1988; Kissel et al., 1985).

Neuropathy associated with systemic necrotizing vasculitis

Peripheral neuropathy is common in systemic vasculitis; it is seen in approximately 50% of patients with polyarteritis nodosa, Churg-Strauss vasculitis or rheumatoid vasculitis and in 10–20% of patients with Wegener's granulomatosis (Scott et al., 1981; Moore & Cupps, 1983; Cohen & Hurd, 1981; Guillevin et al., 1988). Sjögren's syndrome is associated with distal sensorimotor neuropathy, trigeminal sensory neuropathy and a sensory ataxic neuropathy or ganglionopathy. Vasculitis is seen in the majority of cases of distal sensorimotor neuropathy, the most common form (Mellgren et al., 1989). Vasculitic neuropathy also occurs in systemic lupus erythematosus (SLE) (Cohen & Hurd 1981; McCombe et al., 1987a), but probably represents a minority of SLE-associated neuropathies. Similarly, vasculitic

neuropathy can be seen with undifferentiated connective tissue disease, giant cell arteritis, and Behçet's syndrome.

Peripheral neuropathy is reported in 25–50% of patients with essential Type II (mixed) cryoglobulinemia, and nerve biopsy frequently shows evidence of vasculitis (Gemignani et al., 1992). Vasculitic neuropathy also occurs with secondary cryoglobulinemia, for instance, in association with hepatitis C infection.

Vasculitis secondary to malignancy, infection (including HIV) and serum sickness can also be complicated by vasculitic neuropathy and vasculitic neuropathy has recently been reported in association with chronic graft-vs.-host disease (Gabriel et al., 1999).

Isolated peripheral nerve vasculitis (non-systemic vasculitic neuropathy)

Vasculitis confined to the peripheral nerves represents 31–44% of cases of vasculitic neuropathy in biopsy series. The clinical features of the neuropathy are not different to those of the neuropathies associated with systemic vasculitis (Dyck et al., 1987) but clinical and laboratory evidence of systemic disease is lacking. The response to treatment and prognosis may be better than that of the systemic vasculitides (Kissel et al., 1985; Dyck et al., 1987; Said et al., 1988; Davies et al., 1996).

Clinical features

Vasculitic neuropathy characteristically has an acute or subacute onset. It may present across a wide age range, however it is more common in older patients, with the mean age at presentation in several series being in the vicinity of 60 years. The classical clinical picture of multiple mononeuropathies is seen in only 50–66% of patients, and it is important to note that up to one-quarter of patients present with a distal symmetric sensory or sensorimotor polyneuropathy. Most of the remaining patients present with an asymmetric polyneuropathy (Kissel et al., 1985; Said et al., 1988; Hawke et al., 1991; Chia et al., 1996). Rare patients have been described with an isolated small fibre sensory neuropathy associated with vasculitis (Lacomis et al., 1997). Local pain is a feature in 50–70% of patients. Although most patients have both sensory and motor disturbance, the sensory abnormalities are usually more extensive.

Electrodiagnostic studies

The characteristic findings are those of an axonal neuropathy: low amplitude sensory and compound muscle action potentials with preserved or only minimally reduced conduction velocities. Sensory nerve conduction is more often and more severely affected than motor. As with the clinical findings, the electrophysiological abnormalities may be multifocal, asymmetric or diffuse. There have been reports of conduction block in vasculitic neuropathy (Mohamed et al., 1998; Ropert & Metral, 1990) but the presence of widespread conduction block with relatively preserved distal compound muscle action potential amplitudes is more suggestive of an inflammatory demyelinating neuropathy. Needle electromyography typically shows evidence of denervation (positive sharp waves and fibrillation potentials) in muscles supplied by affected nerves. In the systemic vasculitides, peripheral neuropathy is more common than is suggested by clinical examination alone, and electrodiagnostic studies are helpful in detecting subclinical neuropathy.

Laboratory investigations

Non-specific markers of inflammation such as the erythrocyte sedimentation rate (ESR) are often elevated. Kissel et al. (1985) found a moderately elevated ESR in 88% of patients with vasculitic neuropathy, with no difference between isolated nerve vasculitis and cases with underlying vasculitis or connective tissue disease. In our patients with isolated peripheral nerve vasculitis, 63% had mild to moderate elevation of the ESR, antinuclear antibodies were present (in low titre) in only 20% and rheumatoid factor was positive in less than 10% (Davies et al., 1996). In patients with systemic vasculitis, laboratory findings largely reflect the underlying disease.

Pathology

The dominant finding in nerve biopsies is axonal degeneration. The degree of involvement may vary between fascicles or there may be segmental loss of fibres within individual fascicles. The diagnostic features of active vasculitis are a transmural inflammatory cell infiltrate with associated segmental necrosis of the blood vessel wall. The internal elastic lamina of the vessels is disrupted. The presence of perivascular inflammatory infiltrates in association with active axonal degeneration, especially with intra- or interfascicular variation or with all fibres at the same stage of degeneration consistent with a 'point source' insult, is suggestive of vasculitis, but inflammatory cell invasion and necrosis of the vessel wall is required for a firm pathological diagnosis. The vasculitic process most commonly involves epineurial and, to a lesser extent, perineurial vessels. Occlusion of the vessel lumen, some-

times with recanalization and evidence of hemorrhage, may also be seen. Subperineurial edema is often prominent in the acute phase. Healed vasculitis may appear as concentric fibrous scarring and intramural thickening of the vessel wall. In patients with a suspected vasculitic neuropathy, performing both nerve and muscle biopsy may increase the diagnostic yield (Hattori et al., 1999; Said et al., 1988).

Pathogenesis

The eventual cause of vasculitic neuropathy is occlusion of the vasa nervorum, leading to nerve ischemia and consequent axonal degeneration. The pathogenesis of the inflammatory vascular lesion is not fully elucidated, but there is evidence that both cellular and humoral mechanisms are involved. Deposition of immunoglobulin and complement in vessel walls is a frequent finding, and the fact that these deposits are evident only in vessels with inflammatory cell infiltration does suggest a role for immune complexes in the pathogenesis of the vascular lesions (Kissel et al., 1989; Hawke et al., 1991).

Treatment and prognosis

There are no large scale studies of the treatment of vasculitic neuropathy. Most series have reported the results of variable regimens of prednisone alone or in combination with other immunosuppressive agents, most frequently azathioprine or cyclophosphamide. The results of treatment are somewhat variable from series to series. Kissel et al. (1985) reported a moderate to substantial improvements in 75% of patients; 20% of these subsequently developed a remitting relapsing course; a significant proportion of these patients had isolated peripheral nerve vasculitis. On the other hand, Hawke et al. (1991) showed a 5-year survival rate of only 37% for a mixed group of patients with vasculitic neuropathy predominantly in association with systemic vasculitis. A favourable response is reported in 43–53% of patients with vasculitic neuropathy associated with Churg–Strauss or rheumatoid vasculitis, but one-third of those surviving 5 years had moderate sensorimotor sequelae (Hattori et al., 1999; Puéchal et al., 1995). Evidence of more systemic organ damage and increased age are consistently associated with poor outcome.

The prognosis appears to be better for isolated peripheral nerve vasculitis. In the series reported by Davies et al. (1996) and treated with steroids alone or in combination with azathioprine or cyclophosphamide, 24 of 25 patients had survived at a mean of 3.4 years follow-up and 20 of 23 patients were ambulant without walking aids. Thirty per cent of patients had at least one relapse, which is not dissimilar to the rate reported by Kissel et al. (1985).

Hereditary neuropathies

Mary Reilly and Peter K. Thomas

Institute of Neurology, Queen Square, London, UK

The hereditary neuropathies consist of a large group of conditions that for descriptive purposes are conveniently separable into the hereditary motor and sensory neuropathies, the hereditary sensory and autonomic neuropathies and conditions in which the neuropathy is associated with a generalized metabolic disorder. The hereditary motor neuropathies (spinal muscular atrophies) are discussed elsewhere (see Chapters 116, 117).

Hereditary motor and sensory neuropathies

The hereditary motor and sensory neuropathies comprise a miscellaneous group of disorders in which a number of different clinical patterns are recognizable. Broadly speaking, these are the Charcot–Marie–Tooth (CMT) syndrome, Dejerine–Sottas disease (DSD) and congenital hypomyelination neuropathy (CHN) (Reilly, 2000). In addition, there are two examples of inherited recurrent neuropathy, namely hereditary neuropathy with liability to pressure palsies (HNPP) and hereditary neuralgic amyotrophy (HNA) and a number of other rare but important more complex disorders that deserve consideration.

Charcot–Marie–Tooth disease

Charcot–Marie–Tooth (CMT) disease is divisible into three categories, in two of which, types 1 and 2, the inheritance is autosomal and in the third it is X-linked. CMT disease is the commonest inherited neuropathy with a prevalence of about 20–40 : 100 000 (Dyck et al., 1993).

Charcot–Marie–Tooth disease type 1

CMT1 or type 1 hereditary motor and sensory neuropathy (HMSN I) usually begins in the first decade of life, less often in the second and rarely at later ages. The onset is commonly with difficulty in walking or foot deformity with later involvement of the upper limbs. Variable disability develops during childhood and adolescence following which deterioration is slow or sometimes negligible. Inheritance is most frequently of autosomal dominant pattern, less often autosomal recessive. In dominantly inherited families clinical severity is highly variable (Thomas et al., 1997). Some heterozygous gene carriers may be asymptomatic and others may just display foot deformity. The characteristic clinical features are distal muscle wasting and weakness in the limbs giving rise to a 'stork leg' appearance accompanied by atrophy of the small hand muscles. Patients with prominent upper limb postural tremor have been referred to as the Roussy–Lévy syndrome. The distal lower limb weakness gives rise to a drop-foot gait. There is usually accompanying distal sensory loss in the limbs which may affect all modalities, and tendon areflexia. Most patients remain ambulant but rarely they can become wheelchair bound. Diaphragmatic weakness sometimes develops. The peripheral nerves may be enlarged. Associated skeletal deformity is frequent, usually pes cavus or pes equinovarus, clawing of the toes and claw hand, and occasionally kyphoscoliosis.

Motor nerve conduction velocity is characteristically reduced, to less than 38 m/s in the upper limbs, and sensory nerve action potentials are absent. Nerve biopsy shows evidence of axonal loss and widespread demyelination. There are hypertrophic 'onion bulb' changes (Fig. 68.1) consisting of the circumferential proliferation of Schwann cells around axons related to repeated cycles of demyelination and remyelination (Thomas et al., 1997).

Inheritance is usually autosomal dominant. In the majority the disorder is due to a 1.5 megabase duplication on chromosome 17p11.2 – p12 leading to the presence of an extra copy of the gene for peripheral myelin protein 22 (*PMP22*). Such cases are referred to as CMT1A (or HMSN

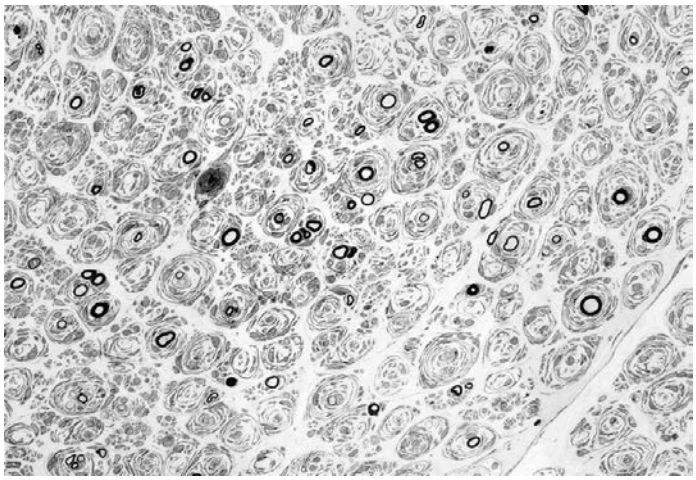

Fig. 68.1. Transverse section of sural nerve biopsy, from cases of CMT1A showing profuse concentric Schwann cell proliferation ('onion bulbs') and a severe loss of myelinated nerve fibres. Thionin and acridine orange stain. ×400.

Ia). The duplication is flanked by a repeat sequence, 17–29 kb in length, termed CMT1A-REP. The duplications appear to arise from misalignment of the distal repeat during meiosis and are usually of paternal origin (Keller & Chance, 1999). Rarely the cause of CMT1A is a point mutation in the *PMP22* gene. PMP22 is a relatively minor component of myelin, the function of which is not yet established. It may have a role both during the early stages of myelination and in the maintenance of compact myelin.

In patients with a chromosome 17p11.2 duplication myelin sheath thickness is initially excessive for axon diameter. This is associated with overexpression of the *PMP22* gene, as assessed by the *PMP22* mRNA content in Schwann cells on nerve biopsy (Vallat et al., 1996). From observations on transgenic mice with extra copies of the *PMP22* gene, it has been established that overexpression of *PMP22* results in demyelination, but what leads to the axonal loss that is the main cause of disability in CMT1A is so far uncertain. Active demyelination tends to be confined to childhood (Gabreëls-Festen et al., 1992) and this is succeeded by axonal loss. Cases with point mutations in the *PMP22* gene are usually more severely affected and nerve biopsy shows hypomyelination rather than hypermyelination (Gabreëls-Festen et al., 1995).

Less commonly, type 1 CMT disease is the result of mutations in the gene for myelin protein zero (P_0, MPZ) (Hayasaka et al., 1993). MPZ is the major myelin structural protein. It is a 30 kDa protein and a member of the immunoglobulin superfamily. It has transmembrane, extracellular and cytoplasmic domains and is probably involved in homophilic interactions between adjacent myelin lamellae and thus controls myelin periodicity. CMT disease related to MPZ mutations is categorized as CMT1B (HMSNIb). The clinical features closely resemble those of CMT1A. The original Roussy–Lévy family has been shown to have CMT1B, but this phenotype can also be a manifestation of CMT1A.

Rarely mutations in the *early growth response 2* (*EGR2/Krox 20*) gene are responsible for a CMT phenotype (Warner et al., 1998). This gene is located on chromosome 10q23 and codes for a protein with a zinc finger domain.

Type I HMSN or CMT1 disease can also be of autosomal recessive inheritance. These disorders are designated CMT4 in the gene-mapping literature. Several different entities have now been identified (Reilly, 2000; Thomas, 2000). A severe sensorimotor neuropathy with an onset in early childhood, has been mapped to chromosome 8q13–21.1. Pathologically the peripheral nerves show hypomyelination and multiple basal laminal onion bulbs, i.e. the central axons are surrounded not by circumferential Schwann cell processes but by concentric double layers of empty basal laminae. Another disorder, mapped to chromosome 5q23–33, again begins in early childhood. Scoliosis is a prominent feature. It is again characterized pathologically by hypomyelination and basal laminal onion bulbs but also by elongated processes extending from the Schwann cells of both myelinated and unmyelinated fibres. A further recessive demyelinating neuropathy identified in a Lebanese kindred has been linked to chromosome 19q13.1–13.3.

Hereditary neuropathy with focally folded myelin is distinguished by the presence of demyelination accompanied by multiple regions where the myelin sheath is thrown into complex folds (Fig. 68.2), either from the external aspect of the sheath or protruding into the axon (Ohnishi et al., 1989). Clinically these patients have a severe early onset sensorimotor neuropathy with involvement of the masticatory, facial and bulbar muscles and also the diaphragm. This disorder is genetically heterogeneous. In some families that have been linked to chromosome 11q23, there are mutations in the *myotubularin related protein 2* (*MTMR2*) gene (Bolino et al., 2000). They have been categorized as CMT4B1. Other families (CMT4B2) have been linked to chromosome 11p15. Although designated as CMT disease, the clinical phenotype, with severe involvement and an early onset, more closely resembles Dejerine–Sottas disease.

Hereditary motor and sensory neuropathy Lom (HMSNL), a disorder recognized in Balkan gypsies and named after the Bulgarian city Lom, combines a severe CMT phenotype with deafness. It has been shown to be due to mutation in the *N-myc downstream regulated gene 1*

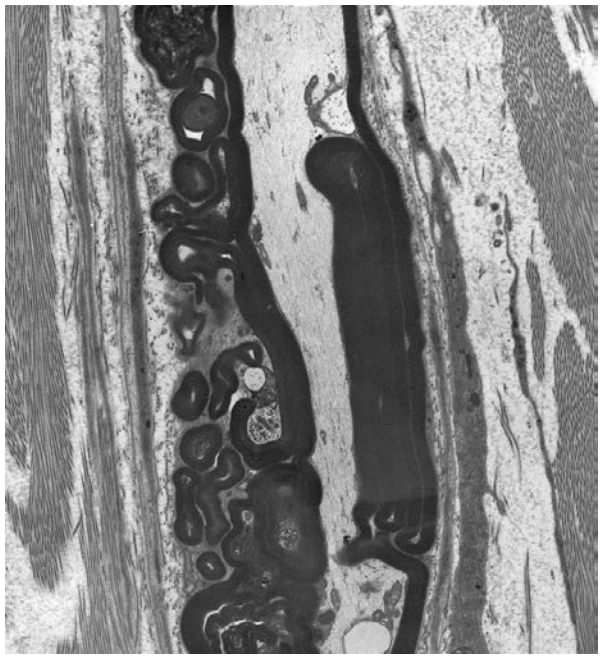

Fig. 68.2. Electron micrograph of longitudinal section through a myelinated nerve fibre showing multiple folds of the myelin sheath both outwards and into the axon. ×5000.

(NDRG1) on chromosome 8q24. NDRG1 is a signalling protein involved in growth arrest and terminal cell differentiation but its role in myelination and axon maintenance is not yet understood.

Charcot–Marie–Tooth disease type 2

CMT2 (HMSN II) shows similar clinical features to those of CMT1 but onset tends to be later, being most often in the second decade and sometimes delayed until late life. Upper limb involvement, the degree of sensory loss and the occurrence of skeletal deformity are less pronounced. Motor nerve conduction velocity is either within normal limits or only mildly reduced. The underlying pathology is an axonopathy of dying-back type in which the axons initially degenerate distally, this progressing proximally towards the cell bodies. Onion bulbs are not present. Inheritance is usually autosomal dominant or rarely autosomal recessive. Three loci for dominantly inherited CMT2 disease have been established, mapping to chromosomes 1p35–36 (CMT2A), 3q13–q22 (CMT2B) and 7p14 (CMT2D). (Reilly, 2000). CMT2B tends to have prominent sensory loss which may lead to a mutilating acropathy, resulting in a phenotypic overlap with type 1 hereditary sensory neuropathy. CMT2C is clinically distinct, the presentation being with vocal cord and diaphragmatic paralysis. It has not yet been localized. A further autosomal dominant disorder with a proximal distribution has been mapped to chromosome 3q13.1. CMT2 can also be the result of mutations in the neurofilament light gene on chromosome 8q24. Occasionally *MPZ* mutations produce a CMT2 phenotype.

Autosomal recessive forms of CMT2 are less well characterized. Onset tends to be in childhood, leading to severe disability (Gabreëls-Festen et al., 1991). One form has been mapped to chromosome 1q21.2–21.3. An X-linked variety associated with deafness also exists.

'Complex' CMT disease

A number of so far poorly characterized disorders combine a CMT phenotype with additional neurological features. These include pyramidal signs (Dyck et al., 1993), optic atrophy (Vizioli type), deafness, optic atrophy and deafness (Rosenberg & Chutorian type) and pigmentary retinopathy (Massion–Verniory disease).

X-linked Charcot–Marie–Tooth disease

CMTX (or HMSNX) produces a similar phenotype to that of CMT1 in males. Carrier females are asymptomatic or less severely affected (Hahn et al., 1990). Motor nerve conduction velocity tends to be intermediate between that of CMT1 and CMT2. Nerve biopsy demonstrates axonal loss with some associated demyelination (Hahn et al., 1990).

The disorder has been shown to be due to mutations in the gene for connexin 32 (Bergoffen et al., 1993). This is a gap junction protein present in Schwann cells at the nodes of Ranvier and Schmidt-Lanterman incisures. It may provide communication between the compartments of the Schwann cell on either side of the myelin sheath.

Dejerine–Sottas disease (DSD)

DSD is genetically heterogeneous. It has been defined as a mixed motor and sensory neuropathy of congenital or childhood onset. Motor milestones are delayed and disease progression leads to severe disability, often with prominent foot and spinal deformities. The peripheral nerves may be enlarged. Motor nerve conduction velocity is markedly reduced, to less than 10 m/s, and sensory nerve action potentials are absent. Nerve biopsy demonstrates chronic demyelination with hypertrophic changes and also hypomyelination so that myelin sheaths are consistently of reduced thickness.

DSD, or type III HMSN, was initially thought to be of autosomal recessive inheritance. Most cases are now known to represent new dominant mutations in the *PMP22* (DSDA) or *MPZ* (DSDB) (Tyson et al., 1997) genes or sometimes in the *EGR2* gene (Warner et al., 1998).

Congenital hypomyelination

This is an uncommon type of neuropathy. Affected children present with hypotonic weakness at birth and show generalized hyporeflexia. They have markedly delayed motor development and remain severely disabled, often with skeletal deformities. It is difficult or impossible to obtain motor responses on nerve stimulation because of a high electrical threshold but if motor conduction velocity is recordable it is very severely reduced at 1–2 m/s. Sensory nerve action potentials are unobtainable. Nerve biopsy shows hypomyelination with extremely thin myelin sheaths or a total lack of myelin. The disorder is genetically heterogeneous and may result from *PMP22, MPZ* or *EGR2* gene mutations (Warner et al., 1998), or from other so far undiscovered mutations. EGR2 has been shown to be involved in the early stages of enwrapment of axons by Schwann cells (Topilko et al., 1994).

Inherited recurrent neuropathies

Hereditary neuropathy with liability to pressure palsies

HNPP is characterized by the occurrence of repeated focal nerve lesions related to external compression or to nerve damage at the common entrapment sites. Painless acute lesions affecting the brachial plexus may occur. Individual lesions usually improve but not always fully so that the patient may gradually acquire persisting neurological deficits. Sometimes a distal neuropathy with a CMT-like phenotype of gradual onset is encountered. Nerve conduction studies, in addition to confirming focal lesions, may or may not demonstrate the presence of a generalized neuropathy. Nerve biopsy shows evidence of widespread demyelination together with multiple focal myelin thickenings referred to as tomacula (tomaculum = sausage in Latin) (Madrid & Bradley, 1975).

The disorder is of autosomal dominant inheritance. Most cases are related to a deletion on chromosome 17p11.2–p12 so that this is a reciprocal of CMT1A with a duplication. *PMP22* gene expression is reduced in Schwann cells (Vallat et al., 1996). Occasionally there is a point mutation in the *PMP22* gene or a mutation at another undiscovered locus.

Hereditary neuralgic amyotrophy

The clinical features in this autosomal dominant disorder are very similar to those encountered in sporadic cases (see pp. xx-xx) but multiple episodes tend to be encountered more frequently and in some families dysmorphic facial features with hypotelorism have been described. The disorder has been mapped to chromosome 17q25 (Pellegrino et al., 1996), but it is probably genetically heterogeneous.

Hereditary sensory and autonomic neuropathies

This is a miscellaneous group of disorders (Dyck, 1993), most examples of which show a predominant sensory neuropathy, sometimes associated with minor motor and varying degrees of autonomic involvement. One example, familial dysautonomia or the Riley–Day syndrome, is characterized both by a sensory neuropathy and by prominent autonomic dysfunction.

Hereditary sensory neuropathies

Type I hereditary sensory neuropathy (HSN I) is an autosomal dominant disorder that has been mapped to chromosome 9q22.1–22.3 (Nicholson et al., 1996). Onset of symptoms is most commonly in the second or third decades and usually begins with painless foot ulceration although spontaneous neuropathic pain may be a feature. Examination reveals distal sensory loss mainly affecting pain and temperature sensibility which is more prominent in the lower limbs. Minor distal motor involvement may be evident and also slight distal anhidrosis. Other autonomic dysfunction is not seen. The disorder is slowly progressive and may lead to the development of neuropathic joint degeneration and to secondary osteomyelitis following chronic foot ulceration. Nerve biopsy shows depletion of unmyelinated axons and a predominant loss of small myelinated fibres. A genetically distinct variant presents with familial 'burning feet' in midlife.

Type II hereditary sensory neuropathy (HSN II) is of congenital or early childhood onset. There is a distal loss of all sensory modalities, often leading to a pronounced mutilating acropathy in all four limbs. Again, there is only minor motor and autonomic involvement. Nerve biopsy shows a severe loss of myelinated fibres of all sizes and also of unmyelinated axons (Ohta et al., 1973). The disorder is of autosomal recessive inheritance.

A further syndrome is congenital insensitivity to pain with anhidrosis (CIPA) which is again of autosomal recessive inheritance. It has been shown to be due to mutations in the gene for TRKA, the high affinity nerve growth factor receptor (Masdy et al., 1999). Onset is congenital or in early infancy with episodes of fever related to high ambient temperature. There is loss for pain and temperature sensibility which leads to a distal acropathy. Self mutilation may be observed. There is also widespread anhidrosis. Affected children may be of reduced intelligence. Pathologically

there is a predominant loss of small myelinated axons and a virtually total absence of unmyelinated axons.

Hereditary sensory neuropathy with selective loss of small myelinated nerve fibres resembles CIPA (Dyck, 1993). It consists of a sensory neuropathy selectively affecting pain and temperature sensibility, together with widespread anhidrosis leading to a mutilating acopathy and sometimes keratitis. Nerve biopsy shows a predominant loss of small myelinated nerve fibres and relative preservation of unmyelinated axons.

Familial dysautonomia

Familial dysautonomia or the Riley–Day syndrome (Dyck, 1993) is of autosomal recessive inheritance and has been mapped to chromosome 9q31–33. It is most commonly encountered in individuals of Ashkenazi Jewish descent. Onset is in infancy with poor feeding, repeated episodes of vomiting, pulmonary infections and failure to thrive. Autonomic dysfunction becomes evident early in life with alacrimia, skin blotching, defective temperature control and labile blood pressure. Prolonged respiratory depression after anesthesia may be encountered. Bladder function is preserved but disorders of esophageal and gastric motility may be demonstrable, as may megacolon. Fungiform papillae on the tongue are absent. There is evidence of widespread reduced pain appreciation including corneal ulceration. Visual impairment and optic atrophy may be present. Growth is impaired and affected children remain of small stature, often with kyphoscoliosis. Intellectual development is probably unaffected.

Neuropathological studies have shown loss of autonomic neurons in autopsied cases and of unmyelinated axons on nerve biopsy.

Inherited motor and sensory neuropathies with multisystem involvement

This group of rare hereditary motor and sensory neuropathies comprises disorders in which the neuropathy is accompanied by characteristic abnormalities affecting other systems.

Giant axonal neuropathy

Giant axonal neuropathy is of autosomal recessive inheritance and has been mapped to chromosome 16q24.1. Onset is in childhood with a slowly progressive distally-accentuated neuropathy which is predominantly motor in type. There are accompanying CNS features including ataxia, nystagmus and mild signs of corticospinal tract dysfunction. A high proportion of the affected children have abnormally curly hair (Fig. 68.3). Nerve conduction studies demonstrate an axonopathy with reduced or absent sensory action potentials. Pathologically the peripheral nerves show axonal loss with multiple focal axonal swellings packed with accumulations of neurofilaments and associated with secondary demyelination. The precise mechanism of the neurofilamentous accumulations has not been established but there appears to be a generalized disorder of intermediate filaments. Mutations of the gene for the cytoskeletal protein gigaxonin have recently been described.

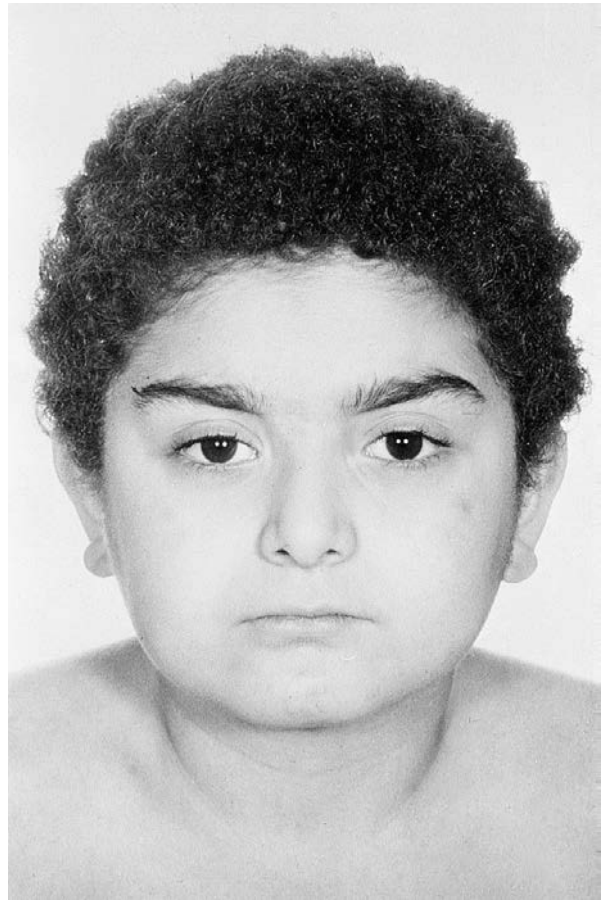

Fig. 68.3. Child aged 9 years with giant axonal neuropathy showing curly hair.

Multiple endocrine neoplasia type 2B

MEN 2B is a complex disorder characterized by the combination of medullary carcinoma of the thyroid, pheochromocytoma, ligamentous laxity and a marfanoid habitus. The disorder is of autosomal dominant inheritance. Peripheral nerve involvement (Dyck et al., 1993) mainly affects the autonomic nervous system and has been referred to as

ganglioneuromatosis. There is a non-neoplastic proliferation of nerves and ganglion cells leading to multiple nodular swellings on the lips, tongue, buccal mucosa, palate and alimentary tract including the salivary glands, pancreas and gall bladder. A variety of gastrointestinal symptoms occur, such as vomiting, diarrhea, constipation, megacolon and dilation of the small intestine and stomach. The somatic nerves are less affected but limb weakness may be present.

MEN2B is a neurocristopathy related to mutations in the RET proto-oncogene. These result in a gain of function leading to constitutive activation of the receptor.

Andermann's syndrome: agenesis of the corpus callosum and neuropathy

Confined to French Canadian families from Quebec, this autosomal recessive disorder combines mental retardation, dysmorphism, and agenesis of the corpus callosum with a progressive axonal sensorimotor neuropathy. The neuropathy can occur in the absence of callosal agenesis. The disorder has been mapped to chromosome 15q13–q15.

Multiple symmetric lipomatosis

Otherwise known as Madelung's disease, many individuals with this disorder develop a progressive distal sensorimotor neuropathy of axonal type (Enzi et al., 1985). The disease is characterized by the presence of a massive rufflike lipoma of the neck together with symmetric lipomas over the shoulders, trunk and proximal limbs. The inheritance is probably autosomal recessive. The disorder may involve disturbed mitochondrial function.

Chédiak–Higashi disease

This autosomal recessive disorder has an onset in childhood with partial oculocutaneous albinism associated with giant melanosomes. Giant peroxidose-positive lysosomes are found in leukocytes. There is defective hair pigmentation, anemia, leukopenia, thrombocytopenia and a liability to lymphoreticular malignancy. Mental retardation, a distal sensorimotor axonal neuropathy or a syndrome resembling a spinocerebellar degeneration, may be accompanying features.

Congenital cataracts facial dysmorphism neuropathy (CCFDN) syndrome

The CCFDN syndrome is a complex autosomal recessive disorder, so far only identified in gypsies. It combines congenital cataracts, a characteristic facial dysmorphism, small stature, moderate mental retardation and hypogonadotrophic hypogonadism with a progressive distal sensorimotor neuropathy. Some patients also show evidence of corticospinal tract dysfunction, mild ataxia and chorea. The disorder has been mapped to chromosome 18qter.

Treatment of CMT and HSN

Treatment for the hereditary motor and sensory neuropathies should include regular neurological or orthopedic supervision during childhood and adolescence for cases with an early onset in an attempt to prevent the development of skeletal deformity. Orthoses to compensate for foot drop may be required as may orthopedic procedures to correct foot deformity or scoliosis, or to improve foot drop or manual dexterity by tendon transfer procedures. Patients with HNPP should be advised to avoid athletic or other activities that would put their peripheral nerves at risk.

The commonest inherited neuropathy is CMT1A, due to a duplication on chromosome 17p11.2–p12. As already stated, this has been shown to result in overexpression of the *PMP22* gene. Definitive treatment will therefore require reducing the expression of this gene. Progress in this direction has been achieved in a transgenic mouse model of CMT1A in which extra copies of the *PMP22* gene are introduced into the mouse genome. This leads to a demyelinating neuropathy in which the severity of the neuropathy is related to the number of copies of the transgenes. To explore the possibility of treatment, a conditional mouse model has been developed in which the *PMP22* transgenes are under the control of a tetracycline-responsive promoter. It has been shown that turning off the expression of the transgenes can prevent the development of the neuropathy and improve established neuropathy (Perea et al., 1999), providing encouragement for the further development of this approach.

In the demyelinating forms of CMT disease, disability is not the direct result of demyelination but of associated axonal loss. Any effective treatment must therefore prevent this axonal loss. There are indications that the loss may be secondary to lack of growth factor support from Schwann cells. A possible treatment approach would therefore be the delivery of growth factors to the axons.

Occasional patients with HMSN may develop an abrupt deterioration and are improved by treatment with corticosteroids or intravenous immunoglobulin. It is likely that such cases represent superimposed chronic inflammatory demyelinating polyneuropathy (CIDP) as a secondary immunological reaction.

In the hereditary sensory neuropathies, education is required to avoid the development of foot ulceration. This includes the provision of suitable footwear and the avoid-

ance of walking on sharp objects or hot surfaces. Appropriate medication may be required for neuropathic pain.

Neuropathies related to generalized metabolic disorders

Familial amyloid polyneuropathy

The amyloidoses are a group of disorders characterized by the deposition of a fibrillar protein with an abundant β-pleated structure in the extracellular space. There are many different proteins that can form amyloid and it is the individual constituent protein that defines the disease. The hereditary peripheral nervous system amyloidoses are called the familial amyloid polyneuropathies (FAP). FAP is classified into three different types based on the constituent fibril protein. The first description of FAP was by Andrade in 1953 when he described an autosomal dominant disorder, characterized by a small fibre neuropathy with autonomic involvement and variable cardiac dysfunction, in a group of Portuguese kindreds (Andrade, 1952). Subsequently the constituent fibril protein for this type of FAP was shown to be transthyretin, previously known as prealbumin (TTR-related FAP). FAP can also occur secondary to apolipoprotein A-1 (apolipoprotein A-1 related FAP) and to gelsolin (gelsolin-related FAP) mutations.

TTR is the product of a single gene on chromosome 18q11.2–q12.1, containing four exons coding for a 127 amino acid mature protein and an 18 residue signal peptide. To date, there have been at least 80 point mutations and one trinucleotide deletion identified in exons 2, 3 and 4 of the TTR gene (Planté-Bordeneuve & Said, 2000), most of which are associated with FAP. The TTR mutations usually exist in the heterozygous state and are inherited in an autosomal dominant manner. The Met 30 mutation is the commonest, accounting for all the original Portuguese cases and other large clusters of the disease in Sweden and Japan and also more recently described in association with FAP in many different countries. Haplotype studies have confirmed multiple founders for this mutation. Although the actual mechanisms whereby TTR mutations lead to the formation of amyloid are not clearly understood, the amyloidogenic potential of TTR is presumed to be partly due to its extensive ß-pleated structure. There is also evidence that mutations in TTR may make conditions more favourable to form an amyloidogenic intermediate.

The clinical features of TTR-related FAP are best described for the TTR Met 30 mutation. The cardinal feature is a length-dependent sensory and motor neuropathy that usually starts in the lower limbs and in the small fibres. The neuropathy eventually progresses to affect all sensory and motor modalities. Autonomic involvement can be very severe and can occur early in the course of the disease. Other features include cardiomyopathy and vitreous deposits. Recently, a few TTR mutations have been shown to present rarely with a central nervous system syndrome, oculoleptomeningeal amyloidosis (OLMA), clinically characterized by vitreous deposits, strokes, progressive dementia, ataxia and hydrocephalus (Brett et al., 1999). Careful genotype–phenotype studies have failed to demonstrate a direct phenotype correlation with any particular mutation although certain mutations, e.g. TTR Ser 84 and TTR His 58, tend to present with upper limb involvement and others, e.g. TTR Ala 60, with cardiac involvement. It is not understood why TTR is deposited in peripheral nerves or how it causes a neuropathy. Transgenic mice have so far failed to answer these questions. Amyloid deposits can be found in any part of the peripheral nervous system including nerve trunks, plexuses, and the sensory and autonomic ganglia and are most commonly found around blood vessels. The neuropathy is an axonal neuropathy and the amyloid deposits are often localized and patchy. Unmyelinated and small myelinated fibres are lost first followed later by the large myelinated fibres.

The diagnosis of FAP relies on a high level of clinical suspicion. Amyloid can be diagnosed on a biopsy from nerve, heart, rectum or other tissues, depending on the clinical presentation. The most widely used technique is a combination of alkaline congo red and polarizing filters to demonstrate the characteristic apple green birefringence. The constituent fibril protein can be identified by immunohistochemistry, although this technique is not completely reliable. Molecular diagnosis has benefited this area enormously with most mutations being detected either by using polymerase chain reaction (PCR) related techniques or by methods used for mutation screening or direct sequencing. The extent of the systemic deposits (excluding the nervous system) can be ascertained using scintigraphic studies with ^{123}iodine labelled serum amyloid protein (SAP).

Until the 1990s symptomatic treatments (e.g. pacemakers) and rehabilitative measures were the only treatments available for FAP and still remain important. Liver transplantation was first considered as 90% of TTR is synthesized in the liver. This procedure was first performed in 1990 and is now available in most large centres dealing with this condition. The biochemical effect of liver transplantation is good, as demonstrated by a dramatic

reduction in variant TTR in plasma and scintigraphic evidence of reduced amyloid deposits postoperatively (Holmgren et al., 1993). The general well being, gastrointestinal symptoms, autonomic symptoms and nutritional state are generally reported to improve. The sensory motor and autonomic neuropathy usually stops or slows its rate of deterioration and a recent study has shown a lower rate of myelinated axon loss postoperatively compared to non-transplanted patients. The cardiomyopathy, especially in non-Met 30 TTR mutations can progress postoperatively. The global mortality (in first 6 months postoperatively) for liver transplantation in TTR-related FAP is 20% and is mainly related to autonomic involvement, cardiac complications, infections and organ rejection (Planté-Bordeneuve et al., 2000). The length of disease preoperatively, the nutritional status of the patient, the severity of the autonomic involvement and comorbidities are important factors in the outcome. It is not known if the different TTR mutations respond differently to this treatment as most of the experience is with TTR Met 30. Liver transplantation is accepted to be the only effective treatment for TTR-related FAP at present. Life expectancy with TTR-related FAP without a transplant is about 10 years. The estimated 5-year survival rate in recent studies in patients after transplantation is 60%. The timing of the transplant should be early in the course of the disease and research is ongoing to see if there are other factors to help select the best candidates and reduce mortality. Treatments that might prevent amyloid deposition are also being investigated.

Apolipoprotein A-1-related FAP

This type of FAP is associated with deposition of a variant of apolipoprotein A-1 in which there is an arginine for glycine substitution at position 26. It has only been described in one kindred from Iowa (Van Allen et al., 1969) and the phenotype is similar to FAP TTR Met 30 except for a higher incidence of renal amyloidosis and gastric ulcers.

Gelsolin-related FAP

Gelsolin-related FAP was first described in a Finnish kindred in 1969 (Meretoja, 1969) and it is still most commonly seen in Finland but has been identified in other countries including the Netherlands, Japan and Czechoslovakia. It usually presents with a corneal lattice dystrophy in the fourth decade followed later by a progressive cranial neuropathy and a mild sensory and autonomic neuropathy. The constituent fibril protein for this type of FAP is an abnormal fragment of gelsolin. The gene for gelsolin is on chromosome 9 and two point mutations in the gene have been associated with this type of FAP, asparagine for aspartic acid at residue 187 and tyrosine for aspartic acid also at position 187.

Porphyria

The porphyrias are a heterogeneous group of disorders caused by a disruption of heme biosynthesis and are a rare cause of peripheral neuropathy. Heme is synthesized in the liver and bone marrow but neuropathy is only encountered with disorders of liver heme synthesis (hepatic porphyrias). Neuropathy is seen in four types of hepatic porphyrias; acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), variegate porphyria (VP) and aminolevulinic acid (ALA) deficiency (Fig. 68.4).

Figure 68.4 shows the eight enzymes involved in heme synthesis. Deficiency of any of these enzymes causes decreased heme production with resulting accumulation of porphyrins and porphyrin precursors in various tissues. ALA deficiency is a rare autosomal recessive disorder caused by a homozygous deficiency of the enzyme ALA dehydrase. Mutations in the gene for this enzyme on chromosome 9 have been shown to be responsible for this condition (Kaya et al., 1994). Deficiency of ALA dehydrase results in elevation of urinary ALA, minimally elevated urinary porphobilinogen and a marked reduction in ALA dehydrase activity. The most common form of porphyria is AIP, an autosomal dominant disorder caused by a partial deficiency of porphobilinogen (PBG) deaminase. Over a hundred different mutations of the gene for PBG deaminase on chromosome 11 have been described in AIP (Grandchamp, 1998). A rise in urinary and serum PBG and ALA during acute attacks with a reduction of erythrocyte PBG deaminase activity is seen with partial PBG deaminase deficiency. A partial deficiency of coproporphyrinogen oxidase causes the autosomal dominant condition HCP. This is much rarer than AIP and mutations in the gene for coproporphyrinogen oxidase on chromosome 3 have been shown to cause HCP (Cacheux et al., 1994). During acute attacks, the reduction in coproporphyrinogen oxidase activity that can be shown in leukocytes, results in elevation of urinary and fecal coproporphyrin and an elevation of urinary ALA, PBG and uroporphyrin. The fourth neuropathy-associated porphyria is VP, an autosomal dominant disorder due to a partial deficiency of protoporphyrinogen oxidase. The gene for this enzyme is on chromosome 1 and several mutations have been found to be associated with VP with one founder mutation accounting for the high prevalence of this disease in South Africa (Meissner et al., 1996). The biochemical profile here during acute attacks is an increase in urinary ALA, PBG and coproporphyrin with an increase in fecal coproporphyrin and

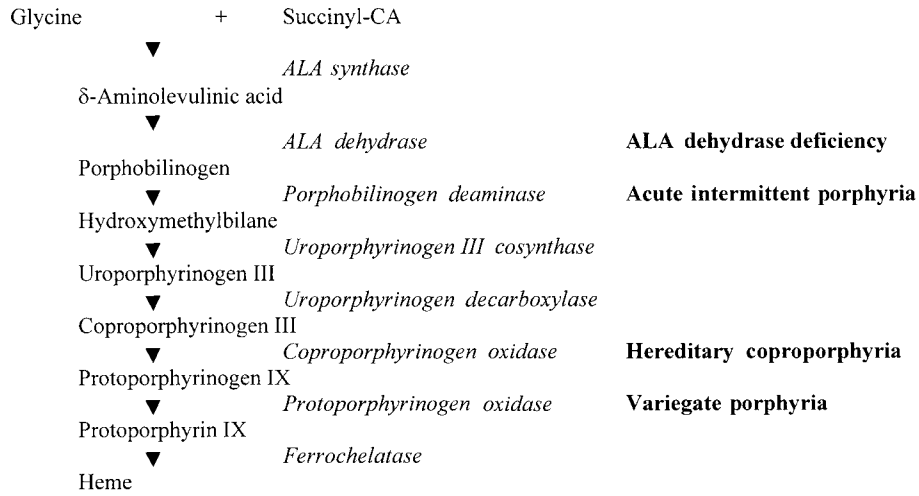

Fig. 68.4. Heme biosynthetic pathway. The eight enzymes in the heme biosynthetic pathway are shown in italics followed by the type of porphyria deficiency of each enzyme causes. Only the porphyrias associated with peripheral neuropathy are shown and are in bold.

protoporphyrin. The activity of protoporphyrin oxidase can be shown to be reduced in leukocytes.

Acute porphyric attacks are associated with neuropathy, CNS symptoms and abdominal symptoms with the addition of skin involvement in HCP and VP. An acute attack usually starts with abdominal symptoms, such as pain, constipation and vomiting. The CNS symptoms include agitation, psychosis, seizures and coma. The neuropathy follows a few days later and is characteristically a patchy motor neuropathy with bulbar involvement mimicking Guillain–Barré syndrome. Autonomic involvement is frequent. Axonal degeneration and chromatolysis are the pathological features described in porphyria. A recent study of motor neuropathy in porphobilinogen deficient mice suggests that heme deficiency may be important in the development of the neuropathy. Acute attacks can be precipitated by drugs, hormonal changes, fasting, alcohol, stress and infection. The list of drugs that can provoke an attack is constantly being updated and includes any drug, e.g. barbiturates, that induces the hepatic microsomal cytochrome P450 system.

A rapid screening test for urinary PBG should be performed when an acute porphyric attack is suspected. If positive the diagnosis should be confirmed by specific quantitative assays in urine, feces and serum. In the latent phase and family studies, enzymatic assays and molecular studies are very useful.

Acute attacks, especially if severe, are now treated with intravenous heme, preferably heme arginate. Carbohydrate administration in the acute attack is also important. Other symptomatic measures, including pain relief, nasogastric feeding, ventilation and seizure treatment may be necessary. The careful use of drugs is important. Prevention of attacks requires the identification of at risk individuals and avoidance of precipitating factors. The mortality from acute attacks has reduced from 30% to less than 10% with modern treatments but the neuropathy, especially if severe, may not recover completely.

Lipid metabolic defects

Metachromatic leukodystrophy

The metachromatic leukodystrophies (MLD) are a group of autosomal recessive disorders characterized by a pathological syndrome of central and peripheral nervous system demyelination and a metabolic abnormality of accumulation of galactosyl sulfatide (cerebroside sulfate) in glia, Schwann cells and macrophages. There are three main types of MLD, late infantile, juvenile and adult onset, which are all caused by a deficiency of arylsulfatase A (cerebroside sulfatase). Mutations in the arylsulfatase A gene on chromosome 22 have been described in all three types of MLD (Gieselmann et al., 1998). Two other rare variants have been described; multiple sulfatase deficiency secondary to deficiencies of arylsulfatases A, B and C and another variant of MLD due to a deficiency of the cerebroside sulfate activator protein, sapsosin B.

The late infantile is the most severe form with onset between 1 and 2 years, starting with ataxia, weakness and hypotonia and gradually progressing to dementia, quadriplegia, blindness, deafness and seizures. Juvenile onset is between 3 and 20 and adult onset is very rare presenting after the age of 21. The adult-onset cases often present with

intellectual deterioration, behavioural disturbances and a peripheral neuropathy. The neuropathy is demyelinating and pathologically shows segmental demyelination and remyelination with the accumulation of metachromatically staining material within Schwann cells and macrophages. Three types of inclusions, Zebra bodies, tuffstone bodies and prismatic inclusions have been shown to account for the metachromatic inclusion material ultrastructurally. The diagnosis is made by assay of arylsulfatase activity in blood leukocytes and serum. MR brain imaging reveals widespread white matter disease. Although the juvenile and adult onset cases progress slowly, the infantile cases usually die before the age of 6. Bone marrow transplantation has been used to replace deficient enzyme activity with varying success (Krivit et al., 1999). Later age of onset and minimal involvement prior to transplantation are the best prognostic factors.

Globoid-cell leukodystrophy (Krabbe disease)

Globoid-cell leukodystrophy (Krabbe disease) is an autosomal recessive disease caused by a deficiency of galactosylceramide ß-galactosidase. The pathological hallmark of the disease is the finding of multinucleated globoid cells in cerebral white matter containing prismatic and tubular inclusions composed of galactosylcerebroside. Many different mutations have been described in the gene for galactosylceramide ß-galactosidase on chromosome 14 (De Gasperi et al., 1996).

The classic form of the disease presents between the ages of 3 and 6 months with motor and intellectual regression. Examination findings include hypertonicity, hyperreflexia, optic atrophy, deafness and evidence of a neuropathy and death usually occurs by 2 years of age. Later-onset cases and even rarely adult-onset cases have been described including presentations with a demyelinating sensory motor neuropathy. Segmental demyelination is seen in the peripheral nerves and a reduction in the myelinated nerve fibre density. Similar inclusions to those seen in the CNS are found in Schwann cells and macrophages. MRI of brain either shows diffuse cerebral atrophy or more distinct white matter changes but the diagnosis is established by the assay of galactosylceramide ß-galactosidase in leukocytes or cultured fibroblasts.

Bone marrow transplantation to replace deficient enzyme activity has been performed successfully in late-onset disease cases.

Adrenoleukodystrophy (ALD) and adrenomyeloneuropathy (AMN)

Adrenoleukodystrophy (ALD) is an X-linked recessive disorder which affects the nervous system and adrenal cortex and is due to an accumulation of very long chain fatty acids (VLCFAs C26: 0 to C22: 0). This accumulation occurs due to defective peroxisomal ß oxidation and ALD is one of a group of disorders, which include classical Refsum disease, in which there is a single peroxisomal enzyme deficiency. Over a hundred mutations have been described in the ALD gene at Xq28 (Moser, 1998), and the protein is located in the peroxisomal membrane and is a member of the family of ABC transporters.

Although many different phenotypes have been described in X-linked ALD, there are two common phenotypes. Classical ALD presents in young males (between 4 and 8 years) and is characterized by progressive dementia, spasticity, deafness and blindness and sometimes adrenal failure. Adrenomyeloneuropathy (AMN) usually presents in adolescence or adult life and may be preceded by hypoadrenalism. It is characterized by a spastic paraplegia and a peripheral neuropathy. Isolated adrenal insufficiency or cerebral dysfunction in adult life are rarer phenotypes. Crucially, there is no evidence for genotype–phenotype specificity even in the same kindred. Pathologically, extensive demyelination is seen in the CNS with lamellar inclusions found in brain macrophages, Schwann cells and the adrenal glands. Nerve conduction studies in AMN cases show a predominant axonal neuropathy and nerve biopsies confirm the presence of Schwann cell inclusions and show loss of all axon types. MRI brain studies show a demyelinating pattern often characteristically involving the parieto-occipital lobes. The diagnosis is based on finding increased VLCFAs in plasma, red blood cells or cultured skin fibroblasts.

Treatment of adrenal deficiency if present is crucial. Restriction of dietary VLCFAs does not cause clinical improvement. 'Lorenzo's oil' (a combination of oleic acid and erucic acid thought to normalize the plasma concentration of C26:0) has not shown improvement in patients with ALD or AMN but is still being assessed in asymptomatic carriers. Immunosuppression has been tried to no effect. Bone marrow transplantation has shown encouraging results in children with classical ALD if they are transplanted when the cerebral involvement is mild.

Neonatal ALD is a rare autosomal recessive progressive neurological disorder belonging to a group of disorders, which includes infantile Refsum disease, in which there is an abnormality of peroxisomal biogenesis rather than a single enzyme defect.

Phytanic acid storage diseases

The main phytanic acid storage disease, classical Refsum disease, is an autosomal recessive disease characterized biochemically by the accumulation of the branched chain

fatty acid, phytanic acid, in serum and tissues. This accumulation occurs because of a deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase, which catalyses the first step in the α-oxidation of phytanic acid to α-hydroxyphytanic acid. Mutations in the gene (PAHX) for phytanoyl-CoA hydroxylase on chromosome 10 have been described in Refsum disease (Mihalik et al., 1997).

Patients usually present in the second or third decade with night blindness due to retinitis pigmentosa and subsequently develop a demyelinating sensory motor neuropathy with or without thickened nerves and a cerebellar ataxia. Other features may include deafness, pupillary changes, cataracts, anosmia, ichthyosis and skeletal abnormalities. CSF protein is generally high with no increase in CSF white cells. The nerve pathology demonstrates diffuse hypertrophy, segmental demyelination, Schwann cell onion bulbs and non-specific inclusions in Schwann cells. The diagnosis is suggested by the finding of raised serum phytanic acid and defective α-oxidation of cultured skin fibroblasts and can be confirmed by genetic analysis. A diet low in phytanic acid is the recognized treatment and if started early and adhered to is very successful. If symptoms suddenly worsen secondary to an increase in phytanic acid (e.g. due to infection), plasma exchange can be beneficial.

Infantile Refsum disease presents early with mental retardation, deafness, retinopathy, hepatomegaly and occasionally a demyelinating neuropathy and is due to abnormal peroxisomal biogenesis.

Fabry disease (alpha-galactosidase deficiency)

Fabry disease is an X-linked disease due to deficiency of the enzyme, α-galactosidase, with resulting accumulation of neutral glycosphingolipids with terminal α-galactosyl moieties especially in vascular lysosomes. Mutations in the α-galactosidase gene on chromosome Xq22 have been described in Fabry disease (Desnick et al., 1995).

The clinical features of the disease, which usually begins in childhood or adolescence, include burning pain secondary to a neuropathy, a maculopapular rash (angiokeratoma corporis diffusum) in the 'bathing trunk' area, hypertension, renal failure, cardiovascular and cerebrovascular disease and corneal opacification. Pathologically, loss of unmyelinated and small myelinated fibres is described and lipid deposition in the nervous system is seen in vascular elements supplying the nerves, perineurial cells and ganglion cells. The diagnosis is suggested by reduced α-galactosidase activity in leukocytes or cultured skin fibroblasts and can be confirmed by genetic studies. Treatment is largely symptomatic including renal dialysis and renal transplantation, management of pain, hypertension and cardiovascular and cerebrovascular complications. Trials of treatment including direct replacement of the deficient enzyme look promising and gene therapy studies in mice suggest that gene therapy may be a viable future treatment.

Hereditary lipoprotein deficiencies

Hereditary high density lipoprotein deficiency (Tangier disease) is a rare autosomal recessive disorder, originally described on Tangier island, characterized biochemically by very low levels of plasma high density lipoprotein (HDL) and pathologically by deposition of cholesteryl esters in many tissues. This disease is due to mutations in the gene encoding the ATP-binding cassette transporter (ABC1) on chromosome 9q31 (Brooks-Wilson et al., 1999).

The most common clinical manifestations of the disease are a neuropathy, hypersplenism, hyperplastic orange tonsils and premature coronary artery disease in some patients. The neuropathy can present in three different ways; a relapsing asymmetric mononeuritic type of neuropathy, a slowly progressive symmetric polyneuropathy and finally a slowly progressive neuropathy characterized by facial and small hand muscle weakness with a dissociated loss of pain and temperature sensation in a syringomyelic-like manner. Pathologically, clear vacuoles are seen in Schwann cells of unmyelinated and small myelinated fibres. The diagnosis is suggested by very low plasma HDL levels, very low plasma cholesterol levels and normal or increased triglyceride levels. Genetic testing can also be done. The prognosis is usually good.

Abetalipoproteinemia (Bassen–Kornzweig disease) is a rare autosomal recessive disease characterized by the virtual absence of apolipoprotein B (ApoB)-containing lipoproteins (that is low density lipoproteins (LDL) and very low density lipoproteins (VLDL)) from plasma. This disease is associated with mutations in a gene encoding a microsomal triglyceride transfer protein (MTP) on chromosome 4q22–24 (Sharp et al., 1993).

The disorder may present in infancy with fat malabsorption or failure to thrive and most people have neurological involvement by age 20. The main neurological features are ataxia, dysarthria, areflexia and proprioceptive loss. A pigmentary retinopathy and extensor plantar responses may also be found. Clinical evidence of a peripheral neuropathy is rarely seen but sensory action potentials may be reduced. Pathologically the neurological features are due to the degeneration of the large sensory neurons of the spinal ganglia. The neurological manifestations are thought to be due to a secondary deficiency of vitamin E. The diagnosis is suggested by characteristic lipoprotein findings (very low VLDL and LDL and normal HDL) in

association with reduced cholesterol and triglycerides. Acanthocytes are commonly seen and vitamin E levels are reduced. Mutational analysis can also be performed. The treatment is vitamin E supplementation. Vitamins A and K are also given when neccessary.

Familial hypobetalipoproteinemia is another rare disorder with the same lipid/lipoprotein profile and the same, if less severe, neurological features in affected patients as abetalipoproteinemia but it is caused by mutations in the ApoB gene. Chylomicron retention disease is another rare ApoB deficient disease in which chylomicrons are absent in plasma.

Cholestanolosis (cerebrotendinous xanthomatosis)

Cholestanolosis (CTX) is a rare autosomal recessive disorder characterized by the accumulation of cholestanol and cholesterol in many tissues especially the nervous system (Thomas, 1993), secondary to a deficiency of the enzyme 27-hydroxylase. Mutations in the gene (*CYP27*) for this enzyme on chromosome 2 have been reported to cause cholestanolosis (Shiga et al., 1999). The disease starts in adolescence or late childhood and the clinical features include dementia, ataxia, a peripheral neuropathy, premature atherosclerosis and the finding of tendon and tuberose cutaneous xanthoma. The neuropathy is mainly sensory and is predominantly an axonopathy on nerve biopsy. The diagnosis is suggested by the finding of a high plasma cholestanol and normal plasma cholesterol and can be confirmed genetically. The treatment is with oral chenodeoxycholic acid to reduce the formation of cholestanol.

Sphingomyelin lipidoses (Niemann–Pick disease)

There are four types of autosomal recessive Niemann–Pick disease (NPD types I to IV or types A to D). Types A and B are true sphingomyelin lipidoses where there is a deficiency of sphingomyelinase (ASM) and accumulation of sphingomyelin in tissues. The gene for ASM is on chromosome 11 and mutations in this gene have been described in NPD types A and B. NPD types C and D have normal ASM activity and are due to abnormalities in cholesterol transport with accumulation of cholesterol in lysosomes. Mutations in the NPC1 gene on chromosome 18q11 account for most cases of NPD C and D. Type A is a fatal degenerative disorder of infancy characterized by dementia, seizures, retinal cherry red spots, hepatosplenomegaly and rarely a peripheral neuropathy. The neuropathy is characterized by segmental demyelination and remyelination, Schwann cell and axon lipid inclusions and endothelial foam cells. Type B is milder with no neurological involvement. Neurological involvement is seen in types C and D but neuropathy has only been described in type D. Types A and B are diagnosed by deficient ASM activity in leukocytes and genetic analysis. Gene therapy and enzyme replacement therapy are being researched as future treatments.

Other inherited neuropathies

Disorders with defective DNA repair

Ataxia telangiectasia (AT) is an autosomal recessive disorder characterized at the cellular level by radiosensitivity and chromosomal instability. Mutations in the gene for AT (ATM) on chromosome 11q22–23 have been described in AT. Clinically, a neurological disorder, oculocutaneous telangiectasia and immunological deficiency are seen. The neurological disorder starts in early childhood with cerebellar ataxia, oculomotor dyspraxia and oculocutaneous telangiectasia. Choreoathetosis and a neuropathy may occur. The neuropathy is characterized pathologically by a loss of large myelinated fibres. Impaired humoral and cellular immunity cause an increased incidence of infections and lymphoreticular malignancies. Endocrine abnormalities such as delayed sexual maturity and glucose intolerance may occur. The diagnosis is suggested by raised α-fetoprotein and can be confirmed by lymphocyte and fibroblast irradiation sensitivity studies and genetic analysis. There is no specific treatment.

Xeroderma pigmentosum (XP) is also a rare autosomal recessive disorder in which there is an increased frequency of sunlight-induced skin cancers as a result of defects in DNA repair or replication after damage by ultraviolet irradiation (UV) or various chemical carcinogens. XP has been divided into seven forms with defective excision repair (XPA to XPG) and another form with a defect in replication of damaged DNA sites (XPV). Eight genes have been identified in XP (Cleaver et al., 1999). The neurological forms of XP (XPA, B, D and G) can have mental retardation, spasticity, seizures, deafness, ataxia, dystonia and a neuropathy. Pathologically the sensory fibres are involved to a greater degree and there is loss of both myelinated and unmyelinated axons. Laboratory testing of the UV sensitivity of fibroblasts and of excision repair are the mainstay of diagnosis although genetic testing will become increasingly available. Treatment is aimed at early diagnosis, genetic counselling and crucially skin care.

Cockayne syndrome (CS) is another very rare condition in which a neurological disorder, short stature and an increased frequency of skin cancer is seen. There are three types of CS (A, B and C) and the genes for types A and B have been cloned (on chromosomes 5 and 10q11–21,

respectively) (Cleaver et al., 1999). The clinical syndrome includes early presentation with sun sensitivity, progeria, growth retardation, mental retardation, deafness, pigmentary retinopathy, ataxia and a demyelinating neuropathy. Segmental demyelination is seen on nerve biopsy. Although genetic analysis will become increasingly available, the diagnosis presently is made by the demonstration of hypersensitivity to killing by UV in cultured CS cells and by delayed recovery of DNA and RNA synthesis following UV radiation.

Neuroacanthocytosis

Neuroacanthocytosis is characterized by a combination of a movement disorder, cognitive dysfunction, an axonal neuropathy and the finding of acanthocytes on blood film. The genetics of this disease are believed to be heterogeneous but most cases are thought to be autosomal recessive. There is one recent report of linkage to chromosome 9q31 in one patient thought to have autosomal recessive neuroacanthocytosis. The age of onset is usually between the third and fifth decade. The movement disorder is variable with chorea, dystonia and tics all being described but the most frequent finding is an orofacial dyskinesia, often with tongue and lip biting. Although the tendon reflexes are often depressed or absent and there may be distal amyotrophy, there is usually no weakness. Sensory action potentials are reduced and denervation changes are seen with normal motor conduction velocities. The pathology is that of an axonopathy. The diagnosis depends on examining fresh blood films for acanthocytes in appropriate clinical circumstances.

A neuropathy can be seen in other inherited diseases such as the hereditary ataxias and the mitochondrial disorders and these are covered elsewhere in this volume.

Disorders of neuromuscular junction transmission

Vinay Chaudhry and Daniel B. Drachman

Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Basic concepts and classification

The neuromuscular junction (NMJ) is undoubtedly the most intensively studied, best understood, and arguably the simplest of mammalian synapses. Its role is to amplify the relatively weak electrical impulses that travel down the motor nerve sufficiently to trigger electrical impulses in the much larger muscle cell, and thereby lead to muscle contraction. It accomplishes this by translating the neural electrical impulse to a chemical signal, acetylcholine (ACh), which in turn elicits an amplified electrical depolarization at the level of the muscle. A single event of neuromuscular transmission takes place in less than a millisecond. Although this process is normally powerful, swift and efficient, it is highly vulnerable to a wide variety of insults, including genetic errors, autoimmune diseases, biological poisons made by bacteria, plants and animals, and pharmacological drugs or chemical warfare agents manufactured by humans. Any alteration in the highly complex and coordinated processes of ACh synthesis, storage and release; transmission across the junction; structure or function of the acetylcholine receptors (AChRs); termination of the event by the enzyme acetylcholinesterase (AChE); or impairment of neighbouring ion channels, can lead to muscular weakness. In this sense, the junction is the Achilles heel of the neuromuscular system. In order to understand the many disorders that can affect the NMJ, it is important to review the basic anatomy and physiology of neuromuscular transmission.

Although one motor nerve cell may innervate as few as 3 or as many as 1500 muscle fibres, each mature muscle fibre is innervated by only a single axonal branch, and has only a single NMJ. The junction is comprised of contributions from both the motor nerve and the muscle cell, including: a motor nerve fibre which branches to form specialized nerve terminals; the basal lamina which intervenes between nerve terminals and muscle cells; the highly invaginated postsynaptic membrane, with concentrations of AChRs at the peaks of the primary folds; AChE in secondary folds; and Schwann cells that roof over the NMJ (Fig. 69.1). In simplest outline, the process of neuromuscular transmission begins with an action potential that depolarizes the motor nerve terminal, triggering the entry of calcium, which leads to the release of ACh from storage vesicles in the nerve terminals. The released ACh binds to AChRs on the apposed muscle membrane. This produces opening of the AChRs' cation channels, which depolarizes the muscle membrane, and triggers muscle contraction. Every aspect of the biology of the NMJ has turned out to be far more complex than was previously envisioned (Boonyapisit et al., 1999; Lindstrom, 2000). The following section summarizes the basic concepts that relate to disorders covered in this chapter.

Presynaptic events

Acetylcholine synthesis, storage, and release

ACh is synthesized in the motor nerve terminal by the enzymatic action of choline acetyltransferase, and is stored in synaptic vesicles for subsequent release. It has been estimated that each vesicle, or 'quantum', normally contains approximately 10 000 ACh molecules, termed the 'quantal size'. ACh release occurs by exocytotic fusion of the vesicles with the nerve terminal membrane at 'preferred' release sites, that are situated directly opposite the areas of highest concentration of AChRs on the postsynaptic membrane. The vesicle's cycle involves synthesis and loading of ACh, docking of the vesicle at the release site, fusion of the vesicle and nerve terminal membranes, release of ACh and finally recycling of the vesicle. The processes involved in quantal

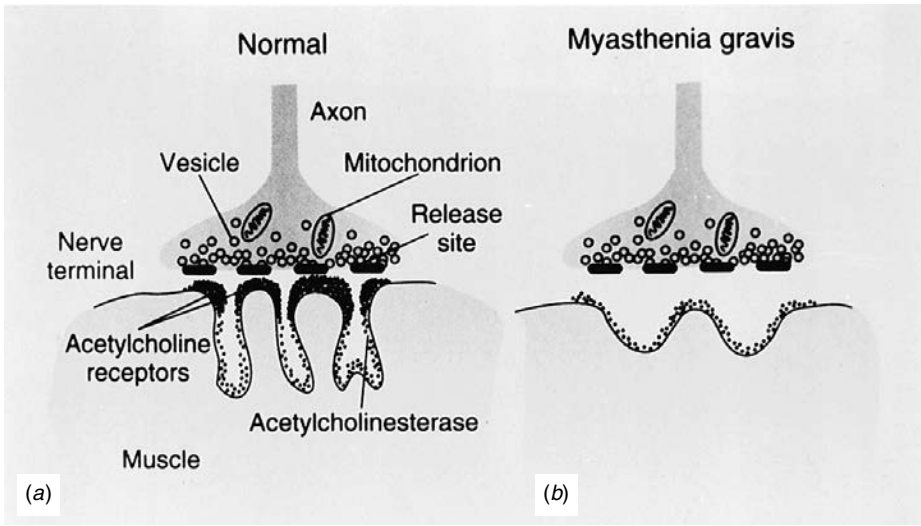

Fig. 69.1. (*a*) Normal (left) and myasthenic (right) neuromuscular junction. In neuromuscular junctions, vesicles release acetylcholine at specialized release sites of the nerve terminal. Acetylcholine crosses the synaptic space to reach receptors that are concentrated at the peaks of junctional folds. Acetylcholinesterase in the clefts rapidly terminates transmission by hydrolyzing acetylcholine. The myasthenic junction has reduced numbers of acetylcholine receptors, simplified synaptic folds, a widened synaptic space, and a normal nerve terminal. (From Drachman, 1994. Reprinted with permission. Copyright 1994 Massachusetts Medical Society. All rights reserved.)

ACh release are now known to involve more than a dozen identified proteins. Destruction of any of these proteins, for example by specific enzymatic cleavage produced by the different strains of botulinum toxin, results in blockade of quantal ACh release and paralysis (see below).

Normally, quantal release of ACh occurs both spontaneously, and in response to nerve impulses. Spontaneous release of ACh involves single vesicles, and gives rise to local low-amplitude depolarizations of the muscle membrane, or 'miniature end-plate potentials' (mepps). When an electrical impulse invades the motor nerve terminal much greater numbers of ACh vesicles (50 to 300, termed the 'quantal content') are released . This results in a larger muscle membrane depolarization, the 'endplate potential', which normally elicits an action potential that is propagated along the muscle membrane, and triggers muscle contraction. Impulse-dependent ACh release is initiated by the influx of calcium through voltage-gated calcium channels (VGCC), which are situated near the release sites, and are arranged in parallel double rows. Interference with the VGCC, for example by autoantibodies in the Lambert–Eaton Myasthenic Syndrome (LEMS), impairs ACh release, and results in muscle weakness (see below). Several toxins, produced by the Funnel web spider and certain cone snails also bind to these calcium channels and block their function. These toxins are useful in diagnostic assays of autoantibodies to the VGCCs in LEMS.

Postsynaptic events

The acetylcholine receptor

The structure, molecular biology, and function of skeletal muscle AChRs are now known in exquisite detail, and have led to the understanding and treatment of autoimmune myasthenia gravis (MG), the genetically determined congenital myasthenic syndromes, and the effects of numerous pharmacological and toxic agents (Lindstrom, 2000). The AChR is a glycoprotein with a molecular weight of approximately 250 000, that is composed of five subunits arranged like barrel staves around a central channel, and projects through the NMJ membrane. In adult innervated muscle the AChR is comprised of two α-subunits, one β-subunit, one δ-subunit, and one ε-subunit (Fig. 69.2). In immature or denervated muscle, a γ-subunit substitutes for ε (Kistler et al., 1982; Unwin, 1995). Each of the subunits has four hydrophobic domains, implying that they traverse the muscle membrane four times, with both the amino and carboxyl termini located extracellularly. The genes for all the subunits have been completely sequenced (Stevens, 1987). Although each subunit is encoded by a distinct gene, the different subunits have considerable homology to each other, suggesting a common ancestral origin. Each α-subunit has one binding site for ACh, that is located extracellularly, centred around amino acids 192 and 193, at

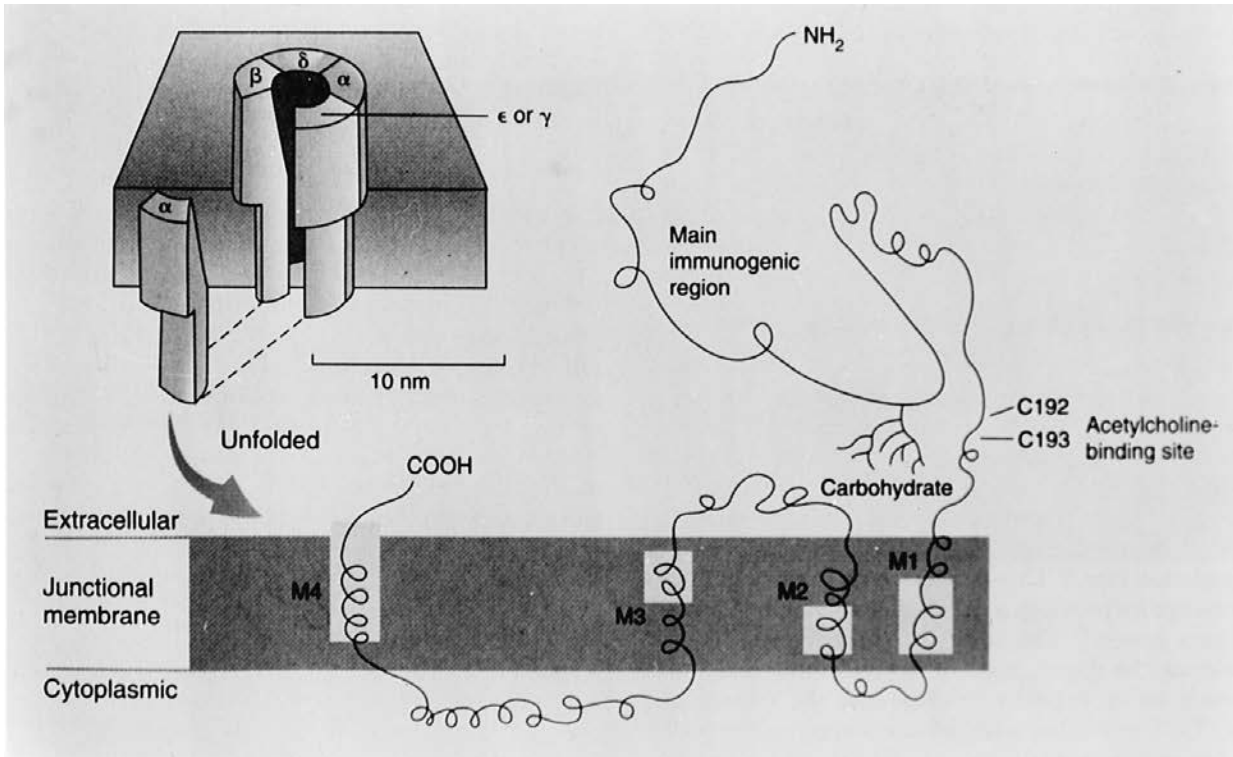

Fig. 69.2. The acetylcholine receptor. The subunits of the acetylcholine receptor – α, β, δ, and λ or ε – are arranged like barrel staves around the central iron pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3, and M4). In the unfolded view of the α subunit, the amino terminal end of the α subunit is extracellular, where it is accessible to the acetylcholine, which binds at the site shown (amino acids 192 and 193). In myasthenia gravis, autoantibodies may bind to various epitopes of all subunits, but a high proportion of antibodies bind to the main immunogenic region of the α subunit. (From Drachman, 1994. Reprinted with permission. Copyright 1994 Massachusetts Medical Society. All rights reserved.)

the interfaces between the α- and δ-subunits, and the α- and γ- or ε-subunits. Functionally, the ion channel of the AChR is closed in the resting state. When both α subunit binding sites are occupied, the AChR molecule twists slightly like a Chinese purse, opening the channel transiently, and allowing the rapid passage of cations. The channel properties of normal and pathologic AChRs have been studied by patch clamp techniques and noise analysis. Abnormalities of AChR channel properties are responsible for some of the congenital myasthenic syndromes (see below.)

AChRs are normally clustered at high concentrations (15 000 to 20 000/μ^2) at the peaks of folds of the NMJ, opposite the motor nerve's ACh release sites. Clustering of AChRs at the NMJ is dependent on motor innervation, and involves the interaction of several anchoring proteins, including rapsyn, agrin, utrophin, dystroglycan, and MuSK (muscle specific receptor protein kinase). MuSK is of particular interest, since it has recently been shown to be a target for antibodies in patients with 'antibody negative MG' (Hock et al., 2001).

AChRs normally undergo continual turnover at the neuromuscular junction. Motor nerves have an important role in this process, regulating the synthesis, subunit composition, distribution, and degradation of AChRs. In muscles with an intact nerve supply, AChRs are localized nearly exclusively at the NMJ, have an ε-subunit rather than a γ-subunit, and are quite stable (half-life of 11 days in mice). Following denervation, the rate of AChR turnover increases (<24 hrs in mice), and new AChRs are also synthesized at an increased rate. The AChRs in denervated muscles contain γ-subunits instead of ε-subunits. These AChRs are distributed over the entire length of the muscle cell membrane (Lindstrom et al., 1988). There is substantial evidence that ACh transmission plays a key role in the neural regulation of these properties. Impairment of neuromuscular transmission in MG may be responsible for increased transcription of AChR genes that has been

reported in an experimental animal model of MG. These processes of turnover and renewal of junctional AChRs permit virtually complete recovery in MG once the autoimmune attack has been brought under control.

Synapse

Acetylcholinesterase

AChE is a glycoprotein enzyme that is is bound to the basal lamina at the postsynaptic membrane of the NMJ, and is most highly concentrated in the secondary clefts. Its function is to hydrolyse ACh rapidly, and thus terminate the process of neuromuscular transmission, permitting repeated activation of the muscle fibre. The molecular structure and function of AChE are now known in detail, and this knowledge has facilitated the understanding of genetic mutations causing endplate AChE deficiency (see below). Drugs that inhibit AChE permit the released ACh to interact repeatedly with AChRs, and are used to improve neuromuscular transmission in MG and some of the congenital myasthenic syndromes. However, failure to remove ACh may cause the AChRs to become desensitized, or unresponsive to further application of ACh. Over the longer term, persistent cholinergic stimulation results in excitotoxic damage to the endplate. This may result from the use of excessive amounts of anti-AChE drugs; from exposure to organophosphate insecticides or war gases, which produce paralysis by irreversibly blocking AChE; or as a consequence of one of the genetic defects in the AChE molecule (see below).

Safety margin of neuromuscular transmission

The concept of the 'safety margin' is useful in understanding disorders of neuromuscular transmission (Waud, 1971). Under normal circumstances, the amplitude of the endplate potential is more than necessary to produce an action potential that triggers muscle contraction. The excess, termed the 'safety margin', depends on several factors: the amount of ACh released by a nerve impulse, the number and functional integrity of AChRs present at the NMJ, and the sensitivity of the neighbouring muscle membrane to propagate an action potential (Vincent et al., 2000). Any reduction in the safety margin may result in failure of neuromuscular transmission. When transmission fails at many junctions, the power of the whole muscle is reduced, which is clinically manifested as weakness. If the safety margin is borderline, repeated stimulation may result in a progressive decline in muscle power, or 'neuromuscular fatigue'. This is a consequence of the reduced safety margin, in combination with the normal phenomenon of ACh 'rundown': During repeated nerve stimulation, the amount of ACh released per impulse normally declines (runs down) after the first few impulses, since the nerve terminal is not able to sustain its initial rate of release (Stalberg et al., 1976). When the number of ACh–AChR interactions falls below the threshold, transmission fails, resulting in progressive failure of contraction of muscle fibres, or 'fatigue'. In healthy individuals, the safety margin is sufficient so that transmission failure and fatigue do not occur except at very rapid rates of nerve stimulation, above 40 or 50 Hz.

Classification of disorders of neuromuscular junction

For the purpose of classifying disorders of the neuromuscular junction, it is convenient to consider those that interfere with presynaptic functions, including the synthesis, storage and release of ACh; abnormalities at the postsynaptic level, involving the AChRs or their channels; and disorders at the synaptic level, which disturb the function of AChE. A classification of the different disorders based on this scheme is given in Table 69.1.

Postsynaptic acquired disorders of neuromuscular transmission

Autoimmune myasthenia gravis

Myasthenia gravis is an autoimmune disorder characterized clinically by weakness and fatigability of skeletal muscles. The pathogenesis of MG involves a reduction in the number of available AChRs at neuromuscular junctions, due to an antibody-mediated immune response. It is not rare, with a prevalence that has recently been assessed to be as high as 2 to 7 per 10 000 population in Great Britain (MacDonald et al., 2000) to ~1.5/10 000 in central and Western Virginia (Phillips et al., 1992). The disease may present at any age, but there is a bimodal peak of incidence, involving younger women (third decade) and older men (sixth and seventh decades). Although the clinical features were first recognized more than 300 years ago, important progress in our understanding of the pathophysiology, immunology and molecular basis of MG has been made during the past 30 years, and this knowledge has been applied directly to the effective diagnosis and treatment of this formerly 'grave' disease. Clinically, the cardinal features of MG are weakness and fatigability of skeletal muscles, often in a characteristic distribution. Diagnosis

Table 69.2. Modified Osserman grading for myasthenia gravis (Jablecki, III et al., 2000)

	Any ocular muscle weakness	Limb or/ and axial muscles	Oropharyngeal or/and respiratory muscles	Intubation ± mechanical ventilation
I	+ to +++	−	−	−
IIa	± to +++	+	±	−
IIb	± to +++	±	+	−
IIIa	± to +++	++	±	−
IIIb	± to +++	±	++	−
IVa	± to +++	+++	−+	−
IVb	± to +++	−+	+++	+/−
V	± to +++	±	± to +++	+ to +++

Notes:
+ = present; − absent; ± = may be present; + = mild; ++ = moderate; +++ severe.

involves electrophysiological and immunological testing. Treatment is directed toward enhancing neuromuscular transmission, and especially toward suppressing the underlying autoimmune process. Properly treated, the great majority of myasthenic patients can be restored to fully productive lives.

Clinical features

The clinical symptoms may be so characteristic that the diagnosis can be made on history alone, though atypical cases may go undiagnosed for years. The presenting complaint consists of muscle weakness, often in a distinctive distribution, with increasing fatigue following repeated or sustained exertion. The elevators of the eyelids and the extraocular muscles are affected very early in about 60% of patients, and ptosis of the lids and diplopia occur at some time in the course of the disease in about 90%of myasthenic patients. Weakness remains confined to these muscles in a small minority (about 15%) of patients, and if it does not involve other muscle groups for 3 years or more, there is a good probability that it may persist as purely 'ocular MG' (Grob et al., 1987). In about 85% of patients, symptomatically significant weakness spreads to affect other areas as well. Involvement of the facial and bulbar muscles may give rise to a characteristic 'snarling' expression on attempting to smile, 'mushy' or nasal speech, and difficulty in chewing and swallowing. Generalized weakness often affects the limb muscles, commonly in a proximal distribution, as well as the diaphragm and neck extensor muscles. If impairment of respiration or swallowing becomes so severe as to require mechanical assistance with respiration or feeding, the patient is said to be in 'crisis'.

On physical examination, the findings are limited to the motor system, without alteration of reflexes, sensation or coordination. There are often distinctive patterns of selective weakness. Asymmetrical ptosis is a common feature. When the examiner lifts one eyelid, ptosis of the other lid may increase ('Cogan's see-saw sign'). The combination of ptosis (weakness of levator palpebrae) and weakness of eyelid closure (orbicularis oculi) muscles is characteristic of MG. Diplopia may occur on gaze in several different directions, due to weakness of more than one extraocular muscle, which may be variable and difficult to define. The baseline strength of the patient should be documented quantitatively, for later evaluation of the results of treatment. The most useful quantitative measures include timed forward arm abduction and lid elevation (up to 5 minutes), vital capacity, and dynamometry of selected weak muscles. The overall severity of MG is usually graded functionally and regionally, according to a modification of a scale proposed originally by Osserman, and recently standardized by an ad hoc committee (Table 69.2) (Jablecki, III et al., 2000): Class I: any ocular muscle weakness; may have weakness of eye closure; all other muscle strength is

normal; Class II: mild weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity (IIa: predominantly affecting limb, axial, or both, may have lesser involvement of oropharyngeal muscles; IIb: predominantly affecting oropharyngeal, respiratory muscles, or both: may have lesser or equal involvement of limb, axial muscles); class III: moderate weakness affecting other than ocular muscles; may also have ocular muscle weakness (IIIa: predominantly affecting limb, axial, or both, may have lesser involvement of oropharyngeal muscles; IIIb: predominantly affecting oropharyngeal, respiratory muscles, or both, may have lesser or equal involvement of limb, axial muscles); class IV: severe weakness affecting other than ocular muscles; may also have ocular muscle weakness of varying severity (IVa: predominantly affecting limb, axial, or both, may have lesser involvement of oropharyngeal muscles; IVb: predominantly affecting oropharyngeal, respiratory muscles, or both- may have lesser or equal involvement of limb, axial muscles); class V: defined by intubation with or without mechanical ventilation, except when employed during routine postoperative management. The use of a feeding tube without intubation places the patient in class IVb.

Pathophysiology

The basic abnormality in MG is a reduction in the number of available AChRs at neuromuscular junctions (Drachman, 1994). This was originally demonstrated by the use of a radioactively labelled snake toxin, α-bungarotoxin (αBuTx), which binds specifically, quantitatively, and irreversibly to AChRs of skeletal muscles, permitting accurate measurement of the numbers of AChRs. Studies of muscle biopsies showed that NMJs of myasthenic patients had on average only one third as many AChRs as those of normal individuals. In general, the clinical severity of MG correlated with the reduction of AChRs, although even patients with purely ocular weakness had reduced numbers of AChRs in clinically strong limb muscles. Neuromuscular junctions from myasthenic patients also show morphological changes of simplification of the postsynaptic membranes, and an increase in the width of the gap between pre- and postsynaptic membranes, visualized by electron microscopy. These changes at the NMJ produce a reduced 'safety margin' for NM transmission, and account fully for the clinical and electrophysiological features of MG. The amplitude of endplate potentials is reduced, with failure of transmission at some fibres, and a decrease in the overall power of muscular contraction, clinically manifested as weakness. Fatigue on repeated or sustained contraction (or a decremental response to electrical stimulation of the nerve) results from the abnormally reduced safety margin in MG in conjunction with the normal phenomenon of ACh 'rundown', described above.

Immune pathogenesis of MG

It is widely accepted that the neuromuscular abnormalities in MG are due to antibody mediated processes (Lindstrom et al., 1988; Ragheb & Lisak, 1998). Many lines of evidence support this concept: First, 80 to 90% of myasthenic patients have antibodies directed against AChR, that are detected by a standard radioimmunoassay (RIA). The RIA measures serum IgG that binds to human AChR that has been solubilized and tagged with ^{125}I-labelled αBuTx. Secondly, the pathogenic antibody binds to the target antigen, AChR at neuromuscular junctions, in myasthenic patients. Thirdly, passive transfer of IgG from myasthenic patients to experimental mice reproduces the disease features. Fourthly, immunization of a wide variety of experimental animals with purified AChR produces an experimental model of MG (experimental autoimmune MG, or EAMG) that has proven useful for testing new therapeutic strategies. Finally, treatments that lower AChR antibody levels result in improvement of the disease.

AChR antibodies have been shown to reduce the number of available AChRs by three different mechanisms (Drachman et al., 1982: (i) cross-linking of AChRs by the divalent antibodies, which accelerates endocytosis and degradation of the AChRs by the muscle cells; (ii) blockade of the receptors' ACh binding sites by antibody; (iii) complement-mediated damage to neuromuscular junctions. Antibodies from some myasthenic patients have a more pronounced effect on degradation of AChRs, while others produce more marked blockade of receptors. Their particular functional properties are probably related to the specific epitopes of the AChR to which they bind. However, the ability of the serum to induce loss of available AChRs by a combination of these mechanisms corresponded most closely to the clinical severity of the patient's MG.

Antibody-negative MG

About 10 to 20% of patients with acquired MG do not have AChR antibodies detectable by RIA. Although this includes patients with mild localized MG, there is also a subgroup with generalized MG, whose disease corresponds to conventional MG with respect to most other clinical, diagnostic, and therapeutic properties (Mossman et al., 1986). Actually, these patients have circulating antibodies that are not detected by the conventional RIA, but do cause accelerated degradation of AChRs in culture systems, and are capable of inducing features of MG by passive transfer to mice. A recent report suggests that at least some of these sera have antibodies that bind to MuSK, a muscle specific

protein kinase that plays a key role in anchoring AChRs at the neuromuscular junction (Hoch et al., 2001). Taken together, these findings indicate that 'antibody-negative' MG is an antibody-mediated autoimmune disorder directed against one or more components of the NMJ that are not detected by the standard anti-AChR RIA.

Role of T-cells in MG

Although production of the pathogenic antibodies in MG is directly attributable to B-cells, T-cells play a pivotal role in the disease process by providing help that is essential for the antibody production (Ragheb & Lisak, 1998). The requirement for T-cells has been formally demonstrated in EAMG in rats, and there is extensive evidence that T-cells play a key role in the autoantibody response in human MG (Newsom-Davis et al., 1989). T-cells from myasthenic patients respond to stimulation with AChR, and augment the production of AChR antibody in vitro. AChR-reactive T-cell lines or clones have been isolated from the peripheral blood lymphocytes or thymuses of myasthenic patients. In contrast to their role in AChR antibody production, T-cells do not act as effector cells in MG. It is noteworthy that lymphocytes from some normal individuals can also respond to AChR, although AChR-specific T-cells are more numerous in myasthenic patients. This is consistent with the concept that potentially autoreactive T-cells can exist in the normal immune system.

Analysis of AChR-specific T-lymphocytes from myasthenic patients has revealed striking heterogeneity in their patterns of responsiveness. The T-cells of each individual respond to a great variety of AChR epitopes, and there are significant differences in the epitopes to which T-cells of different patients respond. The majority of T-cell recognition sites are on the α subunit, but T-cells recognize epitopes on the other subunits as well. Attempts to analyse the repertoire of T-cell receptors that recognize AChRs have not shown a consistent or restricted pattern. The striking heterogeneity of AChR-specific T-lymphocytes must be taken into account when designing specific immunotherapeutic approaches aimed at these T-cells.

Etiology of MG

The origin of the autoimmune response in MG remains an unsolved problem, as is also true in virtually all human autoimmune diseases. The heterogeneity of the repertoires of the AChR-specific autoantibodies and T-cells argues that multiple different factors may trigger MG. The thymus has been implicated as a possible site of origin of MG for several reasons. Approximately 75% of MG patients have thymic abnormalities. Of these, 85% have hyperplasia (germinal centre formation), and 15% have thymic tumours. Thymectomy results in improvement in a majority of patients. Both T- and B-lymphocytes from the thymus of myasthenic patients are more responsive to stimulation with AChR than are peripheral blood lymphocytes from the same patients. In addition to lymphocytes, thymus glands from normal and myasthenic individuals contain muscle-like ('myoid') cells that express surface AChRs. Because of their strategic location within the thymus, surrounded by antigen presenting cells (APCs), and helper T-cells, these AChR-bearing myoid cells are thought to be the source of the autoantigen, AChR. Some alteration of the myoid cells or the lymphocytes may break tolerance, and lead to the autoimmune response. Attempts to implicate viruses as possible agents in precipitating the autoimmune response have been unsuccessful. Viruses could not be cultured from MG thymus tissue in recent onset cases, and antibody titres against a number of common viruses do not differ from those in matched controls. The hypothesis that MG may be triggered by 'molecular mimicry', that is, an immune response to an infectious agent that resembles the AChR, has some support. Antibodies from 6 of 40 patients with MG recognized a peptide sequence of herpes simplex virus that is similar to a sequence of the AChR α-subunit. Cross-reactivity between bacteria and the AChR has also been reported. Genetic factors may influence the likelihood of developing MG. There is a weak to moderate association of MG with the HLA antigens B8 and Drw3 in Caucasians, but Japanese and Chinese patients have different HLA associations. A wide variety of other autoimmune diseases have been reported to occur in some myasthenic patients and their relatives, supporting a defect in immune regulation as a possible causative factor, and suggesting that the predisposition may be inherited.

Diagnosis of MG

The diagnosis of MG usually commits both the patient and the physician to long-term medical treatment and/or surgery, and entails substantial risks. It is therefore essential: (i) to establish the diagnosis unequivocally; (ii) to exclude other conditions that may masquerade as MG; and (iii) to search for associated conditions that may influence the choice of treatment. The history and physical examination (above) are usually the most important initial clues to the clinical diagnosis of MG. However, the clinical impression must be confirmed by further diagnostic testing before initiating treatment.

Anticholinesterase (AChE) test

Inhibition of the enzyme AChE allows the ACh released from the motor nerve to interact repeatedly with the limited number of AChRs at myasthenic NMJs, resulting in

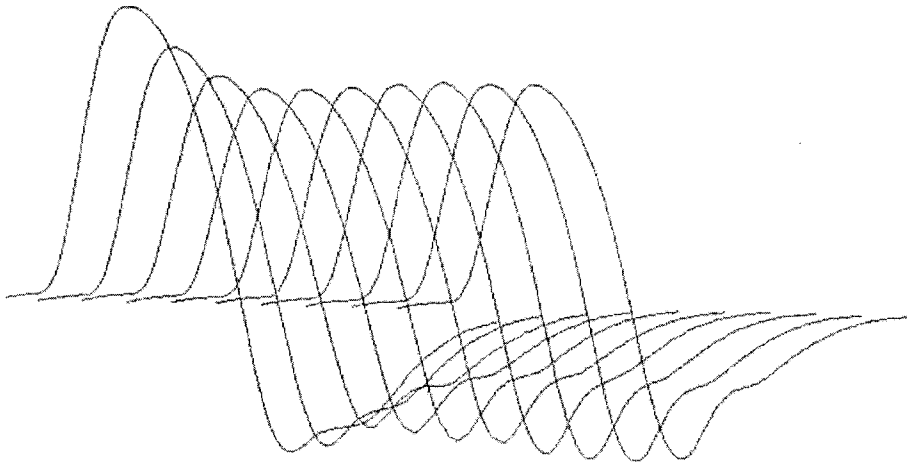

Fig. 69.3. Repetitive nerve stimulation at 3 Hz. shows a decrement of 27% from the first to the fourth response.

at least partially improved muscle strength. Edrophonium (Tensilon®) is commonly used intravenously for diagnostic testing, because of the rapid onset (30 seconds) and short duration (~5 minutes) of its anti-AChE effect (MacDonald et al., 2000). It is essential to select one or more muscles that are unequivocally weak for observation before and after administration of edrophonium. Because edrophonium occasionally produces side effects of bradycardia or hypotension, atropine sulfate (0.6 mg) should be on hand for i.m. or i.v. injection. Initially, 2 mg of edrophonium is injected i.v., and the muscle response is observed for 60 seconds. If there is definite improvement in an objectively weak muscle, the test is considered positive. If the result is doubtful or negative, further injections of 4 to 8 mg are carried out. False-positives may occur in a number of non-myasthenic conditions including brainstem lesions, oculomotor denervation and even in normal control subjects. False-negatives may also occur in myasthenic patients.

Electrophysiologic testing

The *repetitive nerve stimulation* (RNS) test is carried out by supramaximal electrical stimulation of a nerve, while recording the compound muscle action potentials from surface electrodes over the muscle (CMAPs). At low rates of stimulation (3 Hz) the CMAPs of normal individuals do not change appreciably. A rapid reduction in the amplitude of the CMAP (decremental response $\geq$10% by the fourth stimulus) is characteristic of MG, and is considered a positive response (Fig. 69.3). The yield of positive responses is increased when weak muscles, or several proximal muscles are tested. As discussed above, the basis for the decremental response is the reduced 'safety margin' at myasthenic endplates, in conjunction with the normal phenomenon of ACh 'rundown'. As the amount of ACh released by the motor nerve normally diminishes on successive stimuli, the EPPs fail to reach threshold levels at NMJs of myasthenic patients, and there is progressive failure of activation of MAPs (Sanders, 1993; Jablecki, 1991). *Single fibre EMG (SFEMG)* is an electrophysiological technique developed to record action potentials from individual muscle fibres (Stalberg & Trontelj, 1997). By recording several consecutive firings of two or more muscle fibre action potentials belonging to the same motor unit, one can assess the 'neuromuscular jitter', which is the fluctuation in time between activation of the related muscle fibres. Jitter is increased when the safety margin of neuromuscular transmission is reduced (Fig. 69.4). When the defect in neuromuscular transmission is severe, some nerve impulses fail to elicit action potentials, termed 'impulse blocking'. Single fibre EMG is a highly sensitive test, and may be helpful in difficult diagnostic situations. It is positive in 88 to 92% of myasthenic patients, but its specificity is limited, with increased jitter or blocking in other disorders of nerves, muscles, and neuromuscular junctions.

AChR antibody assay

The gold standard for diagnosis of MG is a radioimmunoassay (RIA) that measures antibodies that bind to detergent solubilized human AChR, which is labelled by ^{125}I-α-BuTx (Vincent & Newsom-Davis, 1985). A positive RIA test for AChR antibodies is specific for MG, but antibodies are detectable in only about 80 to 85% of patients with acquired autoimmune MG, and in a lower proportion (~50%) of patients with pure ocular MG. Other tests for

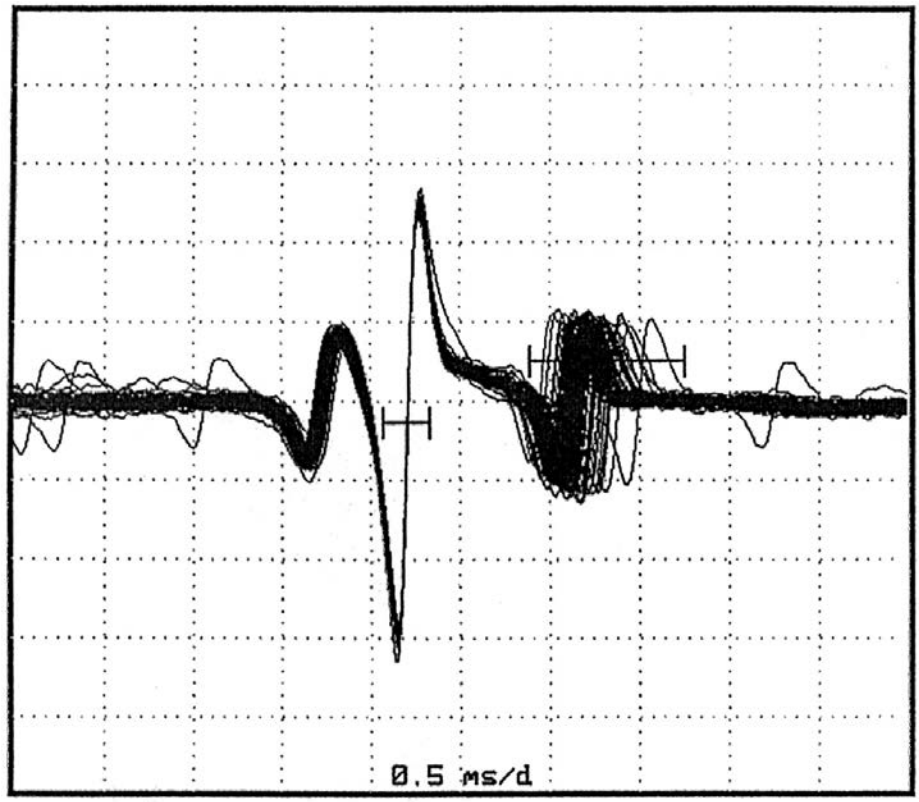

Fig. 69.4. Single fibre EMG shows 2 pairs, one with normal jitter (left) and the other with abnormal jitter (right).

antibodies, measuring accelerated degradation or blocking of AChRs may be helpful in antibody-negative MG. A newly developed test for antibodies to MuSK may prove useful in patients with 'antibody-negative MG', although it is limited to research purposes at present (Hoch et al., 2001). There are few, if any, false-positive RIAs, and a positive test in a patient with compatible clinical features essentially confirms the diagnosis.

Differential diagnosis

Other conditions that may cause weakness of the cranial and somatic muscles must be considered in the differential diagnosis of MG, including LEMS, the congenital myasthenias, and botulism (which will be discussed below), drug-induced myasthenia (penicillamine, aminoglycosides, magnesium), intracranial mass lesions or vascular malformations, progressive external ophthalmoplegia, oculopharyngeal dystrophy, and thyrotoxic ophthalmopathy. Each of these conditions should be considered, and appropriate diagnostic testing carried out. Especially when weakness is confined to the cranial musculature, it is essential to obtain MRI imaging of the brain and orbits to exclude other conditions that can cause similar features.

Associated conditions

Several clinically important conditions may be associated with MG. As noted above, thymic tumours occur in approximately 12% of myasthenic patients, and are reliably detected by CT or MRI imaging. The thymus is normally detectable until mid-adulthood, but persistence of a thymus shadow in a patient with MG who is over 40 years of age, or an increase in its size in any patient on repeated scanning, raises the possibility of a thymoma. Hyperthyroidism occurs in 3% to 8% of patients with MG, and either hyperthyroidism or hypothyroidism may aggravate myasthenic weakness. We routinely screen for other autoimmune disorders, because they may add to the diagnostic picture of immune dysregulation, and because they may complicate therapy. Conditions that may influence the choice of immunosuppressive therapy include unsuspected

Table 69.3. Drugs, dosages, costs, onset of actions, and side effects to be monitored for the immunomodulatory agents used for MG

Drug	Dosage	Costs	Onset	Monitor
Prednisone	60 mg/d	$0.40[a]	3 weeks	BP, BS, Na/K, Wt, Bone density, eyes, stool guiacs
Azathioprine	2–3 mg/kg/d	$4/-[b]	3–6 mos.	MCV, lymphocytes, LFTs
Cyclosporine	5 mg/kg/d (2 divided dosages)	$20/-[c]	4 weeks	Creatinine, BP, CsA levels
Mycophenolate mofetil	1 gm bid	$18/-[d]	3–6 mos.	WBC
Cyclophosphamide	2–3 mg/kg/d	$11/-[e]	4 weeks	CBC, urine, lytes
Plasmapheresis	250 ml/kg qod × 5	$8000/-[f]	3rd exchange	Asepsis, calcium
IVIG	2 g/kg (over 2–5 days)	$6000/-[g]	3–4th day	Infusion rate, creatinine

infections such as tuberculosis, diabetes, peptic ulcer disease, occult gastrointestinal bleeding, renal disease, and hypertension.

Treatment

The outlook for myasthenic patients has improved dramatically as a result of advances in treatment. At present, with optimal treatment, the mortality rate is essentially zero, and virtually all myasthenic patients can be returned to full, productive lives (Grob et al., 1987). The most important methods used in the treatment of MG include anticholinesterase (anti-ChE) medications, immunosuppressive agents, thymectomy, and the short-term treatments such as plasmapheresis or intravenous immunoglobulin (IVIg) (Tables 69.3 and 69.4) (Drachman et al., 1993).

Cholinesterase inhibitors

Anticholinesterase (anti-ChE) agents inhibit the enzymatic elimination of acetylcholine, thereby prolonging its action at the postsynaptic membrane, and enhancing neuromuscular transmission. They are often the initial agents used for treatment. There is no substantial difference in efficacy among the various anti-ChE drugs; oral pyridostigmine bromide (Mestinon®) is the one most widely used in the United States. Its beneficial action begins within 15 to 30 minutes, and lasts for 3 to 4 hours, but individual responses vary. The dosage schedule must be tailored to the needs of the patient, and should be timed to maximize strength prior to anticipated activities, such as 30–60 minutes before meals. The initial dosage of pyridostigmine bromide is 30 to 60 mg every 4–6 hours. The dose may be increased to 60 or 90 mg every 3 hours when awake. The maximum useful dosage rarely exceeds 120 mg every 3

Table 69.4. Step-wise approach to management of MG

Step 1. Firmly establish the diagnosis, by history, examination, anti-AChR antibody, repetitive nerve stimulation, or single-fiber EMG study.

Step 2. Document the severity into ocular; mild, moderate, or severe generalized; and whether bulbar and respiratory functions are involved. Follow with regular vital capacity, ptosis and arm abduction time.

Step 3. Evaluate the thymus by CT scan or MRI of the chest.

Step 4. Test for associated disorders, especially thyroid function tests and CK measurement.

Step 5. Explain the nature of the disease to the patient, especially its variable nature and the known precipitating factors, including certain drugs, temperature, stress, and the premenstrual period in some females.

Step 6. Start treatment with Mestinon®

Step 7. Perform thymectomy in patients with thymoma or generalized myasthenia gravis, if < 60 years of age after stabilizing MG.

Step 8. Use corticosteroids in patients with disabling ocular or generalized myasthenia gravis/ Switch gradually to alternate-day therapy.

Step 10. Start azathioprine, mycophenolate mofetil, or cyclosporine as 'steroid sparing agents'.

Step 11. Use plasmapheresis or intravenous immunoglobulin in myasthenic crisis, before or after thymectomy, to tide over periods of severe weakness while waiting for other immune drugs to take effect.

hours, and higher doses may produce increased weakness. A long-acting pyridostigmine preparation (Timespan® 180 mg) should be used only at bedtime, for patients who are symptomatic at night or in the early morning. The side effects of anti-ChE drugs include gastrointestinal hyperactivity with abdominal cramping or diarrhea, and increased oral and upper respiratory secretions. Anticholinergic medications such as diphenoxylate (Lomotil®) may overcome these muscarinic side effects without diminishing the nicotinic benefit. As a rule, anti-ChE drugs provide only partial improvement in most patients, and their effects often wane after weeks or months of treatment.

Thymectomy

As noted above, the thymus gland is believed to play an important role in the development of autoimmune myasthenia gravis. There are two different indications for thymectomy in MG: (i) Surgical removal of a thymic tumour; and (ii) thymectomy as a treatment for MG. Thymic tumours must be removed because they may spread locally and involve important structures within the chest, although they are usually histologically benign. In the absence of a tumour, there is now broad consensus that patients with generalized MG who are between the ages of puberty and about 60 years should have thymectomy, because up to 85% of patients eventually experience improvement in their MG after thymectomy (Bulkley et al., 1997). Of these, about 35% achieve drug-free remission, while the remaining 50% show some improvement. The advantage of thymectomy is that it offers the possibility of long-term benefit, after months or years, in some cases diminishing or eliminating the need for continuing medical treatment. In view of these potential benefits, and of the negligible risk in skilled hands, thymectomy has gained widespread acceptance in the treatment of MG, even though the evidence for this fails to come from controlled studies (Gronseth & Barohn, 2000). Thymectomy should *never* be performed as an urgent procedure. Unless absolutely necessary, thymectomy should be performed before beginning treatment with immunosuppressive drugs, so as to minimize the risks of infection and delayed wound healing. If MG is severe, or in patients with bulbar or respiratory dysfunction, thymectomy should be carried out only after stabilization of the disease with plasmapheresis, IVIg treatment, or other immunomodulatory therapy (see below). Although various surgical approaches to thymectomy, transcervical, transsternal, or 'maximal', continue to be used at different centres, median sternotomy with cervical exploration is most widely used, since it permits maximal removal of all thymic tissue. Potential complications from thymectomy include the general risks of anesthesia, impaired wound healing, sternal instability, pleural effusion, atelectasis, pneumonia, pulmonary embolism, paresis of phrenic or recurrent laryngeal nerve, and precipitation of myasthenic crisis. To minimize the risk of these complications, thymectomy should always be carried out in a hospital where it is performed regularly, and where the staff is experienced in the pre- and postoperative management, anesthesia, and surgical techniques of total thymectomy.

Immunosuppressive drugs

Most patients can be restored to full activity with optimum immunosuppressive therapy. An increasing number of immunosuppressive agents including glucocorticoids, azathioprine, cyclosporine-A, mycophenolate mofetil, methotrexate, cyclophosphamide, and others are now available (Cornelio et al., 1993; Lanska, 1990). The choice of which drugs or other immunomodulatory treatments to use should be guided by their relative benefits and risks for the individual patient, and the urgency of treatment. It is helpful to develop a treatment plan based on (i) short-term, (ii) intermediate-term, and (iii) long-term objectives. For example, if immediate improvement is essential either because of the severity of weakness or because of the patient's need to return to activity as soon as possible, plasmapheresis or IVIg treatment should be undertaken. For the intermediate term, adrenal corticosteroids and cyclosporine generally produce clinical improvement within a period of 1 to 3 months. The beneficial effects of azathioprine and mycophenolate usually begin after many months (up to a year), but these drugs have advantages for the long-term treatment of patients with MG. The side effects of each drug may preclude its use in some patients, as indicated below.

Steroid therapy

Adrenal corticosteroids, when used properly, produce improvement in myasthenic weakness in the great majority of patients (Johns, 1987). The initial dose of prednisone should be relatively low (15 to 20 mg/d) to avoid the early weakening that occurs in about one-third of patients treated initially with a high-dose regimen. It is then increased by 5 mg every 2 to 3 days as tolerated, until a total dose of 60 mg a day is reached. Prednisone should be administered in a single dose in the morning so as to minimize side effects (which are more pronounced when it is given in divided doses throughout the day), and to mimic the natural diurnal cortisol cycle. After reaching an optimal dose, treatment is continued for 1 to 3 months or until near-maximal or maximal improvement occurs. The treatment schedule is then modified gradually to an alternate-day

regimen over weeks to months. Occasionally, a small dose of prednisone must be given on the 'off' day to prevent fluctuations in strength. The ultimate aim of therapy is to maximize the benefits while minimizing the risks. Since the risks are directly related to the dose and duration of steroid use, the smallest effective dose given on alternate days should be determined for each patient by gradually tapering the dose (usually by no more than 5 mg every month or so). The combination of other immunosuppressive agents (see below) with corticosteroids facilitates the reduction of the steroid dose, while maintaining the therapeutic effect on MG. Potential side effects of steroid therapy include weight gain, cataracts, gastrointestinal irritation and ulcers, psychological changes, hyperglycemia, hypertension, osteoporosis, aseptic necrosis of the hip, suppression of pituitary ACTH secretion, impaired wound healing and increased risk of infection. Because of these side effects, consistent follow-up with close monitoring of blood pressure, blood glucose, electrolytes, bone density, weight, occult infections, stool for occult blood, advice regarding an exercise program, a low fat low sodium diet, calcium and vitamin D supplementation or the use of biphosphonates to prevent osteopenia, and surveillance or treatment for hyperglycemia, should all be part of management of MG patients on corticosteroids. Inability or unwillingness of a patient to be followed closely is an absolute contra-indication to the use of steroid therapy.

Other immunosuppressive drugs

Azathioprine, cyclosporine, mycophenolate mofetil, or occasionally cyclophosphamide, are effective in many patients, either alone or in combination with glucocorticoid therapy.

Azathioprine has been the most widely used of these drugs because of its relative safety in most patients, and long track record (Gajdos et al., 1997). Its therapeutic effect may add to that of glucocorticoids and usually allows the steroid dose to be reduced. However, up to 10% of patients are unable to tolerate azathioprine because of idiosyncratic reactions consisting of flu-like symptoms of fever and malaise, bone marrow depression, or abnormalities of liver function. An initial dose of 50 mg/d should be used to test for adverse side effects. If this dose is tolerated, it is increased gradually until the white blood count falls to approximately 3000 to 4000/μl. In patients who are receiving steroids concurrently, leukocytosis precludes the use of the WBC as a measure of treatment. A reduction of the lymphocyte count below 1000/μl and/or an increase of the mean corpuscular volume of red blood cells may be used as indications of adequacy of azathioprine dosage. The typical dosage range is 2 to 3 mg/kg total body weight (including fat in obese patients). The beneficial effect of azathioprine takes at least 3 to 6 months to begin and even longer to peak.

Cyclosporine is approximately as effective as azathioprine, and is being used increasingly in the management of MG (Goulon et al., 1989; Tindall et al., 1987). Its beneficial effect appears more rapidly than that of azathioprine. It may be given alone but usually is used as an adjunct to steroids, to permit reduction of the steroid dose. The usual dose of cyclosporine is 4 to 5 mg/kg per day, given in two divided doses (to minimize side effects). Side effects of cyclosporine include hypertension and nephrotoxicity, which must be closely monitored. The blood pressure and serum creatinine levels should be monitored on a regular basis. 'Trough' blood levels of cyclosporine are measured 12 h after the evening dose; the therapeutic range, as measured by radioimmunoassay, is 150 to 200 ng/l.

Mycophenolate mofetil, which has been used for immunosuppression in transplant patients, has now proven useful in the treatment of MG (Ciafaloni et al., 2000; Hauser et al., 1998; Chaudhry et al., 2001). Its mechanism of action involves inhibition of purine synthesis by the de novo pathway. Since only lymphocytes lack the alternative 'salvage pathway' that is present in all other cells, mycophenolate inhibits proliferation of lymphocytes, but not proliferation of other cells. It does not kill or eliminate pre-existing autoreactive lymphocytes, and therefore clinical improvement in autoimmune diseases like MG may be delayed for many months to a year, until the pre-existing autoreactive lymphocytes spontaneously die. The advantage of mycophenolate lies in its relative lack of adverse side effects, with only occasional production of diarrhea, and rare development of leukopenia. This drug may become the choice for long-term treatment of myasthenic patients. Unfortunately, the present cost of mycophenolate is high.

Cyclophosphamide is reserved for occasional patients refractory to the other drugs, because of its relatively high risk of adverse side effects, including late development of malignancies (Niakan et al., 1986).

Plasmapheresis and intravenous immunoglobulin

In view of the antibody-mediated pathogenesis of MG, plasmapheresis has been used therapeutically. The plasma, which contains the pathogenic antibodies, is mechanically separated from the blood cells, which are returned to the patient. Plasmapheresis produces a short-term reduction in anti-AChR antibodies, with clinical improvement in many patients (Keesey et al., 1981). It is useful as a temporary expedient in seriously affected patients or to improve the patient's condition prior to surgery (e.g., thymectomy).

The indications for the use of intravenous immunoglobulin are the same as those for plasma exchange: to produce rapid improvement in order to help the patient through a difficult period of myasthenic weakness, or prior to surgery (Gajdos et al., 1984, 1997; Arsura, 1989). This treatment has the advantages of not requiring special equipment or large-bore venous access. The usual dose is 2 g/kg, which is typically administered over 5 days (400 mg/kg/day). If tolerated, the course of IVIg can be shortened to administer the entire dose over a 3-day period. Improvement occurs in about 70% of patients, beginning during treatment or within a few days thereafter, and continuing for weeks to months. The mechanism of action of intravenous immunoglobulin is not known; the treatment has no consistent effect on the measurable amount of circulating AChR antibody. Adverse reactions are uncommon, but include headache, fluid overload, and rarely aseptic meningitis or renal shutdown.

Management of myasthenic crisis

Myasthenic crisis is defined as an exacerbation of weakness sufficient to endanger life, due to respiratory failure caused by diaphragmatic and intercostal muscle weakness. Treatment should be carried out in an intensive care unit staffed with physicians experienced in the management of MG, respiratory insufficiency, infectious disease, and fluid and electrolyte therapy. The most common cause of crisis is intercurrent infection. This should be treated immediately, because the mechanical and immunologic defences of the patient can be assumed to be compromised. The myasthenic patient with fever and early infection should be treated like other immunocompromised patients. Early and effective antibiotic therapy, respiratory assistance, and pulmonary physiotherapy are essentials of the treatment program. As discussed above, plasmapheresis or IVIg is frequently helpful in hastening recovery. Crisis is occasionally due to the improper use of excessive anticholinesterase medication ('cholinergic crisis'). This is best evaluated by temporarily stopping anti-ChE drugs.

Transient neonatal MG

Transient neonatal MG is due to the placental transfer of anti-AChR antibodies from the mother reacting with the infant's AChR (Ohta et al., 1981; Lefvert & Osterman, 1983; Morel et al., 1988). However, even though circulating anti-AChR antibodies can be detected in most infants born to myasthenic mothers, only 10–15% of such children display symptoms or signs of MG. The risk is higher if previous siblings have been affected. There is no correlation between the severity of myasthenia in the mother or the maternal titre of anti-AChR antibodies and the occurrence and severity of transient neonatal myasthenia gravis. Affected newborns manifest hypotonia, weak cry and suck, and respiratory difficulty, usually within the first few hours of life. Rarely, arthrogryposis and polyhydramnios can occur and are due to myasthenic weakness in utero, with virtual immobility of the fetus. Transient neonatal myasthenia requires supportive treatment along with Mestinon® at a dose of 1–2 mg/kg orally/nasogastric tube given every 3–4 hours. Symptoms resolve spontaneously within 1–3 weeks, with mean duration of illness being 18 days. The diagnosis is made on the basis of maternal history, clinical manifestations, AChR antibody assays in mother and infant, and the clinical response to anti-ChE treatment. Electrophysiological study shows decremental response with RNS, but is rarely necessary.

Drug-induced myasthenia gravis

D-Penicillamine is a drug that may be used in the treatment of rheumatoid arthritis, scleroderma, or Wilson's disease. During treatment with D-penicillamine, anti-AChR antibodies, typical clinical manifestation of MG, identical to those of acquired immune myasthenia gravis, may occur (Penn et al., 1998; Wittbrodt, 1997). The symptoms subside gradually after the drug is stopped.

Postsynaptic blockade: snake toxins

The paralytic syndromes of cobra, and krait snake bites are due to blockade of AChRs at neuromuscular junctions, and thus resemble myasthenia gravis (Naphade & Shetti, 1977; Mitrakul et al., 1984). Weakness develops soon after the bite and reaches a peak in 4 hours. Weakness proceeds in the order of ocular, masticatory, facial, palatal, neck, and proximal and distal limb paralysis, with recovery in the same direction. Treatment with antivenom and supportive care is required.

Postsynaptic congenital disorders of neuromuscular transmission

Acetylcholine receptor deficiency

This is a heterogeneous group of disorders caused by inherited autosomal recessive mutations in the AChR subunits (Engel, 1999; Engel et al., 1993; Middleton et al., 1999; Quiram et al., 1999; see Table 69.5). Sporadic cases have also been described. A wide variety of mutations have been identified in each of the subunits, but the ε subunit is

Table 69.5. Congenital myasthenic syndromes

Type	Clinical features	Electrophysiology	Genetics	Endplate effects	Treatment
1. Postsynaptic					
(i) Severe AChR Deficiencies[b]	Early onset (infant to childhood Variable severity (hypotonia, respiratory insufficiency, ocular,bulbar weakness), skeletal deformities	Decremental response to repetitive nerve stimulation Decreased MEPP amplitudes	Autosomal recessive ε mutations most common Heteroallelic	Increased span of endplates Variable synaptic folds	Anti-ChE 3,4- DAP
(ii) Slow Channel[a] (increased response to ACh)	Onset 2–3rd decade Most common Fatigable ptosis, ophthalmoparesis, trunk or extremity (especially forearm extensors) weakness	Repetitive responses on single nerve stim Prolonged channel opening and prolonged MEPPs	Autosomal dominant α,β,ϵ mutations Gain of function	Excitotoxic Endplate myopathy Decreased AChRs Postsynaptic damage	Quinidine Made worse by anti-ChE
(iii) Fast Channel[b] (decreased response to ACh)	Onset early (neonate or infantile) Moderate severity Ptosis, EOM involvement; weakness and fatigue	Brief and infrequent channel openings Opposite of slow channel syndrome	Autosomal recessive May be hetero-allelic	Normal endplate structure Normal AChR	Anti-ChE 3,4- DAP
2. Pre Synaptic					
(i) Familial Infantile MG[a] (Congenital MG with episodic apnoea)	Infancy or early childhood Intermittent hypotonia, fatigable generalized weakness, ptosis, dysphagia, respiratory insufficiency – precipitated by infection or excitement	Decrement at low rates – 10 Hz stimulation for 5–10 min may be required before decrement appears MEPPs decreased	Autosomal recessive	Morphology of synapse normal Defect in synthesis, storage or release	Anti-ChE
(ii) Congenital LEMS[b]	Infants and children Hypotonia, ptosis, fatigable weakness including respiratory	Decrement low rates Increment at high rates Low amplitude CMAP	Case reports	Paucity of ACh vesicles Defects in quantal release	Some respond to guanidine
3. Synaptic					
AChE deficiency[a]	Early onset. Variable severity. Scoliosis. May have normal EOM, absent pupillary responses	Repetitive muscle response on nerve stim. Decremental response	Mutant gene for AChE's collagen anchor	Small nerve terminals; degenerative junctional folds	Worse with anti-ChE meds.

Notes:

[a] Clinical features distinct

[b] Clinical features similar – diagnosis requires in vitro physiologic, morphologic, and molecular genetic studies.

affected in about 75% of these cases. In most, the mutations are heteroallelic; that is, different mutations affecting each of the affected alleles are present. Over 56 AChR subunit gene mutations in 69 congenital myasthenic syndrome kinships have been described. The age of onset ranges from infancy to adulthood. Clinical manifestations include hypotonia, respiratory insufficiency, weakness of ocular and bulbar muscles and skeletal deformities. The majority of patients respond to AChE inhibitors. The findings on electrodiagnostic studies are indistinguishable from those of autoimmune myasthenia gravis. Repetitive nerve stimulation at low rates results in a decremental muscle response. The decrement is partially repaired with exercise, tetanic stimulation or AChE inhibitors as in acquired MG. A reduction in the number of ^{125}I- α-BuTx binding sites on the postsynaptic membrane, and a decrease in MEPP ampli-

tude are seen in patients with congenital AChR deficiency syndrome. Patients with congenital AChR deficiency may respond to a combination of anti-AChE agents, and 3,4-diaminopyridine (3,4-DAP) which acts by enhancing the release of ACh from the motor nerve terminal.

Slow channel syndrome

This is a postsynaptic congenital myasthenic syndrome, characterized by prolonged AChR channel open time (Engel et al., 1982; Harper & Engel, 1998). It is inherited as an autosomal dominant, with mutations having been described in the α, β, or ε subunits (Table 69.5). Clinically, slow channel syndrome is manifested by fatigable ptosis, ophthalmoparesis, trunk or extremity weakness which may be asymmetric, and often selectively involves the forearm extensors. The age of onset and clinical severity are variable. Patients may present from infancy to adulthood with a slowly progressive myopathy with superimposed fatigable weakness. Arms and trunk are often more involved than legs. Weakness does not improve and may worsen with anti-ChE agents. With a single supramaximal motor nerve stimulus, one or more repetitive CMAPs are observed ('double hump') as is also seen with AChE deficiency (see below). The repetitive discharges are accentuated by administration of edrophonium (Tensilon®). Low rate repetitive nerve stimulation produces a decrement with little or no repair on postactivation. Patients do not improve with administration of anti-ChE agents. Microelectrode studies have shown prolonged duration of MEPPs and reduced MEPP amplitudes, but the quantal content is normal. More than 10 single nucleotide mutations have been found in the α, β, and ε subunits of the AChR. Each mutation results in a 'gain of function' abnormality, with prolonged open time of the AChR ion channel due either to increased affinity of the receptor for ACh, or to slow closure of the AChR channel. In addition to sodium, excess calcium passes through the open AChR cation channel. Calcium-mediated activation of catabolic enzymes produces degeneration of the junctional folds and junctional sarcoplasm, resulting in 'endplate myopathy'. Treatment with quinidine, which blocks AChR open channels, not only helps to prevent the endplate damage, but reportedly produces improvement in the weakness.

Fast channel syndrome

This disorder is the opposite of slow channel syndrome, with abnormally brief channel opening responses to ACh, as demonstrated by patch clamp studies (Uchitel et al., 1993) (Table 69.5). This autosomal recessive disorder is symptomatic in the neonatal or infantile period, with hypotonia, ptosis, dysphagia, dysarthria and generalized fatigable weakness. The symptoms are partially responsive to cholinesterase inhibitors. Responses to repetitive nerve stimulation resemble those of autoimmune myasthenia gravis, with a decrement at low frequencies and partial repair following exercise. There is a decrease in the amplitude and duration of MEPPs, and increased resistance to desensitization by ACh. Mutation analysis has revealed a common mutation at ε P121L with the fast channel syndrome, associated with low affinity of the receptor for ACh. Patients with fast channel syndrome respond to a combination of pyridostigmine and 3,4-DAP. A second type of fast channel syndrome has been reported, with both a reduction in the number of AChRs at the motor end plate and reduced affinity for ACh. In some patients the decreased open time is combined with a deficit of AChRs (Walls et al., 1993).

Presynaptic acquired disorders of neuromuscular transmission

Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is an acquired presynaptic disorder of the NMJ that can cause weakness similar to that of MG (O'Neill et al., 1988; Sanders, 1995). The proximal muscles of the lower limbs are most commonly affected, but other muscles may be involved as well. Cranial nerve findings, including ptosis of the eyelids and diplopia, occur in up to 70% of patients and resemble features of MG. However, the two conditions are readily distinguished, since patients with LEMS have depressed or absent reflexes, show autonomic disturbances such as dry mouth, impotence and anhidrosis, and have dramatically different electrophysiological findings. LEMS is caused by IgG autoantibodies directed against P/Q type calcium channels at motor nerve terminals and parasympathetic postganglionic nerve terminals, which can be detected in the serum of approximately 85% of patients by radioimmunoassay. These antibodies block and/or damage the calcium channels at the nerve terminal, and interfere with Ca^{2+} influx. As a result, ACh release is impaired, and the safety margin of neuromuscular transmission is reduced. EPPs fail to reach the critical threshold, producing low CMAPs. However, brief exercise or rapid (50 Hz) nerve stimulation facilitate calcium entry and ACh release, resulting in increased CMAP amplitudes. The most characteristic electrophysiologic findings in LEMS are low amplitude CMAPs in weak muscles, with striking facilitation of 100% or more on rapid rates of nerve stimulation or

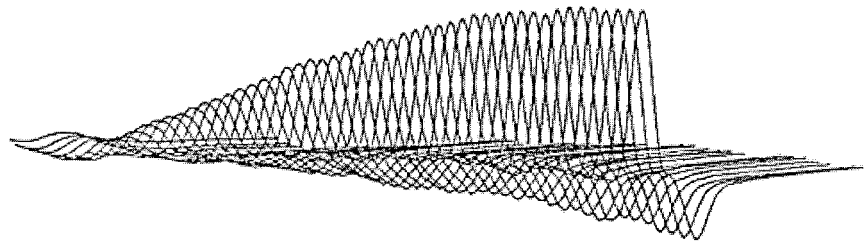

Fig. 69.5. Repetitive nerve stimulation at 50 Hz showing an incremental response in a patient with Lambert–Eaton myasthenic syndrome.

after exercise (Fig. 69.5). At low rates of nerve stimulation, decremental responses occur, as in MG. SFEMG shows increased jitter and blocking. In a majority of patients, LEMS is associated with small cell carcinoma of the lung, which is thought to trigger the autoimmune response. The diagnosis of LEMS may signal the presence of the tumour long before it would otherwise be detected, permitting early removal. However the tumour may not be detected for as long as 5 years after the neurological manifestations. Treatment of the neurological disorder involves plasmapheresis and immunosuppression, as for MG (Chalk et al., 1990). Patients often respond to 3,4-DAP, which increases ACh release (McEvoy, 1994). Treatment with anti-ChE drugs may also be helpful, but the results are usually less effective than those in MG.

Botulism

Clostridium botulinum, an anaerobic bacterium that is virtually ubiquitous in soils throughout the world, produces botulinum toxin, 'the most poisonous poison'. Seven different serotypes of botulinum toxin, and the closely related tetanus toxin, are recognized. Types A, B, E, and F have been associated with human disease; types A and B are the most common. These toxins are highly evolved zinc-containing proteases that enter motor nerve terminals by a 'Trojan horse' mechanism, and then interfere with the complex molecular events of synaptic vesicle docking and release (Pellizzari et al., 1999). As noted above, the release of ACh from vesicles involves at least 12 proteins. Each of the botulinum toxins cleaves one of these proteins in a highly specific manner. For example, synaptobrevin is a protein that is normally associated with and coats the ACh containing vesicle, and is essential for its docking and release. Botulinum toxins of types B, D, F, and G, and tetanus toxin, cleave synaptobrevin, but at different and highly specific cleavage sites. *SNAP25*, another of the synapse-related proteins, is localized at the nerve terminal's vesicle release site, and binds the synaptobrevin-coated ACh vesicle just prior to its release. Botulinum toxins type A and E cleave SNAP25 at different specific sites. The consequence of enzymatic destruction of either of these proteins is paralysis, due to the inability of the motor nerve to release quanta of acetylcholine from the presynaptic terminal in response to an action potential. One of the striking properties of botulinum toxin is its ability to maintain blockade of ACh release for months! The blocked nerve terminals are induced to sprout extensively and develop new endings, which gradually results in recovery of function.

Cl. botulinum is an obligate anaerobe, which forms hardy spores under unfavourable conditions. However, when introduced into an anaerobic nutritious environment, such as is provided by canned food, that has not been sufficiently cooked to kill the spores, the spores replicate and produce toxin. Clinically, patients who ingest botulinum toxin present with weakness involving the ocular and bulbar as well as limb and respiratory muscles, with dilated unresponsive pupils. When paralysis due to botulism begins acutely, it may be confused with a brain stem infarct or encephalitis, but the intact level of consciousness and the decreased reflexes in patients with botulinum poisoning differentiate the two, although imaging and spinal fluid studies may be necessary. The rapid generalization of paralysis and areflexia may mimic the Guillain-Barré syndrome. However, the early loss of pupillary reflexes in botulism and the descending (rather than ascending) paralysis distinguish the two disorders. Weakness resulting from botulism is prolonged, lasting for months, because the toxin permanently impairs the presynaptic release of acetylcholine from the terminals after toxin entry. Infant botulism is a rare but widespread acute paralytic illness caused by the intra-intestinal production of toxin by *Clostridium botulinum* organisms in the GI tract of the infant (Arnon et al., 1977; Cherington, 1990). Clinically, infant botulism presents in otherwise healthy infants at the age of 10 days to 6 months with paucity of movement, poor feeding, weak cry, and respiratory insufficiency occurring over hours to day. There may be a history of painless constipation for several days to 3 weeks before the onset of weakness. Examination reveals an afe-

brile, lethargic, non-irritable infant with diffuse hypotonia, weakness, ptosis, ophthalmoplegia with pupillary dilatation and paralysis, reduced gag and hypoactive reflexes. Many infants progress rapidly to require assisted ventilation. The mean duration of required assisted ventilation is 23 days. Patients typically recover in a pattern that is the reverse of their presentation, with limb movements reappearing before respiration.

Diagnosis by culture or isolation of toxin is slow and has poor sensitivity (Pickett, 1988; Shapiro et al., 1998). The principal electrodiagnostic test for botulism is the demonstration of an incremental compound muscle action potential (CMAP) response to high-rate repetitive nerve stimulation (RNS) in over 90% of patients (Clay et al., 1977).

The management of patients with botulism involves mainly supportive management of ventilation and nutrition. Patients should be watched closely in an intensive care setting and intubated early when signs of airway compromise, bulbar dysfunction, or respiratory insufficiency first arise. Administration of 3,4-DAP has been reported to improve function in some patients by enhancing ACh release.

Black widow spider venom (latrotoxin)

Black widow spider bite results in presynaptic ACh release, followed by blockade (Plomp et al., 1999; Grishin, 1998; Muller, 1993). The 'latrotoxin' binds to synaptotagmin (one of the proteins involved in the calcium-mediated ACh vesicle release process), causing fusion of synaptic vesicles with the terminal axon membrane and release of their contents. The ACh release causes severe muscle contraction and pain, and local erythema, swelling and urticaria also occur at the bite site. The main muscular symptoms are cramping, rigidity, trismus and tremor; and autonomic symptoms include vomiting, salivation, hypertension, urinary retention and diaphoresis. Eventually, exhaustion of the ACh results in inexcitability and presynaptic blockade. Treatment with antitoxin and support of vital function leads to eventual resolution.

Presynaptic congenital disorders of neuromuscular transmission

Familial infantile myasthenia (FIM)

Familial infantile myasthenia is an autosomal recessive disorder defined by default to be presynaptic given that the postsynaptic function including the number of ACh receptors, and the synaptic AChE levels are normal (Robertson et al., 1980; Mora et al., 1987). The precise presynaptic defect is unknown but is thought to be due to an abnormality of synthesis, packaging or release of ACh. The disorder presents in infancy or early childhood with intermittent hypotonia and fatigable generalized weakness, ptosis, dysphagia, weak suck, weak cry and respiratory insufficiency. Because intermittent episodes of severe weakness and respiratory failure precipitated by infection or excitement can occur, the disorder has also been named congenital myasthenia with episodic apnea. Sudden infant death or anoxic encephalopathy can occur during these crises. However, these intermittent crises lessen in frequency and severity in early to mid-childhood, leading to a clinical syndrome that is very similar to autoimmune myasthenia gravis. The symptoms respond to anti-ChE agents at all ages. Repetitive nerve stimulation usually shows a decrement of the CMAP at rest, repair with brief exercise, and the reappearance of the decrement a few minutes later. In mild cases, it may be necessary to carry out prolonged nerve stimulation at 10 Hz continuously for 5–10 minutes before a decrement can be demonstrated. Microelectrode studies show normal MEPP amplitudes and quantal content at rest, but a gradual fall in both after 10 Hz stimulation for 5–10 minutes. The morphology of the synapse, the concentration of AChE, and the number and kinetics of AChRs have all been shown to be normal by ultrastructural and histochemical studies, suggesting that FIM is caused by a defect in either the reuptake of choline into the nerve terminal or the synthesis, storage or mobilization of ACh.

Congenital Lambert–Eaton-like syndrome (LEMS)

Infants and children who present with hypotonia, ptosis, fatigable weakness, including respiratory insufficiency, and demonstrate electrophysiological features like those of LEMS have been reported (Table 69.4). On repetitive nerve stimulation, they show a decrement of the CMAP at slow rates and facilitation following brief tetanic stimulation, similar to that seen in adult LEMS . Microelectrode studies in some have shown a presynaptic defect with very low quantal content. A defect in the synthesis, mobilization or storage of ACh has been postulated. There are individual case reports, but a unified syndrome has not been defined (Albers et al., 1984; Bady et al., 1987).

Synaptic acquired disorders of neuromuscular transmission

Organophosphate and other intoxications

Certain organophosphate anti-ChE agents bind to AChE, producing virtually irreversible blockade of the enzyme,

and resulting in failure to hydrolyze ACh released at the NMJ (Besser et al., 1989; Namba et al., 1971). Their primary use is as insecticides, but extremely potent versions have been devised as nerve gases for chemical warfare (e.g. Sarin, Tabun, Soman). After initial binding to AChE, the organophosphate compounds can establish chemical bonds that cannot be reversed. Intoxication by organophosphates may occur by accidental ingestion, attempted suicide or chemical warfare. Clinically, patients present with the features of cholinergic crisis, with nicotinic and muscarinic overstimulation because of the exaggerated effects of ACh on neuromuscular junctions and autonomic ganglia. Generalized paralysis, cramps, fasciculation, miosis, wheezing, nausea, vomiting, diarrhea, sweating, increased salivation, bradycardia, hypotension and CNS effects such as confusion and seizures can all occur. The electrophysiological findings resemble those of AChE deficiency (see below) and slow channel syndrome, with multiple repetitive CMAPs in response to single supramaximal stimulus. If treated very early with oxime agents (such as 2-pralidoxime) and atropine, the blockade of AChE may be partially reversed. Supportive care is required until regeneration of AChE occurs (Besser et al., 1990).

Synaptic congenital disorders of neuromuscular transmission

End-plate acetylcholinesterase deficiency

Acetylcholinesterase deficiency is an autosomal recessive disease characterized by a deficiency of the asymmetric form of AChE at the neuromuscular junction (Hutchinson et al., 1993a,b; Ohno et al., 1998, 1999, 2000). A defect in the collagen-like tail that anchors the AChE to the basal lamina has been implicated by genetic studies. Patients usually present in the neonatal period or early infancy with severe generalized weakness, hypotonia, poor feeding, weak cry and respiratory insufficiency requiring mechanical ventilation. In some cases, the manifestations may be delayed until later infancy or childhood, and include symptoms similar to those of MG, including fatigable asymmetric ptosis, ophthalmoparesis, dysarthria, dysphagia and weakness of axial and limb musculature. Sluggish pupillary response to light may be seen. Spinal deformities such as scoliosis or lordosis may be present and characteristically worsen after the patient stands for few minutes. In contrast to MG, the symptoms of AChE deficiency are unresponsive to anti-ChE drugs. Electrophysiological findings may suggest the diagnosis, with repetitive CMAPs produced in response to single supramaximal stimuli. Other conditions with similar findings include pyridostigmine overdose, organophosphate poisoning, and the slow channel congenital myasthenic syndrome. The common underlying physiological feature of these conditions is prolongation of the endplate potentials (EPP), which may remain above threshold beyond the refractory period, and thereby trigger one or more additional action potentials. Repetitive nerve stimulation at 2 Hz produces a decrement of the CMAP that is minimally repaired after exercise and is not repaired following the administration of AChE inhibitors. Single fibre EMG shows increased jitter and blocking.

Histochemical studies have revealed the absence of the asymmetric form of AChE at the end plate. Because of the lack of AChE, excitotoxic effects of ACh produce endplate damage (endplate myopathy) similar to that seen with anti-ChE poisoning. There is widening of the synaptic cleft, reduction in the number and complexity of the junctional folds, and degeneration of the subcellular components of the sarcoplasm. Most of the nerve terminals are small in size, and the Schwann cells often extend into the synaptic space. In addition to the above factors, AChR desensitization and depolarization block of the endplate may contribute to the reduced safety margin of neuromuscular transmission in this disease. Quantal content and MEPP amplitude are reduced in most patients.

Disorders of striated muscle

Richard W. Orrell[1] and Robert C. Griggs[2]

[1] Department of Clinical Neurosciences, Royal Free and University College Medical School, University College London, London, UK
[2] Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Muscle cells develop from mesenchymal cells in the embryo. They differentiate into two distinct morphologies, striated and non-striated. Striated muscle has an organized structure, and is able to contract rapidly. This is most commonly found as skeletal muscle, but also as cardiac muscle. Non-striated muscle, or smooth muscle, is generally not under voluntary control, maintains slow contraction, and is found in organs such as blood vessel walls, gastrointestinal tract, and urinary tract. In this chapter we deal with the skeletal form of striated muscle.

The basic unit of skeletal muscle is the muscle fibre. This is a single cell, with many nuclei. The muscle fibres are arranged in fascicles. Connective tissue within the fascicle is termed endomysium, the fascicle is surrounded by perimysium, and the whole muscle is surrounded by epimysium. Individual muscle fibres are 10–60 μ diameter, but are elongated, and may extend the full length of the muscle, up to 30 cm. The cytoplasm of the muscle fibre, or sarcoplasm, is composed of longitudinal threads of myofibrils, 1 μ diameter. In longitudinal section the myofibrils are transected by striations, or Z bands, which divide the myofibril into sarcomeres, 2.5 μ long at rest, and lead to the classification as striated muscle (Williams et al., 1989).

Within the sarcomere, two types of myofilament are present. Actin (5 nm diameter) attached to the Z band, and interdigitating myosin (12 nm diameter). In contracting muscle the actin filaments slide in relation to myosin. It is the making and breaking of connections between lateral projections on the myosin, and the actin, filaments, which causes the mechanical muscle contraction.

Within the muscle fibre are organelles and enzymes to provide the high level of energy necessary for muscle contraction. These include mitochondria, lipid vacuoles, and glycogen granules. Two main physiological groups of muscle fibres are recognized: slow (Type I) and fast (Type II). Slow muscles are more red than fast, and are rich in mitochondria and oxidative enzymes, but poor in phosphorylation. Slow fibres perform aerobic metabolism, in addition to the glycolytic metabolism which predominates in fast fibres. Slow muscles are particularly suited to sustained contraction, as in postural muscles, and fast muscle to more rapid movements. Most muscles contain a mixture of the two types of fibre.

Muscle fibres develop from embryonic mesenchymal cells of the myotomes, forming myoblasts. The myoblasts fuse to form the long multinucleate cylinder, or myotube. Some myoblasts persist into adult life as satellite cells, which lie below the basement membrane. When a muscle fibre is damaged, satellite cells may fuse to form part of the new fibre. Skeletal muscle is capable of regeneration, but with progressive damage may degenerate and be replaced by connective tissue, which may be fibrous, and cause contracture.

Skeletal muscle is dependent on innervation for its development, maintenance and function. The terminal branches of the motor nerves end at the motor end plate on individual muscle fibres. Skeletal muscle is organized at a functional level into motor units. The motor unit is a single alpha motor neuron and the muscle fibres it innervates. In muscles requiring precise control, for example the extrinsic ocular muscles, the motor unit may comprise only 6–13 muscle fibres, while in large limb muscles there may be up to 2000 muscle fibres. The muscle fibres of an individual motor unit may be spread diffusely in the muscle. The nerve impulse releases the neurotransmitter acetylcholine at the motor end plate, causing depolarization of the sarcolemma (the end plate potential), and at a critical level a massive depolarization (the action potential) occurs. This depolarization spreads at 5 m/s over the whole muscle fibre membrane, causing a contraction of the muscle fibre, lasting 25–75 ms. Repeated action potentials cause sustained contraction, but with a refractory

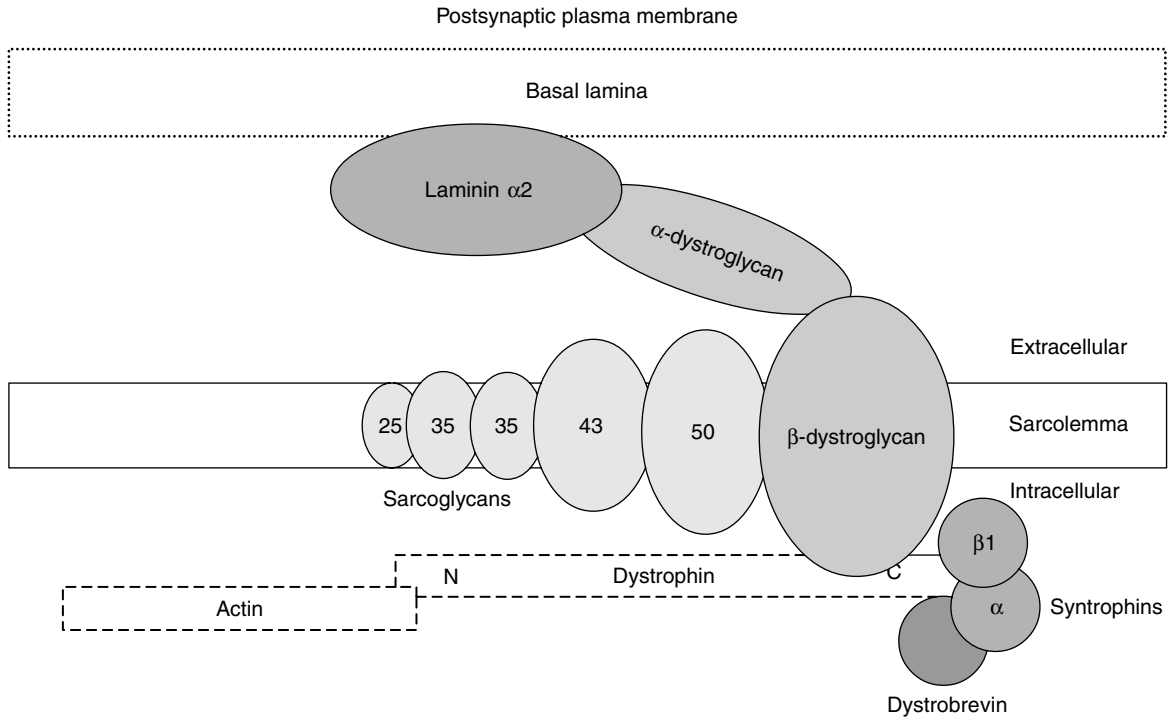

Fig. 70.1. Diagrammatic representation of the dystrophin-associated complex in the muscle fibre membrane.

period of around 10 ms. Isolated muscle fibres attain an 'all or none' contraction, the variable contraction force of a muscle being determined by the recruitment of motor units.

The clinical disorders of human skeletal muscle reflect the organization of the skeletal muscle described above. The muscular dystrophies are predominantly disorders of muscle fibre structural proteins. The molecular pathology of many of these has become clearer in recent years. Other muscle diseases remain defined at a morphological level, for example the core diseases. The inflammatory myopathies place muscle fibres in the context of systemic diseases, with generalized or targeted immunological mechanisms. In some of these, the primary mechanism may be ischemia as a result of vasculitis. Muscle fibres are dependent on an efficient metabolism, and acquired myopathies may be associated with endocrine, toxic, pharmacologic, and other disruptions of the metabolic process. Separate chapters in this book deal with other specific disorders of skeletal muscle, i.e. metabolic myopathies (including mitochondrial disorders), channelopathies (including periodic paralyses), and disorders of the peripheral nerve, motor neuron, or neuromuscular junction, which may cause secondary skeletal muscle dysfunction and disease.

Muscular dystrophies

The muscular dystrophies are genetically determined myopathies, characterized by progressive weakness. They comprise a wide range of disorders, of varying severity. Some present in severe form at birth, and others in mild form in adult life. Original descriptions referred to the clinical presentation, for example limb girdle muscular dystrophy, distal myopathy, facioscapulohumeral dystrophy, and other distinct phenotypes for example Duchenne muscular dystrophy, and Becker muscular dystrophy. The determination of clinical phenotype remains important, but the identification of the molecular basis for many of the muscular dystrophies is leading to a revision of classification based on molecular diagnostics. It is through identification and clarification of the molecular basis for these conditions that effective therapy may be developed in the future (Orrell & Griggs, 1999).

The understanding of the muscular dystrophies requires consideration of the proteins of the sarcolemma related cytoskeleton (Fig. 70.1) (Molnar & Karpati, 1999). These include dystrophin, the sarcoglycans and dystroglycan (Sunada & Campbell, 1995; Beckmann, 1996). The current classification based on identified proteins and genes is given in Table 70.1.

Table 70.1(*a*). A classification of muscular dystrophies based on identified gene and protein abnormalities

Group	Disease	Inheritance	Gene	Gene product
Calpain	Limb–girdle	AR	LGMD3A (CAPN3)	calpain 3
Caveolin	Limb–girdle	AD	LGMD1C (CAV3)	caveolin-3
Collagen	Bethlem myopathy	AD	COL6A1–3	collagen type VI subunit a1, 2 or 3
αB-crystallin	Desmin-related myopathy	AD	CRYAB	αB-crystallin
Desmin	Desmin-related myopathy	AD	DES	desmin
Dysferlin	Limb–girdle	AR	LGMD2B	dysferlin
	Miyoshi distal myopathy	AR	MM	dysferlin
Dystrophin	Duchenne/Becker	XR	DMD (DYS)	dystrophin
Emerin	Emery–Dreifuss	XR	EMD	emerin
Fukutin	Fukuyama congenital muscular dystrophy	AR	FCMD	fukutin
Integrin	Congenital muscular dystrophy with integrin deficiency	AR	ITGA7	integrin α7
Lamin	Emery–Dreiguss	AD	LMNA	lamin A/C
	Limb–girdle	AD	LMNA (LGMD1B)	lamin A/C
Merosin	Congenital muscular dystrophy with merosin deficiency	AR	LAMA2	merosin, or laminin α2 chain
Myotubularin	Myotubular myopathy	XR	MTMX	myotubularin
Nebulin	Nemaline myopathy	AS	NEM2	nebulin
Plectin	Epidermolysis bullosa simplex associated with late-onset muscular dystrophy	AR	MD-EBS	plectin
Polyadenyl binding protein	oculopharyngeal	AD	OPMD (PABP2)	polyadenyl binding protein 2
Protein kinase	Myotonic dystrophy	AD	DMPK	myotonin protein kinase
Sarcoglycan	Limb–girdle	AR	LGMD2D (SGCA)	α-sarcoglycan, or adhalin
		AR	LGMD2E (SGCB)	β-sarcoglycan
		AR	LGMD2C (SGCG)	γ-sarcoglycan
		AR	LGMD2F (SGCD)	δ-sarcoglycan
Skeletal muscle alpha actin	Nemaline myopathy	AR	ACTA1	skeletal muscle alpha actin
Ryanodine receptor	Central core disease	AD	CCD (RYR1)	ryanodine receptor
Tafazzin	Barth syndrome	XR		tafazzin
Telethonin	Limb–girdle	AR	LGMD2G	telethonin
α tropomyosin	Nemaline myopathy	AD	NEM1 (TPM3)	α tropomyosin

Notes:
AR = Autosomal recessive; AD = Autosomal dominant; XR = X-linked recessive.

Phenotypically normal individuals (including hypercemia)

Dystrophinopathies

Duchenne and Becker muscular dystrophies are dystrophinopathies. The dystrophin gene is very large, with around 2.4 million bases (Koenig et al., 1987). It is located on the short arm of the X chromosome. The gene encodes the dystrophin protein, which is a rod shaped molecule, accounting for around 5% of the muscle membrane-associated cytoskeletal protein (Koenig et al., 1988). Dystrophin is especially present at the neuromuscular junction. The function is probably related to mechanical reinforcement of the sarcolemma, and an anchor for the other proteins, such as sarcoglycans. The clinical presentations of dystrophinopathies are shown in Table 70.2.

The most typical presentation of Duchenne muscular dystrophy (Emery, 1993) is of a normal boy at birth, but with delayed motor milestones, and increasing difficulty walking by age 5 years. Muscle weakness is mainly proximal, and leads to Gowers' sign on rising from the floor. Hypertrophy of the calf muscles is often present (Fig. 70.2). Typically the boy is unable to walk by age 10 years, and subsequently respiratory insufficiency is progressive. Cardiomyopathy also develops, with death usually by his 20s (Brooke et al., 1989).

Duchenne muscular dystrophy is X linked, but may present in milder forms in carrier females, and sometimes in a form indistinguishable from that in males (Hoffman et al., 1992). Becker muscular dystrophy is a variant of Duchenne muscular dystrophy, with a milder phenotype, explicable by the molecular mechanisms (Baumbach et al., 1989; Koenig et al., 1989; Medori et al., 1989). Age of onset is usually later than for Duchene muscular dystrophy, up to 20 years, and may be walking to age 40 years, with death from respiratory insufficiency or cardiomyopathy usually between 30 and 60 years age. Milder forms of dystrophinopathy may present with muscle cramps (Gospe et al., 1989), or quadriceps myopathy (Sunohara et al., 1990).

In most individuals with Duchenne muscular dystrophy there is an out-of-frame deletion (Gillard et al., 1989; Abbs & Bobrow, 1992; Bushby, 1992), producing an unstable truncated dystrophin protein. In others there may be a point mutation (Roberts et al., 1992). In-frame mutations are associated with the Becker phenotype, with a less severe disruption of dystrophin (Koenig et al., 1989; Beggs et al., 1991).

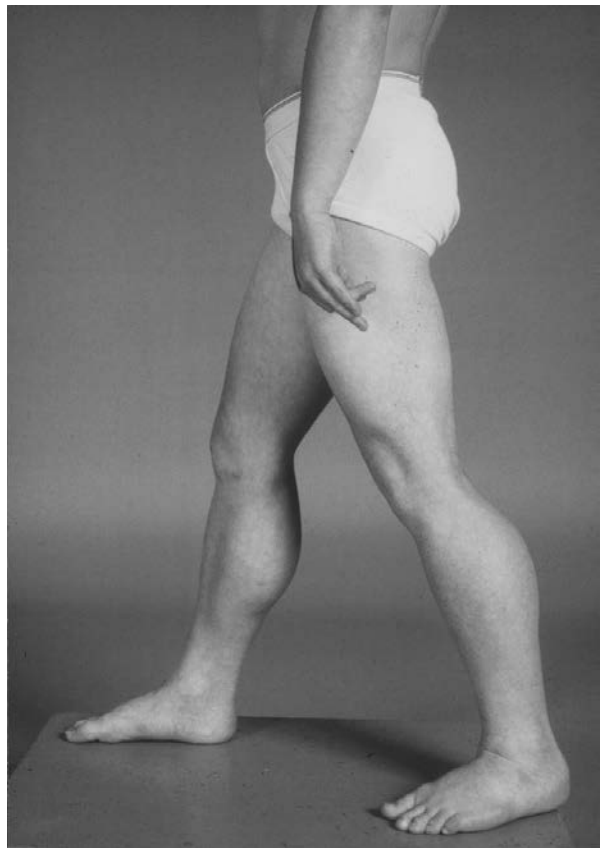

Fig. 70.2. Dystrophinopathy. Calf muscle enlargement is evident in this boy with a partial deficiency of dystrophin. Note that the hand position (palms facing backwards) indicates the presence of shoulder girdle weakness.

Creatine kinase is markedly elevated, EMG will show myopathic features, and ECG may show cardiomyopathy. Multiplex PCR (polymerase chain reaction) will detect common gene deletions (Chamberlain et al., 1988). Total or partial dystrophin deficiency may be identified by Western blot protein analysis (Bulman et al., 1991). Muscle biopsy immunohistochemistry will show absent dystrophin staining. In addition, there is secondary deficiency of immunostaining for α and β dystroglycan, all sarcoglycans, but preserved merosin (Ohlendieck et al., 1993). (In primary sarcoglycanopathy, dystrophin staining is normal.)

Management of patients with Duchenne muscular dystrophy includes attention to issues such as physiotherapy, respiratory support, cardiac care, bracing, and orthopedic surgical procedures. The education and other social needs of the patient and family also require attention. Treatment

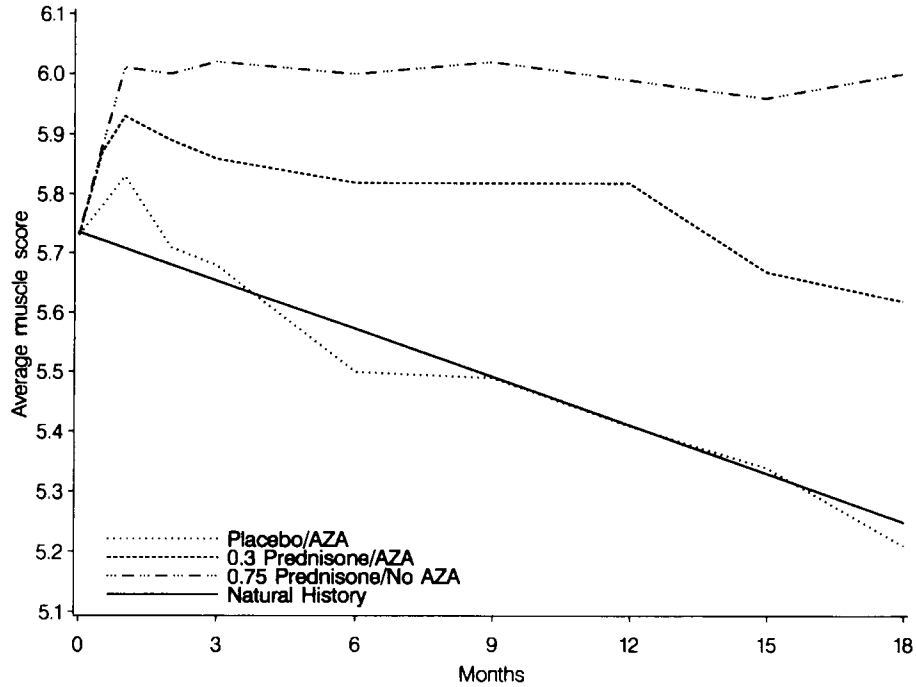

Fig. 70.3. Treatment of Duchenne muscular dystrophy. Comparison of average muscle score on manual muscle testing in the three groups. Azathioprine alone or added to prednisone 0.3 mg/kg/d resulted in no improvement additional to that of prednisone. (From Griggs et al., 1993.)

with steroids has been shown to have benefit in Duchenne muscular dystrophy (Fig. 70.3) (Griggs et al., 1991). Gene therapy is being explored, using various techniques, but has not yet shown clinical benefit (Karpati & Ascadi, 1993). Techniques initially included myoblast transfer (Mendell et al., 1995), and now virus vector transfer, and utilization of utrophin (Blake et al., 1996). Around 70% of dystrophin mutations are inherited from the mother, but in 30% the mutation is new. The genetic implications for the patient and family require careful consideration.

Dystrophin-associated proteinopathies

There are an increasing number of sarcolemmal proteins associated with human muscular dystrophy (Fig. 70.1). The dystrophin-associated sarcolemmal proteins appear to stabilize the membrane during contraction (Ozawa et al., 1995). They also attach the intracellular actin to the extracellular basal lamina.

Sarcoglycanopathies

The sarcoglycan complex is a group of membrane integrated proteins. It contains a number of subunits, including α, β, γ and δ (Roberds et al., 1994). α-Sarcoglycan has been called adhalin (Kaplan & Campbell, 1994; Eymar et al., 1997). An abnormality in one of the subunits may lead to loss of the full complex. In severe childhood autosomal recessive muscular dystrophy (SCARMD), there is loss of the sarcoglycan complex, with mutations in any of the individual subunits. Sarcoglycanopathies account for around 10% of autosomal recessive limb girdle muscular dystrophies (Duggan et al., 1996, 1997).

The clinical presentation of sarcoglycanopathy may be indistinguishable from dystrophinopathy. Phenotypes include SCARMD, Duchenne muscular dystrophy like muscular dystrophy, and limb girdle muscular dystrophy. Age at onset and severity is variable, usually between 2 and 20 years age. There is no cardiac involvement. Five to 10% of patients with dystrophin-positive muscular dystrophies have α-sarcoglycanopathy (adhalin deficiency) (Duggan et al., 1997). Creatine kinase is elevated (10–100×), EMG is myopathic, and muscle biopsy shows dystrophic features. Dystrophin immunostaining of muscle is usually normal. α-, β-, γ-, and δ-sarcoglycans may all be deficient on immunostaining (Sewry et al., 1996; Barresi et al., 1997). Western blot and gene analysis is necessary to determine the primary genetic abnormality. The mutations are in the α (Ljunggren et al., 1995; Piccolo et al., 1995), β (Lim et al., 1995), γ (Noguchi et al., 1995; McNally et al., 1996), and δ (Nigro et al., 1996) genes. Mutations must be identified in both alleles of the gene. Mutations are most commonly found in α sarcoglycan (Hayashi & Arahata, 1997), including

Table 70.3. Genetic classification of limb–girdle muscular dystrophies (LGMD)

	Gene	Gene locus	Gene product
Autosomal dominant LGMD	LGMD1A	5q22–24	?

missense and nonsense point mutations, deletions, and duplications. The clinical management of patients is similar to that of Duchenne muscular dystrophy, although steroids are generally not effective.

Calpainopathy

Calpain 3 (calcium activated neutral protease) is an intracellular protein. Mutations are associated with limb girdle muscular dystrophy (LGMD2A) (Richard et al., 1997). The clinical features are similar to the sarcoglycanopathies, with increased creatine kinase, calf hypertrophy, and weakness especially in the pelvic girdle. Scapuloperoneal weakness may be present.

Merosin-deficient congenital muscular dystrophy

The basal lamina includes a number of laminin proteins. Muscle fibre laminin complex comprises α2 heavy chain, and β1 or β2 and γ1 light chain (Wewer & Engwall, 1996). Laminins that contain α2 heavy chain (laminins 2 and 4) are termed merosin. The dystroglycans link laminin 2 to the dystrophin–actin complex. The complex of actin, dystrophin, dystroglycan and laminin is involved in linking the plasmalemma to the basal lamina, and may mechanically stabilize the sarcolemma during contraction of the muscle fibre.

Congenital muscular dystrophy is a clinical presentation with hypotonicity, wasting and weakness of face and limb muscles, and joint contractures (Dubowitz & Fardeau, 1995). Up to 40% of neonatal-onset congenital muscular dystrophy is due to merosin (laminin α2) deficiency (Sewry et al., 1995). The patient with merosin deficiency shows features of congenital muscular dystrophy from birth, and never walks. Creatine kinase is normal or mildly elevated. EMG is myopathic. MRI of the brain shows high signal lesions in the white matter. Muscle biopsy is dystrophic. Laminin α2 immunostaining is negative, but sarcoglycan immunostaining is positive. Nonsense and splice site mutations of the LAMA2 gene have been identified (Helbing-Leclerc et al., 1995; Guicheney et al., 1997). Clinical management is similar to the muscular dystrophies. Genetic counselling is appropriate, and prenatal diagnosis is possible.

In Japan, Fukuyama congenital muscular dystrophy should be considered (Fukuyama et al., 1981), with mutations in the gene encoding fukutin identified (Kobayashi et al., 1998). Severe mental retardation and other structural brain abnormalities may be associated.

Other dystrophin complex-associated proteinopathies

An increasing number of muscular dystrophies with abnormalities of dystrophin-associated proteins are recognized, as summarized in Table 70.1. Whilst the classification of muscular dystrophies in terms of proteinopathy is helpful for understanding the pathogenesis of the condi-

Fig. 70.4. (*a*) (*b*). Distal myopathy. There is striking atrophy of posterior>anterior compartment muscle atrophy in this man with Miyoshi myopathy.

tions, the clinical phenotype classification remains important. This is illustrated by the limb girdle muscular dystrophies, which are summarized in Table 70.3.

Distal myopathies

This difficulty in classifying on a molecular basis is also reflected in the distal myopathies, where the gene for autosomal recessive distal muscular dystrophy (ARDMD, Miyoshi myopathy) (Miyoshi et al., 1977; Linssen et al., 1997), is the same as that for the limb girdle muscular dystrophy, LGMD2B, and encodes the dysferlin protein (Liu et al., 1998).

The distal myopathies are primary muscle disorders with progressive muscle weakness and wasting, commencing in the hands or feet (Fig. 70.4). They are rare conditions, but genetic abnormalities have been identified in a number of these (Table 70.4) (Orrell & Griggs, 1999).

Facioscapulohumeral muscular dystrophy

Facioscapulohumeral muscular dystrophy has a distinctive pattern of progressive muscle weakness, involving the face, scapular stabilizers, proximal arms, and peroneal muscles (Fig. 70.5). Age at onset is from infancy to middle age. Clinical signs are present in more than 90% of those affected by age 20 years (Lunt et al., 1989). Muscle biopsy shows dystrophic changes, and sometimes inflammatory changes (Orrell & Griggs, 1999).

A reduction in the number of repeats of a 3.3 kb sequence, termed D4Z4, on the terminal region of chromosome 4q, is associated with facioscapulohumeral muscular dystrophy (Wijmenga et al., 1992; Van Deutekom et al., 1993). Molecular diagnostic testing is available (Deidda et al., 1996; Tawil et al., 1998; Orrell et al., 1999). Inheritance is autosomal dominant. Principles of symptomatic management are similar to those of the other muscular dystrophies. Clinical trials of albuterol, a β-adrenergic agonist, showed some initial possible benefit (Fig. 70.6) (Kissel et al., 1998), but more extensive trials have not yet supported its routine clinical use.

Emery–Dreifuss muscular dystrophy

Emery–Dreifuss muscular dystrophy is an X-linked disorder, characterized by slowly progressive wasting and

Table 70.4. Distal muscular dystrophies

Type	Inheritance	Initial weakness	CK	Biopsy	Gene
Nonaka – early adult – onset type I (familial IBM[a])	Autosomal recessive or sporadic	Legs: anterior compartment	Slightly to moderately increased, usually <5× normal	Vacuolar myopathy	9p1–q1
Miyoshi – early adult – onset type II (LGMD 2B[b])	Autosomal recessive or sporadic	Legs: posterior compartment	Increased 10–150× normal	Myopathic, usually without vacuoles; gastrocnemius often 'end stage'	2p13 dysferlin
Laing – early adult – onset type III	Autosomal dominant	Legs: anterior compartment Neck flexors	Slightly increased, <3× normal	Moderate myopathic changes/no vacuoles	14q
Welander–late adult type I	Autosomal dominant	Hands: fingers/wrist extensors	Normal or slightly increased	Myopathic; vacuoles in some cases	2p13
Markesbery–Griggs/ Udd Late adult onset type II	Autosomal dominant	Legs: anterior compartment	Normal or slightly increased	Vacuolar myopathy	2q

Notes:

[a] Autosomal recessive familial inclusion body myopathy (IBM), also known as quadriceps sparing myopathy, has been genetically linked with Nonaka distal myopathy.

[b] Limb–girdle muscular dystrophy type 2B colocalizes with Miyoshi distal myopathy.

weakness of the scapulohumeral, anterior tibial, and peroneal muscle groups. A distinctive feature is early development of muscle contractures, especially in the elbows, Achilles tendons, and posterior cervical muscles. Cardiomyopathy with conduction defects is common. Onset is usually around age 4 years (Emery & Dreifuss, 1966).

Serum creatine kinase may be normal or moderately elevated (10×). EMG and muscle biopsy are myopathic. Deficiency of emerin may be identified on immunostaining of muscle, and mutations of the EDMD gene identified (Bione et al., 1995; Klauck et al., 1995). Emerin is ubiquitously expressed. It is normally localized to the nuclear membrane. Carrier females may show clinical manifestations. Heart block is a common cause of death, and regular cardiac assessment may allow appropriate insertion of a cardiac pacemaker. Active and passive stretching may delay the development of muscle contractures.

A similar phenotype may be present in autosomal recessive and dominant forms, and not all patients with clinical features of Emery–Dreifuss muscular dystrophy have abnormalities of emerin immunostaining. Other genes are involved. Mutations in the LMNA1 gene, encoding the lamin A and C proteins, are present in some autosomal dominant (Bonne et al., 1999) and recessive (Barletta et al., 2000) forms.

Bethlem myopathy should also be considered (Bethlem & van Wijngaarden, 1976). This is an autosomal dominant myopathy, associated with contractures, but without cardiac involvement. Mutations have been found in type VI collagen genes (Jobsis et al., 1996).

Oculopharyngeal muscular dystrophy

Oculopharyngeal muscular dystrophy (Fig. 70.7) affects ocular and pharyngeal muscles, causing ptosis, dysphagia, and dysarthria, but may also affect other limb girdle and distal limb muscles. Muscle weakness progresses slowly, and is rarely disabling (Victor et al., 1962). Ptosis may obstruct vision, and dysphagia may lead to weight loss, unless treated. Muscle biopsy shows myopathic features, and rimmed vacuoles. Inheritance is autosomal dominant, and a short GCG repeat expansion is present in the *PABP2* gene (poly[A]binding protein 2) (Brais et al., 1998). PABP2 protein is involved in mRNA polyadenylation.

Morphologically defined myopathies

A number of rare myopathies remain defined by their morphological features. These include the core diseases, centronuclear myopathy, nemaline myopathy, and desmin myopathy. Many present as congenital myopathies.

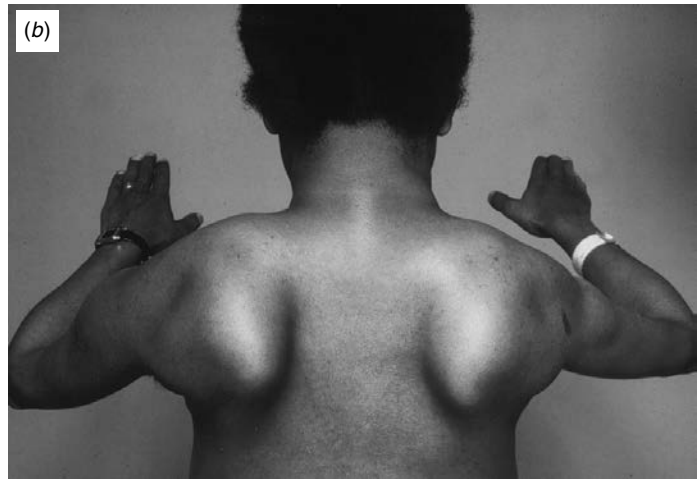

Fig. 70.5. Facioscapulohumeral dystrophy
(*a*) 'Glum' facial appearance and typical shoulder appearance. The scapular winging and descent of the shoulders is evident.
(*b*) Bilateral scapular winging.
(*c*) Atrophy of the elbow flexors and extensors with relative preservation of forearm muscles giving a 'popeye' appearance.

Central core disease

Central core disease is a congenital myopathy, presenting with congenital or early childhood muscle weakness and hypotonia, with developmental delay (Shy & Magee, 1956). There are probably a number of genetic causes, and there is an association with malignant hyperthermia (Denborough et al., 1973). Mutations in the ryanodine receptor gene are identified in central core disease and malignant hyperthermia (Quane et al., 1993). The characteristic morphological feature is the core, which is visible on muscle biopsy as a central, or eccentric, lesion within the muscle fibre. This is probably a result of abnormal maturation and fusion of the myotubes.

Minicore or multicore disease

The cores of minicore or multicore disease are smaller than in central core disease (Paljarvi et al., 1987). The cores are multiple, and the sarcomeres are disrupted. The clinical features are variable, with early childhood onset of slowly progressive muscle weakness. There may be weakness of the extraocular muscles (Fardeau, 1987).

Nemaline myopathy

Nemaline myopathy is a congenital myopathy characterized by formation of rods derived from the Z bands. The term 'nemaline' is derived from the Greek word for thread. The nemaline rods are visible on muscle biopsy (Fig. 70.8, see colour plate section). They are often found in clusters beneath the sarcolemma, but also within the muscle fibre. The ultrastructure of the rods is identical to that of Z bands, containing α actinin (Shy et al., 1963).

Autosomal dominant and recessive forms are

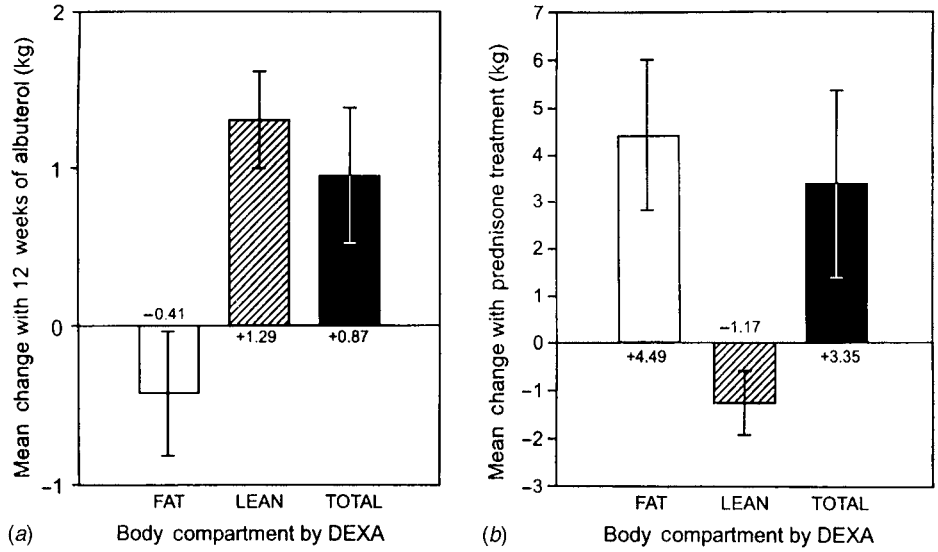

Fig. 70.6. Bar graphs show mean change at 12 weeks in fat, lean, and total body mass compartments for facioscapulohumeral dystrophy patients on albuterol (*a*). The changes contrast with the same determinations made in a prior open-label prednisone trial (*b*). Error bars represent 1 SEM.(From Kissel et al., 1998.)

recognized, as well as sporadic forms. The genes for some forms have been identified: α-tropomyosin (Laing et al., 1995) in autosomal dominant forms, nebulin (Pelin et al., 1999) in autosomal recessive forms, and skeletal muscle α-actin (Nowak et al., 1999) in autosomal dominant and recessive forms. The clinical presentation is most usual in infancy, with hypotonia and proximal or generalized muscle weakness. Facial weakness, and respiratory insufficiency, may be present. More severe neonatal forms, and less severe adult-onset forms occur (Wallgren-Pettersson, 1989; Shimomura & Nonaka, 1989).

Inflammatory myopathies

There are three main groups of inflammatory myopathies: polymyositis, dermatomyositis, and inclusion body myositis, together with some rare conditions such as eosinophilic polymyositis, focal myositis, and myositis associated with other systemic disorders (Dalakas, 1991; Amato & Barohn, 1999).

Polymyositis

Polymyositis is the result of an antigen-specific, cell-mediated immune response directed against skeletal muscle fibres. The specific antigen is not known. On muscle biopsy, there is endomysial inflammation, and mononuclear inflammatory cell invasion of non-necrotic muscle fibres (Fig. 70.9, see colour plate section). These are mainly CD8+ cytotoxic T-cells and macrophages (Arahata & Engel, 1984; Engel & Arahata, 1984). Major histocompatibility complex (MHC) class 1 antigen is expressed on invaded and non-invaded muscle fibres.

Polymyositis most commonly presents in adults, especially women. Initial symptoms are of proximal limb weakness, and neck flexion weakness. Muscle pain and tenderness may be present. Dysphagia may also occur due to oropharyngeal and oesophageal involvement. The myositis may include cardiac muscle, with cardiac failure and conduction abnormalities. Around 10% of patients develop interstitial lung disease, often associated with Jo-1 antibodies (Love et al., 1991). There is a possible mild increased incidence of malignancy in patients with polymyositis (Bohan et al., 1977; Sigurgeirsson et al., 1992; Callen, 1994).

Serum creatine kinase is elevated (5–10×). Jo-1 antibodies are present in around 20% of patients with polymyositis, associated with interstitial lung disease (Hochberg et al., 1984). A more aggressive form of polymyositis may be associated with antibodies to SRP. These patients are resistant to treatment, and have a poor prognosis (Joffe et al., 1993; Miller, 1993). EMG shows features of a myopathy, with additional increased insertional and spontaneous activity.

Polymyositis usually responds to treatment with oral prednisone (Dalakas, 1994). Initial response may take up to 6 months. Prednisone is usually commenced at a high dose, 1mg/kg/day, or higher. Depending on clinical progress, the dose is adjusted, slowly reducing the dose, or converting to alternate day dosing. Azathioprine may be

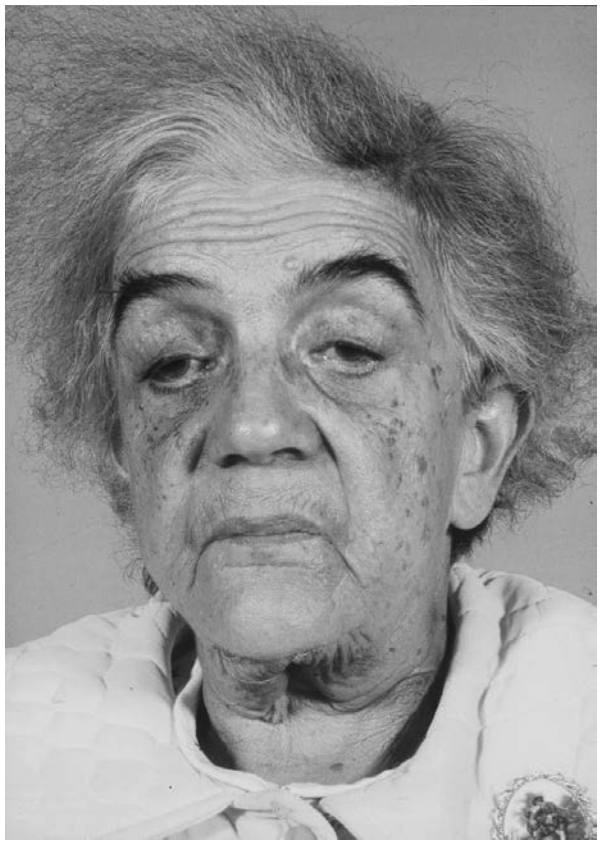

Fig. 70.7. Oculopharyngeal dystrophy: an 84-year-old woman with characteristic appearance. Bilateral ptosis, accompanied by frontalis muscle contraction attempting to elevate the lids. Lower facial weakness is apparent as well.

added if there is inadequate response, or if prednisone is poorly tolerated. The main guide to response is clinical improvement. Serum creatine kinase may be helpful, but may be normal in patients with active disease, or elevated in the absence of disability. If patients become weaker while taking prednisone, a superadded steroid myopathy should be considered. Prophylactic management of steroid-induced osteoporosis is usually indicated, because of the prolonged duration of treatment. In patients refractory to prednisone and azathioprine, other considerations include intravenous immunoglobulin, and rarely other immunosupressants such as methotrexate, cyclophosphamide, chlorambucil, cyclosporine and tacrolimus (Amato & Barohn, 1999).

Dermatomyositis

Dermatomyositis is a humorally mediated microangiopathy, leading to ischemic damage of muscle fibres. Dermatomyositis is an entirely distinct pathological condition from polymyositis, and should not be considered as 'polymyositis with a rash'. Muscle biopsy aids in making the distinction. In dermatomyositis, the muscle biopsy characteristically, although not always, shows perifascicular atrophy (Fig. 70.10, for (*a*) see colour plate section). This has been attributed to a watershed type hypoperfusion of the muscle fascicles, as a result of microangiopathic ischemia. The disease is multifocal. In contrast to polymyositis, invasion of non-necrotic muscle fibres by mononuclear cells is not seen. A perivascular infiltrate may be present in the perimysium. The mononuclear cells are generally macrophages, B-cells, and CD4+ T-helper cells (Arahata & Engel, 1984; Engel & Arahata, 1984).

Dermatomyositis is especially common in childhoood, but may occur at any age, and, as with polymyositis, is more common in women than men. Muscle weakness initially occurs in the proximal limb and neck flexion muscles, but also affects muscles more generally. In children there may be evidence of a more systemic illness with low grade pyrexia and myalgia (Pachman, 1995). Dysphagia may occur in 30% of patients due to involvement of oropharyngeal and esophageal muscles. Involvement of the tongue may rarely cause dysarthria (Tymms & Webb, 1985; Dalakas, 1991).

The characteristic rash of dermatomyositis is called a heliotrope rash, with purplish discoloration of the eyelids, often with some periorbital edema. Papular, scaly, erythematous lesions on the knuckles constitute Grotton's sign. A photosensitive erythematous rash may be present on the face, neck, and other exposed regions. Distal capillary loops may be present in the nail beds, with thrombi or hemorrhage. It is possible for patients to have the characteristic rash, without muscle weakness (Hochberg et al., 1986; Euwer & Sontheimer, 1993).

Subcutaneous calcification is especially common in children with dermatomyositis, but may also occur in adults (Pachman, 1995). This occurs especially on the knees and elbows, but also at other sites, with painful hard nodules, which may ulcerate (Orrell et al., 1998).

The myocardium may be involved, with conduction abnormalities (Haupt & Hutchins, 1982). Around 10% of patients with dermatomyositis develop interstitial lung disease (Dickey & Myers, 1984; Hochberg et al., 1984), often associated with Jo-1 antibodies. The skeletal and smooth muscle of the gastrointestinal tract may be involved, with dysphagia and dysmotility. Vasculitis of the gastrointestinal tract may be a problem, especially in children, with life threatening hemorrhage (Pachman, 1995). The necrotizing vasculitis may affect other tissues including retina, kidney and lungs.

In adults with dermatomyositis there appears to be an increased risk of associated malignancy (Sigurgeisson et

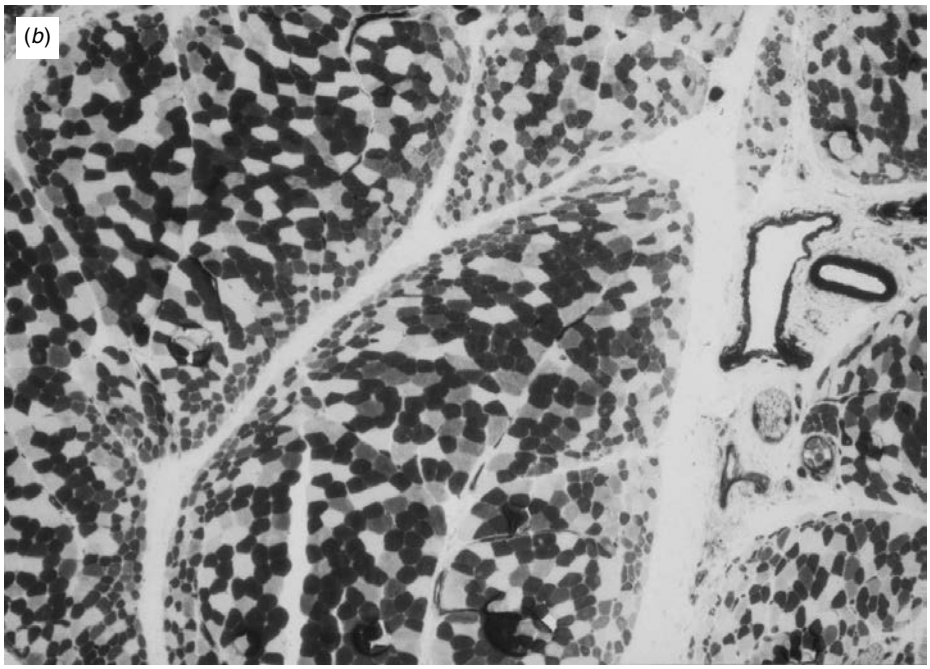

Fig. 70.10. Dermato-myositis muscle biopsy. (*a*) See colour plate section. (*b*) ATPase (pH 9.4) reaction showing that both fibre types are atrophic in a perifascicular distribution.

al., 1992). The extent to which this should be investigated is debatable, but should include full clinical history and clinical examination, with appropriate screening investigations. This examination should be repeated at appropriate intervals. Muscle function may improve after treatment of malignancy.

Serum creatine kinase may be normal or elevated (1–50×). The serum creatine kinase level does not correlate with disease severity. EMG shows features of myopathy, with increased insertional and spontaneous activity.

The treatment of dermatomyositis is similar to that of polymyositis. The rash usually improves with treatment of the myositis. Treatment of subcutaneous calcification is difficult once calcium deposits are found. Oral diltiazem has recently been suggested to be effective (Olizeri et al., 1996).

Overlap syndromes

Myositis may be associated with connective tissue disorders such as scleroderma, and mixed connective tissue disease (mixed clinical features of scleroderma, systemic lupus erythematosus, rheumatoid arthritis, and myositis). This can be either an appearance of polymyositis or dermatomyositis. The diagnostic features are those of the individual connective tissue disease. The myositis is treated as described for polymyositis and dermatomyositis.

Inclusion body myositis

The pathogenesis of inclusion body myositis is unknown. It may be a primary degenerative myopathy, with secondary inflammatory change, or possibly a primary inflammatory myopathy (Griggs et al., 1995). The characteristic findings on muscle biopsy are rimmed vacuoles within the muscle fibres (Fig. 70.11, see colour plate section). Endomysial inflammation may also be present. Amyloid deposition is demonstrated with Congo Red staining. Ragged red fibres may also be present. Electronmicroscopy demonstrates 15–21 nm tubulofilaments in the cytoplasm and intranuclear. An array of proteins including β-amyloid, β-amyloid precursor protein, prion protein, apolipoprotein E, α1-antichymotrypsin, ubiquitin, hyperphosphorylated tau, and neurofilament heavy chain, have been identified within the vacuolated fibres. For diagnostic purposes, the rimmed vacuoles may not always be present on initial biopsy, but may be found on repeated biopsy. The endomysial inflammation is by macrophages and CD8+ cytotoxic T-lymphocytes, invading non-necrotic fibres, and HMC class 1 antigens are expressed on necrotic and non-necrotic fibres. Unlike polymyositis, the T-cell response does not appear to be directed against a muscle specific antigen (Engel & Arahata, 1984).

Inclusion body myositis is the most common inflammatory myopathy in patients over 50 years of age. Patients

exhibit slowly progressive proximal and distal weakness. Unlike polymyositis and dermatomyositis, it is more common in men than women. Muscle weakness and wasting is especially prominent in quadriceps, wrist and finger flexors, and ankle dorsiflexors. Muscle weakness is often asymmetrical. Dysphagia is common, and may be severe. Mild facial weakness may occur. A peripheral neuropathy may be detected. There is no association with cardiac disease or malignancy (Lotz et al., 1989; Amato et al., 1996).

Serum creatine kinase is normal or mildly elevated (1–10×). EMG demonstrates myopathic features, with increased insertional and spontaneous activity, but may also show large polyphasic or 'neurogenic' potentials. Mild axonal sensory neuropathy is present in up to 30% of patients (Amato et al., 1996).

Patients with inclusion body myositis do not respond to treatment with the immunosuppressive agents which are effective in polymyositis and dermatomyositis. It is probable that some patients with steroid-resistant polymyositis have a form of inclusion body myositis. The condition is slowly progressive, and may lead to long term disability, but life expectancy is not usually impaired (Lotz et al., 1989).

Rimmed vacuoles may occur in other myopathies (Table 70.5). The distinction of the hereditary forms is being clarified as the genetic abnormalities are identified. These are termed inclusion body myopathies, as inflammation is not a significant finding.

Table 70.5. Rimmed vacuolar myopathies

Inclusion body myositis
Familial inclusion body myopathy
Distal myopathies
Early adult-onset type II (Nonaka)
Late adult-onset type I (Welander)
Late adult-onset type II (Markesbery–Griggs/Udd)
Oculopharyngeal muscular dystrophy
Miscellaneous myopathies

Eosinophilic polymyositis

The hypereosinophilic syndrome comprises persistent eosinophilia, absence of parasites or other known causes of eosinophilia, and signs and symptoms of organ involvement due to eosinophil infiltration (Moore et al., 1985). Myositis may form part of this syndrome, muscle biopsy showing perivascular and endomysial inflammation, predominantly eosinophils. The cause is unknown, but the muscle necrosis may be related to eosinophilic infiltration.

Clinical features are of slowly progressive muscle pain and proximal weakness, with other systemic features of the hypereosinophilic syndrome. Hypereosinophilia is a diagnostic criterion, and other features include anemia, raised created kinase, and positive rheumatoid factor. Cardiac arrhythmia or conduction block may be present on ECG, chest X-ray may show pulmonary infiltrates, and EMG demonstrates myopathic features with increased insertional and spontaneous activity. Peripheral neuropathy may also be present (Layzer et al., 1977).

Patients may respond to treatment with steroid or other immunosuppressant medication, but for some the multisystem involvement and poor response to treatment may result in a bad prognosis.

Focal myositis

Muscle biopsy demonstrates a mononuclear infiltrate of the endomysium, with macrophages and CD4+ and CD8+ T-cells. The cause is not known, but unlike polymyositis, the cell-mediated response does not appear to be directed against a muscle specific antigen (Caldwell et al., 1995).

The clinical presentation is of a solitary, painful and rapidly expanding skeletal muscle mass, often in the leg. Other diagnostic considerations include soft tissue tumours, and initial focal muscle involvement of sarcoidosis, Behçet's disease, and vasculitis. Serum creatine kinase and ESR are usually normal. The myositis usually resolves spontaneously, without treatment.

Other acquired myopathies

Endocrine myopathies

Abnormalities of muscle have been reported with most forms of endocrine disease, including iatrogenic causes. For many of these conditions, muscle dysfunction resolves on correction of the endocrine abnormality. The commonest causes of muscle dysfunction are thyroid disease (hypothyroid and hyperthyroid), and the corticosteroid disorders (Cushing's disease, Addison's disease, and iatrogenic). Other rarer endocrine causes include growth hormone, insulin, parathormone, and testosterone disturbances (Orrell et al., 1996; Zaidat et al., 1999).

Thyroxine

Hyperthyroid myopathy

Muscle weakness is present in up to 75% of patients with hyperthyroidism, with proximal myopathy being the major manifestation. Cramps, myalgia, fasciculations and

brisk reflexes may resemble amyotrophic lateral sclerosis (Serradell et al., 1990).

Thyrotoxic periodic paralysis
A periodic paralysis clinically resembling hypokalemic periodic paralysis, may be associated with thyrotoxicosis. Proximal limb and truncal weakness may last from hours to a week, and resolves on normalization of thyroid status (Satayoshi et al., 1963).

Exophthalmic Graves' disease
Exophthalmos and ocular myopathy may be associated with autoimmune thyroid disease. Exophthalmic Graves' disease may occur in patients who are biochemically hyperthyroid, but also hypothyroid or euthyroid (Salvi et al., 1990). Enlargement of the extraocular muscles, due to edema, as a result of glycoprotein accumulation and inflammatory changes, may cause optic nerve compression and loss of vision. Treatment of the thyroid disorder should be initiated, but systemic steroids, cyclosporin (Prummel et al., 1989), and rarely surgical decompression of the orbit (Bahn & Gorman, 1987) may be necessary.

Hypothyroid myopathy
Up to 40% of patients with hypothyroidism have evidence of muscle weakness. Hoffmann's syndrome manifests with muscle hypertrophy, weakness, slow movements, painful spasms, and delayed muscle relaxation, in adults (Wilson & Walton, 1959; Klein et al., 1981). In children with congenital hypothyroidism, a similar syndrome, but without cramps, is referred to as Kocher–Debre–Semelaigne syndrome (Debre & Semelaigne, 1935). The muscle symptoms and signs resolve on correction of the hypothyroidism.

Corticosteroids
Glucocorticoid excess
Patients with Cushing's disease, ectopic production of ACTH, and therapeutic corticosteroid administration, may develop a myopathy (Muller & Kugelberg, 1959). Clinical features include a painless, symmetrical, proximal myopathy, affecting the legs more than the arms, together with muscle wasting, and other systemic features of glucocorticoid excess. Recovery of muscle strength may be incomplete following treatment of Cushing's disease (Khaleeli et al., 1983). Treatment of iatrogenic corticosteroid myopathy is often limited by the clinical need for the medication. The lowest dose possible should be given, and alternate day administration may be helpful. A non-fluorinated corticosteroid is less likely to be associated with weakness. Starvation or protein deprivation may exacerbate a corticosteroid myopathy, and adequate nutrition should be given. Physical inactivity may potentiate muscle wasting, and physiotherapy and exercise may be helpful (Falduto et al., 1990).

Critical illness myopathy
A critical illness myopathy has been suggested to be related to steroid administration in critically ill patients (Ramsay et al., 1993). This is an acute, severe myopathy, developing rapidly following administration of high doses of corticosteroids, especially intravenously. This may be an acute necrotizing myopathy in patients with sepsis, and a less severe myopathy in those with uncomplicated asthma (Shee, 1990). The steroids may have a priming effect on the muscle, and other factors such as non-depolarizing blocking agents act as a trigger for the muscle necrosis. Features of critical illness polyneuropathy are usually absent.

Glucocorticoid deficiency
Up to 50% of patients with adrenal insufficiency have symptoms of generalized weakness, muscle cramps and fatigue (Mor et al., 1987). The muscle symptoms recover when the glucocorticoid deficiency is corrected.

Toxic and drug-induced myopathies

Muscle disease or dysfunction is associated with a wide range of toxins and medications (Lane, 1996a,b). An overview is illustrated in Table 70.6. The lists are not exhaustive. The main clinical presentations are of a focal myopathy (related to local administration of toxin or medication), an acute and subacute painful myopathy and a chronic painless proximal myopathy. Medication and toxins should be considered as a cause, and potentially treatable or avoidable cause, of a wide range of muscle symptoms and disorders.

Myopathies associated with systemic disease and infection

Skeletal muscle comprises more than 40% of the body mass, and is vulnerable to involvement in many systemic diseases and infections. Skeletal muscle may be involved in malignant disease, by direct invasion, metastatic spread (Pearson, 1959), carcinomatous neuromyopathy (Brain & Henson, 1958), polymyositis and dermatomyositis (Schulman et al., 1991), and carcinoid syndrome (Swash et al., 1975). Skeletal muscle may be involved in connective tissue disease, including systemic sclerosis (Clements et al., 1978), systemic lupus erythematosus (Tsokos et al., 1981), rheumatoid disease (Haslock et al., 1970), ankylosing spondylitis (Carraba et al., 1984), sarcoidosis (Hewlett

Table 70.6. Drug and toxic myopathies

Type	Drug or toxin	Pathology
Focal myopathy		
Acute	IM injections, e.g. tetracycline, paraldehyde	'Needle myopathy'
Chronic	IM antibiotics or narcotic abuse	Fat, fibrous tissue, loss of muscle cells
Acute and subacute painful myopathy		
Myalgia	anticholinesterases, carbimazole, diuretics, calcium antagonists, β-agonists, danazol, enalapril, topical minoxidil, dipyridamole	
Necrotizing	Alcohol, opiates, lipid-lowering drugs (clofibrate, bezafibrate, fenofibrate, gemfibrozil, lovastatin, pravastatin, memvastatin, simvastatin), ipecac alkaloids, IV steroids, venoms, vitamin A, vitamin E, organophosphates, ε-aminocaproic acid, labetalol, sotalol	Multifocal necrosis, phagocytosis, regeneration
Vacuolar	Drugs or toxins causing hypokalemia, e.g. diuretics, purgatives, amphotericin B, liquorice, carbenoxolone	Cytoplasmic vacuoles
Inflammatory	D-penicillamine, procainamide, and occasionally with many other drugs	Lymphocytic infiltration, necrosis
Mitochondrial	Zidovudine, germanium	Ragged red fibres, abnormal mitochondria on EM
Chronic painless proximal myopathy		
Type 2 atrophy	Alcohol, steroids	Type 2 atrophy
vacuolar	Choroquine, amiodarone, perhexilene, colchicine, vincristine	Lysosomes with myeloid bodies
Drug-induced rhabdomyolysis		
	drug abuse – alchohol, opiates, amphetamines, phencyclidine, ketamine	

Notes:
From Lane (1996), p. 380. By courtesy of Marcel Dekker Inc.

& Brownell, 1975), and other granulomatous disease. Other rare causes of myopathy include vascular and blood disorders (polyarteritis, atherosclerosis, and sickle cell disease), and systemic metabolic disease (hypokalemia, hypomagnesemia, hypophosphatemia, uremic and dialysis myopathy and hypermetabolism of trauma) (Orrell & Lane, 1996).

Muscle may be affected by most infectious agents, including bacteria, viruses, fungi, spirochetes, protozoa, cestodes and nematodes (Orrell & Lane, 1996; Wadia & Katrak, 1999). Of particular importance worldwide are cysticercosis, trichinosis, and human immunodeficiency virus.

Cysticercosis

Human cysticercosis is due to infection with the cestode *Cysticercus cellulosa,* the larval form of *Taenia solium* (the pork tapeworm). The eggs are ingested through human feces. In skeletal muscle, the encysted parasites cause single or multiple nodules, or a pseudohypertrophic myopathy (Jacob & Mathew, 1968). Treatment is with praziquantel. There is a possibility of complications during treatment if large numbers of larvae are rapidly destroyed.

Trichinosis

Trichinosis is due to infection with the larvae of the nematode *Trichinella spiralis*, which is ingested through poorly cooked, infested pork. The larva penetrates the sarcolemma of the skeletal muscle, and encysts within the muscle fibre (Ochoa & Pallis, 1980). The infection may be asymptomatic, or may cause marked myalgia, with tenderness, weakness, and swelling of the muscles. Rapid weakness may cause tetraparesis. Treatment is with thiabendazole, but has the risk of a Herxheimer-like reaction.

Human immunodeficiency virus-associated myopathy

There is an increased incidence of myopathy in patients with human immunodeficiency virus (HIV) infection, although generally not as prominent as the associated neuropathic diseases (Lane, 1996a,b; Wadia & Katrak,

1999). A polymyositis-like inflammatory myopathy is recognized in relation to HIV infection (Dalakas et al., 1986). Also a similar myopathy, but with necrotizing rather than inflammatory features (Simpson & Bender, 1988). HIV-associated myopathy is one of the causes of the relatively common HIV wasting syndrome (Simpson et al., 1990). Myopathy or myositis due to opportunistic infection is relatively uncommon, although staphylococcal pyomyositis (Watts et al., 1987), and muscle infection with, for example, *Mycobacterium intracellulare* (Wrzolek et al., 1989) or microsporidosis (Ledford et al., 1985) may be related to immunosuppression. A myopathy may be associated with treatment of HIV infection. In particular, treatment with zidovudine (AZT) is associated with myalgia and fatiguablity (Simpson et al., 1997). Muscle biopsy in these patients usually demonstrates mitochondrial abnormalities, including ragged red fibres (Dalakas et al., 1990).

The electrical excitability of skeletal muscle enables action potentials to be generated at the motor end plate and propagated along the sarcolemma and into the transverse-tubule (T-tubule) membranes of muscle fibres. This spread of electrical activity is critical for coupling the local synaptic depolarization at the neuromuscular junction to the release of intracellular calcium from the sarcoplasmic reticulum. Several primary and secondary disorders of skeletal muscle are associated with abnormal excitability. An increase in sarcolemmal excitability manifests as a tendency for the autonomous generation of repetitive action potentials, persistent contraction and delayed relaxation, the hallmarks of myotonia. By contrast, intermittent failure of muscle membrane excitability causes paroxysmal weakness or paralysis that is characteristic of periodic paralysis. These alterations in muscle excitability produce a spectrum of clinical syndromes in which a patient may have myotonia, periodic paralysis, or a combination of both (Fig. 71.1).

The physiological basis for the generation of muscle action potentials is now well understood at the cellular and molecular levels. The rapid opening of voltage-gated sodium channels is responsible for the initial upstroke in the muscle action potential and for its propagation along sarcolemmal membranes. The somewhat slower activation of potassium channels contributes to repolarization, while chloride conducting ion channels help stabilize the membrane potential at the resting level to guard against spurious action potential triggering. Many of the ion channel molecules that participate directly in generating muscle action potentials have been defined at the primary nucleotide sequence level, and this work has enabled investigation into the genetic basis of disorders of sarcolemmal excitability. In parallel, advances in cellular electrophysiology coupled with the use of recombinant ion channels have contributed greatly to advancing our knowledge of the molecular pathophysiology of such disorders.

This chapter focuses upon the clinical characteristics and pathophysiology of two categories of abnormal sarcolemmal excitability: myotonia and periodic paralysis. In the past decade, the discovery of the underlying molecular defects responsible for many of the inherited myotonias and periodic paralyses has led to a revised classification of these disorders. The functional consequences of the genetic defects on the physiology of voltage-gated sodium and chloride channels serves as a framework from which to understand the mechanistic basis of these disorders at the molecular level. Finally, the symptomatic treatment of myotonia and periodic paralysis is discussed in relation to the therapeutic principles of compensating for the biophysical defects of mutant ion channels.

Non-dystrophic myotonias

Myotonia is clinically characterized by an abnormal delay in relaxation following voluntary or induced muscle contraction (Streib, 1987; Gutmann & Phillips, 1991). Myotonia is associated with a variety of inherited and acquired disorders (Table 71.1) and certain clinical features may aid in establishing the diagnosis (Table 71.2). Patients with myotonia experience muscular stiffness upon initiating movement that typically resolves within several seconds. The resolution of stiffness associated with continued activity is referred to as the 'warm-up' phenomenon and is most typical of the disorder myotonia congenita which is caused by dysfunction of muscle chloride channels. By contrast, muscular stiffness that is accentuated by continued activity (paradoxical myotonia) is characteristic of the disorder paramyotonia congenita which is caused by mutations in the muscle sodium channel gene. In paramyotonia congenita, myotonic

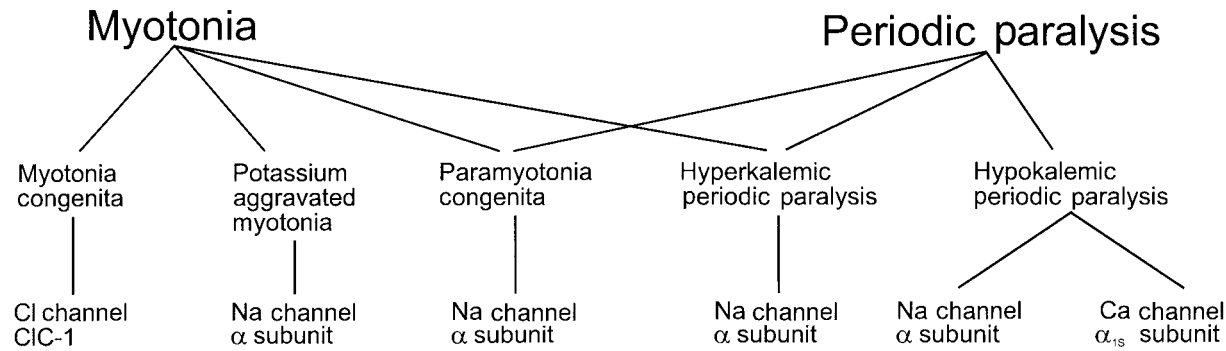

Fig. 71.1. Spectrum of altered skeletal muscle excitability in the hereditary nondystrophic myotonias and periodic paralyses. Enhanced excitability produces myotonia (left side), whereas intermittent loss of excitability results in periodic paralysis (right side). Chloride channel defects cause myotonia, calcium channel mutations give rise to periodic paralysis without myotonia, whereas sodium channel mutations may result in myotonia only, periodic paralysis only, or a combination of both.

Table 71.1. Inherited and acquired myotonias

Non-dystrophic myotonias
Autosomal dominant myotonia congenita (Thomsen's disease)
Recessive generalized myotonia (Becker's myotonia)
Hyperkalemic periodic paralysis
Paramyotonia congenita
Potassium-aggravated myotonia
Other sodium channel myotonias
Chondrodystrophic myotonia (Schwartz–Jampel syndrome)
Dystrophic myotonias
Myotonic dystrophy (DM1)
Proximal myotonic myopathy (PROMM or DM2)
Acquired and drug-induced myotonias
Hypochloremia
Hypothyroidism (unmasks latent PROMM or Thomsen's disease)
Cholesterol lowering drugs (clofibrate, HMG-CoA reductase inhibitors)
2,4-dichlorophenoxyacetic acid (2,4-D)
Anthacene-9-carboxylic acid (9-AC)
20,25-diazacholesterol
Propranolol (unmasks latent myotonic dystrophy)
Vincristine (unmasks latent myotonic dystrophy)

muscular stiffness is usually brought on by exposure to cold temperatures. In other cases, myotonia is exacerbated by ingestion of foods rich in potassium (potassium-aggravated myotonia) or rarely may be associated with pain or cramping in contracting muscles. The term 'sodium channel myotonia' has been introduced to describe inherited forms of myotonia associated with mutations in the muscle sodium channel gene that are difficult to categorize clinically.

Physical examination may reveal a myotonic delay in muscle relaxation after voluntary contraction or percussion myotonia, a persistent dimpling of prominent muscles (e.g. thenar eminence, tongue) following a sudden blunt impact such as the blow from a reflex hammer. The electromyogram in myotonic muscle shows increased insertional activity and high frequency repetitive discharges of motor unit potentials that typically last several seconds following muscle percussion, needle movement or muscle contraction. These repetitive discharges correlate well with the perceived delayed relaxation of muscle and represent the electrophysiological hallmark of the disorder.

Myotonia congenita

Congenital myotonia in the absence of muscular weakness or dystrophy is characteristic of myotonia congenita. Myotonia congenita may be inherited as either an autosomal dominant (Thomsen's disease) or recessive (recessive generalized myotonia (RGM), Becker's myotonia) trait. The clinical features of both conditions are similar except that the recessive form is generally more severe. In addition to myotonic muscular stiffness, patients with RGM may sometimes experience transient (<1 minute) weakness upon initiating movement especially after a period of prolonged rest (Rüdel et al., 1988). In both conditions, myotonia may be manifest soon after birth, although in Thomsen's disease, myotonia is usually not recognized until later in childhood. Mild to moderate muscular hypertrophy is often associated with these conditions and may be the first clinical sign during infancy. Muscular hypertrophy associated with congenital myotonia is presumably caused by chronically increased muscular activity.

Table 71.2. Clinical features of the non-dystrophic myotonias and periodic paralyses

Disorder	Myotonia congenita		Potassium-aggravated myotonia[a]	Paramyotonia congenita	Hyperkalemic periodic paralysis	Hypokalemic periodic paralysis
Inheritance	Dominant	Recessive	Dominant	Dominant	Dominant	Dominant
Penetrance	High	High	High	High	High	↓ females
Age of onset	Congenital	First decade	First decade	First decade	First decade	Second decade (puberty)
Myotonia						
Stiffness	Moderate	Severe	Mild to severe	Moderate	Mild	None
Distribution	Generalized	Generalized, legs	Variable	Hands, face	Hands, face	–
Special features	Improves with warm-up	Improves with warm-up	Fluctuates, aggravated by K^+, Pain with stiffness	Paramyotonia, aggravated by cold	Aggravated by K^+	–
EMG	3+	3+	2+ to 3+	2+ to 3+	0 to 2+	0
Episodic weakness						
Severity	None	Mild	None	Mild to severe	Moderate to severe	Severe (when present)
Distribution	–	Legs or arms	–	Regional or generalized	Regional or generalized	Generalized
Duration	–	Transient (s)	–	Minutes to a day	Minutes to a day	Hours to days
Provocation	–	Forceful effort after rest	–	Cold, rest after exercise	K^+, rest after exercise, fasting	Rest after exercise, carbohydrates
Permanent weakness	None	None	None	None	Variable late-onset proximal weakness	Prominent late-onset proximal weakness

Note:
[a] Includes myotonia fluctuans, myotonia permanens, and acetazolamide-responsive myotonia.

Myotonia may be mild or even subclinical in patients with dominant myotonia congenita but electromyographic evidence of myotonia will usually be evident in these patients (so-called latent myotonia). Electromyographic evidence of myotonia may also be present in asymptomatic carriers of recessive myotonia alleles especially in males (Mailander et al., 1995).

Reduced skeletal muscle membrane chloride conductance in myotonia congenita

Our current understanding of the pathogenesis of myotonia caused by defects in chloride channel function originated with the investigations of Bryant and colleagues that elucidated the membrane abnormalities in the myotonic goat (Bryant, 1979). These animals have been referred to as 'fainting goats' because of their tendency to develop severe acute muscular stiffness and fall when attempting to make sudden forceful movements or when startled. Anecdotal evidence suggests that the myotonic goat phenotype is transmitted as an autosomal dominant trait although most herds have been inbred resulting in a severe condition resembling RGM. The clinical behaviour and electrophysiologic properties of muscle in this animal are remarkably similar to human myotonia congenita. Also similar to the human disease, myotonia in goats is associated with a missense mutation in the muscle chloride channel gene (Beck et al., 1996).

Bryant and colleagues observed that skeletal muscle fibres from myotonic goats have a severe decrease in resting membrane chloride conductance and that this was directly associated with myotonic discharges (Adrian & Bryant, 1974). The link between reduced chloride conductance and myotonia was further supported by their observation that normal muscle fibres became myotonic when bathed in an extracellular solution lacking chloride ions. The importance of the reduced sarcolemmal chloride conductance in the pathophysiology of myotonia has also been supported by the finding of a reduced chloride conductance in myotonia

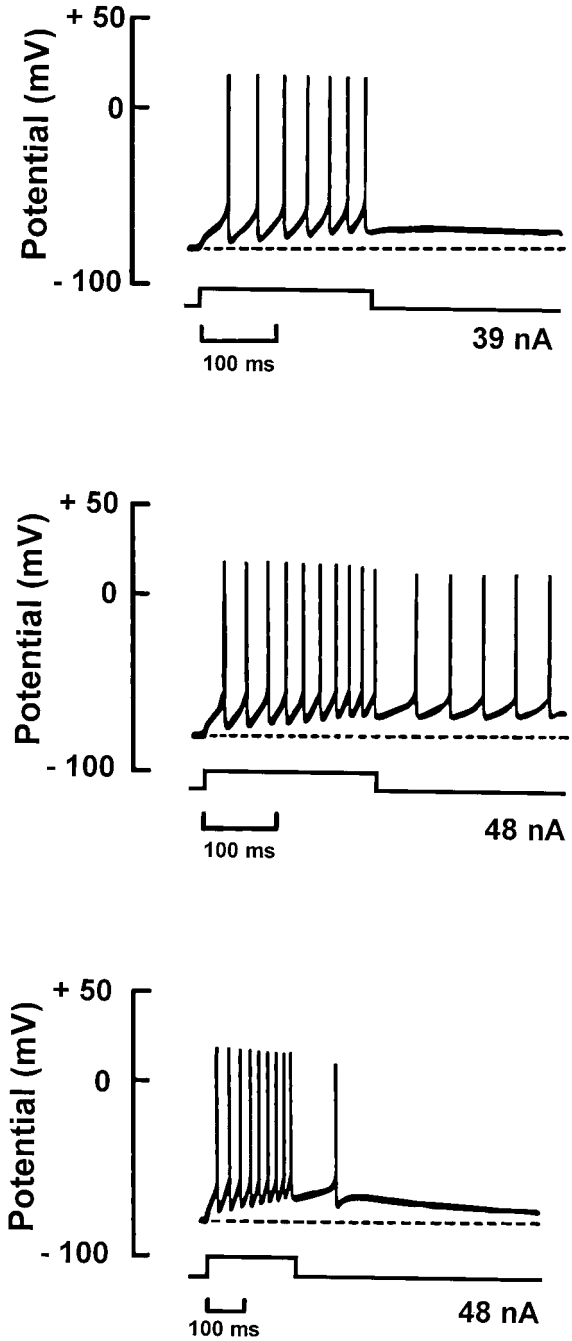

Fig. 71.2. Action potential recordings from myotonic goat muscle in response to graded electrical stimulation (modified after Adrian & Bryant, 1974). In the top tracings, stimulation of muscle fibres (39 nA) produces multiple action potential spikes and a small afterdepolarization visible as the elevated membrane potential above the horizontal dotted line (representing the resting potential). With a stronger stimulus (48 nA, centre tracings) the afterdepolarization reaches threshold voltage and triggers spontaneous action potentials that fire after termination of the electrical stimulus. The lower tracings illustrate the development of the after-depolarization on a compressed time scale.

induced with aromatic carboxylic acids (Furman & Barchi, 1978) and by using computer simulations of muscle action potentials (Barchi, 1975).

Unlike other excitable membranes, skeletal muscle has a high chloride conductance accounting for approximately 70% of the total resting membrane ion conductance (Palade & Barchi, 1977a). To a first approximation, chloride ions are distributed passively across the sarcolemma. This means that on a slow timescale of minutes, chloride moves in or out of the cell until the intracellular concentration is adjusted to set the chloride equilibrium potential equal to the resting potential. Chloride ions do not actively set the resting potential. However, in response to any change in the membrane potential, a large chloride current will flow that tends to return the membrane potential to its previously established resting value. In skeletal muscle the high resting chloride conductance acts like an electrical buffer that is important for stabilization of the resting potential and repolarization after an action potential.

A reduced chloride conductance has two effects on sarcolemmal excitability. First, a smaller electrical stimulus is sufficient to elicit action potentials with a diminished or absent chloride conductance thereby directly demonstrating enhanced excitability (Adrian & Bryant, 1974). Furthermore, with the propagation of action potentials along T-tubule membranes, the local concentration of extracellular potassium rises due to efflux through activated potassium channels. During a sufficiently long train of action potentials, extracellular potassium in the T-tubules rises substantially and exerts a depolarizing effect on the resting membrane potential. Normally, this rise in extracellular potassium has little effect on membrane voltage because of the electrical dampening effect of sarcolemmal chloride conductance. However, in the case of myotonic muscle with a diminished or absent chloride conductance, potassium accumulation in the T-tubule has a substantial impact on membrane voltage. Following each action potential, the membrane potential fails to repolarize to its resting level, producing an afterdepolarization that dissipates slowly over several hundred milliseconds (Fig. 71.2). When sufficient numbers of impulses are propagated rapidly in a myotonic muscle fibre, this afterdepolarization can achieve threshold voltage and trigger spontaneous action potentials in the adjacent surface membranes independent of neuromuscular transmission.

These autonomous action potentials will cause persistent muscle contraction and delayed relaxation after a voluntary movement and thus result in clinical myotonia.

Molecular defects of *CLCN1* in myotonia congenita

The observations of Bryant and colleagues were made in the early 1970s, and a central hypothesis to explain the pathogenesis of myotonia congenita was the existence of defects in the formation of sarcolemmal chloride channels or abnormalities in their regulation. Approximately 20 years later, the first candidate gene encoding a muscle membrane chloride channel was discovered. A new gene family encoding voltage-sensitive chloride channels (the ClC family) was described by Jentsch, and colleagues, with identification of complementary DNA (cDNA) sequences encoding ClC-0 from the electric ray, *Torpedo marmarota* (Jentsch et al., 1990). The first mammalian isoform was identified in rat skeletal muscle (ClC-1) (Steinmeyer et al., 1991a).

Human ClC-1 is a protein of 988 amino acids and is encoded by the 23 exons of the *CLCN1* gene located on chromosome 7q35 (Lorenz et al., 1994). Recombinant human ClC-1 exhibits many of the physiological and biophysical properties of native sarcolemmal chloride channels when reconstituted in heterologous expression systems such as *Xenopus* oocytes or cultured mammalian cells (Pusch et al., 1994; Fahlke et al., 1996). The channel has an ionic selectivity sequence of $Cl^- > Br^- > I^-$, and a current–voltage relationship exhibiting inward rectification (Fahlke et al., 1997a). Human ClC-1 channels have a significant open probability at voltages near the resting membrane potential of skeletal muscle. The ClC-1 channel protein probably has a complex three-dimensional structure consisting of multiple variable length membrane-spanning segments as observed for purified bacterial CIC channels analysed by X-ray crystallography (Dutzler et al., 2002). Two identical ClC-1 subunits are required to form a functional chloride channel (Steinmeyer et al., 1994; Fahlke et al., 1997b) and there is evidence that the channel complex forms two independent ion conduction pathways or ion pores (Saviane et al., 1999) although this is controversial (Fahlke et al., 1998).

Several lines of evidence have indicated that ClC-1 is the principal skeletal muscle chloride channel, an appropriate candidate for genetic abnormalities associated with myotonia congenita. Steinmeyer and colleagues identified mutations in ClC-1 associated with congenital myotonia in the homozygous *adr* (arrested development of righting) myotonic mouse (Steinmeyer et al., 1991b). This work was soon followed by demonstration of linkage of genetic loci near *CLCN1* with myotonia congenita (Abdalla et al., 1992), and the identification of *CLCN1* mutations in both RGM and autosomal dominant myotonia congenita (Koch et al., 1992; George et al., 1993a).

Figure 71.3 illustrates the location and type of most known mutations associated with these two disorders. The majority of mutations associated with autosomal dominant myotonia congenita cause single amino acid substitutions throughout the chloride channel protein (missense mutations). The one exception is a nonsense mutation (R894X) that results in a truncating premature stop codon near the carboxyl terminus of the protein (George et al., 1994). The most common Thomsen's disease mutation found in North America causes the non-conservative substitution of glycine-230 with glutamic acid (G230E) (George et al., 1993a). A missense mutation (P480L) associated with myotonia congenita has also been defined in an extended German pedigree traced back to Dr Julius Thomsen who originally described the syndrome in himself and other family members (Thomsen, 1876; Steinmeyer et al., 1994). A mild form of autosomal dominant myotonia termed myotonia levior has also been associated with mutations in *CLCN1* (Lehmann-Horn et al., 1995). Chloride channel mutations have also been discovered in the myotonic goat (Beck et al., 1996) and myotonic dog (Rhodes et al., 1999).

Most reported *CLCN1* mutations occur in association with RGM or sporadic cases of myotonia congenita, however there are very few common alleles. Perhaps the two most frequently discovered alleles in patients with recessive myotonia are the missense mutation F413C and a 14 base pair deletion inducing a frameshift (Koch et al., 1992; Meyer-Kleine et al., 1994). The majority of mutations have been reported in either single families or isolated cases, and there is a high frequency of compound heterozygosity (inheritance of a different mutant allele from each parent) among RGM patients. In exceptional cases, families have been identified in which more than the two mutations segregate with the disease. This results in the occurrence of different compound genotypes in members of the same family and potentially gives rise to variable myotonia severity within a single family (Sloan-Brown & George, 1997). There are few reliable estimates of the carrier frequency of *CLCN1* mutations, but these disorders are generally considered uncommon.

A few mutations have been associated with either dominant or recessive forms myotonia congenita. In some cases, this may be explained by pseudodominant inheritance whereby an RGM parent having two *CLCN1* mutations mates with a heterozygous carrier to produce offspring with a 50% likelihood of inheriting one disease allele from each parent (Fig. 71.4). Another explanation for this observation is incomplete penetrance (lack of phenotype expression in mutation carriers) of certain dominant mutations.

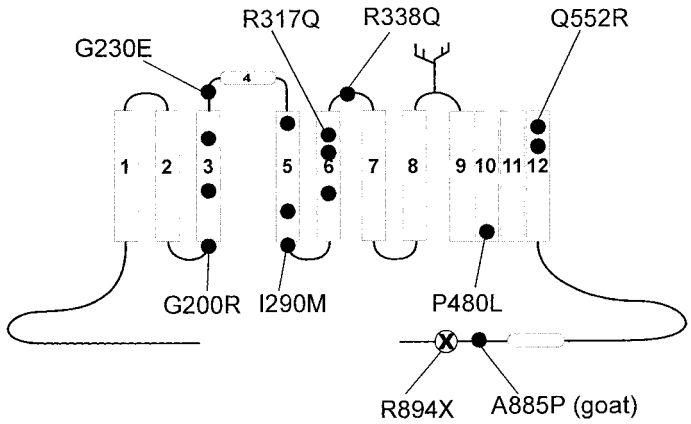

Fig. 71.3. Location and type of mutations in the ClC-1 chloride channel associated with dominant myotonia congenita and recessive generalized myotonia illustrated on a transmembrane topology model of ClC-1. Each symbol represents the approximate position of a single mutation within the channel protein and the type of mutation is coded as indicated by the inset.

Variable phenotype severity and incomplete penetrance associated with certain dominant alleles have not been adequately explained. Current hypotheses include intrinsic differences in the severity of chloride channel dysfunction associated with specific mutations or the existence of modifier genes that affect chloride channel function.

The allelic heterogeneity associated with myotonia congenita indicates that many *CLCN1* mutations arise spontaneously. This creates difficulty for performing molecular genetic analyses because a comprehensive survey of the entire gene sequence is necessary to detect mutations in an individual. In the case of large or consanguineous families with dominant or recessive myotonia, it is conceivable to use linkage analysis with polymorphic markers in and around the chloride channel gene on chromosome 7q35 to help establish a genetic diagnosis. However, most patients with myotonia congenita appear sporadic or are associated with small kindreds. In the future, new methods for mutation detection may facilitate the systematic and comprehensive search for mutations in this gene.

Functional consequences of *CLCN1* mutations

Based on experiments with animal models of myotonia congenita and computer simulations of muscle action

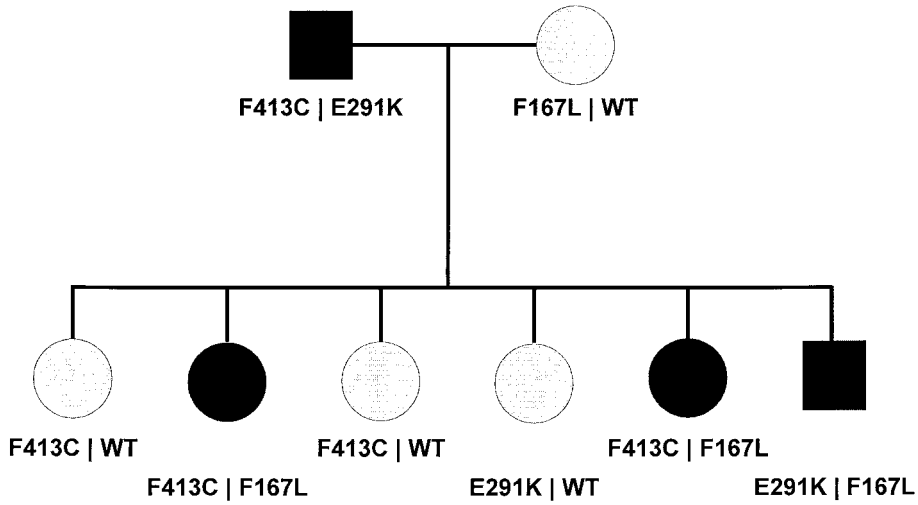

Fig. 71.4. An illustration of pseudodominant inheritance of *CLCN1* mutations in a family with recessive generalized myotonia (RGM). Black symbols indicate affected individuals and grey symbols represent unaffected mutation carriers. Although the mutations F413C, E291K, and F167L have all been associated with RGM, 50% of offspring in this family are affected because of the likelihood that both parents transmit disease-producing alleles.

potentials, it has been deduced that a reduction in sarcolemmal chloride conductance to 20% of normal is required for the occurrence of myotonia (Barchi, 1975). In RGM, this small level of residual chloride conductance is most readily explained by mutations which cause a complete or near complete loss of function of the ClC-1 chloride channel (Heine et al., 1994). As illustrated in Fig. 71.3, approximately half of the *CLCN1* mutations associated with recessive myotonia disrupt the coding sequence of the gene by introducing stop codons, causing defective exon splicing or introducing frameshifts by insertions or deletions. In the case of missense mutations, experiments have been performed with recombinant human ClC-1 chloride channels expressed in heterologous systems including *Xenopus oocytes* and cultured mammalian cells to elucidate their functional effects.

Using electrophysiologic recording techniques, several investigators have ascertained that many missense mutations cause non-function or altered gating behaviour of ClC-1. The most common gating defect caused by a variety of recessive and dominant alleles is a shift in the voltage-dependence of chloride channel activation (Pusch et al., 1995). The open probability of chloride channels is controlled by intrinsic voltage sensitive gating mechanisms such that their activity increases with more depolarized membrane potentials (Fig. 71.5). At the resting membrane potential in skeletal muscle (−85 mV), the probability that chloride channels reside in an active or open state is approximately 30–40%. This open probability increases in a sigmoidal relationship with voltage such that maximal channel opening occurs at positive potentials. Several mutations associated with myotonia congenita shift the relationship between membrane voltage and open probability to more depolarized potentials such that, at the resting membrane potential, the activity of the mutant chloride channels is low.

In heterozygous carriers of mutations, both wild-type and mutant chloride channels will coexist in the same cell. In vitro experiments replicating the combination of wild-type and mutant alleles have illustrated that the presence of a single wild-type allele can overcome the defect associated with recessive mutations but is unable to compensate for dominant mutations (Kubisch et al., 1998). This apparent interaction between alleles most likely occurs at the protein level and is best explained by experimental evidence indicating that the muscle chloride channel is a dimer composed of two identical ClC-1 subunits (Steinmeyer et al., 1994; Fahlke et al., 1997b). In this context, assembly of mutant and wild-type chloride channel proteins results in a dominant-negative reduction in chloride channel activity in the case of mutations in Thomsen's disease. By contrast, recessive alleles may be rescued by assembly with the wild-type allele. A variable degree of rescue of this voltage dependent shift in activation has been observed with certain dominant alleles that exhibit incomplete penetrance in Thomsen's disease families (Kubisch et al., 1998). This has led to the hypothesis that the biophysical mechanism of incomplete penetrance

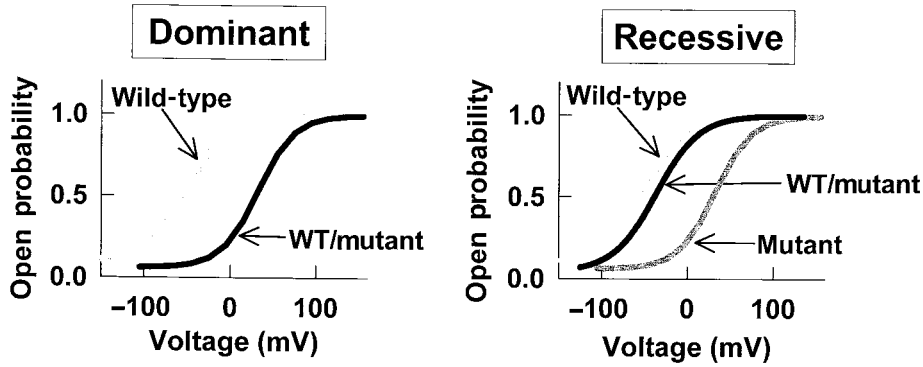

Fig. 71.5. Voltage-dependence of ClC-1 open probability is illustrated for wildtype and mutant channels. Wildtype ClC-1 exhibits a sigmoidal voltage-dependent open probability such that 30–40% of channels will be active at the resting membrane potential of skeletal muscle (−85 mV). A variety of mutations that cause autosomal dominant myotonia congenita and RGM shift the voltage-dependence of ClC-1 open probability to more depolarized potentials thus reducing the proportion of channels that are active at the resting membrane potential. Dominant mutations exert this effect more strongly than recessive alleles and cannot be rescued by coexpression with the wildtype channel.

may relate to a milder degree of dominant-negative effects of the mutant allele on the dimeric channel complex.

A second type of gating disturbance observed in chloride channels with recessive mutations is an inversion of the voltage sensitivity of channel activation. This was first reported in association with the recessive mutation D136G (Fahlke et al., 1995) but has since been reported associated with other alleles (Zhang et al., 2000). Finally, a distinct mechanism of chloride channel dysfunction associated with the common dominant allele G230E has been elucidated (Fahlke et al., 1997c). This mutation causes a dramatic alteration in the ion selectivity of the mutant chloride channel such that there is a reversal in the normal halide ion selectivity sequence and an increase in cation permeability. Disruption of ion selectivity in this context is believed to occur because of a major disruption in the structure of protein segments near the pathway for permeant ions (Fahlke et al., 1997d).

There are two major unanswered questions relevant to the pathophysiology of myotonia congenita. First, there is continued investigation into the explanation for variable penetrance as discussed above. The leading hypotheses include intrinsic variability of the biophysical nature of the channel dysfunction and the variable impact that mutant alleles have on the wild-type channel protein. The second major unanswered question is the etiology of the warm-up phenomenon observed most commonly in myotonias associated with chloride channel dysfunction. There have been suggestions that an activity dependent increase in ClC-1 chloride channel activity may underlie the warm-up phenomenon in some cases (Pusch et al., 1995), although this is difficult to reconcile with myotonia caused by the complete absence of chloride channel protein. It is conceivable that other types of chloride channels contribute to the sarcolemmal chloride conductance in an activity-dependent fashion although there is little evidence to support this presently. The same potassium accumulation that depolarizes the fibre to initiate myotonic discharges may also inactivate a fraction of sodium channels and thereby reduce excitability. Finally, activation of Na^+/K^+-ATPase (sodium pump) during repetitive action potential generation may enable the cell to compensate for after-depolarizations by increasing potassium uptake in the T-tubule membranes and by an increased hyperpolarizing contribution of the sodium pump to the membrane potential.

Acquired myotonia from disruption of skeletal muscle chloride conductance

A small number of drugs and toxins may cause myotonia by reducing sarcolemmal chloride conductance (Kwiecinski, 1981; Mastaglia, 1982). The most well-studied agents are aromatic carboxylic acids including the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) (Bradberry et al., 2000) and the cholesterol-lowering drug clofibrate (2-(*p*-chlorophenoxy) propionic acid) (Conte-Camerino et al., 1984). These agents produce their clinical effects through two distinct mechanisms. Reduction of sarcolemmal chloride conductance by 2,4-D and several other aromatic carboxylic acid compounds is caused by altered ion selectivity of the muscle chloride channel (Palade & Barchi, 1977b). By contrast, clofibrate modulates chloride channel gating (accelerates deactivation) and shifts the voltage dependence of channel activation to more depolarized

potentials (Pusch et al., 2000) similar to many myotonia-producing *CLCN1* mutations. The effects of clofibrate, a racemic mixture, are caused entirely by its negative enantiomer (De Luca et al., 1992; Aromataris et al., 1999). The HMG-CoA reductase inhibitors, simvastatin and pravastatin, can induce myotonia in rabbits by reducing sarcolemmal chloride conductance (Sonoda et al., 1994; Pierno et al., 1995) but there have been no reports of myotonia in humans associated with these agents.

Potassium-aggravated myotonia

Potassium-aggravated myotonia (PAM) is the most recently recognized form of familial non-dystrophic myotonia (Lerche et al., 1993; Mitrovic et al., 1994). PAM presents as dominantly inherited generalized myotonia that often fluctuates over the course of days or in relation to activity or diet. Before the advent of molecular genetic testing, these cases were usually classified as dominant myotonia congenita. Defects in *CLCN1* are not found in PAM, however, and the molecular basis of PAM is missense mutations in the adult skeletal muscle sodium channel gene, *SCN4A* (Fig. 71.6). Functional studies of expressed sodium channels have shown that the mutations associated with PAM partially disrupt fast inactivation (Lerche et al., 1993; Mitrovic et al., 1994; Hayward et al., 1996). This gain-of-function defect increases excitability of the sarcolemma, and predisposes the muscle fibre to runs of myotonic discharges (see further discussion below under HyperPP/PMC). In contrast to other forms of myotonia caused by mutations in *SCN4A*, by definition episodic weakness does not occur in PAM.

After the molecular genetic distinction had been established between PAM and dominant myotonia congenita, several clinical differences between these myotonic syndromes have been recognized. Unlike myotonia congenita, the myotonic stiffness in PAM fluctuates from day to day and may be aggravated by rest several minutes after exercise or by potassium ingestion. Despite the emphasis of potassium sensitivity in the term PAM, exacerbation of myotonia by potassium challenge is not required to establish a diagnosis of PAM. Provocative testing is generally not advisable because this may trigger severe myotonia and muscle pain for hours to a day or more. Cooling does not aggravate myotonia in myotonia congenita, but often worsens the stiffness in PAM. The absence of paramyotonia distinguishes PAM from cases of paramyotonia congenita (PMC, see below) without weakness. Several clinically described variants of dominant myotonia are now considered to be forms of PAM: myotonia fluctuans (Ricker et al., 1994a), myotonia permanens (Lerche et al., 1993), acetazolamide-responsive myotonia (Ptacek et al., 1994a), and painful congenital myotonia (Rosenfeld et al., 1997).

Periodic paralysis

The periodic paralyses are inherited disorders of skeletal muscle that present as recurrent episodes of muscle weakness, without altered consciousness or sensory abnormalities, followed by spontaneous recovery (see Lehmann-Horn & Engel, 1994; Cannon, 1998 for recent reviews). Attacks are episodic, rather than having any regular periodicity, and may range from mild weakness to flaccid quadriparesis. During an attack, affected fibres are depolarized which renders them electrically inexcitable and therefore incapable of generating force. The loss of excitability is caused by the normal voltage-dependent inactivation of sodium channels. Interictally, muscle strength is usually normal. The inheritance pattern is autosomal dominant, with a high degree of penetrance.

Historically, the periodic paralyses were classified according to changes in blood potassium levels that occurred concomitantly with the attacks of weakness. Patients with hypokalemic periodic paralysis (HypoPP) invariably have low serum potassium levels during a spontaneous attack and do not have myotonia. In hyperkalemic periodic paralysis (HyperPP), the serum potassium during an episode of weakness is often high, but may be normal. The changes in serum potassium concentration are primarily due to transient shifts of potassium from the myoplasm to the extracellular space (HyperPP) or from the extracellular space into muscle (HypoPP). HyperPP and related myotonic syndromes (paramyotonia congenita and potassium-aggravated myotonia) are caused by missense mutations in the skeletal muscle voltage-gated sodium channel (for reveiw see Lehmann-Horn & Jurkat-Rott, 1999). HypoPP is genetically heterogeneous. In most families with HypoPP, the molecular defect is a missense mutation in the L-type skeletal muscle calcium channel (Jurkat-Rott et al., 1994; Ptacek et al., 1994b). For a small subset of HypoPP families, missense mutations have been found in the skeletal muscle sodium channel whereas the L-type calcium channel is normal (Bulman et al., 1999; Jurkat-Rott et al., 2000).

Hyperkalemic periodic paralysis and paramyotonia congenita

Periodic paralysis in association with elevated serum potassium was first recognized by Hellweg-Larsen and colleagues (Hellweg-Larsen et al., 1955) and later

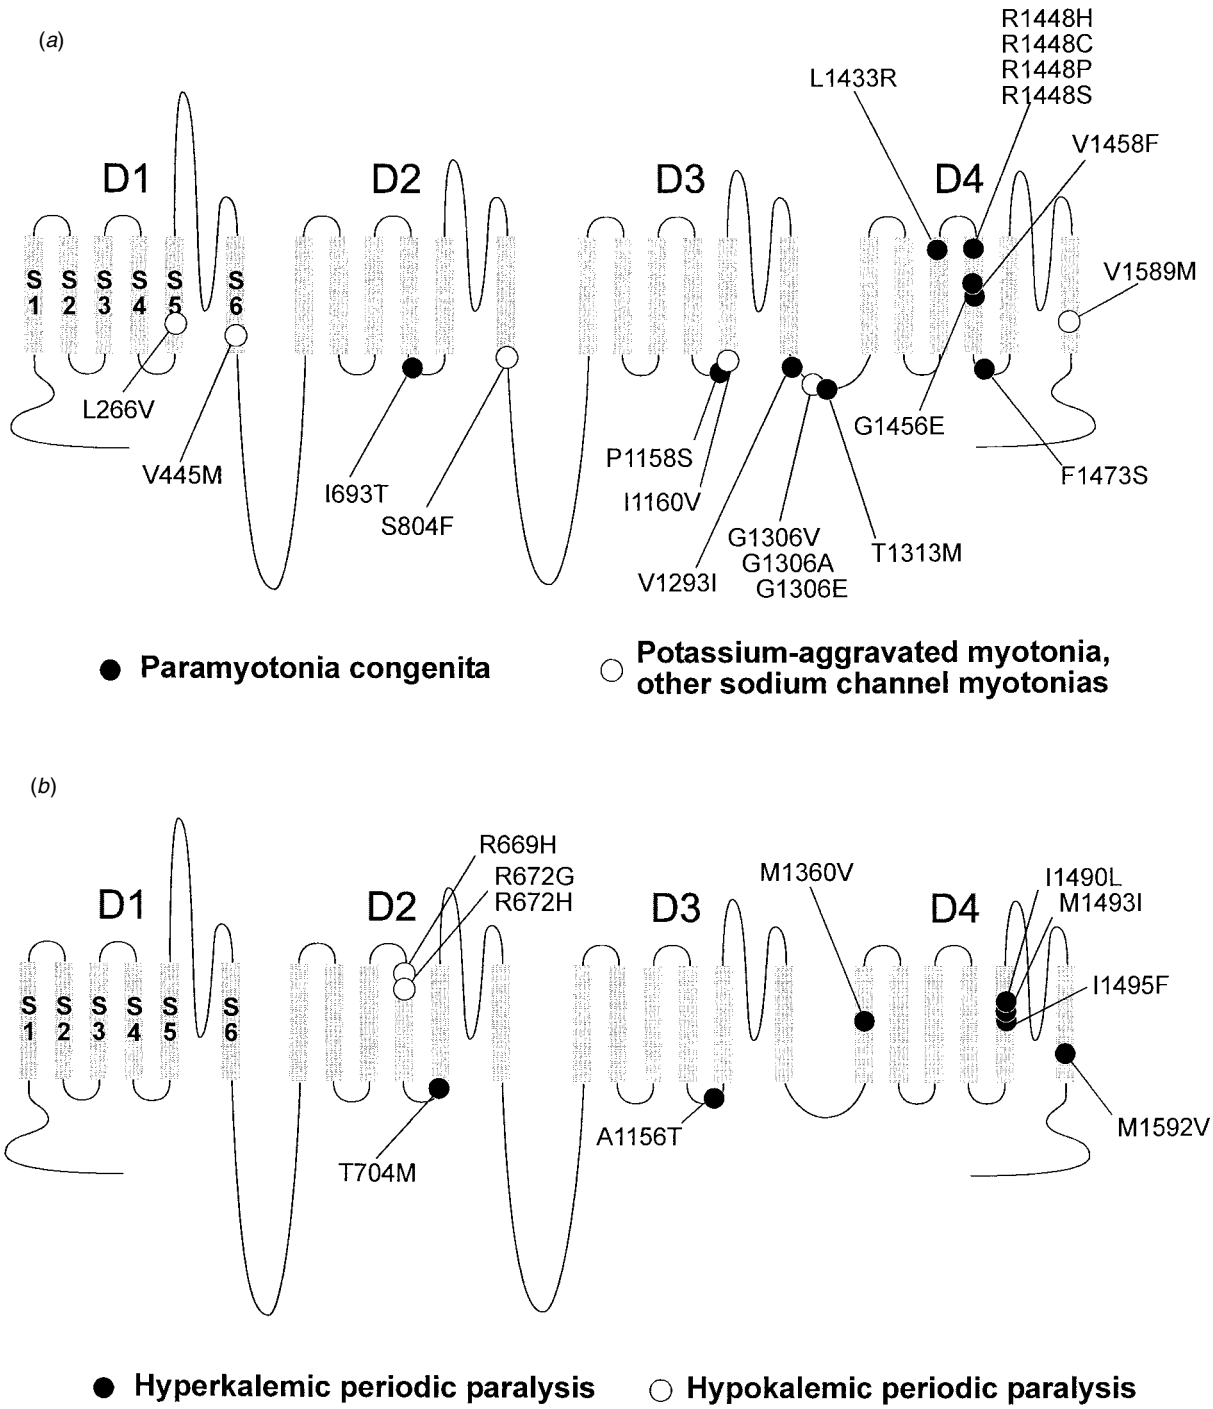

Fig. 71.6. Transmembrane folding diagram of the human adult skeletal muscle sodium channel and locations of missense mutations found in (*a*) myotonia and (*b*) periodic paralysis. (See Lehmann-Horn & Jurkat-Rott, 1999 for references to the original reports of specific mutations.)

described in greater detail by Gamstorp (Gamstorp, 1956), who coined the name adynamia episodica hereditaria. Intermittent attacks of weakness begin during the first decade of life and are often associated with an elevated serum potassium level (5.0 to 8.0 meq/l). A normal serum potassium level does not exclude the diagnosis of HyperPP. A more consistent finding is provocation of an attack by potassium salt administration. Weakness is mild to severe and recovery usually begins within a few hours, although full strength may not return for days. In addition to ingesting potassium-rich foods, several other manoeuvres may elicit an attack: rest after exercise, fasting, cold temperatures, or emotional stress. An incipient attack may be aborted by exercise or a carbohydrate-rich meal. Myotonia or paramyotonia may be present interictally in HyperPP, but intermittent weakness is always the predominant symptom. After the fourth or fifth decade, patients with HyperPP may develop a slowly progressive proximal myopathy. Muscle biopsy may be normal or show only mild non-specific changes (variation in fibre size, central nuclei, vacuolar changes, and proliferation of the sarcoplasmic reticulum).

Paramyotonia congenita (PMC) was first described by Eulenburg (1886), well before HyperPP was recognized as a clinical syndrome. The overlapping signs and symptoms in these two disorders led many clinicians to propose they were allelic disorders with a common molecular defect (de Silva et al., 1990). The pathognomonic feature of PMC is dominantly inherited paramyotonia, especially of the hands and face, that is usually aggravated by cooling. Paramyotonia is the predominant symptom in PMC, but patients may also have severe attacks of generalized weakness, either spontaneous or cold induced, that are indistinguishable from the episodic weakness in HyperPP.

Abnormal sodium currents in skeletal muscle

The membrane defect in HyperPP and PMC was initially identified from microelectrode studies of intercostal fibres biopsied from patients. In a series of landmark studies, Lehmann-Horn and colleagues explored the electrophysiological basis of myotonia that occurred in association with periodic paralysis (Lehmann-Horn et al., 1981, 1983, 1987). Unlike muscle in myotonia congenita or the myotonic goat, the resting chloride conductance was normal. Instead, diseased fibres depolarized excessively in response to raising the extracellular potassium concentration or cooling and had an aberrant inward current not seen in matched controls. Both abnormalities were prevented by tetrodotoxin, a potent and specific sodium channel blocker. These data implicated a defect in the voltage-gated sodium channel.

Molecular defects in hyperkalemic periodic paralysis and paramyotonia congenita

In 1990 genetic linkage was established between HyperPP and *SCN4A* (Fontaine et al., 1990), the gene for the α subunit of the skeletal muscle sodium channel on chromosome 17q23–25 (George et al., 1991). Several months later, PMC was also linked to 17q23–25 (Ebers et al., 1991; Ptacek et al., 1991a). Subsequently, seven different missense mutations in *SCN4A* have been identified in families with HyperPP (Fig. 71.6). The most commonly occurring mutations are T704M and M1592V (Rojas et al., 1991; Ptacek et al., 1991b), which account for about 60% and 30%, respectively, of genotyped HyperPP families. Haplotype analysis did not identify a founder effect, suggesting the same missense mutation has arisen independently in unrelated families (Plassart et al., 1994). Several distinct *SCN4A* mutations have been discovered in patients with PMC (Ptacek et al., 1992; McClatchey et al., 1992a).

The voltage-gated sodium channel in skeletal muscle is a heterodimer of a pore-forming α subunit and non-covalently linked accessory β_1 subunit. The human skeletal muscle α-subunit gene, *SCN4A*, codes for a 1836 amino acid protein (George et al., 1992), contains 24 exons (McClatchey et al., 1992b; George et al., 1993b) and is selectively expressed in skeletal muscle. All of the defects in *SCN4A* that have been associated with periodic paralysis or myotonia result in missense mutations of the α subunit that change conserved amino acid residues (Fig. 71.6). Several structural motifs, with associated functional roles, have been identified in voltage-gated sodium channels (for review see Catterall, 2000). The α subunit contains four internal homologous domains, each of which is composed of six membrane spanning segments (S1–S6). The S4 segment in each domain contains a cluster of positively charged residues (arginine or lysine) that form an integral part of the voltage-sensing mechanism of the channel. Several disease-associated mutations occur in these voltage-sensing S4 segments (Fig. 71.6). The ion-conducting pore is thought to be formed by the four short loops between S5 and S6 segments. The cytoplasmic loop between the third and fourth homologous domains of the sodium channel is critical for the fast inactivation that terminates the action potential and gives rise to the refractory period (West et al., 1992). Five myotonia-associated mutations are located in the fast inactivation gate (Fig. 71.6). Ten other mutations (3 causing HyperPP and 7 causing PMC or PAM) are found in the cytoplasmic ends of S5 or S6 segments, which may form the docking site for the inactivation gate at the intracellular mouth of the pore. The human β_1 subunit is expressed in skeletal muscle, heart, and brain (Makita et al., 1994). No mutations in the β_1 subunit gene have been identified in

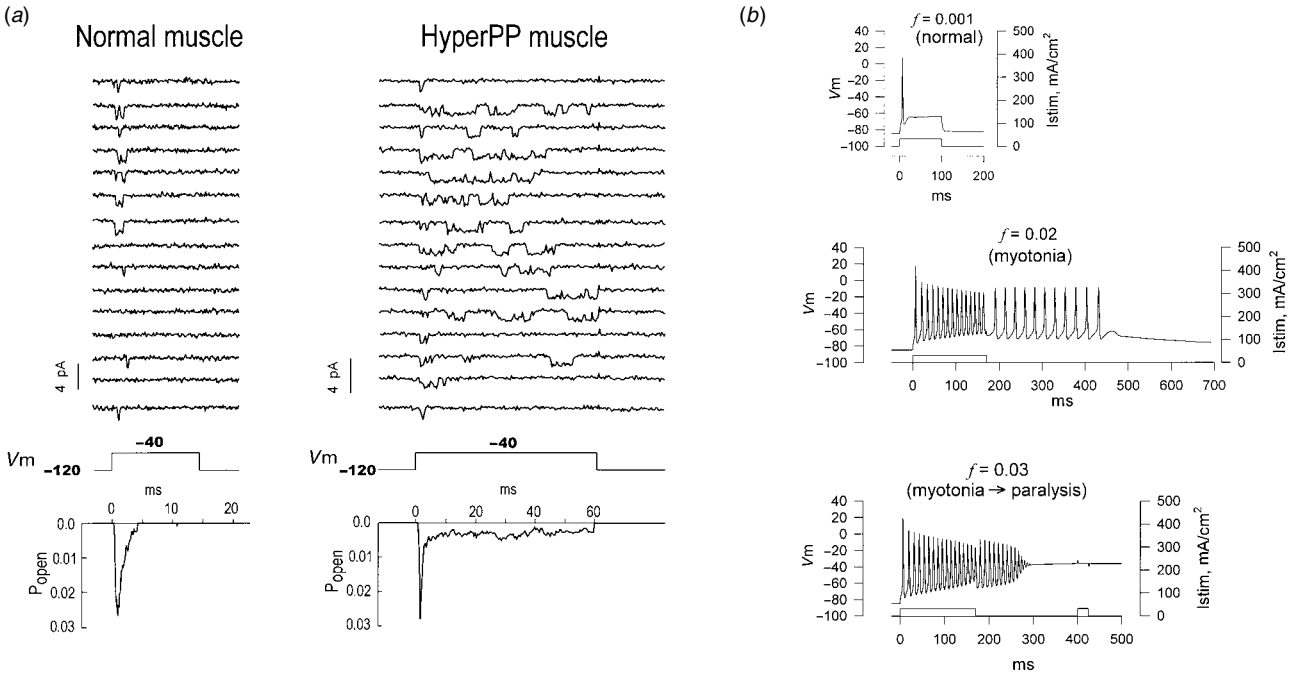

Fig. 71.7. Functional consequences of missense mutations on sodium channel behaviour and muscle membrane excitability. (*a*) Sodium currents were measured in cultured human myotubes from normal (left) and HyperPP (right) muscle using cell-attached patch clamp recording. In response to membrane depolarization, sodium channels quickly open to allow inward net sodium current (brief downward deflections) and then shut to an inactivated state from which further openings normally do not occur. In HyperPP myotubes, mutant sodium channels open and shut repetitively during the depolarization and the duration of individual openings is abnormally prolonged. Both changes are indicative of disrupted fast inactivation. (Figure adapted from Cannon et al., 1991) (*b*) Computer simulations of a model muscle fibre demonstrate that even a subtle disruption of fast inactivation is sufficient to produce myotonia, and slightly more pronounced defects cause depolarization-induced paralysis. Tracings show simulated membrane potential response to injection of a prolonged stimulating current. Normally, only a single action potential is elicited after which the fibre is refractory and repolarizes at the termination of the stimulus (top trace). If fast inactivation is disabled for 2% of the sodium current ($f = 0.02$), then myotonia ensues with repetitive discharges that persist beyond the duration of the stimulus (middle trace). When the fraction of non-inactivating sodium channels is increased to 3% ($f = 0.03$, bottom), then the same stimulus elicits a burst of myotonic discharges, after which the membrane potential settles to an aberrantly depolarized potential. Depolarization inactivates the majority of sodium channels (both wild-type and mutant) and renders the fibre inexcitable, as occurs during episodes of periodic paralysis.

neuromuscular disorders, but a missense mutation has been found to be a rare cause of generalized epilepsy with febrile seizures (Wallace et al., 1998).

Functional defects in mutant sodium channels

Functional studies of sodium channel mutations identified in families with myotonia or HyperPP have revealed gain-of-function defects. Mutant channels pass more inward Na current than normal because the voltage-dependent opening and closing are altered. The ability of sodium ions to pass through the pore is not affected. At the resting potential of −85 mV, sodium channels are in a closed, resting state. In response to membrane depolarization, sodium channels normally open within a fraction of a millisecond and then after about 1 millisecond spontaneously shut to a fast-inactivated state. Channels remain inactivated and unavailable for subsequent opening until they are reprimed by hyperpolarizing the membrane potential.

A defect in sodium channel behaviour was first identified from patch-clamp recordings of sodium currents in myotubes cultured from a patient with HyperPP (Cannon et al., 1991). Mutant channels opened normally in response to depolarization, but occasionally failed to inactivate, as evidenced by bursts of openings and closings during a maintained test depolarization and an increased duration of the open times (Fig. 71.7). On average, 2–5 % of mutant channels were open during a maintained depolarization, whereas for wild-type channels about 0.1% or less remain open. Subsequently, the gating behaviour of 25

different sodium channel mutations associated with myotonia or HyperPP have been characterized in heterologous expression systems. Impaired fast inactivation has been observed as a common feature for all cases (for review see Cannon, 2000). Some mutations disrupt the completeness of fast inactivation, as shown in Fig. 71.7. Others slow the rate of inactivation, shift its voltage dependence, or accelerate the rate of recovery (Chahine et al., 1994; Yang et al., 1994; Hayward et al., 1996). For a few mutants (notably, the most common cause of HyperPP, T704M) activation is enhanced such that channels open at more hyperpolarized potentials (Cummins et al., 1993). Both the inactivation and the activation defects result in more inward sodium current being conducted by mutant channels as compared to wild-type. This aberrant inward current may either trigger myotonic afterdischarges or depolarize the resting potential and render the fibre electrically inexcitable.

Sodium channels in skeletal muscle, heart and brain exhibit more than one form of inactivation. Fast inactivation, as discussed above, occurs on a timescale of milliseconds. This rapid gating behaviour initiates repolarization at the peak of the action potential and produces the refractory behaviour that limits the maximal firing rate. In response to prolonged depolarization lasting seconds to minutes or to high-frequency trains of discharges, sodium channels enter a slow-inactivated state, from which recovery at the resting potential occurs over seconds to minutes. Fast and slow inactivation are not only temporally distinct, they also arise from different functional domains of the channel. Ruff proposed that slow inactivation, as well as fast, must be disrupted if an anomalous persistent sodium current is to cause the prolonged episodes of depolarization-induced inexcitability in periodic paralysis (Ruff, 1994). Otherwise, within seconds, slow inactivation would shut off the persistent current arising from the fast-inactivation defect, and the muscle fibre would repolarize. Expression studies of mutant channels showed that slow inactivation is partially disrupted for the two most commonly occurring mutations in HyperPP (T704M and M1592V) (Cummins & Sigworth, 1996; Hayward et al., 1997) and for another mutation associated with cold-induced attacks of weakness (I693T) (Hayward et al., 1999). On the other hand, slow inactivation was normal for several other sodium channel mutations that are associated with HyperPP (A1156T, M1360V), or PMC with weakness (T1313M, R1448C) (Hayward et al., 1999). Impaired slow inactivation was not detected in any of the nine myotonia-associated mutants (PAM and PMC) tested to date. One interpretation is that disrupted slow inactivation always predisposes the fibre to prolonged episodes of depolarization-induced weakness, but that defective slow inactivation is not a necessary condition for periodic paralysis.

Pathophysiological basis of myotonia and depolarization-induced paralysis from sodium channel defects

The gain-of-function defect in mutant sodium channels is predicted to alter the excitability of the sarcolemma. The anomalous inward current may enhance excitability by depolarizing the fibre and triggering the afterdischarges of the myotonic burst. Alternatively, a persistent inward current could depolarize the resting potential and produce flaccid weakness from a loss of excitability due to chronic inactivation of sodium channels. Two model systems have been used to test these hypotheses and to explore why some mutations in *SCN4A* lead to myotonia only, while others primarily cause episodic weakness, and still others cause both.

In an in vitro toxin-based model, Cannon and Corey simulated the inactivation defect observed for mutant channels by applying sea anemone toxin (ATXII) to normal rat fast-twitch muscle (Cannon & Corey, 1993). In patch clamp recordings, 10 micromolar ATXII partially disrupted fast inactivation so that about 2% of sodium channels remained open in depolarized membranes. Muscle bathed in 10 μM ATXII exhibited myotonia, with trains of repetitive discharges elicited by a single shock and a 20-fold slowing in the relaxation phase of the isometric twitch response. These observations firmly established that even a subtle defect in sodium channel inactivation (2%) is sufficient to produce myotonia.

The toxin-based model also demonstrated a pathomechanism in common between chloride- and sodium-channel based myotonia. In skeletal muscle, each propagated action potential causes an egress of potassium from the myoplasm into the T-tubules. These long narrow invaginations of the surface membrane effectively communicate depolarization to the core of the fibre to elicit contraction, but they also present a substantial barrier to diffusion. This results in activity-dependent accumulation of potassium in the T-tubules (an extracellular space), which will depolarize the fibre. Adrian and Bryant (Adrian & Bryant, 1974) showed that disruption of the T-tubules by osmotic shock prevents the afterdepolarization and afterdischarges recorded after termination of the stimulating current in goat myotonic muscle (chloride channel defect). Similarly, detubulation by osmotic shock abolishes the after-depolarization and the afterdischarges of rat muscle exposed to ATXII (sodium channel defect) (Cannon & Corey, 1993). For both channel defects, the activity-dependent accumulation of T-tubule potassium is the

depolarizing trigger that elicits myotonic discharges. The chloride channel defect attenuates a shunt current, so that an equivalent increase in potassium concentration results in a larger depolarization and afterdischarges. The sodium channel inactivation defect increases the availability of sodium channels at the end of one action potential, so that the mild depolarization from potassium accumulation now triggers an afterdischarge.

In these experiments, muscle weakness was not consistently observed in rat muscle treated with 10 μM ATXII. The interpretation was that the toxin-induced changes in sodium channel inactivation were comparable to the more subtle defects observed for mutations associated with myotonia (PAM), and that if more pronounced gating defects could be produced then paralysis would ensue. Moreover, slow inactivation is not disrupted by ATXII.

Computer simulation has been used as another approach to explore how altered behaviour of mutant sodium channels affects the excitability of skeletal muscle (Cannon et al., 1993). A major advantage of this theoretical approach is that the type of channel defect and the relative proportion of wildtype and mutant channels can be explicitly specified. The model muscle cell consists of two electrically coupled membrane compartments to simulate the surface and T-tubule membranes, each of which contains sodium, potassium, and leakage (chloride) channels.

Figure 71.7 shows the model behaviour in response to a prolonged stimulus current, as the fraction of fast-inactivation defective sodium channels (f) was increased. With normal values for the model parameters ($f = 0.001$ to account for imperfect fast inactivation in wild-type channels), the suprathreshold stimulus elicits a single action potential, and the simulated cell repolarizes at the end of the current injection. This model response is identical to the behaviour observed in wild-type muscle fibres. In agreement with the ATXII toxin studies in rat muscle, even a subtle disruption of fast inactivation ($f = 0.005$ to 0.025) is sufficient to produce myotonic afterdischarges in the computer model (Fig. 71.7(*b*), middle trace). The small pool of inactivation-defective sodium channels that remain available to open at the end of one action potential (in combination with a mild depolarization from activity-dependent potassium trapping in the T-tubules) leads to the generation of a myotonic burst. A slightly larger defect of fast inactivation ($f = 0.03$) results in a myotonic burst of discharges that dissipates to an aberrantly depolarized stable membrane potential. The anomalous persistent sodium current keeps the fibre depolarized. From this depolarized potential of −40 mV, the majority of sodium channels (both mutant and wild-type) are inactivated. Consequently, the fibre is refractory from generating additional action potentials. This model state corresponds to the flaccid weakness, depolarized resting potential, and electrical inexcitability observed in skeletal muscle during an attack of periodic paralysis. This model demonstrates how mutant sodium channels exert a dominant-negative effect via the membrane potential. The gain-of-function channel defect gives rise to a small persistent sodium current that depolarizes the membrane, which in turn inactivates the normally functioning sodium channels. In support of this theoretical analysis, expression studies of sodium channel mutants have shown that paralysis-associated mutations tend to cause more severe defects in gating than those associated with myotonia only (for review see Cannon, 2000).

Computer simulation also provides insights into why some sodium channel mutations cause myotonia only (PAM), others cause depolarization-induced paralysis (HyperPP) and still others may cause both (PMC). Although all of the sodium channel mutations in Fig. 71.6 produce gain-of-function defects, differences in the severity or the type of gating defect presumably determine the clinical phenotype. Expression studies of mutant channels and computer modelling both support this hypothesis. In principle, any gating defect that increases the steady-state open probability of mutant channels could produce prolonged episodes (hours) of depolarization-induced paralysis. Model simulations show that aberrant chronic depolarization and inexcitability are induced most easily by impaired slow inactivation in combination with partially disrupted fast inactivation (as detailed in the above example) or a shift of channel activation to more negative potentials. In contrast, model simulations show that impeding fast inactivation by shifting its voltage dependence to more positive potentials does not readily lead to stable depolarization. Expression studies have shown mutations associated with HyperPP or PMC with weakness usually cause some combination of (i) disrupted fast inactivation (persistent sodium current >1.5% of the peak transient), (ii) hyperpolarized shift of activation (>5 mV), or (iii) impaired slow inactivation. In contrast, expression studies of mutations associated with myotonia only (PAM) have revealed: (i) defects in the rate of fast inactivation (two- to fivefold too slow) but only very small persistent sodium currents (<1% of peak), (ii) only small shifts in activation (<5 mV), and (iii) no impairment of slow inactivation. Slowing the rate of fast inactivation is a common defect observed in many mutations associated with myotonia (PAM or PMC). Model simulations show that the major consequence for this type of inactivation defect is a broadening of the action potential duration, which in turn greatly increases the potassium egress into the T-tubule with each action potential and thereby promotes myotonia.

Although the foundations of the pathogenesis of myotonia and periodic paralysis due to sodium channel defects are now well established, the basis of many clinical phenomena remain to be elucidated. For example, current models predict that raised extracellular potassium and sodium channel gating defects act synergistically to alter membrane excitability. Why, then are attacks precipitated by potassium loading for some disorders (HyperPP, PAM) but not others (PMC)? What is the basis for the cold sensitivity of myotonia in PMC? Expression studies have not identified an aberrant temperature sensitivity in the gating behaviour of channel mutations associated with PMC. How does muscular activity produce paradoxical myotonia or the warm-up phenomena? And, why does rest after exercise provoke attacks of periodic paralysis? Answers to these questions will likely await the development of transgenic animals as model systems to explore these phenomena at the whole-animal level.

Hypokalemic periodic paralysis

Hypokalemic periodic paralysis is the most commonly occurring form of periodic paralysis in humans, but it is still a rare disorder with a prevalence estimated to be about 1:100 000. Familial periodic paralysis was described late in the nineteenth century, but it was not until 1934 that Biemond and Daniels observed that attacks of weakness occurred in association with hypokalemia for some families (Biemond & Daniels, 1934). The clinical hallmarks of HypoPP are episodes of moderate to severe generalized weakness, hypokalemia (often $<$3.0 meq/l) during an attack, and the absence of myotonia. Attacks of weakness typically begin around puberty, but may present any time during the first three decades of life. In comparison to HyperPP, episodic weakness in HypoPP is usually more severe and of longer duration. Acute attacks typically resolve in hours to days, but a more protracted course of mild weakness may persist for weeks or longer. Precipitants of acute attacks include rest after exercise and carbohydrate-rich meals. Many patients with HypoPP develop a mildly progressive late-onset proximal myopathy. HypoPP is inherited as an autosomal dominant trait, and the clinical expression in females is reduced (male-to-female prevalence is about 3:1). For some females, the only manifestation of HypoPP is the late-onset proximal myopathy, without any clinically evident acute attacks of weakness (Links et al., 1990).

During an attack of weakness in HypoPP, affected muscle fibres are depolarized and electrically inexcitable due to inactivation of sodium channels. Hypokalemia results from a shift of potassium from the extracellular space into muscle, but the mechanistic basis for this shift and of the membrane depolarization remains unknown. Under basal conditions, the resting potential of HypoPP muscle is depolarized by 5 to 10 mV compared to normal muscle (Rüdel et al., 1984; Ruff, 1999), and the fibre conduction velocity is reduced (van der Hoeven et al., 1994). In vitro studies on biopsied fibres have shown that reducing the extracellular potassium concentration to 1 mM causes HypoPP fibres to depolarize by 20 mV, whereas normal muscle hyperpolarizes by 10 mV under the same conditions (Rüdel et al., 1984). The paradoxical hypokalemia-induced depolarization is not prevented by sodium channel blockers (tetrodotoxin) (Rüdel et al., 1984) or calcium channel antagonists (nitrendipine) (Ruff, 1999). In patients with HypoPP, insulin administration often provokes an attack of weakness. In part, this effect is due to the ability of insulin to promote a shift of extracellular potassium into muscle. In vitro studies on biopsied HypoPP fibres suggest insulin also promotes depolarization by reducing an inwardly rectifying potassium conductance in diseased, but not normal, fibres (Ruff, 1999).

Molecular defects in hypokalemic periodic paralysis

Electrophysiological studies of HypoPP muscle revealed aberrant depolarization of the resting potential, but did not identify a candidate ion channel or pump as the underlying molecular defect. The molecular defect was discovered by genetic linkage analysis. Fontaine and colleagues mapped the HypoPP locus to chromosome 1q21–31 (Fontaine et al., 1994). The gene encoding the α_1-subunit of the skeletal muscle L-type calcium channel, *CACNL1A3*, had previously been mapped to this region. The calcium channel of skeletal muscle is a heteromeric complex of the pore-forming α_{1S} subunit and four accessory subunits: β_1, α_2 δ, and γ. Subsequent screening of the α_{1S} gene led to the identification of three missense mutations in HypoPP families. Interestingly, all three mutations occur at positively charged arginines in voltage-sensing regions of the channel (Fig. 71.8). The R528H mutation occurs in about 50% of HypoPP families linked to the chromosome 1 locus, and the incomplete penetrance of acute attacks in females is unique to this mutation (Elbaz et al., 1995). The R1239H mutation, in a homologous voltage-sensing region, is the molecular defect in most of the remaining chromosome 1 linked HypoPP families (Ptacek et al., 1994b; Elbaz et al., 1995). A third missense mutation, R1239G, is much rarer.

Hypokalemic periodic paralysis is genetically heterogeneous. Linkage to chromosome 1q21–31 has been excluded in several families with autosomal dominant HypoPP that is indistinguishable clinically from HypoPP in

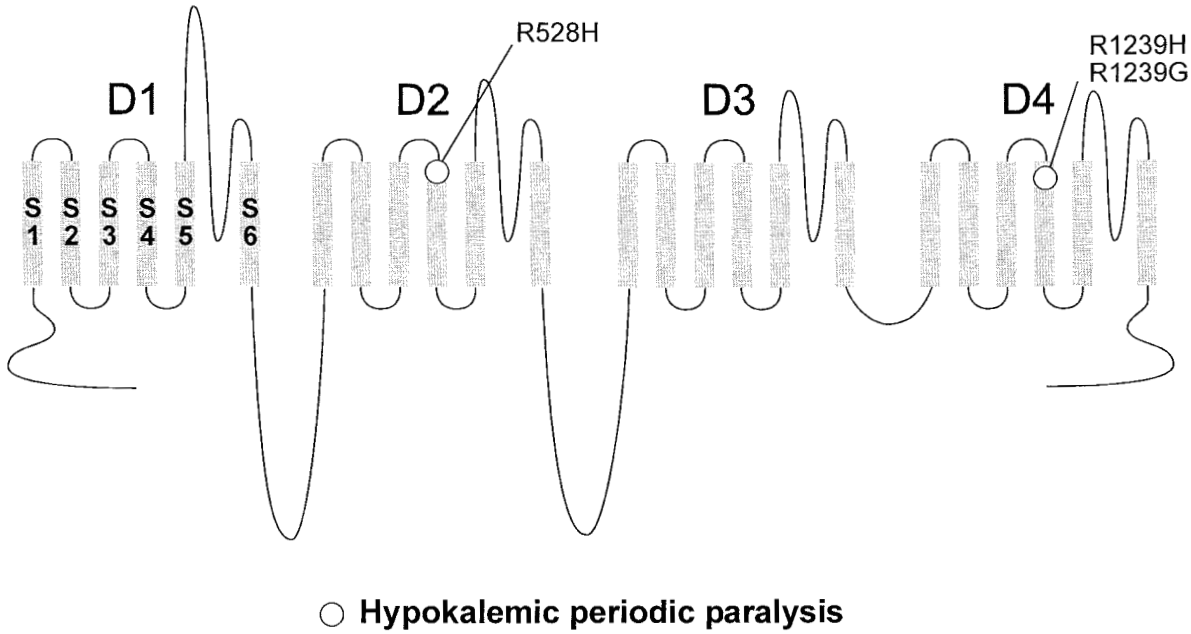

Fig. 71.8. Transmembrane folding diagram for the α subunit of the skeletal muscle L-type calcium channel and location of missense mutations identified in patients with hypokalemic periodic paralysis. HypoPP mutations occur at positively charged arginine residues in the voltage-sensing S4 segments of domains II and IV.

families with a confirmed mutation in the calcium channel α_{1S} subunit gene. Further molecular genetic testing has identified three different mutations in the sodium channel α subunit gene (*SCN4A*) in six families with clinical syndromes typical for HypoPP (Bulman et al., 1999; Jurkat-Rott et al., 2000). Intriguingly, all three mutations occur at positively charged arginine residues in voltage sensing domains of the sodium channel (Fig. 71.6). The R669H mutation in the sodium channel is located at a position that correlates exactly to that of the HypoPP associated R528H mutation in the calcium channel. The other two sodium channel mutations in HypoPP are located at the adjacent arginine within the same voltage sensing region, R672H and R672G.

Functional defects of mutant channels and other skeletal muscle conductances in HypoPP

The functional consequences of the HypoPP missense mutations in the calcium channel and the sodium channel have been characterized by recording ionic currents from biopsied muscle and from heterologously expressed mutant channels. Because all six mutations are substitutions at arginine residues in voltage-sensor domains, it was predicted that the voltage dependence of channel gating would be altered.

The L-type calcium channel has two functional roles in skeletal muscle: (i) voltage-activated calcium channel and (ii) voltage sensor for coupling depolarization of the T-tubule to release calcium from the sarcoplasmic reticulum (excitation–contraction coupling). The defect in maintaining the resting potential for HypoPP muscle implies the channel-forming role has been altered, but both functions could be defective. Excitation–contraction coupling appears to be grossly normal in HypoPP fibres, based on fluorometric measurements of myoplasmic Ca^{2+} transients elicited by depolarization (Jurkat-Rott et al., 1998). Most studies have focused primarily on the calcium-channel properties of α_{1S} mutants. The most consistent change observed in common for all three mutations has been a reduction in the calcium current density by about 50%. This decrease has been found for endogenous mutant channels expressed in cultured HypoPP myotubes (R588H and R1239H) (Sipos et al., 1995; Morrill et al., 1998) and for mutant channels heterologously expressed in mammalian cells (Lapie et al., 1996; Jurkat-Rott et al., 1998) or frog oocytes (Morrill & Cannon, 1998). In addition, the rate of activation at depolarized voltages is slowed by all three mutations (Morrill & Cannon, 1998). The net result of these changes is that in HypoPP muscle less Ca^{2+} entry occurs during a single action potential, and especially in response to a high-frequency burst of discharges. The mechanism by which altered Ca^{2+} entry results in episodic depolarization-

induced paralysis, hypokalemia, and permanent proximal myopathy remains to be elucidated.

Functional studies of mutant sodium channels found in HypoPP suggest that loss-of-function defects are responsible for the attacks of periodic paralysis. Expression studies in mammalian cells showed a two- to fourfold reduction in sodium current density for R672H and R672G mutants, as compared to wild-type channels (Jurkat-Rott et al., 2000). Moreover, the rate of rise of the action potential was decreased in acutely dissected muscle carrying the R672G mutation, which is consistent with a reduced sodium current density for channels endogenously expressed in human muscle. In addition, fast inactivation was enhanced by both mutations at R672 (Jurkat-Rott et al., 2000). For the R669H mutation, fast inactivation was normal, but slow inactivation was augmented, as evidenced by a hyperpolarized shift in its voltage dependence and a slowed time course of recovery (Struyk et al., 2000). In sum, these changes reduce the maximal available sodium current and also cause a greater attenuation of sodium current in response to even mild depolarization of the resting potential. A reduction in sodium current would contribute to the loss of excitability during an attack of HypoPP, but it does not explain the aberrant depolarization of the resting potential or the trapping of potassium in muscle.

Because the behaviour of HypoPP mutant channels studied in isolation has not provided a pathophysiological explanation for clinical features of an attack, attempts to identify functional defects by recording directly from diseased muscle have continued. At present there are no animal models for an inherited HypoPP-like syndrome. The chronically potassium-depleted rat does have insulin-induced attacks of paralysis with muscle depolarization and hypokalemia (Kao & Gordon, 1975), but these animals do not have spontaneous attacks, nor can they be triggered by exercise or carbohydrate ingestion. Consequently, the most informative data comes from experiments on acutely dissociated human HypoPP fibres. Two separate laboratories have reported abnormalities in the potassium conductance of human HypoPP fibers heterozygous for the R528H mutation in the L-type calcium channel gene. Tricarico and colleagues (Tricarico et al., 1999) observed a tenfold reduction in the ATP-sensitive potassium current in excised patch recordings from HypoPP fibres. This decrease was primarily due to a reduction in the open probability of the channel in low ATP, and also partially due to a diminished ability of potassium to flow through the open channel (subconductance states). Ruff reported an insulin-induced reduction in membrane current for HypoPP fibres under conditions that isolated potassium currents (Ruff, 1999). Although not directly proven, this may also reflect a defect in the ATP-sensitive potassium current. Ruff's data also suggested the presence of an anomalous inward current in HypoPP fibres that was not blocked by tetrodotoxin or nitrendipine. The blocker experiments exclude voltage-gated sodium and calcium channels, but the identity of the anomalous current remains unknown. It is not yet known if similar alterations in membrane conductance are present in HypoPP fibres with calcium channel mutations at R1239 or with mutations in the sodium channel.

One intriguing hypothesis for the pathogenesis of HypoPP is that a disruption of Ca^{2+} homeostasis caused by a reduced entry through mutant calcium channels alters the transcription or regulation (e.g. phosphorylation) of other ion channels. This mechanism could account for the reduced ATP-sensitive potassium current. A reduced potassium current would in turn depolarize the resting potential and may trap potassium in the myoplasm.

Thyrotoxic periodic paralysis

A sporadic form of periodic paralysis occasionally occurs in association with thyrotoxicosis. Like familial HypoPP, thyrotoxic periodic paralysis (TPP) presents with profound episodic weakness and hypokalemia, without myotonia (for review see Ober, 1992). Rest after exercise, ingestion of carbohydrates, or administration of insulin may provoke an attack. This disorder is especially prevalent in Asian populations, where it has been estimated that periodic paralysis occurs in 2% of patients with thyrotoxicosis (Okinaka et al., 1957). TPP is much rarer in other ethnic groups, but has been reported in Caucasians and Blacks. There is also a strong gender bias with a male : female ratio of 10–20 : 1. Many patients with TPP do not have overt clinical signs of thyrotoxicosis. Perhaps the acute and dramatic nature of periodic paralysis greatly overshadows the more insidious manifestations of the thyrotoxic state in these patients. Moreover, TPP may occur with either T4- or T3-thyrotoxicosis, and therefore the TSH level is the most sensitive test for distinguishing TPP from HypoPP. Attacks of weakness are abolished by treatments that attain a euthyroid state. Recurrent hyperthyroidism due to relapse or exogenous thyroid hormone may provoke additional attacks of paralysis.

The pathophysiological basis for the attacks of weakness and hypokalemia in TPP remains unknown. The heavily skewed ethnic distribution suggests a genetic component. However, HLA typing has not identified a consistent genetic marker for TPP. A few exceptional cases of familial clustering have been reported, but the mode of inheritance is not clear

and a TPP locus has not been identified by linkage analysis. One hypothesis is that TPP is caused by increased activity of the Na^+–K^+ATPase pump. Thyroid hormone increases the activity and number of the Na^+–K^+ ATPase sites in muscle. Thyrotoxicosis would result in an increased uptake of potassium into muscle. This hypothesis was supported by the finding that platelet Na^+–K^+ATPase activity is higher in hyperthyroid patients with TPP than those with hyperthyroidism without TPP (Chan et al., 1991). The Na^+–K^+ ATPase pump is also stimulated by insulin, which may explain why attacks of weakness are provoked by carbohydrate loading or insulin challenge. The male predominance in TPP may be related to increases in pump activity by androgens and inhibition by estrogen and progesterone.

Diagnosis and treatment of non-dystrophic myotonias and periodic paralysis

Diagnostic approach in the non-dystrophic myotonias

In the differential diagnosis of myotonic syndromes, it is imperative to distinguish those associated with dystrophy from the more benign non-dystrophic forms discussed in this chapter. In most cases this distinction is easily made on clinical grounds. Myotonic dystrophy (DM1) is a multisystem disorder in which late-onset progressive wasting of bulbar and distal muscles usually predominates over a relatively mild degree of myotonia. Additional organ system involvement includes brain (mental retardation), eyes (cataract, retinal degeneration, developmental defects), heart (conduction defects, cardiomyopathy), smooth muscle (dysphagia, megacolon), endocrine (testicular atrophy), and skin (frontal baldness). Inheritance is dominant with high penetrance and progressive worsening in successive generations (genetic anticipation). The molecular defect is an expanded trinucleotide repeat (CTG) in the 3′-untranslated region of the myotonic protein kinase gene (*DMPK*) on chromosome 19 (Brook et al., 1992). Normal individuals have 5 to 40 repeats, whereas patients with myotonic dystrophy have 50 to >2000. Molecular genetic screening for the CTG expansion on chromosome 19 is a sensitive and specific test of myotonic dystrophy. Proximal myotonic myopathy (PROMM or DM2) is a dominantly inherited disorder with several similarities to myotonic dystrophy (Ricker et al., 1994b), but there is no expansion of the CTG repeat in the *DMPK* gene. Unlike myotonic dystrophy, muscle wasting in PROMM is proximal. Most patients with PROMM have mild myotonic stiffness of the legs or hands. Associated features include cataracts, hypogonadism, intermittent muscle pain not associated with myotonia, and in some patients cerebral white matter abnormalities on MRI. Mental retardation and genetic anticipation do not occur in PROMM. The genetic defect in PROMM is a CCTG expanded repeat in intron 1 of the zinc finger protein 9 on chromosome 3q (Liquori et al., 2001).

The non-dystrophic myotonias can usually be distinguished on the basis of clinical features listed in Table 71.2. A true autosomal dominant inheritance pattern excludes a diagnosis of recessive generalized myotonia. On the other hand, the absence of myotonia in both parents is less informative because the disorder could either be recessive or the result of a *de novo* mutation. Paramyotonia of the hands, face and tongue that is aggravated by cooling is pathognomonic for paramyotonia congenita. Cooling may also enhance the myotonia in PAM, but in this latter syndrome the myotonia exhibits warm-up behaviour, rather than paradoxical worsening with repeated muscular activity. In contrast, cooling does not acutely aggravate the myotonia in the chloride channel disorders. Another typical feature of PAM is slow fluctuations in the severity of myotonia over a course of days or in relation to prior exercise. Electromyography is useful in documenting myotonia in clinically ambiguous cases or for detecting latent myotonia. It is not possible to distinguish between the chloride channel and sodium channel based myotonias from the appearance of the EMG. The muscle biopsy often shows fibre hypertrophy, central nuclei, and reduced number of type 2 fibres, but these are non-specific changes that do not distinguish between the different types of non-dystrophic myotonia. At present, a comprehensive molecular genetic screen for all of the mutations in the chloride and sodium channel genes is not available. A few laboratories will screen for a limited number of the more prevalent mutations. The presence of a mutation is highly informative, but the failure to detect a molecular defect does not exclude the diagnosis.

Treatment strategies for myotonia

Many patients with myotonia do not require any pharmacological intervention. Most patients prefer to minimize their symptoms by regulating their level of exercise, dietary potassium intake, or avoidance of cold environments. When these manoeuvres are insufficient, drugs that reduce the excitability of the sarcolemma can be used. The most effective agents for suppressing myotonia due to either a chloride or a sodium channel defect are use-dependent blockers of voltage-gated sodium channels. Mexiletine, starting at 200 mg three times a day is the preferred drug (Ricker et al., 1994a). Elderly patients or those with known cardiac conduction abnormalities should consult a cardiologist before beginning mexiletine. The antiepileptic drugs

phenytoin and carbamazepine may also produce improvement. These agents are anecdotally thought to be less effective than mexiletine, but a controlled comparison has never been performed. A rational approach for ameliorating myotonia due to chloride channel defects (myotonia congenita or RGM) would be to pharmacologically increase the chloride conductance of skeletal muscle. Taurine and the R-(+) isomer of clofibric acid produce measurable increases in the resting chloride conductance of skeletal muscle. The effect is modest, however, and is not sufficient to prevent myotonia (Bryant & Conte-Camerino, 1991).

Diagnostic approach in the periodic paralyses

A diagnosis of periodic paralysis is easily made in the setting of prototypical attacks of weakness and a positive family history of dominant inheritance. The clinical distinction between HyperPP and HypoPP or the recognition of a *de novo* case in the absence of a family history can be more challenging. When ascertaining the family history, the clinician must take into consideration the reduced penetrance for episodic weakness in women with HypoPP. The diagnosis of thyrotoxic periodic paralysis should always be excluded by measuring the TSH, especially for males in whom there is no family history of weakness.

Provocative testing may be used to confirm a suspected diagnosis of periodic paralysis. Exercise-induced changes in the amplitude of the compound muscle action potential provide objective evidence of periodic paralysis (McManis et al., 1986), but the sensitivity of the test is only about 70% and it does not distinguish between HyperPP, HypoPP, and thyrotoxic periodic paralysis. A more specific test is to monitor the patient's serum potassium and strength before and after exercise (Lehmann-Horn & Engel, 1994). After measuring baseline performance, the patient exercises on a treadmill for 30 minutes with the heart rate >120 beats/min. Then the patient is instructed to lay motionless in bed. In normal individuals, serum potassium rises during exercise and then falls to the basal level within minutes. In HyperPP there is a secondary rise in serum potassium 15 to 30 minutes after exercise, often in association with weakness. However, the lack of a secondary rise in serum potassium does not exclude a diagnosis of HyperPP. Patients with HypoPP will have a fall in serum potassium coincident with the onset of weakness. If the exercise test does not elicit weakness or the serum potassium levels are ambiguous, then a more strenuous challenge can be performed in which the serum potassium level is manipulated. In-patient monitoring is required for this more invasive level of testing. In suspected HyperPP, the exercise test is performed after fasting overnight and administration of 40 to 120 meq of a potassium salt orally in an unsweetened solution. An attack usually occurs within one or two hours as evidenced by weakness or a reduction in the amplitude of the compound muscle action potential. To test for HypoPP, an oral glucose load of 2 gm/kg body weight is given in the morning. Weakness and hypokalemia often ensue within 1 hour. If an attack is not elicited, the test can be repeated with coadministration of insulin (10 units subcutaneously) and glucose. In some patients with HypoPP, attacks cannot be reliably induced. Therefore, a positive test is more informative than the lack of a response. The presence of myotonia, either clinically or electromyographically, excludes a diagnosis of HypoPP.

In patients with myotonia and periodic paralysis, the diagnosis could be either HyperPP or PMC. In exemplary cases, the distinction is easily made on the basis of the clinical features listed in Table 71.2. However, there are many clinical variants within the PMC-HyperPP complex that have overlapping signs and symptoms. These intermediate cases have been called normokalemic periodic paralysis, paralysis periodica paramyotonia, and other terms. We favour a simpler scheme in which the criteria for HyperPP and PMC are broadened to include these variants. For example, if the primary symptom is weakness, then the diagnosis should be HyperPP, even if the weakness is cold induced and the serum potassium remains normal.

Treatment strategies for periodic paralysis

A combination of changes in lifestyle and pharmacological intervention is often required to reduce the severity and frequency of attacks in periodic paralysis. Patients with any form of periodic paralysis should avoid excessively strenuous exercise and gradually 'warm down' with progressively decreasing levels of activity to avoid postexercise-induced attacks.

For patients with HyperPP, attacks may be prevented or foreshortened by eating carbohydrate-rich snacks, and avoiding intake of high-potassium containing foods. Judicious use of a diuretic may help (hydrochlorothiazide 25 to 50 mg/day). The most effective prophylactic drug is the carbonic anhydrase inhibitor acetazolamide (McArdle, 1962). The dosage should be started at 125 mg/day and gradually increased until a satisfactory response is obtained or the dose reaches 1500 mg/day. Most patients taking acetazolamide develop distal paresthesias and distaste for carbonated beverages. Chronic use is associated with a high incidence of renal stones (10–20% of patients) (Tawil et al., 1993). The mechanism of acetazolamide's therapeutic effect is not fully understood. One possibility is that the mild metabolic acidosis produced by chronic use results in proton-mediated screening of the fixed negative charges on the outer surface of cell membranes (Lehmann-Horn et al., 1987). Charge screening will cause an apparent depolarized shift in the voltage dependence of

channel gating, and thereby reduce the degree of sodium channel inactivation produced by modest depolarization of the resting potential.

Patients with HypoPP can reduce the frequency and severity of attacks by avoiding strenuous exercise, eating foods rich in potassium, and limiting carbohydrate intake (Lehmann-Horn & Engel, 1994). Oral potassium supplements (20 to 40 meq) may hasten the recovery from an acute attack, but patients should be warned against using escalating dosages of potassium *ad libitum*. For prophylactic management of HypoPP, carbonic anhydrase inhibitors are the preferred drug. Chronic administration of acetazolamide usually reduces the frequency and severity of attacks and improves the interictal low-grade weakness (Griggs et al., 1970). Patients refractory to acetazolamide may respond to a more potent carbonic anhydrase inhibitor, dichlorphenamide 50 to 300 mg/day (Tawil et al., 2000). Agents that reduce urinary potassium loss such as triamterene (150 mg/day) or the aldosterone antagonist spironolactone (100 mg/day) may also reduce symptoms. However, potassium supplements should not be used in conjunction with these drugs. Alternative prophylactic therapies are still being sought because some patients with HypoPP fail to respond to acetazolamide or cannot tolerate its side effects. A placebo-controlled trial of the calcium channel antagonist verapamil did not show significant improvement in nine patients with HypoPP (Links et al., 1998). Another approach has been to search for agents that open potassium channels and thereby repolarize the membrane. In vitro studies in human HypoPP fibres showed that cromakalim, an opener of ATP-sensitive potassium channels, is able to repolarize the muscle membrane and restore twitch force (Grafe et al., 1990). Another K-ATP channel agonist, diazoxide was initially effective in preventing attacks of weakness in patients with HypoPP, but after a few months of continuous use the attacks of weakness returned (Johnsen, 1977). Clinical use of K-ATP channel openers has been limited by side effects of hypotension and hyperglycemia. Different isoforms of the K-ATP channel are present in skeletal muscle, smooth muscle, and pancreatic β cells. If drugs could be found that selectively open K-ATP channels of skeletal muscle, then these agents may be beneficial in preventing attacks of episodic weakness in HyperPP and HypoPP, and in suppressing myotonic discharges.

Pathophysiology of metabolic myopathies

Salvatore DiMauro[1] and Ronald G. Haller[2]

[1] Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY, USA
[2] Neuromuscular Center, Institute for Exercise and Environmental Medicine, Presbyterian Hospital, Dallas, TX, USA

The term metabolic myopathy refers to disorders that impair the metabolism of carbohydrates, lipids or both within skeletal muscle. Many of these disorders are associated with abnormal storage of glycogen (glycogen storage diseases) or triglyceride (lipid myopathies) but others, such as distal glycolytic defects and carnitine palmitoyltransferase II deficiency, usually do not result in excess muscle stores of glycogen or lipid. Some metabolic myopathies, notably acid maltase deficiency, affect non-energy yielding pathways, but the majority of metabolic myopathies are inborn errors of muscle energy metabolism. The pathophysiology of these muscle energy defects relates directly to the role of the affected energy pathway in muscle function.

Muscle fuel at rest and during exercise

The fundamental source of energy for muscle contraction and ion transport is the hydrolysis of adenosine triphosphate (ATP) to ADP and inorganic phosphate (Pi). ADP and Pi in turn activate energy-producing reactions that regenerate ATP via anaerobic or oxidative means. The major anaerobic sources of ADP phosphorylation are the hydrolysis of phosphocreatine (PCr) via the creatine kinase reaction, and anaerobic glycogenolysis in which glycogen is metabolized to lactic acid. Anaerobic energy pathways are the major or sole source of ATP production when muscle blood flow is compromised as in ischemic or isometric exercise, e.g. weight lifting, or when energy demand exceeds the limits of oxidative power output, e.g. maximal effort running. Anaerobic sources of energy have several advantageous features: (i) they are intrinsic to muscle and independent of blood flow or oxygen supply; (ii) they enable muscle to work for brief periods at rates of ATP production (power output) that are two- to threefold higher than those available through oxidative metabolism; and (iii) they can reach these high rates of energy turnover in seconds, whereas acceleration to maximal oxidative power output takes 3–30 minutes (Sahlin, 1986). On the negative side, anaerobic sources of energy are rapidly depleted and/or lead to the accumulation of metabolic end products, e.g. protons, inorganic phosphate, and ADP, that are associated with muscle fatigue (see below) (Fitts, 1994). No human defects in PCr metabolism attributable to inborn errors of creatine kinase have been recognized, although genetic 'knockout' animal models of both cytoplasmic and mitochondrial forms of creatine kinase have been produced. In contrast, many inborn errors of muscle glycogen and glucose metabolism have been identified, most of which share common symptoms of exertional fatigue, cramping, and muscle injury under exercise conditions that normally require anaerobic energy production.

Oxidative phosphorylation is required to supply energy for muscle work that has to be sustained for more than a few minutes. The high yield of ATP per mole of substrate and the fact that the end products of oxidative phosphorylation, water and carbon dioxide, are readily removed from working muscle and do not themselves promote muscle fatigue make oxidative metabolism ideal for powering sustained exercise. The major endogenous oxidative fuel of skeletal muscle is glycogen, while free fatty acids (FFA) and blood glucose are the primary exogenous oxidative fuels. The oxidation of glycogen is critically important for rapid (within about 3 minutes) acceleration to oxidative steady-state in the transition from rest to exercise (Sahlin, 1986). In addition, glycogen is required for maximal rates of oxidative ATP production (Haller & Bertocci, 1994). Blood glucose is the most important exogenous carbohydrate fuel. As exercise is continued, muscle glucose uptake increases and blood glucose is replenished by increasing rates of hepatic glycogenolysis. Also, blood glucose represents an important

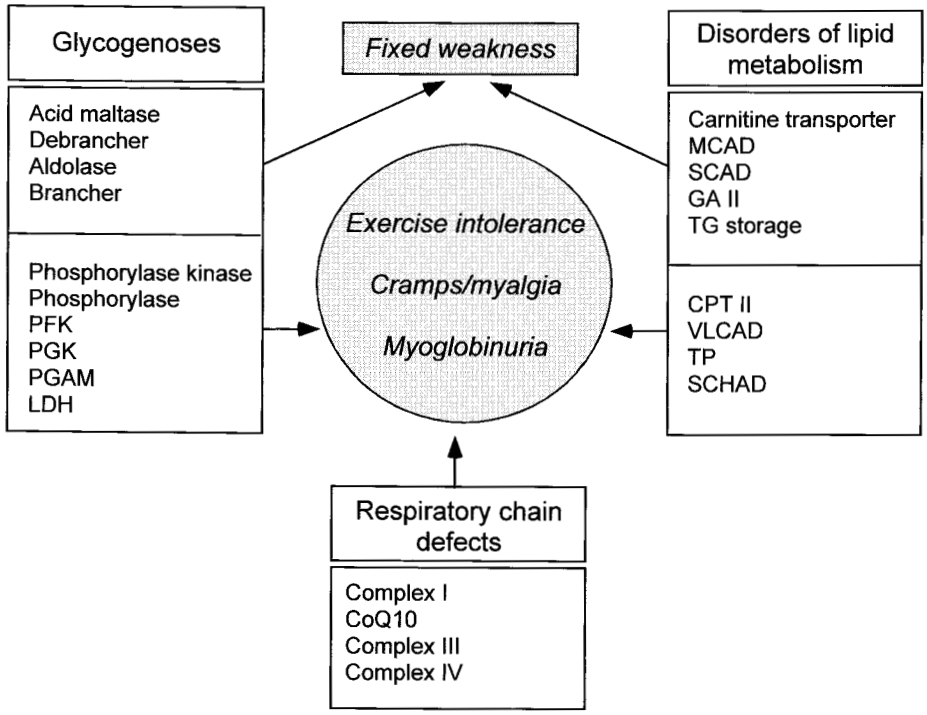

Fig. 72.1. The two major clinical syndromes associated with defects of muscle substrate utilization. Abbreviations: PFK, phosphofructokinase; PGK, phosphoglycerate kinase; PGAM, phosphoglycerate mutase; LDH, lactate dehydrogenase; CPT, carnitine palmitoyltransferase; VLCAD, very long chain acyl-CoA dehydrogenase; TP, trifunctional protein; SCHAD, short chain 3-hydroxyacyl-CoA dehydrogenase; MCAD, medium chain acyl-CoA dehydrogenase; SCAD, short chain acyl-CoA dehydrogenase; GA II, glutaric aciduria type II; TG, triglyceride; CoQ10, coenzyme Q10 (ubiquinone). (Modified from DiMauro & Haller (1999).)

substitute for muscle glycogen, which becomes depleted in prolonged exercise. The most abundant oxidative fuel is lipid, and exercise fueled by fat oxidation can be sustained virtually indefinitely. Peak levels of fat oxidation depend upon the concentration of FFA in blood, which in turn is a function of the rate of mobilization of free fatty acids from triglyceride stores in adipose tissue. Acceleration to peak levels of fat oxidation requires approximately 30 minutes of sustained exercise (Sahlin, 1986), and with prolonged submaximal exercise, lipid is the dominant fuel source for working muscle. Disorders of muscle oxidative metabolism, including mitochondrial myopathies, complete blocks in glycogenolysis/glycolysis and defects of lipid utilization typically impair exercise endurance.

Symptoms in metabolic myopathies

Symptoms in metabolic myopathies may be classified as static or dynamic (Fig. 72.1). The former consist of fixed and often progressive weakness. Dynamic symptoms are provoked by exercise and are the direct result of impaired muscle energy availability within working muscle. These symptoms include abnormal fatigability, cramps, and rhabdomyolysis with myoglobinuria. Muscle pain (myalgia) accompanies cramps and muscle injury and may be a prominent component of exercise intolerance in some of these disorders.

Weakness

Fixed or static weakness is defined as an inability to generate normal muscle force when fully rested. Such weakness generally is attributed to a reduction in functional muscle mass and in the size of functional motor units, and is the dominant feature of some metabolic myopathies, which, in this respect, mimic non-metabolic myopathies. Weakness is typical of acid maltase deficiency. It is also common in some energy defects, such as mitochondrial myopathies and lipid disorders associated with carnitine deficiency. The distribution of weakness is generally symmetrical, affecting predominantly the proximal hip and shoulder girdles, similar to most non-metabolic myopathies. A predilection for extraocular and lid muscles is

typical of mitochondrial myopathies, particularly those attributable to large-scale mitochondrial DNA deletions. Bulbar symptoms also may be a component of myopathic weakness in some mitochondrial and lipid myopathies. Weakness is the most typical neuromuscular presentation of glycogen debrancher deficiency and may complicate other glycolytic defects such as muscle phosphorylase deficiency (McArdle disease) and muscle phosphofructokinase deficiency (Tarui disease). The pathophysiology of weakness in muscle energy defects is poorly understood, but is unlikely to result from disruption of contractile elements due to excess storage of glycogen or lipid, or reduced energy availability. Patients with glycolytic defects and recurrent exertional muscle necrosis may gradually lose muscle mass, potentially exhausting the reserve of satellite cells necessary for muscle regeneration. Energy defects may also play a role in the balance of protein synthesis/catabolism.

Exercise intolerance: abnormal exertional fatigue

Fatigue is defined as an inability to maintain contractile force or power output with repeated muscle contractions. It is a normal phenomenon that is experienced by healthy individuals during intense or prolonged exercise. A hallmark of muscle energy defects is abnormal exertional fatigue in which a decline in muscle force generation occurs prematurely or is provoked by activities that are easily tolerated by healthy individuals.

Normal exertional fatigue

Although the cellular basis of fatigue in healthy individuals is incompletely understood, it must affect one or more steps in the sequence of events involved in normal muscle contraction and relaxation. The mechanism of fatigue and the contribution of various metabolic factors relative to changes in cation levels probably vary depending upon conditions of exercise or experimental paradigms.

Experimentally, the pattern of fatigue in normal muscle is highly dependent upon the rate of stimulation. High-frequency fatigue (HFF) occurs with rates of stimulation around 50 Hz, and has been linked to high levels of extracellular potassium and to increased intracellular sodium/decreased intracellular potassium that accompanies repetitive trains of membrane action potentials (Jones, 1996). These ion shifts tend to lower the transmembrane potential, alter the configuration of the action potential, and ultimately may inactivate sodium channels rendering the sarcolemma inexcitable (Sejersted & Sjøgaard, 2000). Type II muscle fibres (high glycolytic, low oxidative capacity, fast twitch) may be more susceptible to such fatigue (Ruff & Whittlesey, 1992). The activity of Na^+K^+ ATPase (sodium pumps) plays a critical role in the maintenance of membrane excitability under these circumstances, and experimental evidence indicates that reduced pump activity or low pump numbers promote such fatigue, whereas increased pump activity or greater pump numbers are protective (Clausen, 1996). Low frequency fatigue (LFF) accompanies prolonged low rates of muscle stimulation (20Hz). In contrast to HFF where recovery from fatigue is rapid, LFF is associated with a delay of hours or longer before full recovery of muscle force occurs. Impaired release of calcium from the SR with lower levels of intracellular calcium relative to the rate of muscle stimulation has been implicated in LFF, but the cellular mechanisms responsible remain unclear (Favero, 1999).

The major circumstances associated with muscle fatigue are intense and prolonged exercise. As ATP is the ultimate source of energy for muscle contraction, it might be expected that ATP depletion would accompany levels of energy expenditure that outstrip energy supply. In fact, muscle ATP levels change little under conditions of maximal effort exercise (Sahlin et al., 1998). Instead, it appears that the metabolic basis of fatigue in these circumstances involves the accumulation of the end products of ATP hydrolysis and related energy pathways (Fitts, 1994; McLester, 1997). These include inorganic phosphate and diprotonated phosphate and ADP. The accumulation of lactic acid in active muscle during intense exercise has long been linked to fatigue, and experimental studies suggest that acidosis inhibits both force and velocity of muscle contraction (Fitts, 1994). These pH effects may not occur at physiologic temperatures (Pate et al., 1995). These intracellular end products may promote fatigue through inhibitory effects on myosin ATPase. The cross-bridge cycling that underlies muscle contraction depends upon the hydrolysis of ATP to ADP + Pi followed by the sequential release of Pi and ADP from acto-myosin. High levels of Pi and ADP are believed to inhibit the force and/or velocity of contraction by feedback inhibition of this process (McLester, 1997), and may modulate the activity of other ATPases.

A major metabolic mechanism in the development of fatigue with prolonged exercise is glycogen depletion. The necessity for glycogen under these circumstances relates to the fact that the maximal rate of ATP generated from the oxidation of fats is approximately 50% of that achievable from the oxidation of glycogen (Sahlin et al., 1998). This explains the importance of 'glycogen loading' as a prerequisite for prolonged high-level aerobic exercise such as marathon running. The high rates of oxidative phosphorylation obtained with glycogen apparently relate to the fact

that glycogen-derived pyruvate is required to support maximal rates of acetyl CoA production and pyruvate-dependent anaplerosis, thus achieving levels of intramitochondrial malate and related tricarboxylic acid (TCA) cycle intermediates necessary to crank up maximally the TCA cycle flux (Sahlin et al., 1990, 1995). The cellular mechanism of fatigue when glycogen is depleted has been linked to increased levels of ADP, AMP, IMP and ammonia (Sahlin, 1992). High ADP levels result from glycogen depletion which impairs ADP phosphorylation both by oxidative and anaerobic mechanisms. In addition, the kinetics of the proton-dependent creatine kinase reaction are shifted because muscle acidosis is attenuated by the lack of glycogen for lactate production (Radda, 1986). Studies by Sahlin and coworkers have identified two phases of recovery from prolonged, fatiguing exercise in human volunteers: (i) a rapid partial recovery correlates with restoration of metabolic perturbations; (ii) a delayed, non-metabolic recovery phase may correspond to impaired calcium release, as demonstrated in experimental studies of low frequency fatigue (Sahlin et al., 1998).

An important variable for normal fatigue is an individual's level of aerobic or cardiovascular fitness. Aerobic conditioning promotes endurance by increasing peak rates of muscle oxidative phosphorylation, as indicated by higher maximal levels of oxygen consumption (VO_2max). As a result, a given absolute level of exercise represents a lower percentage of maximal aerobic capacity in fit than in less fit persons. Since the duration that aerobic exercise can be sustained rapidly decreases as one approaches VO_2max, a fit person is able to tolerate higher levels of exercise and more prolonged exercise at a given submaximal workload (Sahlin, 1992). An important element in the tolerance of prolonged, submaximal exercise is the ability to utilize fat as an oxidative fuel. A more aerobically fit person covers a greater percentage of the oxidative cost of a given level of exercise by metabolizing fat compared to an individual who is less fit. This person is thus able to sustain such exercise for a longer period of time by preserving limited stores of carbohydrate fuels (Gollnick, 1985).

Mechanisms of abnormal fatigability in metabolic myopathies: oxidative defects

The classical example of impaired oxidative metabolism is mitochondrial myopathy, in which the function of the respiratory chain is impaired. Affected patients have low peak rates of muscle oxidative phosphorylation and low VO_2max with standardized exercise testing (Elliot et al., 1989; Haller & Bertocci, 1994). As a result, even trivial physical activity commonly overtaxes oxidative capacity and engages anaerobic metabolism to meet muscle energy needs. Thus, minor degrees of exercise cause rapid depletion of PCr and increases of lactic acid, inorganic phosphate and ADP, i.e. metabolites that have been linked to fatigue in healthy individuals. These patients resemble, and often are mistaken for, individuals who are severely deconditioned. However, unlike merely deconditioned subjects, patients with severe muscle oxidative defects exhibit a characteristic mismatch between oxygen utilization and oxygen delivery during exercise (Haller & Bertocci, 1994; Haller et al., 1989, 1991).

Oxidative metabolism requires highly regulated cardiopulmonary responses to precisely match O_2 delivery to muscle O_2 utilization in exercise, via neural reflexes activated by metabolites within working muscle that somehow sense the adequacy of O_2 availability relative to muscle oxidative requirements (Haller & Vissing, 1999). In primary muscle oxidative defects this normal relationship is disrupted, resulting in exaggerated O_2 delivery relative to utilization. In severe muscle oxidative defects, increases in cardiac output maybe three – tenfold greater than those accompanying similar levels of exercise in healthy individuals (Taivassalo et al., 2001). Ventilation may also be exaggerated by similar mechanisms. Thus, trivial exercise may cause both muscle fatigue and prominent dyspnea and tachycardia. In fact, exercise limitations in such patients may be incorrectly attributed to primary cardiopulmonary disease (Haller et al., 2000).

Abnormal fatigue with defects in muscle glycolysis/glycogenolysis

Impaired glycogenolysis or glycolysis slows the maximal rate of glycolytic, substrate-level phosphorylation. A characteristic consequence is an abnormally rapid decline in muscle force generation with ischemic or isometric exercise (Dyken et al., 1967; Wiles et al., 1981). Discovery of the exact cellular mechanism or mechanisms responsible for histochemical pattern of fatigue has been elusive. ^{31}P magnetic resonance spectroscopy and needle biopsies indicate that fatigue is not a result of frank depletion of ATP. However, this observation does not exclude the possibility that inadequate availability of discrete pools of ATP may play a role. Experimental studies indicate that ATP generated by substrate-level phosphorylation in glycolysis is tightly coupled to the function of Na^+ K^+ ATPase (sodium pumps) and to Ca^{2+} ATPase, suggesting that impaired glycogenolysis/glycolysis may impair ion transport by limiting the production of this critical source of ATP (James et al., 1996; Xu et al., 1995). Furthermore, patients with muscle phosphorylase deficiency have low levels of sodium pumps, which would exacerbate energy-limited

pump function and could explain the exaggerated increases in extracellular potassium and membrane inexcitability that are typical of this condition (Haller et al., 1998). The mechanism leading to reduced sodium pumps in muscle phosphorylase deficiency is not known, nor is it known whether sodium pumps are decreased in other muscle glycolytic defects. Sodium pump numbers measured in a single case of muscle phosphoglycerate mutase deficiency were normal (Vissing et al., 1999).

A characteristic feature of muscle glycolytic defects is an exaggerated rise in muscle ADP with resulting increases in AMP and in IMP, ammonia and related adenine nucleotide degradation products. Impaired substrate level phosphorylation may contribute to this exaggerated increase in ADP, but a critical mechanism involves the creatine kinase (CK) reaction. The hydrolysis of PCr and phosphorylation of ADP via CK is a proton consuming reaction (i.e. PCr + ADP + H+ ⇋ ATP + Cr). The block in lactate and H+ production that causes muscle to remain at neutral or slightly alkalotic pH during exercise shifts the equilibrium of this reaction to the left, effectively inhibiting the ADP buffering function of CK (Radda, 1986). High ADP levels slow the velocity of cross bridge cycling of acto-myosin by inhibiting myosin ATPase, impair sarcoplasmic reticulum calcium uptake by presumed effects on Ca^{2+} ATPase, and may impair the function of Na^{+}–K^{+} ATPase (McLester, 1997; Ruff, 1996).

Complete blocks of glycogen breakdown in myophosphorylase deficiency (McArdle disease), and of both glycogen and glucose metabolism in muscle phosphofructokinase (PFK) deficiency impair oxidative metabolism primarily by blocking the production of glycogen-derived pyruvate. This results in significant oxidative limitation and intolerance of moderate exercise (Haller & Lewis, 1991; Haller et al., 1985). In addition, such patients experience large swings in exercise capacity, illustrated in McArdle disease by the 'second wind' phenomenon (Pearson et al., 1961). When an activity that initially causes fatigue, breathlessness and tachycardia, is continued beyond 5–10 minutes, exercise suddenly becomes much easier, as increased blood-borne fuels become available to support muscle oxidative metabolism (Pearson et al., 1961; Porte et al., 1966). For reasons that are incompletely understood, patients with PFK deficiency are less able to achieve a second wind, and tend to experience major fluctuations in exercise capacity related to dietary factors that influence the availability of free fatty acids (Haller & Lewis, 1991). Since both glucose and glycogen metabolism are blocked as a result of PFK deficiency, fats represent the major oxidative fuel available to working muscle. When the concentration of free fatty acids falls after glucose infusion or a high carbohydrate meal, exercise capacity plummets, and an activity that was easily tolerated before eating now causes fatigue, tachycardia and breathlessness, the 'out of wind' phenomenon (Haller & Lewis, 1991).

Abnormal fatigue with defects in muscle lipids

The consequences of defects of long chain fatty acid metabolism on fatigability are little studied, and those studies that have been performed have focused primarily upon adult carnitine palmitoyltransferase II (CPT II) deficiency. In CPT II deficiency, tolerance for short-term high-intensity exercise is normal (Lewis et al., 1991). The primary clinical observation is that such patients have reduced tolerance for prolonged, submaximal exercise, particularly under conditions of relative fasting, i.e. exercise that normally depends upon the combustion of fats to meet muscle energy requirements. Patients clearly have reduced endurance to such exercise, and muscle pain and injury are commonly triggered under these circumstances. However, the metabolic mediators of these symptoms are not known. Possible mechanisms include accelerated glycogen depletion and an increase to toxic levels of long chain fatty acids due to the block in fatty acid metabolism.

Chronic fatigue syndrome and related disorders

Subjective complaints of fatigue and fatigability are common in clinical medicine but only rarely attributable to an underlying disorder of muscle metabolism. The relationship of fatigue to exercise is an important clinical clue which can differentiate the abnormal fatigue of metabolic myopathies (brought on by exercise, relieved by rest) from that of psychological disorders or systemic illness. In addition to fatigue that is worsened by exercise, patients with chronic fatigue syndrome and kindred disorders typically have a global loss of energy, which is independent from activity but interferes with their ability to initiate activity. Such patients complain of an unrelenting tiredness that permeates their lives, commonly affecting mental as well as motor functions.

Exercise intolerance: muscle cramps

Cramp refers to an involuntary, typically painful shortening of skeletal muscle. Cramp-like, electrically silent muscle contractures are a hallmark of muscle glycolytic defects, but are not features of other metabolic myopathies (Rowland et al., 1999). They are triggered by brief intense exertion that normally engages anaerobic glycogenolysis to meet energy demands such as maximal effort sprinting,

performing push-ups or pull-ups, or carrying luggage or furniture. The muscle 'locks up' immediately with such exercise and cannot be extended for minutes to as long as an hour. Patients may cautiously and intermittently stretch the affected muscle but sudden lengthening such as that performed to terminate common cramps is not possible and attempts to do so cause extreme pain. Elegant experimental studies by Ruff and coworkers utilizing iodoacetate inhibition of glycolysis have clarified the metabolic basis of these contractures. Contractures were not associated with depletion of muscle ATP, but rather correlated with high intracellular calcium and with increased Ca^{2+} sensitivity of contractile proteins due to combination of high intracellular [ADP] and relative alkalosis (Ruff, 1996; Ruff & Weissman, 1991). These results are compatible with ADP-mediated inhibition of Ca^{2+} ATPase.

Contractures should be differentiated from common cramps, which are mediated by repetitive firing of motor nerve terminals within muscle and are related to neural hyperexcitability, accumulation of metabolites that promote the firing of neural action potentials, or both. In contrast to contractures in muscle glycolytic defects, common cramps usually occur at rest or with non-forceful muscle contractions. They often are heralded by repetitive non-painful muscle twitches. Cramps also may occur after prolonged exercise in otherwise healthy individuals, especially by dehydration and heat stress. Patients sometimes use the term 'cramps' as synonymous with localized muscle pain or with fasciculations. Muscle pain in patients with CPT II deficiency is sometimes referred to as 'cramp-like' but frank muscle cramps are not a feature of this disorder.

Exercise intolerance: exertional muscle injury, rhabdomyolysis, myoglobinuria

Recurrent myoglobinuria is a clinical feature of several metabolic myopathies, especially disorders of glycogenolysis/glycolysis and adult carnitine palmitoyltransferase II deficiency (Tonin et al., 1990). Increasingly, myoglobinuria has been noted in mitochondrial myopathies as well (see below). In muscle glycolytic disorders, rhabdomyolysis is triggered by brief intense exercise. It invariably accompanies muscle contractures. This fact suggests that the same metabolic abnormalities that have been linked to the development of contractures: high intracellular calcium levels, alkalosis, and high concentrations of ADP, may be responsible. In CPT II deficiency, rhabdomyolysis typically is triggered by prolonged, submaximal exercise, particularly when such exercise has been undertaken under fasting conditions. The cellular basis of muscle injury clearly relates to deficient fat oxidation, and the fact that dietary carbohydrate is protective implies that a decline in available carbohydrate plays a role. The basis of rhabdomyolysis in mitochondrial myopathies also is poorly understood. Exercise is often, but not invariably involved, and some patients develop rhabdomyolysis under conditions of fasting, similar to CPT II deficiency.

Although the occurrence of exercise-induced rhabdomyolysis and myoglobinuria always should raise the possibility of an underlying metabolic myopathy, exertional rhabdomyolysis may occur in non-metabolic myopathies and in otherwise healthy individuals. For example, dystrophin deficiency sometimes is associated with exertional rhabdomyolysis and myoglobinuria without frank weakness (Hoffman et al., 1989). Also healthy individuals who engage in unaccustomed heavy exercise, particularly exercise that involves lengthening muscle contractions (eccentric exercise), are prone to exertional muscle injury and pain (Armstrong et al., 1991; Morgan & Allen, 1999). The time course of muscle symptoms differs from metabolic myopathies, however. In contrast to metabolic myopathies, symptoms of muscle pain and pigmenturia do not occur immediately with exercise but rather are delayed in onset 24–48 hours. Such muscle injury is responsible for the syndrome of delayed onset muscle soreness.

Exercise intolerance: muscle pain

Muscle pain routinely accompanies contractures in muscle glycolytic defects and is a feature of rhabdomyolysis attributable to various metabolic myopathies. If patients have developed severe muscle injury, their muscles may be sore for days following the acute insult. Patients with muscle glycolytic defects, who develop focal muscle injury and pain with exercise, may experience a second wave of excruciating pain some hours later due to 'compartment syndrome' (Haller, 1999). Some metabolic myopathy patients experience pain in association with fatigue during exercise, but in many instances myalgia is not an important component of fatiguing exercise in these disorders. Muscle fatigue is commonly experienced as a bland sense of weakness, e.g. 'spaghetti legs', with no particular discomfort. Thus, in general, muscle pain is not the major symptom of metabolic myopathies and the presence of sustained muscle pain or pain as the dominant symptom should suggest a diagnosis other than a metabolic myopathy.

Biochemical and molecular approaches to the diagnosis of metabolic myopathies

Some metabolic myopathies, true to their name, affect only muscle, while others involve one or more non-muscle

tissues. This is explained by various factors, including tissue-specific isozymes or enzyme subunits or, in the case of mtDNA-related diseases, by different degrees of heteroplasmy or by the existence of 'somatic mutations'.

Tissue-specific isozymes

The best example of a muscle-specific isozyme is phosphorylase (myophosphorylase), which is defective in glycogenosis type V (McArdle disease). There are three distinct isozymes of phosphorylase: myophosphorylase, encoded by a gene on chromosome 11 (Lebo et al., 1984); a brain/heart isozyme, encoded by a gene on chromosome 10 or 20 (Newgard et al., 1988), and a liver isozyme, whose gene is on chromosome 14 (Newgard et al., 1986). A variety of mutations in the myophosphorylase gene have been identified in McArdle disease. However, one of them, a nonsense mutation in the first exon of the gene (Arg49Stop) predominates among Caucasian, and especially Anglo-Saxon patients, having been found in 81% of the alleles in British patients (Bartram et al., 1993) and in 63% of the alleles in US patients (El-Schahawi et al., 1996). It is noteworthy, however, that muscle cultures or regenerating muscle from patients with McArdle disease express the brain isozyme (Roelofs et al., 1967; DiMauro et al., 1978), suggesting that muscle phosphorylase undergoes a developmentally regulated transition in isozyme patterns. This has practical implications because the histochemical stain for phosphorylase may be deceivingly positive in biopsies from patients taken too soon after an episode of myoglobinuria and containing regenerating muscle fibres (Mitsumoto, 1979).

Tissue-specific enzyme subunits

Here, examples abound, as many enzymes are multimeric, but one subunit is expressed exclusively or predominantly in skeletal muscle.

Phosphofructokinase (PFK) is a tetrameric enzyme under the control of three autosomal loci. A locus on chromosome 1 encodes the muscle (M) subunit; a locus on chromosome 21 encodes the liver (L) subunit, and a locus on chromosome 10 encodes the platelet (P) isozyme (Vora, 1982). Mature human muscle expresses only the M subunit and contains only the homotetramer M4, while erythrocytes, which express both the M and L subunits, contain five isozymes, the two homotetramers M4 and L4, and three hybrid isoforms. In patients with typical PFK deficiency, genetic defects of the M subunit cause total lack of activity in muscle but only partial PFK deficiency in red blood cells, where the residual activity approximates 50% of normal and is accounted for by the L4 isozyme. Hence, patients with PFK deficiency often have signs of compensated hemolytic anemia (hyperbilirubinemia, increased reticulocyte count), and this can help in the differential diagnosis from McArdle disease.

Two other multimeric glycolytic enzymes are phosphoglycerate mutase (PGAM) and lactate dehydrogenase (LDH). PGAM is a dimeric enzyme composed of a muscle-specific (M) and a brain-specific (B) subunit, and normal muscle contains predominantly the MM homodimer, which accounts for 95% of the total activity. The only other tissues containing substantial amounts of the M subunit are heart and sperm, but there is no evidence of cardiopathy or male infertility in PGAM deficiency (Tsujino et al., 1993).

LDH is a tetrameric enzyme composed of various proportions of a muscle-specific subunit (LDH-A) and a cardiac subunit (LDH-B). LDH-A is encoded by a gene on chromosome 11 and LDH-B by a gene on chromosome 12 (Kanno & Maekawa, 1995).

Heteroplasmy of mitochondrial DNA

One of the distinctive concepts of mitochondrial genetics (as opposed to mendelian genetics) is that each cell contains hundreds or thousands of mitochondria and many more copies of mitochondrial DNA (mtDNA) reviewed in Chapter 119. In most mtDNA-related diseases, some but not all mtDNA molecules harbour a pathogenic mutation (heteroplasmy). The functional consequences of a deleterious mtDNA mutation depend on the relative abundance of mutant mtDNAs in that particular tissue, and a critical minimal degree of heteroplasmy will be needed before oxidative dysfunction becomes manifest (threshold effect). In this respect, skeletal muscle, together with cardiac muscle and brain, is very vulnerable to any impairment of oxidative metabolism.

While mutations in tRNA genes are usually associated with multisystem disorders, in rare cases there is involvement of a single tissue, most commonly skeletal muscle (DiMauro, 2000). It is noteworthy, and a useful diagnostic clue, that four such patients with mutations in the $tRNA^{Leu(UUR)}$ showed preferential involvement of respiratory muscles (Goto et al., 1992; Ogle et al., 1997; Bindoff et al., 1993; Hadjigeorgiou et al., 1999b). In most of the patients, the mutation was also present in blood or cultured skin fibroblasts, implying that the selective muscle involvement was due to 'skewed heteroplasmy', with preferential accumulation of the pathogenic mutation in skeletal muscle.

Only recently we came to realize that mutations in mtDNA protein-coding genes are often tissue specific,

many of them muscle specific. These true mitochondrial myopathies are usually characterized by exercise intolerance, myalgia, and myoglobinuria and can affect subunits of complex I, complex III, or complex IV (DiMauro, 1999), although they seem to be more commonly associated with complex III deficiency (Andreu et al., 1999a). Not only were all of these patients sporadic, but skeletal muscle was the only tissue affected and harbouring the mtDNA mutation. Therefore, these mutations are likely to be 'somatic', that is, spontaneous events that arose in myoblasts or myoblast precursors after germ-layer differentiation and did not affect germline cells.

Is muscle biopsy always necessary?

In those metabolic myopathies in which the enzyme defect is not confined to muscle but involves some or all non-muscle tissues, the biochemical diagnosis can be established in more easily accessible tissues, such as blood cells or cultured skin fibroblasts. For example, debrancher deficiency (glycogenosis type III) and phosphoglycerate kinase (PGK) deficiency (glycogenosis type IX) affect virtually all tissues. Carnitine palmitoyltransferase II (CPT II) deficiency is expressed in lymphocytes and fibroblasts.

Mitochondrial encephalomyopathies due to mutations in mtDNA present a special problem. Even in multisystemic disorders, such as MELAS, MERRF, and NARP/MILS, due to the heteroplasmic nature of these mutations, respiratory chain enzyme defects are invariably partial, and may be difficult to detect in tissues less rich in mitochondria than muscle, such as fibroblasts. In patients with somatic mutations in protein-coding mtDNA genes, muscle biopsy is generally needed for diagnosis, and will show a specific defect of complex I, complex III, or complex IV.

Enzyme defect hunters have been followed by molecular defect hunters, and our molecular knowledge of metabolic myopathies has advanced so rapidly that it is sometimes possible to bypass biochemistry (and muscle biopsy) and go directly to molecular analysis of blood or other accessible cells. To be successful, however, this approach requires at least two conditions: (i) the clinical diagnosis has to be convincing; and (ii) the disease in question must be caused by one, or a few, common mutations. Thus, a Caucasian patient with suspected myophosphorylase deficiency can be tested for the Arg49Stop mutation in genomic DNA extracted from blood with good probability of success. Similarly, European or American patients with suspected CPT deficiency can be tested for the common Ser113Leu mutation (Taroni et al., 1993; Kaufmann et al., 1997). However, negative results do not exclude the diagnosis in either condition and make biochemical studies of muscle the next logical step.

Again, the situation is different in mitochondrial encephalomyopathies due to point mutations in mtDNA, such as MELAS, MERRF, and NARP. In patients with typical clinical phenotypes and evidence of maternal inheritance, looking for the common mutations (A3243G for MELAS; A8344G for MERRF; T8993G for NARP) in blood cells, hair follicles, or urinary sediment is the logical first diagnostic step. However, these mutations may not always be detectable in blood of atypical patients (Sue et al., 1999) or in oligosymptomatic maternal relatives of typical patients (DiMauro et al., 1999). Obviously, this approach does not apply to patients with pure myopathy and somatic mutations in mtDNA protein-coding genes.

Disorders of glycogen metabolism

Eleven hereditary enzyme defects of glycogen metabolism or glycolysis affect skeletal muscle (Fig. 72.2). Of these, one (branching enzyme deficiency, glycogenosis type IV) affects glycogen synthesis, and another (acid maltase deficiency, glycogenosis type II) affects lysosomal glycogen degradation. Presumably, neither of these two pathways is directly involved in energy provision during exercise. Of the remaining seven glycogenoses, three affect glycogen breakdown: phosphorylase b kinase deficiency (type VIII), myophosphorylase deficiency (type V), and debrancher deficiency (type III). Four glycogenoses affect terminal glycolysis: phosphofructokinase (PFK) deficiency (type VII), phosphoglycerate kinase (PGK) deficiency (type IX), phosphoglycerate mutase (PGAM) deficiency (type X), and lactate dehydrogenase (LDH) deficiency (type XI). To these, we should now add two new enzyme defects of terminal glycolysis, each described in a single patient: aldolase A deficiency (glycogenosis type XII) (Kreuder et al., 1996), and β-enolase deficiency (Comi et al., 2001). For each of these disorders, we will provide bullet-like information. Physiopathology and diagnostic approaches have been discussed in previous sections. For detailed clinical and pathological descriptions, the reader is referred to specialized textbooks (DiMauro et al., 1997).

Glycogenoses causing exercise intolerance and myoglobinuria

Glycogenosis type V (myophosphorylase deficiency; McArdle disease)

This is characterized by exercise intolerance with premature fatigue, myalgia, and cramps in exercising muscles, relieved by rest. Symptoms are more likely to occur with intense isometric exercise, such as lifting weights, or with

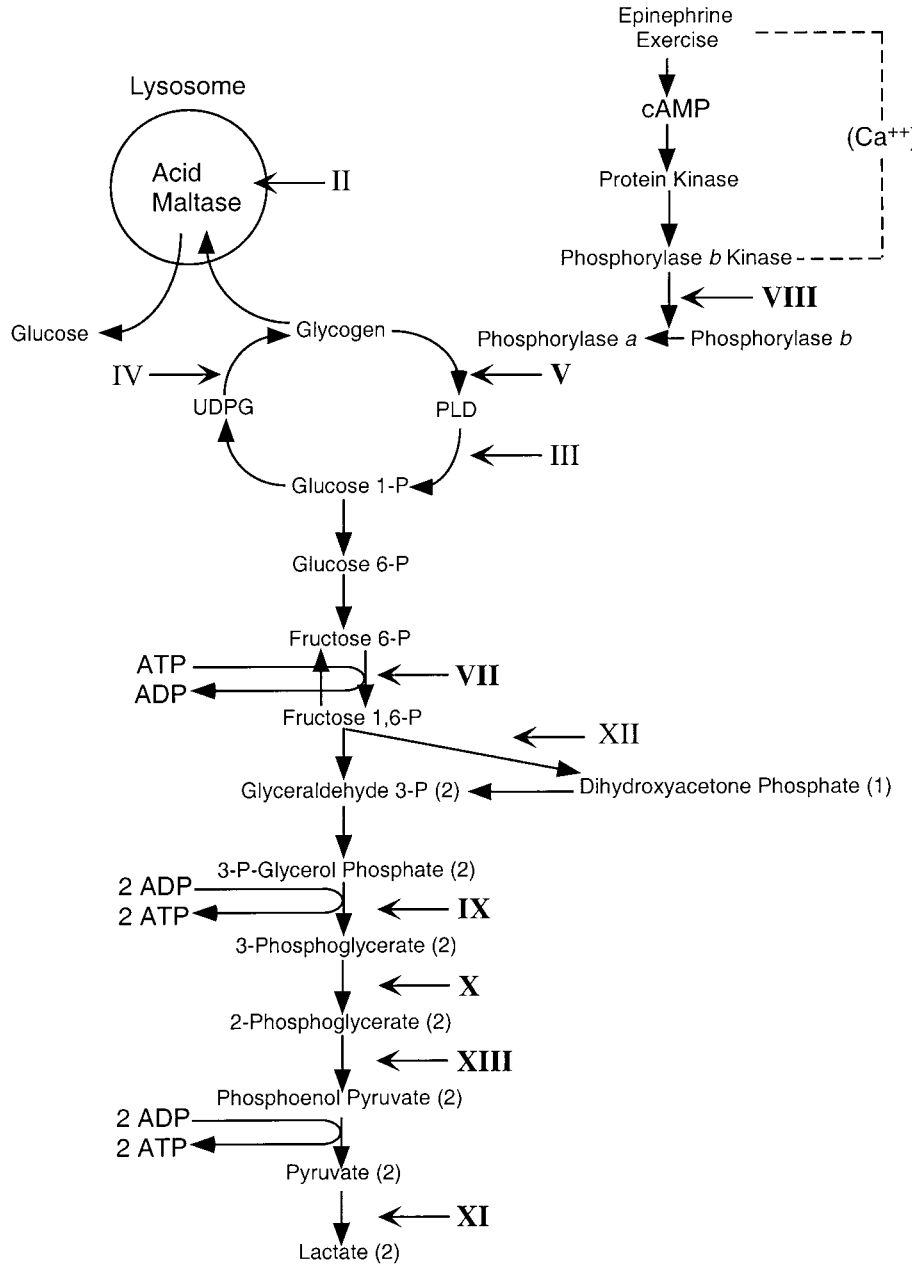

Fig. 72.2. Scheme of glycogen metabolism and glycolysis. Roman numerals indicate enzymes whose deficiencies are associated with muscle glycogenoses: II, acid maltase; III, debrancher; IV, brancher; V, myophosphorylase; VII, phosphofructokinase (PFK); VIII, phosphorylase kinase (PhK); IX, phosphoglycerate kinase (PGK); X, phosphoglycerate mutase (PGAM); XI, lactate dehydrogenase (LDH); XII, aldolase A; XIII, β-enolase. Bold roman numerals indicate glycogenoses causing exercise intolerance, cramps, and myoglobinuria; standard roman numerals indicate glycogenoses causing fixed weakness. Abbreviations: UDPG, uridine diphosphate glucose; PLD, phosphorylase limit dextrion; AMP, adenosine monophosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate. (Modified from DiMauro & Haller, 1999.)

less intense but sustained dynamic exercise, such as walking uphill. About half of the patients have acute muscle necrosis and myoglobinuria after exercise. The severity of symptoms varies considerably, from 'poor stamina' to frequent and almost incapacitating cramps. Patients with typical symptoms may develop fixed weakness later in life.

Laboratory tests show increased serum CK levels even at rest. EMG is usually normal or compatible with mild myopathy. During cramps, however, shortened muscles are electrically silent, true 'contractures'. The forearm ischemic exercise shows no rise of venous lactate, but is not specific for McArdle disease, and is less commonly employed nowadays. Molecular genetic analysis of blood cells may secure a diagnosis, thus avoiding both forearm ischemic exercise and muscle biopsy (El-Schahawi et al., 1996). Muscle biopsy typically shows subsarcolemmal and intermyofibrillar vacuoles filled with glycogen, which are PAS-positive and digested by diastase.

Phosphorylase catalyses the phosphorylytic stepwise removal of α-1,4-glucosyl residues from the outer branches of glycogen with liberation of G-1-P. This reaction goes on until the peripheral chains have been shortened to 4-glucosyl units, and the resulting 'phosphorylase-limit dextrin' (PLD) can be acted upon by the debranching enzyme.

About 30 mutations have been reported, but by far the most frequent among Anglo-Saxon patients is Arg49Stop. The frequency of this nonsense mutation in the very first exon of the gene explains why the enzyme protein is commonly absent in muscle (Servidei et al., 1988; McConchie et al., 1991).

Glycogenosis type VII (PFK deficiency; Tarui disease)

This is clinically indistinguishable from myophosphorylase deficiency, although myoglobinuria may be less frequent than in McArdle disease. Helpful laboratory signs include reticulocytosis, and increased serum bilirubin and uric acid. As in McArdle disease, resting serum CK values are variably increased, and the forearm ischemic exercise causes no increase in venous lactate. Clinical variants include: (i) late-onset weakness; and (ii) fatal infantile myopathy, often accompanied by brain involvement.

Muscle biopsy shows excessive subsarcolemmal and intermyofibrillar normal-looking glycogen. However, a distinctive morphological feature is the additional presence of polyglucosan deposits in many, especially older patients (Agamanolis et al., 1980; Hays et al., 1981; Danon et al., 1988).

PFK catalyses the phosphorylation of fructose-6-P to fructose-1,6-P, and PFK deficiency results in a marked accumulation of both fructose-6-P and its immediate glycolytic precursor, glucose-6-P (G-6-P). As G-6-P is a physiological activator of glycogen synthetase, we proposed that an abnormally increased ratio of glycogen synthetase relative to branching enzyme activity could be responsible for the deposit of polyglucosan (Agamanolis et al., 1980; Hays et al., 1981).

Glycogenosis type VIII (phosphorylase b kinase [PhK] deficiency)

In its myopathic form, PhK deficiency appears like a milder version of myophosphorylase deficiency, with exercise intolerance, cramps, and occasional myoglobinuria (Wilkinson et al., 1994). Some patients, however, have fixed weakness, and others have combined muscle and liver involvement, with static myopathy. Serum CK is variably increased and the lactate response to ischemic exercise is often normal or blunted.

Muscle biopsy shows mild-to-moderate subsarcolemmal accumulation of glycogen, predominantly in type IIb fibres.

PhK is a decahexamer of four different subunits, α, β, γ, and δ: $(\alpha\beta\gamma\delta)_4$. The γ-subunit is catalytic, the α- and β-subunits are regulatory, and the δ-subunit is identical to calmodulin and confers calcium sensitivity to the enzyme. There are two α-subunits, one specific for muscle (α_M), the other specific for liver (α_L), encoded by two distinct genes on the X-chromosome.

The prevalence of affected men is probably explained by the existence of an X-linked muscle-specific α-gene: in fact, both mutations documented thus far in myopathic patients have been in the α_M gene (Wehner et al., 1994; Bruno et al., 1998).

Glycogenosis type IX (PGK deficiency)

This usually causes hemolytic anemia, seizures, and mental retardation. However, isolated myopathy has been reported in half a dozen patients with exercise intolerance, cramps, and myoglobinuria. Resting serum CK levels are inconsistently elevated, and the rise of venous lactate after ischemic exercise is absent or blunted. Muscle biopsy may or may not show diffuse glycogen storage. PGK is a single polypeptide encoded by a gene on the X-chromosome and expressed in all tissues except the testis. A few mutations have been identified in patients with isolated myopathy (Tsujino et al., 1995).

Glycogenosis type X (phosphoglycerate mutase [PGAM] deficiency)

This causes exercise intolerance, cramps, and recurrent myoglobinuria. With the forearm ischemic exercise, there is abnormally low increase of venous lactate. An unusual

number of heterozygous patients can be symptomatic (Tsujino et al., 1993; Hadjigeorgiou et al., 1999a).

Muscle biopsy shows mild glycogen storage, which may be difficult to detect in some patients.

PGAM is a dimeric enzyme containing various proportions of a muscle (M) subunit and a brain (B) subunit. In normal mature human muscle, about 95% of total PGAM activity is accounted for by the MM homodimer. The small amount of residual PGAM activity found in muscle from patients is due to the BB homodimer.

The M subunit of PGAM is encoded by a gene on chromosome 7, and mutations have been identified in all patients with myopathy (Tsujino et al., 1993).

Glycogenosis type XI (lactate dehydrogenase [LDH] deficiency)

This is also characterized by exercise intolerance, cramps, and myoglobinuria. The forearm ischemic exercise causes very little or no increase of lactate but a large increase in pyruvate. LDH is a tetrameric enzyme composed of two subunits, one of which (LDH-M) predominates in skeletal muscle while the other (LDH-H) predominates in cardiac muscle. Random tetramerization results in the formation of five isozymes, the two homotetramers M4 and H4, and three heterotetramers. Muscle from patients contains only the H4 isoform. Mutations in the gene encoding LDH-M (which is on chromosome 11) have been identified in all patients with myopathy (Kanno & Maekawa, 1995).

Glycogenosis type XII (Aldolase A [ALD] deficiency)

This has been reported in a single patient with myopathy, characterized by episodic exercise intolerance and weakness triggered by febrile illnesses (Kreuder et al., 1996). ALD-A is composed of four identical subunits encoded by a gene on chromosome 16. A mutation (Glu206Lys) has been identified in the patient.

Glycogenosis type XIII (β-enolase deficiency)

This has been described in one man with adult-onset exercise intolerance and chronically elevated serum CK (Comi et al., 2001). Enolase is a dimeric enzyme, and the muscle-specific isoform β-enolase is a homodimer of the β subunit, which is encoded by a gene on chromosome 17. The patient was a compound heterozygote harbouring two missense mutations: Gly156Asp and Gly374Arg.

Glycogenoses causing fixed weakness

Glycogenosis type II (acid maltase [AM] deficiency)

This has two major clinical presentations, a generalized form (Pompe disease), and a myopathic form. Pompe disease starts at or around birth, and is characterized by floppiness, massive cardiomegaly, lesser hepatomegaly, sometimes macroglossia. These children rarely survive more than 1 year. The myopathic form of AMD comes in three varieties, depending on time at onset: infantile, childhood, and adult. Patients with infantile AMD resemble children with Pompe disease, but have no cardiopathy and tend to live longer (Slonim et al., 2000). Childhood AMD may mimic Duchenne or other forms of muscular dystrophy: these patients die in the second or third decade of respiratory insufficiency. Adult-onset AMD mimics limb–girdle dystrophy or polymyositis; truncal and respiratory muscles are especially affected. Serum CK is markedly elevated in all forms of AMD, and electromyography shows myopathic features together with fibrillation potentials, bizarre, high frequency, and myotonic discharges.

In Pompe disease and in the infantile and childhood variants of myopathic AMD, muscle biopsy shows massive accumulation of both intralysosomal and free glycogen, which distorts the contractile system. In adult AMD, glycogen accumulation is milder and may be difficult to detect in some muscles. There is no histochemical stain for acid maltase, but intense staining for acid phosphatase, another lysosomal enzyme, provides an indirect clue to the diagnosis.

Acid maltase is an acid α-1,4- and α-1,6-glucosidase, capable of digesting glycogen all the way to glucose. This lysosomal enzyme is a single polypeptide encoded by a gene on chromosome 17 and expressed in all tissues.

An X-linked disorder characterized by cardiomyopathy, mental retardation, and autophagic vacuolar myopathy, can mimick AMD (Hart et al., 1987). This is due to mutations in LAMP-2, a lysosome associated membrane protein not directly involved in glycogen metabolism (Nishino et al., 2000).

Over 50 mutations have been identified in the gene encoding α-glucosidase, and this has simplified prenatal diagnosis.

Glycogenosis type III (debrancher deficiency)

This typically presents as a benign hepatopathy of infancy or childhood, with hepatomegaly, growth retardation, and fasting hypoglycemia. Clinical myopathy is uncommon and often manifests in adult life, with weakness and wasting of distal leg and intrinsic hand muscles, sometimes suggesting motor neuron disease or peripheral neuropathy (DiMauro et al., 1979). Subclinical cardiac involvement is revealed by laboratory tests in most patients. Serum CK is variably increased, and EMG shows myopathic features associated with fibrillations, positive sharp waves, and myotonic discharges. Nerve conduction studies may reflect peripheral nerve involvement.

Muscle biopsy shows severe vacuolar myopathy with deposits of PAS-positive material under the sarcolemma and between myofibrils. Ultrastructurally, the vacuoles correspond to large pools of free, normal-looking glycogen β-particles.

The debranching enzyme is a single polypeptide encoded by a gene on chromosome 1, which possesses two distinct catalytic functions, oligo-1,4-1,4-glucantransferase and amylo-1,6-glucosidase. Patients with debrancher deficiency are classified into three groups: IIIa, lacking both enzymatic activities in both liver and muscle; IIIb, also lacking both activities in liver, while heart and muscle are spared; IIIc, lacking only the transferase activity in both liver and muscle (Chen et al., 1987; Ding et al., 1990). Most patients belong to group IIIa. Because the enzyme defect is generalized, at least in patients belonging to the IIIa group, biochemical assays can be performed in erythrocytes, white blood cells, or cultured fibroblasts.

Several mutations have been identified in both type IIIa and IIIb patients, and can be used for prenatal diagnosis.

Glycogenosis type IV (branching enzyme deficiency)

This is typically considered a rapidly progressive disease of early childhood, with hepatosplenomegaly, cirrhosis, hepatic failure, and death before 4 years of age. However, clinical presentations vary widely, with predominant involvement of muscle, heart, or brain in different patients. Brain involvement ('adult polyglucosan body disease', APBD) is manifested by late-onset progressive upper and lower motor neuron disease, sensory loss, sphincter dysfunction and dementia.

Muscle biopsy shows basophilic, intensely PAS-positive polysaccharide deposits, which are partially resistant to diastase digestion and which, ultrastructurally, consist of filamentous and finely granular material. The abnormal polysaccharide, called polyglucosan, has been documented in skin, liver, muscle, heart, and brain, but the amount varies widely in different tissues from different patients. In APBD, polyglucosan bodies are seen in processes (but not in perikarya) of neurons and astrocytes in both grey and white matter (Robitaille et al., 1980).

The branching enzyme catalyses the last step in glycogen biosynthesis by adding short glucosyl chains (about 7 glucosyl units long) to linear peripheral chains of glycogen in α-1,6-glucosidic bonds. The newly added stubs are then elongated by glycogen synthetase. The enzyme is a monomeric protein encoded by a gene on chromosome 3 and expressed in all tissues, and thus tissues other than muscle, e.g. leukocytes, can be used for diagnosis (Lossos et al., 1991).

The polysaccharide stored in brancher deficiency (polyglucosan) has longer than normal peripheral linear chains and fewer branching points, thus resembling amylopectin. Mutations have been identified in patients with different clinical phenotypes, including myopathy (Bruno et al., 1999) and APBD (Lossos et al., 1998).

Disorders of lipid metabolism

Two major metabolic pathways are needed for long-chain fatty acid utilization: (i) transport and activation of fatty acids (the carnitine cycle); and (ii) mitochondrial fatty acyl-CoA oxidation (β-oxidation) (Fig. 72.3). In this section, we will review briefly only those disorders that cause neuromuscular disease.

Disorders causing exercise intolerance and myoglobinuria

A disorder of the carnitine cycle, CPT II deficiency, is an important cause of exercise intolerance and myoglobinuria, but its clinical presentation can be mimicked by defects of some β-oxidation enzymes.

Carnitine palmitoyltransferase II (CPT II) deficiency

This causes two distinct phenotypes, myopathic and hepatocardiomuscular. The more common, myopathic form, usually presents in adolescents or young adults, predominantly males, with recurrent myoglobinuria following prolonged, though not necessarily strenuous exercise, prolonged fasting, or a combination of the two conditions. Other precipitating factors include cold exposure, lack of sleep, and, especially in children, intercurrent illnesses with high fever. Between attacks, these patients have normal physical and neurological exams. Unlike what happens in the glycogenoses, the attacks of myoglobinuria are not heralded by painful cramps. In addition, exercising muscles are not necessarily the only ones undergoing acute necrosis and a few patients have been admitted to the hospital in respiratory distress (Bertorini et al., 1980). Another distinguishing feature from the glycogenoses is the normal level of serum CK between attacks of myoglobinuria. Plasma carnitine levels are usually normal. CPT II deficiency, first described in 1973 (DiMauro & DiMauro-Melis, 1973), appears to be the most common cause of hereditary myoglobinuria (Tonin et al., 1990).

When muscle biopsy is taken remote from an episode of myoglobinuria, it can be completely normal. When present, lipid storage is much milder than in the primary or myopathic forms of carnitine deficiency.

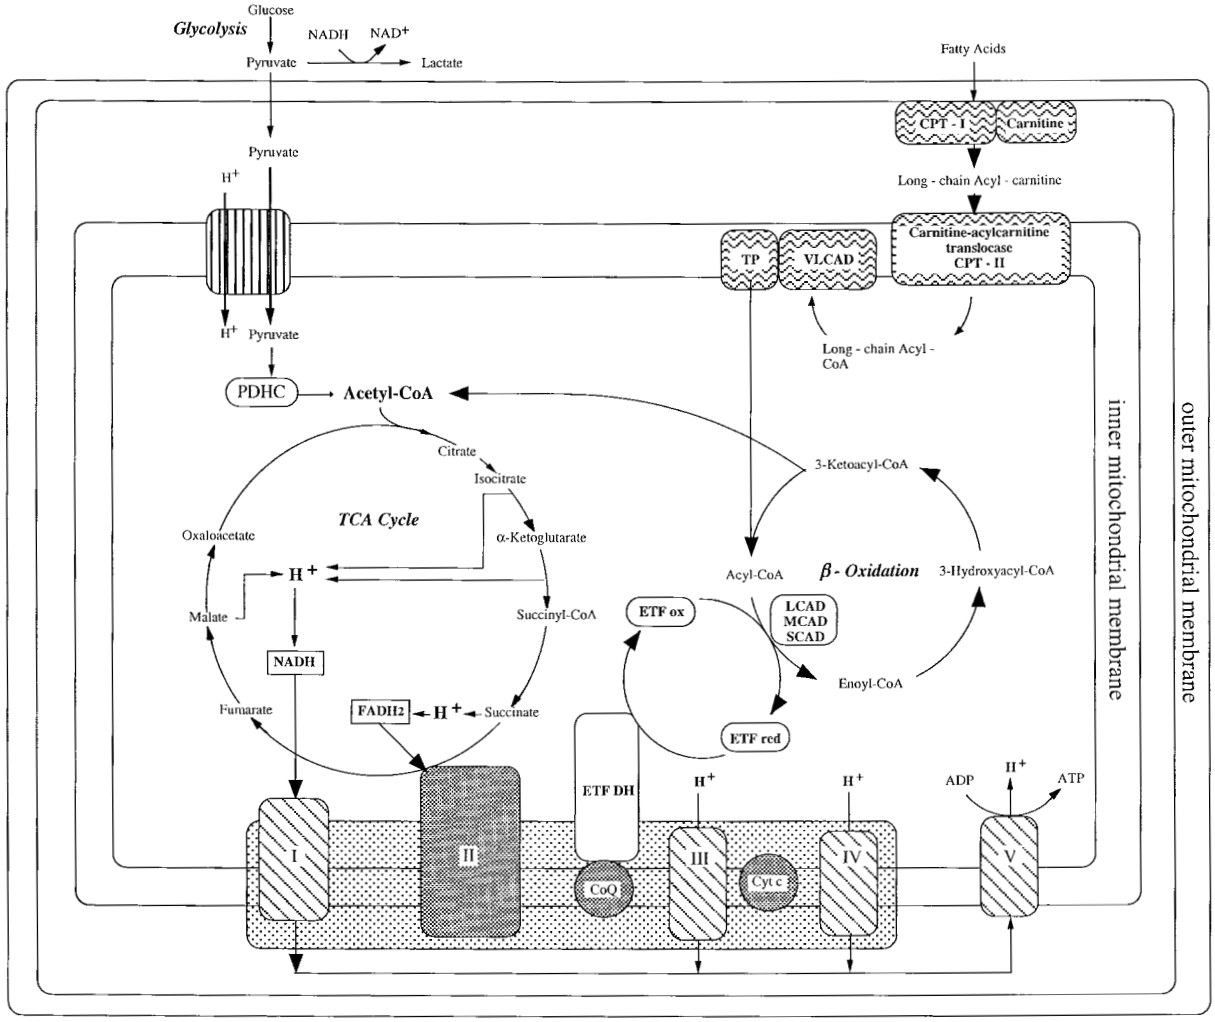

Fig. 72.3. Schematic representation of mitochondrial metabolism. For details, see text. Respiratory chain components or complexes encoded exclusively by the nuclear DNA are solid; complexes containing some subunits encoded by the nuclear genome and others encoded by mtDNA are crosshatched. Abbreviations: PDHC, pyruvate dehydrogenase complex; CPT, carnitine palmitoyltransferase; VLCAD, very long chain acyl-CoA dehydrogenase; TP, trifunctional protein; LCAD, long chain acyl-CoA dehydrogenase; MCAD, medium chain acyl-CoA dehydrogenase; SCAD, short chain acyl-CoA dehydrogenase; HAD, 3-hydroxyacyl-CoA dehydrogenase; KT, 3-ketothiolase; ETFox, oxidized form of electron transfer flavoprotein; ETFred, reduced form of electron transfer flavoprotein; ETF-DH, ETF-coenzyme Q oxidoreductase. (Modified from DiMauro & Haller, 1999.)

Once long-chain acylcarnitines are inside the inner mitochondrial membrane, they have to be reconverted to acyl-CoA esters to enter the β-oxidation spiral. This is catalyzed by CPT II, a single enzyme without tissue-specific isoforms, which is loosely bound to the inner mitochondrial membrane and is encoded by a gene on chromosome 1p32. Numerous mutations have been described, but one of them (Ser113Leu) is commonly encountered in both European and American patients (Taroni et al., 1993; Kaufmann et al., 1997). The relative frequency of this disease and the special circumstances triggering myoglobinuria often suggest the diagnosis. In these cases, the more common mutations can be looked for in blood cells, thus potentially avoiding the need for a muscle biopsy.

The rarer and much more severe hepatocardiomuscular form can affect infants or children. Patients with the infantile form die within weeks, after presenting with hepatopathy, encephalopathy, cardiomegaly, and cardiac arrhythmia. Children with later onset have fasting hypoketotic hypoglycemia, hepatopathy, cardiomyopathy and mild myopathy,

and are at risk for sudden death. In contrast to the myopathic form, plasma carnitine levels are severely decreased in the generalized form.

Very-long chain Acyl-CoA dehydrogenase (VLCAD) deficiency

This causes three major clinical phenotypes: (i) a severe infantile form with hypertrophic cardiomyopathy and early death; (ii) a less severe form with recurrent episodes of hypoketotic hypoglycemia; (iii) a myopathic form closely resembling CPT II deficiency and characterized by recurrent episodes of muscle breakdown and myoglobinuria following prolonged exercise, prolonged fasting, or both together (Straussberg et al., 1997; Minetti et al., 1998; Smelt et al., 1998).

Trifunctional protein (TP) deficiency

This usually presents in infancy, with cardiomyopathy, which is sometimes preceded by episodes of hypoketotic hypoglycemia. However, three patients had a milder presentation, with recurrent myoglobinuria resembling CPT II deficiency and chronic progressive polyneuropathy (Schaefer et al., 1996).

Short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) deficiency

This was described in a 16-year-old girl with hypoketotic hypoglycemic encephalopathy, cardiomyopathy, and recurrent myoglobinuria (Tein et al., 1991). As SCHAD activity was normal in fibroblasts, it was suggested that the defect involved a muscle-specific isoform, but this remains to be proven.

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency

This is a special case of the mitochondrial trifunctional protein (TP) deficiency described above, because LCHAD is one of the functions of TP. However, while in TP deficiency all three enzymatic functions are affected, in this case only the long-chain hydroxyacyl-CoA dehydrogenase activity is impaired. This disorder can present in infancy with episodic hypoketotic hypoglycemia after prolonged fasting due to intercurrent infections. Some infants succumb to rapidly progressive cardiomyopathy. Milder and later onset presentations include a myopathic form with exercise-induced episodic muscle breakdown and myoglobinuria, resembling CPT II deficiency (Dionisi-Vici et al., 1991; Tein et al., 1995). However, these patients often have additional features not seen in CPT II deficiency, including peripheral neuropathy and hepatomegaly with liver dysfunction. A 13-year-old boy with neuropathy, limb–girdle myopathy, and recurrent myoglobinuria responded dramatically to oral supplementation with cod liver oil extract, a rich source of docosahexaenoic acid (DHA), which is deficient in children with LCHAD deficiency (Tein et al., 1999b).

Disorders causing weakness

The main disorders of lipid metabolism causing weakness relate to carnitine deficiency, be it primary, myopathic, or secondary. More rarely, defects of enzymes in the carnitine cycle, such as the carnitine–acylcarnitine translocase, or in the β-oxidation spiral, such as short-chain acyl-CoA dehydrogenase (SCAD) or electron transfer flavoprotein (ETF) dehydrogenase are accompanied by weakness.

Primary systemic carnitine deficiency

This has been described in about 30 patients, of whom almost half had a sibling who had died of cardiomyopathy. Mean age at onset is 2 years, and the most common clinical presentation is progressive cardiomyopathy: echocardiography and ECG show dilated cardiomyopathy, peaked T waves, and signs of ventricular hypertrophy. Myopathy is usually associated with cardiomyopathy and is manifested by mild motor delay, hypotonia, or slowly progressive proximal weakness. Both cardiac dysfunction and muscle weakness respond dramatically to carnitine supplementation, and these patients can live normal lives with continued replacement therapy.

Muscle biopsy shows severe lipid storage. Endomyocardial biopsies or postmortem studies also show massive lipid storage in the heart.

Both total and free carnitine concentrations are extremely low (usually below 10% of normal) in skeletal muscle and in the myocardium.

This autosomal recessive disorder involves a genetic defect of the plasma membrane carnitine transporter in kidney, intestine, muscle, heart, and fibroblasts, but not in liver. The combination of defective renal and intestinal carnitine handling causes carnitine levels to fall in blood. Hence the importance of measuring blood carnitine concentrations in all infants and young children with unexplained cardiomyopathy. Linkage analysis has localized the gene responsible for primary carnitine deficiency to chromosome 5q. The gene, which encodes one member of a family of organic cation transporters, has been isolated and several pathogenic mutations have been identified in patients and their asymptomatic parents (Lamhonwah & Tein, 1998; Tang et al., 1999).

Primary myopathic carnitine deficiency

This is characterized by decreased muscle carnitine but normal serum carnitine (Engel & Angelini, 1973). The existence of this entity, however, is controversial because there

is no definitive documentation of an isolated defect of carnitine uptake in muscle. It is possible that patients with the diagnosis of carnitine deficiency myopathy may have other fatty acid oxidation defects, either generalized or muscle specific. In some of the patients described, symptoms appeared in the first years of life, but in most, onset was between the second and third decade. There was progressive and sometimes fluctuating weakness of proximal limb and axial muscles of variable severity. A few of these patients had associated cardiomyopathy.

In all patients, muscle biopsy showed severe lipid storage, especially in type I fibres.

Muscle carnitine levels were 20% of normal or less, while plasma carnitine levels were normal or slightly reduced. Some of the patients improved with carnitine administration.

Secondary carnitine deficiency

This is characterized by decreased levels of carnitine in blood and, often, in tissues, and it can accompany diverse disorders, including inborn errors of metabolism, acquired medical conditions, and iatrogenic states (Pons & DeVivo, 1995).

Examples of inborn errors of metabolism include numerous defects of fatty acid metabolism affecting both the carnitine cycle and β-oxidation (see below), disorders of branched-chain amino acid metabolism and defects of the mitochondrial respiratory chain.

Examples of acquired medical conditions include those causing decreased carnitine biosynthesis, e.g. hepatic cirrhosis or extreme prematurity, those causing decreased carnitine intake, e.g. malnutrition, chronic total parenteral nutrition, strict vegetarian diet, soy protein infant formula, malabsorption, those causing decreased body stores of carnitine in the face of increased requirements, e.g. pregnancy and lactation, extreme prematurity, infant of carnitine-deficient mother, and those causing increased carnitine loss, such as Fanconi syndrome.

Examples of iatrogenic factors include valproate therapy, hemodialysis, and zidovudine administration.

It is important to keep in mind these diverse causes of carnitine deficiency because carnitine replacement often results in marked improvement.

Carnitine–acylcarnitine translocase deficiency

This causes life-threatening episodes in the neonatal period, with generalized weakness, cardiac arrhythmia, hyperammonemia, and inconsistent hypoglycemia. This inner mitochondrial membrane translocase, encoded by a gene on chromosome 3, is needed to shuttle the acylcarnitines formed by CPT I across the inner membrane in exchange for carnitine.

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency

This usually presents in infancy with poor feeding, vomiting, failure to thrive, lethargy, and hypotonia. Psychomotor retardation, seizures and hyperactivity have also been described.

A single adult case of lipid storage myopathy with SCAD deficiency confined to skeletal muscle (Turnbull et al., 1984) was probably due to a different primary metabolic defect because there are no tissue-specific isoforms of SCAD. Myopathy was also prominent in a 13-year-old girl with congenital facial and neck weakness, which spread to limb, axial, and respiratory muscle (Tein et al., 1999a). She also had ptosis, progressive external ophthalmoplegia, and cataracts. Muscle biopsy showed type I fibre predominance and hypotrophy and multicores.

Electron-transfer flavoprotein (ETF) deficiency; ETF:CoQ10 oxidoreductase (ETFDH) deficiency

Both defects result in multiple acyl-Coa dehydrogenase deficiency (glutaric aciduria type II), and give rise to three major clinical phenotypes: (i) a severe neonatal disorder, with hypotonia, hepatomegaly, hypoglycemia, multiple congenital anomalies, and early death; (ii) a milder disorder, without congenital anomalies and with longer survival, but frequently accompanied by cardiomyopathy; and (iii) a later-onset form with vomiting, hypoglycemia, hepatomegaly, and weakness with lipid storage myopathy. An 8-year-old boy with ETFDH had a limb–girdle syndrome in addition to hepatomegaly and episodic hypoketotic hypoglycemia (DiDonato et al., 1986). Postmortem examination showed severe lipid storage myopathy and muscle carnitine deficiency. Of considerable practical importance is the riboflavin-responsive form of glutaric aciduria type II, which has been seen in adults with lipid-storage myopathy. In these patients, riboflavin administration improved wasting and weakness within weeks (DiDonato et al., 1989).

Defects of the mitochondrial respiratory chain

The respiratory chain, which includes five multimeric complexes and catalyses both electron transport and oxidative phosphorylation, is the 'business end' of mitochondrial metabolism, where the energy generated by carbohydrate and lipid oxidation is released as ATP. A unique characteristic of the respiratory chain is that this is the only metabolic pathway in the cell under dual genetic control. Of the approximately 80 proteins that make up the respiratory chain, 13 are encoded by mitochondrial DNA (mtDNA) and all the others are encoded by nuclear DNA

(nDNA). As indicated by the different shadings in Fig. 72.2, complex II, coenzyme Q, and cytochrome c are entirely encoded by nDNA. In contrast, complexes I, III, IV, and V contain some subunits encoded by mtDNA: seven for complex I; one for complex III; three for complex IV; and two for complex V. Both inheritance and clinical expression of mutations in mtDNA are governed by the distinctive rules of mitochondrial genetics (reviewed in Chapter 120).

From the genetic point of view, defects of the respiratory chain can be divided into two major groups: those due to mutations in mtDNA, and those due to mutations in nuclear DNA (nDNA).

Respiratory chain defects with exercise intolerance and myoglobinuria

While exercise intolerance is common in mitochondrial encephalomyopathies, it is often overshadowed by other symptoms and signs (DiMauro & Schon, 1998). Exercise intolerance, myalgia, and myoglobinuria can be the sole presentation of respiratory chain defects.

Exercise intolerance (without myoglobinuria) was the predominant clinical feature in two sporadic patients with complex I deficiency and COX-positive RRF in their muscle biopsies. One had a nonsense mutation (G11832A) in the ND4 gene (Andreu et al., 1999b), the other had an intragenic inversion of seven nucleotides within the ND1 gene, resulting in the alteration of three amino acids (Musumeci et al., 2000).

Nine patients with isolated complex III deficiency in muscle complained of exercise intolerance, but only two had myoglobinuria (Andreu et al., 1999a; DiMauro, 1999). All patients in whom muscle histochemistry was performed showed COX-positive RRF. The nine mutations in the cytochrome *b* gene were different from one another although, except for a single deletion, they were all G-to-A transitions.

The first mtDNA molecular defect identified in complex IV (COX) deficiency was a 15-bp microdeletion in the COX III gene. The patient was a 16-year-old woman with recurrent myoglobinuria triggered by prolonged exercise or viral illness (Keightley et al., 1996). Between attacks, both physical and neurological exams were normal, as were routine laboratory tests, including serum creatine kinase (CK) and lactate. No tissue other than muscle was affected, and family history was entirely negative. Muscle biopsy showed many SDH-positive, COX-negative RRF and marked isolated COX deficiency. A nonsense mutation (G5920A) has been identified in the COX I gene of muscle mtDNA in a 34-year-old man with life-long exercise intolerance and recurrent myoglobinuria induced by intense or repetitive exercise (Karadimas et al., 2000). Muscle biopsy showed scattered COX-negative RRF and numerous COX-negative non-RRF, and isolated COX deficiency. The mutation was not present in blood or fibroblasts from the patient, nor in blood from his asymptomatic mother and sister.

Isolated, presumably primary coenzyme Q10 (CoQ10) deficiency in muscle has been identified in three clinical conditions: (i) a predominantly myopathic disorder, with exercise intolerance and myoglobinuria (Ogasahara et al., 1989; Servidei et al., 1996; Sobreira et al., 1997); (ii) a severe infantile syndrome dominated by encephalopathy and nephropathy (Rotig et al., 2000); and (iii) a heterogeneous syndrome characterized by cerebellar ataxia, weakness, and cerebellar atrophy (Boitier et al., 1998; Musumeci et al., 2001). It is noteworthy that all patients responded to oral CoQ10 supplementation, although the degree of improvement varied from patient to patient.

In the myopathic variant, muscle biopsy shows both RRF and lipid storage. In the other variants, muscle biopsy shows rather non-specific myopathic changes.

CoQ10 concentration is markedly but variably decreased in muscle (4–35% of normal). CoQ10, or ubiquinone, is a lipophilic component of the electron-transport chain, which transfers to complex III electrons derived from complex I and complex II (Fig. 72.3). CoQ10 also plays a role as a membrane stabilizer and an oxygen radical scavenger.

All three clinical variants appear to be inherited as autosomal recessive traits. Given the complexity of the CoQ10 biosynthetic pathway and the heterogeneity of the clinical presentations, it is likely that different steps may be involved, but this remains to be documented.

Respiratory chain defects causing weakness

As implied by the term, virtually all mitochondrial encephalomyopathies cause some degree of weakness, although this is often overshadowed by the involvement of other tissues. However, isolated myopathies can occur in three circumstances: (i) skewed heteroplasmy of ubiquitous mtDNA mutations; (ii) somatic mtDNA mutations; and (iii) mutations in tissue-specific nuclear genes. We will describe only two conditions presumably belonging to the last group and affecting complex IV of the respiratory chain.

There are two main myopathic presentations of Complex IV (COX deficiency), both with onset at or soon after birth, but with very different outcomes. The first (fatal infantile COX-deficient myopathy), is characterized by generalized and progressive weakness, causing respiratory insufficiency and death before age one year (DiMauro et al., 1980). The second (benign infantile COX-deficient myopathy) has very similar onset, with profound, life-

threatening weakness often requiring assisted ventilation. However, with appropriate support, these infants improve spontaneously and are usually completely normal by three years of age (DiMauro et al., 1981). There is lactic acidosis in both conditions, but blood lactate decreases gradually to normal levels in the benign form.

Initially, muscle biopsy shows RRF and generalized histochemical COX deficiency in both fatal and benign myopathies. However, in the benign form, increasing numbers of fibres reacquire normal COX reactivity while RRF gradually disappear, and later biopsies appear normal.

In both conditions, there is isolated, severe COX deficiency in early biopsies, but COX activity returns to normal within about one year in the benign form.

There is no evidence of maternal inheritance in either condition, both sexes are equally affected, and there have been affected siblings, suggesting autosomal recessive inheritance. The molecular defects remain unknown in both fatal and benign COX-deficient myopathies.

Part IX

Epilepsy

73

The cellular basis of epilepsy

Robert S. Fisher[1] and Jie Wu[2]

[1] Department of Neurology, Stanford University, Palo Alto, CA, USA
[2] Department of Neurology, Barrow Neurological Institute, St Joseph's Hospital and Medical Center, Phoenix, AZ, USA

Epilepsy is the most prevalent serious neurological illness able to affect people of all ages. Treatment of epilepsy is primarily symptomatic, with use of medications to suppress abnormal electrical activity in the brain, or surgical procedures designed to disrupt epileptogenic circuits. Far more satisfactory for the patients and clinician would be a treatment for epilepsy itself, rather than suppression of seizures, with no direct rectification of the underlying disorder. Recent explosive advances in neuroscience and molecular biology have brought such an understanding of epilepsy mechanisms potentially within range. As of mid-year 2000, the key word 'epilepsy' brings forth 57 599 articles in *Medline*, many of them on the subject of epilepsy research. Different dominant themes have transferred from neuroscience to epilepsy research over the decades, as portrayed in Table 73.1.

Recent decades have been characterized by interdisciplinary work that cannot be characterized by any one theme: for example, histological–physiological correlations or genes coding for ion channels. This merging of disciplines is likely to be of great benefit for our understanding of epilepsy, since mechanisms for seizures fail to lie neatly within the traditional disciplines of anatomy, physiology and chemistry. A brief overview such as this one can only touch selected themes. Reference may also be made to prior reviews (Dichter, 1997; Delgado-Escueta et al., 1999; Fisher, 1995; McNamara, 1999).

Table 73.1. Dominant themes in epilepsy research

Pre-1930	Clinical descriptions
1930–1950	EEG findings, anatomic descriptions
1950–1960	Action potentials, resting potentials, potassium and sodium channels
1960–1970	Synaptic potentials: glutamate and GABA
1970–1980	Neurotransmitters and receptors
1980–1990	Ion channels, neurodevelopment
1990–2000	Genes interdisciplinary studies

Table 73.2. Key physiological processes in balancing excitation and inhibition

Excitation
Neuronal depolarization
Excitatory postsynaptic potentials
Action potentials
Inward ionic currents
Long-term excitatory plastic changes
Inhibition
Neuronal hyperpolarization
Inhibitory postsynaptic potentials
Calcium-activated potassium potentials
Outward currents
Metabolic pump potentials
Spike frequency accommodation

Imbalance of excitation and inhibition

Partial and secondarily generalized seizures reflect an imbalance between excitation and inhibition in the brain (Meldrum, 1984). This principle is an extension of the observation made over a century ago by John Hughlings Jackson that epilepsy reflects an excessive and disordered discharge in the highest centres of the brain. Excessive excitation results in rapid neuronal firing during seizures. Output signals from rapidly firing neurons recruit synaptically connected neuronal systems into the excessive discharge. Inhibitory systems also are activated powerfully during seizures, but may be insufficient to control the excessive excitation. Table 73.2 lists several key physiological processes involved in the balance of excitation and inhibition.

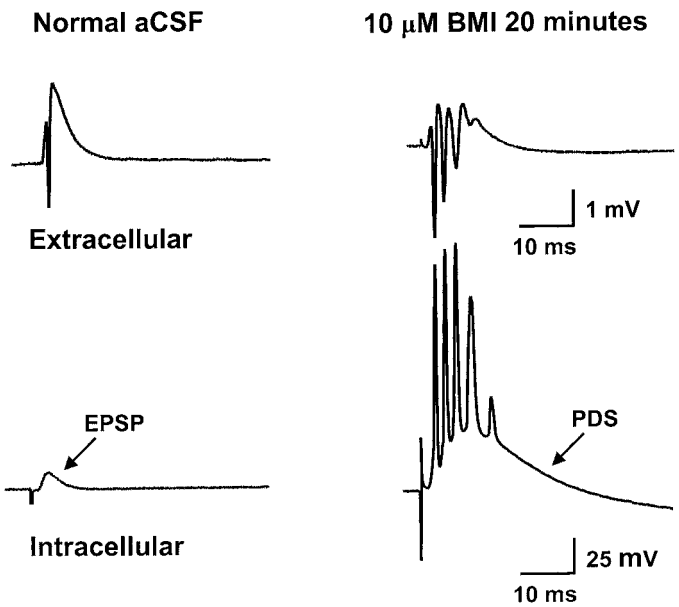

Fig. 73.1. An EPSP (left column) and PDS (right column), shown with extracellular (upper row) and intracellular (lower row) recording from a region CA1 hippocampal pyramidal neuron in a rat hippocampal slice. Abbreviations: EPSP, excitatory postsynaptic potential; PDS, paroxysmal depolarizing shifts; aCSF, artificial cerebrospinal fluid; BMI bicuculline methiodide (an epileptogenic GABA antagonist); mV, millivolts; ms, milliseconds.

Figure 73.1 illustrates an intracellular recording from a hippocampal pyramidal neuron stimulated with an afferent shock in the baseline condition. An EPSP results, giving rise to an action potential. The second part of the figure shows the results of a similar shock given in the presence of bicuculline methiodide. A much larger depolarization, referred to as a paroxysmal depolarization shift (PDS) results, and generates several action potentials, producing a greater degree of excitation. Block of inhibitory interneurons, or the GABA-A receptor-related neurotransmission utilized by such inhibitory interneurons, unleashes excitation.

Excitation and epilepsy

Excessive excitation is a plausible component of some seizures. Excitation is mediated by dozens of known neurotransmitters and neuromodulators, but glutamate receptors are the most important and best studied prototypes for the locus of excitation in epilepsy (Chapman, 1998). The glutamate receptor is a complex macromolecular entity (Meldrum et al., 1999) with many points for possible manipulation, including the cation channel, AMPA, kainate, NMDA receptor sites, three families of metabotropic receptors, two families of neuronal and glial glutamate transporters, and a large variety of modulatory sites.

Much effort has focused on inhibition of the NMDA subtype of the glutamate receptor, because this receptor subtype is activated primarily during times of excess excitation and neuronal depolarization. Blockade of the NMDA channel should, in theory, only interfere with amplification of excitation, and not normal synaptic excitatory transmission mediated by the AMPA and kainate subtypes of the glutamate receptor. Unfortunately, NMDA antagonists so far tested have been excessively toxic. NMDA is involved both in learning and in psychological homeostasis of the human brain. Blockade produces considerable cognitive and psychiatric effects. Work continues in an attempt to isolate the excitatory effects from the psychotomimetic effects of the NMDA receptor. So far, no human seizure disorder has been attributed to mutations directly affecting glutamate (Meldrum et al., 1999).

Inhibition and epilepsy

Inhibition in the brain is arrayed in a hierarchy (Fig. 73.2). At the base of this hierarchy is the all-important fast IPSP mediated by GABA-A receptors. Some neurons also possess a GABA-B receptor, that generates deeper and more prolonged hyperpolarizations, called slow-IPSPs or late hyperpolarizing potentials (LHPs) (Alger & Nicoll, 1979). At the next level of the inhibitory hierarchy is a nonsynaptic potential called calcium-activated potassium (Alger & Nicoll, 1979). Currents underlying this potential are produced by calcium entry into the neuron, resulting in activation of an outward potassium flow. Hyperpolarization from calcium-activated potassium can be profound and last several hundreds of milliseconds. Metabolic pump potentials utilize energy provided by ATP to transport sodium ions out of the neuron and potassium ions back into the neuron after times of neuronal activity. Since the pump transports three sodium ions out for each two potassium ions in, hyperpolarization results (Thompson & Prince, 1986). This hyperpolarization may last for several minutes, and maintain the neuron far away from its action potential firing threshold. It is interesting to speculate as to whether such pump-related hyperpolarizations might be responsible in part for so-called Todd's paralysis after some seizures. Enhancement of response at the GABA-B receptor, or of calcium-activated potassium might be a useful strategy for inhibiting seizures.

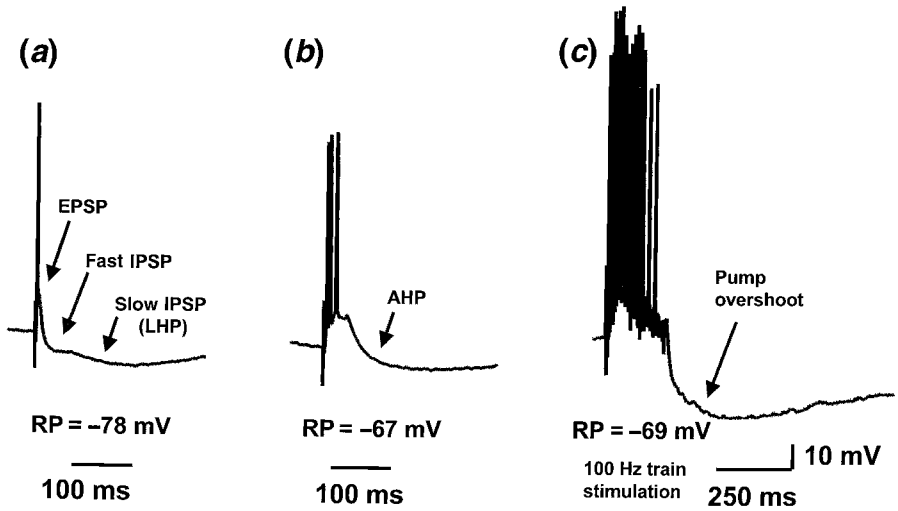

Fig. 73.2. Hierarchy of inhibition in the brain, showing the fast and slow IPSP, the AHP and the pump overshoot hyperpolarizing potential. Recordings were done in a region CA1 hippocampal pyramidal cell in the rat hippocampal slice. Abbreviations: IPSP, inhibitory postsynaptic potential; LHP, late hyperpolarizing potential; AHP, after-hyperpolarizing potential; RP, resting potential.

No single topic has been more explored in epilepsy than the role of GABA and inhibition. The interested reader can refer to several articles devoted to GABA for greater depth (Meldrum, 1989; Roberts, 1986; Tasker & Dudek, 1991). Descriptions have been provided, at the time of this writing, for 16 GABA-A receptors, three GABA-B receptors, and two GABA-C receptors (Chebib & Johnston, 1999). GABA-related targets for AEDs include the postsynaptic GABA-A receptor, the GABA-B autoreceptor and the GABA transporter (Mohler, 1992).

After GABA is released from the presynaptic terminal, it diffuses across the synaptic cleft and binds with the postsynaptic receptor. The GABA-A receptor is a complex macromolecular system, constructed from a family of more than 15 subunits, with different affinities and efficacies of benzodiazepines applying to different subunit assemblies (Mohler, 1992). Subunits available for assembly into a one–five chain complex (probably usually four chains), include 6 alpha, 4 beta, 4 gamma, 1 delta, 1 theta, 1 episilon and 1 pi subchain (Macdonald & Kapur, 1999; Mehta & Ticku, 1999; Whiting et al., 1999). Numbers of subchains found in various systems (for example, chick retina) continue to increase with investigation. Typical native adult GABA-A receptor complexes are composed of two alpha and two beta chains. However, alternative assemblies confer regional and functional specificity of brain inhibition. Mutations in the various chains can lead to a wide variety of dysfunctional GABA-A receptors. It is easy to speculate that such mutations can lead to predispositions to seizures.

The GABA-A recognition site is situated on the beta subunit and the benzodiazepine modulatory site on the alpha subunit (Bormann, 2000), but BDZ sensitivity also can depend upon the gamma chain. Binding of GABA to the GABA-A receptor opens a chloride ionophore on the beta chain. Influx of chloride ion hyperpolarizes the neuron, and further provides inhibition by reducing membrane resistance. The GABA-A receptor GABA recognition site and the chloride ionophore are linked closely with modulatory sites responsive to benzodiazepines and barbiturates. Representatives from each of these categories greatly enhance the inhibitory efficacy of GABA. Barbiturates do so by prolonging mean open time of the chloride channel (Study & Barker, 1981). Benzodiazepines increase the probability of chloride channel opening (Study & Barker, 1981). Endogenous compounds formulated from steroids and related to the hormone progesterone, called neurosteroids, recently have been shown to have various positive and negative actions on GABA systems (Compagnone & Mellon, 2000). Examples include pregnenolone, dehydroepiandrosterone, progesterone itself and their derivatives (Baulieu, 1998). One derivative neurosteroid, ganaxolone, has completed a clinical trial for seizures, with mild efficacy (Monaghan et al., 1997).

Epileptogenic insults selectively can injure GABAergic inhibitory interneurons. A prototype experiment for this hypothesis was performed by counting GAD-positive neurons in a seizure focus produced in a monkey by aluminium hydroxide gel (Ribak et al., 1986). GAD-positive neuronal somata were reduced by about 25–50% in the

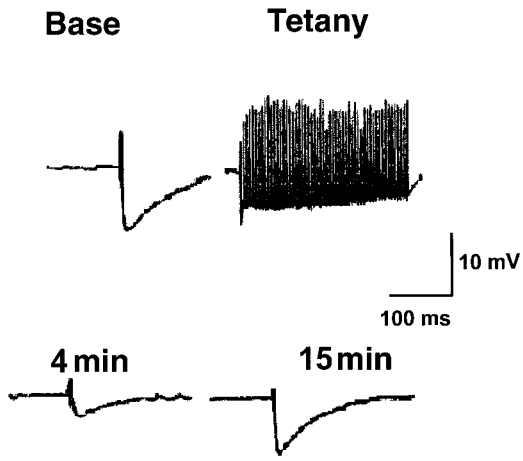

Fig. 73.3. Fade of the IPSP with tetanic stimulation. The intracellularly recorded potentials are from a region CA1 hippocampal pyramidal cell in the rat hippocampal slice. After 15 minutes, the attenuation of the IPSP has reversed.

focus. Acute processes also can decrease GABAergic function. For example, hypoxia depresses the GABAergic inhibitory currents in hippocampal cells before it depresses excitatory currents (Katchman et al., 1994). During this interval of time, brain is hyperexcitable and susceptible to seizures. Nuclear magnetic resonance spectroscopy suggests a significant occipital lobe decline of GABA in brains of patients with uncontrolled seizures (Petroff et al., 1999; Sherwin, 1999).

Decreases in GABA function can be dynamic, and not dependent upon death of GABAergic neurons. Figure 73.3 illustrates a reversible fade of the evoked IPSP in response to tetanic stimulation. Such a dynamic decline of GABAergic transmission could participate in the interictal–ictal transition.

Sloviter has hypothesized that inhibitory basket cells become 'dormant' in chronic temporal lobe epilepsy (Sloviter, 1991). Dormant interneurons also have been documented in the tetanus toxin model (Jefferys & Traub, 1998). The dormant cells are alive and present, but presumably are inactive because of isolation from their usual excitatory afferents. The net result is disinhibition. The dormant basket cell hypothesis has generated considerable controversy. Direct recordings from inhibitory interneurons do not necessarily support the hypothesis (Bernard et al., 1998).

Just as GABA receptors can influence propensity to seizures, so seizures may have an influence on GABA receptors. Status epilepticus produced by pilocarpine in rats led to decreased sensitivity to benzodiazepines, because of alteration in balance of subchains in the receptor (Kapur & Macdonald, 1979). This type of dynamic change in receptor composition provides an opportunity for adaptive plasticity.

Enhancement of inhibition has been a fertile method for antiepileptic drug therapy. A primary target has been the inhibitory postsynaptic potential (IPSP) mediated by the GABA-A receptor. GABA-related inhibition can be augmented in several ways: (i) By increasing synthesis through availability of more precursor by administration of progabide (de Pasquet et al., 1991); (ii) Allosteric modulation of the GABA receptor, for example, barbiturates and benzodiazepines (Study & Barker, 1981); (iii) Inhibition of GABA uptake with tiagabine (Schachter, 1999); and (iv) Inhibition of GABA metabolism by vigabatrin (French, 1999).

GABA has often appeared to be the 'key to epilepsy' (Snodgrass, 1992), but several counterexamples exist to GABA's antiepileptic effects. GABA agonists worsen some cases of absence epilepsy (Snead & Hosey, 1985). The GABA uptake inhibitor, tiagabine, occasionally can precipitate nonconvulsive seizures (Ettinger et al., 1999). GABA agonists injected into the pedunculopontine nucleus increase seizures produced by convulsant chemicals (Snodgrass, 1992). Pilocarpine-induced seizures preferentially injure inhibitory interneurons (Mello & Covolan, 1996). Histochemical markers for GABA-containing neurons show that GABA cells are decreased as expected in models of focal cortical epilepsy, but they are unchanged in certain models of temporal lobe epilepsy, and actually increased in models of absence epilepsy (Houser, 1991). Enhanced GABA transmission can be either anticonvulsant or proconvulsant depending upon the affected system of the brain (Gale, 1992). In acute circumstances, reduction of inhibition can be expected to lower the seizure threshold. The role of inhibition may, however, be different in chronic seizure disorders.

The mass of information on GABA accrued over the past 50 years allows several conclusions pertaining to mechanisms of the epilepsies. First, GABA plays a pivotal role in epilepsy. Acute reduction of GABAergic function is highly likely to reduce threshold for partial and generalized tonic–clonic seizures. Drugs that enhance GABA neurotransmission by a variety of mechanisms serve as useful remedies for partial and generalized tonic–clonic seizures. Secondly, effects of GABA are mediated by actions of at least three types of GABA receptors: A, B and C. The role of the latter in epilepsy is unknown. The GABA-B receptor appears to be involved in spike-wave generation, a subject discussed below. The GABA-A receptor is the most important receptor, but it displays a bewildering array of subchains, heterogeneities and genetic variants. Thirdly,

GABAergic neurons may be selectively vulnerable to injuries, examples including hypoxia, heavy metal deposition models and freeze foci. However, several experimental epilepsy models show no decrease in GABAergic neurons, or in functional inhibition. Epilepsy is diverse. One mechanism does not explain all types of epilepsy.

Other transmitters and epilepsy

Parallel to efforts in the epilepsy research community, the above discussion emphasized glutamate and GABA as neurotransmitters. However, such an emphasis admittedly is myopic, since investigation has disclosed over 200 neurotransmitters and neuromodulators, all of which might be involved in epilepsy (Fisher & Coyle, 1991). Data pertaining to epilepsy is available for aspartate, acetylcholine, norepinephrine, dopamine, serotonin, opiates, adenosine, substance P, neuropeptide Y (NPY), somatostatin, and a variety of other neuromodulators. Future epilepsy research should profitably capitalize on the ability of so many substances to inhibit neuronal activity during particular circumstances.

Rarely, if ever, is it possible to declare a neurotransmitter 'convulsant' or 'anticonvulsant'. All neurotransmitters, even GABA, have multiple synaptic mechanisms in different brain systems. Excitation by a transmitter in one location or circumstance may transform to inhibition in another. As one of many possible examples, GABA is depolarizing when applied to dendrites of hippocampal pyramidal cells, probably because of a dendritic chloride pump that reverses the chloride gradient (Staley et al., 1995).

Cellular and network properties

For many years epilepsy researchers engaged in discussion about whether epileptic activity resulted from disordered neurons, or normal neurons operating within disordered circuitry (Prince, 1985). Both possibilities could theoretically lead to excessive excitation, and both mechanisms now are known to operate in most conditions of epilepsy. Membrane properties of hippocampal neurons from human seizure foci show no obvious change, but bursting is easier to elicit and functional inhibition is decreased (Schwartzkroin, 1994). A few dysfunctioning neurons can serve as pacemakers for recruitment of widely dispersed normal neuronal elements. Normal inhibitory mechanisms restrict development and spread of seizures. Temporal lobe epilepsy correlates with a loss of cells in layer III of the medial entorhinal cortex (Gloveli et al., 1998). Such loss of inhibition allows epileptiform activity induced by low magnesium to propagate from entorhinal cortex to hippocampus (Gloveli et al., 1998).

A physiological hallmark of the disordered epileptiform neuron is the paroxysmal depolarization shift (PDS, Fig. 73.1). The PDS is a giant EPSP (Johnston & Brown, 1984), but also involves the additional elements of voltage-dependent calcium influx into the neuron, triggered by opening calcium channels that normally are closed at or near the resting membrane potential. In normal synaptic circuitry, feed-forward and feed-back inhibitory interneurons truncate the excitatory potential. When these are deficient, excess excitation can result. As will be discussed below, other mechanisms also may play a role in generation of prolonged potentials, for example, genetic alterations in potassium channels.

Computer modelling of circuitry in hippocampus suggests that a decrease in inhibition, or an increase in direct recurrent excitatory connections can throw electrical activity into a positive feedback excitatory mode. Hippocampal slices begin epileptiform bursting when monosynaptic IPSPs are reduced by bicuculline to 17% of their control amplitude (Jeffreys & Whittington, 1996). The brain strikes a delicate balance between synaptic plasticity, useful for enhancing neurotransmission in circuits of importance, and the need to prevent circuits from becoming epileptogenic, in which excitation has crossed some critical threshold.

A characteristic feature of essentially all types of epileptiform activity is increased neuronal synchrony (Wong et al., 1986). During seizures, brain cells fire in mutually linked patterns. Synchrony during seizures may grow out of physiological forms of synchrony, such as that of the alpha rhythm, or thalamo-cortical sleep spindles (Steriade, 1999). In an alumina cream-induced seizure focus in monkeys, interneuronal synchrony was not increased significantly among neurons in the focus (Wyler, 1986). However, in clinical seizures, inter-regional EEG synchrony increases during seizures (Towle et al., 1999) and persists for up to 2 hours after a seizure (Franaszczuk & Bergey, 1999). Inhibition is of major importance in producing intraneuronal synchrony. Recordings of unit (neuron) firing in the region of a temporal seizure focus and contralateral temporal lobe (Colder et al., 1996) show correlation patterns consistent with strong inhibition at the start of a seizure.

Recent discussions of neuronal excitability during seizures have moved beyond synaptic potentials to the underlying ionic currents generating these potentials (Steinlein & Noebels, 2000). In general, sodium and calcium channels mediate neuronal excitation; whereas, a

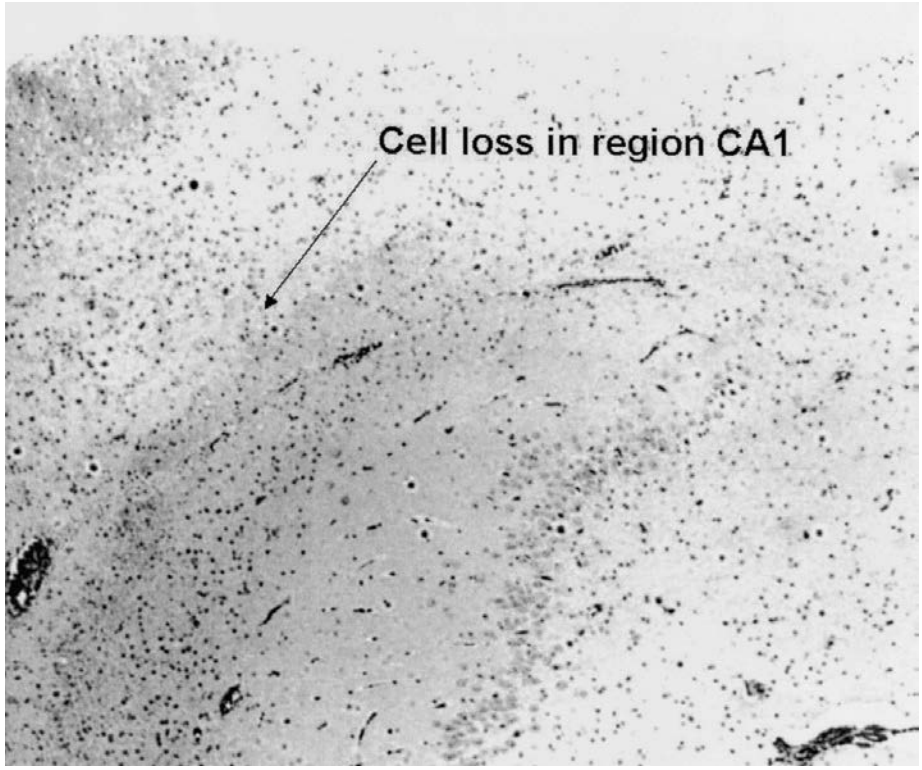

Fig. 73.4. Pyramidal cell loss in region CA1 of hippocampus from a mesial temporal lobectomy surgical specimen from a patient with intractable complex partial seizures. (Courtesy of Dr Allen Wyler, adapted from Fisher, 1998.)

variety of potassium and chloride channels stabilize neuronal firing (Wheal, 1990). Some ion channels increase brain excitability and others may protect brain tissue from effects of seizures (Mody, 1998). Investigators now are looking at channel properties in chronic models of epilepsies. For example, calcium current properties do not change significantly in dentate granule cells from kainate-treated rats, but densities of calcium currents are higher (Beck et al., 1998). In the section below on genes, two clinical epileptic syndromes, benign familial neonatal convulsions and generalized epilepsy with febrile seizures plus, will be seen to be consequent respectively to a sodium and a potassium channel disorder. Channel disorders are starting to explain a variety of previously idiopathic neurological disorders (Davies & Hanna, 1999), and will be of undoubted significance in explaining certain forms of epilepsy.

Epileptogenesis

Brain injury may lead to epilepsy after a latency interval free from seizures. What is the mechanism of such delay in the onset of seizures? Recent research suggests considerable ability for remodeling of injured circuits, although in age-dependent fashion, with young brain better able to remodel and recover. Anoxia–ischemia, trauma, exposure to neurotoxins, and other injuries selectively may affect certain cell subpopulations. When these cells die, axons from surviving neurons sprout additional processes to connect with the partially deafferented neurons (Sutula et al., 1992). For reasons that are unclear, but may relate to selective vulnerability of inhibitory interneurons, the recovered circuit tends to be hyperexcitable. The clinical manifestation of regenerated circuitry in hippocampus is mesial temporal sclerosis, showing an atrophic hippocampus bright on T2 MRI images. Histological views of surgically removed mesial temporal sclerosis tissue demonstrate loss of neurons and replacement with gliotic tissue (Fig. 73.4).

Stains for zinc, which serves as a marker for one type of terminal in region CA3 of hippocampus, show that extra bands of zinc are found in chronic epileptogenic tissue, indicating excessive growth of the zinc-containing terminals (Sutula et al., 1992). Sprouting may be a result of certain patterns of excitation, since it can occur in the

absence of cell death (Stringer et al., 1997). Is mossy fibre sprouting a cause, consequence or epiphenomenon in temporal lobe epilepsy? Longo and Mello (1999) argue that it is an epiphenomenon, since protein synthesis inhibition with cycloheximide inhibits mossy fibre sprouting, but not seizures. Conversely, animals show mossy fibre sprouting with no obvious seizures. Neuropathological analysis of epileptic human temporal tissue is becoming more and more sophisticated (Blumcke et al., 1999), but still suffers from the lack of suitable control tissue.

Recent animal research discloses a small population of primitive neurons available in hippocampus and olfactory cortex able to differentiate into neurons in suitable circumstances, even well into adult life. This novel finding provides another avenue for pathway regeneration after injury. The sprouting of axons and formation of functional connections is governed by a complex system of genes and messengers (Lowenstein, 1996). Epileptogenesis depends not only upon formation of new connections, but upon 'programmed death' or apoptosis of selected cell populations.

Theories of temporal lobe epilepsy have focused upon the hippocampus, but the importance of the hippocampus may be overemphasized because of the popularity of the hippocampal slice. Several other limbic structures, including entorhinal cortex, amygdala and pyriform cortex may be important in TLE (Bertram et al., 1998; Gale, 1992). Medial thalamus may be a pacemaker for limbic structures (Bertram et al., 1998). In experimental models, posterior hypothalamus appears to mediate the zone of hypometabolism around a cortical seizure focus (Bruehl et al., 1998).

Extrasynaptic mechanisms of epilepsy

Most of the business of the brain takes place at synapses, but extrasynaptic processes can influence seizures. Among these are release of extracellular ions and neuronal interactions via non-synaptic field effects. Actions that take place in the extracellular space have been termed 'volume transmission', as opposed to the one-to-one cell-to-cell communication (by chemical synapses or gap junctions) that is termed 'wiring synapses' (Zoli et al., 1999).

Discharging neurons release potassium into the extracellular space. During a seizure extracellular potassium activity can rise from baseline of 3 mM to up to 12–15 mM (Fisher et al., 1976). Increased extracellular potassium depolarizes neurons and brings them closer to their firing threshold, therefore more likely to participate in epileptiform bursting. The resulting cell firing releases more potassium into the extracellular space and produces a positive feedback situation. Counter to this excitation is the glial syncytium, linked by gap junctions and able to serve as a potassium 'sponge' (Lux et al., 1986). In chronic epilepsies, the glial network may function abnormally. Seizures produce a proliferation of astrocytes and a change in the astrocyte cytoskeleton (Khurgel & Ivy, 1996). Astrocytes from human seizure foci show several atypical properties, including highly branched processes, presence of voltage-activated, tetrodotoxin-sensitive channels, and decreased inward-rectifying potassium currents (Bordey & Sontheimer, 1998). These properties conceivably impair the glial syncytium's ability to buffer increases of intracellular potassium.

Other ions than potassium change their extracellular concentrations during a seizure. Sodium, calcium and magnesium all decrease extracellular activity during a seizure (Heinemann & Jones, 1990). Hydrogen ion concentrations increase in the extracellular space during seizures, rendering the ECS more acidic. Since the hydrogen ion competes with the NMDA associated channel, the acidic shift thereby reduces excessive excitation (Tang et al., 1990). Acidification may be part of the mechanism of action of AEDs, such as acetazolamide (Diamox), that block carbonic anhydrase (Reiss & Oles, 1996).

The great debate of the 1940s about electrical vs. chemical synapses was resolved in favour of brain chemical synapses. However, recent times have seen a swing back toward the electrical theory in the form of neuronal and glial gap junctions (Rozental et al., 2000). Gap junctions utilize a protein, connexin, which may regulate cell–cell communication at the junction (Nagy & Rash, 2000). Connexin comes in several forms, connexin26 (Cx26; beta 2), Cx32 (beta 1) and Cx43 (alpha 1), with the balance of these determined by brain region and maturity of development. Gap junctions among neurons have been argued to play a role in neuronal synchrony (Perez-Velazquez & Carlen, 2000), and in the linking of hippocampal inhibitory interneurons (Fukuda & Kosaka, 2000). Pharmacological block of gap junctions decreases seizures in animal models (Carlen et al., 2000). Additionally, gap junctions among hippocampal neurons may play a role in 100–200 Hz oscillatory fast activity (Draguhn et al., 1998) that occurs at the start of some seizures (Fisher et al., 1992).

Another means for non-synaptic spread of epileptiform activity is through the mechanism of axonal backfiring (Hablitz, 1984; Schwartzkroin et al., 1975). With this phenomenon, axon terminals are depolarized distally and fire retrograde to excite their cell soma. The soma then fire all

terminals propagating excitation. Relevance of backfiring to clinical epilepsy remains unknown.

Electric and magnetic fields generated by neuronal activity can influence adjacent neurons directly, without mediation by synapses or gap junctions. Epileptiform activity produced in a hippocampal slice by removing calcium from the bath is eliminated by an applied DC electric field with a gradient of 1–5 mV/mm (Ghai et al., 2000). Similar inhibition can be obtained in hippocampal slices made epileptiform by the GABA antagonist, penicillin (Kayyali & Durand, 1991). Recently, similar inhibition of epileptiform activity is being reported in open-label studies for magnetic field gradients, which have the advantage of being non-invasive and painless (Dobson et al., 2000).

Ictal transition

Clinicians distinguish the EEG finding of an interictal spike, which is a marker for epileptiform activity, from rhythmical ictal discharges, a correlate of clinical partial seizures. Not all patients with partial seizures demonstrate interictal discharges in a given EEG (Salinsky et al., 1987), and not all EEGs with spikes come from people with a seizure history (Gregory et al., 1993). What then are the mechanisms by which the EEG and clinical pattern make the transition from the interictal to the ictal state? This has been a difficult question to address in patients, so investigators have focused upon hippocampal slice model systems.

Epileptiform activity produced in a hippocampal slice by high potassium starts with bursts of 5–7 action potentials, then transforms to large tonic depolarizations (Jensen & Yaari, 1997). Pyramidal cell bursters fire early in the interictal-ictal transition, and eventually recruit non-bursting neurons. Similar findings were observed in slices bathed by high potassium and low calcium (Schweitzer & Williamson, 1995), and these bursts survive blockade of excitatory amino acid synaptic transmission. Interictal–ictal transitions in the pilocarpine-perfused hippocampal slice were influenced by extracellular potassium, GABA-A blockers and NMDA blockers (Rutecki & Yang, 1998). A transition to ictal-like behaviour can be provoked by removing chloride from the perfusion media (Ogata, 1978).

One school of thought argues that interictal activity provides inhibitory control to prevent transition to the ictal state. In the 4-aminopyridine model of seizures in the hippocampal–entorhinal slice, lesion of Schaffer collateral afferents to region CA1 facilitates greater propagation of seizure-like discharges through the slice (Avoli & Barbarosie, 1999).

Mechanisms of absence (spike-wave) epilepsy

Absence epilepsy, formerly called petit mal epilepsy, differs in several ways from partial (focal) seizures. Onset tends to be younger for absence, and a familial component more prominent. Some medications useful for absence, such as ethosuximide, have no value in treatment for partial or tonic–clonic seizures. GABAergic drugs usually improve partial seizures, but may make absence seizures worse (Snead & Hosey, 1985). The EEG patterns of partial seizures present interictal spikes (Fig. 73.5) and rhythmical evolving local ictal events (Fig. 73.6), whereas, EEG of petit mal shows 3–4/s bilateral spike-waves (Fig. 73.7). Some genetic absence models show increased, rather than decreased, GABAergic terminals (Houser, 1991).

These differences lead to a view that absence seizures derive from different mechanisms than do partial seizures. Recent research (Snead, 1995) has contributed significantly to our understanding of these mechanisms. Key in generation of genetic models of spike-waves are outputs of the nucleus reticularis thalami (nRt). If the thalamus can be considered a pacemaker of cortex, then nRt can be considered a pacemaker of the thalamus (de Curtis & Avanzini, 1994). Efferent fibres from nRt release GABA onto GABA-B, and also GABA-A, postsynaptic receptors on thalamic relay nuclei neurons.

In animal models SWs can be shown to depend upon a 'three-legged stool': (i) activation of thalamic neurons by gluatamatergic synapses (McCormick, 1992); (ii) GABAeric outputs from nucleus reticularis thalami (nRt), thalamic relay nuclei (Caddick & Hosford, 1996); and (iii) nRt T-calcium currents generate pacemaking currents (Coulter et al., 1989). GABA-B feed-forward impulses to relay neurons and GABA-A recurrent feedback upon the nRt neurons result in periodic pacing of spike-waves to cortex. Figure 73.8 depicts the cycle of events generating SWs.

First, a variety of cortical, subcortical and thalamic afferents excite nRt neurons via NMDA and non-NMDA glutamatergic receptors. Firing of the nRt neurons generates GABA-B-mediated late hyperpolarizing potentials (slow IPSPs) in thalamic relay nuclei, such as the ventrobasal complex. At the same time, recurrent inhibition in nRt, largely mediated by GABA-A receptors, causes hyperpolarization of nRt neurons. This hyperpolarization 'cocks the trigger' for activation of the so-called low-threshold calcium current (Coulter et al., 1989), which causes calcium entry and cell firing upon movement of the hyperpolarized resting membrane potential to normal resting membrane potential. The resulting firing of nRt cells initiates another cycle of spike and wave. Since the GABA-B mediated hyperpolarization lasts about 300 ms, then SWs cycle at 3–4 per second.

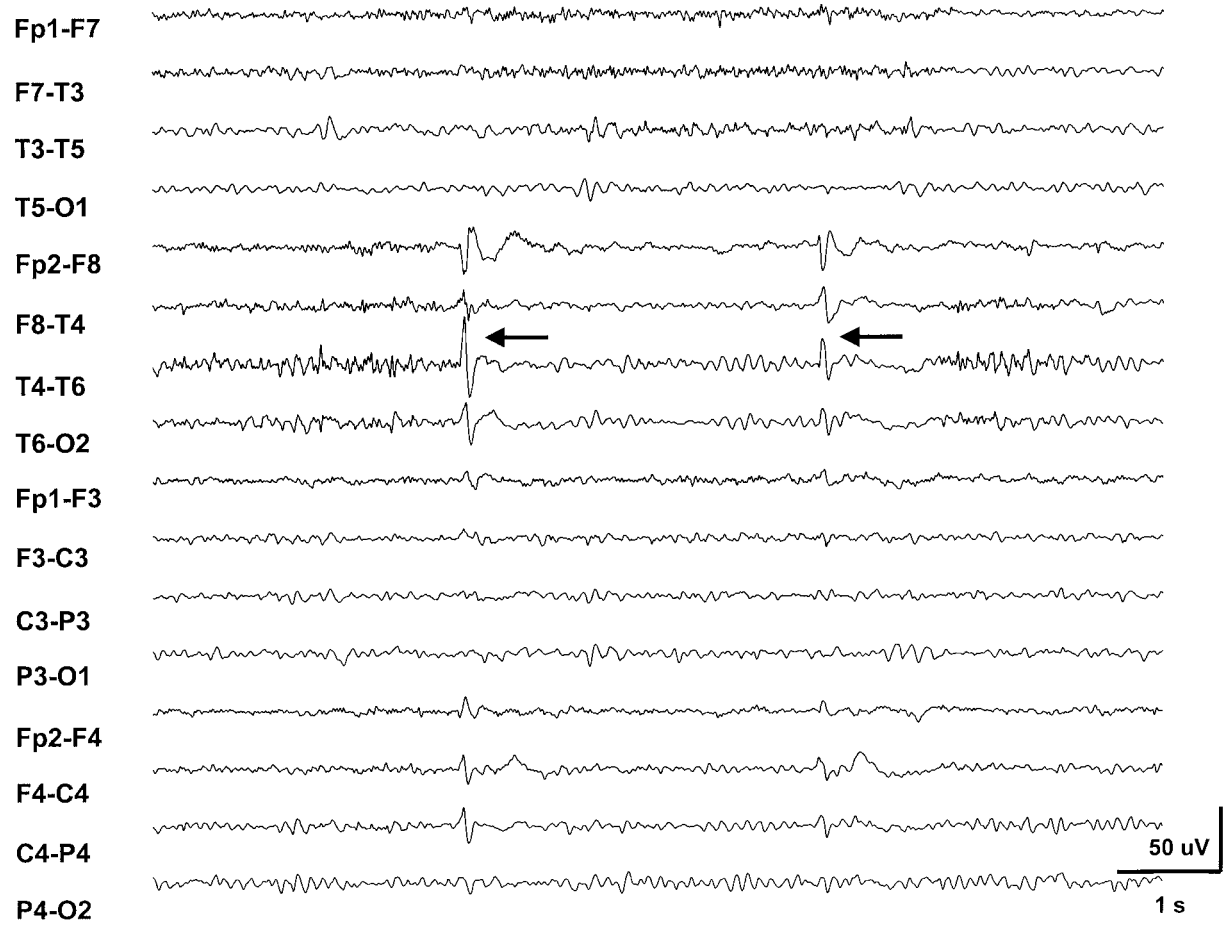

Fig. 73.5. Patient EEG showing an interictal spike with phase reversal (arrow) in the right mid-temporal electrode (T4). Electrode nomenclature is in accordance with the International 10–20 electrode system.

Clinical EEG records, not the thalamic potentials, but the cortical potentials driven by periodic afferent input from thalamic relay nuclei. Intracellular in vivo recordings from laver V cortical neurons of the GAER rat show an EPSP followed by 2–6 IPSPs during spontaneous spike-waves (Charpier et al., 1999). Cortical neurons experience, in addition, a long-lasting hyperpolarization and a tonic increase in input resistance, both of which are of uncertain origin.

SW mechanisms have been studied in rats bred to have spontaneously recurrent SWs and absence seizures, a model called the genetic absence epilepsy rat from Strasbourg (GAERS) (Marescaux et al., 1992). These animals have episodes of activity arrest and staring about 1–2 per minute. EEG recordings show concurrent 7–11 cps spike-wave discharges. Clinically useful antiabsence drugs, including ethosuximide, trimethadione, valproate and benzodiazepines, reduce seizures and spike-waves in this model; while phenytoin and carbamazepine do not (Marescaux et al., 1992). Allopregnanolone, a GABA-A positive allosteric modulator, enhances spike-waves in genetic absence WAG/Rij rats (Budziszewska et al., 1999).

A series of physiological studies of the GAERS (Avanzini et al., 1996) suggests that increased amplitude of the voltage-dependent, low-threshold calcium pacemaker current in nRt is the primary genetic deficit. Impairment of cortical GABA-mediated inhibition and AMPA receptor-mediated excitation also are detectable in this model, but may represent secondary changes. Oscillations can be seen in nRt of GAERS, and these oscillations are not due to any loss of neurons compared to controls (Sabers et al., 1996). Studies of c-fos activation in GAERS (Vergnes et al., 2000) in response to kainic acid and strychnine showed fronto-parietal cortex, rather than limbic or thalamic increases. This emphasizes that spike-wave generation is a task for a system including both thalamus and cortex, as was suggested by Gloor (1978).

Fig. 73.6. Patient EEG showing the start of a right temporal electroencephographic ictal (seizure) event, enclosed by boxed dotted lines.

Basal ganglia also may have a previously neglected role in absence seizures. Inhibition of GABAergic neurons in the substantia nigra pars reticulata (SNPR) suppresses seizures in various animal models (Deransart et al., 1998). Striatum generates a direct GABAergic projection to SNPR, and an indirect projection via the globus pallidus and the subthalamic nucleus. Activation of either pathway, probably via dopaminergic mechanisms, suppresses spike-waves (Deransart et al., 1998). High-frequency electrical stimulation of the subthalamic nucleus has a suppressant action on absence seizures, independent of motor actions of STN (Vercueil et al., 1998). Infusion of both GABA-A and GABA-B agonists into posterior nucleus of thalamus, which links to basal ganglia and substantia nigra, facilitates fluorothyl seizures (Garant et al., 1993). Infusion into ventromedial thalamus has little effect.

Systemic convulsant drugs, such as penicillin (Fisher & Prince, 1977) and bicuculline methiodide (Neckelmann et al., 1998) produce spike-waves with greater synchrony between cortical regions than thalamo-cortical regions. Whether this represents a fundamentally different mechanism or a variation on a continuum remains to be determined.

In the clinical arena, presence of spike-wave patterns on an EEG does not equate with petit mal (absence) epilepsy. SWs can appears in the evolution of tonic–clonic seizures, with a minority of partial seizures, and with syndromes such as the Lennox–Gastaut syndrome of tonic–atonic seizures, cognitive impairment and 2–3/s SWs. Our group (Smith & Fisher, 1996) and others (Bierkamper & Cenedella, 1978) have developed a model of acquired epilepsy produced by inhibition of cholesterol synthesis, using either AY-9944 or U18666A, blockers of conversion of 25-hydroxycholesterol to cholesterol. As little as one injection of the blocker in the first week of a rat's life can lead to apparently lifelong SW discharges and absence seizures.

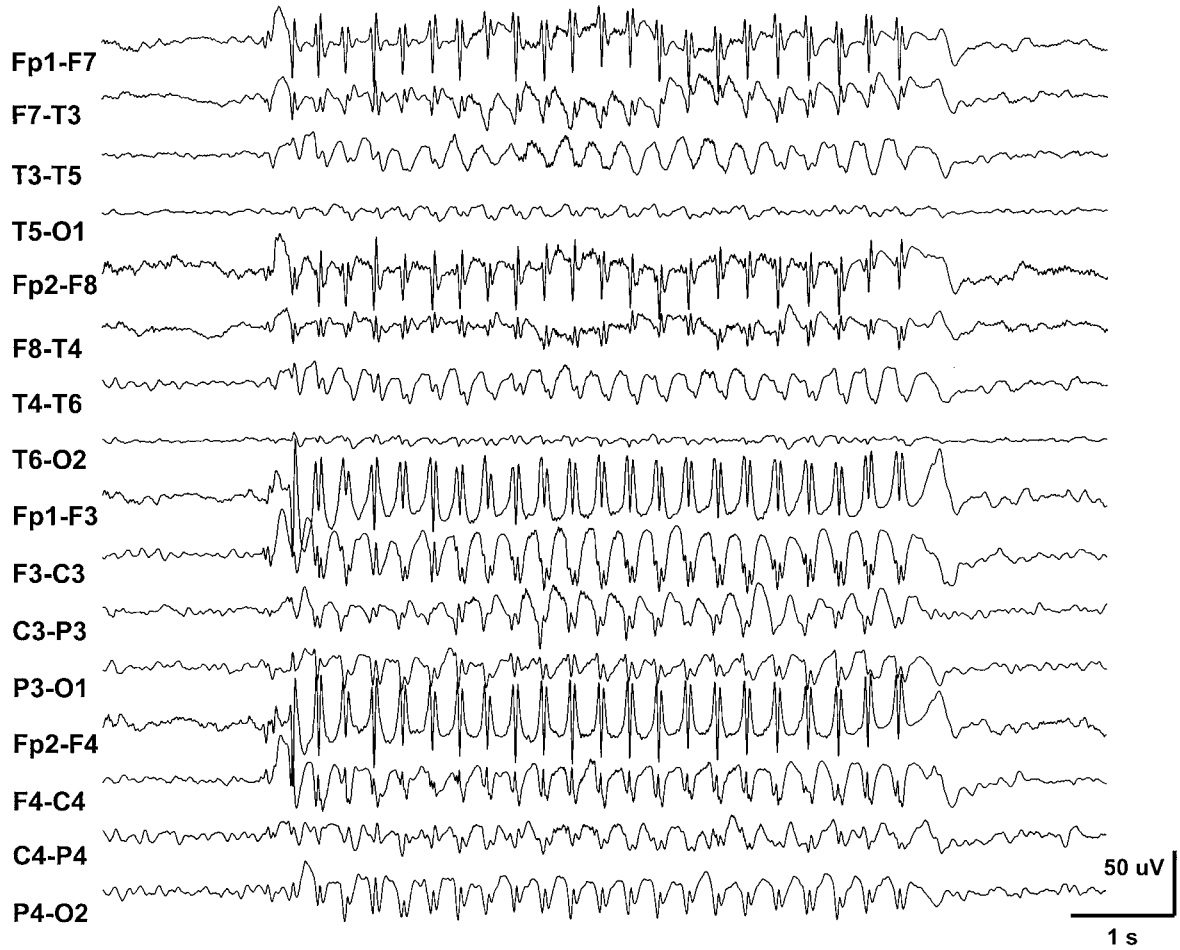

Fig. 73.7. EEG showing 3–4/second spike-waves in a patient with absence (petit mal) epilepsy.

Studies of this phenomenon may give insight into the mechanisms of the acquired, as opposed to inherited, SW epilepsies.

Possible immune mechanisms of seizures

For decades, occasional studies have emphasized a role for the immune system in seizures, although the link between epilepsy and immunology only recently has achieved substantial attention (Aarli, 1993). Disturbed humoral immunity is more likely in people with epilepsy (Schwartz et al., 1989). People with epilepsy and their relatives have been known for years to have decreased IgA levels and altered T4 helper vs. T8 cytotoxic lymphocyte counts (Eeg-Olofsson et al., 1988). Some of these changes could be due to effects of AEDs (Garzon et al., 1996), but similar abnormalities are found in seizure patients on no AEDs (Bostantjopoulou et

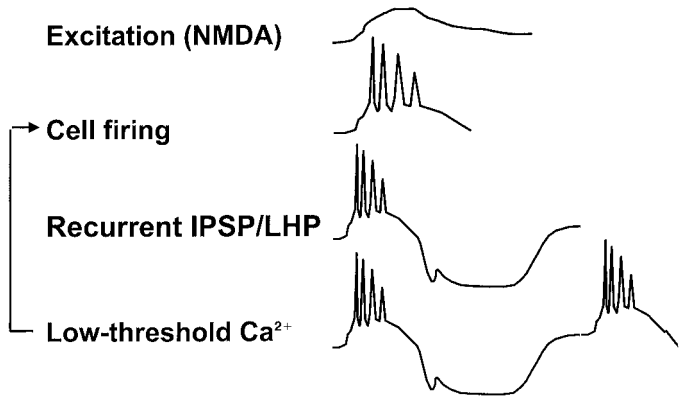

Fig. 73.8. A cartoon portraying the hypothesized sequence of development of spike-waves. See text for explanation. Abbreviations: NMDA, *N*-methyl-*D*-aspartate; IPSP, inhibitory postsynaptic potential; LHP, late hyperpolarizing potential.

al., 1994). After brain injuries, brain-specific antigens and antibodies appear in CSF and in serum (Schwartz et al., 1989).

Systemic lupus erythematosus (SLE) is associated with seizures in from 7% (Sibley et al., 1992) to 18% (Wong et al., 1991) of people with SLE. Some patients with lupus express a circulating anticardiolipin antibody. Years ago (Karpiak et al., 1981), anti-GM1 ganglioside antibodies were demonstrated to produce epileptiform spiking in rats. Anti-GM1 IgG or IgM antibodies were found in 4 in a series of 64 patients with various types of epilepsy (Bartolomei et al., 1996). Some children with seizures (3 of 23) demonstrated antiphospholipid antibody positivity with no clinical nor serological evidence of systemic lupus (Angelini et al., 1998). This antibody can decrease GABA currents in snail neurons (Liou et al., 1994). The Landau–Kleffner syndrome variant, epileptic aphasia, was associated with antibodies to brain cell nuclei or endothelial cells in 5 of 11 patients, but none of two with classical Landau–Kleffner syndrome (Connolly et al., 1999).

Occasional surgical cases of epilepsy show immune attacks on neurons (Andrews et al., 1990). Brain tissue from 16 patients undergoing epilepsy surgery were analysed for presence of viral DNA (Eeg-Olofsson et al., 1995). PCR techniques disclosed cytomegalovirus antigen in 50%, herpes simplex Type I antigen in 44%, and human herpes virus type 6 in 25%. However, only a small control series was available, so it is not possible to interpret the meaning of these associations.

Immunological theories of epilepsy received a boost from the observation that the intractable focal seizures of Rasmussen's encephalitis may derive from antibodies to brain tissue (Rogers et al., 1996). Andrews and McNamara (1996) proposed that Rasmussen's encephalitis might result from antibodies against the GluR3 subtype of the glutamate receptor. Patch–clamp recordings from neurons resected from Rasmussen's encephalitis patients show current and pharmacological sensitivities consistent with disinhibition (Gibbs et al., 1998). The link between immune attack on a glutamate receptor, disinhibition and focal seizures has not yet been forged, but it is possible to speculate that excitatory afferents to inhibitory interneurons might be disabled by the immunological attack.

If some forms of seizures are caused by autoimmune disorders, then it is worth considering immunosuppressive therapy for seizures. Several dozen studies have evaluated efficacy of immune globulin, given intravenously or intramuscularly, for seizures. A meta-analysis (van Engelen et al., 1994) collated data on 368 patients in 24 studies using immune globulin as treatment for intractable seizures. All studies were uncontrolled. Dose of globulin ranged from 0.3–6.8 g/kg, administered over periods of days to a year. Remission was said to occur in 23%. The review could not draw a conclusion about efficacy. A second review, with patient population overlapping that of the prior review, of 373 patients in 29 uncontrolled studies (Duse et al., 1996) concluded that 174 patients with intractable childhood epilepsy benefitted from immune globulin. A single controlled trial of patients with West syndrome or Lennox–Gastaut syndrome showed a trend in favour of immune globulin, but not to the point of statistical significance (Duse et al., 1996). Therefore, immune globulin remains an intriguing, but unproven therapy for seizures. Further work will be required to document efficacy, safety and to define the types of seizures to which immunotherapy might apply.

Very recently, animal studies raise the possibility of providing a vaccine against seizures. An adenovirus vaccine generated antibodies against the NR1 subunit of the NMDA receptor in rats (During et al., 2000). Oral administration of the vaccine conferred protection against kainate-induced seizures. Other intriguing, but anecdotal, immune therapies for seizures have included plasmapheresis for Rassmussen's encephalitis (Andrews et al., 1996), ACTH for infantile spasms (Baram et al., 1996), and corticosteroids for Landau–Kleffner epileptic aphasia (Lerman et al., 1991).

Genes and epilepsy

As the full sequencing of the human genome accelerates rapidly toward the first complete map, the importance of genetics in human disease in general and epilepsy in particular becomes increasingly apparent. Studies of over 20 mouse knockout models for epilepsy suggest that more than 1000 genes can be mutated to influence the presentation of seizures (Frankel, 1999). Over 100 Mendelian single gene disorders include seizures as one component of a syndrome (Gardiner, 1999). Seven regions of the genome, 6p, 8q, 10q, 15q, 16p, 19q, 20q, are now known to contain genes involved in clinical epilepsy (Szepetowski & Monaco, 1998). Unfortunately, the forms of epilepsy for which genetics are relatively simple, such as familial nocturnal frontal lobe epilepsy (Berkovic, 1997) or Baltic myoclonic epilepsy (Alakurtti et al., 2000), are rare. The common forms of epilepsy, such as temporal lobe epilepsy or posttraumatic epilepsy, demonstrate very complex and multigenic patterns of inheritance (Leppert & Singh, 1999). To further increase complexity of genetic analysis in epilepsy, variation in phenotypy can generate two very different appearing types of seizures in two different individuals with the same gene.

Table 73.3. Genetic epilepsy syndromes

Syndrome	Mode	Location	Gene
Benign familial neonatal convulsions	AD	20q, 8q24	KCNQ2, 3
Benign familial infantile convulsions	AD	19q13	?

Generalized epilepsy with febrile Sz plus	AD	19q13	SCN1B

Studies of mouse and rat genetic seizure models have been useful for framing questions about clinical epilepsy. Physiological changes in the genetically epilepsy prone rat (GEPR) include increased membrane resistance, reduced spike frequency adaptation, decreased thresholds for EPSP generation, and reduced GABA-A-mediated inhibition (Verma-Ahuja & Pencek, 1994).

Calcium-controlling genes are of key importance for genetic mouse models of epilepsy (Burgess & Noebels, 1999). The P/Q-type calcium channel regulates neurotransmitter release via the alpha-1A subchain of the pore-forming unit (Plomp et al., 2000). Tottering mutants with ataxia and epilepsy show abnormal acetylcholine release at the neuromuscular junction: more ACh is released initially in response to calcium, magnesium or potassium; but release runs down more quickly and exhausts synaptic transmission (Plomp et al., 2000). The tottering (tg) locus encodes the alpha1 subunit called Cacna1a (Burgess & Noebels, 1999). The lethargic (lh) locus encodes Cacnb4 for the beta subunit. The stargazer (stg) locus encodes the Cacng2 subunit for the gamma chain. Unfortunately, calcium is involved in many biological processes, including synaptic transmission, membrane stabilization, cell survival, cell differentiation, growth and migration and gene expression. This will make it difficult to isolate the mechanisms by which calcium-controlling genes lead to epilepsy.

Table 73.3 summarizes a dozen epilepsy syndromes for which a gene has been positionally cloned, and three for which a function of the defective gene has been identified.

Benign familial neonatal convulsions (Schroeder et al., 1998) is an autosomally dominantly inherited disorder that presents with convulsions on days 2–4 of life. It resolves by 4 months, but 15% develop late seizures. The involved sites, 20q KCNQ2 and 8q24 KCNQ3 code for potassium channels. Related disorders can affect potassium channels in heart muscle and lead to the long Q-T syndrome. Effects of impairing potassium channels can be investigated in laboratory animals. Knockout of the Kv1.1 alpha subunit of the potassium channel produces mice with seizures (Rho et al., 1999). The human homologue is KCNA1, and loss of this locus leads to episodic ataxia and myokymia.

Baltic myoclonic epilepsy of Unverricht and Lundborg (Lehesjoki & Koskiniemi, 1999) is an epileptic disorder with usual onset at age 6–15 years, presenting with stimulus and light sensitive myoclonus. The syndrome results from cystatin B, a cysteine protease inhibitor, gene mutations, in the form of unstable dodecamer repeat expansions (Alakurtti et al., 2000). These satellite repeats disrupt translation and ultimately concentration of cystatin B in neural tissues. Why this leads to seizures is unknown, but loss of cystatin B in mice produces deterioration of cerebellar granule cells (Pennacchio et al., 1998).

Autosomal dominant nocturnal familial frontal lobe epilepsy (Bertrand et al., 1998) is an autosomal dominant syndrome that presents with partial seizures in sleep. Onset typically is from 4–12 years of age. The involved gene site 20q13.2 encodes synthesis of the alpha-4 nicotinic acetylcholine receptor. Impairment of this receptor affects calcium ion flux through the receptor and leads to hyperexcitability of the tissue.

In conclusion, despite major advances in understanding of epilepsy mechanisms, no grand unifying theme yet ties together the means by which genetic predisposition, brain injury, or disturbance of brain metabolism lead to seizures. Investigators have identified only a tiny fraction of the genes that can predispose to or cause epilepsy. We still do

not know why some individuals have seizures, and others do not, nor why a particular seizure happens at a particular time. We are more knowledgeable about properties of ion channels, synaptic potentials, and neuronal circuits, but we still cannot identify the circuitry necessary for clinical seizures, particularly in the case of generalized tonic-clonic (grand mal) seizures.

Much of our current understanding has derived from studies on animal models of the epilepsies (Fisher, 1989). These models are, however, imperfect. The importance of human clinical research in epilepsy cannot be overemphasized (Engel, 1998), despite substantial difficulties inherent in human research.

Epilepsy research has experienced different themes and era, from clinical observation (which continues to this day), through EEG analysis, studies of membrane and synaptic potentials, studies on structural abnormalities in seizure foci, and work on neurotransmitters and neuromodulators, neuroimaging, ion channels and now genes. Future advances will derive from interdisciplinary links among these subjects and from new insights and technologies, not yet imagined.

The clinical spectrum of epilepsy

Renzo Guerrini[1], Lucio Parmeggiani[1] and Pierre Thomas[2]

[1]Institute of Child Health and Great Ormond Street Hospital, University College, London, UK
[2]Service de Neurologie et Consultation d'Epileptologie, CHU de Nice, France

Historical note

An epileptic seizure is a paroxysmal event due to an excessive, usually self-limited, abnormal activity in the cerebral cortex. Epilepsy is defined by the recurrence of seizures and derives its name from the Greek verb $\varepsilon\pi\iota\lambda\alpha\mu\beta\alpha\nu\varepsilon\iota\nu$ which means 'to be seized'. In the past it has been alternatively known as the falling sickness as falling down is a common symptom during a seizure, or the sacred disease because seizures were interpreted as an indication of demonic possession.

For centuries the study of epilepsy was mainly identified with the description of seizures. We know now that the clinical spectrum of epilepsy is extremely wide. It ranges from benign, age-related, isolated idiopathic seizures in normal individuals, to malignant symptomatic epileptic encephalopathies with major disability and cognitive impairment. Although for practical clinical purposes, epilepsy may still be a useful diagnostic category, it would be too simplistic to consider it as a single nosologic entity. Epileptic seizures represent a common response of the brain to different etiologic substrates, which can comprise conditions such as age-related ion channel dysfunction and brain tumours.

Epidemiology

Epilepsy is one of the most frequently occurring neurological diseases. However, epidemiological studies have encountered difficulties due to methodological limitations. These are related to clinical and etiological heterogeneity as well as to the criteria used in order to define the disorder (isolated vs. repetitive seizures) and data collection (population-based studies vs. hospital-based studies or national general practice surveys).

Prevalence of active epilepsy in Rochester, Minnesota (Hauser et al., 1991) was estimated at 0.68% when either spontaneous recurring seizures had occurred or an antiepileptic drug treatment had been taken during the last 5 years. Prevalence rates at 0.5–0.8% appeared in other studies in different parts of the world. The incidence of epilepsy has been estimated to range between 17.3 and 136 per 100 000 individuals. The incidence curve for epilepsy with respect to age, has a peculiar bimodal distribution (Fig. 74.1; Hauser et al., 1993). Although the incidence of various seizure types has not been clearly determined, focal seizures seem to be the more frequent. (Fig. 74.2) The incidence of the various epilepsy syndromes is still under evaluation (Commission, 1993).

Mortality

Mortality rates in patients with epilepsy are two to three times higher than in the general population. Increased mortality risk can be directly related to the etiology of epilepsy (i.e. alcoholism, brain tumours, degenerative neurological disorders), or it can be the accidental consequence of seizures or status epilepticus. The sudden unexplained death syndrome in epilepsy (SUDS) (Earnest et al., 1992), is thought to account for about 10% of deaths related to epilepsy. Patients with nocturnal convulsive seizures are at higher risk. Postulated mechanisms include seizure-related cardiac arrhythmia, respiratory arrest and mechanical asphyxia. No specific anatomopathological features are known.

Natural history

The risk of seizure recurrence without treatment after a first unprovoked episode is close to 80% within 3 years

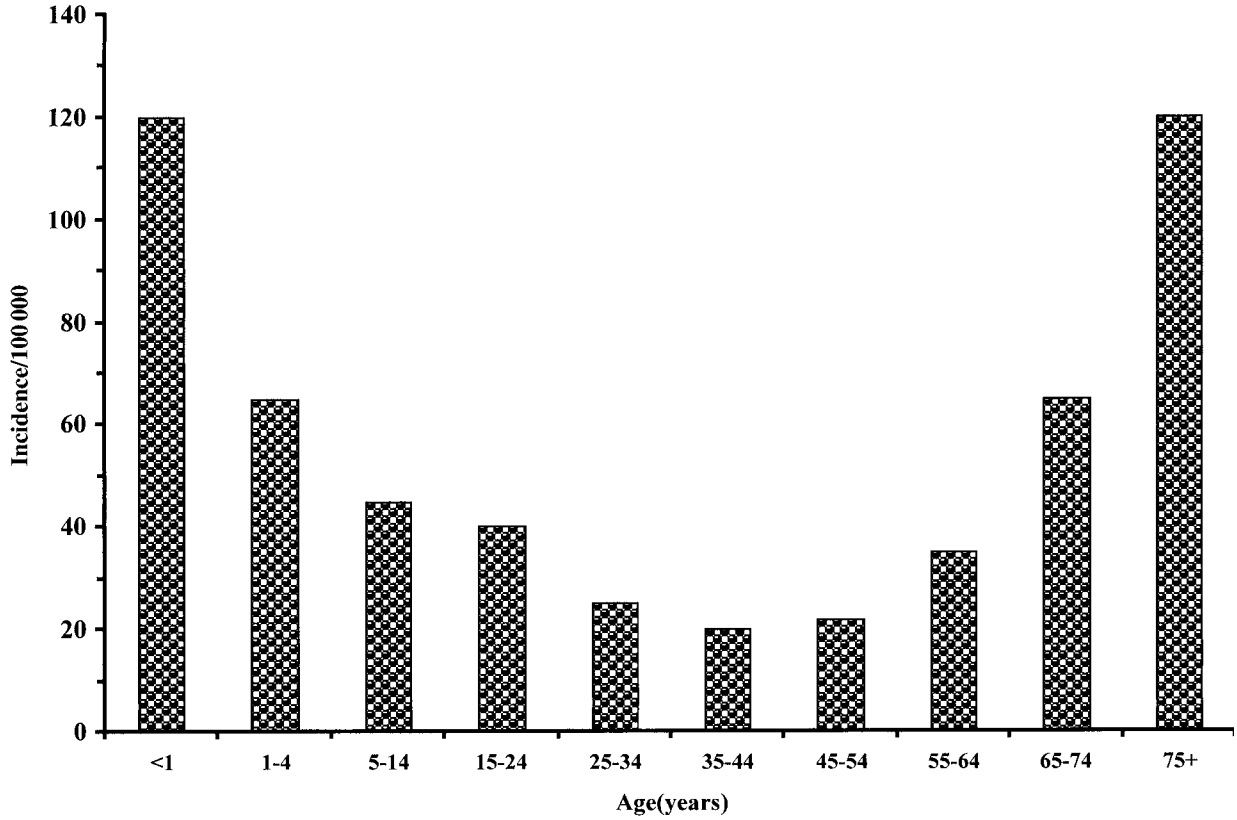

Fig. 74.1. Schematic drawing of incidence of epilepsy per 100 000 people in relation to different ages. There is a clear bimodal distribution with a peak incidence below age 1 year and a second peak above age 75. A lower plateau is present between age 25 and age 54. (From Hauser et al., 1993, modified.)

(Hart et al., 1990). The practical implication of these figures is very limited because the specific epileptic syndrome and etiology have not been considered. On the whole, 70–80% of patients reach remission on AED treatment but subsequent attempts at drug withdrawal after 3 years of complete seizure control, are followed by relapse in about 25% of children and 50% of adults (Schmidt & Graham, 1996). Relapse rate is highly variable, considered as a function of the specific epileptic syndrome: 0% for benign epilepsy with centro-temporal spikes (BECTS), 12% for childhood absence epilepsy, 23% for epilepsy with generalized tonic–clonic seizures (GTCs), 29% for partial epilepsy with secondary GTCs and 80% for juvenile myoclonic epilepsy (Baruzzi et al., 1988).

Prognosis

Patients recently diagnosed with epilepsy may be divided into four, major prognostic groups (Sander, 1993).

The first group includes the spontaneously benign epilepsies with excellent prognosis. Seizures are very rare and may either be precipitated by external factors (alcohol, sleep deprivation), or by the expression of a specific syndrome with good prognosis, i.e. BECTS. If treatment is needed, low doses will suffice to achieve remission. About 20–30% of patients belong to this category.

The second group includes the pharmacosensitive epilepsies, with a similarly good prognosis. Seizure control may be easily achieved by medication and is followed by spontaneous remission after a few years. Childhood absence epilepsy and some forms of partial epilepsy of the adult belong to this category, which accounts for 30–40% of patients.

The third group is defined as pharmacodependant epilepsies in that drug treatment will control seizures but no spontaneous remission seems to occur. Since drug withdrawal is followed by relapse, treatment will be lifelong. This group which includes juvenile myoclonic epilepsy and most non-idiopathic partial epilepsies, accounts for about 10–20% of patients.

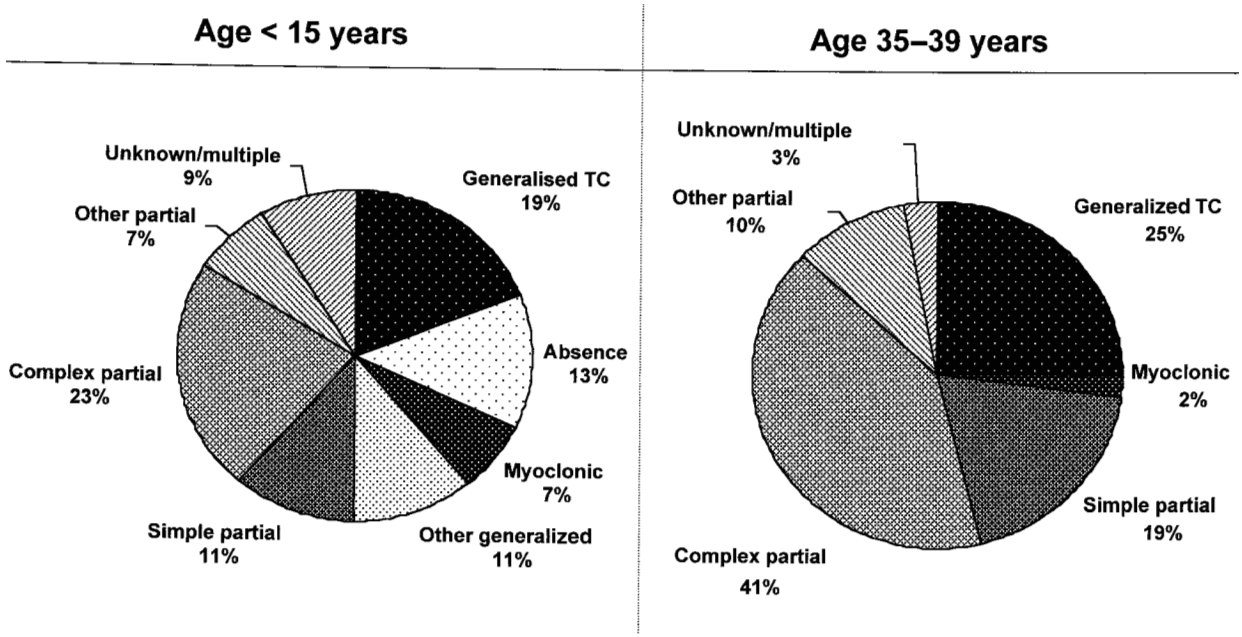

Fig. 74.2. Pie graph showing seizure type distribution in children and adults. Note that generalized seizures (generalized tonic clonic (TC), absence, myoclonic, other generalized seizures) account for 50% of all seizure types below age 15, while they represent only 27% of seizures occurring between age 35 and 39. In the latter age group absence seizures are not frequent enough to reach any measurable percentage. (From Hauser, 1992, modified.)

The fourth group includes the pharmacoresistant epilepsies, with poor prognosis. Pharmacoresistance is defined as the persistence of frequent or disabling epileptic seizures after 2 years of treatment with appropriate antiepileptic drugs. This group accounts for about 20% of patients, most receiving multiple drugs.

Etiology of epilepsy

The etiology of epilepsy is heterogeneous and results from the combination of genetic and acquired factors. In different circumstances, one or the other of these factors will prevail.

Genetic factors

Genetic factors are responsible for around 40% of epilepsies. Multifactorial inheritance is the most frequent. There are different groups of genetically determined epilepsies. They rarely result from chromosomal abnormalities or appear in the context of mendelian inherited syndromes. Most frequent are the idiopathic epilepsies, polygenic or monogenic. The different genetic epilepsies are summarized in Table 74.1. The following section will deal with the most important forms.

Single gene epilepsies

During the last 10 years, some forms of familial epilepsies that are inherited with a mendelian transmission, have been mapped to different loci and for some the genes have been cloned. So far, all identified genes are coding for ion channels responsible for neuronal excitability.

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)

ADNFLE has been described in several families (Scheffer, 2000). Seizures usually start during childhood and are mainly simple/complex partial motor seizures presenting as dystonic/tonic posturing or hyperkinetic behaviour misdiagnosed as parosomnia or nocturnal paroxysmal dystonia (Fig. 74.3). They are often clustered during sleep, but can also present during wakefulness. Carbamazepine treatment is effective in most patients. ADNFLE is genetically heterogeneous, with two subunits of the neuronal nicotinic acetylcholine receptor ($\alpha 4$ and $\beta 2$), responsible for the syndrome in different families (Steinlein et al., 1995; Fusco et al., 2000). A third locus has been mapped on

Table 74.1. Main genetic disorders associated with epilepsy and genetic epilepsies

Chromosomal abnormalities	Chromosomal location/ abnormality	Gene	Epilepsy (%)
Trisomy 21 (Down syndrome)	21	–	12–40
Fragile X syndrome	Xq27.3	FMR1	28–45
Angelman syndrome	15q11–13	UBE3A	80–100
Wolf–Hirschlorn syndrome (4p monosomy)	4p–	–	100
Miller–Dieker syndrome (17p)	17p13.3	LIS1	100
Ring chromosome 20	20 ring	–	100
Autosomal dominant transmission			
Type 1 neurofibromatosis	17q11	NF1	20
Tuberous sclerosis	9q24, 16p13.3	TS1, TS2	60–100
Familial cavernous angiomatosis	7q	CCM1	70
Ceroid lipofuscinosis (dominant)	–	–	100
Benign familial neonatal convulsions	20q13.3, 8q24	KCNQ2, KCNQ3	100
Benign familial infantile convulsions	19q12	–	100
Infantile convulsions and paroxysmal coreoathetosis	16p12–p11	–	80
Autosomal dominant nocturnal frontal lobe epilepsy	20q13.3, 1p21–q24, 15q24	CHRNA4, CHRNAB2	100
Familial lateral temporal lobe epilepsy	10q24	–	100
Familial mesial temporal lobe epilepsy	–	–	100
Autosomal dominant rolandic epilepsy with speech dyspraxia	–	–	100
Generalized epilepsy with febrile seizures plus	19q13, 2q21–q33	SCN1A, SCN1B	60
Familial adult myoclonic epilepsy	8q23.3–24.1	–	100
Familial partial epilepsy with variable foci	22q11–q12	–	70
Autosomal recessive transmission			
Lafora disease	6q23.25	EPM2A	100
Unverricht–Lundborg disease	21q22.3	EPM1	100
Ceroid lipofuscinosis (recessive)	1p32, 1p15.5, 16p12.1, 13q21.1–q32	CLN1, CLN2, CLN3, CLN5	100
Galactosialidosis	20q13.1	GLB2	100
Gangliosidosis GM1 type 1	3p21.33	GLB1	100
Type III Gaucher disease	1q21	–	100
Familial idiopthic myoclonic epilepsy	16p13	–	100
Rolandic epilepsy–exercise-induced dystonia–writer's cramp	16p12–11.2	–	100
X-linked transmission			
Band heterotopia, X-linked lissencephaly	Xq22.3	DCX	90
Bilteral periventricular nodular heterotopia	Xq28	FLMN1	80–90
Aicardi syndrome	Xp22	–	100
X-linked infantile spasms	Xp11.4–Xpter	–	100
Mitochondrial disorders			
MERRF (Myclonus epilepsy and ragged red fibres	Mitochondrial DNA	–	100
MELAS (Mitocondrial myopathy, encephalopathy, lactic acidosis and stroke)	Mitochondrial DNA	–	100

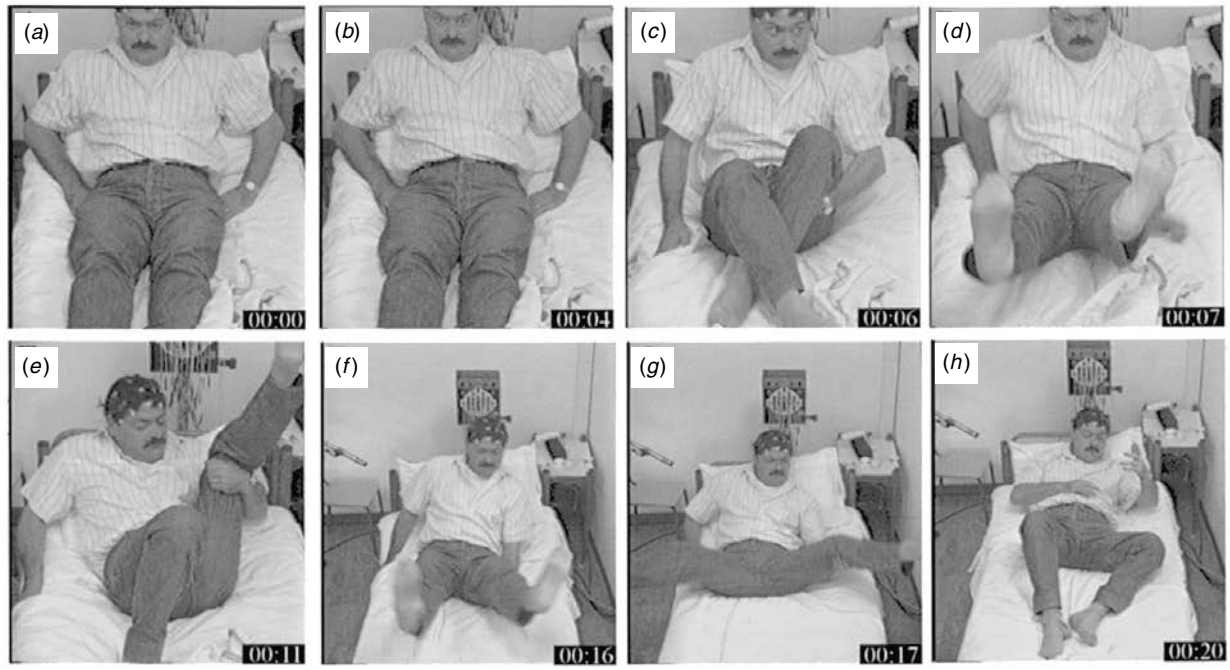

Fig. 74.3. Video recording of a typical hypermotor seizure of frontal lobe origin. In (*a*) the patient has just woken up from sleep. Seizure starts in (*b*) with changing of facial expression. In (*c*)–(*g*) the characteristic motor behaviour appears suddenly with lower limb kicking and thrashing movements. The patient is conscious throughout the episode and tries to hold his legs to prevent involuntary movements (as evident in picture (*e*)). The seizure is over in picture (*h*) and the patient expresses his relief. Numbers on the right bottom corner of each picture indicate time from picture (*a*) in minutes:seconds format.

chromosome 15q24 (Phillips et al., 1998). *De novo* mutations of these genes could be responsible for sporadic cases (Phillips et al., 2001).

Generalized epilepsy with febrile seizures plus (GEFS+)
This syndrome is characterized by heterogeneous phenotypes including febrile seizures (FS) and mild to severe generalized epilepsies (Scheffer & Berkovic, 1997). FS are present in most patients. FS+ are considered fever-related seizures continuing over the age of 6 or associated with afebrile GTCs. FS+ may be associated with absence, myoclonic or atonic seizures. Inheritance is autosomal dominant with 60% penetrance. Mutations of two different genes coding for α1 and for β1 subunit of a voltage-gated sodium channel have been found in different families (Wallace et al., 1998; Escayg et al., 2000).

Familial temporal lobe epilepsy (FTLE)
Two different varieties are described: mesial and lateral FTLE. Onset is during adolescence or adulthood and the course is usually benign. Mesial FTLE is characterized by rising epigastric sensation, psychic symptoms and autonomic phenomena. No loci have been identified (Berkovic et al., 1996). Autosomal dominant lateral TLE is associated with auditory (ringing or humming sounds) or complex visual hallucination and maps to chromosome 10q24 (Ottman et al., 1995).

Benign familial neonatal convulsions (BFNC)
Transmitted with autosomal dominant inheritance, this syndrome manifests on day 2–3 of life with partial seizures that usually disappear within a week. Later seizures are observed in 10% of patients. Two mutations in voltage-gated potassium channel genes (*KCNQ2* and *3*) have been described (Singh et al., 1998; Charlier et al., 1998).

Benign familial infantile convulsions (BFIC)
This autosomal dominant syndrome is characterized by clusters of partial seizures appearing between the ages of 4 and 8 months. Prognosis is good. Two different loci have been identified: one on chromosome 19q and a second on chromosome 16 in patients with associated paroxysmal choreoathetosis (Guipponi et al., 1997; Szepetowski et al., 1997).

Autosomal recessive rolandic epilepsy with paroxysmal exercise-induced dystonia and writer's cramp

The syndrome is characterized by infrequent orobrachial motor seizures during wakefulness, associated with interictal rolandic spikes on EEG, paroxysmal exercise-induced dystonia in childhood, and writer's cramp beginning in childhood and persisting until adolescence (Guerrini et al., 1999a). Linkage analysis points to chromosome 16p within the critical region for benign familial infantile convulsion and choreoathetosis.

Epilepsies with multifactorial inheritance

Most of the idiopathic epilepsies have multifactorial inheritance. Phenotypes in these syndromes derive from the interaction of multiple genes and environmental factors. Penetrance is variable and there is usually an age-dependent expression. A gene for generalized idiopathic epilepsies has been linked to chromosome 8q24 (Zara et al., 1995), and two possible genes for juvenile myoclonic epilepsy have been linked to chromosome 6p (Liu et al., 1995) and 15q24 (Elmsie et al., 1997).

Acquired factors

Pre- and perinatal factors

Multiple perinatal factors can be responsible for epilepsy (Holden et al., 1982). Prenatal causes include cortical malformations, and CNS infections such as toxoplasmosis and cytomegalovirus. The main perinatal factors include hypoxic–ischemic encephalopathy.

Pyridoxine dependency should be suspected in neonates and infants with intractable seizures and excluded by i.v. injection of 50 to 200 mg vitamin B6 during EEG monitoring (Bankier et al., 1983).

Cortical malformations

Cortical malformations are a frequent cause of drug-resistant epilepsies. The use of MRI may permit an early diagnosis (Guerrini et al., 1999b). However, small or microscopic abnormalities escape MRI recognition. Epilepsy can start at any age and progress with variable severity. Mental retardation, focal or bilateral neurological deficit and a positive family history can be observed. Diffuse abnormalities are associated with early onset epileptogenic encephalopathy, usually with infantile spasms. Focal malformations typically induce a focal, drug-resistant epilepsy (Guerrini et al., 1999b). A list of the most common malformations is presented in Table 74.2.

Hippocampal sclerosis

Hippocampal sclerosis is the most frequent lesion observed in human epilepsy. It represents the substrate of the mesial temporal lobe epilepsy syndrome, that accounts for a number of drug-resistant partial epilepsies of adulthood (Baulac et al., 1994). MRI scans can now reliably detect hippocampal sclerosis in most patients (Duncan, 1997). It remains unclear if the lesion is responsible for, or is the consequence of, early-onset prolonged febrile convulsions.

Infections

Febrile illness due to extracerebral causes (upper airway infections, exanthematous diseases) can be responsible for febrile seizures in children below the age of 5. Complicated, prolonged febrile seizures can be both the expression or the cause of CNS structural lesions such as hippocampal sclerosis or HHE syndrome (hemiconvulsion–hemiparesis–epilepsy) (Mahler & McLachlan, 1995), following a fever-related lateralized convulsive status in early infancy (Chauvel et al., 1991). The frequency of HHE syndrome has been reduced since the systematic use of benzodiazepines to treat prolonged febrile seizures. Viral encephalitis, bacterial meningo-encephalitis and cerebral abscess are highly epileptogenic. In children, herpes encephalitis can present as febrile seizures. HIV infection can manifest with epileptic seizures due to direct viral neurotropism or to opportunistic infections.

Cerebral tumours

Epilepsies due to cerebral tumours represent 10–15% of adult-onset epilepsies. On the other hand, epileptic seizures are observed in 20–70% of supratentorial neoplasms (Cascino, 1990). Simple somato-sensory, somato-motor or sensory seizures as well as GTCs are frequent. A brain tumour should be suspected in cases of *de novo* status epilepticus or when there is a gradual changing of clinical characteristics in the course of chronic epilepsy.

Slowly evolving tumours, involving frontal or central cortices are highly epileptogenic. According to pathology, a decreasing epileptogenicity is found in oligodendrogliomas, low-grade astrocytomas, meningiomas, metastases, and glioblastomas. Dermoid, epidermoid and arachnoid cysts have a variable epileptogencity.

Dysembrioplastic neuroepithelial tumours, ganglioglioma, and hamartomas are highly epileptogenic lesions with a low tendency to growth (Cascino, 1990).

Head injury

Post-traumatic epilepsy is fairly common in war-related head injuries (25–50% of cases), but is rare following head

Table 74.2. Main cortical malformations

Malformation type	Epilepsy	Associated signs	MRI
Diffuse malformation			
Agyria (classic lissencephaly)	IS, SGE	Severe mental retardation, quadriparesis	Absent gyral pattern, thickened cortex, vertical sylvian fissure
Pachygyria	IS, SGE	Severe mental retardation	Reduced gyral pattern with thick cortex
Band heterotopia	SPE (variable)	Mental retardation (variable severity)	Double cortex: symmetrical, subcortical grey matter bands, separated from cortex by a white matter band
Periventricular nodular heterotopia	SPE	No signs ⇒ female Severe mental retardation ⇒ male	Periventricular nodules of grey matter
Bilateral regional malformations			
→ Bilateral perisylvian polymicrogyria (congenital, bilateral, perisylvian syndrome)	SGE (variable severity)	Mild to severe mental retardation Oro-facial apraxia	Bilateral perisylvian polymicrogyria with pachigyric appearance of grey matter
Hemispheric malformations			
→ Hemimegalencephaly	IS, SGE, SPE	Mental retardation hemiparesis	Enlarged hemisphere with unilateral gyral malformation; white matter signal abnormalities
Polymicrogyria	SPE, AA, CSWS	Mental retardation hemiparesis	Smaller, polymicrogyric hemisphere
Focal malformations			
Focal cortical dysplasia	Drug-resistant SPE	Related to location and extension	Focal cortical thickening, signal abnormalities in underlying white matter
Focal subcortical heterotopia	SPE (variable severity)	Related to location and extension	Focal grey matter heterotopia within normal looking white matter
Focal polymicrogyria	Variable	Related to location and extension	Focal polymicrogyria, sometimes resembling pseudo-pachigyria
→ Type 1 and 2 schizencephaly	Drug-resistant SPE	No signs ⇒ type 1 Mental retardation, focal deficit ⇒ type 2	Subarachnoid-ventricular fissure, grey matter surrounding the fissure Type 1 ⇒ closed lip schizencephaly Type 2 ⇒ open lip schizencephaly
Complex malformations			
→ Aicardi syndrome	IS, SGE	Mental retardation	Corpus callosum agenesis Corio-retinic alteration Female patients, neuronal migration disorder

Notes:
AA = atypical absences: CSWS = epilepsy with continuous spike-and-wave discharges during slow wave sleep; IS = infantile spasms; SGE = symptomatic generalized epilepsy; SPE = symptomatic partial epilepsy.

injuries in civil life (0.5–5% of cases) (Annegers et al., 1998).

The frequency of early-onset seizures in the first week after a head injury is commensurate with the severity of that injury. These seizures do not always relapse and any treatment started at an early stage can eventually be suspended. Relapsing seizures which onset after the first week can be designated as post-traumatic epilepsy. Penetrating open traumas are more frequently responsible for post-traumatic epilepsy than closed head injuries. Post-traumatic epilepsy appears in around 30–50% of patients with penetrating head injuries. In 70% of patients, epilepsy occurs within 2 years of the injury. Fifty per cent of patients who develop post-traumatic epilepsy will achieve remission.

The presence of neurologic deficit due to cortical damage or intracerebral hemorrhage supports a diagnosis of post-traumatic epilepsy. The presence of at least two of the following: a post-traumatic coma/amnesia longer than 24 hours, a depressed skull fracture or early-onset seizures can support the diagnosis.

Cerebrovascular disease

Cerebrovascular accidents (CVA) are the most frequent cause of epilepsy in the elderly. Simple partial seizures can sometimes precede the onset of a CVA. Acute seizures during a CVA are mostly observed in intracerebral hemorrhages (5–25% of cases) and cerebral venous thrombosis. After a CVA, seizures appear within two years and are more frequently associated with ischemic (10% of cases) than with hemorrhagic lesions (5% of cases). Arterio-venous malformations are associated with epilepsy in 60% of patients (Crawford et al., 1986). If epilepsy proves drug resistant, surgical excision or endovascular embolization should be performed. Small aneurysms can produce seizures in the acute phase following rupture. Cavernous angiomas are always associated with partial, drug-resistant epilepsy (Turjman et al., 1995). Cerebral vasculitis in systemic lupus erythematosus or eclampsia is associated with epileptic seizures.

Toxic, pharmacologic and metabolic factors

Toxic factors

Alcohol can typically induce seizures in patients with epilepsy and excessive intake can precipitate isolated seizures. Abstinence from alcohol by an alcoholic can be linked to GTCs which manifest within a few hours or days after the last intake of alcohol. Alcohol-related epilepsy is characterized by relapsing partial or generalized seizures, appearing in a chronic alcohol-abuser, which occur independently from acute alcohol toxicity or abstinence. Antiepileptic drug treatment is often necessary.

Use of cocaine, codeine, amphetamines and phencyclidine can be associated with GTCs.

Pharmacologic factors

Psychotropic drugs may precipitate seizures following chronic use (antipsychotic drugs: limipramine, fluoxetine), intoxication (antidepressants: lithium), or abstinence (benzodiazepines, barbituarates) (Table 74.3).

Metabolic factors

Hyponatremia and hypocalcemia are highly epileptogenic. Hypoglycemia is associated with isolated GTC seizures, while hyperglycemia with hyperosmolarity can present with recurrent focal seizures.

Myoclonic seizures evolving to myoclonic status are common in uremic encephalopathy. Massive myoclonus is typically observed in postanoxic encephalopathy that can sometimes present with action-intention myoclonus, typical of Lance–Adams syndrome.

Neurological diseases

Some infantile syndromes such as Rett's syndrome and autism are frequently associated with epilepsy. Rarely, epileptic seizures can be observed in the evolution of multiple sclerosis (1.3–10.8% of patients). Epilepsy can be observed in around 10% of patients with Alzheimer's disease and in some patients with Huntington's disease.

Classification of the epileptic syndromes (Table 74.4)

A classification of the epilepsies should allow us to characterize them as different conditions and diseases responsible for seizure recurrence. However, since our knowledge of the mechanisms of epileptogenesis is limited and does not allow us to draw up a classification based upon pathogenesis, a simpler approach is to adopt a syndromic classification. A syndrome is characterized by a group of signs and symptoms that occur in constant association. They include seizure types, characteristic clinical history, clinical signs associated with the epilepsy and neurophysiological/neuroradiological findings. The classification is based on two axes: symptoms and etiology (Commission, 1989).

According to symptoms, epilepsies can be classified as:

(i) *Generalized*: if all seizures are generalized. If motor manifestations are present, they are bilateral. Interictal and ictal EEG show generalized spike, spike-and-wave, polyspike-and-wave discharges.

(ii) *Partial* or *focal*: if seizures originate from a circumscribed cortical region, the epileptogenic zone. Clinical manifestations support a focal onset of the

[c] Low epileptogenic activity.
[d] Moderate epileptogenic activity.
[e] High epileptogenic activity.

epileptic discharge with or without subsequent spread. Ictal and/or interictal EEG show focal abnormalities.

Etiologic classification differentiates:

(i) *Idiopathic epilepsies*: that are not associated with any brain lesions. Background EEG activity is normal. They are considered to be due to a genetic predisposition or to a specific mode of inheritance.

(ii) *Symptomatic epilepsies*: in which focal or diffuse lesions in CNS are present. Structural neuroimaging or biological tests can detect the abnormality.

(iii) *Cryptogenic epilepsies*: are considered as symptomatic forms whose causes remains undetectable. They are not associated with an obvious CNS lesion but lack clinical and neurophysiological characteristics of the idiopathic forms.

Table 74.4. International classification of epileptic seizures

Partial (Focal, local) seizures
Simple partial seizure (without impairment of consciousness)
With motor signs

Combining both symptoms and etiology it is possible to identify the clinical entities (Table 74.4). Seizure classification is indicated in Table 74.5 (Commission, 1981).

Focal epilepsies and epileptic syndromes

Idiopathic partial epilepsies (IPEs)

IPEs are the most frequent epileptic syndromes in children and adolescents. They have an age-dependent course and idiopathic epilepsies may frequently occur in other family members. Seizures are usually brief and can be clustered at the onset. Focal EEG abnormalities have a characteristic morphology, which increase during sleep. Response to antiepileptic drugs (AEDs) is usually satisfactory and the

Table 74.5. International classification of epilepsies and epileptic syndromes

Focal epilepsies/epileptic syndromes:
Idiopathic:
Benign childhood epilepsy with centrotemporal spikes
Childhood epilepsy with occipital paroxysms
Primary reading epilepsy
Symptomatic
Chronic progressive epilepsia partialis continua of childhood
Epilepsy characterized by seizures with specific modes of precipitation
Cryptogenic
The symptomatic and cryptogenic categories comprise syndromes of great individual variability that are based mainly on:
Seizure types (according to International Classification of Epileptic Seizures)
Anatomic localization:
Temporal lobe epilepsies
Frontal lobe epilepsies
Parietal lobe epilepsies
Occipital lobe epilepsies
Bi- and multilobar epilepsies
Etiology (for symptomatic epilepsies)
Specific modes of precipitation
Generalized Epilepsies/Epileptic syndromes
Idiopathic:
Benign familial neonatal convulsions
Benign neonatal convulsions
Benign myoclonic epilepsies of infancy
Childhood absence epilepsy (pyknolepsy)
Juvenile absence epilepsy
Juvenile myoclonic epilepsy
Epilepsy with grand mal (GTC) seizures on awaking
Other idiopathic generalized epilepsies not defined above
Epilepsy with seizures precipitated by specific modes of activation
Cryptogenic or symptomatic
West syndrome
Lennox–Gastaut syndrome
Epilepsy with myoclonic–astatic seizures
Epilepsy with myoclonic absences
Symptomatic
Non-specific etiology
Early myoclonic encephalopathy
Early infantile encephalopathy with suppression–bursts
Other symptomatic generalized epilepsies not defined above
Specific syndrome
Neonate
Non-ketotic hyperglycinemia
D-glyceridacidemia

Infant
Phenylketonuria
Phenylketonuria with biopterin deficiency
Tay–Sachs and Sandhoff disease
Early infantile ceroid lipofuscinosis (Santavouri–Haltia–Hagberg)
Pyridoxine dependency
Child
Late infantile ceroid lipofuscinosis (Jansky–Bielschowski)
Infantile Huntington's disease
Child and adolescent
Gaucher's disease, juvenile form
Juvenile ceroid lipofuscinosis (Spielmeyer–Vogt–Sjögren)
Lafora disease
Progressive myoclonus epilepsy
Cherry red spot myoclonus
Mitochondrial myopathy with abnormal lactate–pyruvate metabolism
Adult
Adult ceroid lipofuscinosis (Kuf's disease)
Epilepsies/epileptic syndromes undetermined as to whether focal or generalized
With both partial and generalized seizures
Neonatal seizures
Severe myoclonic epilepsy in infancy
Epilepsy with continuous spike-waves during sleep
Acquired epileptic aphasia (Landau–Kleffner syndrome)
Other undetermined epilepsies not defined above
Without unequivocal generalized or focal features
Special syndromes
Situation-related seizures
Febrile convulsions
Isolated seizure/status epilepticus
Seizures due to acute metabolic or toxic factors

prognosis is good with remission by late adolescence. It is unclear whether AED treatment influences the outcome (Ambrosetto & Tassinari, 1990).

Benign epilepsy of childhood with centro-temporal spikes (BECTS)

BECTS is the most frequent epileptic syndrome in childhood. Age at seizure onset ranges between 3 and 13 years. Prognosis is excellent with remission by adolescence (Lerman, 1992). Seizures are typically hemifacial, involving mainly the lips, tongue and pharyngeal–laryngeal muscles (Lerman, 1992). Sensory symptoms can involve the same body parts that later present motor phenomena (Lerman, 1992). Sometimes the homolateral upper limb is involved. Attacks are typically sleep related and can determine arousal with ictal anarthria without loss of consciousness. Secondary generalization can supervene. Typically parents are awakened by a grunting sound. They find the child dribbling profusely and unable to speak. Interictal EEG shows typical high amplitude, slow biphasic centro-temporal spikes, with a characteristic tangential dipolar distribution. Spikes greatly increase in frequency and often become bilateral during sleep.

AED treatment can be avoided if seizures are brief and appear only during sleep. If the treatment is necessary carbamazepine or valproate are preferred (Lerman, 1992).

Benign epilepsy of childhood with occipital paroxysms (BEOP)

BEOP was originally described by Gastaut in 1982 as an IPE with age of onset between 15 months and 17 years and with visual seizures (illusions, elementary hallucinations, ictal blindness) evolving either to hemiclonic or complex partial seizures with or without secondary generalization. In around 25% of Gastaut's patients, a migraine-type postictal headache was reported (Gastaut, 1992). Evolution was generally favourable with remission by adulthood. Interictal EEG showed high amplitude, unilateral or bilateral, synchronous or asynchronous, occipital spike-and-wave facilitated by eye closure.

A subset of children with BEOP present brief or prolonged sleep-related partial seizures characterized by tonic eye and head deviation, vomiting and eventually hemiclonic or secondary generalization (Ferrie et al., 1997). The age at seizure onset is between 2 and 8 years. Prognosis is excellent with remission by the age of 12 and with most children having suffered only one seizure (Ferrie et al., 1997).

The EEG abnormalities in this syndrome are not as specific as those of BECTS, in fact similar abnormalities can be observed in cryptogenic or symptomatic focal epilepsies with a less favourable prognosis (Guerrini et al., 2000).

Primary reading epilepsy (PRE)

This type of epilepsy is classified as an IPE, with age-related onset and a specific mode of precipitation (Commission, 1989) but it appears to be not as homogenous as previously considered (Koutroumanidis et al., 1998). Most patients present orofacial/jaw myoclonus induced by prolonged reading aloud. Consciousness is preserved but jerks can progress to a GTCs if reading is not interrupted. In a minority of patients prolonged reading induces partial seizures manifesting as alexia (Koutroumanidis et al., 1998). The average age at onset is 17.7 years. Treatment is not always

necessary, in that seizures are rare and strictly related to reading. Valproate is the most effective AED.

Several other idiopathic partial epilepsy syndromes have been described over the last 15 years (Genton & Guerrini, 1994). While some of these syndromes have been confirmed with several reports, others appear simply to be a variant of the main syndrome groups. It is important to recognize them in that their idiopathic context, EEG characteristics and prognosis are usually benign.

Symptomatic partial epilepsies (SPEs)

Epilepsia partialis continua (EPC) or Kojewnikow syndrome

Two different variants of Kojewnikow syndrome are known.

Type 1

This is observed in children and adults (Bancaud, 1992). An epileptogenic lesion (vascular abnormality, tumour and inflammatory or post-traumatic lesion) involves the motor cortex. Partial motor seizures are usually followed by semi-continuous focal myoclonic jerks involving the same body segment and resistant to AEDs. Epilepsy does not evolve and surgery can be effective at the cost of major motor impairment.

Type 2

This is a progressive neurological disorder known as Rasmussen encephalitis (Hart & Andermann, 2000). It is a chronic encephalitis that can be associated with antibodies against the glutamate receptor 3 in some patients (Andrews et al., 1997). Children present progressive hemiparesis, dystonic movements and cognitive deterioration. MRI shows progressive atrophy of one hemisphere. Medical treatment relies on steroids, antiviral agents and immunoglobulins, but it is usually of little help. Functional hemispherectomy can stop disease progression but it is associated with a variable degree of residual disability.

Epilepsies characterized by seizures with specific modes of precipitation

Different epilepsy syndromes are included in this group usually classified according to the stimulus that provokes them. As an example, we shall discuss startle and hearing-induced epilepsy.

Startle-induced epilepsy

This affects infants, children or young adults with static or progressive encephalopathy. It is rarely observed in neurologically intact individuals. An unexpected noise or a sudden movement can induce a focal or generalized tonic seizure that lasts for 1 to 60 seconds (Rosenow & Lüders, 2000a). Spontaneous seizures are reported by 40 to 95% of patients.

Hearing-induced epilepsy

Complex partial or secondarily generalized seizures can be induced by hearing sounds or music. Age at epilepsy onset varies between 10 and 50 years (Rosenow & Lüders, 2000b). Avoiding the provocative stimulus can reduce seizure frequency but it can be responsible for social isolation.

Lobar epilepsies

These represent the majority of partial epilepsies and are defined according to seizure semiology pointing to an anatomic location. Epileptic discharges can spread and it is therefore important to identify the very first sign or symptom of a seizure to correctly localize its onset. Site definition regarding the onset of focal seizures, when based on clinical and surface EEG findings alone may be very difficult when neuroimaging is normal. Attribution to a definite lobar origin may be misleading in the absence of a highly characteristic clustering of symptoms, in that the epileptogenic area may not respect the anatomic limits of the cerebral lobes. In addition, seizure spread from clinically silent areas may be rapid producing unresponsiveness before subjective symptoms may be reported or memorized.

Temporal lobe epilepsies

These are the most frequent type of partial epilepsies (Bancaud, 1987). Onset is during childhood or early adulthood. Seizures are simple or complex partial and are of relatively long duration (1–2 min). Their onset is characterized by visceral symptoms (rising epigastric sensation, thoracic constriction, hot or cold sensation, olfactory hallucinations) or by psychic or affective symptoms (dreamy state, *déjà-vu*, *déjà-vecu*), usually accompanied or followed by vegetative manifestations (pallor, flushing, tachycardia, poly- or bradypnea, piloerection, midriasis, or sweating). Disruption of consciousness or 'unresponsiveness' appears later and can fluctuate. Sometimes it is not present at all even during automatisms that consist of oro-alimentary behaviour (lip-smacking, swallowing) or gestural automatisms that begin later (Munari et al., 1980). Late somato-motor manifestations such as dystonic posturing of the upper limb, contralateral to the epileptic discharge, represent the propagation to extratemporal cortical regions or activation of subcortical efferent systems. The postictal phase is characterized by prolonged confusion occasionally accompanied by walking.

Aphasia is observed when the dominant hemisphere is involved.

Lateral or neocortical temporal lobe epilepsy
This is characterized by auditory hallucinations or pseudo-vertigo and by aphasic speech arrest.

Mesial temporal lobe epilepsy
This is manifested by a highly characteristic ictal pattern, including epigastric sensation, psychomotor arrest and staring, associated with mastication, lip smacking (oro-alimentary automatisms) and later gestural automatisms in the upper limb, homolateral to the epileptic discharges. Hippocampal sclerosis is frequently found on MRI scans.

Interictal EEGs can be normal or show unilateral or bilateral temporal abnormalities.

Frontal lobe epilepsies
These are frequent (Bancaud & Talairach, 1992). Seizures are usually brief (seconds to tens of seconds) and sleep related. They are often collected in clusters and are highly stereotyped in the same patient. Clinical onset is marked by tonic or postural manifestations causing disabling drop attacks. Disruption of consciousness is highly variable but postictal recovery is very fast. The attack can consist of cephalic, thoracic or abdominal sensation. Other patients can describe psychic symptoms such as forced thought. Secondarily generalized or partial status epilepticus are common. Subjective symptoms are usually ill defined.

Posterior frontal lobe seizures
Seizures emanating from the supplementary motor area are characterized by speech arrest or palialia (involuntary repetition of the same words or sentences) when the dominant hemisphere is involved. This is followed by abduction and elevation of the upper limb, contralateral to epileptic discharge and version of head and eyes to the same side (fencing posture). Secondary generalization is rare.

When the dorsolateral convexity is involved, a contralateral tonic posturing is observed. Frequently, the discharge becomes bilateral with secondary generalization. The involvement of Brodmann's area 4 produces contralateral focal clonic movements. Finally, speech arrest without loss of consciousness is observed when epileptic activity spreads to the *pes* of the third frontal gyrus.

Intermediate frontal lobe seizures
These are associated with a very fast spread of epileptic discharge to other frontal lobe areas. Bilateral tonic manifestations appear suddenly, and can be responsible for a patient's falling. Axial tonic seizures with flexion of head and trunk associated with facial grimace, are typical. The patient can continuously moan and present apnea, due to tonic contraction of the diaphragm.

Anterior frontal lobe seizures
These have a longer duration than other frontal seizures. Secondary generalization is rare. An automatic motor activity appears at seizure onset and involves either upper limbs (fingers snapping, arms windmilling), lower limbs (cycling, rhythmic flexion–extension) or girdles (rocking of pelvis, sexual automatisms). Verbal stereotypes are sometimes observed.

Involvement of specific frontal areas can be suspected when clustering of characteristic symptoms occurs. Forced thought or isolated alteration of awareness (*frontal pseudo-absences*) points to the fronto-polar area. Olfactory hallucination with intense fear, bradycardia and micturition suggests the involvement of fronto-orbital regions. Complex and frantic motor behaviour with screaming and facial expression suggesting terror or rage are typical of anterior *girus cinguli* involvement. Interictal EEG can be normal, but it is sometimes characterized by widespread abnormalities that enable neither lateralization nor localization.

Central region epilepsies
These emanate from the perirolandic cortex (Chauvel et al., 1992). Typical signs include clonic motor or elementary sensory phenomena involving the contralateral hemibody with or without march. Secondary generalization is rare. Some of the seizures originating from this region can be precipitated by sensory or proprioceptive stimulation.

Seizures emanating from the opercular–insular region present with oro-alimentary manifestations such as mastication, swallowing, and salivation. Gustative hallucinations or illusions can be associated. Interictal or ictal abnormalities can be very mild.

Parietal lobe epilepsies
These are rare (Salanova et al., 1995). Fast spreading of epileptic discharges to contiguous lobes (frontal, temporal or occipital) can mask the initial signs or symptoms. Alteration of higher cortical function such as limb movement sensation, and autoscopia (seeing of one's own body image) can be the manifestation of non-dominant hemisphere involvement. In some patients unilateral spatial agnosia can only be recognized because they tend to look preferentially to one side that is homolateral to the epileptic discharge. Visual illusions (macropsia, micropsia, metamorphopsia) are present when posterior parietal

cortex or parietal–occipital junction are involved. Clear rotatory vertigo is associated to epileptic discharge in the inferior parietal region or temporo-parietal junction. Slow rotation of the body directed ipsilaterally to the epileptic discharge and dystonic posturing of the contralateral upper limb are usually due to an involvement of inferior parietal cortex. Interictal and ictal EEG abnormalities may be widespread involving central, parietal, temporal and occipital regions.

Occipital lobe epilepsies

These are rare and difficult to identify correctly because rapid spreading of epileptic discharge to contiguous lobes may mask initial symptoms (Guerrini et al., 2000). Elementary visual hallucinations (coloured blobs, flashes of light) associated with peri-ictal peripheral visual field deficit (hemianopia) are typical and testify to the involvement of the contralateral pericalcarine region. Ictal or postictal headache are frequent, sometimes mimicking migraine attacks. Eye movements are frequent in the course of the seizure. They can be phasic (oculo-clonic movement or epileptic nystagmus) or tonic (slow version of eyes contraleral to the epileptic discharge). Occipital lobe seizures can rapidly propagate to the frontal region, being responsible for the patient's falling, or to the mesial temporal lobe. Interictal EEG abnormalities involve the posterior regions and are usually increased during eye closure.

Cryptogenic partial epilepsies (CPEs)

CPEs do not substantially differ, in terms of their clinical presentation, from SPEs. This nosologic category is intended to include patients suffering from SPEs whose cause cannot be identified with the available diagnostic tools. Since high-resolution MRI scans have become available the number of patients with CPEs has dropped remarkably. The definition of CPEs has apparently been misinterpreted and some authors have lumped CPEs and IPEs together. CPEs do not fulfil the clinical and EEG characteristics of IPEs, although their prognosis is in general better than SPEs.

Generalized epilepsies and epileptic syndromes

Generalized epilepsies are a heterogeneous group of syndromes including benign and frequent forms on one side of the spectrum and rare and severe forms on the other. Seizures are generalized and EEG abnormalities bilateral and synchronous.

Idiopathic generalized epilepsies (IGEs)

IGEs are frequent and usually benign syndromes. Their onset is in infancy or adolescence. A family history of epilepsy is frequent. IGEs seem to be genetically determined even if the exact mechanism of inheritance is known only in a minority of them. Common characteristics to all IGEs syndromes are as follows.

(i) Primary generalized seizures are *Generalized tonic–clonic seizures (GTCs)* absence, and myoclonic seizures. Myoclonic and GTCs usually appear during wakefulness or upon awakening. GTCs have a sudden onset with immediate loss of consciousness. There is a brief tonic phase (10–30 s) with a whole body tonic contraction associated with a loud scream and vegetative symptoms such as tachycardia, midriasis, increased blood pressure, and apnea. Tongue biting if present, is produced at this stage. The clonic phase lasts around 30 s–1 minute and is characterized by bilateral clonic jerks that gradually reduce in intensity and frequency. The postictal phase which can last for several minutes up to hours, is characterized by body relaxation, hypotonia, and sleep. Urination, if present, takes place at this stage. Finally the patient gradually recovers and appears confused, presenting sometimes automatisms, headache, and muscle pain. *Typical absence seizures* are brief (5–20 s). They appear mostly in children and are clinically characterized by sudden interruption of ongoing activity and staring straight ahead or drifting upwards. There is complete loss of awareness during the seizure. The onset and offset is sharp. Possible associated manifestations include slight rhythmic (3 Hz) eyelid myoclonus, slight decrement or increment of postural tone, simple gestural automatisms (if the absence is of long duration) and vegetative symptoms (urinary incontinence, pupil dilatation, pallor, flushing, tachycardia, change in blood pressure). Absence seizures can be easily produced if the child is asked to hyperventilate. Concomitant EEG abnormalities are typical generalized spike-and wave discharge at 3 Hz.

Myoclonic seizures are present with brief symmetrical muscular jerks of different intensity. Proximal muscles such as girdle muscles are mostly involved. During stronger attacks, there is possibility of the patient falling over. The patient is usually fully conscious during the seizure. Myoclonic seizures may often be triggered by photic stimulation.

(ii) Interictal EEG shows generalized spike-and-wave discharges at a frequency higher than 3 Hz.

(iii) Drug treatment (especially valproic acid) is highly effective.

Benign familial neonatal convulsions (BFNC)
See Etiology of epilepsy section (p. 1250).

Benign neonatal convulsions (BNC)
BNC are manifested as hemiclonic seizures migrating from one side to the other, or frequent apnea spells usually taking place on day 5 of life. Tonic seizures are never observed. Evolution is benign with permanent remission.

Benign myoclonic epilepsy in infants (BMEI)
This is a rare syndrome characterized by brief generalized myoclonic seizures with onset during the first or second year of life in otherwise normal children (Dravet et al., 1992a). Valproic acid is effective in controlling jerks. Rare cases are reported with behavioural problems or GTCs appearing during adolescence. Ictal EEG shows generalized polyspike-and-wave discharges, which are time locked with the myoclonic jerks. Interictal abnormalities are very rare.

Childhood absence epilepsy (CAE)
This is a frequent form of IGE with onset in school-aged normal children. Children present very frequent typical absence seizures (up to 200–300 per day). Interictal EEG shows normal background activity and generalized 3 Hz, spike-and-wave discharges that translate into a clinical seizure, if their duration outlasts 4–5 seconds.

Evolution is quite, though not uniformly benign. Treatment with AEDs (valproic acid, ethosuximide or lamotrigine) controls absence seizures, which tend to disappear in adolescence. Phenobarbitone and carbamazepine are not effective and can even increase seizure frequency (Guerrini et al., 1998). GTC seizures can appear from adolescence in one-third of cases. Late onset (above age 8), initial drug resistance and photosensitivity are associated with a less benign prognosis (see Juvenile absence epilepsy).

Typical absence seizures are also part of other rare syndromes, which are not included in the classification, such as eyelid myoclonus with absences and perioral myoclonus with absences.

Juvenile absence epilepsy (JAE)
JAE has its onset around puberty and is characterized by rare typical absence seizures which cluster upon awakening (Wolf, 1992a). In 80% of patients, GTC seizures are also present. Valproic acid is effective. Ictal EEG can show either a typical 3 Hz or a faster (4–5 Hz) spike-and-wave discharge.

Juvenile myoclonic epilepsy (JME)
JME affects around 4% of all patients with epilepsy referred to different epilepsy centres in Europe (Wolf, 1992b). Its onset is between age 6 and 25 years with a peak incidence between 12 and 17 years. Myoclonic seizures are always present. They usually involve the face and the upper limbs. Consciousness is retained and the patient may fall to the ground if the lower limbs are involved. Seizures are typically experienced on awakening when they interfere with fine motor tasks.

GTCs are observed in 90% of patients. They are preceded by a crescendo of bilateral jerks and bring the patient to medical attention, while myoclonic seizures can go unnoticed for months or even years. Ten to 15% of patients can present brief absence seizures. Clinical or EEG photosensitivity is present in 30–40% patients. Sleep deprivation and alcohol intake can be triggering factors, especially for GTCs. Interictal EEG shows generalized or asymmetric polyspike-and-wave discharges at 3 Hz or faster. Myoclonic jerks are time-locked to polyspike-and-wave complexes. A characteristic increase in polyspike-and-wave discharges is observed upon awakening (Fittipaldi et al., 2001).

JME is genetically determined, possibly through a polygenic inheritance (see Etiology of epilepsy section (p. 1250) for details).

Response to treatment (valproic acid, primidone, benzodiazepines) is usually good but JME is a pharmacodependent epilepsy. Withdrawal of AEDs is associated with relapse in 90% of patients, even late in life. Carbamazepine use in patients with JME is associated with seizure worsening, rarely escalating to status epilepticus.

Epilepsy with grand mal seizure on awakening (GMA)
GMA develops during adolescence and it is more frequent in female patients. GTC seizures take place mostly or exclusively within 2 hours of awakening or during evening relaxation. Sleep deprivation, high alcohol intake and induced arousals from sleep are all triggering factors. Interictal EEG can be completely normal or can show generalized spike/polyspike-and-wave discharges that are increased upon awakening. They tend to cluster in the early minutes after arousal from sleep (Fittipaldi et al., 2001).

JAE, JME, and GMA create a syndrome spectrum partially overlapping in age at onset and seizure characterization. It is possible that some patients diagnosed with GMA have JME (Delgado-Escueta et al., 2001).

Epilepsy with seizures precipitated by specific modes of activation
This group is mainly constituted by photosensitive or visual sensitive epilepsy. Visual sensitive epilepsy is a

common manifestation among IGEs, but it can also be found in other generalized as well as partial epilepsies. In pure photosensitive IGEs, seizures are exclusively triggered by photic stimuli such as sunlight through tree foliage, sunlight reflected from water surfaces, stroboscopic light in discos and TV or computer screens. Seizure types are GTC (84% of patients), absence (6%), partial (2.5%), and myoclonic (1.5%) (Binnie & Jeavons, 1992). EEG shows characteristics overlapping IGEs. The photosensitive range should carefully be defined, finding the lowest and highest IPS frequency capable of generating a photoparoxysmal response. AED treatment can have incomplete efficacy because patients may be very sensitive to light or compulsively self-induce seizures. It is essential to teach patients to avoid causative stimuli and/or to occlude one eye in front of them. Dark lenses can sometimes be beneficial.

Some patients are exclusively sensitive to high contrast patterns (blinds, wallpaper). In *photosensitive occipital lobe epilepsy* partial seizures can be induced by photic stimluation (video-games, TV) (Guerrini et al., 1995). They can last several minutes and are characterized by visual symptoms (colourful blobs, flashing light, followed by amaurosis), followed by vegetative symptoms and headache (Guerrini et al., 1995). Clinical characteristics and age at onset around adolescence, partially overlap with those of migraine from which the disorder should be differentiated.

Cryptogenic or symptomatic generalized epilepsies (CGE or SGE)

Four syndromes are included among CGE or SGE. All of them usually have a guarded prognosis.

West syndrome (WS)

WS is characterized by the triad, which is sometimes incomplete, of infantile spasms, developmental arrest, and hypsarrhythmia from the Greek word 'hypsarrhythmia': its own rhythm, appearing during the first year of life (Dulac et al., 1993). Incidence is around 1 in every 5000 children. Infantile spasms usually occur in clusters upon awakening or falling asleep. Each cluster can consist of several spasms whose intensity and frequency follow an increasing-plateau-decreasing pattern. Thus the first spasms in a cluster may be barely visible, presenting a forced opening of the eyes or slight nodding of the head. Gradually, they become more evident and consist of a brief (0.5–2 s) tonic contraction of the neck and trunk in flexion, extension or in a mixed flexed–extended posture. Upper limbs are fast abducted or adducted. Other partial or generalized seizures can be present in some children before, during or after the spasm cluster. Development regression usually accompanies spasm onset but it can precede it. The interictal EEG is highly disorganized. It features high amplitude slow waves, spikes or sharp waves, whose spatio-temporal distribution is anarchic. The ictal EEG is characterized by pseudo-periodic slow polyphasic EEG discharges that are concomitant with the spasms. Occasionally, EEG activity related to spasms is a diffuse electrodecremental pattern. Electromyographic activity from deltoids and neck muscles shows a characteristic rhomboid pattern during the spasm, usually lasting 0.5–2 seconds.

The etiology is divided between symptomatic forms (around 65–70% of cases), bearing a severe prognosis, and a cryptogenic form (30–35% of cases) with a variable evolution. Different cerebral lesions can be associated with WS, in particular anoxic encephalopathies, cytomegalovirus infections, postischemic porencephaly and cerebral malformations (agyria–pachygyria spectrum, focal cortical dysplasia, Down's syndrome). Tuberous sclerosis is the single most frequent specific etiology. Defined metabolic disorders such as phenylketonuria, non-ketotic hyperglycinemia, and mitochondrial encephalopathies, are rarely responsible for WS. Major AEDs are of little help in treating infantile spasms. ACTH and steroids can be immediately effective in suppressing spasms but the long-term effects on cognitive regression are still debated. Some children respond to valproic acid or benzodiazepines. Spasms in children with tuberous sclerosis, or other brain malformations, respond to vigabatrin (Chiron et al., 1990).

Lennox–Gastaut syndrome (LGS)

LGS is a severe form of childhood epilepsy (Genton et al., 2000). Its definition is based on clinical and EEG characteristics. Seizure types associated to LGS include atonic seizures, tonic seizures and atypical absences. Generalized 1–2.5 Hz spike-and-wave discharges are the characteristic interictal EEG pattern. LGS is usually drug resistant from early stages and it is accompanied by mental retardation and behavioural problems.

Onset is before 8 years of age with a peak incidence between 3 and 5.

Tonic seizures are the most characteristic type of seizure. They consist of a sustained, symmetric or asymmetric body contraction lasting usually between 5 and 20 seconds and involving the whole body or just the neck and upper girdle muscles (axo-rhizomielic seizures) (Fig. 74.4). Unresponsiveness is constantly present during the attacks. Sleep facilitates their appearance but they can also manifest during wakefulness, being responsible for traumatic drop attacks. They may cluster, sometimes evolving to status epilepticus. The ictal EEG shows a characteristic

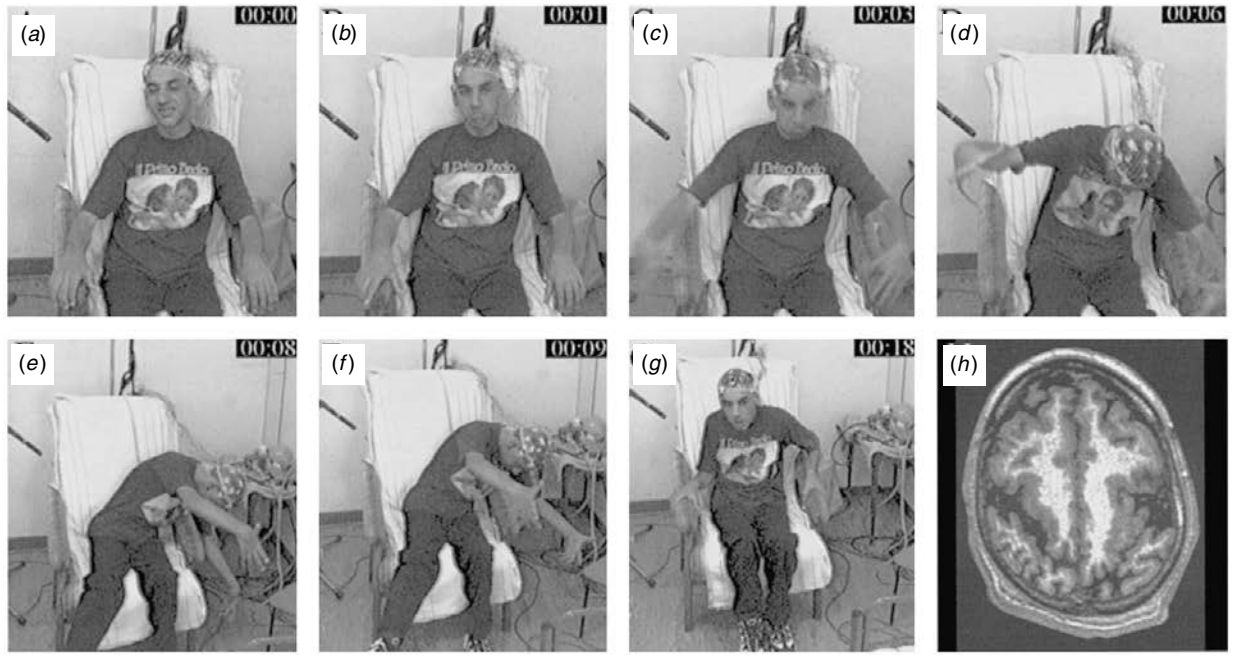

Fig. 74.4. Video recording of a tonic seizure in a patient with symptomatic Lennox–Gastaut syndrome due to bilateral perisylvian polymicrogyria. In (*a*) the patient is talking with the EEG technician and laughing. Seizure starts in (*b*) with change of facial expression (pouting). A contraction involves the upper limbs and the axial muscles, producing a relatively slow flexion of the trunk and abduction and extension of both upper limbs (pictures (*c*)–(*f*)). In (*g*) the tonic seizure has ended and the patient regains the original posture. Numbers on the right top corner of each picture indicate time from the picture (*a*) in minutes:seconds format. An axial T_1-weighted MRI scan from the same patient is presented in picture (*h*). The Silvian fissures appear open and surrounded by a thick cortex.

10 Hz polyspike generalized discharge, lasting as long as the tonic contraction (Fig. 74.5).

Atonic seizures are characterized by decrease or complete inhibition of postural tone. They manifest as head nodding, dropping of the jaw or of a limb or falls, leaving the patient motionless on the ground. Pure atonic seizures are, however, exceedingly rare. The ictal EEG usually is characterized by generalized slow spike-and-wave discharges.

Atypical absences are characterized by incomplete loss of consciousness appearing as a slight confusion and by a progressive onset and offset. Frequently associated manifestations are postural tone, decrement or increment. Ictal EEG shows a 1–2.5 Hz spike-and-wave discharge lasting several seconds. Non-convulsive status epilepticus can easily supervene in children with LGS.

Generalized myoclonic jerks, GTC or partial seizures are observed in some patients. Interictal EEG shows slow background activity associated with frequent generalized 1–2.5 Hz spike-and-wave discharges. Very frequent polyspike discharges occur during sleep, sometimes accompanied by tonic seizures.

A wide range of congenital or acquired cerebral lesions is observed in LGS. However, some children present a cryptogenic form. Prognosis is usually poor both in terms of seizure control and cognitive outcome. Polypharmacy is necessary in order to produce a reduction in seizure frequency. Lack of response to AED can produce a pharmacological escalation that in turn increases sleepiness and tonic seizures.

Myoclonic–astatic epilepsy (MAE)

MAE has its onset between 6 months and 6 years of age with a prominence in boys (Doose, 1992). A genetic predisposition is observed in this syndrome whose nosological boundaries are not well defined. Overlap with other severe childhood epilepsies (LGS and severe myoclonic epilepsy) is possible. Children present atonic or myoclonic-atonic seizures and absence seizures with a clonic or tonic component, and GTCs. Tonic seizures can appear late in the course in particular in drug-resistant children. Non-convulsive myoclonic status with prolonged unresponsiveness can be observed in around 30–35% of children. The interictal EEG, normal at the onset, shows generalized spike/polyspike-and-wave discharges later during the course. Prognosis is variable but it is usually less severe than in LGS.

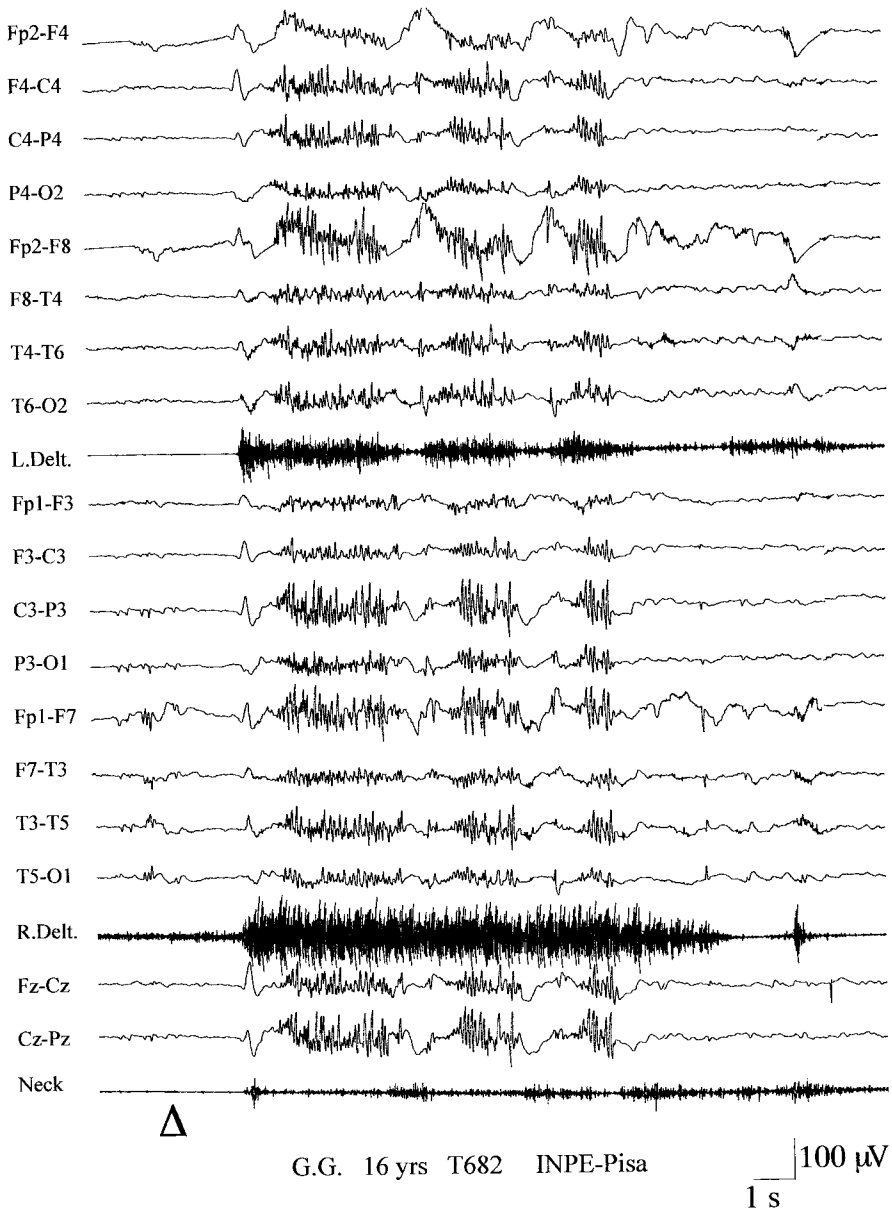

Fig. 74.5. Polygraphic recording of the same seizure as was shown in Fig. 74.4. EEG at seizure onset is characterized by high amplitude, diffuse slow spike complex, that is followed by a diffuse, high amplitude, fast, rhythmic activity, that lasts for around 10 seconds and ends abruptly. EMG from right and left deltoids (R. and L. Delt.) shows an interferential pattern that starts in concomitance with the sharp wave onset and outlasts the fast (recruiting rhythm) polyspike discharge by around 1–2 seconds. The triangle on the left bottom part indicates when picture (*a*) in Fig. 74.4 was shot.

Epilepsy with myoclonic absences (EMA)
EMA is a rare disorder (around 0.5–1% of all patients with epilepsy) with onset around age 7 (Tassinari et al., 1992a). Children present myoclonic absences that appear several times per day, as episodes of interruption of ongoing activity associated to rhythmic jerks in axial muscles causing a rhythmic movement of shoulders, head and arms. Ictal EEG shows generalized 3 Hz spike-and-wave discharges resembling those of CAE, synchronous with myoclonic jerks. Prognosis is variable ranging from poor, with evolution to different seizure types and mental retardation, to very good with remission. A combination of different AEDs (valproic acid + ethosuximide or lamotrigine) is the most effective treatment.

Symptomatic generalized epilepsies (SGE)

SGE have their onset during childhood when different seizure types (myoclonic, tonic, atonic, atypical absence seizures) occur in the same patient. The interictal EEG abnormalities are diffuse. Neurological examination, neuropsychological or neuroadiological investigations, support the presence of a diffuse encephalopathy.

SGE without a specific etiology

Two syndromes are included in this group (Ohtahara et al., 1992).

Early myoclonic encephalopathy
This has its onset by the third month of life with multifocal myoclonic jerks. The course is later characterized by the appearance of partial seizures, tonic seizures, and generalized myoclonic jerks. EEG shows a characteristic pattern with periods of electrical silence separated by generalized polymorphic abnormalities (*suppression bursts*). The etiology is usually metabolic and prognosis is very poor.

Early infantile epileptic encephalopathy with suppression-burst

Early-infantile epileptic encephalopathy with suppression–burst similarly, has its onset early in life. Children show tonic spasms, eventually associated with partial seizures, and a suppression–burst EEG pattern. The etiology is a cerebral malformation or lesion but metabolic screening is necessary. Prognosis is poor with evolution to WS or LGS.

SGE with specific etiology

This can be considered as neurological disorders in which epilepsy is a prominent symptom. They include progressive myoclonus epilepsies, neurocutaneous and other rare disorders such as Aicardi syndrome or disorders due to inborn errors of metabolism.

Progressive myoclonus epilepsies (PMEs)
PMEs are a group of epileptic syndromes including Lafora disease. Unverricht–Lundborg disease, myoclonus epilepsy with red ragged fibres (MERRF), early infantile, late infantile, juvenile and adult ceroid-lipofuscinosis, and sialidosis (Roger et al., 1992).

The clinical picture is rather homogeneous and includes multifocal and generalized myoclonic jerks, GTC or clonic–tonic–clonic seizures, progressive cognitive deterioration, and cerebellar and extrapyramidal signs.

Lafora disease is an autosomal recessive disorder and is produced by cerebral storage of polyglucosane, an abnormal glycoprotein. Patients, frequently originating from Mediterranean countries, develop myoclonic epilepsy around puberty. A diagnosis of JME can sometimes be erroneously suspected at an early stage. Some patients present occipital lobe seizures. The later course is characterized by worsening of the myoclonic syndrome and cognitive deterioration. Death supervenes a few years from onset.

Skin biopsy including sweat glands can allow a diagnosis, based on the presence of storage material in the secretory channel of the glands. The EPM2A gene on chromosome 6p23.25, coding a tyrosine–phosphatase synthesis (Minassian et al., 1998) is responsible for the disease in some families (Table 74.1).

Unverricht–Lundborg disease (ULD) is an autosomal recessive disorder. A progressive myoclonic syndrome is associated with GTC seizures, slight mental deterioration, and a cerebellar syndrome. A highly variable expression of the disorder is typical. The gene (EPM1) responsible for ULD is located on chromosome 21q22.3 and synthesizes B cystatin, an inhibitor of lysosomial proteases.

Mitochondrial encephalopthy such as MERRF or mitochondrial myopathy, encephalopathy with lactic acidosis and stroke (MELAS) can be present as PME. The diagnosis is supported by the determination of enzyme activity in the mitochondrial respiratory chain on biopsed muscles.

Neurocutaneous disorders

Neurocutaneous disorders are characterized by the association of neurological and skin lesions (neuroectodermosis).

Tuberous sclerosis is an autosomal dominant disorder with variable penetrance (Table 74.1). The dermatologic syndrome includes adenoma sebaceum on the face (Pringle adenoma), periungual fibromas (Koenen tumours), and hypomelanotic maculae. Patients may have epilepsy, cognitive impairment and behavioural problems combined or none of these. Severity of epilepsy, the age at seizure onset,

number, size, and location of cortical tubers are correlated with mental outcome. Therefore, children with early onset infantile spasms usually have a prominent cognitive deterioration. A possible visceral syndrome with renal and cardiac involvement can be associated. Magnetic resonance imaging and CT scan show periventricular calcifications, cortical tubers and sometimes, giant cells tumours.

Sturge–Weber syndrome is a sporadic disorder characterized by pial angioma, overlying the parieto-occipital cortex. Unilateral facial angioma of variable distribution and extension is usually associated. Patients may have epilepsy (70–90%), episodes of transitory hemiparesis, which can be postictal or vascular, acquired hemiplegia subsequent to early status epilepticus (26–31%), hemianopia (25%) and a variable degree of mental retardation (54%).

Epilepsies and epileptic syndromes undetermined as to whether focal or generalized

Epilepsies with both partial and generalized seizures

Neonatal seizures

These have a peculiar clinical presentation. Partial seizures are polymorphous and they can sometimes remain undiagnosed because of discrete clinical expression. Generalized tonic seizures observed in intraventricular hemorrhage and myoclonic seizures typical of early onset myoclonic encephalopathy, bear a poor prognosis.

Severe myoclonic epilepsy of infancy (SME)

This has its onset during the first year of life in seemingly normal children with prolonged unilateral clonic or GTC seizures, frequently fever related (Dravet et al., 1992b). Subsequently, partial seizures, atypical absences and a myoclonic syndrome with distal multifocal and generalized jerks, appear. Tonic seizures are never observed. EEG, normal at onset, is later characterized by generalized spike-and-wave discharges, and multifocal abnormalities. Twenty per cent of patients are photosensitive. Developmental delay becomes progressively apparent and the prognosis is poor.

Epilepsy with continuous spike-and-waves during slow wave sleep (CSWS)

CSWS onset is during the school age period (Tassinari et al., 1992b). Three different periods are observed in its evolution:

(i) Age at onset is usually around 4. Children initially present rare nocturnal partial motor or GTC seizures.
(ii) Around 8 years old intractable atypical or atonic absences appear and are associated with mental stagnation or deterioration. Focal atonic events in the form of epileptic negative myoclonus can also be observed (Guerrini et al., 1993). Sleep EEG recordings contain continuous spike-and-wave discharges that cover most of the slow-wave sleep.
(iii) Finally, around 12 years old epilepsy and CSWS remit and cognitive performances improve, although some children can continue to manifest cognitive deficit according to the duration of the disorder.

CSWS bears some similarity with Landau–Kleffner syndrome, BECTS and atypical benign rolandic epilepsy. AEDs are not constantly effective against CSWS. Benzodiazepines, valproic acid and ethosuximide can sometimes be beneficial. Carbamazepine should be avoided in that it can make seizures worse. Steroid treatment is the most effective. Children with CSWS should be carefully evaluated with serial sleep EEG recordings and neuropsychological tests.

Landau-Kleffner syndrome (LKS)

LKS is characterized by acquired aphasia and multifocal spike or spike-and-wave prominent in the temporo-parietal regions (Gordon et al., 1997). Seizures of variable semiology are present in 75–85% of patients, usually remitting by puberty. Aphasia starts as verbal auditory agnosia frequently associated with hyperkinetic behaviour. LSK can be misdiagnosed as acquired hypoacusia or autistic disorder at this stage. A cause–effect correlation between EEG abnormalities and aphasic disorder is difficult to assess fully and remains open to debate. Aphasia can have a variable course. Although AEDs (valproic acid, ethosuximide, benzodiazepines) or steroids may suppress EEG abnormalities, subsequent language recovery can be delayed or incomplete.

Epilepsy without unequivocal generalized or focal features

This diagnostic category includes all syndromes for which clinical and neurophysiological data are insufficient to establish whether the epilepsy is focal or generalized. A typical example is provided by GTC seizures occurring during sleep.

Special syndromes

These syndromes are due to a transient and reversible epileptogenic conditions also known as situation-related

seizures. They are not epilepsies *stricto sensu*, but seizures can relapse when the patient is re-exposed to the provoking factor.

Febrile convulsions (FC)

FCs are convulsive epileptic seizures that appear during a febrile illness, not associated to intracranial infection or other defined causes of seizures, in a normal child between age 3 months and 5 years. FCs are common and affect between 2 and 5% of children below age 5. Epilepsy will develop in only 5% of children who had FC (O'Donohoe, 1992).

Simple FCs

These appear after the first year of life and bear an excellent prognosis. They are characterized by bilateral clonic or tonic–clonic movements, lasting less than 15 minutes, not relapsing during the same febrile illness and not followed by postictal deficit. Seizures take place within 24 hours from fever onset at peak temperature or during defervescence. EEG is not useful in evaluating children with simple FCs. Temperature control is the best prophylaxis. Chronic AED treatment (valproic acid) should be reserved for children with more than three relapses. Subsequent epilepsy is observed in less than 2.4% of cases.

Complicated FCs

These appear within the first year of life in children who frequently have a family history of epilepsy. They represent a febrile status epilepticus characterized by lateralized, prolonged (>15 min), clonic seizures, often relapsing during the same febrile illness and followed by postictal paresis lasting less than 48 hours. An acute treatment with intrarectal (i.r.) diazepam should be used to stop the seizures. A complete neurologic work-up including EEG lumbar puncture and neuroradiologic tests, should be considered if an intracerebral infection is suspected. Prophylactic AEDs should be started and continued for at least 2 years after the last FC. Epilepsy can develop in up to 50% of children particularly if prolonged relapsing seizures followed by postictal paresis are observed. The risk of developing mesial temporal lobe epilepsy with hippocampal sclerosis is proportional to FC duration.

Isolated seizures/isolated status epilepticus

These can appear in a patient without a family history of epilepsy and can remain an isolated event, not developing into an epilepsy syndrome. Isolated simple partial seizures can frequently be observed in adolescents.

Seizures due to acute metabolic or toxic factors

They are very frequent and do not need chronic AED treatment. A list of different metabolic and toxic factors responsible for occasional seizures is supplied in Table 74.5.

Status epilepticus

Hannah Cock and Simon Shorvon

Institute of Neurology, The National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

Status epilepticus (SE) is defined traditionally as a condition in which a seizure continues for 30 minutes or more, or in which repeated seizures recur within 30 minutes without the patient regaining consciousness (Dodson et al., 1993). There has been recent debate concerning the proposition that this time interval be shorted to 20 minutes or even 5 minutes, in view of the physiological changes in prolonged seizures, but in normal clinical practice, 30 minutes is considered a useful guide. Any type of seizure can evolve into SE, but classification has been controversial, needing to encompass not only seizure type, but also the observed variations with age, underlying etiology and pathophysiology. A classification proposed by Shorvon (1994), and revised in 2000 is given in Table 75.1. This chapter will concentrate on the syndromes that cross all ages and a detailed discussion of specific neonatal/childhood syndromes will not be included here.

Epidemiological observations about SE have been complicated by inconsistent definitions and different classifications. Furthermore until recently most published data was restricted to tonic–clonic SE, and even here incidence and prevalence figures are of doubtful accuracy. Up to 10% of all epilepsy patients may experience status epilepticus at some point (Lennox, 1960), with a higher incidence in children, those with mental retardation and patients with structural pathology, especially in the frontal lobes. Typical estimates of the annual incidence of convulsive SE range between 18 and 28 cases/100 000 population, (Walker, 1998), with peaks in childhood and old age. However the number of cases of non-convulsive status, often unrecognized particularly in the mentally handicapped population, is probably far higher (Shorvon, 1994).

Table 75.1. Classification of status epilepticus

Status epilepticus confined to early childhood
Neonatal SE
SE in specific neonatal epilepsy syndromes
Infantile spasms
Status epilepticus confined to later childhood
Febrile SE
SE in the partial epilepsy syndromes
SE in myoclonic–astatic epilepsy
Electrical SE in slow wave sleep
Landau–Kleffner Syndrome
Status epilepticus occurring in childhood and adult life
Tonic–clonic SE
Absence SE
Epilepsia partialis continua
SE in coma
Specific forms of SE in mental retardation
Syndromes of myoclonic SE
Simple partial SE
Complex partial SE
Status epilepticus confined to adult life
De novo absence SE of late onset

Note:
Key: SE = Status epilepticus
Source: From Shorvon (2000).

Mechanisms/pathology

The neurophysiological processes which initiate status have been extensively studied in animal models of both focal and generalized epilepsies, and are similar to those producing isolated seizures. They have been reviewed elsewhere (Shorvon, 1994, pp. 139–51), and will not be covered here.

The consequences of status epilepticus, particularly with respect to neuronal damage, have also been much studied, both in man and animal. The hippocampus seems to be especially susceptible to even focal seizure activity, with a characteristic pattern of cell death involving pyramidal cell loss (mainly in the CA1 and CA3 regions), and relative sparing of the CA2 interneurons and dentate granule cells. This is the same pattern of cell death seen in patients with chronic temporal lobe epilepsy and hippocampal sclerosis. Furthermore, both in humans and animal models, status epilepticus can be followed by the development of chronic epilepsy. Such observations have fuelled a debate on whether such changes are the cause or effect of seizures. In addition to hippocampal changes, damage has also been observed in other regions including certain regions of the cerebral neocortex, specific nuclei of the thalamus, and in the cerebellum. These findings are not specific, and have also been documented following, for example, global ischemia or hypoxia, but as in animal models at least they occur in the absence of systemic metabolic upset, or extrinsic toxins (Sloviter, 1983; Tuunanen et al., 1999), and there seems little doubt that they can result from seizure activity *per se*. The mechanism of cell death is probably excitotoxic, involving excessive glutamatergic postsynaptic stimulation and consequent activation of cytoplasmic and mitochondrial pathways including those involved in calcium homeostatis, free radical production and apoptosis (for general reviews on excitotoxic cell death see Sattler & Tymianski, 2000; Kroemer & Reed, 2000). In the epilepsy field there is much work currently under way attempting to unravel the intricate mechanisms of cell death, but those already published support this principle (Cock et al., 2002).

To what extent this cell death and consequent altered circuitry contributes to epileptogensis remains uncertain, but it presumably does contribute to the morbidity observed in some cases following prolonged convulsive status which is further discussed below. In this context alone an increased understanding of the mechanisms of damage following status, and clearer indications as to which forms carry most risk, with the potential to develop neuroprotective strategies, would be of clinical benefit.

Other well-documented changes following status include altered neurotransmitter levels and receptor properties, including both the major inhibitory (GABA) and excitatory (glutamate) pathways, as well as numerous other systems. Again, to what extent such changes are cause or consequence in status is uncertain. Interested readers are referred to the review by Shorvon (1994), pp. 139–74 and Alldredge and Lowenstein (1999).

Diagnosis and management

Some general principles apply to all types of SE, although it is in tonic–clonic SE that complications and significant morbidity/mortality are most often seen. As for any medical emergency for all patients presenting with SE the assessment and protection of cardiorespiratory function takes first priority. Particularly in convulsive status, hypoxia may be much worse than expected and oxygen should always be given. In tonic–clonic SE regular neurological observations, pulse, blood pressure and temperature reading should be taken, accompanied by ECG monitoring, oximetry, and regular measurements of glucose, electrolytes, creatine kinase, blood gases and pH. In all cases if there is any suspicion of hypoglycemia this should be treated, and baseline renal and liver function, calcium and magnesium, hematology and anticonvulsant levels should be recorded. Severe electrolyte disturbances may contribute to the SE and should be rectified where possible. Serum and urine and samples for toxicology screening, including alcohol, should also be taken for future analysis if the cause of the status is not apparent.

Where possible, the diagnosis of SE should be secure before commencing treatment as the drugs used are not without risks. Ideally this should include EEG, but in practice this is often not available in the acute setting and the diagnosis must be made solely on clinical grounds. The clinical and EEG features of the major SE types will be discussed separately in the following sections, but diagnostic difficulty most often arises in cases of non-epileptic attack disorder (NEAD), presenting with what appears to be tonic–clonic SE. Normal blood gases despite prolonged convulsions, irregular flailing limbs, opistothonus and pelvic thursting may alert the treating clinician to the possibility of NEAD, but none are reliable indicators and if there is doubt and EEG is not available cases should be treated as for SE.

In all cases, concurrent with the emergency management, investigations as to the cause of the SE should be initiated. Most cases of tonic–clonic SE occur *de novo*, without a prior history of epilepsy, in which case an acute cerebral event is usually responsible. Common causes include cerebrovascular events, cerebral tumours and cerebral infection, as well as acute toxic or metabolic disturbances. In people with known epilepsy, drug changes or intercurrent illness may be precipitors, or progression of the underlying neurological disease and SE is more common in symptomatic than idiopathic epilepsies. In patients with focal status epilepticus, either convulsive (epilepsia partialis continua) or non-convulsive (complex partial status), the incidence of underlying focal cerebral

abnormalities is high. Thus all patients not known to have epilepsy should have a full biochemical/toxicology screen, structural imaging (CT or if possible MRI), and if this is non-contributory CSF analysis. The latter should also be considered in known epileptics in the absence of any other clear precipitator. As well as potentially needing treatment in its own right, identification of the cause of SE will guide the clinician in decisions about long-term antiepileptic drug (AED) management. In people with known epilepsy, every effort to maintain therapeutic levels of regular AEDs should be made, with parenteral administration if necessary, and increased doses or the addition of new AEDs where indicated. In patients presenting *de novo* with SE this is generally accepted as an indication for long-term AED therapy, unless a clearly identified remediable cause has been identified, and maintenance AEDs should be commenced.

Tonic–clonic status epilepticus

This is the most commonly recognized form of status epilepticus. Many cases will be preceded by a premonitory stage of some hours during which seizure activity increases from its usual level. In patients with generalized epilepsies this may include progressive myoclonic jerking, or more subtle mental changes/confusion representing subclinical seizure activity, as well as an increase in the frequency/severity of the patient's usual seizure type. Other patients may have an abrupt onset. Most cases present with repeated discrete tonic–clonic seizures lasting 2–3 minutes without regaining consciousness in between seizures, but continuous convulsions can also occur. As the status develops, typically the tonic phase becomes prolonged, and the clonic jerking tends to become less pronounced, and finally ceases altogether. At this stage, designated subtle status epilepticus, the patient will be deeply unconscious and the diagnosis less clinically obvious unless a clear history of prior convulsions is obtained. Thus this diagnosis should be considered in patients found unconscious, even if no overt clinical seizure activity is seen, and EEG will usually be diagnostic.

Depending on the cause of the status, there may be additional focal neurological signs, or a focal onset to the seizures. Plantar responses are often but not always extensor, either unilaterally or bilaterally.

Associated with the seizure activity are a number of physiological changes, usually divided into Stage 1 (compensatory) and 2 (decompensated) (Walton, 1993), with transition into the second stage said to occur after about 30 minutes of continuous seizure activity, athough in clinical practice there is great variation. Early on, the seizure activity results in a greatly increased cerebral metabolic demand, which is met by physiological mechanisms to increase blood flow, oxygen and glucose supply. These include increased levels of circulating catecholamines, causing a rise in systemic, left atrial and pulmonary blood pressures, hypertension, and tachycardia. There may also be hypersalivation, hyperpyrexia, hyperglycemia, acidosis, cardiac arrythmias and incontinence at this stage, reflecting the profound autonomic changes. As the status progresses, however, the increased cerebral demands cannot be met, and cardiorespiratory functions may become overwhelmed and unable to maintain the homeostasis. Cerebral autoregulation fails and thus becomes dependent on systemic blood pressure. At the same time, cardiac pressures and blood pressure fall, confounded by increasing acidosis, endocrine changes, and often by drug therapy. Hypoxia is almost universal, and may be more significant than clinically suspected, with both brain and muscle creating huge demand at a time when spontaneous respiration may be compromised for many reasons including ventilatory muscle spasm, excess tracheobronchial secretions, respiratory obstruction or pulmonary edema. Other reported metabolic changes include rhabdomyolysis and myoglobulinuria, sometime severe enough to cause renal failure, disseminated intravascular coagulation, hypo- or hyperkalemia, hyponatremia, and hepatic failure. A leukocytosis in blood is usual, and may also be apparent in CSF, with cell counts of up to 100/mm^3 reported (Shorvon, 1994).

Any combination of complications may/may not be present in individual patients, but with such widespread physiological disturbance it is not surprising that tonic–clonic status epilepticus has a significant mortality and morbidity. Historical series report mortalities of up to 50% (Clark & Prout, 1903). However, even with modern treatments the mortality is probably still in the region of 5–10% based on a review of all published series in 1994 (Shorvon, 1994). Large clinical series often report higher figures (e.g. 35% in the 282 adult cases admitted to an ITU reported by Goulon & Lévy-Alcover (1985)) but as in this case often reflects a bias in the study population. In all series it is difficult to separate the contributions of the status itself from those of the underlying cause, and certainly the prognosis is better in idiopathic cases than those with known cerebral insults. In survivors, formal studies of long-term neurological and psychometric outcome are lacking. In children new motor deficits and mental impairments following status have been well documented, but again are difficult to separate from underlying causes. In adults, clinical experience is that permanent mental and personality deterioration, and/or motor deficits such as

ataxia or psychomotor slowing can certainly occur, but the extent or significance of the problem, and to what extent it reflects the status *per se* is hard to define.

The EEG in tonic–clonic status epilepticus usually starts with the classic EEG pattern of the discrete seizures, including flattening (desynchronization) at the onset, followed by a recruiting rhythm of about 10 Hz interrupted by bursts of high voltage slow activity in the clonic phase, and then ending with post-ictal slowing. As the status evolves however, the discrete seizures may merge, with waxing and waning of the amplitude and frequency of EEG rhythms, eventually resulting in continuous seizure activity. Later still, this may be punctuated with low voltage 'flat' periods, and in extremis no typical seizure activity may be seen with only periodic lateralized epileptiform discharges (PLEDS) visible on a flat background (Treiman et al., 1990). However, individual cases vary in their progression through these stages, and the underlying cause, systemic physiological changes and drug treatment may modify the EEG considerably.

Treatment of tonic–clonic SE is a medical emergency, and as outlined previously must include general measures and the prompt recognition and appropriate management of systemic complications. A treatment protocol is recommended in order to facilitate prompt treatment, as suggested in Fig. 75.1. Parenteral drug treatment during the premonitory or early stages of status epilepticus, usually with a benzodiazepine, will often abort the seizures, and should be given as early as possible. Commonly used drugs include rectal or intravenous diazepam, intravenous lorazepam, or rectal, buccal or intramuscular midazolam. All are highly effective, although lorazepam has the advantage of a longer duration of action and less cardiorespiratory depression (Appleton et al., 1995).

Once seizures have continued for more than 30 minutes, or if initial treatment fails, the patient should be regarded as having entered the stage of established SE. First-line treatment alternatives in these circumstances include subanesthetic doses of barbituates, phenytoin or fos-phenytoin as outlined in Figure 75.1. All require intravenous loading, followed by repeated oral or i.v. supplementation. Benzodiazepine infusions have previously been used in established status, but with the possible exception of midazolam, should be avoided as they can result in dangerous cardiorespiratory depression.

Experience with midazolam, and with valproate which has also been proposed as a suitable treatment, is currently limited. In most patients, if these measures fail, or if seizures have continued for more than 60–90 minutes, full anesthesia and intensive care admission is indicated. Ventilatory support is also indicated at this stage to avoid dangerous hypoxia as previously discussed. The choice of anesthetic agent is controversial. Barbituates are potent antiepileptics and there is much experience with their use in SE, but have poor pharmacokinetic and pharmacodynamic profiles, often associated with hypotension and prolonged recovery. Newer agents such as propofol have received recent favour (Stecker et al., 1998), but there is as yet no good large comparative trial. Ideally, patients in refractory status should have EEG or cerebral function monitoring, to confirm abolition of seizure activity. Outside regional neuroscience centres, however, intermittent EEG recordings should be used as the minimum acceptable standard. Concomitant with the emergency treatment, once initial treatment is successful, in patients presenting *de novo*, chronic antiepileptic drug therapy should be introduced, and in existing patients medication must be reviewed to minimize the risk of recurrence. In patients who fail to respond to the above measures, which is unusual, a search for complicating factors must be made. These may include inadequate maintenance antiepileptic drug treatment, additional medical complications, failure to recognize or treat the underlying cause, or misdiagnosis (e.g. non-epileptic status)

Absence status

Traditionally, absence status has been divided in to typical and atypical cases, although each have considerable clinical and electrographic overlap. Nonetheless, this distinction is probably still valid as each has a different response to treatment and prognosis. More confusing is that much of the literature has addressed 'non-convulsive status', including cases of non-convulsive complex partial status which certainly is a different condition which will be covered in the next section.

Typical absence ('petit mal') status occurs in the setting of primary generalized epilepsy, and is probably relatively common occurring in up to 10% of patients in this group, especially children. Clinical features may range from only a slight clouding of consciousness or loss of concentration, through more marked impairment with a trance-like state, to profound obtundation or an 'epileptic stupor' (Roger et al., 1974). Motor features occur in about 50% of patients, including myoclonus, especially facial or eyelid, hippus, and atonia. Relative preservation of speech, in contrast to complex partial status, is not uncommon. Episodes may last hours or even days, and termination of the status with a tonic–clonic convulsion is very characteristic, but not universal. There may be precipitating factors such as menstruation, flashing lights, sleep deprivation, or medication

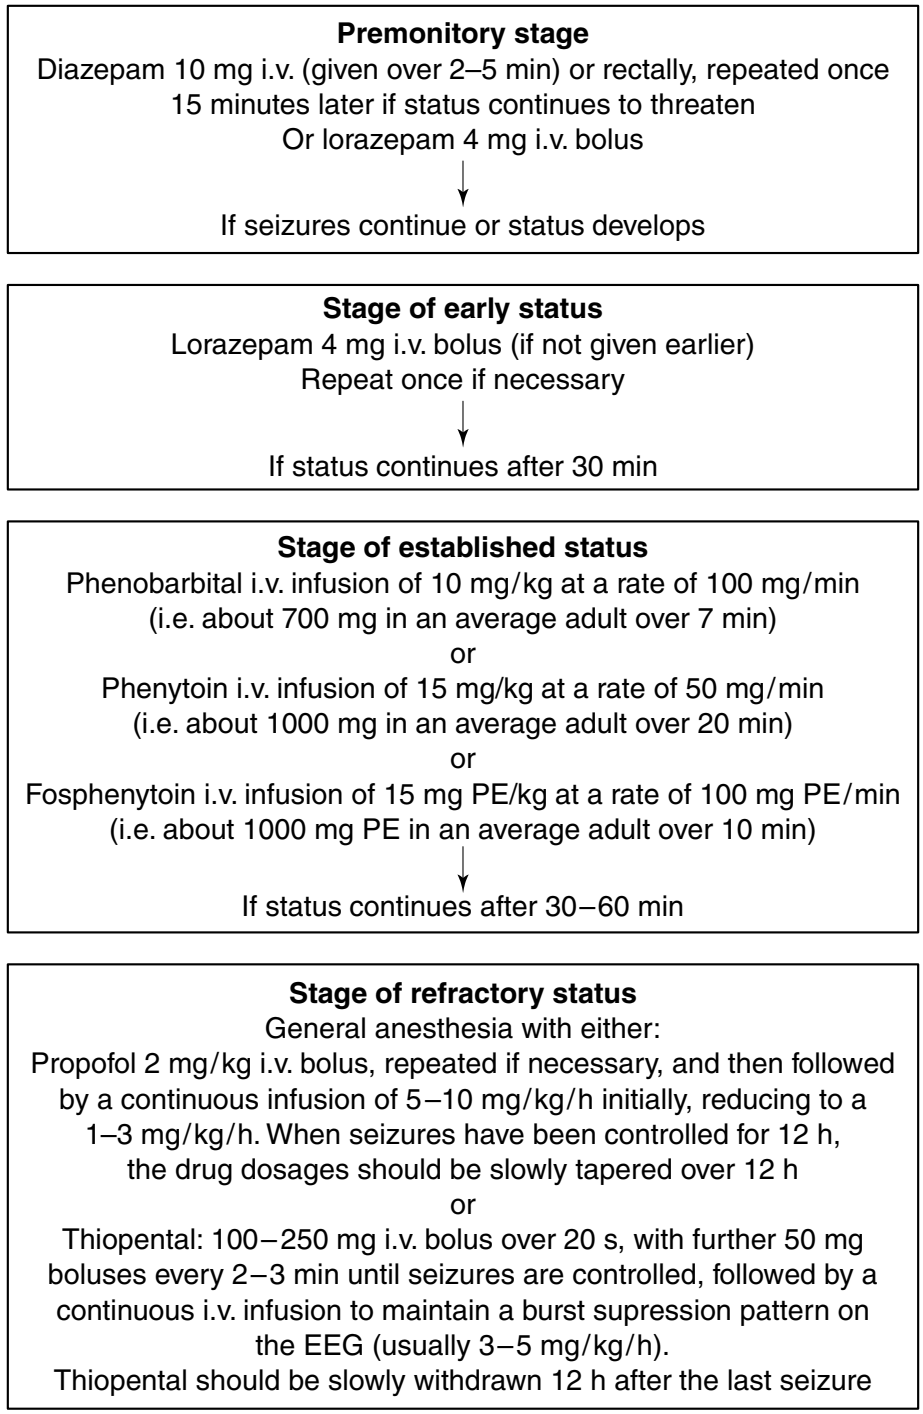

Fig. 75.1. Management of tonic–clonic status epilepticus.

changes (carbamazepine and tiagabine seem to be particular provokers), or the status may be spontaneous anytime in the course of the epilepsy. There are also case reports of occurrence *de novo* during benzodiazepine withdrawal (Thomas et al., 1993). This seems to be particularly common in the elderly, and is often misdiagnosed as a stroke, dementia, or psychosis. Other precipitants include toxins such as radiographic contrast media (Obeid et al., 1988).

Atypical absence status occurs largely in patients with secondarily generalized epilepsy such as the Lennox–Gastaut type, but may be clinically indistinguishable from that described above. However automatisms including facial grimacing, and even ambulatory fugues may occur, together with incontinence, pseudoataxia and pseudodementia. In this population of patients, who are often also significantly learning disabled, diagnosis in subtle cases, and differentiation from non-convulsive complex partial status, can be difficult. Confusion with psychotic, behavioural or affective changes are more suggestive of the latter, contrasting with the fluctuating confusional state with myoclonus characteristic of absence status (Rohr-Le Floch et al., 1988).

The diagnostic EEG pattern is continuous or almost continuous bilateral synchronous symmetrical spike-wave activity, classically at 3 Hz, with little or no reactivity to sensory stimuli. In atypical cases, other frequencies from 1.5–6 Hz have been described, and sometimes prolonged bursts of spikes, generalized periodic triphasic sharp waves or polyspike and wave may be seen. However, overall there is a poor correlation between clinical features and the EEG pattern.

Both forms of absence status are usually rapidly terminated by intravenous benzodiazepines such as diazepam or lorazepam. Rarely additional valproate or phenytoin may be needed, but all cases should have maintenance therapy (usually valproate or ethosuximde in primary generalized cases) optimized, unless a clear precipitating reversible cause has been identified. The prognosis for patients, even with repeated prolonged episodes of typical absence status prior to the advent of modern therapies, appears to be very good, with no deaths of long-term morbidity reported (Krumholz, 1999). The prognosis for atypical cases is less clear, particularly given the potential confusion with complex partial status which certainly has a worse prognosis, and because many atypical cases occur in association with refractory seizures of other types confusing the picture. In syndromes such as Lennox–Gastaut, whether episodes of atypical absence status cause cerebral damage, or whether both are due to the underlying encephalopathy is undetermined.

Non-convulsive simple partial status

Non-convulsive simple partial status is less common than the convulsive form (epilepsia partialis continua p. 1278), and very varied in clinical form depending on the focus. Clinical features in reported cases with electrographic confirmation include oculoclonic status epilepticus (nystagmoid status), prolonged ictal paralysis, complex visual hallucinations, prolonged sensory symptoms, or specific cognitive defects (for review, see Shorvon, 1994, pp. 110–16). Prominent psychic symptoms such as fear may also occur, but are rare in isolation. The ictal EEG changes, usually include spikes or spike-wave paroxysms in the appropriate neocortial or mesial temporal sites, with considerable individual variability in the frequency and degree of spread. Attacks of simple partial status are usually self limiting, or may occur as prolonged auras terminating in a convulsive or complex partial seizure. This form of status rarely requires intravenous therapy, and should be managed as with any partial epilepsy. Attacks may be recurrent, however, and relatively resistant to conventional treatment, particularly in the presence of an underlying focal structural abnormality. There is uncertainty about whether simple partial status results in secondary cerebral damage, but none the less in such cases with structural pathology and distressing symptoms, or additional more severe seizure types, surgical treatment should be considered and may be very effective (Manford & Shorvon, 1992).

Complex partial status

Complex partial status has suffered from problems of definition and classification perhaps more than any other type, is most likely much underdiagnosed, yet arguably the commonest form of status encountered in clinical practice. The most encompassing definition is probably that suggested by Shorvon in 1994: ‘a prolonged epileptic episode in which fluctuating or frequently recurring focal electrographic epileptic discharges, arising in temporal or extratemporal regions, result in a confusional state with variable clinical symptoms’. Others have tried to be more prescriptive, for instance requiring a clear cyclical clinical evolution or specific EEG changes (Delgado Escueta & Treiman, 1987). Although such cycling between unresponsive and partially responsive states is characteristic, and contrasts with absence status, numerous case reports and clinical observations suggest it may only be present for part of the episode, or indeed not at all, and any definition must reflect this.

Confusion is the cardinal and essential clinical feature of complex partial status, of variable severity, but can be

associated with a huge variety of other signs. There may be alterations in posture, convulsive movements or tonic spasms, particularly adversion of the head and eyes, and occasionally adversion of such significance that the patient walks in circles, occurring intermittently throughout the episode. Some degree of expressive language difficulty is usual, and a motor aphasia is not uncommon. There may also be autonomic disturbances such as pupillary dilatation or even fever. Behavioural changes, ranging from agitation or excitation through to severe psychomotor retardation, and psychotic or autistic symptoms such as delusions, hallucinations, paranoia or perseveration may also occur. Motor features, however, are rarely as marked as they are in individual seizures, and in cases with prominent psychic phenomena this may lead to a psychiatric misdiagnosis. The possibility of complex partial status should always be considered in confused patients where other medical causes have been excluded, particularly if there are psychiatric/motor features, however subtle.

The EEG findings in complex partial status are extremely varied. Treiman and Delgado-Escueta (1983) suggest diagnostic features should include bimedial temporal or lateralized temporal 8–20 Hz spikes, alternating with one of three patterns: low voltage fast activity with bursts of diffuse slow, rhythmical bilateral diffuse spike or slow waves, or anterior temporal spikes on a normal background. This cycling EEG pattern may certainly be seen in some patients, particularly those with clear clinical cycling, but equally other widespread or focal spikes or spike slow-wave paroxysms and episodes of desynchronization may be observed. In some patients the ictal scalp EEG may differ little from the interictal pattern. Furthermore, although a clinical and EEG response to intravenous benzodiazepines may be demonstrable, this is non-specific and can also be seen in the other non-epileptic confusional states. SEEG has provided more consistent information, with a mixture of discrete and continuous focal activity, but is not practical from a diagnostic perspective. Such studies have however counteracted the prior supposition that most cases of complex partial status were temporal in origin, with most documented reports demonstrating an extratemporal onset, e.g. Williamson et al. (1985).

To what extent complex partial status contributes to cerebral damage is controversial. On the one hand, animal models of focal limbic status epilepticus (Sloviter, 1983), without the metabolic and systemic features associated with convulsive status, show considerable neuronal death after even brief periods of seizure activity (Tuunanen et al., 1999). In keeping with this, markers of neuronal damage such as neuronal specific enolase are elevated in patients after non-convulsive status (DeGiorgio et al., 1996), and postmortem studies have documented neuronal damage (Fujikawa et al., 2000), although in reality it is difficult to ascribe this to seizure activity and not the underlying cause with any certainty. In contrast, death does not occur, and clinical studies have rarely reported significant neurological deterioration, sometimes even following months of continuous seizure activity. Further work is required to resolve this issue, which also has important implications for management. Thus the urgency with which complex partial status should be treated remains uncertain. In most cases intravenous benzodiazepines will be effective, followed by oral maintenance therapy, although high doses of both may be needed. Carbamazepine, phenytoin or phenobarbitone are the drugs of choice for oral therapy, although any of the newer drugs may also tried. In truly intractable cases, despite high doses of multiple anticonvulsant drugs, whether general anesthesia is justified in the hope of 'switching off' the seizure activity and regaining control is controversial. In clinical practice this may be effective, but only temporarily so with seizure activity recurring as anesthesia is withdrawn. As for other focal status syndromes, the search for a possible treatable or resectable underlying cause should be intensified in such cases and offers the best prognosis.

Myoclonic status

The clinical features and management of myoclonic status vary according to etiology, and are best considered separately as follows.

Myoclonic status in coma

This is undoubtedly the most frequently encountered form, most commonly occurring with anoxic encephalopathy such as following cardiorespiratory arrest (Young et al., 1990). By definition the patients are unconscious, and typically the myoclonus starts within hours of the insult and consists of irregular asynchronous small amplitude jerking of the facial muscles, and to a lesser extent the limbs. Stimulus sensitivity to touch or sound is not uncommon. Other seizure types including generalized tonic–clonic seizures also occur. It is important to distinguish myoclonic status in coma from the postanoxic action myoclonus (Lance & Adams, 1963). The EEG most commonly reveals a burst–suppression pattern, although generalized periodic complexes, and spike-wave discharges have also been observed. The myoclonus is usually treatment resistant, and aggressive management does not alter the eventual outcome. The presence of myoclonic status in this setting is

a universally poor prognostic indicator (Wijdicks et al., 1994), and management decisions should reflect this.

Myoclonic status in primary generalized epilepsy

This is rare, and may reflect changes in therapy. The jerks are synchronous and bilateral, predominantly proximal and occur in preserved consciousness at a rate of 3–6 Hz, usually in a patient known to have PGE. EEG shows bilateral diffuse spike discharges preceding each jerk, often with an anterior predominance. The status usually responds to intravenous benzodiazepines (e.g. diazepam 10 mg or lorazepam 4 mg), and the prognosis is very good. Increases in maintenance therapy (usually valproate or lamotrigine), or the addition of clobazam should be considered if there is no clear precipitant.

Myoclonic status in the progressive myoclonic epilepsies

Myoclonic status is not uncommon, particularly in the later stages, in patients with PME. This rare heterogeneous group of disorders typically present in childhood or young adult life with a combination of seizures (including myoclonus) and ataxia on a background of general cognitive and motor decline (Berkovic et al., 1986). There are numerous mainly genetic causes, and all are relentlessly progressive with only symptomatic treatment available. All such patients should be investigated in a neuroscience centre and a diagnosis made where possible, allowing appropriate genetic counselling. The myoclonus may be generalized or focal, and usually occurs with preserved consciousness except in the very late stages of the disease. EEGs are always abnormal, with diffuse background abnormalities in addition to frequent spike-wave discharges. As with other forms of status, benzodiazepine therapy is the first choice in patients presenting acutely, and for recurrences either valproate, clonazepam or clobazam may help. Zonisamide (not yet licensed in the UK) has also been reported to be of benefit in these notoriously resistant patients (Kyllerman & Ben-Menachem, 1998), although further experience is awaited. The long-term prognosis in this group of disorders is poor, but every effort to control seizures should be made in order to improve quality of life.

Epilesia partialis continua

EPC is a form of simple partial status epilepticus, usually arising from a focus in the prefrontal motor cortex. It may develop at any age and has a broad spectrum of underlying causes. The definition of Obeso et al. (1985) is the most widely accepted: 'spontaneous regular or irregular clonic muscle twitching of cerebral cortical origin, sometimes aggravated by sensory stimuli, confined to one part of the body and continuing for hours, days or weeks.' Any muscle group can be affected, though distal involvement is more common than proximal. Typically, there would be persistent jerking of a hand or foot, with cocontraction of antagonist and agonist muscle groups, with preserved consciousness. The jerking usually persists through sleep, although it may lessen in amplitude.

Up to 50% of cases, particularly in children, are caused by Rasmussen's encephalitis, a chronic inflammatory process of unknown etiology affecting one hemisphere and presenting with a progressive hemiplegia, seizures including EPC, and sometimes cognitive decline. However any pathology affecting the rolandic cortex can be associated with EPC including stroke, structural lesions, infections and in some cases metabolic disorders including not-ketotic hyperglycemia, hepatic encephalopathy, and rare disorders including the mitochondrial diseases. Despite the broad range of potential causes, EPC is rare with an estimated prevalence of less than 1 in a million in the UK (Cockerell et al., 1996).

All patients with EPC should have routine metabolic screening, and modern imaging, preferably by MRI to look for structural pathology. Routine EEG recordings may be normal or reveal only non-specific abnormalities, although if the focus is superficial spike discharges may be visible. More commonly specialized investigation is required to confirm a cortical origin, such as jerk-locked (using concomitant EMG) back-averaging of EEG recordings. Abnormally enlarged SSEPs from the affected limb help to confirm cortical pathology, and more recently functional imaging studies have sometimes demonstrated focal abnormalities where other investigations have been normal, though these are still largely research tools.

EPC is notoriously pharmacoresistant, and single case reports in the literature of successful treatments are difficult to interpret as a proportion of cases spontaneously remit after variable time periods. However EPC is not a medical emergency, and depending on the location, frequency and amplitude of the jerking, EPC may continue unabated for years in individual patients, apparently causing more inconvenience than harm. In acute onset cases parenteral therapy with benzodiazepines, e.g. i.v. diazepam, lorazepam, phenytoin, or phenobarbitone, may abort the episode, but it often recurs on cessation of treatment. The same applies to the use of general anesthesia although this may sometimes be required in very intractable cases where the patient is getting exhausted. Most of the conventional antiepileptics have also been tried, with carbamazepine, clonazepam, valproate and phenytoin

reported to be of limited benefit (Cockerell et al., 1996). Focal resection of the underlying lesion, or in cases of Rasmussen's hemispherectomy (Anderssen, 1991), carries the best prognosis in terms of seizure control, but given the location of the focus often leaves permanent neurological deficit. Patients should be referred to specialist centres for evaluation.

Assessment of the patient with epilepsy

John S. Duncan

National Society for Epilepsy and Institute of Neurology, Queen Square, London, UK

Is epilepsy the diagnosis?

Differential diagnosis

Of patients referred to 'first seizure clinics' generally less than 30% are considered to have had an epileptic seizure. Further, 15–20% of patients referred to specialist clinics with refractory epilepsy have another condition as the cause of their episodes (Smith et al., 1999). The history from the patient and any witnesses to the attack is most crucial. The patient will have only a limited recall of events and can only summarize what witnesses related. A videotape record often provides invaluable objective data on the nature and sequence of events in a seizure (Samuel & Duncan, 1994; Rugg-Gunn et al., 2001).

The differential diagnosis of seizures varies with the predominant clinical features of the presenting symptoms (Table 76.1). Often, however, these occur in combination, with one or other being the differentiating feature (e.g. loss of awareness with either drop attacks or psychic phenomena).

Table 76.1. Main categories of episodic symptoms that may be caused by epilepsy

Loss of awareness
Generalized convulsive movements
Drop attacks
Transient focal motor attacks
Transient focal sensory attacks
Facial muscle and eye movements
Psychic experiences
Aggressive or vocal outbursts
Episodic phenomena in sleep
Prolonged confusional or fugue states

Table 76.2. Key features of syncopal attacks

Evidence of precipitant factors
Lightheadedness, dizziness, nausea
Pallor
Ringing in the ears
Bilateral loss of vision
Collapse
Some twitching movements may occur
Rapid recovery when supine
Sweating, subsequent flushing

Loss of awareness

The three main causes of loss of awareness are: syncope, epilepsy and cardiac arrhythmias. Microsleeps (very short daytime naps) may occur with any cause of severe sleep deprivation or disruption. Other causes of diagnostic confusion are much rarer and include: hypoglycemia or other intermittent metabolic disorders, transient cerebral ischemia, or lesions affecting the brainstem, or CSF circulation. Syncope (Table 76.2) is considered in more detail in Chapter 52.

Epilepsy

Seizures that may present with loss of awareness include absences, complex partial, tonic or atonic seizures. Typical absences involve arrest of activity, reduced or lost awareness, eyelid blinking or twitching, and sometimes small myoclonic facial or limb jerks, or brief facial automatisms. Typical absences are usually brief but frequent, often occurring many times per day. There may be other associated seizure types, such as myoclonic jerks on waking. The EEG changes are characteristic. 'Atypical absences' are usually associated with mental retardation and other

seizure types, and are often more prolonged. Atonic seizures usually give rise to drop attacks but may appear to cause blank spells if the patient is sat or laying down and so cannot fall. Complex partial seizures may cause loss of awareness with few other features. Enquiry must be made for associated psychic or motor phenomena that may raise the possibility of a seizure disorder.

Transient cardiac arrhythmias may cause episodes of abrupt loss of awareness. There are often prodromal features similar to those seen with simple syncope, as well as palpitations, chest pain, shortness of breath. Stokes Adams attacks due to transient complete heart block are abrupt and short with rapid loss of consciousness. Apparently syncopal features are followed by rapid collapse and sometimes secondary anoxic seizures. Usually the attacks last for less than 1 minute. Sometimes the lack of cardiac output is due to short episodes of ventricular tachycardia or fibrillation. Prolongation of the QT interval may lead to such events (Pacia et al., 1994). There is a high risk of sudden death. The resting ECG often shows some evidence of heart block or bundle branch block. Cardiac valve disease, especially mitral valve prolapse and aortic stenosis may also present with episodic loss of awareness due to fluctuating cardiac output or associated arrhythmias. Aortic stenosis and hypertrophic cardiomyopathy is especially prone to present with episodes of sudden collapse with loss of awareness during exercise. Patients with unexplained blackouts require cardiac evaluation, with ECG, 24-hour ECG tape, chest radiograph, echocardigram and if events are infrequent an implantable ECG loop recorder.

Microsleeps

Sleep deprivation may lead to brief day-time naps, or microsleeps, sometimes lasting for only a few seconds. The most important cause is obstructive sleep apnea. This results in chronic daytime hypersomnolence that may be manifest as daytime naps. Rarely narcolepsy can present with short periods of suddenly falling asleep during the day-time that are misinterpreted as brief epileptic attacks of loss of awareness.

Panic attacks

Panic attacks usually present with feelings of fear and anxiety, associated with autonomic changes and hyperventilation, with lightheadedness, paresthesia, carpopedal spasm, twitching, blurred vision, and nausea. Occasionally these preludes may be forgotten, and attacks present with loss of awareness. Often there is a clear precipitant, such as a particular situation, or the recall of a previous distressing experience. None of these features is consistent, however, and differentiation from epilepsy can sometimes be difficult.

Hypoglycemia

Hypoglycemic attacks causing loss of consciousness are extremely rare except in patients with treated diabetes mellitus. Occasional cases are due to insulin secreting tumours. In these there may be a history of a missed meal prior to the attack and previous weight gain due to increased appetite. The attacks are usually preceded by autonomic features (tachycardia, sweating) and light headedness and may include features such as mood change, irrational behaviour, or involuntary movements (Winer et al., 1990).

Non-epileptic attack disorder

The diagnosis of non-epileptic attack disorder (NEAD), involves both the exclusion of organic causes, and identifying positive phenomena of this entity (Meierkord et al., 1991). Typically episodes of NEAD fall into two broad types:

(i) attacks involving motor phenomena
(ii) attacks of lying motionless.

The latter are often prolonged, continuing for several minutes or sometimes hours. Such behaviour is very rare in epileptic seizures: there will nearly always be other positive phenomena in epileptic attacks that last for more than a few minutes. The sequence of events of NEAD is usually different to that of epileptic attacks (Table 76.3). They may slowly wax and wane. There is often excess salivation but cyanosis is extremely rare. During attacks patients may resist examination, and screw up their eyes if attempts are made to open them and if their own hand is held above their face and then released, the hand deviates to one side, missing the face. If the patients are examined they may show directed violence. Urinary incontinence is uncommon, but may occur, as can self-injury. Recovery is variable and may be much quicker than expected from the duration of the attack. Patients may respond, often claiming to have some recall of things that were said to them during the attacks, and may become tearful after the attacks. The longer the duration of such episodes the less likely they are to be epileptic.

Patients with NEAD often have a history of abnormal illness behaviour. Non-epileptic attack disorder is commoner in females than males, and usually commences in adolescence or early adulthood. Occasionally, there is an obvious secondary gain, but usually the psychological basis is more complex. A history of sexual abuse is common, but this may be coincidental and is not that rare in patients with epileptic seizures. Similarly there may be previous overt psychiatric illness. Attacks are usually resistant to antiepi-

Table 76.3. Differentiation of epileptic seizures and non-epileptic attack disorder (NEAD)

	Epileptic attack	NEAD
Precipitating cause	Rare	Common, emotional and stress related
When alone or asleep	Common	May be reported
Onset	Usually short	May be short or over several minutes
Aura	Various, usually stereotyped	Fear, panic, altered mental state
Speech	Cry, grunt at onset; muttering, words in automatisms	Semi-voluntary, often unintelligible
Movement	Atonic, tonic; if clonic synchronous small amplitude jerks	Asynchronous flailing of limbs; pelvic thrusting; opisthotonous
Injury	Tongue biting, fall; directed violence rare	May bite tongue, cheeks, lip, hands, throw self to ground. Directed violence not uncommon
Consciousness	Complete loss in generalized tonic–clonic; may be incomplete in complex partial	Variable, often inconsistent with seizure type
Response to stimulation	None in generalized tonic–clonic; may respond in complex partial and postictally	Often reacts and this may terminate episode
Incontinence	Common	Sometimes
Duration	Few minutes	Few minutes, may be prolonged
Recovery	Depends on seizure type. Few minutes and more prolonged confusion	May be rapid or very prolonged

leptic drug treatment and this may lead to escalating dosages and iatrogenic complications. The diagnosis should be considered in anyone with prolonged drug resistant attacks. The most useful test is to record an attack with simultaneous EEG and video, but the feasibility of this depends upon their frequency and reproducibility. Videotapes of seizures may provide useful diagnostic data, and can be combined with 24-hour ambulatory EEG recordings (Samuel & Duncan, 1994). Some patients have both epileptic and non-epileptic attacks, but usually one of these types clearly predominates.

Generalized convulsive movements

Epilepsy

The convulsive movements usually last for a minute or so, and as the attack proceeds the jerking slows in frequency and increases in amplitude. There is often cyanosis, and irregular breathing followed by confusion, headache and sleepiness. When all or most of these features are present, there is little room for diagnostic confusion.

Syncope with secondary jerking movements.

People who faint often have small, myoclonic twitches of the extremities (Lempert et al., 1994). With prolonged cerebral hypoperfusion (e.g. due to preventing the subject lying flat) these may be more prominent, and become reported as 'a convulsion'. The myoclonic jerking is usually irregular, short lived and does not have a pattern which evolves in the same way as do the convulsive movements of a tonic–clonic seizure.

Primary cardiac or respiratory abnormalities presenting with secondary anoxic seizures.

In any patient presenting with a convulsion, the possibility of primary cardiorespiratory disease and secondary anoxic seizures should be considered. Stokes–Adams attacks are especially prone to cause confusion. Occasionally, syncopal features are followed by rapid collapse and sometimes secondary anoxic seizures.

Non-epileptic attack disorder

Non-epileptic attacks with prominent motor phenomena are commoner than those with arrest of activity. Movements are varied but often involve semi purposeful thrashing of all four limbs, waxing and waning over many minutes, distractibility or interaction with the environment, prominent pelvic movements and back arching (Table 76.3). Non-epileptic attacks may be difficult to differentiate from frontal lobe complex partial seizures, with bizarre motor attacks, some retained awareness and with quick recovery and no scalp EEG changes.

Table 76.4. Causes of drop attacks

Epilepsies
Secondary generalized tonic or atonic seizures (including startle-induced seizures and Lennox–Gastaut syndrome)
Cardiovascular
Syncope
Stokes–Adams attacks
Transient brainstem ischemia (vertebro-basilar insufficiency)
Movement disorders
Hyperekplexia
Steele–Richardson–Olzweski syndrome
Parkinson's disease
Multisystem atrophy
Paroxysmal kinesogenic choreoathetosis
Subcortical myoclonus
Other
Brainstem, spinal or lower limb abnormalities (e.g. Arnold–Chiari malformation, cervical disc disease, spinal angioma, cauda equina disease)
Third ventricle tumours
Vestibular
Cataplexy
Metabolic (e.g. periodic hypokalemia)
Non-epileptic attack disorder

Drop attacks

Any cause of loss of awareness may proceed to a sudden collapse or drop attack. Epilepsy, syncope and other cardiovascular disorders are the most common causes (Table 76.4).

Transient focal motor and sensory attacks

The commonest cause of transient focal motor and sensory attacks is epilepsy. In children and adolescents consideration should be given to tics and associated syndromes. Paroxysmal movement disorders are rare. Transient cerebral ischemia usually presents with negative phenomena. Tonic spasms of multiple sclerosis are usually seen once other features of the illness have become apparent, but may be a presenting feature.

Tics usually present with stereotyped movements in childhood or adolescence, sometimes restricted to one particular action but may be multiple. They can be suppressed voluntarily, although to do so leads to a rise in psychological tension and anxiety that is then relieved by the patient allowing the tics to occur. Repetitive tics and stereotypies are particularly common in the mentally retarded.

Transient ischemic attacks (TIAs) usually present with negative phenomena, although positive phenomena such as paresthesiae may occur. Involuntary movements can be seen with basal ganglia ischemia. Transient ischemic attacks may last for a few minutes, but may persist for up to 24 hours. TIAs are not usually stereotyped or repeated with the frequency of epileptic seizures, and are usually associated with features of vascular disease.

Benign rolandic epilepsy usually presents with seizures in childhood affecting the face, often with unilateral grimacing, hemicorporeal sensory and motor phenomena, or secondarily generalized seizures occurring in sleep. Focal motor seizures may cause twitching of one side of the face, although this may be bilateral due to the bilateral representation of the face in the primary motor cortex, that may be restricted to specific areas. Eye deviation may be seen with frontal, parietal or occipital seizures. Complex partial seizures may cause automatisms with lip smacking, chewing, swallowing, sniffing or grimacing, with amnesia and impaired awareness.

Psychic experiences

Intermittent psychic phenomena can be seen in partial seizures (especially of temporal lobe origin), migraine, panic attacks, transient cerebral ischemia, drug induced flashbacks, or with illusions associated with loss of a sensory modality as well as psychotic illnesses.

Aggressive or vocal outbursts

These are rarely epileptic in nature if they occur in isolation. They are especially common in adults and children with mental retardation (Donat & Wright, 1990). In this setting there is organic brain disease which could lower the overall seizure threshold. Care should be given to attempting to elicit other clinical features of epilepsy. EEGs are often abnormal because of the underlying brain disorder and, unless unequivocal, interictal changes are not in themselves strong support for a diagnosis of epilepsy in this setting. A forensic issue is the occurrence of violent, or other, crimes in patients with epilepsy, and the defence claim that the crime was committed in a state of automatism. Certain features are strong evidence against an epileptic basis to the attack (Table 76.5).

Episodic phenomena in sleep

Attacks occurring during sleep (Table 76.6) present particular diagnostic difficulties because they are often poorly witnessed, and the patient may have little, if any, recall of the event or the preceding circumstances.

Table 76.5. Features against there being epileptic basis to an aggressive attack

Absence of a prior history of epilepsy with automatisms
Premeditation and evidence of planning or preparation
Directed violence
Evidence of complicated and organized activity during the episode
Recall of events during the episode
Witness accounts not indicative of a disturbance of consciousness
Subsequent attempts at escape or concealment of evidence.

Prolonged confusional or fugue states

Epileptic seizures usually last for seconds or minutes. There may be confusion for many minutes, after generalised convulsions or complex partial seizures, but rarely more than an hour. Such episodes only present diagnostic difficulty if the initial seizure is unwitnessed or forgotten. The differential diagnosis of prolonged epileptic confusional states (non-convulsive status) includes: acute encephalopathy, non-convulsive status epilepticus, transient global amnesia, intermittent psychosis, hysterical fugue (NEAD).

Investigations to assess patients with epilepsy

The principal objectives of investigating new and chronic patients referred for evaluation are: (i) to clarify the diagnosis of epilepsy or non-epileptic attacks; (ii) to determine the nature of the seizure types and epilepsy syndrome; (iii) to identify the laterality and localization of partial seizure onset; (iv) to identify the etiology of the epilepsy; (v) to identify concomitant neurological, psychological, psychiatric and medical problems; (vi) to monitor the progression of the condition and the consequences of the epilepsy and its treatment.

Answers to these questions allow the formulation of a rational treatment plan, and the provision to the patient and their family of accurate information regarding their diagnosis, treatment and prognosis.

Electroencephalogram

Use and misuse of the electroencephalogram (EEG)

In the assessment of a patient with a seizure disorder the EEG is a useful test to address the following questions: Are there epileptiform changes to support the clinical diagnosis of epilepsy? Is the seizure disorder likely to be partial or generalized? Does the patient have photosensitivity? Is there evidence of an encephalopathy?

Table 76.6. Episodic phenomena in sleep

Normal physiological activity
Whole body jerks (hypnic jerks)
Fragmentary myoclonus
Periodic movements of sleep
Epilepsies
Frontal lobe seizures
Other partial epilepsies
Generalized convulsions
Sleep disorders
Pathological fragmentary myoclonus
Restless leg syndrome
Non-REM parasomnias
REM parasomnias
Sleep apnea

An EEG also helps to classify the type of epileptic syndrome, especially in childhood and adolescence, and virtually all such patients require an EEG to answer these questions.

In clinical practice it must be remembered that: a normal interictal EEG does not exclude epilepsy; the EEG is not specific or sensitive at diagnosing the presence or absence of underlying structural cerebral lesions; normal EEG variants may mimic epileptiform activity; all EEG changes need to be considered in the clinical context; with the exception of patients with idiopathic generalized epilepsy and 3 Hz spike-wave activity, the interictal EEG is a poor guide to seizure control or to the likelihood of seizure relapse in a patient who has become seizure free and in whom withdrawal of antiepileptic drugs is being contemplated.

EEG recording techniques

The routine EEG comprises 20–30 minutes recording during the awake state including overbreathing for 3 minutes and photic stimulation. Only 30–40% of patients with epilepsy show epileptiform discharges on a single wake record (Ajmone Marsan & Zivin, 1970).

A sleep EEG should be requested when the routine EEG is normal or borderline abnormal and further confirmation of the diagnosis or syndromic classification is required. Epileptiform changes are seen on a sleep EEG in 70–80% of patients with clinical epilepsy. About 50% of patients with unhelpful wake records show definite interictal epileptiform activity during a sleep record (Gastaut et al., 1991). Most of the additional yield occurs during drowsiness or light sleep rather than deep sleep.

Overnight sleep deprivation only marginally improves the yield, and there is the risk that significant sleep deprivation may trigger additional seizures. It may occasionally be helpful in suspected idiopathic generalized epilepsy if EEG confirmation is essential.

Ambulatory EEG

This allows the detection of generalized spike and slow wave discharges, infrequent interictal localized epileptiform discharges, and diagnostic screening of ictal events in patients with frequent paroxysmal attacks of unknown nature. Sixteen channels may be recorded digitally and the data reformatted and remontaged after acquisition. A push button marker may be used to identify the timing of events, but artefacts may be difficult to detect without simultaneous documentation of motor behaviour. Simultaneous videotape recording is useful, but precise electro-clinical correlation is not possible unless the EEG recorder and video recorder are time locked. Only definite EEG patterns should be considered to be of diagnostic importance.

Video–EEG telemetry

Video–EEG telemetry provides long-term monitoring of the EEG and time locked video of the patient. It is the most definitive method for the diagnosis of paroxysmal attacks and is feasible if episodes are occurring more than once per week or can be provoked. It is much easier to identify artefact than with ambulatory records, and the technology is more flexible and appropriate for presurgical assessment.

Normal EEG findings

The normal EEG evolves with age and varies between subjects. Posterior rhythms are relatively slow in infancy (typically 4 Hz at 6 months of age), increasing to 8 Hz by age 2–4 years and thereafter increasing further to the normal mature pattern of 8–12 Hz (alpha activity). These posterior rhythms are usually symmetric, and attenuate with eye opening or alerting. Posterior delta waves (2–4 Hz) may occur intermittently in adolescence or early adulthood (posterior slow waves of youth). Theta activity (5–8 Hz) is often seen in the central regions particularly with drowsiness. Low amplitude beta (15–22 Hz) activity is best seen anteriorly.

Important normal EEG variants may mimic epileptiform discharges (Klass & Westmoreland, 1985) and lead to erroneous support being given to a diagnosis of epilepsy.

Abnormal EEG findings

These are of three types: interictal epileptiform discharges, ictal electrographic activity, non-epileptiform changes.

Interictal epileptiform discharges

Interictal epileptiform discharges consist of spikes (duration 20–70 ms) or sharp waves (duration 70–200 ms), with or without associated slow waves. These may be localized, multifocal or generalized. Epileptiform abnormalities are seen in less than 1% of apparently healthy subjects without a history of epilepsy (Gregory et al., 1993). The false-positive rate is higher in patients with other neurological abnormalities. Lesions such as strokes and tumours may be associated with sharp waves or spikes without any clinical seizures. Skull defects may cause 'breach rhythms' (Cobb et al., 1979), sometimes producing apparent spikes or runs of rhythmic sharp activity mimicking a seizure, but are of no clinical significance.

Ictal electrographic patterns

An EEG recording taken during an epileptic seizure can take many forms, depending upon the seizure type and pathways of spread. They are usually sustained, rhythmic, clearly different from the interictal record and, at least in partial epilepsies, evolve in frequency and/or amplitude, sometimes being followed by flattening of the trace and/or slow activity. Simple partial seizures are often not associated with any change in the scalp EEG. Frontal lobe attacks often have prominent motor components that obscure the EEG, and there may be few evident changes.

Non-epileptiform EEG abnormalities

Non-epileptiform EEG abnormalities include asymmetry of amplitude or frequency, localized and generalized slow waves. Asymmetries of the background EEG activity may reflect areas of localized damage. Widespread or generalized slow waves suggest an encephalopathic process, including antiepileptic drug toxicity, and may also occur postictally.

EEG findings characteristic of epilepsy syndromes

Idiopathic generalized epilepsy

The key features are: generalized epileptiform discharges, often at 3 Hz, normal background and, often, photosensitivity. In contrast, EEGs of partial epilepsy commonly have focal or multifocal epileptiform discharges, abnormal background activity and rarely photosensitivity. Confusion can occur. Focal spikes may propagate to produce bilaterally synchronous discharges mimicking generalized epilepsy. This is most likely to occur with extratemporal epilepsy, especially if due to parasagittal lesions or cortical dysgenesis. EEGs in patients with idiopathic generalized epilepsy may contain focal discharges or show asymmetries (Grunewald & Panayiotopoulos, 1993). Occasional patients have both idiopathic generalized and partial epilepsy.

Photosensitivity is age dependent. In the peak age group of 7–19 years 10% of patients with newly presenting seizures show unequivocal photosensitivity on the EEG, with a female: male ratio of 3: 2, while it rarely presents at other ages (Fish et al., 1993). Photosensitive EEG responses have been classified by Waltz et al. (1992) into four categories: (i) occipital spikes; (ii) occipital spike and slow waves with spread to the parieto-occipital regions; (iii) occipital spike and slow waves with frontal spread; (iv) generalized spike and slow wave discharges.

Type 4 responses are the most common in patients with idiopathic generalized epilepsy, but may occur in progressive myoclonic epilepsies, metabolic disorders, and occasionally in occipital partial epilepsies.

EEG findings in partial epilepsies

EEG findings in partial seizure disorders reflect the site of onset and the etiology of the epilepsy. Foreign tissue lesions are likely to be associated with localized slow activity, while neocortical atrophic processes may be associated with a relative paucity of normal rhythms.

In temporal lobe epilepsy interictal spikes are usually maximum over the temporal or fronto-temporal regions. Even in patients with unilateral temporal lobe lesions or hippocampal sclerosis who are good surgical candidates the interictal spikes are often bilateral and independent, especially during sleep. The ictal scalp EEG often shows rhythmic theta at the onset that may be localized to the affected temporal lobe or be bilateral. In frontal lobe epilepsy there is much variability between patients in the scalp EEG, reflecting the heterogeneity of syndromes and the difficulties in recording from the frontal cortex. The interictal EEG often shows no epileptiform activity, bilaterally synchronous spikes or widespread spiking. Localized unifocal spikes are relatively uncommon. The ictal scalp EEG is often obscured by muscle and movement artefact, and because of rapid seizure propagation, localized changes are rare. Even when movement artefact does not obscure the trace, the scalp EEG may remain unchanged or only show poorly formed postictal slowing.

In parieto-occipital lobe epilepsy interictal spikes may be posterior, but there are often more anterior discharges, over the temporal regions or bilateral, synchronous widespread discharges. The latter may be the most apparent feature. Similarly, ictal scalp recordings may show more anterior changes than would have been expected.

Infantile spasms

The resting EEG shows a characteristic disorganized high voltage pattern, with generalized attenuation during the spasms. Hypsarrythmia may be seen bilaterally or, in some cases, unilaterally.

Benign rolandic epilepsy

This condition is characterized by unilateral or bilateral, triphasic, large-amplitude spikes that are maximum in the central or centro-temporal areas, without background abnormalities (Loiseau & Beaussart, 1973).

Benign occipital epilepsy

Posterior 1.5–3 Hz spike and slow wave discharges may occur singly or in long runs, may be lateralized, and usually attenuate with eye opening. Spread of activity may occur to produce a picture of generalized epileptiform discharges (Newton & Aicardi, 1983).

Lennox–Gastaut syndrome

The background EEG is usually slow and disorganized, with 1–2.5 Hz generalized, anteriorly predominant spike and slow wave discharges. During sleep there are often bursts of fast generalized spikes.

Electrical status epilepticus in slow wave sleep

More than 85% of slow wave sleep shows spike and wave activity, which is usually generalized.

Non-epileptic seizures

In non-epileptic seizures, rhythmic head movements can produce EEG artefacts that may mimic cerebral ictal activity, and this may lead to erroneous conclusions. In non-epileptic attack disorder, however, the record abruptly returns to normal in-between the movements and alpha activity may then be seen which attenuates with alerting stimuli such as calling the patient's name or forced eye opening (Meierkord et al., 1991).

Assessment of possible encephalopathy

Herpes simplex encephalitis has a characteristic appearance with disorganized and slow background rhythm with periodic lateralized epileptiform complexes at 2–4 second intervals, which are often particularly evident over the fronto-temporal areas. These features may, however, be lacking or only evolve over several days. In a metabolic encephalopathy, background rhythms are slowed and there is widespread excessive theta and delta activity. These appearances however are non-specific and the EEG appearances are not a good guide to the cause of an encephalopathy.

Magnetic resonance imaging (MRI)

The investigation and treatment of patients with epilepsy has been revolutionized by MRI. The superiority of MRI over X-ray computed tomography (CT) scanning in terms

of sensitivity and specificity for identifying the etiology of epilepsy in both adults and children is clear (Kuzniecky et al., 1993). The most common abnormalities are hippocampal sclerosis (HS), malformations of cortical development (MCD), vascular malformations, tumours, and acquired cortical damage. X-ray CT, however, may be preferred to MRI if a patient is disturbed or acutely unwell, as the patient is more accessible during the procedure. An X-ray CT scan is also valuable for the investigation of possible acute intracranial hematomas and skull fractures, and as a supplement to MRI for clarification of possible intracranial calcification.

MRI epilepsy protocol

Indications for neuroimaging of patients with epilepsy

The Neuroimaging Commission of the International League against Epilepsy has produced consensus statements of recommendations. The rationale for imaging the brains of patients developing epilepsy is first to identify underlying pathologies such as vascular lesions and tumours that require specific therapy; and second to assist the formulation of syndromic and etological diagnoses (Berkovic et al., 1997). Further recommendations have been made for patients with refractory seizures (Berkovic et al., 1998) and for functional imaging techniques (Duncan et al., 2000).

MRI should include T_1- and T_2-weighted sequences to cover the whole brain in at least two orthogonal planes, with the minimum slice thickness possible on the scanner used. Gadolinium contrast enhancement is not indicated routinely, but may clarify findings in occasional patients (Cascino et al., 1989). Sequences should include a volume acquisition with a partition size of 1.5 mm or less to permit reformatting in any orientation and three-dimensional reconstruction of the data set. In the first two years of life, incomplete myelination results in poor grey–white matter contrast, making identification of cortical abnormalities difficult, and in these cases MRI may need to be repeated after 1 to 2 years.

In an acute situation when seizures occur in the context of a neurological insult, X-ray CT is an appropriate initial investigation if MRI is not readily available or not possible for technical reasons, for instance if the patient has a cardiac pacemaker or requires attention during the scan.

The best practice is to obtain MRI in all patients with epilepsy, with the exception of those with a definite diagnosis of idiopathic generalized epilepsy or benign rolandic epilepsy of childhood with centrotemporal spikes. MRI is particularly indicated in patients with: onset of partial seizures, at any age; onset of generalized or unclassified seizures in the first year of life, or adulthood; evidence of a fixed deficit on neurological or neuropsychological examination; difficulty obtaining seizure control with first-line antiepileptic drugs; loss of seizure control, or a change in the pattern of seizures.

Patients who are candidates for surgical treatment of epilepsy require detailed brain imaging (see chapter 78).

In situations in which access to MRI is limited, essential indications for MRI are: patients with partial or secondary generalized seizures, and apparently generalized seizures, that are not controlled with AEDs; patients who develop progressive neurological or neuropsychological deficits.

A typical presurgical MRI protocol would be: volume acquisition T_1-weighted data set that is acquired in an oblique coronal orientation, orthogonal to the long axis of the hippocampi, and covers the whole brain in 0.9 mm partitions. This sequence produces approximately cubic voxels, allowing for reformatting in any orientation, subsequent measurement of hippocampal morphology and volumes, and for three-dimensional reconstruction and surface rendering of the brain; oblique coronal spin-echo sequence, with proton density (TE = 30) heavily T_2-weighted (TE = 90 or 120) and FLAIR acquisitions that are orientated perpendicularly to the long axis of the hippocampus, to demonstrate any increase in T_2-weighted signal intensity.

Structural cerebral abnormalities underlying epilepsy identified with MRI

Hippocampal sclerosis

This is the single most common pathology underlying refractory partial seizure disorders. Two-thirds of patients with HS become seizure free after an anterior temporal lobe resection (Berkovic et al., 1995). The hippocampus is best visualized in two planes: along its long axis and orthogonal to this. These imaging planes may be readily determined on a sagittal scout image: the axial plane being in the line joining the base of the splenium of the corpus callosum to the inferior, posterior border of the frontal lobe and the coronal plane being perpendicular to this, parallel to the anterior border of the brainstem.

The features of HS identified by MRI are hippocampal atrophy, demonstrated with coronal T_1-weighted images, and increased signal intensity within the hippocampus on T_2-weighted spin-echo images (Jackson et al., 1990), decreased T_1-weighted signal intensity and disruption of the internal structure of the hippocampus (Jackson et al.,

1993a). Atrophy of temporal lobe white matter and cortex, dilatation of the temporal horn and a blurring of the grey–white matter margin in the temporal neocortex (Meiners et al., 1994) variably accompany HS.

Quantitative MRI assessment of the hippocampus

Assessment of atrophy can be improved by measurement of the hippocampal volumes (Cascino et al., 1991). However, a satisfactory operative outcome is possible in patients with bilaterally symmetric mesial temporal sclerosis (Jack et al., 1995), underlining the fact that factors other than MRI need to be taken into account in presurgical decision-making. Identification of a structural lesion does not always indicate the site of seizure origin. Clinical, EEG and other data all need to be considered (Holmes et al., 1999).

The severity of hippocampal atrophy on the side of the language-dominant hemisphere is an important determinant of impairment of verbal memory following hippocampal resection. The more severe the atrophy preoperatively, the less likely it is that there will be a significant decline of verbal memory after surgery (Trenerry et al., 1993).

Hippocampal volumetry is demanding and time consuming, requiring a skilled operator and a postprocessing computer (Cook et al., 1992). In clinical practice, hippocampal asymmetry of 20% or more is reliably visually apparent to skilled neuroimaging specialists, but lesser degrees of asymmetry require quantification (Van Paesschen et al., 1995).

Hippocampal T2 signal may be quantified by measurement of hippocampal T2 relaxation time (HT2). T2 relaxation time measurements are a useful identifier of hippocampal pathology, with marked elevations being associated with HS and intermediate values being seen in patients without qualitative MRI evidence of HS, contralateral to HS, and some patients with extratemporal seizures (Jackson et al., 1993b). There is an inverse correlation between HT2 and the ratio of glial to neuronal density in the hippocampus and a close correlation between HT2 and severity of hippocampal volume loss, allowing delineation in vivo of a spectrum of the severity of HS, using quantitative MRI (Van Paesschen et al., 1995, 1997a,b). This may be used in the evaluation of patients and also in longitudinal studies to determine whether there is any evidence of progression of the condition.

HS may be of varying severity along the length of the hippocampus. Hippocampal atrophy and increase in T2 may be confined to the anterior centimetre (Duncan et al., 1996; Woermann et al., 1998). Hippocampal T2 measurements and hippocampal volumes, corrected for the intracranial volume, are useful methods for identifying bilateral hippocampal sclerosis (Van Paesschen et al., 1997a; Free et al., 1995).

Although MRI has made a considerable difference to the evaluation of patients with refractory seizures who are candidates for surgical treatment, the technique does not make other investigations redundant. Clinical and functional data (neurophysiological, psychological and, in some cases, functional imaging) all need consideration in reaching a consensus for individual patients (Spencer, 1995). Some patients with seizure onset outside of the temporal lobe may have MRI features of HS (Cascino et al., 1993).

Malformations of cortical development

Malformations of cortical development (MCD) are common causes of epilepsy and neurodevelopmental deficits. The range of MCD identified with MRI include schizencephaly, agyria, diffuse and focal macrogyria, focal polymicrogyria, minor gyral abnormalities, subependymal grey matter heterotopias, bilateral subcortical laminar heterotopia, tuberous sclerosis, focal cortical dysplasia and dysembryoplastic neuroepithelial tumours (DNTs). The best results are obtained using T_2-weighted and high resolution T_1-weighted volumetric techniques with thin partitions, covering the whole brain and allowing viewing of the structures in two orthogonal planes. Analysis of MRIs of young children needs to take into account the normal development of myelination and the indistinct grey–white matter boundary on T_2-weighted images in children aged less than two years.

Dysembryoplastic neuroepithelial tumours are regarded as benign developmental tumours and not infrequently underlie refractory partial seizures. A circumscribed cortical mass may indent the overlying skull and extend subcortically, with low signal intensity on T_1-weighted images, high signal on T_2-weighted images that is similar to CSF, and slightly higher signal intensity in the lesion than CSF on proton density images. Cyst formation and enhancement with gadolinium–DTPA may occur. Calcification is present in some cases and may be more readily demonstrated with X-ray CT. Confident differentiation from low-grade astrocytomas and ganglioglioma is not possible by MRI (Koeller & Dillon., 1992; Raymond et al., 1994, 1995).

Granulomas

Tuberculomas and cysticercosis are the most common identified causes of epilepsy in developing countries. Epilepsy is the most common manifestation of neurocysticercosis (Aubry et al., 1995; Gulati et al., 1991). MRI is more sensitive than X-ray CT in demonstrating various stages in

the development of non-calcified cerebral cysticercosis lesions (Sanchetee et al., 1991).

Cavernomas

Cavernomas are often not identified on X-ray CT, but have a characteristic appearance on MRI (Requena et al., 1991). Cavernomas have the characteristic appearance of a range of blood products. The central part contains areas of high signal on T_1- and T_2-weighted images, reflecting oxidized hemoglobin, with darker areas on T_1-weighted images due to deoxyhemoglobin. The ring of surrounding hemosiderin appears dark on a T_2-weighted image. There may be calcification, which usually appears dark on T_1- and T_2-weighted images. There is no evidence of arteriovenous shunting. Arteriovenous malformations with high blood flow have a different and distinctive appearance.

Other pathologies

Focal and generalized atrophy, tumours, scars, cysts, ischemic and traumatic lesions underlying and associated with epilepsy are all well demonstrated with MRI. Ischemic lesions associated with epilepsy are particularly common in the older age group and are well demonstrated with MRI (Kilpatrick et al., 1991).

Indolent gliomas are clearly identified using MRI. These lesions are commonly ill defined, non-cystic, do not enhance, and appear to arise from deep white matter. Intracranial epidermoid cysts may give rise to refractory partial seizures and a fixed neurological deficit that is stable over many years.

MRI in evaluation for surgical treatment of epilepsy

MRI has had a marked impact on presurgical evaluation (Berkovic et al., 1998; Spencer, 1995; Cascino, 1994; Zentner et al., 1995). While MRI may identify lesions underlying refractory epilepsy, such as HS, MCD and cavernomas, clinical and functional data (neurophysiological, psychological and, in some cases, functional imaging) also need consideration to reach a consensus for individual patients. Refer to Chapter 78 for more details.

Functional MRI

Ictal and interictal epileptiform activity

Functional MRI (fMRI) can detect ictal changes in cerebral blood flow (Jackson et al., 1994; Detre et al., 1995; Warach et al., 1996). Limitations of the method include movement artefact, and the fact that it is impracticable for a patient to lie for hours in an MRI scanner awaiting the onset of a seizure.

The development of safe and reliable EEG recording from subjects having fMRI studies has been a major step forward in the fMRI of interictal epileptiform activity (Ives et al., 1993; Allen et al., 1998). Focal increases in cerebral blood delivery have been identified in patients with frequent interictal spikes (Krakow et al., 1999). These methods will aid EEG interpretation and understanding of the pathophysiological basis of epileptic activity. Their application, utility and limitations in defining the irritative zone of the cortex and its relationship with the epileptogenic zone in patients in whom surgical treatment is being considered will need careful evaluation.

Localization and lateralization of cognitive function

An important use of fMRI is to delineate areas of brain that are responsible for specific functions, such as the primary sensory and motor cortex, and to identify their anatomical relation to areas of planned neurosurgical resection (Puce et al., 1995; Rao et al., 1995). In patients with cerebral lesions, the localization of cognitive activation may differ from the pattern in normal subjects (Alsop et al., 1996).

Language function may be lateralized using fMRI (Binder et al., 1996) and fMRI language studies have generally concurred with carotid amytal testing (Desmond et al., 1995; Benson et al., 1999). fMRI results, however, do not always accord with the carotid amytal data (Worthington et al., 1997). Further, identification of the areas of brain involved in language is not the same as determining if someone can speak when half of the brain is anesthetized. Studies in which word generation is compared with the rest state usually show activation of anterior language areas. Comparisons of semantic tasks with non-linguistic control tasks show more widespread activation in the dominant hemisphere (Binder et al., 1997).

At present, many candidates for anterior temporal lobe resection require carotid amytal tests in order to determine whether they would be at risk of severe memory impairment following the surgery. The test is crude and indicates whether the contralateral temporal lobe is able to subserve basic short-term memory functions. Several fMRI studies have shown activation of bilateral posterior medial temporal lobe during encoding of novel verbal and spatial material (Gabrieli et al., 1997). A complex visual scene encoding task that activates mesial temporal structures has been used during fMRI. Activation patterns were nearly symmetric in normal subjects, but asymmetries were noted in patients with temporal lobe epilepsy (Detre et al., 1998). The development of appropriate fMRI visual and verbal memory tasks is an area of intense research (Otten et al., 2001; Maguire et al., 1998). fMRI may have a

role in preoperative assessment of memory function, but the integration of cognitive activation data into surgical decision-making needs to be cautious. There are two principal caveats: first, if a cerebral area does not activate on a specific task this does not imply that it may be removed with impunity; secondly, the activation of a particular cerebral area with a specific task does not necessarily imply that surgery to that area would cause a clinically significant fixed deficit.

Proton magnetic resonance spectroscopy

In epilepsy studies in vivo, the principal signals of interest have been those from *N*-acetyl aspartate (NAA), creatine + phosphocreatine (Cr), choline-containing compounds (Cho), and lactate (Lac). NAA is located primarily within neurons and precursor cells and a reduction of NAA signal is usually regarded as indicating loss or dysfunction of neurons. Cr and Cho are found both in neurons and in glial cells. In temporal lobe epilepsy caused by HS, reduction of NAA and increases of choline-containing compounds and creatine + phosphocreatine, reflecting neuronal loss or dysfunction and astrocytosis are commonly found (Connelly et al., 1994; Cross et al., 1996; Woermann et al., 1999). The implication from these data was that there is neuronal loss or dysfunction and astrocytosis in the temporal lobes of patients with temporal lobe epilepsy. Abnormalities of metabolite profiles may be found in temporal lobes with normal MRI (Knowlton et al., 1997; Connelly et al., 1998; Woermann et al., 1999). At present, ^{1}H MRS appears to be a sensitive method for detecting regional neuronal integrity and may identify areas of gliosis. The rapid developments now being made in MR hardware and software may enable parametric imaging of the cerebral concentrations of these compounds, and this may have important consequences for the non-invasive investigation and the medical and surgical treatment of patients with epilepsy.

Single photon emission computerized tomography (SPECT)

Single photon emission computerized tomography is principally used to image the distribution of cerebral blood flow (CBF). In addition, there have been a few studies of specific receptors in the brain.

Interictal SPECT studies

The marker of an epileptic focus studied interictally is a region of reduced CBF, but the results are not always reliable (Stefan et al., 1987; Ryvlin et al., 1992). In one large representative series, there was correct localization in 38% in interictal studies of patients with unilateral temporal lobe EEG foci (Rowe et al., 1991). Localization with interictal SPECT is more difficult in patients with extratemporal epilepsy. In a blinded comparative study, interictal SPECT was less effective at lateralizing the focus of temporal lobe epilepsy than MRI, with correct lateralization in 45% compared to 86%. Furthermore, agreement of MRI and EEG data was a good predictor of a satisfactory result from surgical treatment, whereas SPECT was not and was prone to give an incorrect result in patients whose MRI was not lateralizing (Jack et al., 1994). In consequence, interictal SPECT has little place in the routine investigation of patients with epilepsy.

Ictal and postictal SPECT studies

The increase in CBF associated with a seizure may be detected using SPECT (Bonte et al., 1983). This may provide useful localizing information in patients with partial seizures. An injection of ^{99m}Tc-HMPAO at the time of a seizure results in an image of the distribution of CBF 1 to 2 minutes after tracer administration, which is then stable for several hours so that the patient may be imaged when the seizure is over. The general pattern is of localized ictal hyperperfusion, with surrounding hypoperfusion, that is followed by accentuated hypoperfusion in the region of the focus, which gradually returns to the interictal state. Combined data from interictal and ictal SPECT scans give a lot more data than interictal scans alone. A meta-analysis showed that in patients with temporal lobe seizures, the sensitivities of SPECT relative to diagnostic evaluation were 0.44 (interictal), 0.75 (postictal) and 0.97 (ictal) (Devous et al., 1998).

Ictal SPECT investigations may be carried out in children (Cross et al., 1995; O'Brien et al., 1998a). In one large series, ictal SPECT achieved 97% correct localization in unilateral temporal lobe epilepsy, compared with 71% for postictal SPECT and 48% for interictal scans. In extratemporal seizures ictal SPECT studies localized the focus in 92%, compared to 46% for postictal studies, and interictal SPECT was of little value (Newton et al., 1995). The coregistration of interictal with ictal or postictal SPECT images, to result in an 'ictal difference image' that may be coregistered with an individual's MRI enhances objectivity and the accuracy of data interpretation (Zubal et al., 1995; O'Brien et al., 1998b, 1999). In conclusion, SPECT gives the ability to obtain images representative of CBF at the time of seizures. These data need careful and cautious interpretation and are non-quantitative.

Positron emission tomography (PET) studies

An epileptogenic focus, studied interictally, is associated with an area of reduced glucose metabolism, and reduced blood flow, that is usually considerably larger than the pathological abnormality (Engel et al., 1982). ^{18}FDG-PET scans provide superior resolution and greater reliability for identifying a focal deficit than do PET scans using ^{15}O-water or SPECT scans of cerebral blood flow (Ryvlin et al., 1992). Partial seizures are associated with an increase in regional cerebral glucose metabolism and blood flow in the region of the epileptogenic focus, and often a suppression elsewhere (Engel et al., 1983). In general, ictal PET scans can only be obtained fortuitously, because of the two minute half-life of ^{15}O and the fact that cerebral uptake of ^{18}FDG occurs over 40 minutes after injection, so that cerebral glucose utilization data will reflect an amalgam of the ictal and post-ictal conditions. The place of this technique has been re-evaluated in the light of developments in MRI as the finding of a definite focal abnormality with the latter technique, such as HS, may render an ^{18}FDG–PET scan superfluous (Heinz et al., 1994; Gaillard et al., 1995).

There is a 60–90% incidence of hypometabolism interictally in temporal lobe epilepsy (Engel et al., 1982; Ryvlin et al., 1992), and in about 60% of patients with frontal lobe epilepsy. In 90% of those with a hypometabolic area, structural imaging shows a relevant underlying abnormality. In common with temporal lobe epilepsy, the area of reduced metabolism in frontal lobe epilepsy may be much larger than the pathological abnormality. In contrast, however, the hypometabolic area may be restricted to the underlying lesion (Engel et al., 1995). Overall, ^{18}FDG–PET does not appear to provide additional clinically useful information in the majority of patients with frontal lobe epilepsy.

Studies with ^{18}FDG-PET have defined the major cerebral metabolic associations and consequences of epilepsy but the data are non-specific with regard to etiology and abnormalities are more widespread than the pathological lesions. The role of ^{18}FDG–PET in the clinical evaluation of patients has been reduced by the advances made in MRI over the last 5 years. Activation studies may be performed with $H_2{}^{15}O$ but these studies are now increasingly performed with functional MRI.

Specific ligands

Positron emission tomography may be used to demonstrate the binding of specific ligands, for example, ^{11}C-flumazenil to the central benzodiazepine–$GABA_A$ receptor complex and abnormalities of binding may identify functional abnormalities that are more widespread than structural abnormalities identified by MRI (Duncan & Koepp, 2000).

Neuropsychological assessment

A minority of patients with epilepsy, particularly those with poorly controlled seizures, are at risk of disorders of cognitive function and benefit from a detailed neuropsychological assessment.

Assessment of newly diagnosed and chronic patients

Testing may reveal a specific cognitive deficit. Subsequent assessments can determine whether there is progressive impairment of focal or widespread cerebral dysfunction, which requires further evaluation and treatment.

Monitoring of the effects of AEDs

All AEDs, at high doses, may impair cognitive function. The predominant effects of AEDs are slowing on tasks with a motor component and impairment of mental speed, attention and concentration. Neuropsychological assessment can identify deficits in these areas and repeat testing after changes in AED therapy may be used as an indicator as to whether function has improved or not. Computerized psychological tests add precision to assessments, particularly in recording the speed of processing (Thompson, 1991). It may be difficult to ascertain the effects of continued seizures, AEDs and fixed cerebral deficit on motor and mental speed, attention and concentration.

Assessment of individual potential

People with intractable epilepsy frequently may have their abilities under- or overestimated because a global IQ figure may mask an uneven cognitive profile. Identifying an individual's strengths and weaknesses helps realistic goals to be set regarding independent living and employment and to identify whether they have untapped potential that may respond to a period of rehabilitation. This knowledge can avoid misunderstandings, particularly when there are hidden deficits. Assessment may also determine whether there is evidence of progressive decline of cognitive functions. Identification of deterioration has important implications for investigations of the cause and for the making of care plans.

Neuropsychological test schedules

There is no one cognitive deficit that is characteristic of patients with epilepsy and a broad range of functions needs to be assessed. A basic neuropsychological schedule for patients with epilepsy would comprise the subtests of the WAIS-R, tests of language, memory, perception and spatial functioning. The Nelson Adult Reading Test provides an estimate of an individual's premorbid intellectual function. Measures considered sensitive to frontal lobe

function are also employed. Additional more detailed testing of functions is undertaken if specific difficulties are uncovered during the routine neuropsychological screen.

Interpretation of data in patients with epilepsy

The neuropsychological assessment of patients with epilepsy needs to take into account the possible effects of AED therapy, recent seizures and ongoing seizure activity. Sometimes this is obvious, for example the patient who has had a generalized tonic–clonic seizure two hours previously and who is still drowsy, or the child in whom absences are occurring every few minutes throughout the test session. The possibility of occult disturbance by seizures needs to be considered if performance is less good than expected, and can be assessed by simultaneous video–EEG recording.

The relevance of performance on neuropsychological tests to day-to-day functioning is not always evident. Measures of general intelligence can be linked to educational attainment and potential to live independently. The finding of frontal lobe deficits can help explain why an apparently able individual is functioning poorly in daily living situations, for example being dependent on others to structure activities. Language difficulties may have been covert for many years and contribute to disturbed behaviour.

Memory

Patients with epilepsy frequently complain of memory difficulties, but on neuropsychological assessment of memory may perform at an average level. Memory is an umbrella term and formal neuropsychological assessment generally focuses on the ability to learn new information. Important areas that current tests do not adequately evaluate include prospective memory functions, such as the ability to take medication or attend an appointment (Corcoran & Thompson, 1993; Blake et al., 2000).

Assessment of patients with mental handicap

There is only a limited range of assessment measures suitable for patients with moderate to severe learning difficulties. The general approach is to employ measures that have been developed for use with children, which may not be appropriate for use with adults. Instruments such as The British Ability Scale however, allow consideration of relative strengths and weaknesses of different cognitive functions (Elliott et al., 1983).

Assessment of mood, wellbeing and behaviour

At present, such measures have little use in the day to day management of patients, but are used in research protocols that attempt to evaluate the effect of medical and surgical treatment on broader aspects than suppression of seizures. Data are usually gathered from patient compiled questionnaires that result in a single score or a profile of scores (Hermann et al., 1992; Vickery et al., 1992; O'Donoghue et al., 1998). Behavioural disturbance sometimes accompanies epilepsy, often in the setting of mental handicap, and may be compounded by some medications. It can be useful to quantify the extent of this disturbance in order to monitor the effects of changes in medication, environment and behavioural management programmes, with the use of questionnaires and rating scales compiled by relatives, carers and teachers.

Presurgical neuropsychological evaluation

Detailed neuropsychological evaluation is fundamental to the consideration of patients for epilepsy surgery (see Chapter 78), particularly when a temporal lobe resection is contemplated.

Other investigations at initial assessment

This should include a biochemical screen and full blood count. HIV and other serological tests should be considered. There is usually a rise in serum prolactin concentration for up to 20 minutes after a generalized tonic–clonic seizure to above 1000 mU/l. It is important to compare postictal prolactin levels with a baseline value, to differentiate between a postictal rise and a persistent elevation of prolactin concentration. Serum prolactin does not generally elevate after non-epileptic convulsive seizures. These data may be diagnostically useful, in conjunction with video and EEG data (Rao et al., 1989). Prolactin may rise however after a severe syncopal event. Serum prolactin does not rise as far or as consistently following complex partial seizures. Seizures arising from a temporal lobe are more likely to be associated with a rise than those from the frontal lobes (Meierkord et al., 1992). No consistent rise is seen after simple partial seizures (Pritchard et al., 1983).

Cardiac investigations are indicated if there is a suspicion of arrhythmias or other cardiac disease.

Inborn errors of metabolism only rarely give rise to epilepsy but need to be considered, particularly if there is evidence of other neurological disease. The more common include: pyridoxine dependency, that presents in the neonatal period and responds rapidly to intravenous pyridoxine; adrenoleukodystrophy, diagnosed by finding increased very long chain fatty acids in plasma; non-ketotic hyperglycinemia; D-glyceric acidemia; phenylketonuria; porphyria; biopterin deficiency; GABA transaminase deficiency with 4-hydroxybutyric aciduria; urea cycle defects; mitochondrial

cytopathy; neuronal ceroid lipofuscinosis; GM2 gangliosidosis; Gaucher's disease; sialidosis I & II; Lafora body disease; globoid cell leukodystrophy.

Examination of the cerebrospinal fluid (CSF) is not routinely indicated in the evaluation of patients developing epileptic seizures.

Assessment of neurological and cognitive decline in patients with epilepsy

Approach to investigation

As epilepsy often occurs in the context of mental handicap and fixed neurological deficit, it is necessary to determine whether a patient with mental and/or neurological dysfunction has a static or progressive deficit and to establish the etiology. A static deficit may result from an acquired brain insult or congenital malformation (Table 76.7). Investigation should be pursued more aggressively if there is evidence of progressive deterioration, to determine whether there may be a remediable pathology, to give an estimation of prognosis so that appropriate care may be arranged, and to ascertain whether there is an inherited condition that may carry genetic implications for the patient's relatives.

Clinical features

It is not always straightforward to determine whether or not a patient is showing progressive decline. A careful history and clinical examination are essential as are knowledge of the behaviour and development of normal children. Important aspects of the history are to determine from relatives and carers what social, motor, language and self-care skills a patient had at best, and whether further skills are being acquired, whether the situation is static, or whether once-held skills are being lost. This assessment needs to take into account the normal processes of acquisition of skills through the first two decades of life. Normal development may mask the occurrence of gradually progressive dysfunction until the late teens. Further, if a patient is functioning at a low level, it may be difficult to detect a progressive deterioration. A careful family history, including enquiries about consanguinity and of more distant relatives than the immediate family, is essential if there is any suggestion that the patient has a genetically determined disorder. In the history and examination particular attention should be paid to identifying any cognitive decline, pyramidal signs, dystonia, myoclonus, other movement disorders, cerebellar ataxia, visual deficit, peripheral neuropathy or myopathy.

Table 76.7. Causes of epilepsy and static cognitive and neurological deficit

Inherited
Tuberous sclerosis
Neurofibromatosis
Incontinentia pigmenti
Hypomelanosis of Ito
Angelman's (Happy puppet) syndrome
Non-inherited congenital malformations
Chromosomal abnormalities: trisomy, deletions, fragile X
Neuronal migration defects, cortical dysplasia (may also result from prenatal, postnatal insult).
Aicardi syndrome
Sturge–Weber syndrome
Other cerebral malformations
Acquired
Prenatal
Antepartum hemorrhage
Toxemia
Brain infection (encephalitis, meningitis): especially CMV, toxoplasmosis, herpes, rubella, Epstein–Barr, influenza, syphilis
Perinatal
Anoxia
Hypoglycemia
Hypocalcemia
Postnatal
Brain infection (encephalitis, meningitis)
Hydrocephalus
Cerebral trauma
Cerebral ischemia, infarction
Cerebral hemorrhage
Postimmunization encephalopathy
Malignancy
Radiation
Status epilepticus

Iatrogenic causes

It is essential to consider whether apparent cognitive and neurological decline may be iatrogenic, as a result of AEDs or other medication. In patients with pre-existing cognitive and motor impairment, the expected features of dose-related intoxication may not be apparent and serum AED concentrations should be checked. Further, some patients, particularly those with mental handicap, may be intoxicated with AEDs at serum concentrations that are not above the widely quoted 'therapeutic ranges'. If there is a possibility that AEDs may be contributory the appropriate course is to reduce the dose and to then reassess the patient.

Table 76.8. Conditions in which epilepsy is the only evident disorder causing progressive impairment

Iatrogenic: Intoxication with medication
Cryptogenic infantile spasms (West syndrome)
Non-convulsive epileptic status epilepticus (including some patients with the Lennox–Gastaut syndrome)
Focal epileptic encephalopathies (e.g. Landau–Kleffner syndrome)
Electrical status epilepticus in slow wave sleep
Epileptic encephalopathy: frequent seizures, episodes of status

Although most frequent with barbiturates and phenytoin, this situation may also arise with more modern AEDs, and a 'pseudodementia' in association with sodium valproate is well recognized (Pakalnis et al., 1989, Jones et al., 1990).

Conditions in which progressive neurological impairment is secondary to the epilepsy

These are summarized in Table 76.8.

Investigation of progressive neurological diseases

It is difficult to lay down criteria for when a patient's cognitive deterioration is disproportionate to the severity of their epilepsy and a neurodegenerative condition of which epilepsy is just one manifestation should be sought. The possibility should be considered if a patient is deteriorating, particularly if evidence of other fixed neurological dysfunction becomes apparent.

Identified conditions that give rise to a progressive impairment of higher mental function and epilepsy are mostly genetically determined (Table 76.9). There are many common clinical features to diseases causing progressive neurological and cognitive decline and there is a considerable overlap between syndromic groupings and identified etiologies. It is, however, possible to identify clinical syndromes which have a limited range of etiologies and necessary investigation can be restricted. The investigations that may be useful in the assessment of progressive neurological conditions of which epilepsy is a part are summarized in Table 76.10.

Progressive myoclonus epilepsy (PME)

The progressive myoclonus epilepsies form a recognizable syndrome, with several identified etiologies. The key features of this syndrome are progressive myoclonic seizures, occasional tonic–clonic seizures, ataxia and cognitive impairment (Berkovic & Andermann, 1986). This syndrome

Table 76.9. Progressive neurological conditions of which epilepsy may be part

Structural lesions
Hydrocephalus
Progressive structural lesions, e.g. glioma
Cerebrovascular disease
Storage disorders
GM2 and GM1 gangliosidosis
Neuronal ceroid lipofuscinosis
Niemann–Pick Disease
Gaucher's disease
Sialidosis
Lafora body disease
Leukodystrophies
Metachromatic
Globoid cell (Krabbe's)
Adrenoleukodystrophy
Spongiform leukodystrophy (Canavan's)
Alexander's disease
Pelizaeus–Merzbacher disease
Defined neurometabolic disturbance
Amino acidurias
Urea cycle disorders
Organic acidemias
Non-ketotic hyperglycinemia
Progressive neuronal degeneration of childhood with liver disease
Mitochondrial cytopathy (MERRF and MELAS)
Menkes' disease
Wilson's disease
Porphyria
Disorders of folate and cobalamin metabolism
Lesch–Nyhan disease (and other disorders of purine and pyrimidine metabolism)
Biochemical defect uncertain
Rett's syndrome
Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy
Neuroacanthocytosis
Juvenile Huntington's disease
Infective causes
Human immunodeficiency virus
Creutzfeldt–Jakob disease
Subacute sclerosing panencephalitis
Syphilis
Uncertain etiology
Rasmussen's encephalitis
Alzheimer's disease

Table 76.10. Investigations of progressive neurological conditions of which epilepsy may be part

1	Careful history, including a detailed family history
2	Examination, including skin with UV light, slit lamp examination of eyes
3	Serum AED concentrations
4	Neurophysiology
	EEG: waking, sleep, prolonged monitoring
	electroretinogram (ERG)
	Visual evoked response (VER)
	Somatosensory evoked response (SER)
5	Imaging: brain MRI, X-ray CT scans
6	Hematological indices
	Full blood count and film
	B12 and folate
	Lymphocyte vacuolation in peripheral blood
7	Blood chemistry
	Immunoglobulins
	Electrolytes, glucose, liver function
	Amino acids
	Serum acid phosphatase
	Porphyrins, porphobilinogen
	Leukocyte lysosomal enzymes
	Ammonia: fasting and after protein-containing meal
	Plasma copper, ceruloplasmin
	Very long chain fatty acids
8	Serology
	Viral: HIV, measles, rubella,
	Syphilis
9	Urine
	Amino acids and organic acids
	Porphyrins, porphobilinogen
	Bile salts
	Dolichols (urine sediment)
	Sialyloligosaccharides
10	Genetic analysis
	Karyotype
	Analysis of DNA in lymphocytes
	Mitochondrial cytopathy
	Prion mutation
	Huntington's disease
11	CSF examination
	Lactate and amino acids
12	Biopsy
	skin
	muscle
	bone marrow
	liver
	brain

needs to be differentiated from conditions which result in a progressive encephalopathy, but in which myoclonic seizures are not usually a prominent feature.

Causes of progressive myoclonus epilepsy (PME)

Unverricht–Lundborg disease; Lafora body disease; sialidosis type I and type II; neuronal ceroid lipofuscinosis; mitochondrial cytopathy (MERRF: myoclonus epilepsy ragged red fibres); Gaucher's disease; neuroaxonal dystrophy; dentatorubral–pallidoluysian atrophy; biotin responsive encephalopathy.

The most common etiology is Unverricht–Lundborg disease, which is autosomal recessive and is due to a deficiency of cystatin B (Alakurtti et al., 2000).

Neurophysiology

The EEG in PME usually shows generalized spike or polyspike and slow wave discharges and photosensitivity is often present. There is slowing of the background activity, reflecting the underlying progressive disorder. The EEG patterns do not help to distinguish the different etiologies.

In neuronal ceroid lipofuscinosis, the electroretinogram is usually undetectable. The visual evoked response (VER) is enlarged in the late infantile form and the EEG may show a low frequency photic stimulation response. The VER is reduced in the juvenile form and in sialidosis. Giant cortical responses to somatosensory stimulation are common in PME, but are not specific to the etiology. Peripheral neuropathy may occur with sialidosis I and mitochondrial cytopathy.

Neuroimaging

Variable degrees of atrophy may occur, but the appearances are not specific for the subtypes of PME.

Urine

Sedimentary dolichol is often increased in neuronal ceroid lipofuscinosis. Sialyloligosaccharides are increased in sialidoses. Organic acids are increased in biotin-responsive encephalopathy.

Blood

Lymphocyte vacuolation may be seen in neuronal ceroid lipofuscinosis and sialidosis. Gaucher's disease is commonly associated with a pancytopenia. Assays of leukocyte enzymes can diagnose the sialidoses (α-*N*-acetylneuraminidase, alpha-galactosidases) and Gaucher's disease (beta-glucocerebrosidase). In sialidosis type 1 alpha-*N*-acetylneuraminidase is reduced, in sialidosis type 2, activities of both alpha-*N*-acetylneuraminidase and beta-galactosidase are deficient. Analysis of mito-

chondrial DNA may reveal mutations that underly mitochondrial cytopathy.

Biopsies

Pathological examination of eccrine sweat glands in a skin biopsy for polysaccharide-containing inclusion bodies, using PAS, is a reliable method for diagnosing Lafora body disease. Lafora bodies may also be identified on a liver biopsy. Electron microscopy examination of eccrine secretory cells and other tissues reveals fingerprint profiles, deposits and curvilinear bodies in neuronal ceroid lipofuscinosis. The axon spheroids found in neuroaxonal dystrophy may not be seen in sections of peripheral nerve, but have been reported in autonomic nerve terminals.

A muscle biopsy is currently needed to diagnose mitochondrial cytopathy causing MERRF, but in the future may be obviated by advances in analysis of leukocyte DNA. Gaucher's disease may be diagnosed by finding characteristic foam cells on bone marrow examination. Brain biopsy is only very rarely indicated, when less invasive investigations have not yielded an answer, and when there is rapid progression, the possibility of a remediable etiology, when the patient and family wish to have as precise an explanation as possible, and when the diagnosis has profound implications for genetic counselling. Currently, neuroaxonal dystrophy and atypical inclusion body diseases may only be diagnosed in this way.

Principles of pharmacotherapy of the epilepsies

Emilio Perucca

Clinical Pharmacology Unit, Department of Internal Medicine and Therapeutics, University of Pavia, Italy

With a prevalence of 0.5 to 1% and over 50 million people affected worldwide, the epilepsies as a group represent the most common serious neurological disorder. In recent years, major advances have been made in characterizing their clinical and prognostic features and in clarifying their etiologies and pathophysiological mechanisms. Contrary to common belief, many epilepsies are potentially life threatening, with significant mortality being ascribed not only to the underlying disease but also to the seizures and their consequences (Nilsson et al., 1999). Moreover, seizures carry an important risk of morbidity, including traumatic injuries, psychiatric disturbances and impaired quality of life (Baker et al., 1997; Spitz, 1998). Even in educated societies, epilepsy is associated with significant stigma, and affected people may suffer more from prejudice and discrimination than from the actual manifestations of the disease (The Rest1 Group, 2000).

Fortunately, most epilepsy syndromes are fully treatable, and up to 70% of patients may achieve complete seizure control and live a normal life, mainly thanks to the availability of effective drugs. Appropriate management requires knowledge of the characteristics of the disease, its associated risks, its natural prognosis and, not least, the clinical pharmacology of antiepileptic drugs (AEDs). It is the purpose of this chapter to discuss the basic principles underlying rational drug selection and optimization of therapy.

Objectives of treatment

The treatment of epilepsy should fullfil at least two primary objectives.

Prevention of seizure recurrence

If exception is made for the control of ongoing seizures and status epilepticus, AEDs are prescribed to prevent seizure recurrence. The ultimate goal should be complete seizure control, but in severe epilepsies this may not be achievable, and a reduction in seizure frequency becomes a more realistic objective.

Minimization of side effects

Most AEDs have a narrow therapeutic index, i.e. the dosage required to achieve seizure control is close to that which produces significant toxicity. Skillful management rests with the ability to select the drug whose side effect profile is least likely to interfere with the patient's wellbeing, and to optimize its dosage to reduce the risk of side effects. Seizure control should not be achieved at any cost. Physicians should avoid the situation whereby patients are made to suffer more from the side effects of treatment than from the manifestations of the disease.

Additional goals to be actively pursued whenever feasible or relevant include the following.

Reduction of mortality and morbidity

When seizures are triggered by an identified treatable cause, e.g., a brain tumour, etiological therapy is essential to reduce morbidity and mortality and, in some cases, to cure the epilepsy. Even when no etiological treatment is available, improved seizure control would be expected to have a positive impact on seizure-related mortality and morbidity, including injuries and impaired quality of life (Perucca et al., 2000).

Control of subclinical epileptic activity

Although therapy should be aimed primarily at controlling seizures and not at normalizing interictal EEG activity, there may be situations, especially in children with generalized epilepsies, where frequent paroxysmal discharges

lead to subclinical functional impairment, detectable at cognitive testing. In these patients, suppression of EEG discharges may become an objective of treatment, provided that this can be shown to result in significant functional improvement.

Reduction of seizure severity

When seizures cannot be controlled completely, there may be advantages in a treatment that reduces seizure severity. Although this is a poorly explored area, preliminary evidence suggests that some AEDs may modify ictal manifestations and reduce the severity of seizures or associated subjective distress (Smith et al., 1993).

Avoidance of adverse drug interactions

Since AEDs are administered for prolonged periods, often for a lifetime, adverse drug interactions may be troublesome (Perucca, 1995). Drugs with a low interaction potential offer distinct advantages.

No obstruction to patient's life

The ideal treatment should interfere as little as possible which the patient's lifestyle. AEDs which can be given twice daily or, preferably, once daily are less likely to obstruct daily activities and to cause psychosocial embarassment, and they are associated with a better compliance.

Prevention of epileptogenesis

Although, theoretically, suppression of epileptogenesis (i.e. the mechanism by which an epileptic condition becomes established) should be top priority, there is no evidence that this is achievable with current pharmacological tools. Some animal experiments do suggest that uncontrolled seizure activity leads, with time, to structural brain damage and establishment of a self-sustained epileptic condition, and some AEDs exert a putative antiepileptogenic effect in these models (Löscher, 1998). However, whether repeated seizures also lead to chronicity in some forms of human epilepsies is debated (Chadwick, 1995; Reynolds, 1995), as shown by the controversy on whether hippocampal sclerosis is a cause or a consequence of temporal lobe seizures (Jefferys, 1999; Perucca et al., 2000). If uncontrolled ictal activity leads to chronicization of the disorder, there would be a strong case for early and aggressive treatment, and for preferential use of drugs which antagonize putative epileptogenic processes. Available evidence, however, suggests that in most epilepsy syndromes AEDs exert merely a symptomatic effect and do not affect the natural course of the disease (Camfield et al., 1996; Shinnar & Berg, 1996). This does not deny that some conditions may exist in which early effective treatment does improve the ultimate prognosis, possible examples being West syndrome and other early childhood myoclonic encephalopathies associated with progressive cognitive decline. In these conditions, early seizure control seems to be important for prognosis, even though its ultimate benefits may relate to cognitive outcome rather than seizures (Shinnar & Berg, 1996).

Indications for treatment

As a general rule, a correct diagnosis should be formulated before treatment is instituted, and special care should be taken in differentiating epileptic from non-epileptic attacks such as psychogenic or syncopal episodes. Every effort should also be made to identify seizure type and syndromic form, because these are essential in determining drug selection and prognosis. Basically, pharmacological treatment is indicated whenever the expected benefits outweigh potential risks. The risk/benefit equation is determined by the stage of the epilepsy, its type and severity, the age of the patient, associated medical conditions, the characteristics of the drug(s) being considered and the presumed influence of treatment on the patient's wellbeing and aspirations (Perucca et al., 2000). In certain situations, indications are clearly defined, but grey areas exist where the optimal therapeutic strategy is uncertain. The reasons for starting or for deferring treatment, together with corresponding implications, should be discussed with the patient, whose own views should be considered in the decisional process. Most cases will fall into one of the following categories.

Patients with a single seizure

A common situation generating therapeutic uncertainty is that of a patient with a single tonic–clonic seizure whose nature is considered to be probably epileptic. Because many such patients will not have a recurrence (Berg & Shinnar, 1991), and because treatment after a first seizure does not improve long-term prognosis (Musicco et al., 1997), drug therapy should generally be deferred in these patients until a second seizure occurs. Treatment after a first seizure, however, may be considered when specific prognostic factors (in particular, interictal epileptiform EEG abnormalities and/or an identified persisting cause for the seizures) indicate a high risk of recurrence, or when it is felt that the physical or psychosocial consequences of

a recurrence outweigh the risks associated with AED treatment (Beghi & Perucca, 1995).

Patients with infrequent seizures or seizures precipitated by specific triggers

In patients with rare seizures, e.g. every 12 months or longer, especially when these occur at night or cause little psychosocial inconvenience, treatment may be witheld. Individual considerations, such as patient's age, attitude towards seizures and need for a driving license, play a key role in determining whether treatment is indicated. When seizures are precipitated by specific triggers, avoidance of the latter may be sufficient. Some forms of photosensitive epilepsy for example, can be managed by instruction on how to avoid exposure to offending light frequencies.

Patients with benign self-remitting seizure disorders

In these patients, treatment should be given only when the frequency, timing or severity of seizures cause significant psychosocial or functional impairment, as in childhood absence epilepsy. Children with benign partial epilepsy with centrotemporal spikes (rolandic epilepsy) generally do not require treatment, unless seizures are frequent and occur during daytime. Continuous pharmacological prophylaxis is also unwarranted in children older than 1 year with febrile seizures (American Academy of Pediatrics, 1999).

Patients with epilepsies not having a clearly self-remitting course

These patients generally require drug therapy.

In exceptional cases, AED treatment may be indicated even in the absence of any previous seizure. For example, it has been argued that in infants with tuberous sclerosis early therapy may be considered to prevent the occurrence of infantile spasms and, possibly, associated neurological worsening (Perucca et al., 2000). Many physicians, particularly neurosurgeons, recommend long-term anticonvulsant prophylaxis in seizure-free patients considered to be at risk for epilepsy after severe head trauma, or in patients undergoing supratentorial surgery. This practice would be justified if prophylactic treatment reduces the incidence of epilepsy in these patients, but there is no evidence that this is the case. While long-term prophylaxis cannot be justified in this situation, an argument could be made for the short-term use of intravenous phenytoin in selected cases to prevent acute seizures in the immediate postoperative period, e.g. in the first week after supratentorial surgery.

Table 77.1. Advantages of monotherapy

Complete seizure control in most patients (up to 70–80%)
Minimization of side effects
Easier management (effects of individual drugs can be evaluated separately)
Improved compliance
Avoidance of adverse drug interactions
Lower treatment costs

Factors affecting drug selection

Treatment should be started with a single drug (Table 77.1), whose dosage should be adjusted gradually to produce the optimal response (Reynolds & Shorvon, 1981). Up to 60–70% of patients with partial seizures and up to 80% of those with primarily generalized tonic–clonic seizures achieve complete seizure control on the initially prescribed drug (Mattson et al., 1985, 1992; Richens et al., 1994; Heller et al., 1995; Verity et al., 1995; De Silva et al., 1996). Even better response rates are achieved in children with absence epilepsy, whereas most symptomatic generalized epilepsies are often resistant to treatment (Beghi & Perucca, 1995).

Following the introduction of several new AEDs in the last decade, physicians are faced with a complex pharmacological armamentarium (Gatti et al., 2000). No single drug can be proposed as being optimal for all patients, and a number of factors need to be taken into account when selecting an AED for an individual patient.

Efficacy spectrum

Since AEDs differ in their spectrum of activity (Table 77.2), a drug should be chosen whose spectrum extends to the seizure type(s) affecting the individual patient. If a syndromic diagnosis has been formulated, drug choice may be also influenced by prediction of additional seizure types which might occur as part of the natural history of the disorder. For example, the fact that tonic–clonic seizures develop later in life in some children with absence epilepsy can be an argument for prescription of a drug effective against both these seizure types (valproate) instead of one effective against absences only (ethosuximide).

In recent years, evidence has accumulated that certain AEDs paradoxically worsen or precipitate specific seizure types, particularly in children with generalized epilepsies (Perucca et al., 1998). Carbamazepine, tiagabine and vigabatrin may trigger or worsen myoclonic and absence seizures, gabapentin may precipitate or worsen myoclonus,

Table 77.2. Efficacy spectrum of antiepileptic drugs in different seizure types

Effective or possibly effective against all seizure types	Effective against all seizure types except absences	Effective against partial and generalized tonic–clonic seizures	Effective against absence seizures
Valproic acid	Phenobarbital	Carbamazepine[f]	Ethosuximide[h]
Lamotrigine[a]	Primidone	Phenytoin[f]	
Benzodiazepines[b]		Oxcarbazepine[f]	
Topiramate[c]		Gabapentin[f]	
Zonisamide[d]		Tiagabine[f]	
Levetiracetam[e](?)		Vigabatrin[f,g]	
Felbamate[d]			

Notes:

[a] Lamotrigine may aggravate severe myoclonic epilepsy. Efficacy is best documented for partial and secondarily generalized tonic–clonic seizures, primarily generalized tonic–clonic seizures, absence seizures, and drop attacks.

[b] Benzodiazepines occasionally precipitate tonic seizures, particularly after intravenous use in patients with Lennox–Gastaut syndrome.

[c] Efficacy against absence seizures has not been documented. Topiramate efficacy is best documented for partial and secondarily generalized tonic–clonic seizures, primarily generalized tonic–clonic seizures, and drop attacks.

[d] Evidence of efficacy against some generalized seizure types is preliminary. Efficacy is best documented for partial and secondarily generalized tonic–clonic seizures. With felbamate, efficacy is also well documented in drop attacks associated with the Lennox–Gastaut syndrome.

[e] Tentative classification. Broad-spectrum efficacy is suggested by findings in animal models but adequately controlled clinical studies have been completed only in partial and secondarily generalized seizure types.

[f] Carbamazepine, phenytoin, vigabatrin, tiagabine and oxcarbazepine may exacerbate myoclonic and absence seizures. Gabapentin may exacerbate myoclonic seizures. Carbamazepine may be effective against tonic seizures associated with the Lennox–Gastaut syndrome.

[g] Vigabatrin is also effective against infantile spasms.

[h] Ethosuximide may also be effective against myoclonic seizures.

Source: Modified from Gatti et al. (2000).

barbiturates may aggravate absence seizures, and lamotrigine may aggravate severe myoclonic epilepsy of infancy (Guerrini et al., 1998). These observations reinforce the importance of a correct syndromic diagnosis. The difficulties in early differentiation between syndromic forms led some authors to stress the advantages of broad spectrum drugs (Richens & Perucca, 1993).

Mechanisms of action of AEDs

For a pharmacological treatment to be rational, two conditions must be met: (i) the pathophysiological mechanisms of the disease should be known and (ii) a drug must be available which counteracts specifically these mechanisms. Unfortunately, our understanding of the epilepsies and the modes of AED action is too fragmentary to allow mechanism-driven rational drug selection. Although a number of primary modes of actions have been identified for most AEDs (Table 77.3), additional actions have been described for virtually all of these agents: for example, phenytoin also acts on GABAergic transmission and calcium channel conductance, carbamazepine and oxcarbazepine modulate potassium channels, lamotrigine, felbamate and MHD (the active metabolite of oxcarbazepine) inhibit voltage-activated calcium channels, and lamotrigine may act as an antagonist or negative modulator of 5-HT1A receptors (Gatti et al., 2000). Although the precise contribution of these actions to antiepileptic efficacy remains to be determined, this represents an important area for research: some day, for example, we might be able to identify a putative subgroup of patients in whom seizure susceptibility is related to impaired GABAergic transmission, and to demonstrate a superior response to GABAergic drugs in this subgroup.

Recent evidence suggests that knowledge of modes of drug action will become increasingly important for prescribing. For example, a consistent pattern is emerging whereby drugs which act by increasing GABA levels in the synaptic space (e.g. vigabatrin, tiagabine and possibly, gabapentin) can be useful in controlling partial seizures but can be aggravating on absence and/or myoclonic seizures. Mechanistic considerations are also important in selecting drug combinations in refractory patients (Brodie et al., 1997).

Table 77.3. Main mechanisms of action of available antiepileptic drugs. For most drugs, additional mechanisms have been described

Benzodiazepines	Potentiation of GABAergic transmission through amplification of $GABA_A$ responses at benzodiazepine receptors
Carbamazepine	Blockade of voltage-dependent sodium channels
Ethosuximide	Blockade of T-type calcium channels in thalamic neurons
Felbamate	Blockade of voltage-dependent sodium channels Attenuation of excitatory neurotransmission by an action at the glycine modulatory site of the NMDA receptor Potentiation of postsynaptic GABA responses
Fosphenytoin	Phenytoin prodrug
Gabapentin	Potentiation of GABAergic transmission through increased brain GABA synthesis Modulation of voltage-sensitive calcium channels Inhibition of release of several monoamine neurotransmitters
Lamotrigine	Blockade of voltage-dependent sodium channels Blockade of voltage-activated calcium channels
Levetiracetam	Unknown
Oxcarbazepine	Prodrug for MHD, which acts primarily by blocking voltage-dependent sodium channels
Phenobarbital	Potentiation of GABAergic transmission, partly through increased chloride conductance
Phenytoin	Blockade of voltage-dependent sodium channels
Primidone	Main effects mediated by conversion to phenobarbital
Tiagabine	Potentiation of GABAergic transmission through inhibition of synaptic GABA reuptake
Topiramate	Blockade of voltage-dependent sodium channels Potentiation of GABAergic transmission Attenuation of excitatory neurotransmission through antagonism at kainate/AMPA receptor sites Inhibition of high voltage-activated calcium channels Inhibition of carbonic anhydrase
Valproic acid	Blockade of voltage-dependent sodium channels Potentiation of GABAergic transmission Inhibition of gamma-hydroxybutyrate release
Vigabatrin	Potentiation of GABAergic transmission through irreversible inhibition of GABA transaminase
Zonisamide	Blockade of voltage-dependent sodium channels Blockade of T-type calcium channels Inhibition of carbonic anhydrase

Source: Modified from Gatti et al. (2000).

Etiology of epilepsy

As discussed above, the relation between etiology of the disease and modes of drug action is still poorly understood. There are reports, however, suggesting that, within a syndromic form, response to treatment may vary depending on underlying etiology. For example, infantile spasms associated with tuberous sclerosis respond to vigabutrin better than infantile spasms associated with other etiologies (Chiron et al., 1997; Vigevano & Cilio, 1997). In preliminary studies, seizures associated with glial tumours responded well to tiagabine (Dean et al., 1998).

Adverse effect profile

In newly diagnosed patients, no major differences in efficacy exist among those AEDs which are effective in a given seizure type (Mattson et al., 1985, 1992; Richens & Perucca, 1993; Richens et al., 1994; Heller et al., 1995; Verity et al., 1995; De Silva et al., 1996; Perucca & Tomson, 1999). There are, however, important differences in side effects produced by individual drugs and tolerability profile is a major factor influencing the treatment algorithm (Beghi & Perucca, 1995; Perucca, 1996a).

An overall evaluation of comparative side effect profiles (Table 77.4) usually leads to choosing preferentially

Table 77.4. Most common adverse effects and interactions with antiepileptic drugs

Drug	Adverse effects	Adverse drug interactions
Benzodiazepines	Sedation, cognitive dysfunction, dizziness, incoordination, withdrawal seizures, and, in children, hyperactivity, behaviour disturbances and hypersalivation. *Respiratory depression (i.v. use)*	Benzodiazeines may occasionally increase the levels of other anticonvulsants
Carbamazepine	Dizziness, fatigue, somnolence, diplopia, headache, incoordination, mild skin rashes, *serious hypersensitivity reactions*	As an enzyme inducer, carbamazepine decreases the levels of many drugs, including valproate, lamotrigine, tiagabine, steroids, cyclosporine and many cardiovascular agents Carbamazepine levels are decreased by barbiturates and phenytoin, and increased by macrolide antibiotics, verapamil, diltiazem, propoxyphene and many other drugs
Ethosuximide	Nausea, vomiting, anorexia, sedation, headache, hiccups, behavioural disturbances, *hypersensitivity reactions*	Ethosuximide levels are decreased by phenytoin, carbamazepine and barbiturates
Felbamate	Nausea, vomiting, headache, dizziness, insomnia, behaviour disturbances, weight loss, *aplastic anemia (1:4000), hepatotoxicity (1:30 000), other serious hypersensitivity reactions*	Felbamate increases the levels of phenytoin, phenobarbital, valproic acid, carbamazepine-10,11-epoxide and decreases the levels of carbamazepine and oral contraceptives Felbamate levels are decreased by carbamazepine, phenytoin and barbiturates and increased by valproic acid
Gabapentin	Dizziness, fatigue, somnolence, ataxia, tremor, weight gain. Behaviour disturbances (children)	None significant
Lamotrigine	Dizziness, blurred vision, diplopia, somnolence, ataxia, headache, fatigue, nausea, mild skin rashes, *serious hypersensitivity reactions*	Lamotrigine levels are decreased by carbamazepine, phenytoin, barbiturates, oxcarbazepine and methsuximide, and increased by valproic acid
Levetiracetam	Somnolence, fatigue, headache, behaviour disturbances	None significant
Oxcarbazepine	Fatigue, headache, dizziness, sedation, incoordination, hyponatremia, mild skin rashes, *serious hypersensitivity reactions*	Oxcarbazepine decreases the levels of lamotrigine, oral contraceptives and felodipine The levels of the active hydroxymetabolite of oxcarbazepine are decreased by carbamazepine, phenytoin and barbiturates
Phenobarbital	Sedation, cognitive dysfunction, incoordination, dizziness, withdrawal seizures and, in children, hyperactivity and behaviour disorders. Mild skin rashes, *shoulder-hand syndrome, serious hypersensitivity reactions*	As an enzyme inducer, phenobarbital decreases the levels of many drugs, including valproate, lamotrigine, tiagabine, steroids, cyclosporine and many cardiovascular agents Phenobarbital levels are increased by valproate, felbamate, phenytoin, propoxyphene and other drugs
Phenytoin	Dizziness, tremor, ataxia, dysarthria, diplopia, nystagmus, cognitive dysfunction, headache, mild skin rashes, *serious hypersensitivity reactions*	As an enzyme inducer, phenytoin decreases the levels of many drugs, including valproate, lamotrigine, tiagabine, steroids, cyclosporine and many cardiovascular agents Many drugs, including valproate, displace phenytoin from plasma albumin leading to altered relation between plasma phenytoin levels and response Phenytoin levels are increased by felbamate, isoniazid, diltiazem and many other drugs
Primidone	Similar to phenobarbital. In addition, primidone may initially produce an acute intolerance syndrome (nausea, vomiting, dizziness, malaise)	Since primidone is converted to phenobarbital, the same interactions described for phenobarbital apply

Table 77.4 (*cont.*)

Drug	Adverse effects	Adverse drug interactions
Tiagabine	Dizziness, fatigue, headache, tremor, nervousness, impaired concentration, *abdominal pain, depression*	Tiagabine levels are decreased by carbamazepine, phenytoin and barbiturates
Topiramate	Dizziness, somnolence, mental slowing, dysnomia, anorexia, fatigue, ataxia, weight loss, paresthesias, *nephrolithiasis (1–2%)*	Topiramate occasionally increases phenytoin levels Topiramate reduces the levels of oral contraceptives Topiramate levels are decreased by carbamazepine, phenytoin and barbiturates
Valproic acid	Nausea, vomiting, weight gain, tremor, dizziness, sedation, *encephalopathy, hyperammonemia, thrombocytopenia, liver toxicity (1:800 in infants). Spina bifida on fetal exposure*	Valproate increases the levels of phenobarbital, lamotrigine and carbamazepine-10,11-epoxide Valproate displaces phenytoin from albumin (see phenytoin) Valproate levels are increased by felbamate and isoniazid and decreased by phenytoin, carbamazepine and barbiturates
Vigabatrin	Irreversible visual field constriction (30%, symptomatic in 1–3%), somnolence, fatigue, dizziness, weight gain, behaviour disturbances, *psychosis, depression*	Vigabatrin occasionally reduces the levels of phenytoin
Zonisamide	Fatigue, dizziness, somnolence, anorexia, mental slowing, confusion, ataxia, gastrointestinal symptoms, paresthesias, *nephrolithiasis*	Zonisamide affects inconsistently the levels of carbamazepine and phenytoin Zonisamide levels are decreased by carbamazepine, phenytoin and barbiturates

Notes:
Some adverse effects not common but clinically relevant are listed in italics. The risk of fetal malformations following prenatal exposure to older generation anticonvulsants is about 4–6% compared to 2% in the general population. Teratogenic risks associated with newer drugs are unknown.

carbamazepine for partial epilepsies and valproate for generalized epilepsies. Although some newer AEDs may be better tolerated compared to older agents, they are rarely used as first-line therapy due to limited clinical experience and cost considerations (Perucca & Tomson, 1999). In practice, the process of drug selection should be flexible and take into consideration how side effects could impact on the physical and functional characteristics of the individual patient. For example, the cosmetic side effects of phenytoin, particularly hirsutism, are of far greater concern in a young girl than in an elderly male. Carbamazepine has a relatively high allergenic potential and may not be the best choice for a patient with a history of severe immune-mediated drug reactions. Valproate tends to cause weight gain, and it may be poorly tolerated in a patient who is already struggling to keep her weight under control. Associated diseases may represent specific contraindications: most AEDs, for example, are best avoided in acute intermittent porphyria, whereas vigabatrin should be preferably avoided when there is a history of psychiatric disturbances.

Interaction potential

Carbamazepine, phenytoin and barbiturates are inducers of certain cytochrome P450 enzymes and they stimulate the elimination of several drugs, including other anticonvulsants, steroid oral contraceptives, glucocorticoids, cyclosporine and several cardioactive agents. Among newer AEDs, topiramate, oxcarbazepine and felbamate also induce the metabolism of oral contraceptives (Perucca, 1996b). Interactions by which non-epilepsy medications affect the kinetics or response to AEDs also need to be considered: for example, erythromycin, verapamil and diltiazem may cause carbamazepine intoxication by inhibiting its metabolism.

Available AEDs differ markedly in their interaction potential (Table 77.4).

Ease of use

Ease of use encompasses some of the properties discussed above: for example, a broad spectrum of efficacy, an excellent tolerability and a low interaction potential all contribute to ease of use. Additional favourable properties include:

Easy titration
Some AEDs, e.g. levetiracetam, gabapentin, can be titrated rapidly to maintenance dosage, whereas others require a slower dose escalation to minimize central nervous system intolerance, e.g. topiramate, primidone, or idiosyncratic reactions, e.g. lamotrigine.

Wide therapeutic index
Ease of use is enhanced when the therapeutic dose range is much smaller than that associated with toxicity

Easy individualization of dosage
A small variability in dosage requirements across patients facilitates clinical use. Within-patient dosage adjustments are easier for drugs which have linear kinetics. Saturation kinetics leading to a curvilinear relationship between dosage and steady-state serum concentration makes phenytoin a difficult drug to use (Perucca, 1996a). Similarly, dose-dependent autoinduction may complicate the use of carbamazepine.

No tolerance and no withdrawal seizures
Loss of response and seizure exacerbation after drug withdrawal, as seen most commonly with benzodiazepines, complicates clinical management.

Once or twice daily dosing
The need for more frequent dosing is inconvenient and adversely affects compliance.

Availability of a parenteral formulation
This is important when an intercurrent condition, e.g. abdominal surgery or prolonged vomiting, prevents oral treatment.

Drug availability and cost
In 28 countries, which are host to 40% of the world population, the per capita annual gross national product barely suffices to buy a year's supply of carbamazepine or valproate for one or two patients (Meinardi, 1993). As cost containment is a priority even in affluent societies, the price of medications and reimbursability considerations affect prescribing patterns.

Route of administration

When a rapid effect is required, as in status epilepticus or ongoing convulsive seizures, the intravenous route is usually preferred. Intramuscular injection of phenytoin, phenobarbitone and diazepam is not recommended, because absorption after injection of these drugs into muscle tissue may be slow and poorly predictable (Perucca, 1996a). By contrast, rectal administration of diazepam in the form of solution, gel or rectal capsules ensures rapid and efficient absorption and may be especially valuable for non-medical personnel, for example to prevent or terminate febrile seizures (American Academy of Pediatrics, 1999). Recently, interest has also focussed on intranasal midazolam as a potentially useful alternative to obtain rapid control of recurrent seizures.

Whenever AEDs are used long term to prevent seizure recurrence, the oral route is preferred, although a parenteral administration may be required when a patient is temporarily unable to take a drug orally. Regrettably, an injectable formulation is available for only few drugs, and for none of the newer drugs.

Dosing optimization and therapeutic monitoring

Due to marked interindividual differences in pharmacokinetics and pharmacodynamics, the dosage required to produce an optimal response varies considerably across patients. Therefore, identifying the best individual dosage is as important as selecting the correct drug. The need to follow closely the prescribed dosing schedule and the danger of status epilepticus associated with abrupt discontinuation of therapy should be discussed carefully with the patient.

Dose escalation and initial target maintenance dosage

In recently diagnosed patients, an aggressive approach aimed at achieving rapidly a relatively large maintenance dosage is seldom indicated. In most cases, it is desirable to aim initially at a target maintenance dosage at the lower end of the effective range and, if necessary, to make further adjustments based on clinical response (Beghi & Perucca, 1995). For most drugs, optimal dose escalation schedules have been identified to minimize the incidence and severity of side effects. To fully assess the effect of the initial maintenance dosage (and any subsequent dosage adjustment), an appropriate interval must elapse which should take into account both the half-life of the drug (four half-

Table 77.5. Main pharmacokinetic parameters of antiepileptic drugs in adults

Drug	Oral bioavailability	Plasma protein binding	Apparent volume of distribution[a] (l/kg)	Half-life (h)		Main routes of elimination
				Patients not taking enzyme inducers[b]	Patients taking enzyme inducers[b]	
Clobazam[c]	Nearly complete	90%	1.4	10–30	8–16	Oxidation[c]
Clonazepam	Nearly complete	85%	3	20–60	10–30	Reduction and oxidation
Carbamazepine[d]	About 80%	70%	1.2	15–25	5–15	Oxidation[d]
Ethosuximide	Nearly complete	nil	0.6	40–60	20–40	Oxidation
Felbamate	Nearly complete	30%	0.8	14–23	10–18	Oxidation, renal excretion
Fosphenytoin[e]	Prodrug	90%	0.7[f]	10–80[g]	10–80[g]	Oxidation
Gabapentin	35–60%[h]	nil	0.8[f]	5–7	5–7	Renal excretion
Lamotrigine	Nearly complete	55%	1.2	15–30[i]	8–20[i]	Glucuronidation
Levetiracetam	Nearly complete	nil	0.6	6–8	4–8	Renal excretion, hydrolysis
Oxcarbazepine[j]	Pro-drug	40%	–	8–15	7–12	Glucuronidation
Phenobarbital	Nearly complete	55%	0.6[f]	50–170	50–170	Renal excretion, oxidation
Phenytoin	Nearly complete	90%	0.7[f]	10–80[g]	10–80[g]	Oxidation
Primidone[k]	Nearly complete	20%	0.6	10–20	5–10	Renal excretion, oxidation[k]

Topiramate	Nearly complete	13%	0.7	20–30	10–15	Renal excretion, oxidation
Valproic acid	Nearly complete	90%	0.2	12–18	6–12	Oxidation, glucuronidation
Vigabatrin	60–70%	nil	0.8	5–8	5–8	Renal excretion
Zonisamide	≥ 50%	50%	1.5	50–70	23–35	Glucuronidation acetylation, oxidation

Notes:

[a] Calculated assuming complete bioavailability after oral dosing.

[b] Enzyme inducers include carbamazepine, phenytoin, phenobarbital and primidone.

[c] The active metabolite *N*-desmethylclobazam (half-life 35–45 h) contributes to pharmacological effects.

[d] The active metabolite carbamazepine-10,11-epoxide may contribute to carbamazepine effects.

[e] Kinetic parameters refer to phenytoin, for which fosphenytoin is a pro-drug. The half-life of fosphenytoin conversion to phenytoin is about 8–15 min. Phenytoin half-life is dose dependent.

[f] Calculated after intravenous doses.

[g] The half-life of phenytoin is dose-dependent and increases with increasing serum phenytoin concentration.

[h] Bioavailability decreases with increasing oral dosages.

[i] Lamotrigine half-life is 30 to 90 hours in patients comedicated with valproic acid without enzyme inducers and 15 to 30 hours in patients comedicated with valproic acid and enzyme inducers.

[j] Kinetic parameters refer to the monohydroxyderivative (MHD), for which oxcarbazepine is a pro-drug

[k] Primidone is partly converted to phenobarbital, which is primarily responsible for its pharmacological effects.

lives are required to reach steady-state serum drug concentrations) and the baseline seizure frequency.

Number of daily administrations

For drugs possessing a long half-life (e.g. phenobarbitone) or an irreversible mode of action (e.g. vigabatrin), once or twice daily dosing is preferred to maximize convenience and compliance. Drugs with a short half-life such as carbamazepine, gabapentin and tiagabine usually require more frequent administrations to minimize side effects or the risk of breakthrough seizures related to excessive fluctuations in serum drug concentration. Half-lives of AEDs are given in Table 77.5. For some drugs, most notably carbamazepine and valproate, sustained release formulations allow prolongation of the dosing interval.

Need for dosage adjustments

If seizures persist in a compliant patient without significant side effects, an increase in dosage is usually appropriate. Failure to increase dosage, if necessary up to the

highest tolerated level, is a common cause of therapeutic failure (Perucca, 1998). With phenytoin, adjustments should be made carefully because small increments in dosage can result in disproportionate changes in the serum concentration, with the attendant risk of toxicity.

Monitoring serum drug concentrations

For a number of AEDs, serum drug concentration ranges have been identified at which the majority of patients exhibit an optimal response. Measuring drug concentrations can be useful in selected cases, for example when seizures are not controlled despite intake of a large dosage, when toxicity or a drug interaction are suspected, or when compliance is in doubt (Eadie, 1995). Monitoring serum drug concentrations, however, is no substitute for clinical observation, and the golden rule is to treat the patient and not the serum level (Jannuzzi et al., 2000). Intraindividual variability in optimal serum drug concentrations is considerable. When a patient is well controlled at serum drug levels below the usually quoted optimal range, there is no justification for adjusting dosage. Likewise, there are patients who require and tolerate concentrations in the 'toxic' range.

Adequate studies to determine the potential value of serum drug concentration measurements have not been conducted with the new AEDs, partly because measuring drug concentrations is seen as unfavourable for the marketing of a new drug. This view, however, has been questioned and while at present there is no justification for routine measurements of concentrations of new AEDs, there are reasons for considering some of these drugs as potential candidates for monitoring (Perucca, 2000).

Strategies in patients not responding to treatment

Lack of response to the initially prescribed drug should prompt diagnostic re-assessment and consideration of possible causes, such as inappropriate drug choice, inadequate dosing schedule, and poor compliance. If seizures persist at a maximally tolerated dosage, the best strategy initially is to switch to monotherapy with an alternative drug (Perucca, 1997). Up to 40% of patients with partial and/or generalized tonic–clonic seizures failing on the initially prescribed drug become seizure free on alternative monotherapy, which is usually better tolerated than polypharmacy. Switching to the alternative drug may be accomplished by discontinuing gradually the initial medication while increasing simultaneously the dosage of the second agent. Many neurologists, however, prefer to titrate the dosage of the second agent up to the maintenance level and to discontinue gradually the initial agent thereafter. This offers the advantage of minimizing withdrawal seizures, but potentially adverse drug interactions may occur while escalating the dosage of the second agent.

In patients refractory to two or more sequential monotherapies, a trial with combination therapy is generally warranted, and early consideration should be given to the possibility of epilepsy surgery. While the probability of achieving seizure control with pharmacotherapy in these cases is comparatively small, there are patients in whom seizure control can only be achieved by using a combination of two or, rarely, three drugs, even though this entails a higher risk of side effects and drug interactions (Krämer, 1997). When opting for combination therapy, it makes sense to associate drugs with different (or possibly, even antagonistic) side effects, and to avoid drugs associated with adverse interactions. Theoretically, it might also be appropriate to combine agents with a different mechanism of action, although it is as yet unclear what combined actions (if any) would be expected to be particularly beneficial. Clinical experience does suggest that certain combinations may offer greater benefits than others: examples include valproate plus ethosuximide in refractory absence seizures (Rowan et al., 1983) and valproate plus lamotrigine in a variety of refractory seizure types (Panayiotopoulos et al., 1993; Brodie et al., 1997; Pisani et al., 1999). The latter combination is also advantageous in pharmacoeconomic terms, because valproic acid inhibits lamotrigine metabolism and reduces the dosage requirements (and associated cost) of lamotrigine.

The natural history of epilepsy entails spontaneous fluctuations in seizure frequency. Because patients seek medical help more frequently at the time of exacerbation, it is difficult to determine whether any improvement in seizure frequency seen after adding another drug is due to a real effect or, rather, to spontaneous amelioration of the disorder (the so-called 'regression to the mean'). For this reason, pharmacological treatment should be reviewed regularly and the need for combination or high dosage therapy reassessed critically (Perucca, 1995). Patients should never be made to suffer more from the toxic effects of drugs than from the manifestations of the disease, and in refractory epilepsies the aim is the best compromise between maximal seizure control and need to keep side effects within acceptable limits. In many patients who fail to achieve sustained benefit from an added drug, restoration of monotherapy often leads to relief of side effects without deterioration, and sometimes even with improvement in seizure control.

How long should treatment be continued?

In patients who have been free from seizures for a prolonged period (usually at least two years), the possibility of discontinuation should be considered, especially in children who show a higher prevalence of self-remitting epileptic syndromes and in whom the psychosocial consequences of seizure relapse are less severe than in adults (Chadwick, 1994). Drug discontinuation should be carried out gradually, to allow assessment of response at each dose level and to minimize the risk of withdrawal seizures. The proportion of patients whose seizures recur within 2 years following discontinuation of therapy is on average about 30% (Berg & Shinnar, 1994), but this figure in itself has little meaning because relapse rates range from close to zero to over 90% depending on the characteristics of the population. Risk of relapse increases with increasing age, presence of an underlying neurological condition (symptomatic epilepsy), an abnormal EEG and a longer duration of active disease prior to seizure control (Beghi & Perucca, 1995). The most important predictor is, however, the syndromic form: relapse rates are very rare in rolandic epilepsy, relatively rare (5–25%) in childhood absence epilepsy, intermediate (25–75%) in cryptogenic or symptomatic partial epilepsies and high (85–95%) in juvenile myoclonic epilepsy (Perucca & Beghi, 1995).

The option of discontinuing treatment should be discussed with the patient taking into consideration not only the probability of relapse, but also any side effects of treatment, the patient's psychological attitude to continuation of treatment and to the possibility of relapse, and legal implications with special reference to driving regulations.

Epilepsy surgery: disease treatment and investigative opportunity

Guy M. McKhann II[1] and Matthew A. Howard III[2]

[1] Department of Neurological Surgery, Columbia University, Neurological Institute, New York, NY, USA
[2] Division of Neurosurgery, University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Epilepsy surgery has long been and remains one of the areas of clinical neuroscience that best lends itself to a combination of disease treatment and scientific investigation. The surgical treatment of various forms of epilepsy is highly effective in rendering patients seizure-free or markedly improved. At the same time, investigations in the intraoperative and extraoperative setting allow for detailed study of both mechanisms of cerebral organization and cognition, as well as the opportunity to study epilepsy pathophysiology at the single cell, brain tissue slice, and systems levels. This brief overview of epilepsy surgery will outline the history of epilepsy surgery, goals of surgery, criteria used to determine patient suitability, the various types of epilepsy surgery, and anticipated outcomes of these approaches. Research opportunities that are currently being applied during the surgical management of epilepsy patients to study both normal and abnormal brain function, will be highlighted.

Historical background

Prior to the mid- to late nineteenth century, epileptic patients were treated with a variety of surgical treatments including trephination, cauterization, castration and circumcision. Advances in epilepsy surgery were made possible by the parallel discovery of the localization of cerebral functions and the development of tools to map these functions. Stimulation mapping of the mammalian cerebral cortex evolved in the late nineteenth century as a means to experimentally test two opposing theories of cortical localization: the theory of cerebral equipotentiality and the theory of precise localization of different brain functions. Following novel focal stimulation and resection experiments in animals, Flourens concluded in 1824 that the cerebrum was inexcitable and that, although function was located in various parts of the brain, intellectual and perceptual functions were diffusely represented. He was thus the first to propose a theory of cerebral equipotentiality (Flourens, 1824; Tizard, 1959).

Subsequently, on the basis of clinical and pathological data, the opposing view of precise cortical representation of function was hypothesized for language by a group of French scientists including Bouillaud, Broca, and Aubertin and for sensorimotor function by the English neurologist, Jackson. Jackson carried out clinical observations of patients' ictal symptoms and subsequent postmortem examination of their cerebral lesions in the mid-nineteenth century. Based on his clinicoanatomical investigations, he recognized that partial seizures may have a focal pathological substrate in the brain. His pioneering work provided evidence both for the localization of cerebral function and the focal nature of partial epilepsy.

Jackson believed that an anatomically distinct sensorimotor cortex existed that was responsible for contralateral movements following neuronal excitation (Clarke & Dewhurst, 1996). The first experimental confirmation of this notion was provided by the work of Fritsch and Hitzig in Berlin in 1870. They demonstrated the electrical excitability and localized motor functions of the cerebral cortex by stimulating dog cortex and eliciting contralateral limb movements (Fritsch & Hitzig, 1870). Soon thereafter, the British school of cortical stimulation and ablation emerged. Ferrier carried out experiments in dogs and monkeys, confirming Jackson's views of cortical localization and further defining mammalian motor cortex (Ferrier, 1876). Other British investigators extended Ferrier's monkey observations including Horsley (Paget, 1919) and Sherrington, the latter in collaboration with Grunbaum (Grunbaum & Sherrington, 1902). Although many early investigators transposed their monkey results onto outlines of the human brain, mapping of the human

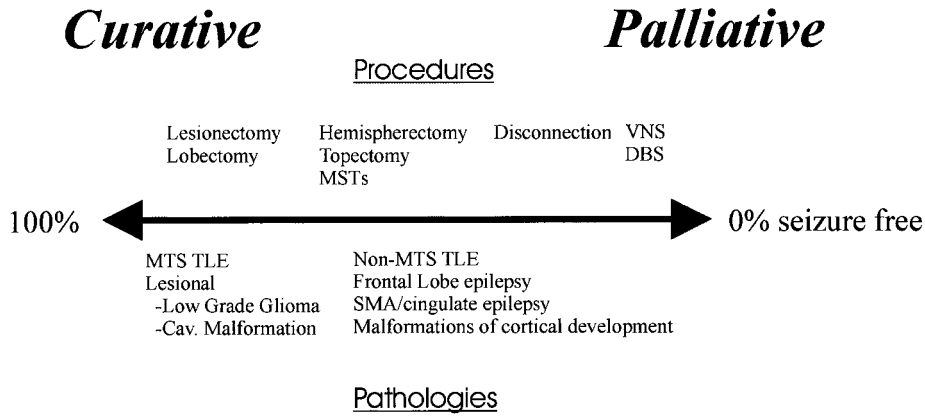

Fig. 78.1. Schematic diagram outlining the continuum of epilepsy surgical procedures from curative to palliative.

motor cortex was not performed until neurosurgeons Mills and Frazier in Philadelphia (Mills & Frazier 1905–1906), Cushing in Baltimore (Cushing, 1909), and Krause in Berlin (Krause, 1911; Foerster, 1936; Walker, 1951) sequentially produced stimulation derived drawings of the primary motor area between 1905 and 1911. In Berlin, Foerster subsequently began extensive stimulation experiments in man in 1924 in an attempt to corroborate the comparative stimulation and cytoarchitectonic experiments that had been carried out in the long-tailed monkey by the Vogts during the previous decade. His cortical localization studies confirmed the Vogts' monkey results and were used to form a 'synthetic' map of cytoarchitectonic and stimulation-induced cortical localization (Foerster, 1936). Because of Foerster's expertise in resection of epileptogenic cortex and cerebral localization, Penfield studied under him during 1928 and then subsequently returned to Montreal and devoted his professional life to these areas of study.

Based on the principles of functional localization established by Jackson, Broca, and others, Macewen in 1879 and Horsley in 1886 removed epileptogenic lesions to treat focal seizures. Horsley's initial surgery was carried out with the intraoperative assistance of both Jackson, a neurologist, and Ferrier, a neurophysiologist. This multidisciplinary team approach was subsequently adopted by Penfield, following his epilepsy surgery training with Foerster. In collaboration with Boldrey, Rasmussen, Jasper, and Milner, Penfield established the Montreal Neurological Institute (MNI), forming the predominant epilepsy clinical and research centre for much of the twentieth century. Much of our early knowledge regarding the utility of electroencephalography (EEG) to detect temporal lobe seizure onsets; the neocortical organization of human language, sensation, and movement; and the material specific functions of the left and right temporal lobes was obtained by this team. The collaborative team approach remains the optimal way to combine clinical care with scientific investigation in the management of epilepsy.

Surgical epidemiology and goals

Epilepsy is a very common disorder, with a cumulative lifetime incidence of 3%. Based on a point prevalence of ~0.5%, there are over one million people suffering from epilepsy in the United States. Approximately 40% of these individuals have complex partial seizures and 20% have other secondary epilepsies; 50–65% of these 600 000 patients can become seizure free with antiepileptic medications. Of the 250 000–300 000 remaining epileptics, at least one-third are potential candidates for epilepsy surgery. Thus, by conservative estimates, there are at least 100 000 epilepsy surgery candidates in the United States, with an estimated 5,000 new patients who may benefit from surgery each year (Engel & Shewmon, 1993).

Epilepsy surgery can be divided based on the goals of the operation into palliative and curative procedures (Fig. 78.1). Examples of curative procedures include lesional resection, lobectomy, corticectomy, and most cases of hemispheric surgery and multiple subpial transections. There is preliminary evidence that gamma knife radiosurgery may be curative in temporal lobe epilepsy and for cavernous malformation-associated epilepsy (see below). The primary goal of a curative surgery is for the patient to be able to lead a normal life, preferably off all antiepileptic medications. There is gathering evidence that early surgical intervention is favourable for a variety of reasons. Becoming seizure free at a younger age may lessen the cognitive, behavioural, and psychosocial problems experi-

enced by epilepsy patients, potentially improving societal integration. Additionally, because continued seizures may result in progressive neurological damage over time, surgery has the potential to be neuroprotective in comparison to continued medically refractory seizures. If a hemispheric procedure is required or if 'eloquent' areas of brain are within the epileptogenic zone, the potential for recovery of language and sensorimotor functions is better when patients are younger.

Palliative procedures by definition only very rarely result in cessation of seizures; rather these surgeries may prevent the occurrence of a particularly morbid type of seizure such as drop attacks or lessen the frequency or severity of seizures. Palliation may be a desirable result in patients with seizure-related injuries or with a predominance of one seizure type that can be eliminated with surgery. Examples of palliative surgery include some cases of hemispheric surgery, multiple subpial transections, disconnection procedures including callosotomy, and stimulation procedures including vagal nerve stimulation, and deep brain stimulation. There is a continuum between likely curative and likely palliative, and patient and family expectations must be adjusted accordingly. For example, the procedure of choice for a patient with invasive monitoring documented mesial temporal lobe epilepsy (TLE) who has no magnetic resonance imaging evidence of mesial temporal sclerosis (MTS) is resection of the anteromesial temporal lobe through one of a variety of surgical options (see below). The likelihood of seizure freedom in this patient is ~60%, in contrast to at least 80–90% seizure freedom if MTS is present. Although the goal of this surgery is curative, there is a significant likelihood that the outcome will be palliative.

The ultimate decision making in epilepsy surgery will depend on the type of seizures, location of the epileptogenic zone, presence or absence of a lesion, the patient's clinical and developmental status, and the natural history of the epilepsy syndrome. Complete discussion of all epilepsy syndromes amenable to surgical treatment is beyond the scope of this chapter; however, many of the commonly treated surgically remediable syndromes are described below under types of surgery.

Surgical patient evaluation

Medical intractability

In order for patients to be considered for epilepsy surgery, they must first be deemed to be medically intractable such that they are unable to achieve seizure control despite adequate trials with a sufficient number of drugs at doses that are associated with acceptable side effects (Bourgeois, 2000). However, there are no standardized definitions of what constitutes adequate seizure control, acceptable side effects, adequate trials, or a sufficient number of drugs. For example, the spectrum of sufficient number of drug trials ranges from two major drugs at maximal tolerated dose to four major drugs and six combinations, totalling ten trial periods. This variation is because there remains a small chance of seizure freedom with subsequent antiepileptic medications after failing a first-line major drug. In a recent examination of 470 untreated epilepsy patients, just 47% became seizure free with one drug, with improvement to 64% with 3 medications or combinations of medications. However, the probability of controlling seizures after failure with 2 drugs was less than 10% (Kwan & Brodie, 2000). Despite the recent introduction of a number of new antiepileptic medications (gabapentin, lamotrigine, topiramate, vigabitrin) and the vagal nerve stimulator (discussed in more detail below), less than 5% of medically intractable patients achieve seizure freedom with the addition of one of these therapies (Lhatoo et al., 2000).

Not all epilepsy syndromes have the same degree of intractability, raising the possibility that medical intractability may be able to be documented after two to three adequate medication trials in many surgically amenable conditions. Patients with temporal lobe epilepsy, malformations of cortical development, dual pathology, and head injury are some of the groups least likely to have their seizures effectively controlled with antiepileptic medications. In a recent study of 2200 adult outpatients in France, of whom 62% had partial epilepsy, only 20% of temporal lobe epilepsy patients achieved seizure control, defined as more than 1 year without seizures (Semah et al., 1998). In addition, previous analysis of 74 adult surgery candidates who had not received the maximal tolerated dose for three major drugs revealed that no patients became seizure free with further antiepileptic therapy and less than 10% had marked (>80%) seizure reduction (Hermanns et al., 1996).

Taken together, the low likelihood of achieving adequate seizure control in patients with many of the surgically remediable epilepsy syndromes combined with the detrimental social, developmental, and possibly neurobiological consequences of persistent seizures makes early surgical intervention a logical treatment course. However, even for the best understood surgically remediable syndrome, temporal lobe epilepsy with MTS, early surgery is not yet the standard of care. A recent prospective randomized trial in London, Ontario confirmed what has long been known by epilepsy surgery centres caring for patients with temporal

lobe epilepsy. In this study, 65% of patients who underwent surgery were seizure free at 1 year follow-up in comparison to 8% of patients randomized to best medical therapy. Operated patients also had improved quality of life (Wiebe et al., 2001). A multicentre prospective trial is currently being organized to investigate the potential benefits of early surgery in MTS TLE.

Presurgical evaluation

Once a patient has been determined to be medically intractable, extensive preoperative evaluation is necessary to classify that patient's epilepsy and determine whether it can be treated with surgery. The goals of the preoperative evaluation are to determine: (i) to which side of the brain the patient's seizures are lateralized; (ii) to which specific area of the brain these seizures are localized; and (iii) the extent of the epileptogenic zone, the region that is necessary and sufficient for initiating seizures and whose removal or disconnection is 'necessary for abolition of seizures'. Unfortunately, no currently identifiable imaging, EEG, clinical evaluation, or other examination methods fully elucidate the epileptogenic zone. A number of other zones have been defined in epilepsy evaluation: (i) the irritative zone, which is the cortical area capable of generating interictal discharges; (ii) the ictal onset zone, as defined by EEG recording; (iii) the epileptogenic lesion, as defined by MR imaging or histopathological examination; (iv) the functional deficit zone, which refers to the area of interictal non-epileptic dysfunction identified during neurological examination; neuropsychological testing; or perfusion or metabolism studies, such as PET or SPECT scanning; and (v) the symptomatogenic zone, the area of the brain that produces the initial ictal symptoms (Luders et al., 1993).

The overall strategy of presurgical evaluation is to use a combination of testing modalities to identify structural abnormalities, deficits in non-epileptiform function, and areas of ictal and interictal EEG abnormality; and to then identify the surgical removal area where the testing results are concordant. The exact methodologies that are used vary somewhat from epilepsy centre to centre, particularly the utilization of PET, SPECT, MR spectroscopy, and other specialized neuroimaging techniques. It is possible that in the future, advances in MR technology will simplify presurgical evaluation by eliminating the need for many adjunctive components. MR is already used on sporadic basis in select centres to capture ictal activation zones, as well as interictal patterns of MR activation. In addition, MR localization of cerebral language and memory function will likely eventually replace the intracarotid amobarbital (Wada) investigation for determination of hemisphere dominance and memory function.

The exact preoperative evaluation is determined by the location of EEG seizure onsets, whether a structural abnormality is present, and which procedure is being considered. For example, the standard evaluation of temporal lobe epilepsy patients usually includes multiple interictal EEG recordings, MRI examination for the detection of structural abnormalities, sodium amobarbital (Wada) intracarotid perfusion testing, and neuropsychological testing, resulting in lateralization of the seizure process to one anterior temporal lobe. The majority of patients have video EEG telemetry monitoring of ictal events. Several seizures are analyzed for ictal onset. Brain MRI includes coronal images of the temporal lobes in all patients, using both T_1-weighted, T_2-weighted, and inversion recovery (STIR) images to assess the degree of hippocampal atrophy and increased hippocampal signal (Fig. 78.2). Many centres employ either high-resolution phase arrayed surface coils to allow better definition of local hippocampal pathology, or hippocampal volumetric calculations that are compared to a normalized control database. Adjunctive interictal neuroimaging tests applied in selected tertiary centres include ^{18}F-fluorodeoxyglucose positron emission tomography (PET) scanning to detect localized areas of decreased brain metabolism, single photon emission computed tomography (SPECT) scanning to show areas of decreased perfusion; and magnetic resonance spectroscopy to look for localized alterations in brain chemical spectra. SPECT scanning is particularly useful when interictal images are computer subtracted from ictal images, delineating areas of ictal hyperperfusion (SISCOM scanning) (O'Brien et al., 1999, 2000).

Wada testing is applied to lateralize language and memory function between the two hemispheres, while neuropsychological testing strengthens localization by providing information regarding temporal lobe dysfunction. If all of these studies are concordant, implicating the same temporal lobe in a patient's seizure pathogenesis, an anteromesial temporal lobe resection is performed. In those patients with discordant test results, non-localizing EEG, or bilateral temporal seizure onset by scalp EEG, intracranial monitoring with subdural strip and/or grid electrodes is performed to confirm a unilateral side of onset. In some centres, a minority of patients do not undergo either video EEG monitoring or invasive recording prior to surgery. These individuals have strictly unilateral interictal epileptiform abnormalities on multiple preoperative EEGs and no discordance on any of the other preoperative studies (Holmes et al., 1996).

Types of surgery

Anesthesia/intraoperative recording

The majority of epilepsy surgery procedures are carried out at specialized centres where a multidisciplinary group of epilepsy neurologists, clinical physiologists and neurosurgeons employ a systematic approach to surgical planning. Though there is typically consistency in surgical strategies within an institution, approaches vary considerably across centres. One fundamental point of departure relates to the use of general anesthesia. In some centres all cortical resections are carried out in awake patients under local anesthesia, while at other centres resections are usually done under general anesthesia. These different anesthetic strategies reflect differences of opinion regarding the utility of intraoperative monitoring of neurological function and EEG recordings from awake patients during surgery. Surgeons who perform 'tailored' resections rely on the results of intraoperative EEG recordings obtained directly from the brain surface to guide certain stages of their surgical planning. The quality of these recordings, and ability to detect interictal discharges, is optimal in an unanesthetized brain. These surgeons also use stimulation mapping to identify cortical locations that are essential for language function, and tailor their resection to avoid these sites. The disadvantage of an awake craniotomy is that surgeon and anesthesiologist must keep the awake patient comfortable and cooperative throughout the procedure. In centres where this approach is used routinely, experienced operating room teams rarely encounter significant difficulties with this approach. Proponents of general anesthesia prefer the control and familiarity of this approach and believe that in properly selected patients the impact of intraoperative EEG and functional mapping is not significant. This issue continues to be a point of debate and is unlikely to be resolved in the near future.

Temporal lobe resections

The temporal lobe is the most common seizure focus site targeted for resection surgery; specifically the mesial structures (i.e. amygdala and hippocampus). Patients with a temporal lobe seizure focus have a high incidence of refractoriness to medical management, and conversely have the best overall results from seizure surgery. Properly selected temporal lobe epilepsy patients have an up to 80–90% probability of being seizure free following resection surgery. A variety of technical approaches have evolved, all of which are directed at the common goal of eliminating temporal lobe seizures. The differences

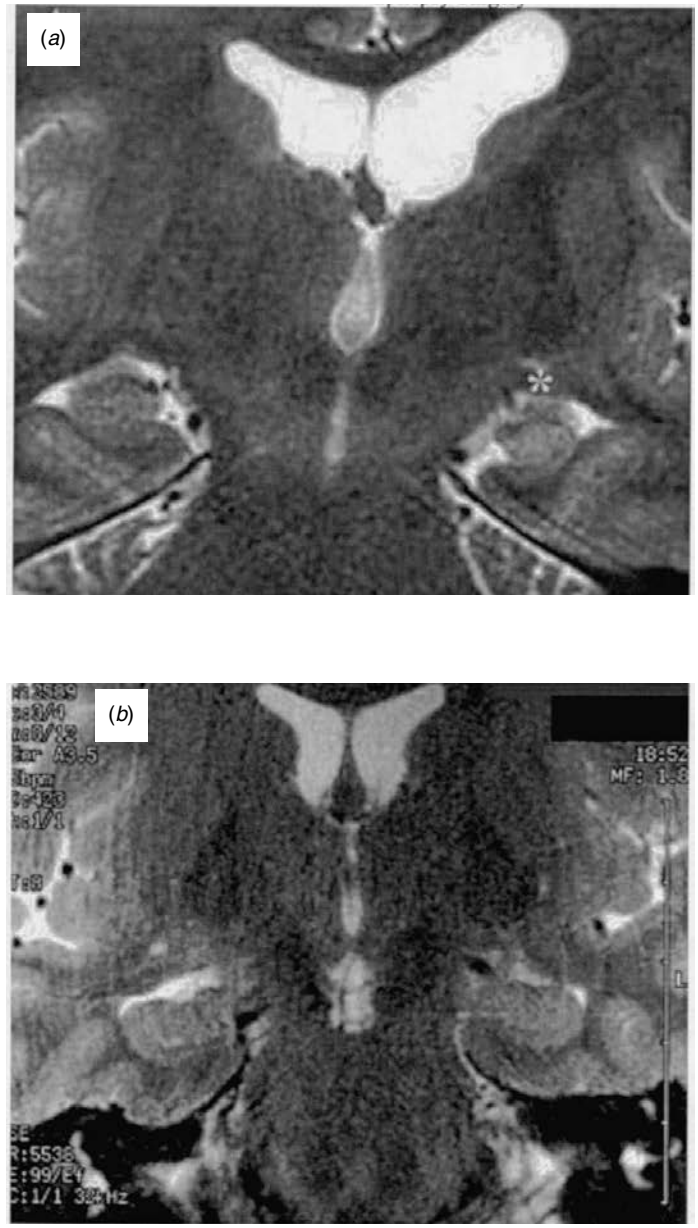

Fig. 78.2. Representative coronal MR image from a patient with mesial temporal sclerosis (*a*) and a patient with MR symmetric hippocampi (*b*). The hippocampus with the atrophy and increased signal is marked with an asterisk. Both of these patients presented with mesial temporal lobe epilepsy. The preoperative prediction of seizure freedom following surgery is 80–90% for patient (*a*) and 50–60% for patient (*b*).

between techniques stem from varying opinions regarding what temporal lobe regions should be resected, and how the extent of resection should be planned. One area where different surgeons vary their technique is in their approach to the anterior lateral temporal neocortex. Based on the rationale that the temporal lobe seizure focus is typically confined to mesial structures, Yasargil and colleagues developed and described the selective amygdalohippocampectomy (Yasargil et al., 1993). With this procedure, the surgeon gains access to the mesial structures via a trans-Sylvian route, an approach that spares the lateral temporal lobe neocortex. The approach is technically more challenging and is dependent on the use of fine microdissection techniques that evolved from aneurysm surgery. Despite excellent results reported by proponents of the selective amygdalohippocampectomy, the procedure has not been widely adopted by epilepsy surgeons elsewhere. The Yasargil technique has been modified to avoid the need to microdissect the Sylvian fissure. In these approaches, an MRI frameless stereotactic image guidance system is used to facilitate dissection through the superior temporal sulcus, middle temporal sulcus, or middle temporal gyrus down to the temporal horn of the lateral ventricle, from which selective amygdalohippocampectomy is performed (Roberts, 2000).

The more common, and classical approach to temporal lobe resections involves removal of some portion of the anterior lateral temporal neocortex. There are two reasons for using this strategy; (i) the lateral neocortex may serve as a seizure focus in some patients; and (ii) removal of a portion of the lateral cortex affords optimal surgical access to mesial structures. As was described in the section on anesthesia, surgeons employ varying strategies when deciding what portion of the lateral temporal lobe should be resected. Proponents of tailored resections will carry out EEG recordings directly from the exposed brain surface in order to identify interictal discharges. If a clear discharge focus is identified, that region of neocortex will be incorporated into the lateral resection. If no lateral discharges are noted, only a small region of the temporal tip will be removed in order to gain access to mesial structures. In the dominant hemisphere, proponents of tailored resections identify temporal lobe sites that are essential to language function using electrical stimulation disruption methods in the awake patient. Cortical sites that subserve critical language functions are spared from resection. Epilepsy surgeons who do not subscribe to the need for intraoperative EEG recordings and language mapping carryout standardized lateral resections that typically incorporate the most anterior 3–4 cm of lateral temporal lobe on the language dominant side, and 4–5 cm in non-dominant cases. There is no compelling evidence in the literature indicating superior seizure control efficacy for the tailored vs. standard resection technique. The majority of epilepsy centres do not use intraoperative ECoG to guide the extent of lateral neocortical resection in patients with mesial temporal lobe epilepsy.

All successful surgical techniques designed to treat complex partial seizures of temporal lobe origin emphasize the importance of resecting the hippocampus. From the seizure control perspective, it is preferable to remove as much hippocampus as is technically feasible, particularly if intraoperative hippocampal ECoG is not utilized to guide hippocampal resection. The surgical technique developed and popularized by Spencer at Yale results in nearly complete resection of the hippocampal formation (Spencer et al., 1984). Support for a more radical hippocampal resection was provided by a randomized prospective study by Wyler et al. (1995). All patients who were candidates for a mesial temporal resection were randomized to an anatomical hippocampal resection that was either 'partial' (to the anterior peduncle) or 'total' (to the collicular cistern), regardless of any differences in regional electrophysiological abnormalities as detected during preoperative evaluation. The authors found that patients with a 'total' hippocampal resection were more likely to be seizure free and had a greater average time to first postoperative seizure. However, 38% of the patients with 'partial' resections were seizure free, raising the issue of whether this subgroup of patients can potentially be identified and spared a larger hippocampal resection.

One of the problems with performing an extended hippocampal resection in all patients is the possibility that it may increase the rate of postoperative memory deficits. Patients with a larger hippocampal resection have been found to have a greater impairment in verbal memory following dominant temporal resection or non-verbal memory following non-dominant temporal resection, respectively (Milner, 1971; Katz et al., 1989; Helmstaedter & Elger 1998; Nunn et al., 1999). However, other studies found no correlation between memory outcome and extent of hippocampal resection (Wolf et al., 1993; Wyler et al., 1995; Hermann et al., 1999). Some investigations show that postoperative memory decline correlates most closely with a lack of pathologically demonstrated hippocampal neuronal loss (Sass et al., 1990, 1992, 1994; Baxendale et al., 1998; Bell & Davies 1998; Davies et al., 1998; Martin et al., 1998).

Some surgeons use EEG recordings to determine the extent of hippocampal resection. The rationale for using recording data to plan the hippocampal resection is based on the assumption that it is desirable to spare more poste-

rior regions of the hippocampus if these areas are not epileptogenic. This is of particular concern in patients who have an normal hippocampus MR imaging that is being resected or in rare patients with dysfunctional contralateral hippocampus. These patients are at increased risk of neurocognitive deficits following hippocampal resection, particular on the dominant side. Recent analysis of 140 consecutive TLE patients operated at the University of Washington utilizing an ECoG tailored resective strategy provides evidence that the seizure outcome is the same for all sizes of hippocampal resection if the amount of hippocampectomy is determined by hippocampal electrophysiology (McKhann et al., 2000). Whether preserving a portion of hippocampus during surgery provides any functional benefit remains to be determined.

In contrast to the hippocampus, it is less clear how important the amygdala is as a target for resection. Surgical cases of amygdalar sclerosis without hippocampal sclerosis have been documented (Miller et al., 1994; Zentner et al., 1999). The ventrobasal amygdala is almost always incorporated into any form of mesial resection due to its immediate proximity to the hippocampus and safety of resection. In order to perform a nearly complete amygdala resection, however, the surgeon must extend the mesial resection dorsally into the region of the temporal stem and caudal basal ganglia. This introduces additional surgical risks, and the seizure control benefit of this approach is unclear.

In patients with medically refractory temporal lobe epilepsy there are no new medications that can be offered that would even approximate the high rates of seizure free outcomes that can be expected from epilepsy surgery (Wiebe et al., 2001). Despite this fact, surgical treatment is underutilized because of fear of complications. Modern surgical techniques have improved considerably compared to the early days of epilepsy surgery, and the vast majority of patients have uncomplicated procedures, but significant risks still exist. Untoward results can be attributed to removal of brain tissue intentionally resected, or be a consequence of unexpected surgical complications. Resection of any brain tissue to treat epilepsy risks damaging the neurologic functions mediated by the brain regions that were removed. Following dominant temporal lobe epilepsy surgery, patients may experience a significant decline in verbal memory function, particularly if their MRI does not demonstrate MTS or their preoperative verbal memory function is not already compromised (Hermann et al., 1999). If the neocortical resection abuts or includes a cortical area that is essential for language function, a patient is likely to have at least transient worsening of postoperative language (Ojemann & Dodrill, 1987; Ojemann et al., 1989).

The most feared complications of temporal lobe epilepsy surgery result from inadvertent injury of vascular structures abutting the medial temporal lobe, or mechanical disruption of the optic tract or brain tissue deep to the temporal stem (Behrens et al., 1997). Approximately 1–2% of patients will develop a permanent hemiparesis, presumably as a consequence of damage to the anterior choroidal artery or branches of the posterior communicating artery. The optic tract is immediately adjacent to the hippocampal formation and can be injured mechanically or from a vascular insult, resulting in visual field deficits of varying density. In the worst case, a patient can develop a disabling homonymous hemianopsia.

Extratemporal resections

Patients with intractable epilepsy referable to a cortical seizure focus outside of the temporal lobe represent a difficult surgical treatment challenge. This is a heterogeneous group of patients who have developed a neocortical seizure focus, the pathophysiology of which is usually poorly understood. Unlike temporal lobe epilepsy patients who present with characteristic and clearly recognizable complex partial seizures, the anatomical site of seizure onsets cannot be as readily characterized based solely on clinical criteria in patients with extratemporal lobe epilepsy (Olivier, 1995; Olivier & Boling, 2000). Often the earliest stage abnormal electrical activity develops in a functionally silent region of the brain, then spreads rapidly into multiple distant brain regions causing convulsive clinical features that do not reflect the true anatomical site of seizure onsets. The spatial resolution of scalp EEG monitoring is frequently inadequate to resolve the location of these seizure onsets. Brain MRI and metabolic imaging studies are utilized in the hopes of identifying an anatomical or metabolic abnormality that can help localize what regions of the brain should be targeted for further investigation. Ictal scalp video–EEG clinical information, combined with these anatomical studies, is used to guide the placement of intracranial electrodes. Customized arrays of surface grids, strip electrodes, and depth electrodes are implanted to cover and 'bracket' the brain regions thought most likely to harbour the focus of seizure onsets.

In addition to determining the site of seizure onsets, intracranial electrodes are used to functionally map the location of eloquent brain regions that may abut or represent a portion of the seizure focus. When consistent evidence has been gathered that clearly defines a seizure focus and surrounding eloquent brain regions, an effective resection strategy must be formulated balancing the needs to carry out a comprehensive resection of all tissue

constituting the seizure focus, while avoiding neurological morbidity. Certain functional regions can be resected with minimal long-term morbidity, such as non-dominant face motor and sensory cortex, and certain regions of extrastriate visual cortex (Nawrot et al., 2000). Other functionally defined regions, such as hand, arm and leg regions within the pre- and postcentral gyri, and language critical sites in the frontal and parietal lobes, cannot be safely resected. Morrell and colleagues have described a technique of multiple subpial transections (MST) to address seizure foci within such eloquent regions of cortex (Morrell et al., 1989). The MST method is based on the hypothesis that abnormal propagation of epileptic activity is dependent on horizontal spread of cortical activity whereas the normal functions of the cortex are largely mediated by activity within vertical columns. A fine dissecting tool is introduced into the neocortex along the width of a gyrus at 4–5 mm intervals to disrupt local horizontal fibre tracts while preserving the structural integrity of vertical columns of neurons. In experienced hands, this technique can substantially improve seizure control without causing significant neurological morbidity. However, recent concerns have been raised over the durability of seizure control following MSTs (Orbach et al., 2001).

Patients who have little functional use of the contralateral limb represent a distinct population of epilepsy surgery patients. In these patients with congenital hemiplegia or chronic encephalitis, hemispherectemy is a viable treatment option. Careful attention must be paid to the functional status of the patient's affected hand and foot, in that no useful fine motor control of hand or foot will be preserved following this procedure. Initially, hemispherectemies were performed by surgically ablating all neocortical tissue and underlying white matter external to the deep grey matter structures (Rasmussen, 1983). This approach has subsequently undergone several modifications to achieve a 'functional' hemispherectemy or hemispherotomy (Tinuper et al., 1988; Behrens et al., 1997; Schramm & Behrens 1997; Yoshioka et al., 1999). In these procedures, varying degrees of peri-Sylvian, insular and temporal lobe structures are initially resected. The lateral ventricle is then entered and a complete corpus callosotomy is carried out. In the final steps, frontal and parieto occipital white matter disconnections complete the isolation of the involved hemisphere. The modified approaches have been sequentially designed to avoid the development of superficial hemosiderosis or hydrocephalus, either of which can develop in a delayed fashion following anatomical hemispherectemy. In addition, modified procedures result in less operative blood loss, decreasing the need for transfusion in this young patient population.

Difficulties related to localizing seizure onsets, the need to avoid damaging eloquent brain regions, and the wide variability in clinical–pathological features among patients with extratemporal epilepsy all contribute to suboptimal seizure control results following surgery. Although many more patients experience some degree of improvement in seizure control, long-term seizure free outcomes are achieved in only 40–60% of patients who undergo extratemporal neocortical resections. In properly selected children who undergo hemispherectomy, the seizure free outcome can be better than 50% (Edwards et al., 2000).

Corpus callosotomy

The normal role of the corpus callosum is to transmit action potentials between the two hemispheres, and this electrophysiological conduit allows certain forms of seizure activity to synchronously engage both hemispheres with adverse clinical consequences. A wide range of disconnection procedures have been used in the past with the intent of disrupting the propagation of seizure activity, including sectioning the corpus callosum, interhemispheric commissures, the mass intermedia, and the fornix. In more recent years it has become increasing clear that the only midline disconnection procedure that should be considered as an epilepsy surgery treatment option is callosotomy; there are no clear benefits to resecting additional midline structures (Luessenhop et al., 1970; Wilson et al., 1978; Gates et al., 1987; Sass et al., 1988).

Sectioning the corpus callosum does not eliminate seizure activity, it simply inhibits synchronization between the hemispheres. If the patient has a focal seizure disorder, it is preferable to identify the epileptic focus and carry out a neocortical resection procedure as described above. Patients whose seizures cannot be localized to a specific brain locus, and who suffer from abrupt synchronous, bilateral loss of motor tone and posture control may benefit from callosal sectioning. These are patients with falling spells and atonic (akinetic) seizures. Greater than 65% of patients who undergo callosotomy experience a diminution in the frequency of these drop attacks. In the past, the entire corpus callosum was resected, often in a staged procedure. More recent reports suggest that near equal efficacy can be achieved by simply sectioning the anterior two thirds of the callosum. Clinically significant disconnection syndromes are rare, particularly if the posterior one third of the callosum is spared (Sass et al., 1988).

Stimulation techniques: vagal nerve stimulation, deep brain stimulation

Some of the most exciting and rapidly advancing areas of modern neurosurgery involve chronically delivering electrical stimuli to the nervous system. Because of technical advances in material sciences and microelectronics it is now feasible to implant stimulating devices that can deliver precisely controlled currents to targeted structures throughout the peripheral and central nervous system for a period of years. These developments have had a significant impact on the surgical treatment of epilepsy, most notably with the wide spread adoption of the vagal nerve stimulator (VNS). The exact mechanisms by which vagal nerve stimulation affects seizure activity are unclear, although vagal afferent projections via the nucleus of the tractus solitarius to more rostral structures such as the hypothalamus, thalamus, amygdala, locus ceruleus, and raphe nuclei have been implicated (Woodbury & Woodbury, 1990). However, the positive impact of VNS on seizure frequency has been consistently demonstrated in clinical studies. One attractive attribute of this treatment approach is ease of surgery and patient safety. The stimulator leads are placed around the left vagus nerve in the neck and the stimulator housing is implanted in the soft tissue of the chest wall. In some institutions this is done as an outpatient procedure. Unlike brain resection techniques, there is almost no risk of serious neurological injury. The drawback to VNS relates to its limited efficacy compared to brain resection procedures. Although approximately half of patients implanted with a VNS will experience a 50% decrease in seizure frequency, less than 5% of patients are seizure free long term (Woodbury & Woodbury, 1990; Amar et al., 1998; Patwardhan et al., 2000). For these reasons, VNS is recommended for patients with intractable epilepsy who cannot benefit from traditional resection treatments.

Another electrical stimulation strategy being pursued on an experimental basis involves activating deep brain structures with the intent of disrupting generalized seizure activity (Velasco et al., 1993). This strategy is based on the understanding that certain targets such as the anterior nucleus of the thalamus and the subthalamic nucleus are critical relay stations in the network of seizure propagation. High frequency deep brain stimulation has the potential to (i) functionally inactivate the neurons in the area of stimulation, inhibiting downstream projections and (ii) exert a desynchronizing effect on on-going EEG activity. The safety of long-term subcortical stimulation has been clearly demonstrated in extensive studies of patients treated with deep brain stimulation for Parkinson's disease. Whether thalamic or subthalamic stimulation for the control of epilepsy will be similarly effective is unclear at this time. This novel treatment approach, along with efforts to directly infuse inhibitory compounds into targeted brain structures, appears to have considerable potential. Separate multicentre trials are beginning to investigate the safety and efficacy of bilateral DBS of the anterior thalamus and subthalamic nucleus in the management of epilepsy.

In addition to their utility as therapeutic devices, both VNS and DBS are being studied to better understand the pathways and mechanisms of neuronal network synchronization in the brain.

Gamma knife radiosurgery

The ability of radiosurgery to control seizures has been extensively documented in patients with intracerebral arteriovenous malformations (AVMs), who most commonly present with either hemorrhage or seizures. Following radiosurgical treatment of AVMs using a variety of techniques including proton beam, linear accelator, and gamma knife radiotherapies, 55–80% of patients with pretreatment seizures have achieved seizure freedom following treatment. The chance of becoming seizure free inversely correlates with the duration of epilepsy; while complete AVM obliteration is not required for seizure freedom. Radiosurgery does have the potential to induce seizures in a minority of patients ($<5\%$) (Heikkinen et al., 1989; Kurita et al., 1998; Kida et al., 2000; Ghossoub et al., 2001).

Because radiosurgery delivers focused radiation to selective targets within the brain using stereotaxic guidance, it has been used to treat other 'lesional' epilepsies including cavernous malformations, mesial temporal sclerosis temporal lobe epilepsy (MTS TLE), and hypothalamic hamartomas. In the largest reported series of epilepsy associated with cavernous malformations managed with gamma knife radiosurgery, 26/49 patients were seizure free beginning one year after treatment. However, in the subgroup with mesial temporal lesions, only 2/12 were seizure free (Regis et al., 2000a,b,c). Eight patients from seven centres were recently reported following gamma knife radiosurgical treatment of their hypothalamic hamartoma-associated epilepsy. Four patients were rendered seizure free, two of whom required second treatments (Regis et al., 2000a,b,c).

Experience has been gathering using gamma knife radiosurgery for MTS TLE. Animal research using both electrical stimulation and kainic acid models of limbic epilepsy demonstrates marked reduction of seizures following

radiosurgery, even at doses that do not induce necrosis (Maesawa et al., 2000; Regis et al., 2000a,b,c; Chen et al., 2001; Kurita et al., 2001). Based on initial promising results in humans, with 13/16 patients seizure free at 2 year follow-up (Regis et al., 2000a,b,c), there are ongoing European and NIH supported American multicentre trials applying gamma knife radiosurgery to patients with MTS TLE.

Whether radiosurgery offers any neuropsychological benefit over open surgical resection of the mesial temporal structures remains to be determined. There are risks of radiosurgery including radiation necrosis or edema, neurological deficits referable to the targeted area, radiation damage to structures outside targeted zone, and a possible increase in auras prior to reduction in seizures. In general, the effects of radiosurgery are not maximal until up to 1 year following treatment. In addition, there are rare (four as of summer 2001) reports of radiation-induced neoplasms following over 135 000 cases of gamma knife treatment worldwide. The potential benefit of using 'subnecrotic' dosing of radiosurgery to treat epilepsy remains intriguing and is being further investigated.

Research opportunities provided by epilepsy surgery

Cerebral localization of function

Intraoperative sensorimotor/language/cognitive/memory paradigms

Despite recent advances in non-invasive functional mapping methods, there remains a compelling need to carry out additional direct cortical mapping procedures during surgery. The rationale for this approach relates to important distinctions between the physiologic mechanisms that are monitored using non-invasive methods and the functional consequences of direct electrical stimulation of cerebral cortex. Non-invasive investigative methods such as scalp EEG, MEG, PET and fMRI are used extensively by investigators seeking to better understand brain physiological events that mediate human sensorimotor, language, cognitive and memory functions. These powerful methods have provided important insights into normal brain function and pathophysiology. By their nature, however, these techniques cannot accurately predict the consequence of creating a localized brain lesion in a given surgical patient. This lack of predictability relates to a distinction between the relatively widespread regions of neocortex that demonstrate changes in electrical, magnetic or metabolic activity during performance of a task, vs. the much more localized area of cortex that is 'essential' to carrying out the task (Ojemann & Dodrill, 1987). Resections of functionally active cortex outside of the essential region result in minimal or no detectable deficits, whereas removal of the 'essential' cortex leads to a profound neurological deficit. To date, the most accurate method available for identifying and sparing these essential regions involves the use of direct electrical stimulation disruption techniques.

This approach has been used for more than a century and in its current form is a key element of the epilepsy surgeon's technical armamentarium. The method involves having the awake patient carry out a series of tasks as the surgeon delivers disruptive currents to localized regions of cortex. The electrical stimuli are delivered via a hand held electrode in the operating room (Fig. 78.3), or through brain surface recording contacts in patients undergoing video–EEG monitoring with intracranial electrodes. EEG recordings are obtained from the brain tissue being electrically stimulated to insure that abnormal electrical activity (e.g. afterdischarges) does not persist or spread after the period of electrical stimulation.

If the patient is unable to perform the task during the stimulation period, the stimulated brain region is identified as essential to that task. The predictive accuracy and interpretability of electrical stimulation functional mapping has been clearly demonstrated in language, motor and sensory systems. Attempts at using disruption techniques to identify memory critical regions have been less successful and are not utilized routinely. Perhaps the most robust example involves the identification of language critical sites. In the simplest form of language mapping, patients are instructed to name objects or count as the surgeon reversibly deactivates regions of the frontal, parietal and temporal lobes. The exact brain sites that will disrupt this function cannot be predicted based on simple anatomical criteria, the pattern of 'language critical' sites varies significantly from one patient to the next (Ojemann et al., 1989). Disruption sites are highly localized in that movement of the stimulation site by a few millimetres frequently results in a complete elimination of the effect.

Electrical stimulation mapping can be combined with pre and postoperative functional MRI investigations to compare fMRI detected areas of activation for a particular task with electrical stimulation based regions of inactivation. These studies are necessary to determine how to use the information gleaned from fMRI to most accurately facilitate operative planning. In addition, the ability to obtain preoperative fMRI images that can then be compared with postoperative studies provides the opportunity

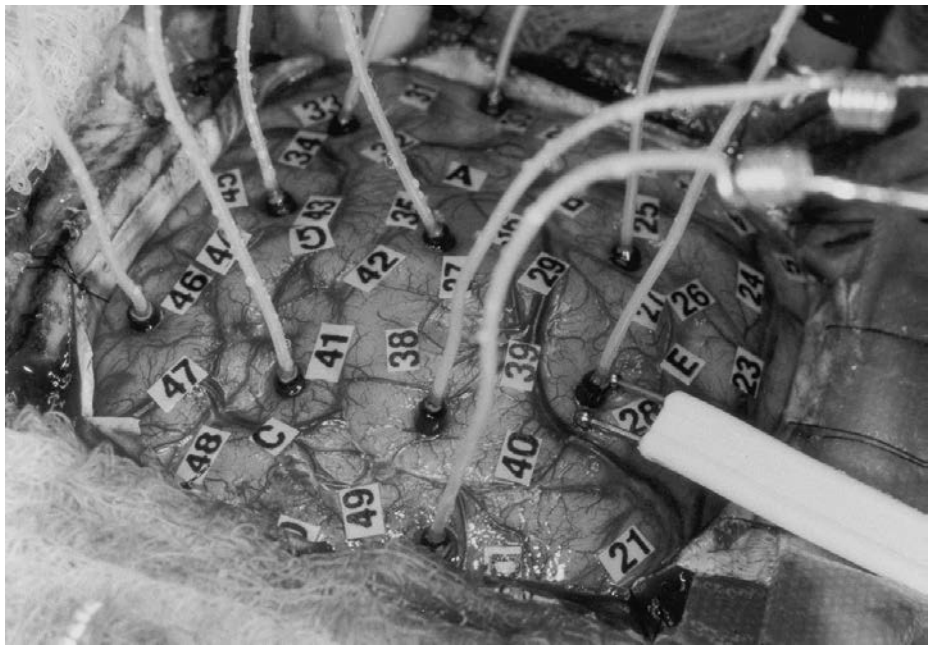

Fig. 78.3. The Ojemann brain stimulator being used for intraoperative stimulation mapping of brain function.

to investigate postoperative recovery of function in patients who develop new deficits following epilepsy surgical resection.

Tract tracing methods

One of the salient characteristics of brain organization is the existence of functional connections between different brain regions. The nature of these functional connections is of great scientific interest and the focus of intensive animal research in experimental laboratories. The most powerful, and highly refined methods for examining connections between brain regions involve injecting compounds into a targeted brain region in a living animal, allowing time to pass, and then processing the brain for histological analysis and observing where these compounds have been transported along axons.

Most of these anatomical tract tracing methods cannot be used to study connections in the human brain, thus necessitating the use of alternative methods. The oldest approach involved bluntly dissecting postmortem brain specimens in an effort to part the tissue along densely packed white matter tracts. The classic descriptions of the major subcortical fibre bundles in humans were compiled using this method. Though valuable in its time, this method is incapable of reliably delineating fine fibre bundles or discerning the manner in which fibre tracts originate and terminate in subcortical or cortical brain regions. Recently, an in vivo MRI anatomical tract tracing method has been described which has advantages over the postmortem blunt dissection method but still lacks the resolving power of histological techniques. The compound DiI has been used to histologically trace connections in postmortem human brain specimens. However, the DiI technique relies on passive diffusion over short distances and thus cannot be used to examine the long-range connections that are of great interest in the human brain.

One technique that can be used to examine long distance functional connections in the human brain involves delivering electrical stimuli to one site, and recording evoked responses from other brain regions that are functionally connected to the brain site that was stimulated. This approach has been used extensively in experimental animals, and carries with it the additional advantage of providing information of the physiologic properties of the connection. By examining the evoked waveforms, it is possible to determine the speed with which signals are conducted between the two sites, and discriminate distinct populations of conduction fibres. This approach is ideally suited for applications in epilepsy surgery patients, in conjunction with the electrophysiologic methods already described in this chapter. There are no known risks associated with the technique, and electrical stimulation functional mapping is used routinely for purely clinical purposes in these patients. Using this method, investigators have identified

and characterized functional connections between primary auditory cortex located within Heschl's gyrus and a secondary auditory field of the posterior superior temporal gyrus (Howard et al., 2000) (Fig. 78.4).

This same group has been systematically investigating the century old hypothesis that a functional connection exists between Wernicke's and Broca's area. Wernicke reasoned that a connection must exist between the auditory receptive region of the posterior superior temporal gyrus and a motor speech centre within the posterior inferior frontal gyrus. Results of blunt dissection postmortem examinations have demonstrated large fibre bundles (e.g. superior longitudinal fasciculus and arcuate fasciculus) that might represent components of the hypothetical connection, but this method is incapable of accurately resolving connections from one cortical site to another. Using the electrical stimulation track tracing method in epilepsy patients, investigators recently demonstrated a robust functional connection between the posterior superior temporal gyrus and the posterior inferior frontal gyrus (Fig. 78.5). The physiological characteristics of this connection indicate that information is being conducted along large calibre axons at velocities that are among the highest known to exist in the central nervous system.

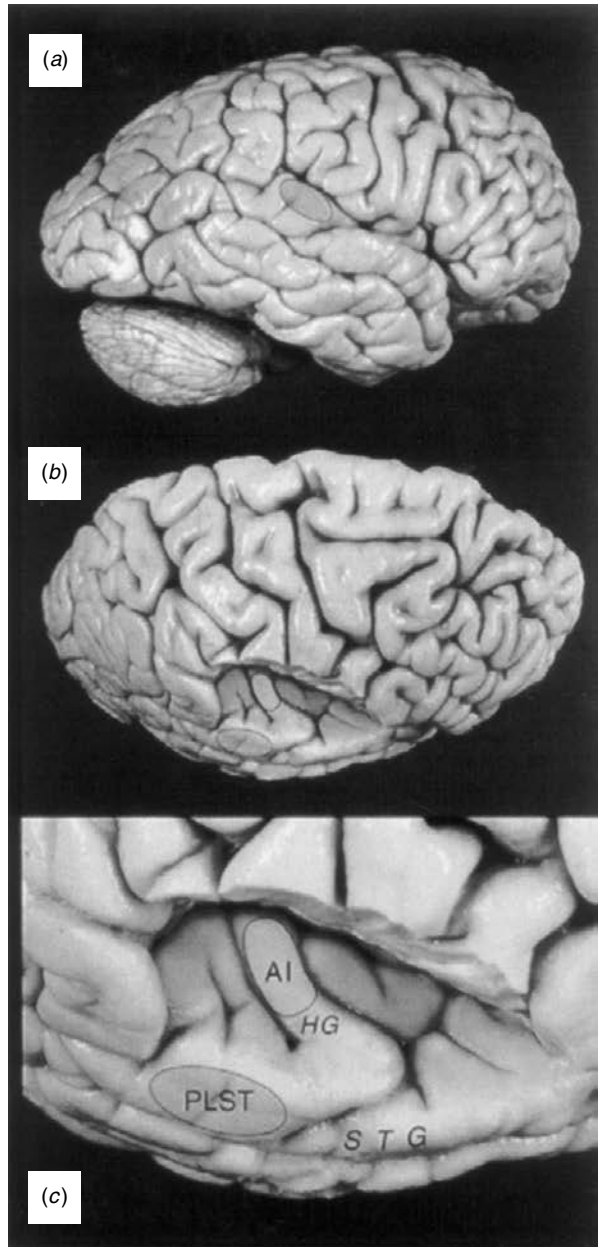

Fig. 78.4. Photographs of the lateral surface (*a*) and superior temporal plane (*b*), (*c*) of a postmortem human brain showing the relative size and location of a discrete auditory cortical field identified on the posterior lateral superior temporal lobe (field PLST). This field was identified and characterized using direct recording and electrical stimulation track-tracing techniques in epilepsy surgery patients. Field PLST is distinct from, but functionally connected to, primary auditory cortex located on the mesial aspect of Heschl's gyrus.

Investigations of higher cortical function

Many advances in brain neurobiology have been catalysed by the development of new research techniques. In the realm of experimental animal research, many of the most powerful and widely used brain research techniques are invasive, i.e. instrumentation is positioned directly within brain tissue. In order to study the electrophysiological characteristics of individual brain neurons, for example, it is necessary to place a small recording electrode within approximately 100 μm of the cell being studied. Microdialysis techniques, whereby the extracellular fluid in a select brain region is extracted and analysed, also require positioning a fine instrument directly into brain tissue.

The brain is the most highly evolved organ of the human species, and many fundamental questions concerning human cognition, speech neurobiology, and our evolution from non-human primates can only be addressed by studying human subjects. Additionally, the ability of humans to follow commands and describe experiences makes them uniquely cooperative research subjects for investigations of even the most basic brain functions. For example, in order to understand how the brain mediates effortless shifts of attention from one environmental stimulus to the next, this can be accomplished in human subjects simply

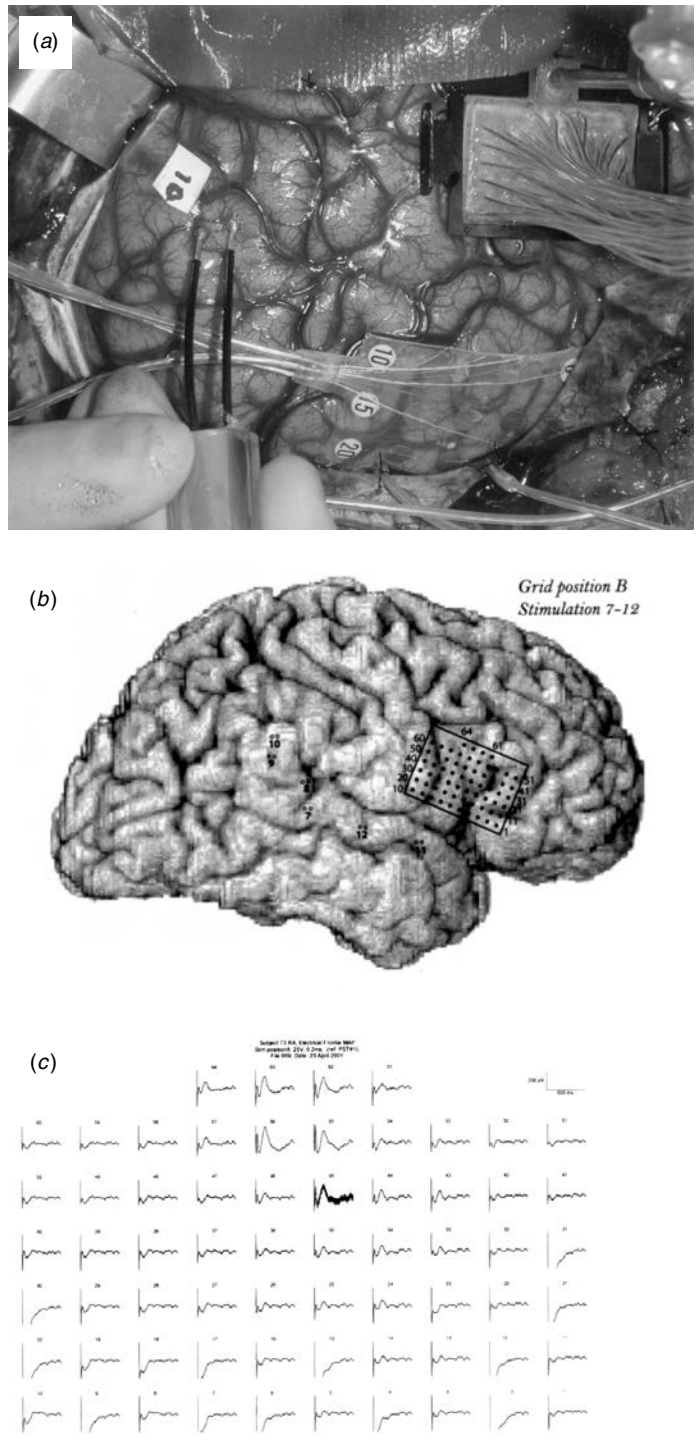

Fig. 78.5. Intraoperative photograph (*a*) during an electrical stimulation tract tracing experiment. A high-density multicontact recording platform is positioned over the right frontal lobe, as sites along the superior temporal gyrus are electrically stimulated with a hand-held probe. The stimulation and recording sites are depicted on the patient's 3D surface-rendered MRI (*b*). A large amplitude electrical stimulation evoked response is observed from recording sites overlying the pars opercularis when the superior temporal gyrus is electrically stimulated at the site labelled 7 (*b*). (*c*) This representative result provides evidence of a robust functional connection between the posterior superior temporal gyrus and inferior frontal gyrus; a pathway that may play an important role in human communication.

by explaining the nature of the experimental task. In contrast, experimental animals must be conditioned over relatively long time periods to display the desired behaviour, and the conditioning process itself may be a confounding variable.

Ideally, investigators studying human brain neurobiology would be able to employ the full range of invasive experimental methods used in the laboratory. Although there is a compelling rationale for direct human brain experimentation, there is always a degree of risk associated with placing devices directly into the human brain. No human subject can be exposed to this risk solely for the purpose of research. It is for this reason that invasive methods, which are indispensable components of experimental animal neuroscience research, are so rarely utilized in humans. Epilepsy surgery patients represent a unique group of human subjects with whom investigators can systematically study normal human brain physiology using powerful invasive research methods.

Patients undergoing epilepsy surgery are presumed to have a localized seizure disorder that can be treated by resecting the focus of seizure onsets. However, as described in an earlier section of the chapter, it is not always apparent from the pre-operative data where the seizure focus is located. In order to detect the site of seizure onsets it is often necessary to place an array of penetrating and surface electrodes over a wide range of brain sites, many of which will subsequently be identified as functionally normal and not the focus of seizure onsets. Additionally, certain normal brain regions must sometimes be resected in order to gain access to a seizure focus. A typical example is the need to resect the lateral neocortex of the anterior temporal lobe in order to gain access to a seizure focus in the amygdala or hippocampus. In essence, in this unique patient population there are opportunities to invasively access normal brain tissue in awake, behaving humans without exposing the subjects to additional surgical risk.

Conventional microelectrode recordings

Investigators at the University of Washington, led by Professor George Ojemann, have compiled the greatest experience in obtaining single neuronal recordings from awake epilepsy surgery patients. In their protocol, standard research microelectrodes are advanced into the exposed lateral temporal neocortex in the brain of awake subjects in the operating room. Recordings are restricted to neocortical regions that will be resected subsequently during the procedure. In this way, damage caused by a microelectrode is irrelevant because the brain region penetrated by the electrode is removed as part of the standard clinical treatment plan.

During these intraoperative experiments, patients are able to visualize an examiner on the opposite side of the surgical drapes and cooperate fully with complex interactive tasks. The period of research recording is typically 30 minutes. Over a period of decades, Professor Ojemann's group has recorded from hundreds of subjects and examined the firing properties of neocortical neurons during memory and language tasks. This work has resulted in a uniquely important body of knowledge concerning human temporal lobe physiology. Using the microelectrode technique these investigators have clearly identified patterns of firing at the single neuron level that demonstrate the distributed nature of temporal lobe neural networks (Ojemann et al., 1988; Creutzfeldt & Ojemann, 1989; Creutzfeldt et al., 1989a,b; Haglund et al., 1994; Ojemann & Schoenfield-McNeill, 1998, 1999). Such high temporal and spatial resolution physiological information cannot be obtained using non-invasive research techniques.

Hybrid depth electrodes

Under optimal conditions, microelectrode recordings obtained in the operating room provide excellent resolution of action potentials from individual neurons. There are, however, three distinct limitations to this technique. First, 'research only' electrodes can only be placed in brain tissue that will subsequently be resected during the epilepsy surgery procedure. For all practical purposes this in effect limits the potential recording sites to the anterior portion of the temporal lobe and a few extratemporal locations. Secondly, the time available for experimentation is limited. Although a moderate prolongation of a standard neurosurgical procedure does not carry with it any known increase in risk, out of consideration for patient comfort the entire research period available for intraoperative experimentation is typically limited to 30 minutes. Finally, because the patient is lying constrained on an operating room table there is a limitation to the types of tasks that can be carried out.

These limitations have been partially circumvented with the development of hybrid depth electrodes (HDE). As described earlier in this chapter, depth electrodes are widely used to detect seizure foci that cannot be resolved using non-invasive diagnostic methods. The typical clinical depth electrode is approximately 2 mm in cross-sectional diameter and has a series of low-impedance contacts positioned along the shaft of the electrode. The electrode is stereotactically implanted into an anatomical target defined on the preoperative MRI or CT scan. Patients are then transferred to the epilepsy ward where continuous video–EEG recordings are obtained from the low impedance contacts. Chronic monitoring is carried out for a period of up to 2 weeks during which time the patient is awake and alert, minimally encumbered by the monitoring equipment, and fully capable of participating in complex neuropsychological and psychophysical testing protocols.

Investigators at the UCLA epilepsy centre were the first group to make use of this clinical depth electrode platform to obtain systematic chronic microelectrode recordings in awake humans. The low impedance contacts on the standard depth electrode have a large surface area and are designed to record field potentials generated by the activity of thousands of neurons located in the general region of the recording site. These low impedance contacts are not capable of resolving individual action potentials. The UCLA team modified the standard depth electrode by advancing fine recordings wires ($< 50\,\mu$m o.d.) through the hollow lumen of the electrode, out the end of the tube and into the brain tissue surrounding the tip of the electrode. This group also described a technique for measuring extracellular neurochemicals by cerebral microdialysis with simultaneous recording of electroencephalographic (EEG) and single-unit (neuron) activity in selected targets in the human brain (Fried et al., 1999). In the course of evaluating large numbers of epilepsy surgery patients with complex seizure disorders these investigators have targeted a broad range of brain locations, all of which could then be investigated at the single neuron level. Using these novel methodologies, the UCLA group has made numerous important and unique contributions to our understanding of human brain physiology, most notably in their studies of the amygdala, hippocampus, and cingulum (Fried et al., 1999, 2001; Kreiman et al., 2000a,b; Cameron et al., 2001).

More recently, investigators at the University of Iowa and Radionics Inc. introduced a further modification of the HDE concept (Fig. 78.6). The Iowa HDE differs from the UCLA prototype in that the fine microelectrode wires are positioned at sites all along the length of the depth electrode, thus enabling investigators to obtain microelectrode recordings from multiple brain regions along the trajectory

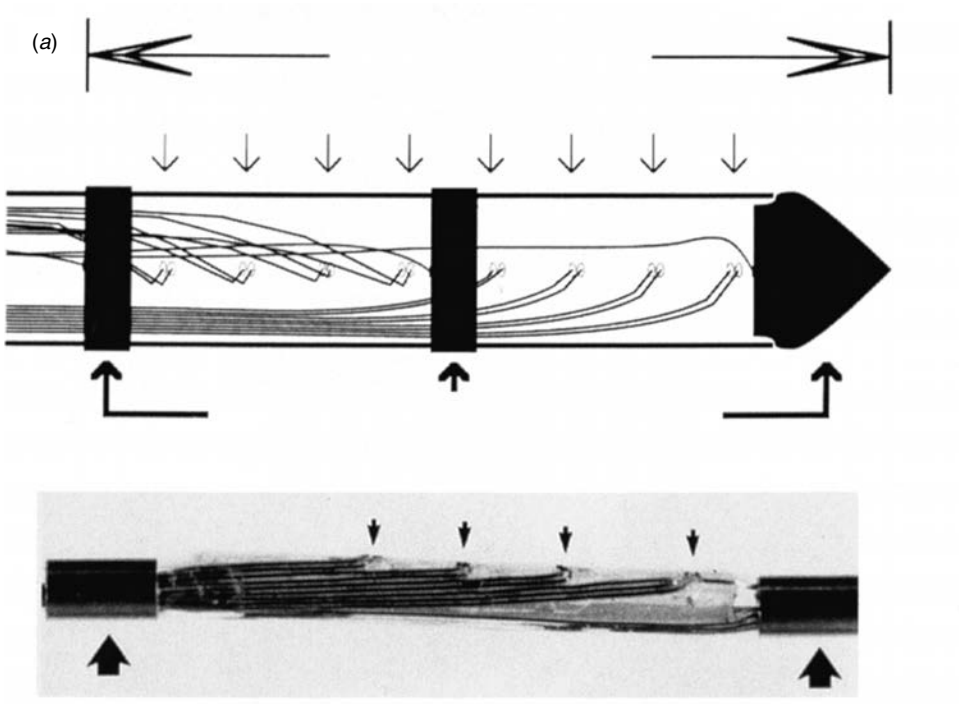

Fig. 78.6. (*a*) Schematic diagram (upper) and photograph (lower) of a hybrid depth electrode (HDE). Clinical EEG data is collected using the low impedance concentric ring recording contacts (large arrows), while microelectrode research recordings are obtained from multiple fine wire high-impedance recording sites (small arrows). (*b*) Representative chronic microelectrode recordings from two epilepsy surgery patients implanted with hybrid depth electrodes (HDE). Action potentials from individual units can be identified and discriminated.

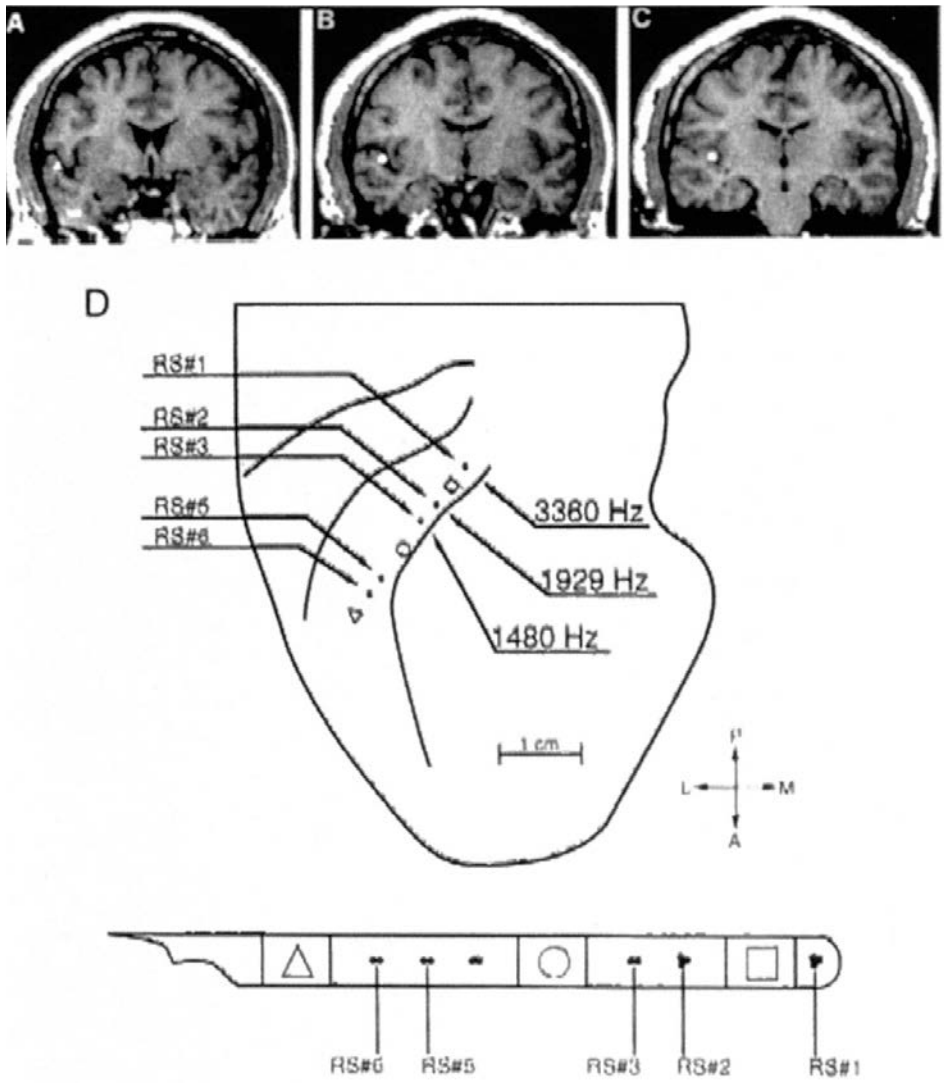

Fig. 78.7. Anatomical and physiologic data demonstrating the tonotopic organization of human auditory cortex in an epilepsy patient. A HDE has been placed along the crest of Heschl's gyrus, as indicated by the coronal MRI images (*a*)–(*c*) and top-down scaled schematic view of the supratemporal plane (*d*). The best frequencies of individual neurons were determined at each high impedance recording site, and the average best frequency for each site is depicted in panel (*d*). This data provided the first evidence at the cellular level of the functional organization of human primary auditory cortex.

of the electrode. By embedding the microelectrode wires in known geometric configurations it is also possible to use advanced single unit isolation techniques based on stereotrode and tetrode principles. This isolation technique was originally developed to enhance the ability of investigators to reliably isolate action potentials from individual neurons during chronic recordings in experimental animal preparations, and is now applied to human recordings using the Iowa HDEs (Howard et al., 1996b). Making use of this capacity to simultaneously record from multiple cortical sites along a linear trajectory, the Iowa group was able to precisely characterize the location, tonotopic organization, and cellular properties of human primary auditory cortex (Howard et al., 1996a) (Fig. 78.7). This knowledge of human auditory neurophysiology could not be obtained prior to the development of this new research tool.

Multidisciplinary research techniques

Another distinct advantage of carrying out chronic human recordings outside the operating room is that the epilepsy

ward setting is well suited to multidisciplinary research collaboration. The well-controlled, spacious environment of the epilepsy ward lends itself to active participation by neuropsychologists, linguists, and neurophysiologists. After an initial period of recovery from the implantation surgery the study patients are typically awake, alert and fully able to participate in complex research protocols. These subjects are confined to the monitoring room for an average period of two weeks while waiting for seizures to occur, and most patients view participation in research studies, and interacting with the investigators, as a welcome diversion.

This multidisciplinary approach has been pursued at the University of Iowa for the purpose of better understanding the neurophysiological properties of human emotion. Over a period of decades, Professors Antonio Damasio, Hanna Damasio, Ralph Adolphs, and colleagues in the Department of Neurology have made seminal contributions to our understanding of the biological basis of human emotion by systematically investigating patients with brain lesions. More recently, these same scientists, in collaboration with neurosurgical investigators, have begun to examine the functional properties of individual neurons within brain regions known to play a role in the representation of emotional states. HDEs are frequently placed in the ventral frontal lobe and amygdala, and the epilepsy research subjects are fully capable of cooperating with carefully controlled experiments designed to evoke a variety of emotional states. Using this approach, these investigators discovered that cells within the human ventral frontal lobe are able to characterize and respond to emotional stimuli with extraordinary speed (Kawasaki et al., 2001). Abrupt changes in firing patterns occurred within 120 ms of the onset of an aversive visual stimulus, providing the first direct evidence that humans carry out high speed emotional categorizations of their environment at a subconscious level.

Optical imaging of intrinsic signal is another technique that is being applied to investigate human physiology as well as pathways of seizure spread. This technique takes advantage of activity-induced changes in the intrinsic optical scattering and absorption properties that accompany neuronal activation of specific brain regions. While the exact mechanisms of these changes (blood flow, neuronal activity, changes in extracellular space size) remain under investigation, the power of these techniques has been well demonstrated. Optical techniques have already been used to image sensory, motor, and language functions in awake patients in the operating room as well as human, primate, and ferret epileptiform activity (Haglund et al., 1992; Haglund, 1997; Schwartz & Bonhoeffer, 2001). Newer optical imaging technology combines submillimetre spatial resolution capabilities with millisecond temporal resolution (Hochman, 1997; Schwartz & Bonhoeffer 2001). In addition, it is likely that transcranial optical imaging of activity-dependent intrinsic signal changes will be possible in the future, allowing these techniques to be implemented extraoperatively.

In addition to the utilization of intracranial electrode arrays for the mapping of primary functional areas and for anatomical tract tracing as described above, subdural implants offer unparallelled opportunites to investigate cognitive tasks and mechanisms of seizure generation in awake functioning humans. For example, in the area of cognition, a recent collaborative effort between the epilepsy surgery team at Children's Hospital in Boston and neuroscientists at Brandeis University has revealed that theta oscillations may play a role in both spatial processing, as is known from rodent investigations, as well as in working memory (Kahana et al., 1999; Raghavachari et al., 2001). Another team of researchers from the University of Pennsylvania and the Georgia Institute of Technology have combined to study the overall signal energy during EEG recordings leading up to temporal lobe seizures (Litt et al., 2001). They found that subclinical bursts of energy became more prevalent in the hours leading up to a seizure, with the accumulated energy increasing in the 50 minutes before a seizure in all five patients studied. These results, together with other efforts using the theory of chaotic dynamics to study non-linear parameters of the EEG (Lehnertz et al., 1999, 2001), raise the possibility of seizure prediction prior to the actual clinical event. Feedback devices are being developed to allow this information to be coupled with electrical stimulation (Litt et al., 2001) or drug delivery (Stein et al., 2000) to potentially abort a developing seizure.

Investigation of resected tissue (in conjunction with appropriate animal models)

Another area of epilepsy research that is fostered by epilepsy surgery is the in vitro investigation of resected tissue. Because of the lack of appropriate human control tissue, particularly in the area of electrophysiological investigation, parallel animal model research into the basic mechanisms of epileptogenesis is required. Nevertheless, resected human tissue is an extremely valuable resource for the investigation of epilepsy pathophysiology. An increasing variety of scientific techniques are being applied to these studies including electrophysiological techniques, single cell genetic amplification combined with genomics, and proteomics. Detailing the many areas of scientific inquiry utilizing resected tissue is beyond the

scope of this chapter. Examples of some of the potentially epileptogenic mechanisms under investigation include synaptic reorganization of temporal lobe and neocortical microcircuits, changes in neurotransmitter transporters and receptors, perturbations of astrocytic functions such as potassium homeostasis and pH regulation, and alterations in glial–neuronal–extracellular space interactions. Combining techniques such as single cell electrophysiological recording followed by genetic amplification of aspirated contents of individual cells promises to provide further insight into the pathophysiology of temporal (Brooks-Kayal et al., 1998; Coulter, 2001) and extratemporal epilepsy, neuronal migration disorders (Crino et al., 2001), Rasmussen's encephalitis and various other pathological conditions.

Human tissue resected during epilepsy surgery is also extremely valuable as a potential source of progenitor cells. Together with the recent realization that neurogenesis is a normal process in the adult mammalian hippocampus (Eriksson et al., 1998; Kempermann et al., 2000), resected temporal lobe tissue can be used to isolate neuronal and glial precursor cells from human dentate gyrus and white matter specimens obtained during epilepsy surgeries. A promoter-based fluorescence activated cell sorting (FACS) technique is used for the neural progenitor isolations (Roy et al., 2000), while glial progenitor cells have cell surface antigens such as A2B5, NG-2, CD-44, AC133, and RC1 that allow them to be sorted by FACS without requiring plasmid transfection. Exciting recent advances have demonstrated that radial glial cells are the likely progenitor cells for migrating neurons during embryonic development (Noctor et al., 2001) and that hippocampal astrocytes may differentiate into granule cells (Seri et al., 2001). It is thus possible that white matter glial progenitor cells or dentate gyrus radial glial cells isolated from resected epilepsy surgery tissue may provide potential pools of stem cells that can be utilized to generate neurons for therapeutic purposes in the future.

Part X

Cerebrovascular disorders

79

Physiology of the cerebral circulation

Peter J. Goadsby and Richard P. White

Institute of Neurology, Queen Square, London, UK

The human cerebral circulation is anatomically unique in its degree of extracranial to intracranial anastamoses and its need to supply a highly developed and metabolically highly dependent cerebral neocortex. The physiology of the cerebral circulation is key to understanding its pathophysiology and thus the management of patients with cerebrovascular disease. It has been covered by a number of monographs (Edvinsson et al., 1993; Mackenzie et al., 1984; Mraovitch & Sercombe, 1996; Purves, 1972; Welch et al., 1997) and particular aspects are routinely and expertly reviewed in specialized journals, such as the *Journal of Cerebral Blood Flow and Metabolism*. The cerebral circulation has certain key physiological features that can be clinically meaningful:

(i) the relationship between brain blood flow and metabolism, vasoneuronal coupling;
(ii) the maintenance of constant flow in the face of variations in perfusion pressure, autoregulation;
(iii) the effect of key respiratory gases, oxygen and carbon dioxide, on cerebral blood flow (CBF); and
(iv) the direct effects of nerves on the cerebral circulation, neurovascular influences on CBF.

Vasoneuronal coupling is a well-established principle (Kuschinsky, 1989), as is the fact that the brain can regulate flow in the face of changes in perfusion pressure. The effect of changes in CO_2 and O_2 on CBF is also an old and established concept. Neural control or neurogenically mediated changes in cerebral blood flow are a relatively recently accepted concept, although the observation that nerves exist on the vessels dates to Thomas Willis in 1664. Some established concepts will be considered here as a backdrop to the clinical discussions that follow. The classical view of the cerebral circulation has been that blood flow and cerebral metabolism are tightly coupled under the influence of substances, such as H^+, adenosine, and K^+ that ensure a rapid and matched supply of blood when required without neural influence. As the role of the neural innervation and its neuromodulators emerges and their functions are clarified opportunities for intervention and understanding will arise and eventually inform the management of patients with cerebrovascular disorders.

Vasoneuronal coupling

The fact that cerebral blood flow tracks closely cerebral metabolic activity remains a tenet of cerebrovascular physiology. It is the basis for many modern functional neuroimaging methods (Frackowiak & Friston, 1994). As early as 1890 Roy and Sherrington (1890) identified hydrogen ions as a byproduct of cellular metabolism, which could effect changes in regional CBF by vasodilatation. However, increases in regional CBF can be shown to precede any interstitial pH changes. Potassium release also follows neuronal activation and is also a potent vasodilator. Interstitially released K^+ is taken up by astrocytes and is associated with their depolarization and further K^+ release at their distal perivascular processes so buffering the perineuronal K^+ changes (spatial buffering) (Paulson & Newman, 1987). Such a mechanism effectively siphons K^+ towards the microvasculature to effect regional vasodilatation. However, as with interstitial pH changes, the functional significance of this model is questioned by the observation that astrocyte K^+ uptake inhibition with Ba^{2+} does not alter the regional increases in CBF accompanying local cortical electrical stimulation (Iadecola, 1993). Furthermore the time course of vasodilatation after topical application of potassium is too slow to account for the rapidity of regional vascular regulation.

Adenosine, a metabolic byproduct of adenosine monophosphate dephosphorylation, has received the most experimental support in rCBF regulation. Adenosine is a

potent vasodilator of cerebral vessels when applied topically in vivo, and marked elevation in levels is observed with hypoxia, epileptic seizure, hypotension and focal cortical stimulation. However, the latter has not been consistently demonstrated, since pretreatment of brain cortices with adenosine deaminase inhibitors does not inhibit sciatic stimulation-induced cortical hyperemia. For adenosine to mediate vasoneuronal coupling its synthesis would have to increase by an order of magnitude before the onset of vasodilatation to overcome washout effects and then switch off equally rapidly at the end of activation, a situation not supported experimentally. It is plausible that adenosine may contribute to the maintenance of regional vasodilatation in the situation of prolonged activation or tissue hypoxia, such as severe hypotension and ischemia (Winn et al., 1981).

Nitric oxide

Considerable excitement has surrounded the prospect that nitric oxide (NO) may link brain blood flow and metabolic activity (Iadecola, 1993). The role of the endothelium, a monocellular cell layer, in the tonic, dynamic regulation of cerebrovascular tone was first demonstrated by the dependence on the endothelium of vascular relaxation in response to topical application of acetylcholine (Furchgott & Zawadzki, 1980). That this EDRF could be NO was demonstrated using chemiluminescence detectors originally designed to monitor atmospheric levels of NO (Moncada et al., 1991). The NO:L-arginine pathway is of early phylogenetic origin present in species as diverse as slime mould and horseshoe crab, and is both highly functionally conserved across the species barriers and ubiquitously distributed within the body as an intercellular messenger and host defence system. NO is a small lipophilic molecule and therefore easily diffuses across cell membranes. As a signal transducer it binds to the haem moiety of guanylate cyclase to effect increases in cyclic-GMP in surrounding cells so producing most of its biological activity, although at higher concentrations it also has some activity as a hyperpolarizing agent by an action on membrane potassium channels. The half-life of NO is 1 second in a blood-free isolated perfused guinea pig heart with a maximum diffusion distance of 100 μm.

The physico-chemical properties of this potent vasodilator, the compartmentalization of the endothelial and neuronal NO synthase isoforms within different neuronal populations, and the demonstration of the physiological and ultrastructural coupling of NO synthase activation to *N*-methy-D-aspartate receptor activation by glutamate, has made a compelling argument for a central role for NO in vasoneuronal coupling. Animal models using NO synthase inhibitors of varying selectivity for the different isoforms have suggested that NO from neuronal NO synthase may have a role, but the fact that mice lacking genes for the different isoforms have relatively normal cerebrovascular physiology indicates that there are other mediators in the absence of NO. Studies in humans are complicated by the difficulties of blood–brain barrier penetration by NO synthase inhibitors and the difficulties of quantification of local NO inhibition, but do suggest that NO derived from the vascular endothelium does not play a significant role (White et al., 1999).

Autoregulation

Autoregulation is that property of a vascular bed maintaining a constant blood flow in the face of changes in perfusion pressure. It is not confined to the brain but the discussion in this section relates to the phenomenon as it affects cerebral blood flow (Fig. 79.1). The perfusion pressure for the brain is the difference between the arterial blood pressure and either the venous or cerebrospinal fluid pressure, dependent on that which is greater. Autoregulation is achieved by alterations in vessel calibre so that when perfusion pressure drops, flow is maintained, and when it elevates there is no excess of flow in comparison to brain requirements. Experimental data suggest that autoregulation is predominantly a function of smaller intracortical resistance vessels. Autoregulation to changes in cerebral perfusion pressure is a rapid homeostatic mechanism with a time constant in seconds, superimposed over and above systemic pressor regulatory mechanisms. Considered to be a property of the vessels the phenomenon is conventionally studied using steady state techniques. Figure 79.1 illustrates the constancy of cerebral blood flow between limits, which are themselves not fixed but dependent upon resting autonomic neurogenic input, particularly from the sympathetic nerves, and regional myogenic or metabolic activity. Beyond the limits of autoregulation flow is passively dependent upon perfusion pressure, although at the lower end flow may fall to zero if the perfusion pressure falls below that critical level required to overcome the elasticity of the vessel, the critical closing pressure.

The most convincing data explain autoregulation as an intrinsic myogenic mechanism, such that stretch-dependent vasoconstriction or vice versa maintains a constant blood flow. Such a mechanism would be responsive to changes in transmural pressure. However both pressure dependent vasoconstiction and flow-dependent vasodila-

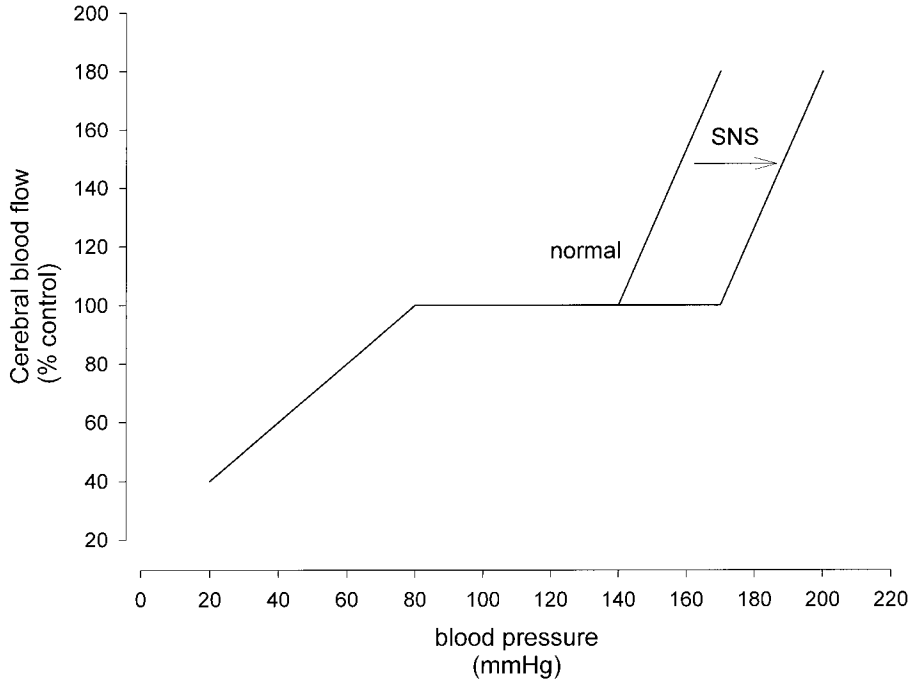

Fig. 79.1. Classical autoregulatory control of the cerebral blood flow with stable flow over a range of perfusion pressures (mmHg abscissa). The sympathetic nervous system (SNS) has been shown to extend the upper limit of cerebral autoregulatory limits.

tation are endothelium dependent, pointing either to an endothelially synthesized factor or ultra structural linkage to myocytes, which probably involves calcium entry into endothelial cells during stretch. Studies of NO inhibition in animals have been conflicting, either suggesting no role for NO or an increase in upper and lower autoregulatory limits as a passive response to changing basal vascular tone and resting blood pressure. However, there is evidence that at lower blood pressures local changes in adenosine may contribute to maintaining cerebral blood flow.

It is perhaps a surprise that, despite the relatively simple nature of the response and its consistency, the precise mechanisms involved in autoregulation remain to be elucidated. Partly, this reflects the lack of temporal resolution of steady-state techniques in studying dynamic phenomena and it is probable that several effectors of varying time constants of action are involved in both initiation and maintenance of altered vascular tone (White et al., 2000).

Autonomic neural influences on cerebral autoregulation

It has been established for some time that stimulation of the sympathetic nerves during hypertension will extend the upper limits of autoregulation. It is considered that the shift in the autoregulatory curve seen with sympathetic activation is a protective phenomenon against cerebral damage that can be caused by excessive pressure. Both noradrenaline and neuropeptide Y (NPY) seem to be involved in this protective process. A similar mechanism may be activated to modulate intracranial pressure. Certainly, sympathetic nerve stimulation can alter intracranial pressure. The regulation of venous capacitance and the dense innervation of the choroid plexus by adrenergic nerves is likely to have an important influence upon intracranial pressure and is the subject of ongoing research.

Influences of carbon dioxide and oxygen

Hypercapnic and hypoxic cerebral vasodilator responses are basic features of normal cerebrovascular physiology. Hypercapnic vasodilatation is a potent effect that is clearly impaired after cortical spreading depression (Lauritzen, 1994) and is otherwise a test of cerebrovascular integrity from a physiological viewpoint. This response has been considered a function of changes in perivascular pH analogous to the proposed interstitial pH changes following cellular metabolism. The vasodilatory response to hypercapnia is notably more marked that that due to metabolic

acidosis; an effect presumed to reflect the ease of diffusion of CO_2 from the circulation to the myocyte, as opposed to the polar H^+ ions. However, there is no direct evidence that alterations in $PaCO_2$ alter myocyte pH *per se*, or an accepted cellular mechanism whereby pH alters myocyte contractility. Furthermore cerebrospinal fluid pH can be shown to remain constant despite plasma pH changes following hypercapnia or intravascular acid/alkali injection. Thus at least part of the response may require other mediators. Noradrenergic effects on vascular tone are pH dependent, and hypercapnic hyperemia is attenuated by indomethacin, although other eicosanoid inhibitors such as diclofenac do not possess this property.

Evidence for a role for NO in modulating the hyperemic response has come from NO synthase inhibitor studies in several animal species including subhuman primates which show attenuation of hyperemia to moderate degrees of hypercapnia only (Iadecola & Zhang, 1996; Wang et al., 1992). As for studies of basal flow the reduction in hypercapnic hyperemia post NOS inhibition occurs independently of any change in metabolic activity. For extreme hypercapnia the hyperemic response is NO independent. Equally it is unclear which compartment of NO activity may be participating: endothelial ablation does not abolish the response to hypercapnia, and sectioning of NO synthase-expressing nerves originating at the sphenopalatine ganglion has no effect on the hyperemic responses. Furthermore, endothelial NOS knockout mice have normal hypercapnic responses. Myocytic NO synthase activity is not constitutively expressed and therefore unlikely to play a significant role.

Furthermore, not all animal studies have shown a role for NO in hypercapnic hyperemia, with appreciable differences in the sensitivity to NO synthase inhibitors reported between models and within species. These differences may partly be explained by the dose and time dependence of total NO synthase inhibition following arginine analogues in different experimental models. Recently, using the putative neuronal NOS inhibitor 7-nitro-indazole (7NI) it has been reported that the effects of NO inhibition in hypercapnic hyperemia are permissive since basal NO replacement with NO donors reversed the reduction observed. Thus the direct extrapolation of data derived in different animal models to humans is potentially misleading and more studies in humans with newer imaging methods may be helpful.

Hypoxia is a potent vasodilatory stimulus for the cerebral vasculature independent of any coincident changes in CO_2 levels. However, its mechanism remains poorly understood and is independent of any changes in underlying cellular metabolic rate. There is evidence that physiological changes in arterial oxygen levels may directly influence myocyte contractility possibly via an interaction with membrane calcium uptake, but further work is needed to clarify the physiology of this fundamental cerebrovascular response.

Table 79.1. Intrinsic neural innervation of the cerebral circulation-implicated structures

Structure	Effect on CBF	Possible neuromodulator
Medulla		
Dorsal medullary reticular formation	↑	
Rostroventrolateral medulla	↑	Adrenaline
Pons		
Locus ceruleus	↓	Noradrenaline

↑, increased cerebral blood flow; ↓, decreased cerebral blood flow; when the listed structure is stimulated.

Neurogenic control of the cerebral circulation

The neural innervation can be divided into intrinsic and extrinsic systems. The division is somewhat arbitrary but underlies some common themes. The intrinsic systems consist of nerves that arise from within the brain and pass through brain substance to innervate parenchymal vessels (Table 79.1). The extrinsic systems while arising in the brain pass out of the brain to traverse peripheral nerves returning to innervate large intracranial and pial vessels (Table 79.2). These nerves may have several roles including modulating local vasoneuronal coupling, providing trophic influences on vessels, or as reserve systems in times of physiological threat. They are reviewed in detail elsewhere (Goadsby, 2002). The intrinsic systems are perhaps less clear in their immediate clinical consequences, although will, no doubt,

Table 79.2. Extrinsic innervation of the cerebral circulation

	Ganglia	Effect of stimulation on CBF	Neuromodulators
Sympathetic	superior cervical	–	Noradrenaline Neuropeptide Y (NPY)
Parasympathetic	sphenopalatine otic IC miniganglia	↑	Acetylcholine VIP PHI (M) PACAP Helodermin Helospectin I and II Nitric oxide (NO)
Trigeminal	trigeminal	↑	Substance P CGRP Amylin Neurokinin-A (NKA) Cholecystokinin-8 PACAP NO

Abbreviations:
CGRP, calcitonin gene-related peptide; IC, internal carotid; PACAP, pituitary adenylate cyclase activating polypeptide; PHI (M), peptide histidine isoleucine (methionine); VIP, vasoactive intestinal polypeptide

become more interesting as they are better understood. The extrinsic systems will be dealt with in some greater detail because of their direct potential role in diseases, such as pure autonomic failure syndromes (See also Neurodegeneration Section) and primary neurovascular headaches (See also Headache Section).

Parasympathetic influences on the cerebral circulation

The parasympathetic innervation of the cerebral circulation represents potentially the most powerful of the neural vasodilator influences. Its influence cannot be overlooked in any pathophysiological situation. The parasympathetic system is basically vasodilator in nature and is capable of altering brain blood flow independently of the prevailing metabolic demand and perfusion pressure. It is a potential reserve system that is well characterized in experimental animals but still lacks detailed analysis in humans.

Anatomy

The parasympathetic system is that system arising from the superior salivary nucleus and passing out of the brain in the facial (VIIth cranial) nerve, distributing fibres through the pterygopalatine (sphenopalatine) and otic ganglia and carotid miniganglia to dilate vessels, almost certainly by way of a peptidergic transmitter. The terms pterygopalatine and sphenopalatine imply the same structure, with the former being the preferred term in humans because of its relationship to the pterygopalatine fossa. Pharmacologically the system is characterized by the presence of one or more substances, such as acetylcholine, vasoactive intestinal polypeptide (VIP), and peptide histidine methionine (PHM; isoleucine in the rat, thus PHI).

Transmitters and modulators

The parasympathetic system contains a number of transmitter or neuromodulator substances that are often colocalized in the same neurones. All the substances known to exist in the parasympathetic nerves are vasodilator (Table 79.2) but their precise role and, in particular, relationship to one another remains unclear. Whether these anatomical subgroups with one, two, three or even four colocalized transmitters have functional correlates remains to be established.

Of the localized transmitters, vasoactive intestinal polypeptide (VIP) is particularly potent and, coexistent with it, peptide histidine methionine (PHM). VIP is a 28-amino acid basic polypeptide that was first isolated from the porcine duodenum. It belongs to a structural superfamily of peptides along with glucagon, secretin, and gastrin inhibitory peptide. The family is characterized by helodermin/helospectin-like peptides that are distributed in the central nervous system and in endocrine cells, such as the C cells of the thyroid. It has been shown that each of helodermin and the helospectins I and II are vasodilatory in the cerebral circulation. There are as yet no data that address the inter-relationship of these transmitters, although they can have added effects.

Nitric oxide (NO)

Because of its unique position as a gaseous transmitter NO is worthy of special mention. Whilst the effects of blockage of NO production on non-neural responses, such a hypercapnia and autoregulation, remain somewhat controversial in terms of quantity, and its role in vasoneuronal coupling is still open to debate, its role in parasympathetic responses seems clearer. Blockade of NO synthesis reduces the effect of parasympathetic stimulation in the cerebral circulation. This observation is important because NO can be both deleterious through direct oxidative toxicity in ischemic brain and yet protective by allowing regional vasodilatation, a dichotomy of function partially dependent upon the levels of production and underlying redox state of ischemic tissue. Modulation of parasympathetic tone has potential for protective neurovascular dilatation in the cerebral circulation without fuelling oxidative stress.

Physiological effects

Given that the cranial parasympathetic outflow to the cerebral vessels via the facial nerve is marked by many neurotransmitters or neuromodulators (acetylcholine, VIP, NO, and PHI (M)), what is the effect of blocking this outflow? The responses that characterize normal cerebral blood flow (CBF) are the hypercapnic vasodilator response, the autoregulatory response to changes in blood pressure, and the hypoxic vasodilator response. None of these are affected by parasympathetic blockade.

Direct stimulation of the facial nerve in humans leads to an increase in total cranial blood flow. These responses are mediated through a classical parasympathetic ganglion as they can be blocked by hexamethonium, and probably use vasoactive intestinal polypeptide as the major transmitter of the system. Studies of the peripheral ganglion mediating facial nerve vasodilatation have included peripheral reflex (trigeminal ganglion) and central structure (locus ceruleus) stimulation. It is clear that effects mediated by the facial nerve can be substantially blocked by sphenopalatine ganglion removal and that this same response is VIP mediated.

In summary, the cranial parasympathetic pathway to the cerebral vessels arises in the superior salivatory nucleus in the pons; it traverses the facial nerve, joining the greater superficial petrosal nerve to be distributed to the vessels after synapsing chiefly in the pterygopalatine (sphenopalatine) or otic ganglia. A variable small number of fibres in different species (including humans) have this peripheral synapse located in microganglia on the wall of the internal carotid artery, particularly near the carotid siphon. The transmitters contained in this system are acetylcholine, VIP, PHM(I), nitric oxide, and helospectin-related peptides. A classical parasympathetic nicotinic ganglion mediates the ganglionic transmission in the periphery, while current data would suggest that VIP is the major neuroeffector substance at the nerve–smooth muscle junction. The pathway does not play a role in either hypercapnic or hypoxic vasodilator responses or autoregulatory responses to changes in arterial perfusion pressure. The system can be activated by either direct stimulation or via connections with other important central neural vasoactive nuclei to increase cerebral blood flow independent of cerebral metabolic needs. The parasympathetic system is ideally placed to engage when ordinary metabolic driving factors are impaired.

Sympathetic influences upon the cerebral circulation

The sympathetic nervous innervation of the cerebral circulation is by far the best characterized of the neural modulators of CBF. It is involved in augmenting autoregulation (see above) and has interesting potential trophic roles for cerebral vessels.

Anatomy

The sympathetic nervous innervation of the cerebral circulation arises in the hypothalamus as first-order neurons and projects to the intermediolateral cell column of the spinal cord. Second-order neurons arise from the sympathetic chain and proceed to synapse with third-order neurons in the superior cervical ganglion. The innervation is lateralized and largely respects the midline, with subsequent projection to the cerebral vessels being provided by sympathetic nerves that run rostral with the carotid artery.

There is a dense innervation, particularly of more proximal large arteries, which follows vessels out to the pia and along the brain surface but generally only follows penetrating vessels for a short distance into the cerebral parenchyma. The largest part of the adrenergic supply of the intraparenchymal vessels is supplied by the locus ceruleus (Table 79.1). The sympathetic nerve terminals are often located close to smooth muscle cells in the outer media.

Transmitters and neuromodulators

The main transmitter of the sympathetic innervation is the classical autonomic amine transmitter, noradrenaline. The effect of noradrenaline release is to constrict the vessels through activation of α-adrenoceptors in the vessels. In humans the predominant receptor subtype is the α_1-adrenoceptor, while in some experimental animals α_2-adrenoceptors can be seen. These receptors mediate vasoconstriction.

In addition to the classic constrictor aminergic transmitter, sympathetic nerves release the vasoconstrictor peptide neuropeptide Y (NPY). NPY is widely distributed in the brain and peripheral nervous system. Fibres that contain NPY form a dense network around cerebral arteries and veins and double stain for noradrenaline. Retrograde tracing studies have shown NPY-positive fibres that have cell bodies in the superior cervical ganglion, and these fibres are substantially reduced by sympathectomy. NPY is a potent constrictor of cerebral vessels at the $NPY Y_1$ receptor. This receptor has been identified on cerebral vessels using PCR for the human $NPY Y_1$ receptor.

Physiological effects

Direct stimulation of the cervical sympathetic nerves in experimental animals results in large vessel constriction but no change to small calibre vessels. The effect is more prominent on the cerebral veins and is blocked by α_1-adrenoceptor blockade. The influence of the sympathetic innervation of the cerebral circulation is discussed above under 'Autoregulation' and this is by far its best-described effect. In this context it is probably primarily permissive, setting a background vascular tone upon which autoregulatory mechanisms are superimposed and protecting the brain from hyperperfusion during transient hypertensive systemic responses to stress. There are some data to suggest that hypercapnic vasodilatation is influenced by the sympathetic innervation, such that the response is enhanced, but this requires further study.

There are excellent data that have established a role for the sympathetic nerves in development, particularly of the muscular layer of the wall of cerebral vessels. The trophic effects of the sympathetic nerves deserve further investigation.

Stroke syndromes

Louis R. Caplan

Department of Neurology, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA

Clinical diagnosis is made by systematic, logical, inductive probablistic reasoning facilitated by pattern matching. We recognize Tom because we know what he looks like especially if we have seen him before. This chapter shares various common patterns of stroke-related symptoms and signs.

Stroke subtypes

Stroke mechanisms are divided into those that cause ischemia and those related to hemorrhage.

Ischemic mechanisms

These can be divided into three main pathophysiological groups.

Thrombosis

This term is used to indicate a local process within an artery or vein that causes a lack of blood to its supply zone. It includes a variety of vascular pathologies: atherosclerotic plaques and stenosis, dissection, arteritis, fibromuscular dysplasia, etc. The vascular disorder can involve large extracranial or intracranial arteries or small penetrating arteries. The disease process narrows the lumen of the artery diminishing distal blood flow. Often, white and red thrombi form and cause occlusion of the vessel. The signature of the local 'thrombotic' process is transient ischemic attacks all in the same vascular territory. If and when a stroke develops, it can occur suddenly or show fluctuations and gradual, stepwise, or stuttering devlopment of neurological signs and symptoms. The local process in the artery ('thrombosis') can also be the source of intra-arterial embolism.

Embolism

In this ischemic mechanism, the material that blocks a recipient artery arises from a different proximal donor site. Donor sites include the heart, aorta, and arteries proximal to the recipient artery. The signature of embolism is the very sudden onset of neurological deficits that are maximal at onset. In some patients there may be a single stepwise worsening within 48 hours. Sudden dramatic improvement in a neurological deficit also can occur when emboli pass or are lysed.

Systemic hypoperfusion

Thrombosis and embolism are characterized by blockage of single vessels that cause focal ischemia in the region of supply of the blocked vessels. In contrast systemic hypoperfusion refers to a general decrease in blood flow to the brain. A number of systemic disorders can be responsible including myocardial infarction, cardiac arrythmia, pulmonary embolism, gastrointestinal or other sites of blood loss, etc. Patients feel light headed and vision can become dimmer and noises sound more distant. They lose the ability to think clearly and feel as if they will pass out and many do lose consciousness. Lateralized motor, sensory, and visual symptoms and signs are not present.

Hemorrhagic stroke syndromes

There are two relatively distinct hemorrhagic stroke syndromes.

Subarachnoid hemorrhage (SAH)

Blood issues rapidly into the space around the brain and spinal cord, usually under systemic arterial pressure because of the rupture of an arterial aneurysm or a vascular malformation. This causes sudden severe headache that is usually generalized but may be more prominent on

the side of the leaking vessel. The headache is often located in the neck and may radiate into the back and even into the buttocks and lower extremities mimicking sciatica. Vomiting is very common near the onset of the headache. The sudden increase in spinal fluid pressure causes a cessation of brain activity that may lead to the knees buckling and the cessation of making of new memories. The increased CSF pressure may lead to decreased consciousness: either restless agitation or stupor. Usually, there are no major focal neurological signs.

Intracerebral hemorrhage (ICH)

Bleeding in this subtype is directly into brain parenchyma. The earliest signs relate to the location of the hemorrhage. Symptoms and signs may gradually increase. If the hemorrhage becomes large, symptoms and signs of increased intracranial pressure develop including headache, decreased alertness, and vomiting. The commonest causes are hypertension, trauma, amyloid angiopathy, bleeding diathesis, drugs and vascular malformations.

Syndromes of occlusive disease and brain ischemia in the anterior–carotid circulation

Internal carotid artery (ICA) stenosis or occlusion in the neck

Atherosclerotic disease

The modern era in ischemic cerebrovascular disease began with the key report of Miller Fisher that called attention to the clinical findings associated with occlusion of the ICA in the neck (Fisher, 1951). The major cause of ICA occlusive disease in the neck is atherosclerotic narrowing. The lesion usually begins in the distal CCA and extends into the first few centimetres of the ICA. Occlusive disease of the coronary, iliac and femoral arteries often accompanies carotid atherosclerosis. Atherosclerotic plaques gradually narrow the ICA lumen. Ulceration, attachment of platelets and clot to crevices in plaques, and hemorrhage into plaques all become more common as the arterial lumen becomes increasingly stenosed. Plugs of platelets and thrombin may detach from the arterial wall and embolize to intracranial arteries causing transient or prolonged neurological dysfunction. The single most important clue to an ICA localization is an attack of transient monocular visual loss. The visual loss is described as a dimming, darkening, or obscuration. An apparent shade or curtain usually falls from above but may move from the side like a theatre curtain. After seconds or a few minutes, the curtain lifts or recedes, usually leaving no permanent visual loss. Transient visual obscurations are caused by decreased blood flow through the ophthalmic artery, the first tributary of the ICA. Transient monocular visual loss occurs when the lesion affects the ICA proximal to the ophthalmic artery (in the neck or proximal carotid siphon) or involves the ophthalmic artery itself. Some patients with severe ICA occlusive disease report unilateral spells of reduced vision after exposure to bright light, a type of retinal claudicaton.

Also common are episodes that reflect hemispheral ischemia. The episodes of hemispheral ischemia are also usually brief. Attacks may be quite varied and include different deficits in different limbs during individual attacks, but sometimes the spells are stereotyped. Numbness and/or weakness of the hand and arm are the most common symptoms, aphasia is also common. In some patients with critical stenosis, the attacks are very frequent and may be precipitated by suddenly standing or by a drop in blood pressure. Embolism of clot from the ICA causes sudden onset strokes which usually cause syndromes of middle cerebral artery dysfunction (described below).

Dissection of the ICA in the neck

After atherosclerosis, dissection is the next most common lesion that affects the carotid artery in the neck. Dissections usually involve the pharyngeal portion of the artery above the origin but below entry into the skull. Dissections cause symptoms primarily by the presence of luminal compromise and luminal clot. Dissections through the adventitia lead to rupture into the surrounding neck muscles and fascia, a process that causes neck pain and formation of a pseudoaneurysm. Thrombus is present within the lumen because of rupture of intramural clot into the lumen, or thrombus formation *in situ* within the lumen. Narrowing of the lumen by the intramural blood alters blood flow and irritates the endothelium causing release of endothelins and tissue factors which activate platelets and the coagulation cascade contributing to formation of intraluminal thrombus. Brain ischemia can result from hypoperfusion usually from acute luminal compromise. Hypoperfusion usually causes transient ischemia. Infarction is more often due to embolization or propagation of luminal thrombus.

The major symptoms of extracranial carotid artery dissection are: neck and head and face pain, Horner's syndrome, pulsatile tinnitus, transient ipsilateral monocular visual loss, transient hemispheral attacks with contralateral limb numbness/weakness, sudden onset strokes, and palsy of the lower cranial nerves (IX–XII). (Caplan, 2000; Bogousslavsky et al., 1987) Some patients have pain and

headache as the only symptom, and do not have neurological findings. Pain is often in the neck, face or jaw. Headaches may be generalized, but are most common on the side of the dissection. Features of Horner's syndrome are caused by involvement of the sympathetic fibres along dilated carotid artery segents. Pulsatile tinnitus is another common symptom since the carotid artery courses near the tympanic membrane. Neurological symptoms related to hypoperfusion are usually multiple brief TIAs. Sudden onset strokes are usually casused by embolism of clot from the region of dissection. The distended dilated carotid artery at the skull base can compress lower cranial nerves (IX to XII) which exit in this region.

Internal carotid artery occlusive disease intracranially

Narrowing and thrombotic occlusion of the ICA occur at the siphon less frequently than at the ICA origin. The ophthalmic artery originates from the ICA within the siphon. TIAs are less frequent and fewer in number in patients with siphon disease, as compared to ICA-origin disease. The ratio of strokes to TIAs and of asymptomatic patients is higher in carotid-siphon disease.

The presence of transient monocular visual loss depends on the level of the siphon lesion; it occurs when the stenotic lesion is proximal to the opthalmic artery origin. Hemispheral attacks are indistinguishable from those that occur in ICA disease in the neck. The symptoms and signs that develop when strokes occur are those related to anterior and middle cerebral artery territory infarcts and are described under those arteries.

Occlusion or severe stenosis of the middle cerebral artery stem or its major upper and lower trunks

Patients with MCA occlusive disease, when compared to patients with ICA disease, are more often black or Asian, young, female, hypertensive and diabetic (Caplan et al., 1986a). Patients of Japanese, Chinese and Thai descent, as well as diabetics and women taking contraceptive pills, have a propensity for MCA pathology. TIAs are less common in patients with MCA disease compared with ICA disease and occur during a shorter timespan.

Patients with MCA disease often develop their deficits more gradually than comparable patients with ICA disease. Patients with MCA disease often note their abnormalities on awakening in the morning or from a nap, and they have a high incidence of subsequent fluctuation or progression during the next 1 to 7 days. This gradual onset and progressive course support a low-flow mechanism of the ischemia (Caplan et al., 1985). In contrast, patients with ICA disease more commonly have sudden-onset deficits while awake and thereafter remain stable, a course better explained by embolism from their ICA lesion than by low flow.

Basal ganglia and internal capsule infarction is usually due to occlusion of the main-stem MCA before its lenticulostriate branches. There is excellent potential for collateral circulation over the convexities, but poor collateral circulation in the deep basal grey nuclei and the internal capsule. For this reason, some patients with MCA occlusion have selective ischemia of the deep lenticulostriate territory ('striatocapsular infarcts'; Adams et al., 1983; Weiller et al., 1990).

Patients with striatocapsular ischemia are invariably hemiparetic, but the distribution of weakness in face, arm and leg is variable. Sensory loss is usually minor because the posterior portion of the internal capsule is spared. When the lesion is in the left hemisphere, after a short period of temporary mutism, speech is sparse and dysarthric, but repetition of spoken language is preserved. Comprehension of spoken and written language depends on both the size and the anteroposterior extent of the lesion. When the right hemisphere is involved, there often is neglect of contralateral visual and tactile stimuli, usually more transient than with parietal cortical infarction.

Superior division of the MCA ischemia

The superior trunk of the MCA supplies the frontal and superior parietal lobes. Ischemia is most often due to embolism to the superior division but *in situ* narrowing does occur. The findings include hemiplegia, more severe in the face and hand and upper extremity, with relative sparing of the lower extremity; hemisensory loss, usually including decreased pinprick and position sense, sometimes sparing the leg; conjugate eye deviation, the eyes resting toward the side of the brain lesion; and neglect of the contralateral side of space, especially to visual stimuli. Visual neglect is usually more severe in patients with right-hemisphere lesions.

When the lesion is in the left, dominant hemisphere, there is invariably an accompanying aphasia. Verbal output is sparse, and patients do not do what they are asked with either hand, although they may follow whole-body commands. They may nod appropriately to yes/no questions asked verbally, but comprehension of written material is poor. With time, a pattern of Broca's aphasia evolves, with sparse effortful speech, poor pronunciation of syllables, and omission of filler words but preserved comprehension of spoken language.

In superior-division right hemisphere MCA infarcts, patients frequently seem unaware of their deficit (anosognosia) and may not admit that they are hemiplegic or

impaired in any way. Some patients are also impersistent, performing requested tasks quickly but they do not persevere, and terminate tasks prematurely.

Inferior divison of the MCA ischemia

Ischemia is almost entirely due to embolism to this arterial territory. In contrast to patients with lesions of the superior division, these patients usually have no elementary motor or sensory signs. They often have visual field defect, either hemianopia or upper-quadrantanopia, affecting the contralateral visual field.

When the left hemisphere is involved, patients have a Wernicke-type aphasia. Speech is fluent and syllables are well pronounced, but patients use wrong or non-existent words, and what is said makes little sense. Comprehension and repetition of spoken language are poor. There may be relative sparing of written comprehension, with the patient preferring that words be written. When the right hemisphere is affected, patients draw and copy poorly and may have difficulty finding their way about or reading maps (Caplan et al., 1986b).

Behavioural abnormalities often accompany temporal lobe infarctions. Patients with Wernicke's aphasia are often irascible, paranoid and may become aggressive. Patients with right temporal infarcts often have an agitated hyperactive state resembling delirium tremens. The key findings in patients with right inferior MCA division infarcts are a left visual-field defect, poor drawing and copying and agitation (Caplan et al., 1986b).

Ischemia in the territory of the anterior cerebral artery

Intrinsic occlusive disease of the ACA is unusual. Most ACA territory infarcts are caused by embolism from the heart or the ICA (Bogousslavsky & Regli, 1990; Gacs et al., 1983). Many patients with intrinsic disease of the ACA also have extensive ICA and MCA disease, often with multiple infarcts. Some ACA-territory infarcts are due to occlusive disease of the ICA, and others are caused by vasospasm-related ischemia in patients with SAH due to anterior communicating artery aneurysms.

The single most important clue to an ACA-territory infarct is the distribution of motor weakness. Paralysis is usually greatest in the foot but is also severe in the proximal thigh. Shoulder shrug is weak on the involved side, but the hand and face are usually normal if the deep ACA territory is spared. Some patients with anterior or large ACA territory infarcts have a hemiplegia. Cortical sensory loss is also present in the weak limbs but is usually slight. A grasp refex is often present in the hand contralateral to the infarct. When the infarct involves the left ACA territory and the supplementary motor cortex, a transcortical motor and sensory aphasia often results.

Occasionally, patients have the sudden development of bilateral ACA territory infarction explained by hypoplasia or absence of the A1 segment of the ACA on one side. In that circumstance, the territories of the ACA on both sides are supplied by one ACA. Occlusion of the ICA or ACA supplying both sides leads to bilateral frontal-lobe infarction. The resulting clinical picture is that of sudden apathy, abulia, and incontinence. When the paracentral lobule is involved, there is weakness on one or both sides, predominantly affecting the lower extremities.

Occlusion of the anterior choroidal artery

Many patients with AChA-territory infarcts are diabetic or hypertensive. Most often infarction in AChA territory is due to occlusion of the AChA. Carotid artery occlusion, vasospasm in patients with carotid artery aneurysms, and cardiac-origin embolism occasionally cause AChA territory infarction, often coupled with MCA territory infarcts. The syndrome of the anterior choroidal artery includes: (i) hemiparesis affecting face, arm, and leg; (ii) prominent hemisensory loss, which is often temporary; (iii) homonymous hemianopia; (iv) when the lateral geniculate body is infarcted, an unusual hemianopia, with sparing of a beak-shaped tongue of vision within the center of the hemianopic visual field; and (v) absence of important persistent neglect, aphasia, or other higher-cortical-function abnormalities (Helgason et al., 1986).

Hemiparesis is the most consistent finding. Dysarthria and hemisensory abnormalities are less often present and usually do not persist. Hemianopia is the least common sign. Some patients with bilateral AChA territory capsular infarcts have severe dysarthria and may even be mute.

Ischemia within the posterior (vertebrobasilar) circulation

The most common occlusive lesion within the posterior circulation is occlusion or severe stenosis of the proximal portion of the vertebral artery in the neck (Caplan, 1996; Wityk et al., 1998). Atherosclerosis of the intracranial vertebral arteries (ICVAs) and of the basilar artery are also very common. Dissection of the extracranial vertebral artery (ECVA) and ICVA are also frequent causes of ischemia within the posterior circulation. Atherostenotic lesions of the innominate and subclavian arteries do cause TIAs but seldom cause strokes. Syndromes relating to disease of

these arteries will be discussed according to localization within the territories supplied by the posterior circulation arteries.

Occlusion or severe stenosis of the subclavian and innominate arteries

The extracranial vertebral arteries (ECVAs) arise from the proximal subclavian arteries, so disease of the subclavian or innominate arteries before the VA origin can diminish VA flow. In the subclavian-steal syndrome, obstruction to the proximal subclavian artery produces a low-pressure system within the ipsilateral VA and in blood vessels of the ipsilateral upper extremity. Blood from a higher-pressure system, the contralateral VA and basilar artery, is diverted and flow retrograde down the ipsilateral VA into the arm.

Most often, subclavian artery disease is detected when patients with coronary or peripheral vascular occlusive disease are referred to ultrasound laboratories for non-invasive testing. Most patients with subclavian artery disease are asymptomatic. Neurological symptoms are uncommon unless there is accompanying carotid artery disease. The most frequent symptoms of subclavian artery disease relate to the ipsilateral arm and hand. Coolness, weakness, and pain on use of the arm are common. Dizziness is by far the commonest neurological symptom of the subclavian-steal syndrome and usually has a spinning or vertiginous character. Diplopia, decreased vision, oscillopsia, and staggering all occur, but less frequently, often accompanying the dizziness. Attacks are brief and occasionally are brought on by exercising the ischemic arm. In most patients exercise of the ischemic limb does not provoke neurological symptoms or signs.

When the lesion affects the innominate artery, signs and symptoms of decreased carotid artery flow also can occur. Innominate artery disease is much less common than subclavian artery disease (Brewster et al., 1985; Caplan, 1996). Ipsilateral monocular visual loss, ipsilateral hemisphere ischemia in ACA and/or MCA territory, ipsilateral arm ischemia, and ischemic symptoms referable to the distal portion of the posterior circulation and/or the cerebellum indicate innominate artery disease.

Atherosclerotic occlusion or severe stenosis of the extracranial vertebral artery

The most frequently reported symptom during TIAs is dizziness. Attacks are indistinguishable from those described by patients with subclavian steal, except that VA TIAs are not precipitated by effort or by arm exertion. Although dizziness is the commonest symptom, it is seldom the only neurological symptom. Usually, in at least some attacks, dizziness is accompanied by other signs of hindbrain ischemia. Diplopia, oscillopsia, weakness of both legs, hemiparesis, or numbness are often reported.

Dissection of the ECVA

Dissections usually involve the distal portion of the ECVA as it winds around the upper cervical vertebrae. Sometimes dissections involve the proximal ECVA between the origin and entry into the vertebral column – usually at C5 or C6. Pain in the neck and/or occiput and TIAs or strokes involving the proximal intracranial posterior circulation territory are the commonest findings. Occasionally cervical root pain and signs, and spinal cord ischemia can develop.

Localization of brain lesions within the posterior circulation

Localization within the posterior circulation is simplified by dividing the vertebrobasilar territory into proximal, middle, and distal territories (Caplan, 1996). The proximal intracranial posterior circulation territory includes regions supplied by the ICVAs: the medulla oblongata and the posterior inferior cerebellar artery (PICA)-supplied region of the cerebellum. The ICVAs join together to form the basilar artery at the medullopontine junction. The middle intracranial posterior circulation territory includes the portion of the brain supplied by the basilar artery and its penetrating artery branches up to its superior cerebellar artery (SCA) branches: the pons and the anterior inferior cerebellar artery (AICA), supplied portions of the cerebellum. The distal intracranial posterior circulation territory includes all of the territory supplied by the rostral basilar artery and the SCA, posterior cerebral artery (PCA) and their penetrating artery branches, midbrain, thalamus, SCA, supplied cerebellum, and PCA territories. This distribution is shown diagrammatically in Fig 80.1.

Lesions within the medulla are most often unilateral and predominantly lateral tegmental. When an infarct is found in the medulla on one side, the ipsilateral ICVA or its branches must have been obstructed at one time. Infarcts in the pons tend to be bilateral and medial-tegmentobasal when the basilar artery is occluded. When a penetrating branch is occluded, the infarcts are unilateral and in the territory of a branch. Infarction in the midbrain, thalamus and posterior portions of the cerebral hemispheres supplied by the PCAs is due to disease within the distal basilar artery or its branches.

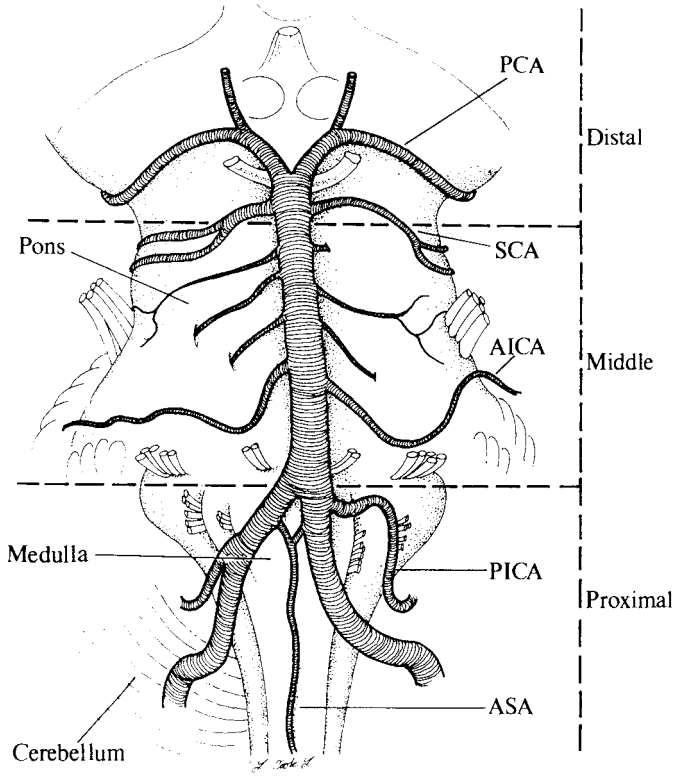

Fig. 80.1. Sketch of the base of the brain showing the intracranial vertebral and basilar arteries and their branches. The section is divided into proximal intracranial territory, middle intracranial territory, and distal intracranial territory. ASA = anterior spinal artery; PICA = posterior inferior cerebellar artery; AICA = anterior inferior cerebellar artery; SCA = superior cerebellar artery; PCA = posterior cerebral artery. Proximal intracranial territory

Lateral medullary infarction

The symptoms and signs found in patients with lateral medullary ischemia depend on the dorsal–ventral, medial–lateral, and rostro-caudal location of the infarcts.

Vestibulo-cerebellar symptoms and signs are nearly always present in patients with lateral medullary infarcts. Most patients describe feeling dizzy or off-balance. Others report vertigo: turning, rotating, whirling or moving in relation to their environment. Some patients feel as if they are being pulled or are falling towards one side (most often ipsilateral to the lesion); other patients describe a swaying, rolling feeling as if they are moving from side to side. Feelings of tilting or leaning are also frequent.

Patients with vestibular system abnormalities often describe blurred vision or frank diplopia. Some patients report oscillopsia, rhythmic motion or oscillation of objects on which they attempt to focus. Less common is tilting or inversion of the visual environment.

Ataxia is also very common. Some patients cannot feed themselves using the ataxic arm. They overshoot targets and have difficulty pointing accurately to moving targets. Nystagmus is nearly always present in patients with lateral medullary infarcts especially in patients who report dizziness or vertigo. The nystagmus usually has both horizontal and rotational components. The rapid phase of the rotatory nystagmus usually moves the upper border of the iris towards the side of the lesion. Most often, larger amplitude, slower nystagmus is present on gaze to the side of the lesion, while smaller amplitude quick nystagmus is found on gaze directed to the contralateral side. Ocular torsion is also often present; the ipsilateral eye and ear may rest in a down position below the contralateral eye and ear (Morrow & Sharpe, 1988). At times, ocular torsion is accompanied by a head tilt and skew deviation with the ipsilateral eye positioned downward. This combination of findings is referred to as the ocular tilt reaction (Keane, 1992; Brandt & Dieterich, 1994). Deviation of the perception of the visual–vertical axis is more common than the full ocular tilt reaction. A rarer oculomotor abnormality is ocular lateropulsion, a forced conjugate deviation of the eyes to one side.

Patients with lateral medullary infarcts initially often have difficulty sitting upright without support. They topple, lean or veer to the ipsilateral side when they sit or stand. In many patients standing or walking is impossible during the acute period and helpers may need to support patients in the erect position. When they become able to walk, patients often feel as if they are being pulled to the side of the lesion. They veer, list or weave to the side especially on turns. Hypotonia of the ipsilateral arm can be shown by having the patient quickly lower or raise the outstretched hands together, braking the ascent and descent suddenly. The arm on the ipsilateral side often overshoots and is not as quickly braked. In some patients, the ipsilateral arm also makes a slower ascent or descent.

Sensory symptoms and signs are also very common. Pain or dysesthetic feelings in the face are sometimes the earliest and most prominent feature of the lateral medullary syndrome and are diagnostic of a lateral tegmental brainstem localization. The facial pain is usually described as sharp jolts or stabs of pain most often in the ipsilateral eye or face. Sometimes, pain persists and is limited to the forehead and frontal scalp region. At times, the abnormal sensation is described as hot, burning, or scalding. Although contralateral loss of pain and thermal sensation involving the contralateral body and limbs is usually found on examination, most patients with contralateral hypalge-

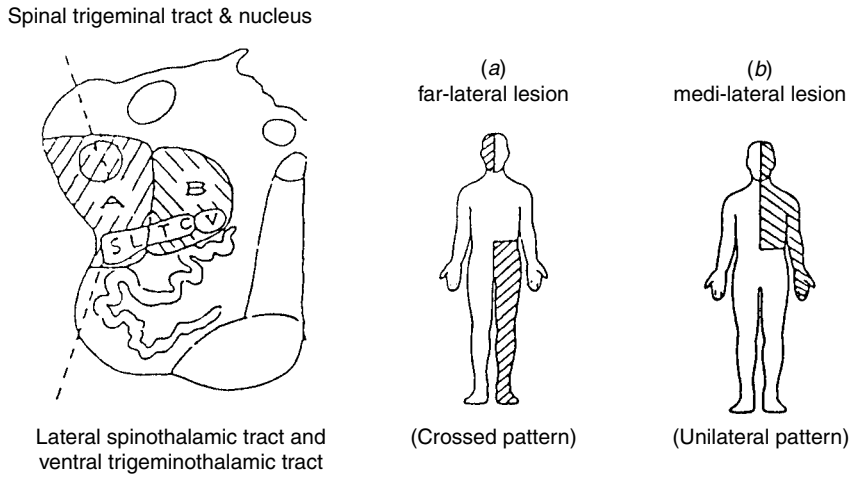

Fig. 80.2. Distribution and localization of pain fibres in the medulla. On the left is a cartoon of half of the medulla. Hashed lines point to the localization of the lateral spinothalamic tract and the spinal trigeminal tract and nucleus. The letters S = sacral, L = lumbar, T = thoracic, C = cervical, V = ventral trigeminothalamic tract show the posited localization of pain and temperature sensation fibres from these body parts. The cartoons on the right show the pattern of loss of pain and temperature sensation due to lesions at A and B in the medulla as shown on the left. (From Matsumoto et al., 1988, with permission.)

sia are unaware of their sensory loss until they are tested. Some notice loss of thermal sensation when they touch hot or cold objects. They then realize that they cannot tell the temperature of objects with their contralateral upper and/or lower limbs. Examination usually shows decreased pain and temperature sensation in the ipsilateral face. The corneal reflex is usually reduced in the ipsilateral eye, and the corneal stimulus also fails to evoke a contralateral blink. Initially, the contralateral hypalgesia can extend to the jaw, but a sensory level may be present on the thorax or abdomen. Pain and temperature sensibility may be normal in the arm. Sensory levels may appear during recovery.

The most common pattern of sensory abnormality is loss of pain and temperature sensation in the ipsilateral face and the contralateral trunk and limbs. The next most frequent combination is hypalgesia in the ipsilateral face and contralateral face, trunk and limbs. Less often, the hypalgesia can be solely contralateral involving the face, arm and leg or sometimes only the face and arm (Matsumoto et al., 1988). The least common pattern of sensory loss is hypalgesia only involving the contralateral trunk, arm and leg or parts thereof. Figure 80.2 from Matsumoto et al., 1988 shows diagrammatically the anatomical basis for the patterns of involvement of the somatosensory tracts in the lateral medulla.

The ipsilateral eye often shows features of Horner's syndrome. Weakness of bulbar muscles innervated by the lower cranial nerves is a very prominent feature in patients whose lateral medullary infarcts extend medially. Involvement of the nucleus ambiguus causes paralysis of the ipsilateral palate, pharynx and larynx resulting in hoarseness and dysphagia. The paralysis of the muscles of the oropharynx results in food being trapped in the piriform recess of the pharynx. Food and secretions have relatively free access into the air passages. Patients try to extricate the food with a cough or throat-clearing manoeuvre which makes a characteristic crowing-like sound. Examination shows paralysis of the ipsilateral vocal cord and a lack of elevation of the ipsilateral palate on phonation. The uvula often deviates to the contralateral side. Dysarthria and dysphonia are common. In some patients dysphagia and aspiration are prominent. Aspiration and pneumonia are very important complications of abnormal pharyngeal function. Usually the abnormality is unilateral. Hiccoughs are also a relatively common and annoying complaint.

Respiratory dysfunction is an important feature of lateral medullary ischemia. Control of inspiration and expiration and their automaticity lies within the ventrolateral medullary tegmentum and the medullary reticular zone. The most common abnormality described in patients with lateral tegmental caudal brainstem lesions is failure of automatic respirations, a phenomenon especially apparent during sleep. This failure to initiate respiration has been referred to as Ondine's curse. Other autonomic functions are also occasionally affected. Abnormalities of sweating, thermal regulation, and vasomotor control are occasionally present. Cardiovascular abnormalities include tachycardia, orthostatic hypotension without cardiac rate acceleration, and

intermittent bradycardia (Caplan, 1996). Gastrointestinal autonomic dysfunction includes decreased esophageal motility, gastroesophageal reflux, and gastric retention. Some patients have labile blood pressures, tachycardia, unusual sweating and arrythmias.

Medial medullary infarction

The most consistent finding in patients with medial medullary ischemia is a contralateral hemiparesis (Tyler et al., 1994; Caplan, 1996). Usually, the hemiparesis is complete and flaccid at onset. Later, increased tone and spasticity develop. Sensory symptoms are related to ischemia of the medial lemniscus. In about one-half of patients, the face is also involved. Facial weakness when it occurs is usually slight and transient and rarely persists. Some patients report paresthesias or less often dysesthesias in the contralateral lower limb and trunk. Less often, sensory symptoms occur in the arm and hand. In many patients with sensory symptoms there are no objective signs of touch, vibration, or position sense loss. Proprioceptive dysfunction with slight loss of position and vibration sense in the contralateral foot are found in some patients. Ipsilateral tongue paralysis is the least common but most topographically localizing sign of medial medullary infarction. Tongue paresis causes slurring of speech especially of lingual consonants.

Hemimedullary infarction

Occasional patients have infarction that involves both the lateral and medial medullary territories on one side. Symptoms are identical to those found in patients with lateral medullary ischemia with the addition of a hemiparesis contralateral to the lesion. The hemiparesis may develop concurrently with lateral medullary symptoms and signs or can occur later.

Cerebellar infarction in PICA distribution

PICA cerebellar infarcts can be divided into: (i) infarction in the territory of the medial branch of PICA (mPICA) affecting mostly the inferior cerebellar vermis, (ii) infarction limited to the lateral branch of PICA (lPICA) affecting mostly the lateral surface of the posterior inferior cerebellar hemisphere, and (iii) full PICA territory infarcts involving both the mPICA and lPICA territories. Full PICA territory infarcts are often accompanied by edema formation and mass effect, so-called pseudotumoral cerebellar infarcts. About one-fifth of PICA territory cerebellar infarcts are accompanied by infarction in the dorsal or dorsolateral medulla (Caplan, 1996). The combination of lateral medullary and PICA cerebellar infarction occurs when the ICVA is occluded and blocks the orifice of both PICA and the lateral medullary penetrators. Most often mPICA territory infarcts are accompanied by dorsal medullary infarcts since the mPICA branch has some supply to the dorsal medulla (Amarenco & Hauw, 1989; Amarenco et al., 1989; Caplan, 1996).

Infarcts limited to the medial vermis in mPICA territory usually cause a vertiginous labyrinthian syndrome that closely mimics a peripheral vestibulopathy (Amarenco et al., 1990). Severe vertigo with prominent nystagmus are the major findings. Some patients also have truncal lateropulsion characterized by feelings of magnetic pulling of the trunk to the ipsilateral side. Ocular lateropulsion may also be present. Lateral cerebellar hemisphere PICA territory infarcts are usually characterized by minor degrees of dizziness and gait incoordination with veering to the side of the lesion. Minor limb hypotonia and incoordination are found. A common syndrome is acute unsteadiness with ataxia but without vertigo or dysarthria. Body sway towards the side of the lesion, ipsilateral limb ataxia, and abnormal rapid alternating movements are also common.

When the full PICA cerebellar territory is involved, headache is usually present in the occiput or high neck on the ipsilateral side. The head may also be tilted with the occiput tending ipsilaterally. Vomiting, gait ataxia, truncal lateropulsion, and limb incoordination are other common findings. The truncal dysfunction is similar to that found in the lateral medullary syndrome; the body is often tilted or pulled ipsilaterally upon sitting or standing. The limb incoordination consists mostly of hypotonia rather than a rhythmic intention tremor.

The syndrome of pseudotumoural cerebellar infarction is most often found after large full PICA territory infarcts. After the first day or so, patients develop increased headache, vomiting, and decreased consciousness. At first, they become drowsy and later stuporous. Bilateral Babinski signs are an early sign of cerebellar mass effect. Most characteristic of large cerebellar space-taking infarcts are the oculomotor abnormalities which develop. Most common are a conjugate gaze paresis to the side of the lesion or a paresis of abduction limited to the ipsilateral eye. Bilateral VIth nerve paresis may occur. Later bilateral horizontal gaze palsies may develop often accompanied by ocular bobbing. These signs are due to compression of the pontine tegmentum by the swollen cerebellar infarct. Stupor is followed by deep coma when the oculomotor abnormalities become bilateral.

Vascular lesions and stroke mechanisms in patients with proximal intracranial territory infarction

Lateral medullary infarcts are most often explained by intrinsic disease, atherosclerotic stenosis often with super-

imposed thrombosis or arterial dissection of the distal ECVA or the ICVA (Caplan, 1996; Mueller-Kuypers et al., 1997; Graf et al., 1997). Less often, cardiogenic or artery-to-artery emboli usually from the ECVA explain lateral medullary infarction.

Most often, ischemia in the medial medullary base has accompanied lateral medullary ischemia (hemimedullary infarction) and is caused by occlusions of the ipsilateral ICVA (Caplan, 1996). Unilateral medial medullary infarction usually results from atheromatous branch disease or the vascular pathology within penetrating ASA branches that underlies lacunar infarction, in which case the infarct is usually limited to one medullary pyramid. The most common cause of PICA territory cerebellar infarction is embolism to the ICVA from the heart or the proximal ECVA (Amarenco et al., 1990, 1994; Graf et al., 1997; Caplan, 1996). Less often, occlusion of the ICVA is due to *in situ* atherosclerosis with superimposed thrombosis. PICA branch territory infarcts are almost always embolic, the source being the heart, aorta, or ECVA (Caplan, 1996).

Middle intracranial territory

Pontine ischemia due to basilar artery occlusive disease

Most patients with symptomatic basilar artery occlusive disease and pontine ischemia have some transient or persistent degree of paresis and corticospinal tract abnormalities (LaBauge et al., 1981; Kubik & Adams, 1944; Caplan, 1996). The initial motor weakness is often lateralized and has been referred to as the 'herald hemiparesis' of basilar artery occlusion. Hemiparetic patients with basilar artery occlusion almost always show some motor or reflex abnormalities on the non-hemiparetic side: slight weakness, hyperreflexia, an extensor plantar reflex or abnormal spontaneous movements such as shivering, twitching, shaking or jerking on the relatively spared side. Asymmetry but bilaterality is the rule. Limb adventitious movements are occasionally seen and can be prominent. Movements are variable and can be small fasciculation-like movements or large shivering, shuddering, jerking or a tremulous intermittent shaking motion. Movements are sometimes intermittent. Movement of the limbs or painful stimuli may precipitate a flurry of abnormal movements. At times, there are large repetitive jerking and twitching movements especially in limbs contralateral to a hemiparesis (Ropper, 1988).

Ataxia or incoordination of limb movements is another common motor finding. Ataxia is invariably combined with some degree of paresis. Incoordination is usually more severe in the legs. Toe-to-object and heel-to-shin testing usually shows a rhythmic 'cerebellar' type component to the dysfunction. The ataxia is invariably bilateral but may be asymetric and more severe on the weaker side. Intention tremor is not common.

Weakness of bulbar muscles is very common and is an important cause of morbidity and mortality. The face, pharynx, larynx and tongue are most often involved. The pattern may be that of crossed motor loss, e.g. one side of the face and the contralateral body but, more often the bulbar muscle weakness is bilateral. Bulbar symptoms include facial weakness, dysphonia, dysarthria, dysphagia and limited jaw movements. Some patients become totally unable to speak, open their mouth, protrude their tongue, swallow or move their face at will or on command. Secretions pool in the pharynx and aspiration is an important and serious complication. Patients with ventral pontine infarcts frequently have exaggerated crying and laughing spells and are hypersensitive to emotional stimulus. Despite the inability to voluntarily move the muscles, the jaw, face and pharyngeal reflexes may be exaggerated and clonic jaw movements or clamping down on a tongue blade may occur as a response to attempts to pry the mouth open and to insert a tongue blade. When all voluntary movement other than the eyes is lost but consciousness is retained, the deficit is referred to as the 'locked-in syndrome'.

Some patients with pontine ischemia develop palatal myoclonus, a rhythmic involuntary jerking movement of the soft palate and pharyngopalatine arch which can involve the diaphragm and larynx (Caplan, 1996). This movement disorder usually begins sometimes after the brainstem infarct. The movements of the palate vary in rate between 40 and 200 beats per minute. The movements are readily seen by watching the palate and pharynx when the mouth is open. The movements involve the eustachian tube and make a click that the patient and doctor can hear.

Oculomotor symptoms and signs are common. Few patients with pontine infarction due to basilar artery occlusive disease have normal eye movements. Abnormalities include: complete horizontal gaze palsy, unilateral horizontal conjugate gaze palsy, unilateral or bilateral internuclear opthalmoplegia (INO) and a one-and-a-half syndrome (conjugate gaze palsy + an INO). Skew deviation of the eyes and ocular bobbing may also be present. Horizontal, gaze paretic nystagmus is common and, when asymmetric, usually is more prominent when gaze is directed to the side of a unilateral pontine tegmental lesion. Dissociated nystagmus, that is nystagmus that is more severe in one eye and not rhythmically concordant in the two eyes, and vertical nystagmus are found in patients with an INO. Ptosis of the upper eyelids is also very frequent. The

pupils may remain normal or become small. In some patients the pupils are bilaterally very small ('pinpoint'). Use of a magnifying glass can show that, despite their very small size, the pupillary response to light is preserved, although the amplitude of the response is slight.

Somatosensory abnormalities are not prominent in patients with basilar artery occlusions. Paresthesias on one side of the body and limbs reflects involvement of the contralateral medial lemniscus in the paramedian dorsal portion of the basis pontis. Bilateral paramedian lesions that include the medial lemnisci on both sides can cause bilateral paresthesias. Usually proprioceptive loss is minimal or absent despite the paresthesias. Some patients with basilar artery occlusive disease have unusual burning pain in the face usually located in the centre of the face near the midline. Tinnitus and hearing loss relate to involvement of the central auditory tracts and nuclei (auditory nuclei, lateral lemnisci, trapezoid bodies, inferior colliculi) or to ischemia of the VIIIth nerves or the cochlea.

Alteration in the level of consciousness is an important sign in patients with basilar artery occlusion.

Anterior inferior cerebellar artery territory infarction

When infarction is limited to unilateral AICA territory, the clinical findings are identical to those found in patients with lateral medullary infarcts except that VIIth and VIIIth nerve findings are present rather than symptoms and signs related to Xth nerve (nucleus ambiguus) dysfunction (Amarenco & Hauw, 1990). The lesion may involve the facial, vestibular and cochlear nuclei, the VIIth nerve fibres within the lateral tegnentum and base, the VIIIth nerve peripheral fibres, or the cochlea and vestibule. Weakness of the contralateral limbs and an extensor plantar sign are found when the infarct extends to the pontine base. The internal auditory artery is most often a branch of AICA. In some patients, especially diabetics, ischemia of the inner ear structures supplied by the internal auditory artery can herald a full AICA territory infarct (Oas & Baloh, 1992). Tinnitus, hearing loss and vertigo are the most common symptoms related to inner ear ischemia.

Vascular lesions and stroke mechanisms in patients with middle intracranial territory ischemia

When pontine ischemia is bilateral, the causative vascular lesion is almost always an intrinsic lesion within the basilar artery: most often atherostenosis with or without superimposed thrombosis. Dissection of the basilar artery can produce a similar syndrome. Sometimes thrombosis begins in one distal ICVA and extends into the basilar artery or the occlusion involves a basilarized ICVA, the contralateral ICVA being hypoplastic, or ends in PICA (Caplan, 1996). When infarction is limited to the territory of one AICA, the cause is almost always atheromatous branch disease (Caplan, 1996). When there is AICA + infarction, then basilar artery or bilateral ICVA occlusions are usually present.

Distal intracranial territory

Rostral brainstem ischemia as part of the 'top of the basilar' syndrome

Occlusion of the rostral portion of the basilar artery can cause ischemia of the midbrain and thalami as well as the temporal and occipital lobe cerebral hemispheral territories supplied by the PCAs. In many patients infarction is limited to either brainstem or hemispheral structures. The major abnormalities associated with rostral brainstem ischemia involve alertness, behaviour, memory and oculomotor and pupillary functions.

The most common abnormalities of eye position and movement involve vertical gaze and convergence (Caplan, 1980, 1996; Mehler, 1988). There is often a disparity between paralysis of voluntary vertical gaze and vertical eye movements induced by vertical oculo-cephalic manoeuvres, simultaneous caloric stimulation of both ear canals or Bell's phenomenon. Some patients have a loss of all voluntary and reflex vertical eye movements. Reflex movements are sometimes preserved despite loss of voluntary vertical eye movements. Either up gaze or down gaze can be selectively involved, but in most patients both directions of vertical gaze are involved. Upgaze and vertical gaze palsies are more common than down gaze palsies (Caplan, 1996). Monocular elevation palsies, ipsilateral or contralateral to the lesion and vertical one-and-a-half syndromes (bilateral upgaze palsy and monocular downgaze palsy or bilateral downgaze palsy and monocular upgaze palsy) also occur. Asymmetric or unilateral lesions in the midbrain tegmentum and posterior thalami can cause contraversive ocular tilt reactions in which the contralateral eye and ear are down. The abnormalities include skew deviation, ocular torsion, and abnormal estimation of the visual vertical (Brandt & Dieterich, 1994).

Convergence abnormalities are also very common. Usually one or both eyes are hyperconverged. One or both eyes may rest inward or down and in at rest. On attempted upgaze, the eyes may show adductor contractions causing convergence movements.

Retraction of the upper eyelid to widen the palpebral fissure has been called Collier's sign when the abnormality is due to a rostral mesencephalic lesion near the level of the posterior commissure. In some patients both lids are retracted but one eye may have normal lid position or

ptosis. Lesions in the rostral brainstem often affect the pupillary light reflex so that the pupils react slowly and incompletely, or not at all to light. The pupils are often small at rest in patients with diencephalic lesions and may be fixed and dilated if the lesions involve the third nerve Edinger–Westphal nuclei. A combination of diencephalic and midbrain lesions cause midposition fixed pupils. In midbrain lesions, the pupil may become eccentric ('corectopia') (Caplan, 1980) or oval.

Abnormalities of alertness and behaviour are common in patients with rostral brainstem infarcts. Hypersomnolence and abulia are common. Abnormal reports and hallucinations probably relate to the altered sleep–wake dreaming cycle present in patients with rostral basilar artery territory infarction (Caplan, 1980). Reports often consist of replies to queries that have no relation to reality. The patient may mislocate themselves in place, giving the names of far distant geographical locations, and in the personal time dimension, saying that they are presently performing activities that they had done only in their childhood, adolescence, or much earlier in their adult life. Peduncular hallucinations are predominantly visual but there may be some minor tactile and auditory components. Visual hallucinations are often quite vivid and contain colours, objects, and scenes. The hallucinations occur predominantly after sunset (Caplan, 1980, 1996).

Some patients with rostral brainstem infarcts that include the thalamus have prominent and sometimes persistent memory deficits. The amnesia involves both anterograde and retrograde memory and usually includes both verbal and non-verbal memory.

Sensory and motor abnormalities are usually absent in patients with top of the basilar infarction unless the proximal PCAs are also occluded. Movement disorders especially hemiballism have been described in some patients with small infarcts and hemorrhages involving the subthalamic nuclei, but hemiballism is rare in patients with well documented top-of-the-basilar infarcts.

Superior cerebellar artery territory infarction

Most often SCA territory infarcts are accompanied by other infarcts in regions supplied by other arteries that arise at the rostral end of the basilar artery. The classic SCA syndrome is said to consist of: ipsilateral limb ataxia; ipsilateral Horner's syndrome; contralateral loss of pain and temperature sensibility of the face, arm, leg, and trunk; and contralateral IVth nerve palsy (Caplan, 1996). Abnormal ipsilateral spontaneous involuntary movements also occur. The classic syndrome is present when the pontine and midbrain tegmentum and superior cerebellar surface are infarcted. The full syndrome is quite rare.

Slight dizziness, vomiting, ipsilateral limb dysmetria, gait ataxia, and dysarthria are common. Vertigo is usually not prominent in patients with isolated SCA territory infarcts. Limb incoordination, limb ataxia, intention tremor and dysarthria are more common in SCA territory cerebellar infarcts than in either AICA or PICA territory cerebellar infarcts (Caplan, 1996). Patients with infarcts in the territory of the lateral branch of the SCA have prominent limc ataxia, varying from slight clumsiness to severe incoordination and dysmetria, and dysarthria. Cerebellar gait ataxia and veering and pulling of the trunk to the ipsilateral side, so-called axial lateropulsion also occur.

Dysarthria and abnormal speech rhythm are common in patients with SCA territory infarcts, no matter whether the lesion involves the full territory or the medial or lateral branches.

Posterior cerebral artery territory infarction

The most common finding in patients with PCA territory infarction is a hemianopia (Pessin et al., 1987b; Caplan, 1996, 2000; Yammamoto et al., 1999). If just the lower bank of the calcarine fissure is involved, the lingual gyrus, a superior-quadrant field defect results. An inferior quadrantanopia results if the lesion affects the cuneus on the upper bank of the calcarine fissure. When infarcts are restricted to the striate cortex and do not extend into adjacent parietal cortex, patients are aware of the visual defect. Usually described as a void, blackness, or a limitation of vision to one side, patients usually recognize that they must focus extra attention to the hemianopic field. When given written material or pictures, patients with hemianopia due to occipital lobe infarction are able to see and interpret stimuli normally, although it may take them a bit longer to explore the hemianopic visual field. In patients with occipital lobe infarcts, physicians can reliably map out the visual fields by confrontation. At times, the central or medial part of the field is spared, so-called macular sparing. Optokinetic nystagmus is preserved. Some patients, although they accurately report motion or the presence of objects in their hemianopic field, cannot identify the nature, location, or colour of those objects. When the full PCA territory is involved, visual neglect can accompany the hemianopia.

In patients with PCA territory infarcts, lateral thalamic ischemia is the major reason for somatosensory symptoms and signs (Caplan et al., 1988). Patients describe paresthesias or numbness in the face, limbs and trunk. On examination, touch, pinprick, and position sense are reduced. The combination of hemisensory loss with hemianopia without paralysis is virtually diagnostic of infarction in the PCA territory. The occlusive lesion is within the PCA before the thalamogeniculate branches to the lateral thalamus.

Rarely, occlusion of the proximal portion of the PCA causes a hemiplegia (Hommel et al., 1990; Caplan, 1996).

When the left PCA territory is infarcted (Caplan, 1996, 2000), alexia without agraphia, anomic or transcortical sensory aphasia (Kertesz et al., 1982) and Gerstmann's syndrome may be found. Defective acquisition of new memories is common when both medial temporal lobes are damaged but also occurs in lesions limited to the left temporal lobe (Caplan, 1996). The memory deficit in patients with unilateral lesions is usually not permanent but may last up to 6 months. Patients cannot recall what has happened recently, and when given new information, they cannot recall it moments later. They often repeat statements and questions spoken only minutes before. Some patients with left-PCA territory infarction have difficulty in understanding the nature and use of objects presented visually (associative visual agnosia) (Caplan & Hedley-White, 1974). They can trace with their fingers and copy objects, demonstrating that visual perception is preserved and can name objects presented in their hand and explored by touch or when verbally described.

Infarcts of the right PCA territory are often accompanied by prosopagnosia, difficulty in recognizing familiar faces (Damasio et al., 1982). Disorientation to place and an inability to recall routes or to read or revisualize the location of places on maps are also common (Fisher, 1982). Patients with right occipito-temporal infarcts also may have difficulty revisualizing what a given object or person look like. Dreams may also be devoid of visual imagery. Visual neglect is much more common after lesions of the right than of the left PCA territory.

When the PCA territory is infarcted bilaterally, the commonest findings are cortical blindness, amnesia, and agitated delirium (Caplan, 1980, 1996). Bilateral PCA territory infarction is most often due to an embolus that blocks the distal basilar bifurcation. Cortically blind patients cannot see or identify objects in either visual field but have preserved pupillary light reflexes (Symonds & McKenzie, 1957). Amnesia due to bilateral medial temporal-lobe infarction may be permanent and closely resembles Korsakoff's syndrome. Infarction of the hippocampus, fusiform, and lingual gyri, usually bilaterally, leads to an agitated hyperactive state that can be confused with delirium tremens (Caplan, 1980, 1996).When infarction is limited to the lower banks of the calcarine fissures bilaterally, the major findings are prosopagnosia and defective colour vision.

Vascular lesions and stroke mechanisms in patients with distal intracranial territory infarcts

Most distal posterior circulation intracranial territory infarcts are caused by embolism from the heart, aorta, and ECVAs and ICVAs (Caplan, 1980, 1996). Rostral brainstem infarcts that are unilateral and are within the territory of single penetrating branches such as the polar artery, thalamic–subthalamic artery, posterior choroidal artery, and midbrain penetrating arteries are caused by disease of those branches, lipohyalinosis or atheromatous branch disease. Most infarcts that are limited to the lateral thalamus in the territory of the thalamogeniculate arterial pedicle are caused by atheromatous branch disease and not disease of the parent PCA (Caplan et al., 1988). Superior cerebellar artery territory infarcts are predominantly embolic especially when infarction is limited to mSCA or lSCA branches. Occasional patients with bilateral SCA territory have a stenosing lesion involving the basilar artery affecting the region of the artery from which the SCAs originate.

Unilateral PCA territory infarcts are also predominantly embolic. Emboli most often have been documented to arise from the heart and the ECVAs and ICVAs but the aorta may also be a frequent source (Pessin et al., 1987b; Caplan, 1993, 1996; Yammamoto et al., 1999). Occasional patients have an intrinsic atherostenotic lesion within the PCA. These patients often have TIAs characterized by visual, sensory, or visual and sensory symptoms before their strokes (Pessin et al., 1987a; Caplan, 1996).

Penetrating artery disease syndromes

Hypertension and aging cause degenerative changes within arteries that arise perpendicularly from the major basal cerebral arteries. Disruption and narrowing of the lumens of these arteries cause small deep infarcts in the basal ganglia, cerebral white matter, thalami and brainstem. Atheromatous branch disease (Caplan, 1989) also causes small deep infarcts. The commonest syndromes of deep (lacunar) infarction are: (i) pure motor stroke: weakness of face, arm, and leg with increased reflexes and a Babinski sign on one side of the body without cognitive, behavioural, sensory, or visual abnormalities (infarct in internal capsule or pons); (ii) pure sensory stroke: numbness or paresthesias in face, arm, leg and often trunk on one side of the body without accompanying motor, visual or cognitive or behavioural abnormalities (small infarct in the ventrolateral thalamus or in sensory tracts within the brainstem); (iii) ataxic hemiparesis: weakness and ataxia of the limbs on one side of the body usually without visual, cognitive or behavioural abnormalities but sometimes with paresthesias (infarct in the pons or posterior portion of the internal capsule); (iv) dysarthria–clumsy hand syndrome: slurred speech usually with facial and tongue

weakness and clumsiness of the hand on the same side, small brainstem infarct).

Intracerebral hemorrhage syndromes

Hemorrhages of the lateral basal ganglia, putamen, and internal capsule

The commonest location of hypertensive ICH is the lateral basal–ganglionic–capsular region. These lesions are usually referred to as *putaminal hemorrhages* because they most often begin in the putamen. The usual findings include contralateral hemiparesis and hemisensory loss, and conjugate deviation of the eyes toward the side of the hematoma. The pupils are generally normal, and gait is hemiparetic. Patients with a left putaminal hemorrhage usually have a non-fluent aphasia with relative preservation of the ability to repeat spoken language. Right-sided lesions are associated with left visual neglect, motor impersistence, and constructional dyspraxia. If the hematoma enlarges and becomes sizable, patients develop increasing stupor; the ipsilateral pupil at first becomes smaller, and later larger than the opposite pupil; the ipsilateral plantar response becomes extensor; and a bilateral horizontal gaze palsy develops.

The findings described above are those found in patients with large hematomas that involve the medial and most anterior portions of the posterior putamen and the anterior two thirds of the posterior limb of the internal capsule (Kase & Caplan, 1994; Chung et al., 2000). This location is the commonest site for putaminal hemorrhage because it is supplied by the largest of the lateral lenticulostriate arteries. Some lesions affect the anterior limb of the internal capsule and anterior putamen and produce a milder, more transient hemiparesis without sensory abnormalities. When hematomas are located in the posterior third of the internal capsule and far posterior extreme of the putamen, sensory abnormalities predominate with little or no hemiparesis. An inferior quadrantanopia or hemianopia may be present. Lesions in the far posterior left putamen may cause fluent Wernicke-like aphasia because of undercutting of the temporal lobe or extension of the lesion into the temporal isthmus, giving the hematoma a hockey-stick-like configuration.

Caudate hemorrhage

Caudate hematomas frequently discharge quickly into the adjacent lateral ventricle or may spread laterally toward the internal capsule or inferiorly toward the hypothalamus (Kase & Caplan, 1994; Stein et al., 1984). Early ventricular dilation by blood probably accounts for the most common symptoms of caudate hemorrhage: headache, vomiting, decreased alertness, and stiff neck. Some patients also are confused, disoriented, and have poor memory. Larger parenchymatous hematomas cause a contralateral hemiparesis, conjugate deviation of the eyes to the side of the lesion, conjugate gaze palsy to the opposite side, and an ipsilateral small pupil or Horner's syndrome. Sensory findings are usually absent or minimal.

Thalamic hemorrhage

Neurologic signs in patients with thalamic hemorrhages differ greatly depending on the size, location within the thalamus of the hematoma, and dissection into and pressure effects on the third ventricle and adjacent brain structures (Kase & Caplan, 1994; Chung et al., 1996). The largest hemorrhages are located in the ventrolateral and posteriomedial thalamus in the territories of the thalamogeniculate and thalamic-subthalamic arteries. Other hemorrhages are located anteriorly in the territory of the tuberothalamic (polar) arteries and dorsally in the territory of the lateral posterior choroidal arteries (Chung et al., 1996). Most thalamic hematomas are posterior to the pyramidal-tract fibres in the internal capsule, so that contralateral sensory abnormalities are usually more prominent than contralateral hemiparesis. Some large thalamic hematomas dissect rostrally and involve the anterior portion of the posterior limb of the internal capsule causing a hemiplegia. Sometimes, the limbs contralateral to the hematomas are ataxic or have choreic movements. The contralateral hand may rest in a fisted or dystonic posture. The key neurological findings that separate thalamic from caudate and putaminal hemorrhages are the eye signs. Patients with caudate or putaminal hemorrhages have conjugate deviation of the eyes toward the side of the lesion and paresis of conjugate gaze to the opposite side. The characteristic oculomotor abnormalities in patients with thalamic hematomas are: (i) *paralysis of upward gaze,* often with one or both eyes resting downward; (ii) *hyperconvergence of one or both eyes,* a combination of these findings giving patients the appearance of peering downward and inward at the tops of their noses; (iii) *ocular skew* in which one eye rests below the other, with this divergence in vertical eye position remaining constant in gaze in all directions; (iv) *eyes gazing the wrong way,* resting toward the opposite side; (v) *disconjugate gaze,* with limited abduction of one or both eyes, so-called pseudo-sixth-nerve paresis. The pupils are usually small and react poorly to light because of interruption of the afferent limb of the pupillary reflex arc.

Patients with large left thalamic hemorrhages often have an unusual aphasia. After beginning a conversation almost normally, patients may lapse into a remarkable fluent aphasia, with many jargon or non-existent words and poor communication of ideas. In contrast to patients with Wernicke's aphasia, comprehension of spoken language is good. Patients with thalamic ICH may repeat and duplicate words or syllables at the ends of words in both spoken and written language. Paraphasic errors and poor naming are also common. Patients with right thalamic hematomas often have left visual neglect, anosognosia, and visuospatial abnormalities. Decreased levels of alertness and consciousness and hypersomnolence are very common at the onset of thalamic hemorrhage.

Lobar hemorrhages

ICH may develop beneath the region of the grey–white junction of the cerebral cortex. These subcortical hemorrhages usually spread in a linear direction along white-matter pathways (Kase & Caplan, 1994). Symptoms and signs depend on the lobes affected, as follows.

Frontal hematomas

Far anterior lesions usually cause abulia. Patients appear apathetic and have reduced spontaneity, prolonged latency in responding and short, terse replies. If the lesions extend deeply or toward the precentral gyrus, conjugate eye deviation toward the side of the hematoma and contralateral hemiparesis are found.

Paracentral hematomas

Lesions near the central sulcus produce contralateral motor and sensory signs, sometimes with aphasia if the lesion is in the left hemisphere.

Parietal hemorrhages

These hematomas cause contralateral hemisensory loss, with neglect of the contralateral visual field. The limbs contralateral to the hemorrhage are often incoordinated. Apahsia and disorders of reading, writing, and arithmetic functions are present when the lesions involve the left inferior parietal lobule. Patients with right inferior parietal hematomas have hemianopia or quadrantanopia and defective drawing and copying and may have difficulty with visual-spatial functions.

Occipital hematomas

These cause a severe contralateral hemianopia, often with slight contralateral hemisensory or motor signs and visual neglect.

Temporal-lobe lesions

These lesions often cause agitation and delirium. Wernicke-type aphasia accompanies left temporal lesions. Temporal-lobe hematomas are particularly likely to swell and may cause herniation without preceding hemiparesis. Brainstem compression may develop insidiously, with deepening stupur and then an ipsilaterally dilated pupil.

Pontine hemorrhage

Primary brainstem hemorrhages are located most often in the pons. Primary pontine hemorrhages usually begin in the centre of the pons at the tegmental–basal junction. These hematomas grow quickly usually destroying the centre of the tegmentum and the base of the pons. The blood may dissect rostrally into the midbrain but rarely extends caudally into the medulla. Hematomas frequently dissect into the fourth ventricle. These large pontine hemorrhages arise from the larger median pontine penetrating vessels that originate from the basilar artery (Kase & Caplan, 1994).

The signs accompanying large medial pontine hematomas are: quadriparesis, often with limb stiffness and rigidity; coma; absent horizontal eye movements; small but reactive pupils; and rapid or irregular respirations. Headache and vomiting occasionally occur. Some pontine hemorrhages develop gradually, and early findings may be asymmetrical. A hemiparesis is common early in the course. Deafness, dysarthria, facial numbness, asymmetsic facial or limb weakness, and dizziness occasionally precede the development of coma. Some patients have shivering, or spasmodic limb movements, usually culminating in decerebrate rigidity. Vertical reflex eye movements are preserved unless the lesion extends rostrally into the midbrain. In some patients, the eyes spontaneously and repeatedly bob downward.

Lateral basal hematomas can cause pure motor hemiparesis, ataxic hemiparesis, or the dysarthria–clumsy hand syndrome mimicking findings in lacunar infarction involving the pons. Lateral basal lesions can spread into the adjacent tegmentum, causing unilateral cranial nerve signs and contralateral hemiparesis. Lateral tegmental hematomas arise from penetrating vessels that course from lateral to medial after branching from the lateral circumferential pontine arteries. These lesions involve the rostral pons, and the findings are those of a predominantly unilateral tegmental lesion. Most distinctive and diagnostic of lateral tegmental pontine hematomas are the oculomotor abnormalities, which include ipsilateral conjugate gaze paresis, ipsilateral INO, or a combination of INO and gaze palsy (a 'one and one-half syndrome') in which the only preserved eye motion is abduction of the contralateral eye. Because

the sensory lemniscus is lateral tegmental, accompanying loss of pinprick, temperature, and position sense on the opposite side of the body is common. Limb and truncal ataxia are usually present and may be bilateral or predominantly ipsilateral. Unilateral facial numbness or weakness, ipsilateral miosis, and transient deafness may also be present.

Cerebellar hemorrhages

The most consistent symptom is inability to walk (Kase & Caplan, 1994). Some patients have difficulty maintaining a sitting or standing position, often leaning or tilting toward the side of the hematoma. Headache is common, usually affecting the occiput or neck or frontal region. Dysarthria, hiccups, and tinnitus occur but are less frequent. Loss of consciousness at onset is unusual, but when these patients reach the hospital, about one-third are obtunded. Neurological signs include an ipsilateral abducens or gaze palsy toward the side of the hematoma; small pupils, with the ipsilateral pupil slightly smaller; rebound overshoot of the rapidly elevated ipsilateral arm; and gait ataxia. Hemiparesis probably does not occur in cerebellar hemorrhage, but cerebellar lesions do produce an apparent asthenia or slowness of the affected limbs. Inferior extremity reflexes are usually symmetrically exaggerated, but plantar responses are flexor. Patients with large cerebellar hematomas often have brainstem compression. They develop increasing stupor, lateral gaze palsy toward the side of the hematoma, and bilateral extensor plantar responses.

The treatment of acute ischemic stroke

Robert A. Felberg and James C. Grotta

Department of Neurology, University of Texas – Houston Medical Center, Houston, TX, USA

Historically, the treatment of stroke has been viewed with nihilism. With the approval of intravenous tissue plasminogen activator (i.v.-rTPA) (Nat. Inst. Neurol. Disorders, 1995), the past attitudes of helplessness in the face of stroke are changing. Despite the efficacy of thrombolytic therapy, less than 3% of all ischemic stroke patients are actually treated with i.v.-rTPA. The major reason for this lack of treatment appears to be the short time window. Both human and animal studies suggest that the time window for therapy will remain at approximately 3–6 hours even with the development of successful neuroprotection (Fig. 81.1). For this reason, time is a critically important factor in the treatment of acute stroke.

The approach to acute stroke can be separated into five overlapping concepts. The first and, thus far, most successful is restoring flow through the occluded vessel. The second is altering the ischemic cascade. Third is maximizing collateral flow. Fourth is the prevention of complications and the final concept is the use of a multidisciplinary team and designated Stroke Units to maximize patient care. Recovery and its augmentation is a sixth concept that is beyond the scope of this chapter.

Restoration of flow

The normal perfusion to brain grey matter is 60–70 ml for every 100 grams of brain tissue every minute. When perfusion decreases to less than 25 ml/100 mg/min, the neuron is no longer able to maintain aerobic respiration. If perfusion is not restored, the ischemic tissue will reach a point of no return where cell death is inevitable. This process is very time dependent, with irreversibility occurring after 5–6 hours. However, if flow is restored, then the brain tissue can potentially be spared and neurological function preserved (Figs. 81.2 and 81.3) (Jones et al., 1981). This concept has led to the use of pharmacological and mechanical attempts to disrupt the occluding thrombus. To date, this remains the most efficacious treatment of acute stroke and represents the only Food and Drug Administration approved therapy.

Intravenous thrombolysis

There have been multiple recent trials of intravenous thrombolytics in the setting of acute ischemic stroke. Streptokinase was examined in three major trials enrolling 1192 patients (MAST-I, 1995; Donnan et al., 1996; Multicenter Acute Stroke Trial, 1996). An increased rate of intracerebral hemorrhage with significantly worse outcomes in the treatment groups in persons treated with streptokinase negated possible benefit and forced early stoppage of the trials. The use of intravenous streptokinase is discouraged.

Intravenous rTPA was shown to reduce disability at 90 days in the setting of acute stroke. The NINDS trial (1995) was two sequential trials of rTPA vs. placebo in patients treated within 3 hours of symptom onset based on clinical criteria (i.e. angiographic demonstration of obstructing clot was not required prior to treatment). Patients were stratified into half treated within the first 90 minutes, and the other half within 180 minutes of stroke onset. A total of 624 patients were enrolled. In the pivotal second part of the trial, a normal to near normal recovery occurred in 31% of the treatment arm versus 20% in the placebo group (Fig. 81.4). A similar significant benefit was found at 90 days in part 1. This response rate included those 6.4% of patients who suffered a symptomatic ICH. Note in Fig. 81.4 that despite the increased incidence of ICH in treated patients, mortality was no higher and death or severe disability was less in those treated with rTPA.

There have been multiple post-marketing studies confirming the therapeutic effect of i.v. rTPA. The most notable

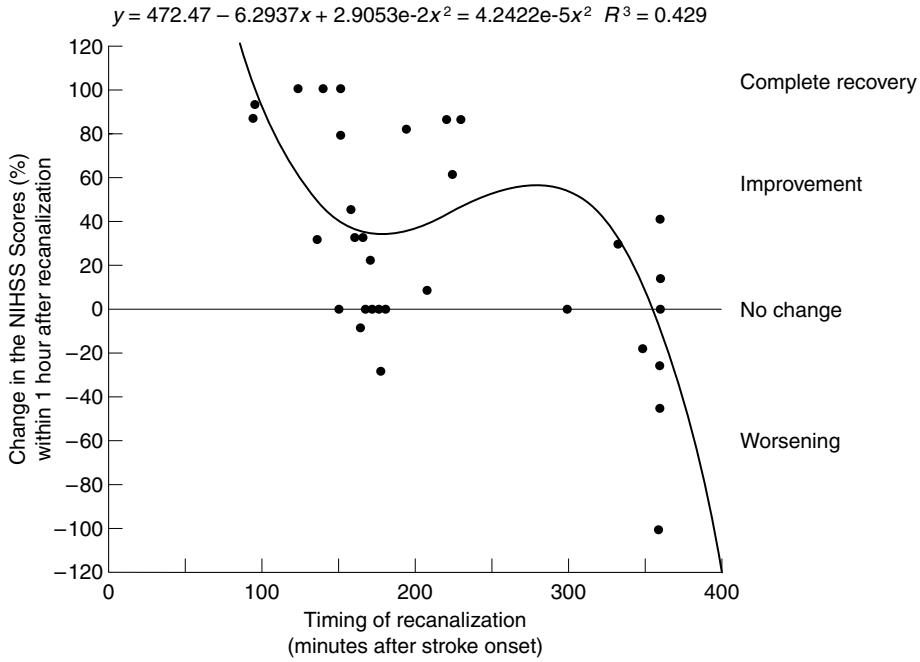

Fig. 81.1. Recovery from acute ischemic stroke correlates with the total time of ischemia. By using Transcranial Doppler to asses time until flow is restored, the link between early restoration of flow and good outcome is shown above. Note the lack of good outcome past 300 minutes of ischemia. (From Christou et al., 2000, with permission.)

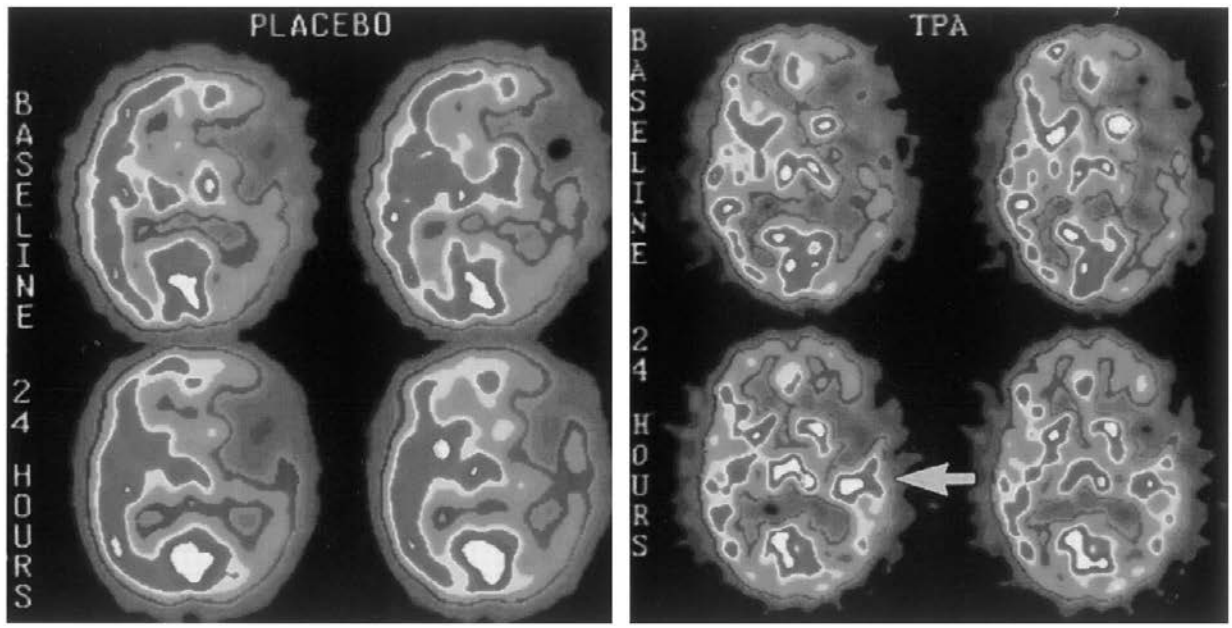

Fig. 81.2. SPECT scan demonstrating restoration of flow following intravenous tissue plasminogen activator. The image on the left is a patient who received placebo. No significant improvement is noted. The image on the right demonstrates a significant flow improvement to the ischemic region (arrow). This patient dramatically improved within 24 hours after treatment. (From Grotta & Alexandrov, 1998, with permission.)

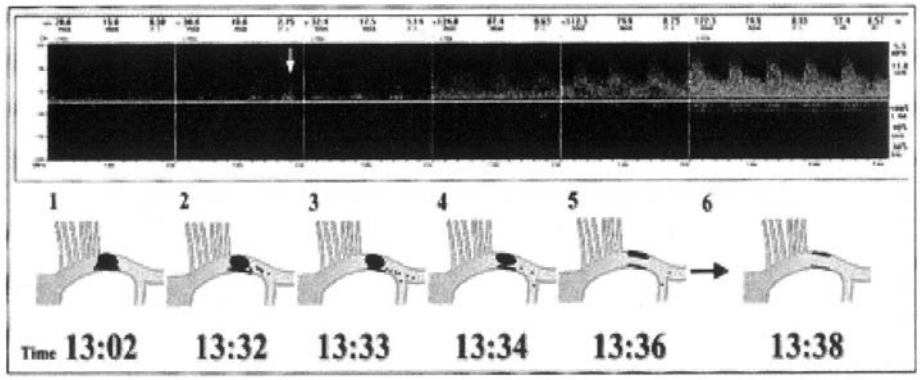

Fig. 81.3. Transcranial Doppler ultrasound representation of restoration of flow. The transcranial Doppler is shown in the upper figures. The bottom image is the interpretation of the transcranial Doppler signal. The occlusion at the M1 middle cerebral artery level begins to recanalize 30 minutes into intravenous thrombolysis with tissue plasminogen activator. As flow restoration occurs, the Doppler signature improves. The patient went on to have a dramatic recovery following restoration of flow. (From Demchuk et al., 1999, with permission.)

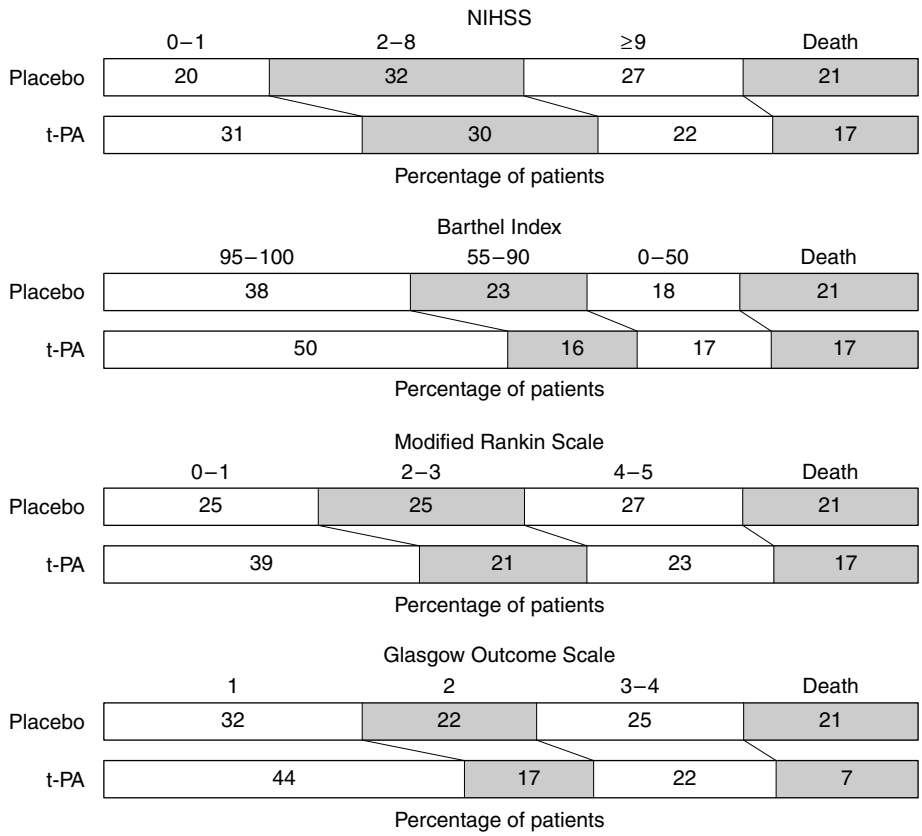

Fig. 81.4. Outcome at 90 days in the NINDS tissue plasminogen activator trial. Note the shift towards decreased disability. Although there was a trend towards lower mortality in the treatment group, this was not statistically significant. (From The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995, with permission.)

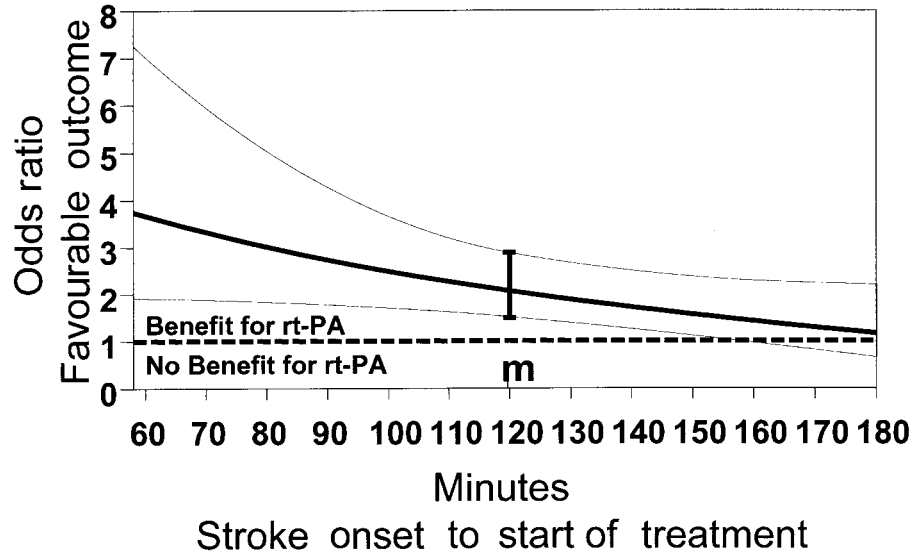

Fig. 81.5. Time to treatment with intravenous rTPA and outcome. Patients treated earliest into the course of their stroke had the best outcome. (From Marler et al., 2001, with permission.)

to date was the Standard Treatment with Alteplase to Reverse Stroke (STARS) (Albers et al., 2000) trial that duplicated the outcome benefit while showing a symptomatic ICH rate of 3.3%. The STARS trial along with other post marketing studies has shown that protocol violations result in a higher ICH rate. For this reason, strict adherence to treatment algorithms is advised.

The time to treatment is the single most important factor in determining outcome from i.v. rTPA therapy. (Fig. 81.5). Patients treated within 90 minutes do significantly better than patients treated closer to the 180-minute time window. Trials looking at the 3–6 hour time window have been negative, although a *post hoc* meta-analysis has suggested a trend towards decreased deficit (Wardlow et al., 2000).

At present, i.v. rTPA is the only FDA approved treatment for acute ischemic stroke. Quickly becoming the standard of care, all qualifying patients should be strongly considered for i.v. rTPA therapy. An outline of rTPA care is included (Fig. 81.6). It is imperative that neurologists work with Emergency Medical Services and Emergency Medical Departments to integrate the care of stroke patients. The Brain Attack Coalition (Alberts et al., 2000) has recommended the formation of Stroke Centres in an attempt to increase access to medical care (Fig. 81.7). We recommend a formal system of acute stroke triage, whereby patients are diverted from non-stroke centres to emergency departments that are capable of thrombolysis and post thrombolysis care.

Intra-arterial thrombolysis

There have been many anecdotal reports and two major trials of intra-arterial (i.a.) thrombolysis. The Prolyse in Acute Cerebral Thromboembolism II (PROACT II) (Furlan et al., 1999) trial showed a benefit for patients with an anterior stroke syndrome and middle cerebral artery occlusion. Patients showed benefit if treatment began up to 6 hours after stroke onset, potentially increasing the time window for that segment of stroke patients eligible for i.a. therapy. Patients were screened with an initial cerebral angiogram before being randomized. For every one patient randomized, four patients received a screening angiogram. Forty per cent of the patients who received i.a. prourokinase recovered to normal or near normal compared to 25% who did not receive i.a. thrombolysis.

The i.a. approach to thrombolysis has certain advantages and disadvantages. Because angiography is performed, it makes possible direct visualization of the thrombus with the ability to confirm the occlusion and determine the etiology in certain cases. Serial examinations can be performed and restoration of flow can be assessed. If thrombolysis is not successful, mechanical techniques such as the use of suction devices might be used to maximize clot dissolution. The greatest advantage of i.a. thrombolysis is the evident increase in the time window of therapy.

The disadvantages of i.a. thrombolysis are mainly related to access and time issues. Few centres have the

Intravenous tissue plasminogen dosing:

- *0.9 mg/kg total dose*
  - *Maximum total dose 90 mg*
- *10% bolus [(0.9 mg/kg) × (0.10)] over 1 minute*
  - *Maximum bolus 9 mg*
- *Remaining infusion dose over 60 minutes*

Eligibility:

- *Clinical diagnosis of stroke causing measurable deficit*
- *Time of onset within 180 minutes of initiating therapy*

Contraindications:

- *Evidence of hemorrhage on CT*
- *Clinical presentation consistent with SAH*
- *Active internal bleeding*
- *Known bleeding diathesis*
- *Within 3 months of intracranial surgery, traumatic brain injury or stroke*
- *History of ICH, AV malformation, or aneurysm*
- *Uncontrollable hypertension*

Warnings:

- *Minor or rapidly improving symptoms*
- *GI or urinary hemorrhage withing 21 days*
- *Major surgery or trauma within 14 days*
- *Recent lumbar puncture or arterial puncture at non-compressible site*
- *Hyper- or hypoglycemia*
- *Seizure at onset of stroke symptoms*
- *Postmyocardial infarction pericarditis*

Fig. 81.6. Overview on intravenous tissue plasminogen activator therapy for acute ischemic stroke. Time of onset is defined by the last time a patient is known to be normal. See package insert for further directions.

Elements of a stroke centre:

- Patient care services
  - Acute stroke teams
  - Written and easily accessible care protocols
  - Emergency medical services and emergency department
  - Stroke unit
    - Only required for those stroke centres that will provide ongoing in-hospital care for patients with stoke
  - Neurological services
    - Available within reasonable time and geographical distance

Support services

- Commitment and support of medical organization
- Designated stroke centre director
- Neuroimaging and laboratory services
  - 24 hour availability
- Outcome and quality of care assessment and improvement
- Medical education activities

Fig. 81.7. Stroke Centre guidelines per the recommendations of the brain attack coalition. (From Alberts et al., 2000, with permission.)

expertise and equipment required to treat all eligible patients on a consistent basis. As time to restoration of flow is critical in determining outcome, the added time of transport, alerting the angiography team, and gaining intravascular access can significantly delay time to restoration of flow. In an attempt to minimize these disadvantages, the combination of an initial i.v. dose of rTPA followed by i.a. thrombolysis is being investigated. The need for a high number of screening angiograms also reduces the attractiveness of i.a. therapy. Transcranial Doppler is a promising screening technique in the ED that might be used for identifying patients who would be likely to have treatable arterial occlusions (Denchuk et al., 2000).

ProUrokinase, the agent used in the PROACT II trial is not currently available in North America. The agent with the most reported use outside of the PROACT trial is Urokinase, but this drug has supply difficulties and is often not available. Tissue plasminogen activator is gaining popularity as an i.a. thrombolytic agent. Intra-arterial thrombolysis is not currently an approved procedure and should

only be attempted at centres with experienced personnel and under investigational conditions.

The role of i.a. thrombolyis in posterior circulation events has been reported in anecdotal reports and case series. Thus far, no randomized trials have investigated safety or effectiveness. Posterior circulation strokes, especially those involving occlusion of the basilar artery, have a dismal prognosis with a high mortality. The posterior circulation may have a relative resistance to ischemia, with reports of recovery following thrombolysis out to 18 hours. For this reason and the overall poor outcome, it is reasonable to consider i.a. thrombolysis in patients with basilar artery occlusion who do not respond to conventional i.v.-rTPA or who are not candidates due to time constraints. The investigational nature of such procedures based on anecdotal and case series evidence must be emphasized and informed consent should be obtained.

Heparin

The use of anticoagulation with heparin and heparin-like products goes back nearly 50 years. Despite the lack of evidence in favour of its use and the significant possibility of hemorrhagic transformation, heparin remains a commonly used agent in the treatment of acute stroke. Heparin theoretically inhibits new thrombus formation or extension of preformed thrombus to prevent recurrent stroke or worsening of prior infarction.

Heparin was evaluated in the International Stroke Trial (1997). A total of 19435 patients within 48 hours of acute stroke onset were enrolled into no treatment, 5000 i.u. of subcutaneous heparin b.i.d., 12500 i.u. of subcutaneous heparin b.i.d., both heparin doses with or without aspirin 300 mg daily, and aspirin alone. No improvement in outcome was found in any of the heparin treatment groups. Most significantly, the benefit seen in the higher heparin dose (0.9% prevention of recurrent stroke) was diminished by an increase in hemorrhagic stroke (0.8% absolute increase). The combination of 300 mg of aspirin daily with 5000 i.u. of Heparin BID was associated with the best outcome (1.2% decrease of death or non-fatal recurrent stroke at 14 days) without a significant increase in hemorrhagic stroke when compared to 300 mg of aspirin alone.

Heparinoids, low molecular weight heparin derivatives formed by enzymatic cleavage, have been evaluated in multiple well-designed trials. Danaparoid was evaluated in the Trial of ORG 10172 in Acute Stroke Treatment trial (TOAST) (1998). Patients treated within 24 hours of acute stroke showed no difference in outcome from the control group. A *post hoc*, subgroup analysis suggested benefit in those patients with stroke due to large vessel atherosclerotic disease (Adams et al., 1999). This finding remains to be confirmed by further prospective study. Another heparinoid, nadroparin was evaluated in two randomized trials (Kay et al., 1995; Bath et al., 2000). The first, smaller trial suggested benefit. This was not confirmed in a larger follow-up study.

Much misinformation and many queries remain concerning heparin and heparinoids. There is belief that heparin is beneficial for 'stroke in progression'. This hypothesis has not been validated by results from controlled trials. There is also a concern that the current trials have not replicated the North American practice of an i.v. bolus followed by an i.v. continuous infusion. However, this argument is also not supported by data since this type of dosing is very similar to the negative TOAST trial protocol, and there was also no evidence of a dose effect suggesting even a marginal benefit in other trials. An important discovery from the heparin and heparinoid trials is the relatively infrequent rate of recurrent stroke (approximately 2–4% in the first 14 days), lessening concern for the need for anticoagulation to prevent recurrent strokes in the first days following an acute stroke.

In conclusion, full dose heparin or heparinoids cannot be recommended in most settings based on the outcome of well-designed trials enrolling nearly 20000 patients. At present, the only clearly effective treatment for acute stroke is thrombolysis and this should be made available to as many patients as possible. In certain acute stroke situations, such as high-grade large vessel stenosis or dissection, or established cardiac conditions likely to cause embolization, i.v. heparin might be used with caution, recognizing the significant risk of hemorrhagic transformation of the stroke. Subcutaneous low dose heparin appears beneficial, likely by preventing deep venous thrombosis, and is recommended for routine use.

Ancrod

By decreasing the availability of fibrinogen, Ancrod decreases the ability to form thrombi. Derived from the Malaysian Pit Viper, ancrod was shown to be beneficial in patients treated within three hours of acute stroke (Sherman et al., 2000). At 90 days, 42% of the treatment arm recovered to normal or near normal when compared to 34% of the placebo group. Ancrod has not yet been approved for the treatment of acute stroke. Although a promising modality, ancrod administration is a rather burdensome procedure that may prevent general acceptance. Its utility compared to thrombolyis, and the role of ancrod

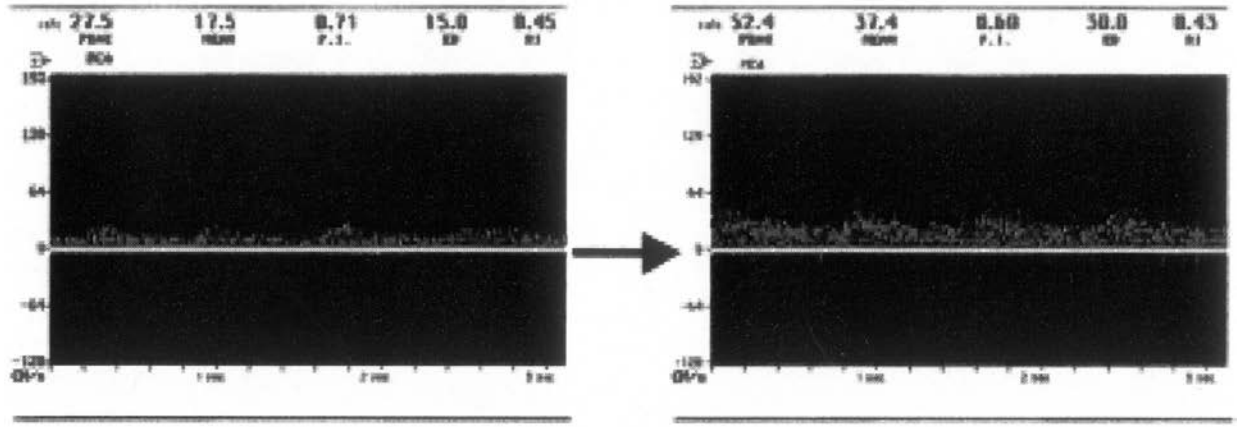

Fig. 81.8. Response to change in head of bed position. Transcranial Doppler images of the right middle cerebral artery. The image on the left shows the wave tracing with the head of bead at 70°. The patient has a moderate left leg paresis. The image on the right shows the response of lowering the head of bed to 0°. The patient had a complete recovery of leg paresis when the head of bed was lowered. (From Alexandrov et al., 2000, with permission.)

combined with thrombolytics and antiplatelet agents remain to be seen.

Aspirin

Aspirin given early in acute stroke was minimally beneficial in a combined analysis (Chen et al., 2000) of the Chinese Acute Stroke Trial (1997) and International Stroke Trial (1997). This trend suggested an overall decrease of further stroke or in-hospital death for 9 per 1000 acute stroke patients treated with aspirin versus placebo.

The mechanism of this benefit is uncertain. Besides preventing recurrent stroke, aspirin prevents hyperthermia, myocardial infarction, and potentially prevents deep venous thrombosis. The role of aspirin in combination with thrombolytics and the role of other antiplatelet agents in acute stroke still needs to be investigated. Aspirin, 81mg to 325 mg, can be recommended for all acute ischemic stroke patients who do not qualify for thrombolysis, and after 24 hours for those who receive rTPA. As there is reason to believe that aspirin could potentially extend an intracerebral hemorrhage, patients or emergency medical personnel should not use aspirin prior to appropriate neuroimaging.

Altering the ischemic cascade

Much attention has been given to the potentially salvageable ischemic penumbra. Neuroprotective strategies and agents have been the subject of multiple clinical trials. Although this concept remains promising, thus far no agents have shown benefit. This topic is covered in greater detail in Chapter 5.

Collateral flow

Along with neuroprotection, attempts to salvage the ischemic penumbra have often focused on collateral flow and 'miserly perfusion'. Miserly perfusion is a concept arising from positron emission tomographic imaging, simultaneously measuring cerebral blood flow and oxygen metabolism in ischemic brain regions (Baron et al., 1981). These studies demonstrated that ischemic brain parenchyma extracts the maximum oxygen available from the blood, much like a 'miser' would take the maximum resources available. The outlaying border zone regions of the ischemic penumbra may receive potentially nutritive perfusion via leptomeningeal collateral flow from adjacent vascular territories. By increasing the quantity and quality of collateral flow to the ischemic penumbra, there is the potential for 'reversing' miserly perfusion resulting in parenchymal rescue.

Multiple reports suggest that decreasing collateral flow is harmful. Since the capacity for autoregulation of cerebral blood flow in ischemic regions is diminished, cerebral perfusion is directly affected by changes in blood pressure. This is the basis for avoiding excessive lowering of blood pressure in the setting of acute stroke, either pharmacologically or by dehydration. Anecdotally, many patients show clinical improvement simply by lowering the head of the bed from upright to $<$30 degrees, presumably decreasing orthostatic hypotension and hypoperfusion (Fig. 81.8).

To date, no trial has conclusively proven that interventions to increase collateral flow are beneficial. The Hypervolemic Hemodilution Treatment of Acute Stroke Trial (1989) used pentastarch, a synthetic albumin-like oncontic agent, in acute stroke patients to increase intravascular volume, cardiac output, and presumably brain perfusion. Although no benefit was seen, a *post hoc* analysis suggested a significant benefit in those patients who received pentastarch and had a 10% increase in cardiac output when compared to those who received either placebo or pentastarch with a $<$10% increase in cardiac output. Conversely, congestive heart failure and low cardiac output is associated with poor outcome in stroke patients.

A particularly interesting approach to increasing perfusion of the ischemic penumbra is the use of transvenous retroperfusion (Frazee et al., 1990). Arterialized blood from the femoral arteries is delivered via a catheter system to the central venous sinuses. There, arterialized blood is perfused in a retrograde fashion to the compromised cortex, circumventing the arterial occlusion. Besides acting as a method to increase oxygenation, transvenous retroperfusion represents a unique method of drug delivery. Despite early encouraging results in a few patients, logistic issues have hindered further evaluation.

To maintain or improve collateral flow to penumbral regions in acute stroke patients, the following are recommended guidelines (Adams et al., 1994).

Excessive lowering of elevated blood pressure should be avoided. In general, the patients' usual antihypertensive agents (if any) should be held. Recommendations are that systolic pressures $\leq$200 mm Hg not be treated, unless there is evidence of end organ damage such as myocardial ischemia or aortic dissection, or the patient is a candidate for thrombolysis. In patients receiving rTPA, systolic and mean arterial pressures can safely be reduced to 180 and 130 mm Hg, respectively (Brott et al., 1998). If blood pressure is lowered, easily titrated drugs should be used, and pressures reduced gradually while monitoring the patient's neurological status. Dehydration, which is common in stroke patients (Grotta et al., 1985), should be avoided. Intravenous normal saline solution up to150 cm^3/h should be given over the first 24 hours after stroke. Patients with unstable blood pressure or fluctuating neurological exam should be kept at bedrest for 24 hours with the head of bed $<$30 degrees. Mobilization is then encouraged, with close monitoring for orthostasis. In some cases, blood pressure support with volume expanders or pressors might reverse clinical deterioration, particularly if mean arterial blood pressure has fallen below 100 mm Hg.

Preventing complications

Poststroke complications are common and can often be avoided. Through standardization of admission orders, a multidisciplinary approach to patient care, and, most importantly, skilled and experienced nursing care, outcome can be improved. This is the paradigm behind the Stroke Unit concept that is discussed below. The importance of monitoring, recognizing, and treating hypotension, hypovolemia, and decreased cardiac output is emphasized above

Nosocomial infections, particularly pneumonia from aspiration and urinary tract infections from indwelling catheters, are a common source of increased morbidity. Before feeding, patients should be screened for aspiration risk, and speech pathology should be consulted in all at-risk patients. Nurses should be trained in recognition of silent aspiration and should be empowered to initiate appropriate measures. We have found that dyspnea, with respiratory rates $>$22/minute is a sensitive early marker of aspiration pneumonia. A rapid and predefined urinary continence protocol should be developed to decrease the exposure to indwelling catheters.

Both hyperglycemia and hypoglycemia have been implicated as harmful to acute stroke patients, most likely through accentuating the ischemic cascade. Serum glucose should be measured on admission in all patients. Known diabetics or those with hyperglycemia should receive an aggressive blood glucose monitoring protocol. Though not proven by prospective studies, serum glucose levels above 150 mg/dl should be lowered pharmacologically. Glucose-containing intravenous solutions should be avoided to minimize iatrogenic hyperglycemia.

Hyperthermia has been shown to worsen outcome in both animal stroke models and human stroke patients (Ginsberg & Busto, 1998). Conversely, hypothermia is neuroprotective in experimental models and associated with better outcome in small case series (Schwab et al., 1998). All stroke patients' temperature should be closely monitored. Hyperthermia should be actively treated through a predefined algorithm with the goal of maintaining normothermia to mild hypothermia.

Any cardiopulmonary condition leading to hypoxemia is problematic in this population. Blood oxygenation should be monitored. Heparin 5000 i.u. b.i.d. is discussed above and should be used to prevent deep venous thrombosis (DVT). The importance of early and aggressive mobilization, and prevention of aspiration, should be emphasized to prevent both DVT and pneumonia.

Stroke units

Specialized geographical units caring only for stroke patients are beneficial in improving outcome, decreasing length of stay, decreasing complications, and decreasing overall mortality up to 10 years after discharge (Indredavik et al., 1999b). Other than i.v. rTPA and aspirin, Stroke Units are the only other proven beneficial intervention in acute stroke.

The benefit of a Stroke Unit seems to result mainly from skilled nurses and the intermediate level of care that they provide. A recent review suggested that the close monitoring and management of blood pressure and body temperature lead to the improved outcome seen in Stroke Units (Indredavik et al., 1999a). A multidisciplinary approach with other medical specialties, rehabilitation services, speech pathology, case management, social work services, and often pastoral services ensures rapid evaluation, fosters a positive attitude in patients and families, and facilitates discharge to appropriate levels of long-term care.

Given the large body of evidence that Stroke Units improve outcome and are more cost effective than general ward or Intensive Care Unit admission, Stroke Unit admission should become the standard of care for appropriate patients.

In conclusion, acute ischemic stroke is a treatable condition. Recovery is a time-dependent process, with a time window of 3–6 hours. Restoration of flow with thrombolysis is the most effective therapy and should become standard treatment for all appropriate patients. By maximizing collateral perfusion, admitting patients to a Stroke Unit, and actively preventing complications, outcome can be maximized.

The neurologist has a responsibility to work closely with emergency medical specialists to increase access to proven interventions. As the therapeutic era of stroke management progresses, the leadership of neurologists in the medical community will become even more important to reduce the significant burden caused by this illness.

Behavioural manifestations of stroke

Ricardo E. Jorge and Robert G. Robinson

Department of Psychiatry, The University of Iowa College of Medicine, Iowa City, IA, USA

Introduction

Recent studies have concluded that neuropsychiatric complications (i.e. emotional, behavioural, and cognitive disorders) may have a negative effect not only on the social functioning and overall quality of life of stroke survivors (King, 1996) but on the recovery of their motor functioning as well (Clark & Smith 1997). This chapter will discuss a number of these neuropsychiatric disorders (Table 82.1), including their effect on recovery and methods of treatment.

Poststroke depression (PSD)

Depression is among the most common neuropsychiatric disorders that occur after stroke. Despite its high frequency and negative influence on the overall recovery of stroke patients, a study by Schubert et al. (1992) reported that poststroke depression (PSD) was under-diagnosed by non-psychiatric physicians in 50% to 80% of cases.

Epidemiology

The frequency of PSD has been examined in numerous studies. The frequency depends upon whether patients are examined in hospital or in community surveys and whether they are studied during the acute poststroke period or many months following stroke (Table 82.2). In addition, the use of cutoff scores to define the existence of PSD, rather than structured interviews and diagnostic criteria have also contributed to reported differences in the prevalence rates of PSD.

The mean prevalence in hospitalized acute stroke patients was 22% for major depression and 17% for minor depression. In outpatient populations, the mean prevalences were 23% for major depression, and 35% for minor depression; while in community samples was 13% for major depression and 10% for minor depression. (Table 82.2)

Diagnosis

The diagnosis of PSD may be difficult or impossible in some groups of patients with stroke. For instance, the presence of language comprehension disorders and/or significant cognitive impairment may prohibit the reliable assessment of symptoms of depression (Gustafson et al, 1991).

While the DSM-IV (American Psychiatric Association, 1994) criteria for 'mood disorders due to a medical condition' are applicable for the diagnosis of PSD (Starkstein & Robinson, 1989), some investigators have suggested that several symptoms used by DSM-IV for the diagnosis of major depression, such as loss of energy and appetite, and insomnia, are also found among euthymic stroke patients secondary to hospital environment, the use of medications, other associated medical conditions or the stroke itself (Harrington & Salloway, 1997). In 1991, a study by Fedoroff et al. (1991) examined the frequency of depressive symptoms among both depressed and non-depressed patients with acute stroke. This study found that, with the exception of early morning awakening, all neurovegetative and psychological symptoms of depression were significantly more frequent among patients with depressed mood compared to patients without depressed mood. Even when the frequency of non-specific symptoms among the non-depressed was taken into account, the frequency of major depression decreased only 2%, from 23% to 21%.

Thus, although PSD cannot be reliably diagnosed in patients with severe comprehension impairments, the

Table 82.1. Neuropsychiatric disorders associated with stroke

Syndrome	Prevalence	Clinical features
Poststroke depression	35%	Depressed mood, appetite or weight loss, insomnia, social withdrawal
Mania	rare	Elevated mood, decreased sleep, flight of ideas, pressured speech, grandiosity
Bipolar disorder	rare	Alternating symptoms of depression and mania
Anxiety disorder	25%	Apprehensive expectation, restlessness, loss of energy, muscle tension
Apathy without depression	20%	Loss of interest and drives
Psychotic disorder	rare	Delusions and halluciations
Pathological affect	20%	Out of proportion emotional outbursts
Catastrophic reaction	20%	Burst of aggressive behaviour, anxiety, crying

Notes:

[a] Since minor depression was not included, these values may be low. PSE = present state examination; SADS = schedule for affective disorders and schizophrenia; RDC = research diagnostic criteria; CIDI = composite international diagnostic interview; HDRS = Hamilton depression rating scale.

Source: Robinson (1998).

DSM-IV diagnostic criteria for 'depression due to stroke with major depressive-like episode' are applicable to patients with PSD and the phenomenology of these depressions was found by Lipsey et al. (1986) to be similar to those found in elderly patients with primary depression. DSM-IV criteria for depression due to stroke with major depressive-like episode requires the presence of either depressed mood or loss of interest during 2 or more weeks following a stroke accompanied by at least four of the following symptoms: decreased or increased appetite or weight; insomnia or hypersomnia; psychomotor agitation or retardation; loss of energy; feelings of worthlessness or inappropriate guilt; loss of concentration; and recurrent suicidal ideation.

Minor depression is a DSM-IV research diagnosis which requires the presence of more than two, but less than five major depressive symptoms including either a depressed mood or loss of interest. Although it excludes depressions 'due to a general medical condition', we have used this diagnosis to identify stroke patients with milder (subsyndromal) forms of depression. Our studies have provided some validation for this diagnosis by identifying differences between major and minor depression in the frequency of past personal history of depression (Morris et al., 1992), the association with cognitive impairment (Downhill & Robinson, 1994) and association with lesion location (Paridiso & Robinson, 1999).

Although most authors have used these standardized criteria for the diagnosis of poststroke depression (Astrom et al., 1993a; House et al., 1990b; Morris et al., 1992; Eastwood et al., 1989), Gainotti et al. (1999), however, have disagreed with the comparability of poststroke depression with primary depression and the distinction of major and minor depression. Using their own Post-stroke Depression Rating Scale (PSDRS), these investigators found that 153 patients with stroke, compared to 30 patients with endogenous (primary) major depression, showed higher scores on catastrophic reactions and hyperemotionalism and were more likely to attribute their depression to handicap or disabilities, while endogenous depression patients were higher on suicide and anhedonia. Gainotti et al. (1999) also asserted that the failure to assess these aspects of depression (included in the PSDRS) demonstrated methodological errors in the assessment of depression by Robinson et al. The inclusion of catastrophic reactions, hyperemotionalism and patients' attribution of their depression to disability are clearly idiosyncratic criteria for the diagnosis of depression added to show differences with primary depression. Validation of a new form of depression should include predictable demonstration of the course of the disorder, specific clinical and pathological correlates, and response to treatment that are not found when the widely accepted and validated criteria for 'standard' depression are used. Furthermore, symptoms such as hyperemotionalism and catastrophic reactions are seen in patients with and without depression (see later sections of this chapter of these disorders) and are not specific to poststroke depression.

Duration

The duration of depression has been examined in several longitudinal studies. In a prospective study of mood disorders in 65 acute stroke patients (Robinson et al., 1987), we found that 9 patients (14%) had an in-hospital symptom cluster of major depression, while 12 patients (18%) had a symptom cluster of minor depression. All of the follow-up patients with major in-hospital depression were improved by 2 years, whereas only 3 patients (30%) with in-hospital minor depression recovered by this time.

Morris et al. (1990) found that the mean duration of poststroke major depression was 34 weeks, while the mean duration of minor depression was only 13 weeks. Aström et al. (1993b) also found that the majority of major depressions remitted by 1-year follow-up. Yet, 30% of patients with in-hospital major depression remained depressed at 1-year follow-up, 25% were depressed at 2-year follow-up, and 20% were still depressed at 3-year follow-up.

Thus, although the mean duration of major depression appears to be about 9 months, there are a significant number of patients with major or minor depression in-hospital who remain depressed for several years following stroke.

Anatomical correlates

Since the 1980s there has been a growing interest in finding a correlation between lesion location and PSD in order to delineate a pathophysiological hypothesis to explain this disorder.

In one of the earliest studies that examined the relationship between PSD and lesion location, we found that 14 of 22 patients with left hemisphere lesions suffered either major or minor depression while these disorders occurred in only 2 of 14 patients with right hemisphere lesions. We later compared 13 PSD patients with predominantly left-sided lesions to a group of stroke patients without depression matched for age, lesion size and location. We found that subcortical atrophy (as evidenced by increased ventricular: brain ratios) was associated with the presence of PSD (Starkstein et al., 1988). In yet a later study of 93 patients with right-sided lesions, both right frontal (i.e. 6 of

17 depressed patients and 1 of 25 non-depressed patients had a frontal lesion) and right parietal lesions (i.e. 11 of 17 depressed and 9 of 25 non-depressed had a parietal lesion) were associated with PSD (Starkstein et al., 1989).

Although some of these findings have been replicated by other authors (Aström et al., 1993a; Morris et al., 1996), numerous studies have not found lateralized effects (House et al., 1990b). We have recently shown that these laterality effects are present only during the acute stroke period, and many studies which examined patients several months or several years after stroke would not be expected to show laterality effects. Some studies done within the first few months poststroke have failed to show this laterality effect. For example, Gainotti et al. (1999) examined lesion location in 53 patients using MRI or CT scans. Among patients who were less than 2 months poststroke, only one of nine patients had major depression while three of seven with right anterior lesions had major depression. This failure to replicate findings was referred to by Gainotti as a 'factual error of Robinson et al.' (Gainotti et al., 1999) Negative findings happen all the time and failure to replicate is far from proving the null hypothesis (Gainotti proposes no clinical pathological correlation). Thus, this area of investigation and whether there is a strategic lesion location which leads to depression is still a matter of controversy.

Mechanism

While the cause of PSD remains unknown, we have hypothesized (Robinson & Starkstein, 1990) that the depletion of monoaminergic amines occurring after lesions in the frontal lobe or basal ganglia of the brain may play a role in PSD. Norepinephrine and serotonin nuclei send ascending projections from their location in the brainstem to the frontal cortex through the median forebrain bundle. These ascending axons then arc posteriorly running through the deep layers of the cortex where they arborize and send terminal projections into the superficial cortical layers.

Lesions of the frontal lobe or basal ganglia have been shown in animal models to disrupt these pathways (Robinson, 1998). Furthermore, we reported higher serotonin receptor binding in ipsilateral, non-injured, temporal, and parietal cortex of patients with right compared to left-sided lesions. Among patients with left hemisphere stroke, we found a significant correlation between severity of depression and the absence (i.e. decreased amount) of serotonin receptor binding (Mayberg et al., 1988). Disruptions of dopaminergic pathways ascending from ventral tegmental area have also been implicated in the pathogenesis of PSD (Herrmann et al., 1993).

Association between physical impairment and PSD:

Stroke survivors often suffer some degree of long-term impairment. The relationship between PSD and functional impairment is complex. The measurement of physical impairment usually involves both the neurological motor and sensory examinations and quantification of deficits in the performance of daily activities (ADL). In one of our earliest studies of PSD (Robinson et al., 1983), we found a significant correlation among 130 patients between the severity of depressive symptoms measured using the Zung depression scale, the HAM-D scale, or the PSE scale and the severity of impairment in ADL including the patient's ability to dress and feed themselves, walk, find their way around, express needs, read and write, keep their room in order, and to maintain sphincter control.

While most stroke patients experience some natural recovery of their neurological functioning and ability to perform activities of daily living, we have reported that, at 2 years follow-up, patients with major or minor depression after acute stroke were significantly more impaired in their ADL than comparably impaired patients without depression. Furthermore, a recent study found that 24 patients with major or minor PSD who had remission of depression were significantly more improved in their ADL scores than 35 comparably depressed patients who were not improved in their depression (Chemerinski et al., 2001). In addition, however, in-hospital impairment in ADL was found to correlate with severity of depression at both 3 and 6 months follow up (Robinson, 1998). These findings suggest that depression influences ADL recovery and that severity of ADL impairment influences the duration and severity of depression.

Association between cognitive impairment and PSD

Deficits in one or more domains of cognitive function are, along with motor impairment, the most common complications of stroke. We first reported a specific association between cognitive impairment and major PSD in 1986 (Robinson et al., 1986). In this study, 38 patients who had single infarcts in the left hemisphere, as documented by either CT scan or clinical history, were grouped according to whether they had major depression ($n=11$), minor depression ($n=10$), or no depression ($n=17$). Although there were no significant differences in terms of background characteristics and neurological findings among groups, patients with major depression had significantly more cognitive impairments measured with the Mini

Mental State Exam (MMSE) than minor depression or non-depressed patients (Folstein et al, 1975).

Using a comprehensive neuropsychological battery, we (Bolla-Wilson et al., 1989) subsequently found that patients with major depression and left-hemisphere infarcts had significantly greater deficits in tasks involving language, temporal orientation, executive motor, and frontal lobe functions than patients with comparable lesions but without depression.

Longitudinal studies of the course of cognitive impairment and PSD found that this association tended to decline with time. House et al. (1990a), for example, found that the high correlation between depression measured with the Beck depression inventory (BDI) and cognitive impairment that was seen in 76 patients at 1 month after stroke failed to reach significance at the 1-year follow-up. In a 2-year longitudinal study of 103 patients, we found that patients with in-hospital diagnosis of major depression following a left hemisphere stroke had significantly greater cognitive impairment at the in-hospital, 6-month ($P=0.03$) and 12-month ($P=0.02$) follow-up but no difference in cognitive function at 2-year follow-up (Downhill & Robinson, 1994).

Treatment

The widespread belief that depression is an understandable psychological reaction to the physical impairments of stroke, and the increased frequency and severity of side effects that psychotropic drugs (e.g. tricyclic antidepressants) might produce in this mostly advanced-age patient population, are factors that probably account for the reluctance by many physicians to use antidepressant medications in PSD.

There are currently at least four double-blind placebo-controlled studies which have examined the efficacy of antidepressant medication in PSD. The first controlled treatment trial of poststroke depression was conducted by our group and reported in 1984 (Lipsey et al., 1984). In this study, 39 patients with stroke who met the diagnostic criteria for major or minor depressive disorder were enrolled in a double-blind placebo-controlled study of the efficacy of nortriptyline among this population. Of the 39 patients entered in the study, five dropped out within 1 week. Of the 34 remaining patients, 14 received nortriptyline and 20 received placebo. Repeated-measures analysis of variance of depression scores and *post hoc* tests demonstrated that the nortriptyline group had significantly greater improvement than the placebo group at 4 and 6 weeks of treatment. All 11 patients who completed the course of nortriptyline treatment responded, while only 5 of the 15 placebo patients responded ($P=<0.001$).

In a controlled study by Reding et al. (1986), 7 PSD patients with an abnormal dexamethasone suppression test (DST) treated with trazodone had a significantly greater improvement in activities of daily living at 2–3 months following stroke measured with the Barthel ADL scale, compared to 9 comparable patients treated with placebo.

Andersen et al. (1994) assessed the efficacy and tolerability of the selective serotonin reuptake inhibitor antidepressant citalopram in a controlled study of 66 patients with stroke. The HAM-D and the Melancholia Scale (MES) scores were significantly better at both 3 and 6 weeks among patients who received citalopram compared to patients given placebo.

We have recently compared the efficacy of nortriptyline and fluoxetine in the treatment of depression and recovery following stroke in an entirely different socioeconomic population (Robinson et al., 2000). A total of 104 patients with acute stroke were randomized to receive either nortriptyline, fluoxetine or placebo over 12 weeks of treatment. Patients treated with nortriptyline (25 mg week 1, 50 mg week 2, 75 mg weeks 3–6 and 100 mg weeks 7–12) had a significantly greater decline in HDRS scores than either fluoxetine (10 mg weeks 1–3, 20 mg weeks 4–6, 30 mg weeks 7–9 and 40 mg weeks 10–12) or placebo-treated patients at 12 weeks of treatment ($F=3.73$, $df=2,53$, $P=<0.031$). (Fig. 82.1). There were no significant differences between fluoxetine and placebo. The successful treatment rate for nortriptyline was 77% for patients who completed the study while the successful treatment rate for fluoxetine was 14% (Fisher Exact Test, $P=<0.0018$). Thus, nortriptyline was superior to fluoxetine in treating poststroke depression. There was no effect of nortriptyline or fluoxetine on cognitive recovery as measured by Mini Mental State Examination (MMSE) scores or psycho-social outcome as measured by Social Functioning Examination (SFE) (Starr et al., 1983) scores. However, at 9 and 12 weeks, nortriptyline-treated patients showed significantly better activities of daily living functioning as measured by Functional Independence Measure (FIM) (Forer & Granger, 1987) scores than the fluoxetine treated patients.

Of the 104 patients enrolled in the study, 25 patients dropped out before completing the protocol (15 of the 40 patients receiving fluoxetine, 5 of the 31 patients receiving nortriptyline and 5 of 33 patients receiving placebo). The dropout rate was significantly greater in the fluoxetine than the nortriptyline or placebo group ($\chi^2=4.1$, $P=0.04$). Gastrointestinal side effects, insomnia and headache were more frequent in the fluoxetine-treated group. In addition, fluoxetine led to an average 14 pound weight loss over 12 weeks that was not seen with other treatments.

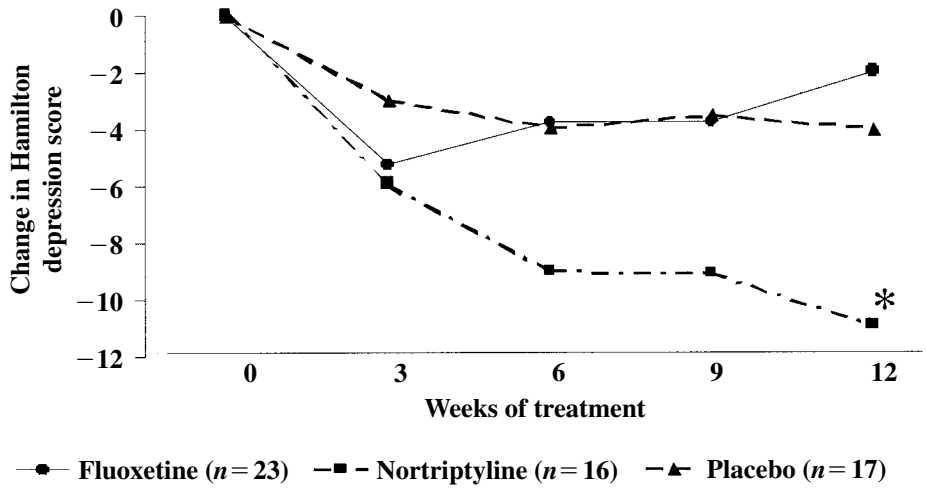

Fig. 82.1. Comparison of Hamilton Depression Rating Scale scores over 12 weeks of double blind treatment with nortriptyline, fluoxetine or placebo. Nortriptyline was superior to placebo or fluoxetine treatment. Fluoxetine was not significantly different from placebo in this population. Hamilton scores were significantly lower in the nortriptyline treated patients comparerd with the fluoxetine or placebo patients at 12 weeks of treatment (reprinted from Robinson et al., 2000 with permission).

There were no cardiovascular side effects attributable to treatment with nortriptyline, although patients with a recent myocardial infarction or cardiac conduction abnormalities were excluded from the study.

We have also studied the effect of antidepressants on the cognitive impairment associated with PSD. Patients whose depression remitted (predominantly associated with nortriptyline treatment) had significantly greater recovery in cognitive function than patients whose mood disorder did not remit (predominantly associated with placebo treatment) (Fig. 82.2) (Kimura et al., 2000). Thus, successful treatment of depression may constitute one of the major strategies of promoting cognitive recovery in victims of strokes.

Although other treatment modalities such as stimulant medication and electroconvulsive therapy have been used for PSD, they have not been evaluated in controlled studies, therefore most clinicians agree that antidepressant drugs constitute the first choice for the treatment of PSD. Since depressive symptoms have a negative influence on functional recovery, medication should be administered as soon as these symptoms are recognized in order to diminish the risk of long-term impairment.

Poststroke anxiety disorder

Epidemiology

A significant comorbidity exists between poststroke anxiety and PSD. In a study of 98 acute stroke patients, we (Starkstein et al. 1990) found that, while only 6 patients met modified DSM-III criteria for GAD (i.e. excluding the 6-month duration criteria) in the absence of any mood disorder, 23 of 47 patients with major depressioin also met criteria for GAD.

In another study (Castillo et al., 1995), we reported that 78 (27%) patients of a population of 288 stroke patients met the modified DSM-III criteria for GAD (i.e. excluding the 6-month duration criteria). Major or minor depression was also present in most of them (i.e. 58 of 78 GAD patients).

Similar results were reported by Aström (1996) in a 3-year longitudinal study of 80 patients with acute stroke. In this study, the prevalence of GAD in the acute stage was 28% with no significant decrease through the 3 years of follow-up. Criteria for major depression were met by 85% of those poststroke GAD patients at some time during the 3-year follow-up period.

Diagnosis

The DSM-IV categorizes poststroke generalized anxiety disorder (GAD) as 'anxiety disorder due to stroke with generalized anxiety'. The criteria for primary GAD requires the presence of sustained worrying state associated with at least three anxiety symptoms including restlessness, decreased energy, difficulties in concentration, irritability, muscle tension and sleep disturbance, for a period of at least 6 months. In order to study patients in the acute poststroke stage, most studies of poststroke GAD have not required the 6-month duration.

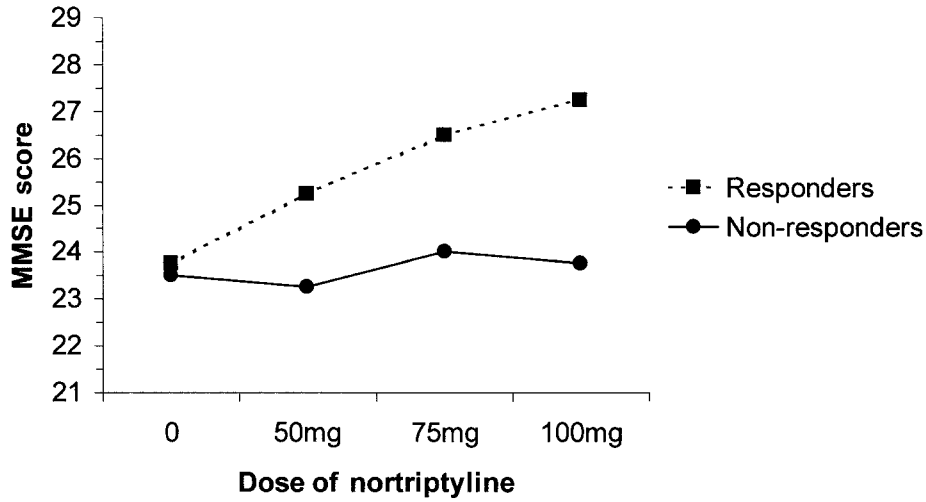

Fig. 82.2. Cognitive function as measured by the Mini-Mental State Exam (MMSE) at varying doses of nortriptyline. Patients who were treated with 75 or 100 mg of nortriptyline and responded to treatment had significantly higher (less impaired) MMSE scores than patients who were given nortriptyline or placebo and failed to respond to treatment. These findings indicate that successful treatment of poststroke major depression leads to significantly better recovery of cognitive function compared to patients who do not respond. (Reprinted from Kimura et al., 2000 with permission.)

Using our overall population of stroke patients, we examined the frequency of symptoms of GAD among patients who acknowledged the symptoms of anxiety or worry. With the exception of decreased energy, all the individual symptoms of GAD were significantly more frequent among patients with anxiety (Robinson, 1998). Thus, since anxiety symptoms are not associated with the stroke itself, poststroke generalized anxiety disorder can be diagnosed using DSM-IV symptom criteria.

Anatomical correlates

Our original population of 98 stroke patients were divided into those with anxiety only, those with anxiety plus depression, those with depression only, and those with no mood disorder (Starkstein et al., 1990). The examination of the CT scans of these patients showed that anxious–depressed patients had a significantly higher frequency of cortical lesions than did either the depression-only group or the control group (Fig. 82.3). Moreover, the depression-only group showed a significantly higher frequency of subcortical lesions than did the anxious–depressed group.

We subsequently reported in our overall group of 288 patients, that depression plus anxiety was associated with left cortical lesions, whereas anxiety alone was associated with right-hemisphere lesions (Castillo et al., 1995).

In the 3-year longitudinal study of stroke patients by Aström (1996), similar findings were reported. In the acute poststroke period, pure GAD was significantly associated with right hemispheric lesions, whereas comorbid anxiety/depression was significantly associated with left-hemipsheric lesions. Another important finding of this study was that, at 3 years after stroke, GAD was significantly associated with both cortical and subcortical atrophy. Aström suggested that this atrophy might play a role in the prolonged maintenance of GAD after stroke.

Risk factors and effect on recovery

Longitudinal studies of poststroke GAD have shown that functional recovery of patients with stroke was negatively affected by the presence of GAD. For example, in her 3-year longitudinal study, Aström (1996) found that ADL impairment was associated with GAD not only in the acute period but at all time periods after discharge from the hospital. Thus, anxiety was more than an immediate reaction to loss of function. In another study of 142 patients, we found that patients with GAD ($n=18$) and depression had significantly greater impairment in ADL at a 2-year follow-up than patients with PSD alone ($n=9$) (Shimoda & Robinson, 1998). We suggested that one possible explanation was that, as the comorbidity of PSD and GAD produced a longer duration of depression than PSD alone, this prolonged depression might lead to more profound adverse physical and social functioning outcomes.

Treatment

Benzodiazepines are the most commonly prescribed medications for the treatment of GAD but tend to accumulate

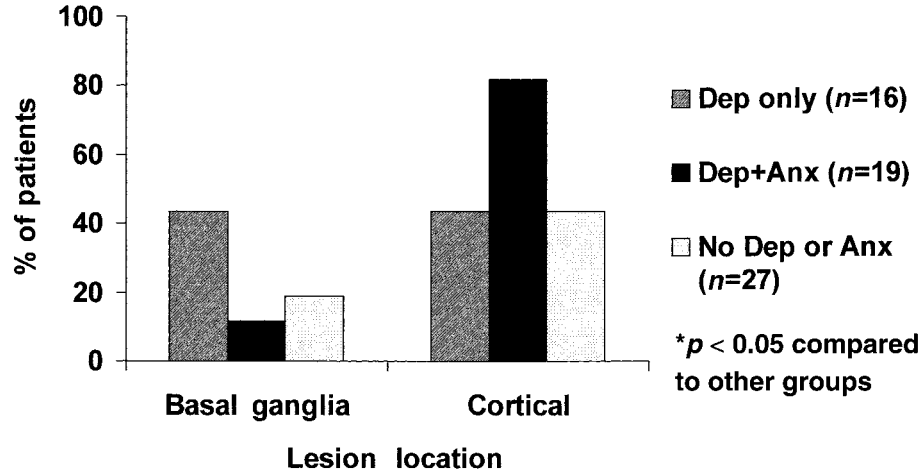

Fig. 82.3. Comparison of the frequency of basal ganglia and cortical lesions among patients with major depression only (Dep only), major depression plus generalized anxiety disorder (Dep + Anx), and no mood or anxiety disorder (No Dep or Anx). Major depression alone was associated with basal ganglia lesions while major depression plus generalized anxiety disorder was associated with cortical lesions. (Reprinted from Robinson, 1998 with permission.)

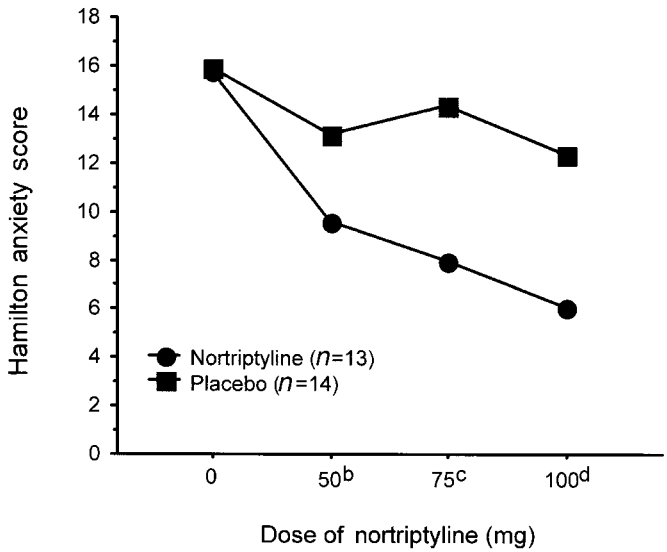

Fig. 82.4. Results of a double-blind study of poststroke anxiety disorder showing Hamilton anxiety score and corresponding dose of nortriptyline. At doses of 50 (*b*) ($P<0.05$), 75 (*c*) ($P=0.01$) and 100 (*d*) ($P=0.02$) mg, the patients who met criteria for both generalized anxiety disorder and post-stroke major or minor depression had significantly lower Ham-A scores than patients given placebo. (Reprinted from Kimura et al., 2000.)

in older people. Given the fact that stroke patients constitute an older population, benzodiazepines should be used as a time-limited treatment. Buspirone, an anxiolytic medication with partial serotonin agonist properties, has been reported (Rickels & Schweizer, 1987) to have a similar efficacy of diazepam in the treatment of GAD but with a more tolerable side effects profile. The utility of buspirone in this population has not been examined.

We have examined the efficacy of nortriptyline treatment for patients with comorbid GAD and depression after stroke (M. Kimura & R.G. Robinson, unpublished data). Patients receiving nortriptyline treatment ($n=13$) showed significantly greater improvement on their Hamilton anxiety symptoms than patients receiving placebo ($n=14$), demonstrating that poststroke GAD can be effectively treated with nortriptyline (Fig 82.4). In addition, the Hamilton anxiety score declined significantly more than the Hamilton depression score during the first 2 weeks of treatment, suggesting that the response of anxiety symptoms is both independent of depression and more rapid than the response of depressive symptoms in poststroke patients.

Other poststroke neuropsychiatric disorders

Apathy

Marin defined apathy as the absence or lack of feeling, emotion, interest, concern and motivation. He has pro-

posed diagnostic criteria for apathy based on the overt behavioural, cognitive and emotional concomitants of goal directed behaviour (Marin, 1991).

Few studies have examined the prevalence of apathy in stroke patients. Starkstein et al. (1993a) found apathy in 18 out of 80 patients (22%) with acute stroke lesions. In nine of these patients apathy coexisted with a depressive syndrome. Among depressed patients, apathy was significantly more frequent in those with major depression compared with those that have minor depression. This suggests that while depression and apathy can occur independently, apathy is significantly associated with major but not minor depression.

Marin et al., studied the prevalence of apathy among patients with chronic stroke lesions. Apathy was diagnosed in 7 out of 40 stroke patients (17.5%). There was no significant comorbidity with depression, suggesting that apathy and depression may be related early after stroke but not in the chronic stage (Marin et al., 1993).

In our experience, apathetic patients tend to be older and have a greater physical and cognitive impairment than stroke patients without apathy. In addition, Okada and associates found that most of their patients with mild dementia were also apathetic (Okada et al., 1997).

Several studies have examined the association between apathy and lesions in specific brain regions. Bogousslavsky et al. (1986) reported apathy in patients with bilateral lesions to ventrolateral and dorosmedial thalamic nucleus. Andersson et al found a higher frequency of apathy in patients with either subcortical or right hemisphere lesions compared with patients with left hemisphere damage (Andersson et al., 1999). Other studies have found a higher frequency of apathy in patients with lesions involving the posterior limb of the internal capsule and adjacent globus pallidus (Helgason et al., 1988). Cummings proposed that apathy in poststroke patients may result from dysfunction of cortico-subcortical circuits involving the prefrontal cortex, basal ganglia and thalamus (Cummings, 1993). To our knowledge, there have not been any controlled treatment studies of poststroke apathy.

Marin et al. (1995) suggested the use of dopamine agonists for patients with basal ganglia and frontal lobe lesions, whereas patients with multiple infarcts or with comorbid depression may obtain benefits from stimulant drugs or antidepressants with a more stimulant profile like bupropion.

Catastrophic reaction

In 1939, Goldstein first used the term 'catastrophic reaction' to describe a series of symptoms (i.e. anxiety, aggressiveness, refusal and renouncement) that may occur in patients with brain injury and appear to be due to the 'inability of the organism to cope with physical or cognitive deficits'.

Starkstein et al. (1993b) developed a scale (i.e. the Catastrophic Reaction Scale) for the assessment of the existence and severity of catastrophic reactions. Using this scale, we reported that a catastrophic reaction was present in 19% ($n=12$) of a consecutive series of 62 patients with acute stroke. Moreover, since catastrophic reactions were significantly associated with both major depression and basal ganglia lesions, we suggested that this phenomenon might represent the release of depressive emotions provoked by anterior subcortical damage.

The preferred treatment for the catastrophic reaction is prophylactic (Benson, 1979). Since this condition appears frequently in patients with non-fluent aphasia, speech therapists and physical therapists should be careful to not stress patients who are known to display catastrophic reactions.

Pathological affect

Pathological affect is characterized by frequent and easily provoked episodes of crying and/or laughing that are not appropriate to the situation or are in excess of the underlying emotion. Several studies (Andersen, 1995; Morris et al., 1993) have reported that approximately 15% of acute stroke patients manifest this condition. We (Robinson et al., 1993) demonstrated the reliability and validity of the Pathological Crying and Laughing Scale (PLACS) for the assessment of emotional lability in 54 patients with acute stroke. Furthermore, in a double-blind drug trial of nortriptyline versus placebo, patients receiving nortriptyline ($n=14$) showed a significantly greater decrease in PLACS scores (i.e. less pathological affective symptoms) at 4 to 6 weeks of treatment compared to patients receiving placebo ($n=14$) (Fig. 82.5). In another double-blind drug trial using a crossover design, Andersen et al. (1993) reported that all 13 patients treated with the selective serotonin reuptake inhibitor (SSRI) citalopram responded to treatment as measured by a reduction in the number of crying episodes by at least 50% as compared to two placebo responders. Although significant improvement in Hamilton depression scores were also seen in our treatment study, analysis of the data to exclude the effect of depression demonstrated that nortriptyline was an effective treatment for pathological emotions.

Poststroke psychosis

Delusions or hallucinations are rare complications of stroke. Rabins et al. (1991) screened all individuals ≥ 60

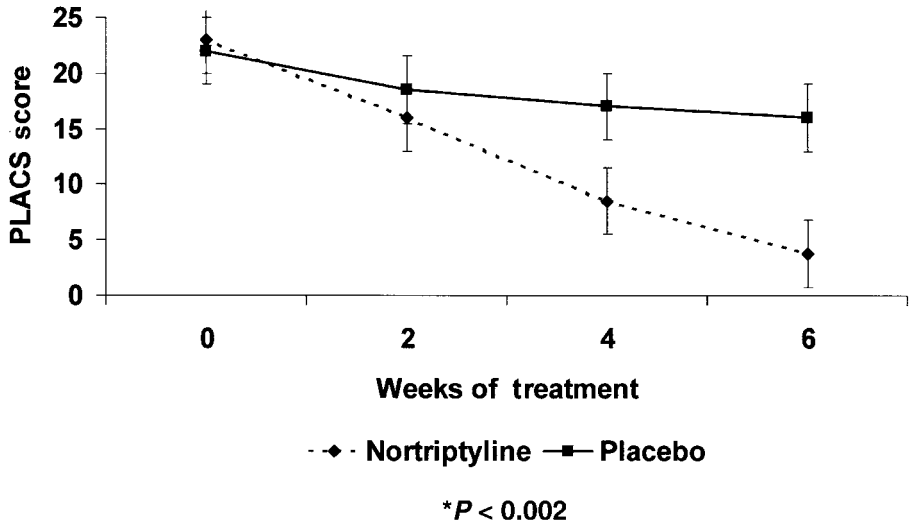

Fig. 82.5. Comparison of pathological laughter and crying scale (PLACS) scores over 6 weeks of double-blind treatment with nortriptyline or placebo. Nortriptyline produced significantly lower PLACS scores than placebo at both 4 and 6 weeks of treatment. (Reprinted from Robinson et al., 1993 with permission.)

years who were admitted to a hospital during a 9-year period and identified five patients with poststroke psychosis. All of them had right frontoparietal lesions and showed a significantly greater degree of subcortical atrophy compared to five stroke patients matched for age, gender and lesion size and location but without psychosis. Moreover, three of the five patients with poststroke psychosis had seizures while no seizures were seen in any of the five nonpsychotic patients.

Generally, patients respond to treatment with neuroleptic medications, although some treatment-resistant cases have been reported (Levin & Finkelstein, 1982). In treatment-resistant cases, anticonvulsant medications have been reported to be useful (Levin & Finkelstein, 1982).

In conclusion, there are numerous neuropsychiatric disorders which may occur following stroke (Table 82.1). The limited space for this review has restricted us to examining only a few of these disorders. Depression and anxiety disorder are two of the most common poststroke neuropsychiatric disorders and they frequently occur as comorbid conditions. In addition to producing a significant degree of psychological distress, both of these disorders have been shown to be associated with particular lesion locations and to adversely affect the physical recovery from stroke.

Similarly, apathy, catastrophic reactions, pathological effect and poststroke psychosis are disorders which may occur following stroke and probably influence the course of recovery as well as quality of life following stroke. Given the frequent occurrence of these disorders and the magnitude of the public health problem produced by stroke, it is remarkable how few treatment studies have been conducted. Apart from the early treatment interventions to prevent new vascular events, treatment of the neuropsychiatric disorders following stroke appears to have the greatest potential to improve the outcome and quality of life for people who have suffered a stroke.

Intracerebral hemorrhage

Juan R. Carhuapoma and Daniel F. Hanley

Department of Neurology, Johns Hospital, Baltimore, MD, USA

Approximately 500 000 new strokes occur yearly in the US. Fifteen per cent of these patients are diagnosed with intracerebral hemorrhage (ICH). Despite development of specialized stroke and neurological intensive care units, overall mortality of ICH patients remains high and patients who survive are often left with profound disabilities. However, new treatment avenues seem to be evolving for this disorder.

In addition to its use as thrombolytic therapy for myocardial infarction, the last 3 years have witnessed a more widespread use of rTPA for the treatment of acute ischemic stroke. Since blood pressure was controlled after rTPA or placebo administration during the NINDS Stroke with an improved rate of hemorrhagic complications in relation to other thrombolytic trials, it seems that uncontrolled hypertension may increase the risk of hemorrhagic transformation or hematoma formation in ischemic brain tissue after thrombolysis. For this reason, the American Heart Association and American Academy of Neurology have provided guidelines for blood pressure control when thrombolytic therapy is used in ischemic stroke victims (Guidelines for thrombolytic therapy, 1996). In this chapter, we will review the epidemiology, physiopathology, pertinent clinical features, complications and the available therapies for non-traumatic, supratentorial ICH as well as current and future avenues of research in this field.

Epidemiology

Spontaneous intracerebral hemorrhage comprises approximately 13% of all stroke types (Broderick et al., 1993). Although significant geographical variability in the incidence of ICH exists, Asian countries have a two- to threefold higher incidence of ICH. Whether the reason for this striking difference in incidence rate resides only in genetic factors is unclear, but environmental factors certainly play an important role. In the United States, ICH affects 37 000 persons annually and it has a 30-day mortality rate of 35 to 52%. Only 20% of ICH patients have some degree of functional independence at 6 months (Counsell et al., 1995). Some of the clearly defined risk factors include presence of systemic hypertension, alcohol consumption, hypercholesterolemia, use of anticoagulants, and recreational drug abuse. In the elderly, cerebral amyloid angiopathy (CAA) becomes a prevalent cause of ICH.

Since the 1950s, a consistent fall in mortality due to ICH has been documented worldwide (Broderick et al., 1993). Although better control of risk factors is partly responsible for this phenomenon, widespread advent of CT technology has also helped in the detection of smaller, non-lethal hematomas, thus reducing the apparent fatality rate of the disease. Nevertheless, ICH remains an important cause of morbidity and mortality among stroke victims.

Clinical features

The presence of intraparenchymal hematomas produces different neurologic syndromes in relation to their specific location. These syndromes have, however, high variability due to (i) secondary enlargement of the hematoma and (ii) development of surrounding white matter edema. Furthermore, when the mass effect associated with the hematoma, edema, or both, becomes significant enough to overcome intracranial compliance adaptability, the development of herniation syndromes may further complicate the clinical presentation of an individual patient. The presence of supratentorial ICH can lead to the development of one of the following syndromes according to their location and/or extension.

Putaminal hemorrhage

Several syndromes derive from putaminal hemorrhages (Hier et al., 1997). They can be defined based on their size, ventricular extension and patterns of extension from the putamen. The classic, large putaminal hemorrhage produces the syndrome of dense hemiparesis, hemisensory loss, homonymous hemianopsia, and aphasia or hemiinattention when present in the dominant or non-dominant hemisphere, respectively. These deficits, although abrupt in onset, tend to gradually worsen within the first hours after the stroke. Conjugate eye deviation towards the injured hemisphere can be seen when the frontal eye fields or their output are involved. Presence of intraventricular extension, once associated with poor functional and survival prognosis, is currently believed to be a surrogate marker of large putaminal hematomas.

Caudate hemorrhage

This form of hemorrhage represents 5 to 7% of cases of ICH and its clinical presentation is relatively constant (Stein et al., 1984). Headache of sudden onset followed by vomiting have been described. Nuchal rigidity and behavioural changes such as disorientation, confusion and short-term memory loss are common in patients with this type of hemorrhage. Sometimes horizontal and vertical conjugate gaze abnormalities are found. Intraventricular extension of the hemorrhage is an almost uniform occurrence. Acute obstructive hydrocephalus and meningismus are the result of obstruction of CSF circulation and chemical meningitis respectively. The outcome after caudate hemorrhage is favourable in the vast majority of cases, with only a small percentage of patients requiring external ventricular drainage.

Thalamic hemorrhage

This form of hemorrhage represents 10 to 15% of all cases of ICH. The onset of symptoms is usually abrupt as opposed to putaminal hemorrhages (Walshe et al., 1977). Headache is not a prominent symptom. Hemiparesis and hemisensory loss are uniformly found due to compression or extension of the hemorrhage into the internal capsule. A conspicuous finding on the physical exam is the presence of upward gaze palsy with miotic, unreactive pupils. This is likely the result of extension of the hemorrhage or edema in the mesencephalic tectum. The syndrome of 'wrong-way' eye deviation is sometimes observed after thalamic hematomas. The mechanism of this conjugate gaze deviation contralateral to the lesion remains obscure. Brainstem damage due to extension of the hematoma has been suggested. Nevertheless, oculocephalic and caloric testing can overcome this gaze abnormality, as in supratentorial horizontal gaze abnormalities. The lateral expansion of the hematoma or edema can produce aphasia or hemiinattention when this occurs in the dominant or non-dominant hemisphere, respectively.

Lobar hemorrhage

Lobar hemorrhages are more prevalent in temporal, parietal and occipital locations. This form of ICH does not commonly involve the frontal lobes. Systematic hypertension explains 35% of the lobar hemorrhages. Therefore, AVMs, tumours and CAA should be actively investigated in these patients as cause of the ICH. Headaches and seizures are common after lobar hematomas. The level of consciousness is usually not significantly impaired, likely because of the remote location of the intraparenchymal hematomas in relation to midline structures. The specific neurological deficits are dictated by the location and size of the hemorrhage.

Cerebellar hemorrhage

Most often seen in hypertensive patients, this form of hemorrhage constitutes a potential life-threatening emergency. The evolution of symptoms in these patients follows the described sequence outlined by Heros for posterior fossa mass lesions such as ischemic and hemorrhagic stroke (Heros, 1982). In early stages symptoms such as dizziness, vertigo, vomiting, unsteadiness, are related mainly to destruction of cerebellar tissue and its connections. During the intermediate stages, reduced level of consciousness can develop as a manifestation of obstructive hydrocephalus (due to either compression of the fourth ventricle or associated intraventricular hemorrhage). In later stages, direct compression of the brainstem by the expanding mass can induce coma and cardiorespiratory instability, as a manifestation of lower brainstem injury. Patients with cerebellar hemorrhages larger than 3 cm^3 and with evidence of neurological deterioration are deemed surgical candidates for hematoma evacuation (Broderick et al., 1999). Open suboccipital craniotomy with either paramedian or midline approach with clot evacuation is the standard procedure performed. The use of external ventricular drainage (EVD) can alleviate symptoms derived from hydrocephalus. However, the use of EVD only, in the presence of posterior fossa mass effect, is felt by many to increase the risk of upward cerebellar herniation and therefore to add further neurological damage.

Mechanisms of neurological damage

It seems widely accepted that the initial neurologic deficit after ICH is the product of tissue disruption by the sudden mass of blood, which can be associated with abrupt ICP elevation in cases of large hematomas. As mentioned previously, the presenting neurological syndrome depends fundamentally on the discrete location of the hematoma. However, the subsequent neurological deterioration will depend on a variety of factors, particularly ongoing bleeding and vasogenic edema formation. When combined, these two components can inflict significant mass effect and tissue distortion that, according to the location of the hematoma, could trigger herniation syndromes followed by death or subsequent permanent neurological damage. If the presence of mass effect is not significant or is well tolerated by the cranial vault, another threat, subsequent neuronal 'toxicity' or 'damage', has the potential to modify long-term neurological outcome due to its effects, not only on perihematoma regions, but also remote to it. Thus, the effects of the blood clot on remaining viable brain tissue can be divided into mechanical and biochemical.

Mechanical effects

The immediate effects of the hematoma on neurological function are directly related to the size of the blood clot and its location. If large enough, elevated ICP can induce global reduction in cerebral perfusion pressure and a superimposed global ischemic encephalopathy. Furthermore, several studies have demonstrated ongoing bleeding in ICH patients during the first hours after hemorrhage. Brott and coworkers showed that up to 38% of ICH patients develop enlargement of the hematoma within the first 20 hours of the ictus, and that this enlargement is associated with clinical deterioration (Brott et al., 1997). After reviewing their experience with 627 patients, Fujii and coworkers have shown that admission shortly after the onset of the stroke, heavy alcohol drinkers, irregularly shaped hematoma, decreased level of consciousness, and low levels of fibrinogen, were associated with hematoma enlargement (Fujii et al., 1994).

It is becoming more apparent that early blood pressure reduction does not induce a superimposed ischemic insult in perihematoma regions, since the presence of such a region of ischemic 'penumbra' has not been consistently demonstrated. Closer neurological and hemodynamic monitoring of these higher risk patients may therefore be warranted and blood pressure may perhaps be safely controlled during the early hours after the ictus.

A subject receiving renewed attention is the generation of cerebral edema after ICH. Although recognized for many years as a factor with potential to influence neurological deterioration, our knowledge of its pathophysiology and natural history remains incomplete. There is animal as well as human pathologic data confirming the presence of an intense inflammatory component characterized by the early presence of inflammatory cells surrounding the blood clot during the early hours after the ictus. This is paralleled by the disruption of the blood brain barrier in surrounding capillaries that allows the passage of coagulation proteins to the interstitium furthering the development of white matter edema. The presence of vasogenic edema superimposed on the hematoma mass can produce not only acute neurological deterioration but also delayed worsening as recently demonstrated (Zazulia et al., 1999). Development of perihematoma vasogenic edema is therefore a target at which current basic and clinical research is directed to reduce the risk of neurological worsening after ICH. Although there is no specific therapy directed towards preventing hematoma-induced edema formation, animal research seems to suggest (Xi et al., 1998; Altumbabic et al., 1998) that rapid evacuation of blood products either by surgical removal or infusion of a thrombolytic agent into the clot may prevent the development of this form of edema by reducing the exposure of brain tissue to thrombin and hemoglobin degradation products.

Biochemical effects

Recent interest has centred on secondary neuronal injury after ICH. Early animal models of ICH using inflatable balloons and collagenase injections showed evidence of an ischemic penumbra surrounding the hematoma. However, the more recent available evidence does not support the concept of neuronal ischemia as a predominant mechanism of secondary neuronal injury in this patient population. SPECT, PET, and MRI studies in ICH patients have failed to show cerebral ischemia in surrounding brain tissue (Carhuapoma et al., 2000; Diringer et al., 1998; Mayer et al., 1998; Qureshi et al., 1999). Evidence of decreased cerebral blood flow or blood volume cannot be interpreted as an indicator of ischemia in the absence of an associated reduction of cerebral metabolism (oxygen tissue extraction fraction in PET studies, or reduced diffusion coefficient for water on diffusion-weighted MRI). This is particularly true because non-ischemic forms of neuronal injury can also induce a coupled decrement in regional blood flow (Mayer et al., 1998; Miyasaka et al., 1998).

Lee and coworkers demonstrated that thrombin plays a central role in the development of vasogenic edema, and neuronal toxicity (Lee et al., 1996b) using a rodent ICH model (Lee et al., 1995, 1996b, 1997; Nishino et al., 1994;

Suidan et al., 1992; Vaughan et al., 1995; Zurn et al., 1998). These effects of thrombin appear attenuated after the simultaneous administration of specific thrombin inhibitors. Furthermore, as in other forms of brain injury such as ischemia, controlled pretreatment with thrombin can induce future tolerance to brain edema formation.

The effects of blood and specifically thrombin may not be limited to the induction of vasogenic edema. Since the 1990s, data has been collected that involves thrombin as a direct neurotoxin in several animal models of neuronal injury. In brief, animal studies revealed that injections of thrombin into brain tissue produces inflammatory cell infiltration, proliferation of mesenchymal cells, angiogenesis induction, reactive astrocytosis and spongiosis (Nishino et al., 1993).

Complications

Intraventricular hemorrhage

Extravasation of blood in the ventricular system from a dissecting intraparenchymal hematoma complicates 40% of spontaneous, hypertensive ICH (Naff & Tuhrim, 1997), and independently increases the morbidity and mortality associated with ICH (Tuhrim et al., 1998). Obstructive hydrocephalus resulting from blood in the ventricles is thought to induce an ischemic encephalopathy, however a recent report suggests that use of intraventricular catheters (IVC) to drain CSF has not modified the natural history of this condition (Adams & Diringer, 1998). Intraventricular administration of thrombolytic agents, specifically urokinase (UK) is being studied in some centres as an alternative to CSF drainage alone (Coplin et al., 1997; Findlay et al., 1991, 1993; Findlay & Wong, 1997; Mayfrank et al., 1997; Rohde et al., 1995; Todo et al., 1991). Based initially in animal models, and currently on clinical studies, evidence collected so far seems to suggest that use of intraventricular UK and rTPA may accelerate clot lysis (Findlay et al., 1991, 1993; Rohde et al., 1995; Todo et al., 1991; Pang et al., 1986a,b,c). More rapid clot lysis may reduce the risk of complications associated with prolonged CSF drainage (Kanter et al., 1985; Mayhall et al., 1984). Although the use of intraventricular thrombolytic drugs seems safe, careful monitoring is required since secondary hemorrhages have been reported (Schwartz et al., 1998b).

Vasogenic edema formation

The development of brain edema contributes significantly to subacute neurological deterioration after ICH. There is convincing evidence that thrombin plays an important role in the development of blood–brain barrier disruption and water accumulation in the interstitial space. More recently, Mun-Bryce and Rosenberg have provided evidence that serum metalloproteinases play a central role in the development of this form of edema (Mun-Bryce & Rosenberg, 1998; Rosenberg & Navratil, 1998). Once fully developed, edema volume sometimes exceeds hematoma volume itself, behaving as an additional mass lesion. There is no specific therapy directed to prevent hematoma-induced edema formation. However, animal research seems to suggest (Xi et al., 1998; Altumbabic et al., 1998) that rapid evacuation of blood products either by surgical removal or infusion of a thrombolytic agent into the clot may prevent the development of this form of edema by reducing exposure of brain tissue to thrombin and hemoglobin.

Diagnosis

The combination of appropriate epidemiologic background (e.g. hypertension, coagulopathy, etc.) and the form of onset and progression of the neurologic deficits (progressive rather than fluctuating or resolving) in combination with computerized tomographic (CT) imaging of the brain are required to make the diagnosis of ICH in the acute setting. Computerized tomography provides information about the location of the hemorrhage, its causal relationship to the patient's signs and symptoms and its relation to midline structures as well as the potential to progress towards brain herniation. The presence and extent of surrounding edema predominantly in white matter can also be identified on brain CT as a hypodense halo surrounding the hematoma. It has been observed that hematomas related to thrombolytic therapy for myocardial infarction or ischemic stroke have a conspicuous lack of surrounding edema, develop fluid levels in the core of the clot and tend to be multifocal (Gebel et al., 1998; The NINDS t-PA Stroke Study Group, 1997).

Acute MRI has shown to be very sensitive for the diagnosis of acute ICH based on paramagnetic properties of blood and its products. However, brain CT remains the gold standard for the diagnosis of ICH in the emergency room where patients with acute onset of neurologic deficits are first identified.

The diagnosis of underlying causes of ICH such as vascular malformations or tumours should include brain MRI with gadolinium. Follow-up studies after resolution of the blood and edema allow a better visualization of brain tissue and tissue abnormalities such as AVM malforma-

tions. Similarly, for stable young patients (<45 years) without risk factors for ICH, cerebral angiography should be considered to investigate the presence and define the anatomy and location of vascular malformations (AVMs, cerebral aneurysms, dural fistulas). New, non-invasive diagnostic modalities such as 3D magnetic resonance angiography and CT angiography are being currently tested to help in the non-invasive diagnosis of these patients. When the diagnosis of cerebral amyloid angiopathy (CAA) is entertained, gradient echo MRI can assess the presence of prior lobar petechial hemorrhages, which together with APOE $\varepsilon 2$ and $\varepsilon 4$ genotype testing can add further information towards the diagnosis of probable CAA in normotensive patients 60 years or older without other apparent cause for ICH (Greenberg et al., 1999).

Treatment

There is no disease-specific therapy for ICH to date. Several studies before and after the introduction of CT have been conducted in attempts to determine the best surgical indications for hematoma evacuation, and if one form of therapy is superior to another. However, no consensus has been reached thus far.

Medical

Medical therapy offered to this patient cohort is provided in a monitored setting when uncontrolled hypertension may increase the risk of recurrent bleeding or when vasogenic edema is present early. Although the acute control of blood pressure may contribute to a decreased risk of hemorrhage after administration of rTPA for acute ischemic stroke, as suggested by the rTPA NINDS Stroke Study Group, its contribution in primary, spontaneous ICH enlargement seems more controversial. Given the absence of consistent evidence of an ischemic penumbra, and the positive epidemologic evidence that poor blood pressure control is a risk factor for hematoma enlargement, it seems reasonable to recommend judicious early lowering of blood pressure (Tietjen et al., 1996). The use of beta-blocker agents (e.g. i.v. labetalol, esmolol) is recommended by the American Heart Association Guidelines for the treatment of ICH patients (Broderick et al., 1999) leaving direct vasodilator agents (e.g. i.v. nitroglycerine and sodium nitroprusside) as alternative drugs due to their potential to increase cerebral blood volume and intracranial pressure (Table 83.1). Hypotension of any cause, on the other hand, can produce reflex cerebral vasodilation, elevated CBV and further ICP elevations. Therefore, when it occurs, it should initially be treated aggressively with i.v. fluid administration and with vasoactive agents if required, with cerebral perfusion pressure (CPP) endpoint of 70 mmHg.

Table 83.1. Elevated blood pressure: recommended agents

Labetalol	5–100 mg/h by intermittent bolus doses of 10–40 mg or continuous drip (2–8 mg/min)
Esmolol	500 mg/kg as a load; maintenance use, 50–200 μg/kg min^{-1}
Nitroprusside	0.5–10μg/kg min^{-1}
Hydralazine	10–20 mg Q 4–6 h
Enalapril	0.625–1.2 mg Q 6 h as needed

Because psychomotor agitation, pain and incoordination with the ventilator (when airway artificial protection or ventilation are required) can increase ICP secondary to reduced venous return, sedation is often central to the care of ICH patients. Although concerns regarding clouding clinical neurological monitoring are valid, adequate choice of sedative agent as well as depth of sedation are crucial. Nevertheless, occasionally, ICP monitoring becomes necessary to tailor medical and/or surgical therapies.

The management of brain edema and elevated ICP in ICH patients can be approached using hyperventilation and mannitol in the acute stage. Mannitol, as well as other osmotic agents such as hypertonic saline solutions achieve serum osmolarity capable of promoting shift of free water from the interstitial to the intravascular space. Hypertonic saline, which has received recent attention as alternative therapy for brain edema in several clinical scenarios, should be administered with caution in this setting however, as a form of malignant cerebral edema can be associated with its use in ICH patients (Qureshi et al., 1998).

Surgical hematoma evacuation

Hankey and Hon in a recent meta-analysis did not find either medical or surgical therapies to be superior in the treatment of ICH (Hankey & Hon, 1997). However, the differences in diagnostic modalities available at the time when these studies were conducted, differences in level of medical care provided to these patients, and perhaps more important, differences in the level of involvement of the surgical team in the care of these patients limits this meta-analysis of treatment modalities for ICH. In an attempt to minimize this type of bias, the surgical evacuation of the

hematoma, as any other therapy modality available for a medical condition, should and currently is being investigated following the scientific method routinely applied in medical research to other forms of treatments. More recently, a single-centre randomized clinical trial comparing early surgical clot removal versus medical therapy in patients with ICH concluded that early surgery is feasible and that there seems to exist a modest improvement in early mortality (Zuccarello et al., 1999; Morgenstern et al., 1998). However, these results should be considered preliminary, as Hacke and coworkers have suggested that surgical therapy of ICH did not improve outcome at discharge in their cohort of patients (Schwartz et al., 1998a,b). In the US, the American Heart Association has developed concensus recommendations for the surgical treatment of ICH based on our limited current level of knowledge of the natural history of this disease and the effects of medical and surgical therapies on the outcome of these patients (Table 83.2).

Table 83.2. Recommendations for surgical treatment of ICH

Non-surgical candidates

1. Patients with small hemorrhages ($<10 cm^3$) or minimal neurological deficits (levels of evidence II through V, grade B recommendation).
2. Patients with a GCS Score <4 (levels of evidence II through V, grade B recommendation). However, patients with a GCS score <4 who have a cerebellar hemorrhage with brainstem compression may still be candidates for lifesaving surgery in certain clinical situations.

Surgical candidates

1. Patients with cerebellar hemorrhage >3 cm who are neurologically deteriorating or who have brainstem compression and hydrocephalus from ventricular obstruction should have surgical removal of the hemorrhage as soon as possible (levels of evidence III through V, grade C recommendation).
2. ICH associated with a structural lesion such as an aneurysm, arteriovenous malformation, or cavernous angioma may be removed if the patient has a chance for a good outcome and the structural vascular lesion is surgically accessible (levels of evidence III through V, grade C recommendation).
3. Young patients with a moderate or large lobar hemorrhage who are clinically deteriorating (levels of evidence II through V, grade B recommendation).

Best therapy unclear

1. All other patients.

Notes:

Level of evidence

- Level I: Data from randomized trials with low false-positive (α) and low false-negative (β) errors
- Level II: Data from randomized trials with high false-positive (α) or high false-negative (β) errors
- Level III: Data from non-randomized concurrent cohort studies
- Level IV: Data from non-randomized cohort studies using historical controls
- Level V: Data from anecdotal case series

Strength of recommendation

- Grade A: Supported by Level I evidence
- Grade B: Supported by Level II evidence
- Grade C: Supported by Levels III through V evidence

Use of thrombolytic agents

For a long time concepts such as blood and its degradation products inducing neuronal damage have been entertained as explanations of secondary neuronal damage. However, it is only recently that these concepts have been incorporated as the driving force behind attempts to remove blood from the subarachnoid space and brain parenchyma in intracranial hemorrhage patients. Hondo and coworkers reported their early experience with catheter evacuation of deep hematomas after lysis with a thrombolytic agent (Hondo, 1983). Using a stereotactically placed silicone catheter urokinase (UK) was administered and was followed by aspiration. Further UK was injected every 6 to 12 hours until the clot was totally removed. The hematoma, when treated in this manner, usually disappears 2 or 3 days postprocedure onset. More recently, Andrefsky and Montes independently reported on their experiences using UK in the treatment putaminal ICH patients and concluded that the administration of intraparenchymal thrombolytic agents is safe and able to significantly reduce hematoma size (Andrefsky et al., 1998; Montes et al., 2000).

When ICH extends into the ventricular system, several processes have potential to complicate the management and therefore outcome of these patients. Acute obstructive hydrocephalus, mechanical distention of midline and lateral ventricular structures, neurotoxic effects of blood on surrounding brain tissue and impairment of normal CSF resorption mechanisms impact upon neurologic function in the acute and subacute periods. Furthermore, standard treatment with external ventricular drainage has also the potential to damage viable brain tissue as well as become a source of CSF contamination and infection. The use of thrombolytic drugs administered directly into the ventricular system via intraventricular catheters has evolved from early animal models to more clinically sound evidence obtained from human data. Thus far, this form of therapy appears safe when appropriate patients are care-

fully screened and seems able to significantly reduce mortality after IVH.

If substantiated by larger and controlled prospective studies, these newly attempted therapies could improve upon the observed natural history of patients after ICH.

Prognosis

The role that the volume of blood has in outcome prediction after ICH has been clearly delineated in recent years. Tuhrim and coworkers, after developing an approach to estimate the chances of surviving after ICH, observed a direct correlation with the admission Glasgow Coma Score. ICH can occur in many cerebral locations and has many distinct sizes. However, despite well-known relationships between ICH locations and neurologic deficits, no clear relationship exists between ICH location and mortality. ICH volume does relate to mortality. There is an incremental, direct relationship of volume to mortality for ICH volumes greater than 30 cm^3, with an apparent threshold at 30 cm^3 at which level ICH mortality is a low frequency event (occurring at a rate of approximately 20%). Currently, all available data support the concept that mortality in small (<30 cm^3) ICH with IVH extension is in large part related to the extent or volume of IVH.

Current and future research areas in ICH

Treatment of ICH has remained mainly supportive throughout the years. It is only recently that basic and clinical research is being dedicated to the understanding of the natural history of secondary neuronal damage after human ICH. In particular, the following questions remain unanswered in this field:

What are the underlying mechanism(s) and natural history of ICH-induced brain edema?

Several lines of evidence are pointing towards inflammation and accompanying blood brain barrier disruption as the mechanism of perihematoma cerebral edema. Nevertheless, the actual trigger of the inflammatory cascade remains to be firmly identified. Thrombin and other blood components have been implicated; however, their precise role in this process is yet to be defined.

Although the rate of evolution of brain edema after ischemic stroke has been already delineated, its counterpart, brain edema after ICH, remains poorly defined. Clinical experience demonstrates that this type of edema progresses at a different rate and may reach sufficient magnitude to produce acute and subacute neurologic deterioration after ICH. If better understood, therapies aiming to arrest or decrease the intensity of brain edema may be able to be instituted at a time when the inflammatory cascade has not been irreversibly triggered.

What is the nature of the secondary neuronal injury induced by the contact of blood and brain tissue?

After years of basic and clinical research it has become apparent that cerebral ischemia in perihematoma regions does not add significantly to secondary neuronal damage after ICH. Inflammation and apoptosis may have a role in functional neurologic outcome in these patients due to their effects in perihematoma regions and perhaps in areas remote to the hematoma. Further knowledge will be required before rational criteria are used in the design of enrolment for future ICH clinical trials.

Aneurysms and arteriovenous malformations

Marcus A. Stoodley[1] and Bryce K.A. Weir[2]

[1] University of New South Wales, Institute of Neurological Sciences, Prince of Wales Hospital, Randwick, NSW, Australia
[2] Pritzker School of Medicine, University of Chicago, Chief, Section of Neurosurgery, University of Chicago Medical Center, Chicago, IL, USA

Intracranial aneurysms and arteriovenous malformations (AVMs) are structural vascular lesions that are life threatening by virtue of their propensity to cause intracranial hemorrhage. The Greek word 'aneurysma' is derived from a combination of 'ana-' (up, through) and 'eurynein' (to widen) (Haubrich, 1984). Peripheral aneurysms were well recognized by Hippocratic times, when physicians were familiar with superficial traumatic vascular lesions (Weir, 1987). The first description of an intracranial aneurysm was probably by Biumi, in 1765 (Biumi, 1778) and the first clinical description differentiating subarachnoid hemorrhage (SAH) from other types of apoplexy was in 1813 (Blackall, 1825). Various surgical attempts were made to treat intracranial aneurysms in the late nineteenth and early twentieth centuries, including proximal ligation by Horsley and others and packing with muscle by Dott (1933), before the first definitive cure by clip application, which was performed by Dandy in 1937 (Dandy, 1938).

Cerebral arteriovenous malformations (AVMs) are some of the more challenging lesions to come under the ambit of neurological surgery. Regarding surgery for AVMs, Cushing considered any attempt at excision 'foolhardy' (Cushing & Bailey, 1928) and Northfield stated, 'The dangers of fatal hemorrhage and the extensive damage to brain forbid any attempt' (Northfield, 1940). It was not until the mid-twentieth century that these lesions were recognized as malformations rather than neoplasms. With the advent of arteriography and its widespread use by the 1940s and 1950s, an understanding of the configuration of feeding arteries and draining veins of AVMs emerged, along with more favourable surgical results (Bergstrand et al., 1936; Olivecrona & Riives, 1948; Pilcher, 1946).

Clinical presentation

Spontaneous disruption of the abnormal walls of AVMs and aneurysms results in intracranial hemorrhage with obvious catastrophic consequences. Most aneurysms and AVMs are not detected until such a rupture occurs. A minority of lesions will come to clinical attention because they cause mass effect on cranial nerves or the brain, obstruction of cerebrospinal fluid pathways, or epilepsy. Aneurysms occasionally present with ischemic deficits caused by thromboemboli originating from the aneurysm sac. Investigation of neurological symptoms with high resolution CT or MRI is leading to an increase in the incidental detection of vascular abnormalities.

The hallmark of intracranial hemorrhage of any cause is the instantaneous onset of headache of unparalleled severity. The clinical features of aneurysmal and AVM hemorrhage differ somewhat by virtue of the location and severity of the bleed. Aneurysms are located in the subarachnoid space and most hemorrhages are therefore subarachnoid or intraventricular. Occasionally the hemorrhage is purely intraparenchymal or subdural. Over 90% of aneurysms present with rupture and approximately 15% of these patients die before reaching hospital (Weir, 1987). Up to 80% of patients have at least a brief loss of consciousness (Rodman & Awad, 1993). Additional clinical features include meningism and vomiting. It is distinctly unusual for patients suffering a SAH, who remain conscious, to *not* vomit (Shaw, 1987). Cranial nerve dysfunction, particularly of the oculomotor, is caused by direct pressure of an aneurysm on the nerve during its subarachnoid course. The majority of aneurysmal ruptures do not cause significant intraparenchymal hemorrhage, so focal neurological deficits other than cranial neuropathies are uncommon. Rupture of a middle cerebral artery aneurysm is an exception; hematomas within the Sylvian fissure

often cause hemiparesis or dysphasia. Intraocular hemorrhage, thought to result from an acute elevation of intracranial pressure transmitted to ocular venous pressure, is more common with severe SAH and correlates with poor outcome (Weir, 1987). Arterial hypertension is a common finding, even in patients without a corresponding history. Electrocardiographic changes, notably ST segment depression, are also common and probably result from release of catecholamines and blood pressure disturbance (Rodman & Awad, 1993). Clinical SAH grading scales have been designed in an attempt to predict outcome (Table 84.1); the worst pre-treatment grade appears to be the best predictor of outcome (Chiang et al., 2000). SAH is frequently preceded by a 'warning' headache that is not caused by rupture (Rodman & Awad, 1993).

Haemorrhage is also the most common presentation of an AVM, occurring in approximately 50–60% of cases (Brock, 1999). Although associated with a mortality of 10–30%, AVM rupture is generally less severe than aneurysmal SAH (Brown, 1999). It is unusual for AVMs to present with pure SAH and clinical features identical to aneurysmal rupture. More commonly the hemorrhage remains intraparenchymal, so that meningism, vomiting, and cranial neuropathies are less common and focal neurological deficits are more likely. AVMs can present with epilepsy (20–40% of cases) (Brock, 1999) or as a mass lesion. The arteriovenous fistula in some lesions is sufficient to cause a low pressure shunt and steal of blood from the surrounding vascular bed, causing chronic ischemic deficits or intermittent focal deficits clinically similar to embolic transient ischemic attacks. Unusual presentations include a bruit, palpable enlarged scalp vessels and heart failure in children. It remains unclear whether migraine headaches are more frequent in patients with AVMs, but such headache is often relieved when the malformation is treated (Steinberg et al., 1990). Spinal vascular malformations present with hemorrhage or the effects of raised venous pressure, which causes a progressive deterioration in lower limb function (Henn et al., 1999).

Aneurysms

Classification

Cerebral aneurysms are classified by pathology (Fig. 84.1), size and location. S*accular* aneurysms are focal outpouchings of the vascular wall that usually occur at arterial branching points. Aneurysm walls do not have an internal elastic lamina, the media contains fibrohyaline tissue and little smooth muscle, and the adventitia is thinner than in normal arteries. There may be luminal thrombus, calcification, and fatty or atherosclerotic plaques (Weir, 1987). *Fusiform* aneurysms, usually a result of atherosclerosis and therefore occurring in older age groups, are dilated and elongated arterial segments. In contrast to saccular aneurysms, the dilatation is circumferential so there is no neck, or orifice, between the vessel and the aneurysm. The internal elastic lamina and media are deficient and atherosclerotic changes are usually prominent. Laminated luminal thrombus is common. Fusiform aneurysms also occur in young patients with diseases affecting the arterial wall such as Marfan's syndrome, homocysteinuria, pseudoxanthoma elasticum, syphilis, and giant cell arteritis (Weir, 1987). Dissecting aneurysms result from an intimal tear and separation of the mural layers by blood that forms a new false channel. The new channel can rupture back into the original lumen or through the adventitia to cause subarachnoid hemorrhage. The original lumen is narrowed irregularly and the angiographic appearances can be of a tapering stenosis (Fig. 84.2), narrow residual lumen (string sign), dilatations, or combinations of dilatations and narrowing (pearl and string sign). Etiological factors include trauma, atherosclerosis, fibromuscular dysplasia, and diseases affecting the arterial media. False aneurysms contain none of the normal layers of the arterial wall. The very fragile aneurysm 'wall' in these cases is composed of thrombus and surrounding connective tissue. Trauma is the usual cause and there is a high risk of rupture. Infectious aneurysms are usually bacterial and occasionally fungal (the term 'mycotic' should be applied only to the latter). Endocarditis is the usual source of emboli that may cause abscesses in addition to aneurysms. Infection of the arterial wall affects predominantly the intima and media, with necrosis of the wall and fusiform dilatation of the vessel. These aneurysms are very fragile and have a high rupture rate. Most of the following discussion relates to saccular aneurysms, which are the most common cause of non-traumatic subarachnoid hemorrhage.

Intracranial aneurysms are classified anatomically as those affecting the internal carotid artery and its branches ('anterior circulation') or those affecting the vertebral and basilar arteries and their branches ('posterior circulation'). Non-saccular aneurysms are classified according to the vessel involved whereas the nomenclature of saccular aneurysms relates to the branch at which the aneurysm occurs (for example, an aneurysm of the internal carotid artery at the origin of the posterior communicating artery is classified as a posterior communicating artery aneurysm).

Saccular aneurysms are categorized as small (<10 mm diameter), large (10 mm–25 mm), and giant (>25 mm).

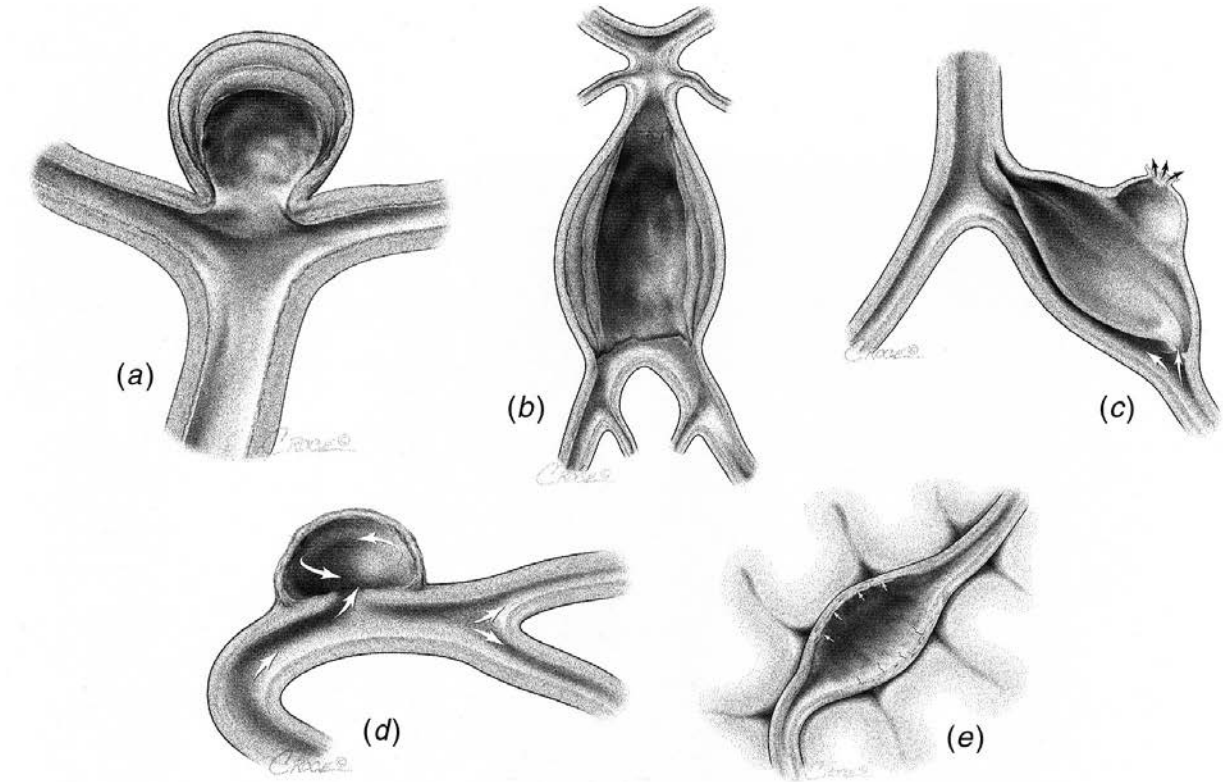

Fig. 84.1. Pathological classification of cerebral aneurysms. The most common aneurysm encountered in clinical practice is of the saccular type (*a*). Other lesions included in the general category of aneurysms include fusiform (*b*), dissecting (*c*), false (*d*), and infectious (*e*).

Epidemiology

Aneurysms affect all racial groups and are found at postmortem in 1–3% of autopsies and incidentally in 2.7% of patients undergoing angiography. The incidence of subarachnoid hemorrhage is approximately 10 per 100 000 population per year; there appears to be a slightly higher incidence in Finland and Japan (Weir, 1987). Men are more frequently affected than women until about the fifth decade, beyond which women predominate. Proximal internal carotid artery aneurysms are more common in women whereas anterior communicating artery aneurysms are more frequent in men. The internal carotid bifurcation and the basilar artery are sites of predilection in children. The average age of patients suffering SAH is approximately 50 years and the incidence of SAH increases with age. In familial cases the average age at the time of SAH is approximately 10 years younger than in other patients. Middle cerebral artery aneurysms are more common in familial cases. Diseases associated with aneurysms include coarctation of the aorta, polycystic kidney disease, fibromuscular dysplasia, moyamoya disease, sickle cell disease, and arteriovenous malformations. Cigarette smoking predisposes to aneurysm formation and rupture.

Risk of rupture and natural history

Based on a prevalence of unruptured aneurysms of 0.5% and an annual incidence of SAH of 10 per 100 000 per year, there might be a 2% annual rupture risk for previously unruptured aneurysms (Weir, 1987). This rate is supported by several clinical studies, but it is unlikely that a nonselective prospective trial will ever determine the true rate (Asari & Ohmoto, 1993; Juvela et al., 1998). Some authors have argued that small aneurysms are unlikely to rupture (International Study, 1998; Wiebers et al., 1987). This is difficult to reconcile with the fact that the majority of ruptured aneurysms are small and the absence of evidence that aneurysms shrink after rupture (Weir, 1987). Unruptured giant aneurysms carry a particularly poor prognosis, with a 5-year survival rate of less than 50%.

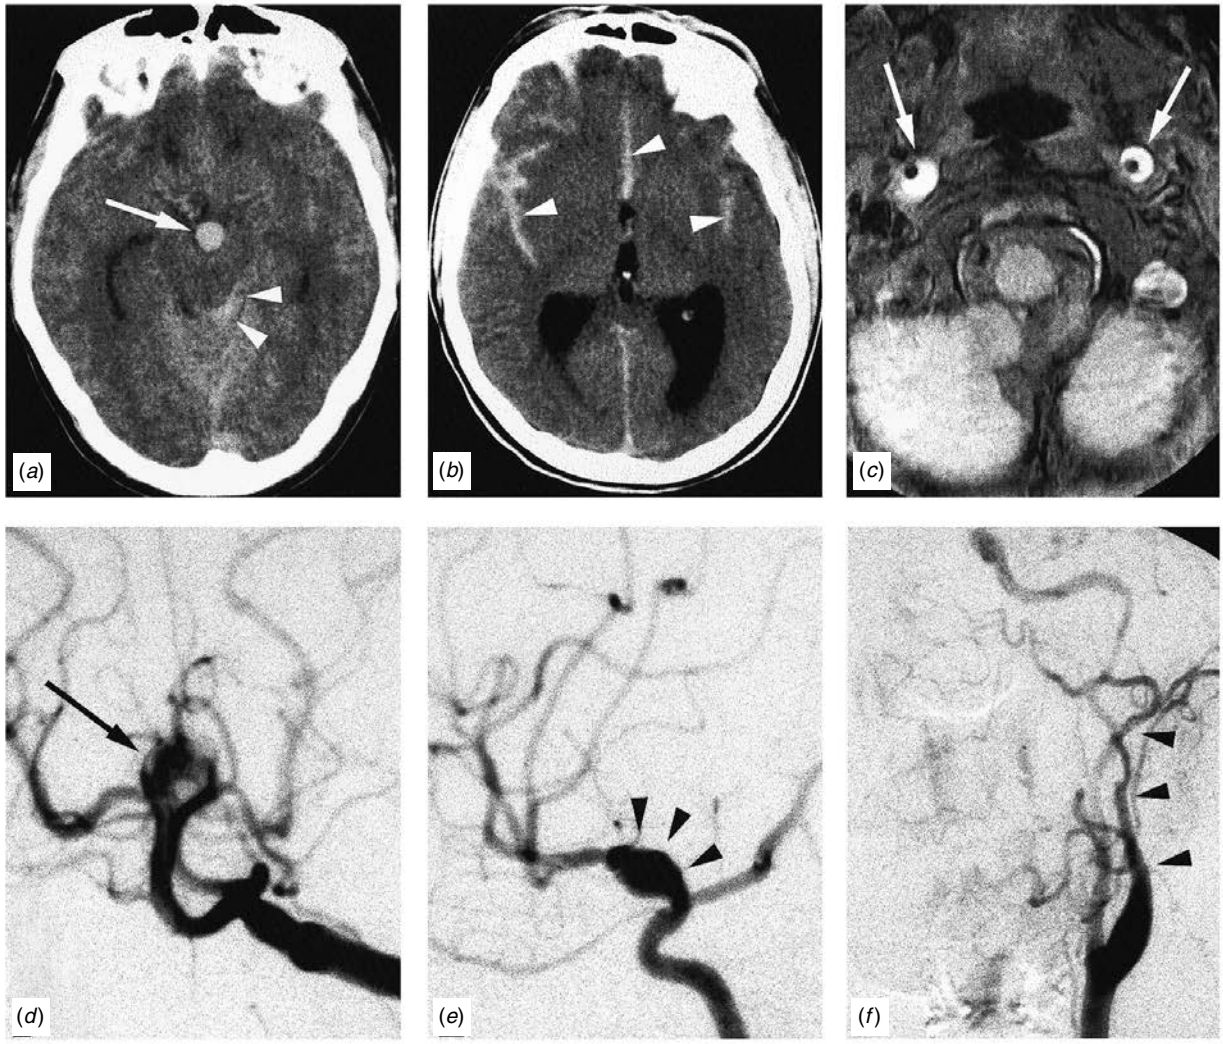

Fig. 84.2. Imaging studies of aneurysms. (*a*) CT scan demonstrating thrombus within a basilar bifurcation saccular aneurysm (arrow) and subarachnoid blood in the left ambient cistern (arrowheads). (*b*) CT demonstrating diffuse subarachnoid hemorrhage from a ruptured mycotic aneurysm with blood in the Sylvian fissures and interhemispheric fissure (arrowheads). (*c*) Bilateral dissecting aneurysms of the cervical internal carotid arteries (arrows). In this axial MR scan, the normal hypointense flow void of each carotid artery is surrounded by the hyperintensity of fresh blood within the wall of the vessel. (*d*) Vertebral angiogram demonstrating a basilar bifurcation saccular aneurysm (arrow) (same case as (*a*)). (*e*) Right internal carotid angiogram demonstrating a mycotic aneurysm of the right intracranial internal carotid artery (arrowheads). There is fusiform enlargement of the artery beyond the posterior communicating artery origin to the carotid bifurcation (same case as (*b*)). (*f*) left internal carotid angiogram revealing a carotid artery dissecting aneurysm, with irregular narrowing of the internal carotid artery beyond the common carotid bifurcation (arrowheads) (same case as (*c*)).

Posterior circulation location and morphological features such as daughter loculi are probably associated with an increased risk of rupture, although this has not been proven.

The natural history of aneurysmal rupture is poor. Approximately 10–20% of patients die immediately after rupture and are not admitted to hospital. The outcome of patients who survive the initial hemorrhage correlates with clinical grade (Table 84.1). Adverse prognostic features include a history of hypertension, smoking, or cocaine use and CT evidence of thick subarachnoid clot, midline shift, intracerebral hemorrhage, or intraventricular hemorrhage. Patients with posterior circulation aneurysms fare worse than their counterparts with anterior circulation

Table 84.1. Clinical grading scales and mortality for patients suffering subarachnoid hemorrhage.

Grade	Hunt and Hess (1968)	World Federation of Neurosurgical Societies (1988)	Approximate mortality (%)
I	Asymptomatic, or minimal headache and slight neck stiffness	GCS 15, no motor deficit	10
II	Moderate to severe headache, no neurological deficit (except cranial nerve palsy)	GCS 13–14, no motor deficit	15
III	Drowsy, confusion, or mild focal deficit	GCS 13–14, motor deficit	20
IV	Stupor, moderate to severe hemiparesis, early decerebrate rigidity and vegetative disturbances	GCS 7–12	40
V	Deep coma, decerebrate rigidity, moribund	GCS 3–6	70

Table 84.2. Correlation between subarachnoid blood assessed with CT scan and risk of vasospasm.

Fisher grade	Blood	Risk of vasospasm
1	Not detectable on CT	Low
2	Diffuse subarachnoid blood with all vertical layers <1 mm thick	Low
3	Localized clots and/or vertical layers of blood ≥ 1 mm thick	High
4	Intracerebral or intraventricular clot with diffuse or no subarachnoid blood	Low

Source: From Fisher et al. (1980).

lesions. Without treatment, the overall mortality from an initial aneurysmal rupture is approximately 50% at 30 days (Le Roux & Winn, 1998; Pakarinen, 1967). The major causes of morbidity and mortality after the initial hemorrhage are rebleeding and vasospasm. Untreated, 50% of patients will suffer a repeat hemorrhage within 6 months. The risk is probably highest within the first few hours, is 25% within 2 weeks, and gradually diminishes thereafter. If a patient survives to 6 months and remains untreated, the annual risk of rupture remains slightly higher than with unruptured aneurysms. Rebleeding has a 70–80% mortality rate. The onset of vasospasm is 3–4 days after the SAH, with a peak severity at 7–10 days. Angiography during this time will demonstrate arterial narrowing in approximately two-thirds of patients and half of these will have symptomatic ischemic deficits. Long-term morbidity from vasospasm occurs in 10–15% of patients and approximately 5% of patients die from vasospasm alone. The effects of vasospasm are more severe in poor grade patients and those with thick subarachnoid blood (Table 84.2) (Weir, 1987).

Investigation and diagnosis

Current generation CT scans have a greater than 95% sensitivity in detecting SAH if the scan is performed on the day of hemorrhage (Fig. 84.2). There is a gradual reduction in sensitivity with time so that by day three a CT will be positive in only 70–80% of cases and in 50% after 1 week. The pattern of blood on CT scan is helpful in determining the location of an aneurysm and in the case of blood confined to perimesencephalic cisterns, can predict a non-aneurysmal cause for the hemorrhage. CT will also detect intraparenchymal and intraventricular hemorrhage, the amount of subarachnoid blood (and hence the risk of vasospasm), and hydrocephalus. MRI is generally not helpful in assessment of acute SAH, but can detect blood in cases where the presentation is delayed and CT is negative.

Lumbar puncture is reserved for those cases where a clinical suspicion of SAH is not confirmed on CT. Hemorrhage caused by the lumbar puncture itself cannot reliably be differentiated from SAH by examining serial specimens from the same tap. Red cells begin lysing within a few hours after SAH so in most cases the supernatant will be xanthochromic to the eye, although it is detected definitively by spectrophotometry. Lumbar puncture is contraindicated in the presence of an intracranial mass lesion, so that at a minimum it should be preceded by fundoscopic examination and a CT scan if it is available.

Detection of a structural vascular cause for SAH is most effectively done with digital subtraction catheter angiography (Fig. 84.2). MR and CT angiography have not yet reached the sensitivity required for detection of small aneurysms. In addition, catheter angiography provides important dynamic information such as collateral and

dominant flow that is not available with other techniques. The risks of modern catheter angiography are extremely low. We therefore have a low threshold for investigating patients where there is a clinical suspicion of a ruptured aneurysm because the consequences of failing to make the diagnosis are potentially disastrous. When SAH has been proven and angiography is initially negative, a delayed repeat study is warranted unless the pattern of SAH is of the benign perimesencephalic type. We also carry out MR angiography and MRI to exclude a freshly thrombosed aneurysm if initial angiography is negative.

Medical management

Initial management of patients with SAH depends on the consciousness level and hemodynamic status. For poor grade patients, priorities in the emergency department are ventilation and oxygenation, hemodynamic stabilization, and control of raised intracranial pressure (Le Roux & Winn, 1998). Stabilization in the emergency department should occur even before the diagnosis is established. Poor grade patients are sedated and ventilated and have the intracranial pressure monitored. Patients who are alert at presentation are kept resting in bed with close neurological monitoring. Avoidance of hypo- or hypertension is critical. Hypertension is exacerbated by pain, which is difficult to control without sedation. An adequate level of analgesia is achieved with morphine. Other pharmacological measures are used as required to control blood pressure; we prefer sodium nitroprusside initially. Maintenance of normal serum sodium and blood volume is important to avoid delayed ischemic deficits. A central line is sometimes used to guide fluid management; dehydration must be strictly avoided. Hyponatremia is especially common after rupture of anterior communicating artery aneurysms and associated hypothalamic dysfunction. Prophylactic anticonvulsants are given only for younger patients with ruptured middle cerebral artery aneurysms and intracerebral hematomas, who are at high risk of seizures.

The mortality and morbidity associated with vasospasm are reduced with the prophylactic administration of the calcium channel blocker nimodipine. The mechanism of action is probably small vessel dilatation or a neuroprotective effect, rather than preventing narrowing of large basal arteries (Le Roux & Winn, 1998). Therapy for established vasospasm includes elevating cerebral perfusion pressure and increasing blood volume. Some authors advocate endovascular therapy such as angioplasty or intra-arterial infusions of papaverine immediately that neurological deficits develop (Eskridge et al., 1998). We have tended to reserve these invasive interventions for those cases that do not respond to fluid and blood pressure management. Intrathecal thrombolytic therapy after aneurysm clipping in highly selected cases probably reduces the incidence of vasospasm (Findlay et al., 1995).

Surgical and endovascular management

Impaired conscious state in many poor grade patients is predominantly a result of hydrocephalus. Judicious ventricular drainage in such patients is valuable in treating intracranial hypertension, although drainage does increase the transmural pressure and slightly increases the risk of rebleeding until the aneurysm is obliterated. We generally keep the opening pressure of such drains at 15–20 cm H_2O to minimize this risk, while avoiding further ischemic deficits from insufficient cerebral perfusion pressure. Raised intracranial pressure from an intracerebral hematoma is an indication for urgent surgery; the aneurysm should be clipped at the same operation.

A central goal in the management of a patient with a ruptured aneurysm is to prevent rebleeding by obliterating the lesion. Results of delayed surgery are good, but the overall management outcome is better with early surgery because this policy prevents more rebleeding episodes (Haley et al., 1992). The current standard method of aneurysm obliteration is with surgical clipping (Fig. 84.3). Endovascular coiling (Fig. 84.3), trapping, and proximal occlusion are alternatives in certain situations. The main advantages of clipping are a high rate of complete occlusion and a proven low rate of aneurysm reformation. Other advantages of direct surgery include the ability to evacuate subarachnoid and intracerebral clot and to control intraprocedure aneurysm rupture. Temporary clipping of parent vessels reduces intra-aneurysmal pressure and improves the safety of neck dissection and clip application. Intraoperative electrophysiological monitoring is sometimes used for the early detection of ischemic changes during temporary clipping and inadvertent major branch or perforator occlusion (Lopez et al., 1999). Intra-operative angiography has also been useful in detecting branch occlusion and incomplete clipping, providing immediate feedback and the opportunity for clip adjustment (Alexander et al., 1996).

Occlusion of major proximal arteries has been an aneurysm treatment method for over a century. Good results are obtained with proximal occlusion for giant aneurysms of the anterior and posterior circulation, making this a viable alternative when the risks of direct surgery are considered excessive (Steinberg et al., 1993). Aneurysm trapping by placing clips proximal and distal to the aneurysm is a curative manoeuvre that can be used in situations where collateral flow to the distal vessel is sufficient and there are no

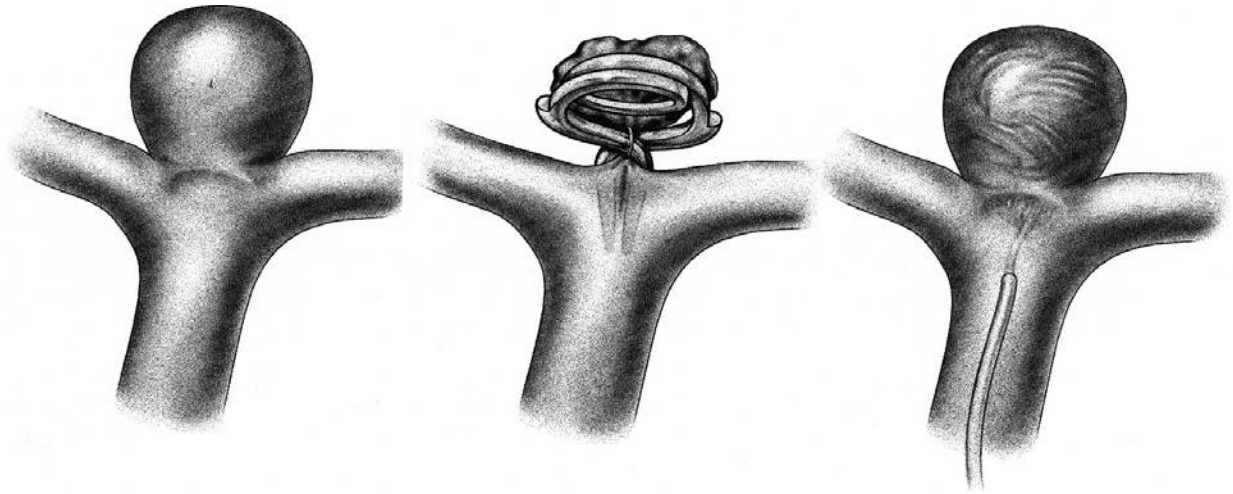

Fig. 84.3. Methods for obliterating aneurysms. Left: aneurysm with neck at an arterial bifurcation. Centre: surgical clipping. The aneurysm neck is occluded and the intimal surface is reconstructed. Right: endoluminal coiling. Complete obliteration of the lesion depends on thrombosis within the aneurysm sac. The intimal surface is not reconstructed.

perforators arising from the trapped segment. In very unusual circumstances a revascularising bypass graft is used to supplement flow distal to a trapped aneurysm.

Endovascular packing of the aneurysm lumen with platinum coils is a relatively new technique that has been increasingly used for cases unsuitable for surgery. In general, coiling is best suited to those aneurysms that are also amenable to surgery. Broad necked, large or giant, or partially thrombosed aneurysms are relatively less suited to endovascular techniques. Coiling does not reconstitute the intimal lining and often leaves residual aneurysm that can enlarge with time (Fig. 84.3). The precise role of coiling in the overall management of aneurysms remains to be determined and technical advances are occurring rapidly.

Arteriovenous malformations

Classification and pathology

The pathological classification of brain vascular malformations (Fig. 84.4) is based on the work of McCormick, who categorized lesions according to their gross and microscopic features (McCormick, 1966). The term 'arteriovenous malformation' has been used ambiguously as a general name for all vascular abnormalities and as a specific subtype of vascular malformation. The subtype arteriovenous malformation, referred to by some authors as 'high flow' AVM, occurs throughout the brain and spinal cord. They are present in 0.5–1% of the population and are presumed congenital in origin (Henn et al., 1999). An AVM is a fistula between an artery or arteries and a draining vein or veins, without an intervening capillary bed. There are arterial feeders, a nidus, which is the location of the fistulous connections, and a venous outflow. Arterial pressure is transmitted directly to the nidus by the feeding arteries. Arterial blood is then shunted to the draining veins, which are described as 'arterialized'. Arterialized veins carry oxygenated blood and are dilated and tortuous. The pressure change across the nidus depends on fistula resistance. In low resistance AVMs, there is steal of blood from surrounding brain, with dilatation of small arteries and arterioles that has been described as 'angiomatous change'. The general configuration of an AVM is a pyramidal-shaped lesion with its base at the surface of the brain and the apex directed towards the ventricle. Any brain parenchyma within the lesion tends to be abnormal, demonstrating gliosis, edema, or necrosis. There is often a gliotic reaction adjacent to the nidus and evidence of previous hemorrhage such as hemosiderin staining, thrombosis, and hyalinization (Henn et al., 1999). Although the vessels within an AVM are identifiably arteries and veins, there are degenerative and reactive changes that are presumed secondary to increased flow through the lesion (Henn et al., 1999). The vessels are generally dilated and the walls tend to be irregularly thickened or thin. Draining veins show evidence of fibrosis and do not have an elastic lamina (Henn et al., 1999). Associated aneurysms can be venous, within the nidus, on feeding arteries, or on unrelated arteries (Steinberg & Stoodley, 2000). A widely used grading scale is used to assess the risks associated with surgical treatment (Spetzler & Martin, 1986). One point is assigned to lesions

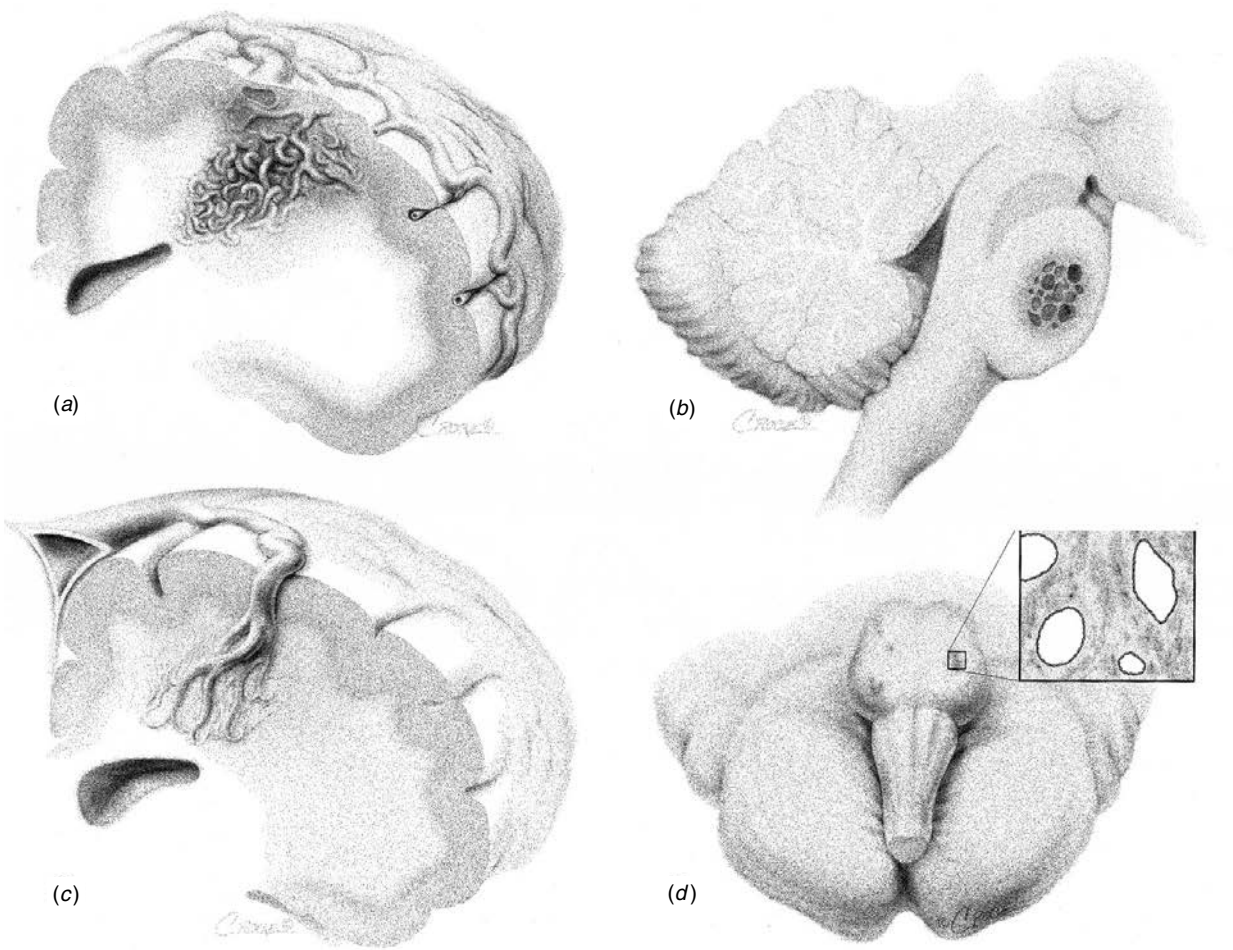

Fig. 84.4. Pathological classification of brain vascular malformations. (*a*) Arteriovenous malformation. (*b*) Cavernous malformation. (*c*) Venous malformation. (*d*) Capillary telangiectasia.

that are less than 3 cm in maximum diameter, 2 points for lesions between 3 cm and 6 cm diameter and 3 points for AVMs larger than 6 cm. Additional points are added for malformations that have drainage to the deep venous system and those located in eloquent regions of the brain. Higher grade lesions are associated with higher surgical risks.

Cavernous malformations, also referred to as cavernomas, cavernous hemangiomas, and cavernous venous angiomas, are compact lesions consisting of abnormal, thin-walled sinusoidal vessels without intervening brain parenchyma (Henn et al., 1999). Approximately 0.5% of the population harbour these malformations, which occur in all parts of the brain and spinal cord. There is a predilection for subcortical white matter, external capsule, and pons (Challa et al., 1995). Gross appearances are of a well-circumscribed, multilobulated lesion resembling a mulberry (Henn et al., 1999). There can be a collagenous capsule. The thin-walled vessels have a single endothelial layer adjacent to a fibrous outer layer, without elastin, smooth muscle, or basement membrane (Henn et al., 1999). Almost all cases show evidence of previous hemorrhage, with hemosiderin, organizing thrombus, and calcification within and around the lesion. The presumed congenital nature of these lesions has recently been questioned. New malformations arise in familial and non-familial cases, regions of brain treated with radiotherapy, and there is laboratory evidence to suggest a possible etiological role of viral infection (Flocks et al., 1965; Henn et al., 1999). The genetic mutation responsible for cavernous malformations has been localized to the long arm of chromosome 7 (Günel et al., 1995).

Venous malformations, or venous angiomas, are composed of a large, morphologically normal, vein that drains

into a deep or superficial venous sinus. Blood enters the large vein from small veins that are arranged radially around the trunk to give the appearance of a 'caput Medusa' (Fig. 84.4). There is no arteriovenous fistula or shunt and normal brain lies between the veins. These malformations are essentially developmental anomalies of normal venous drainage and are present in approximately 3% of the population. As many as 30% of cavernous malformations are associated with venous malformations and if a hemorrhage occurs near a venous malformation it is almost always from an associated cavernous malformation.

Capillary telangiectases are congenital lesions that are thought to result from a focal failure of capillary involution that normally occurs in the second month of gestation (Henn et al., 1999). The pons is a site of predilection, but they can be found anywhere in the central nervous system. They are rarely symptomatic and are usually an incidental finding at autopsy, occurring in 0.1–0.8% of the population.

Mixed or 'transitional' lesions occur. The particular relationship between cavernous malformation and venous malformation has been mentioned, and all possible combinations of lesions have been reported. Mixed histological features have also been noted, for example some lesions combine elements of cavernous malformation and capillary telangiectasia.

Dural arteriovenous fistulae were originally considered malformations, but are now classified separately. There is a fistulous connection between arteries and veins and the nidus is within the dura. Venous drainage is usually by dural venous sinuses or cortical veins. The cavernous, transverse, and sigmoid sinuses and dural veins at spinal nerve root sheaths are most commonly affected (Henn et al., 1999). A congenital origin is likely in some cases; however, most lesions probably follow trauma, surgery, or venous sinus thrombosis. One hypothesis relating to formation of these lesions is that angiogenic activity creates a fistula at the site of thrombosis or trauma. Neurological deficits are caused by raised venous pressure or hemorrhage. Borden and colleagues have classified dural arteriovenous fistulae into those that drain directly into dural venous sinuses (Type I), those that drain into dural sinuses and cortical veins (Type II), and those that drain only into cortical veins (Type III) (Borden et al., 1995). The risk of hemorrhage is highest in types II and III. The carotid cavernous type has been subdivided into direct (from a ruptured aneurysm or traumatic disruption of the intracavernous internal carotid artery) and indirect (from the external carotid artery or meningeal branches of the internal carotid artery) (Barrow et al., 1985).

Epidemiology and natural history

The approximate incidence of intracranial vascular malformations is 2 per 100 000 population per year and the prevalence is 20 per 100 000 population (Brown, 1999). AVMs are the most common type presenting clinically, followed by cavernous malformations and venous malformations. Most AVM ruptures occur in adults under the age of 40. Hereditary hemorrhagic telangiectasia and Wyburn Mason syndrome are associated with a higher incidence of AVMs and in these cases there can be multiple lesions.

The best available data concerning the natural history of AVMs indicates an annual hemorrhage risk of 2–4% per year, regardless of whether a malformation has previously bled (Brown, 1999; Steinberg & Stoodley, 2000). There is an elevation in risk (6%) during the first 6 months after a hemorrhage. Mortality from an initial hemorrhage ranges from 10 to 30% and morbidity is up to 40% (Brown, 1999). Numerous imaging features of AVMs have been associated with an increased risk of hemorrhage. These include the presence of aneurysms, periventricular or intraventricular location, deep venous drainage, absence of angiomatous change, impairment of venous drainage, deep venous drainage, arterial supply by perforators, and high feeding artery pressure (Brown, 1999).

Cavernous malformations account for 5–10% of vascular malformations presenting clinically. The mean age at presentation is approximately 40. Familial forms with near 100% penetrance occur, particularly in the Hispanic population. Multiple lesions are more common in familial cases. The low risk of fatal hemorrhage with this type of lesion is probably related to the low pressure within the abnormal vessels and the small bleeds that occur. Morbidity depends on the location of the lesion; posterior fossa lesions are typically more prone to developing neurological deficits. The overall risk of hemorrhage is approximately 4% per year (Porter et al., 1997). An increased risk is seen with familial cases or if there has been a previous hemorrhage (Wascher & Spetzler, 1999). Females present more commonly with hemorrhage and there appears to be an increased risk during pregnancy (Brown, 1999). The clinical course of brainstem lesions is more malignant, characterized by clinical deterioration associated with recurrent hemorrhage and a less than 50% recovery rate from each hemorrhage (Porter et al., 1997; Wascher & Spetzler, 1999).

Venous malformations and capillary telangiectasia appear to have a very benign natural history and treatment for them is not generally recommended. Hemorrhages occurring in the presence of these lesions are often from an associated cavernous malformation.

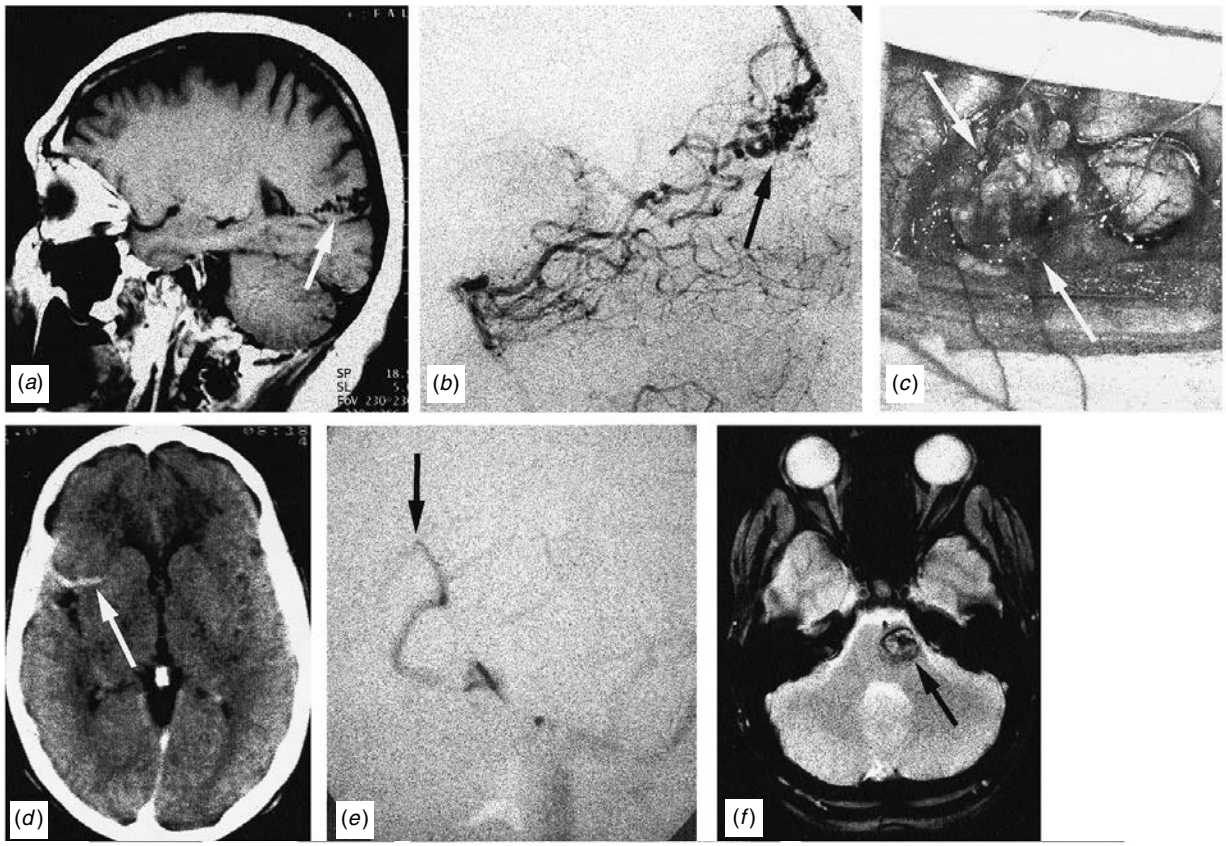

Fig. 84.5. Imaging studies of vascular malformations. (*a*) Sagittal T_1-weighted MRI demonstrating a parieto-occipital arteriovenous malforxmation (arrow) with the apex of the lesion reaching the occipital horn of the lateral ventricle. (*b*) Same case as (*a*). A vertebral angiogram shows filling of the malformation (arrow) and venous drainage to the superficial and deep venous systems. (*c*) Same case as (*a*) and (*b*). The malformation has been dissected from the surrounding brain (arrows) and is about to be detached from its superficial and deep venous attachments, which is the last step in removing the lesion. (*d*) CT scan with contrast demonstrating an enhancing vascular lesion in the right Sylvian fissure (arrow). On venous phase carotid angiography (*e*), this was revealed as a venous malformation with a typical 'Caput Medusa' appearance. (*f*) MR scan revealing a large cavernous malformation in the left side of the pons.

Investigation

Hemorrhage from an AVM is usually detected on CT, but the underlying malformation might not be detected, even with intravenous contrast enhancement. Subtle calcification is the only evidence on CT in some cases. MRI is more sensitive because the feeding arteries, draining veins and nidus will usually produce signal flow voids (Fig. 84.5), but there will still be false negatives. MR angiography is not sensitive enough to replace catheter angiography, which remains the gold standard for the detection of AVMs. Angiography demonstrates collateral vessels, risk factors for hemorrhage and surgery (such as aneurysms and venous drainage patterns), and feeding vessels including basal perforators. MRI is valuable in determining the anatomical location of the lesion and in planning treatment.

In contrast, MRI is the gold standard for the detection of cavernous malformations (Fig. 84.5), which are absent or seen as a faint blush on angiography. Typical MR appearances are of a well-circumscribed lesion with heterogeneous signal characteristics, and a rim of low signal intensity hemosiderin on T_1- and T_2-weighted images. Gradient echo sequences are very sensitive in the detection of cavernous malformations. T_1-weighted axial images are required for brainstem lesions because an assessment of the proximity of the malformation to the surface is crucial for surgical planning.

Venous malformations are seen as a 'caput Medusa' on venous phase angiography (Fig. 84.5). There is no early

venous filling or shunting of blood and the arterial pattern is usually normal. Capillary telangiectases are seen as faint blushes on angiography, if at all. Dural arteriovenous fistulae are generally not detectable on CT or MRI. Often internal carotid and vertebral angiography will also be normal; external carotid branches must be injected for the detection of these lesions. Spinal angiography with catheterization of each radicular branch is necessary to evaluate spinal dural arteriovenous malformations and fistulae.

Management

Acute medical management of ruptured vascular malformations is similar to other causes of intracranial hemorrhage. Nimodipine is generally not used as the risk of vasospasm is small unless there is thick basal subarachnoid hemorrhage. Anticonvulsants are used for patients presenting with seizures and for those with lesions involving cerebral cortex.

Decision making regarding management of vascular malformations is complex and is best made by a multidisciplinary management team of a vascular neurosurgeon, interventional neuroradiologist, and radiosurgeon. The risks of treatment are balanced against the natural history risks and analysed with regard to the patient's age, medical condition, psychological state, and the mode of presentation. A large AVM presenting with a single seizure in an elderly patient is not likely to be treated, whereas a case can be made for treating all but the most formidable lesions in young patients. The risk of hemorrhage from AVMs and cavernous malformations does not diminish until they are completely obliterated. Therefore, partial treatment is not an acceptable goal, with the possible exception of specific treatment of such risk factors as associated aneurysms. The main aim of treating these lesions is to prevent hemorrhage, although easier control of seizures and headaches is a common sequel to obliterating a malformation. Dural arteriovenous fistulae, if treated, must be eradicated completely; any residual arteriovenous connection is likely to enlarge with time.

Treatment options for vascular malformations are surgery, radiosurgery, endovascular embolization, and combinations of these modalities. Surgical excision remains the preferred treatment for most malformations because it provides immediate protection from hemorrhage and has the highest rate of complete obliteration. While having the attraction of being 'less invasive' radiosurgery is effective only for small lesions. Even malformations less than 3 cm diameter have obliteration rates of only 70–80% with this modality, and there is a risk of delayed radiation necrosis that must be considered. Radiosurgery is therefore usually reserved for cases that would have excessive surgical risk, such as those in the brainstem and thalamus. Endovascular embolization is rarely curative, although it is often used as an adjunct to the other modalities. It can be used to reduce a malformation to a size suitable for radiosurgery. Used prior to surgery, it is valuable for lowering intranidal pressure and reducing intraoperative hemorrhage, occluding arterial feeders that would be difficult to access, and possibly effecting more gradual restoration of normal hemodynamics that might lower the incidence of 'breakthrough' postoperative hemorrhage (Steinberg & Stoodley, 2000).

The immediate risk of recurrent hemorrhage from a vascular malformation is not as high as it is with aneurysms and there is consequently usually no urgency in treating the underlying lesion. AVMs with high risk factors identified on angiography are an exception. The precise timing of surgery is individualized to avoid operating in the presence of an edematous, swollen brain, yet early enough to take advantage of dissection produced by a hemorrhage. There is no reason for prolonged delay in cases with minor hemorrhage. Urgent evacuation of the hematoma is indicated for cases with life-threatening hematomas, but in contrast to aneurysm surgery the underlying vascular malformation is usually left for removal at a later time.

Current indications for treating cavernous malformations include recurrent hemorrhage of a superficial lesion and a single hemorrhage from a brainstem malformation. A critical factor in determining suitability for surgery is accessibility. In the brainstem a lesion is generally accessible only if it reaches a pial or ependymal surface. This is best judged preoperatively on T_1-weighted MR images, but some cases deemed suitable by this criterion will be discovered at surgery to be covered by a thin layer of normal parenchyma that should not be transgressed. Deep supratentorial lesions are usually not suitable for surgical excision, unless they also approach a deep pial or ependymal surface. There is some evidence to suggest that control of seizures is easier if superficial cortical lesions are removed early, but this is not a strong indication for surgery. Once access is gained to a cavernous malformation, its removal is less demanding than for AVMs; there are few feeding vessels and usually a gliotic plane. The effectiveness of radiosurgery is not sufficient for it to be a first-line therapy and there is evidence that the complications of such treatment exceed those associated with the treatment of other vascular lesions (Chang et al., 1998). In addition, radiosurgery tends to make subsequent surgical excision more difficult, in contrast to AVM surgery after radiation. We consider using radiosurgery only for lesions that have multiple hemorrhages and remain surgically inaccessible.

Dural arteriovenous fistulae are difficult lesions to manage. Spontaneous thrombosis does occur in a small proportion of cases. Indications for treatment include cortical venous drainage, which corresponds with a high risk of intracranial hemorrhage, and intolerable bruit. Carotid cavernous fistulae generally should be treated because the natural history is of progressive enlargement of the lesion with proptosis and cranial nerve palsies. Embolization is the preferred initial treatment in most cases. A transarterial route is usually used first, although venous catheterization with occlusion of the draining venous sinus is an option in many cases. This does not usually risk causing venous infarction because the sinus is already under high pressure and causing retrograde flow. The goal is complete occlusion of all arterial feeders or the draining venous sinus. If any fistulous connection remains, there is a high likelihood of further feeding artery recruitment and enlargement. Surgical obliteration by skeletonization of the dural venous sinus, division of all feeding arteries, and division of retrograde-flowing subarachnoid veins is a demanding undertaking reserved for cases with angiographic or clinical features of high risk that are not completely embolized. Radiosurgery has been used with some success (Guo et al., 1998). Spinal arteriovenous fistulae are usually located in the nerve root sleeve, even though there are dilated abnormal veins within the subarachnoid space and on the spinal cord. Simply dividing the fistula at the nerve root sleeve or its draining vein immediately that it enters the subarachnoid space, will usually be curative. Endovascular embolization is an option in cases where the general condition is a contraindication to surgery.

In conclusion, central nervous system aneurysms and arteriovenous malformations are a diverse group of conditions that are life threatening in many cases. Treatment is usually indicated for those lesions that have bled, or are considered at high risk of hemorrhage. The preferred method of treatment is surgery in most cases. Endovascular coil embolization is an alternative treatment of aneurysms that is likely to play a more prominent role as there are improvements in the technology and techniques of this method. Embolization of various occlusive substances into AVMs is also becoming more useful, although it is not likely that this will be a frequent curative treatment in the near future. For certain types of AVM, radiosurgery is effective in many cases, although this method is generally reserved for those patients who are unsuitable for surgery. For complex and difficult AVMs, combinations of the three treatment modalities are proving to be safer and more effective than a single approach.

Hereditary causes of stroke

Martin Dichgans

Department of Neurology, Klinikum Großhadern, München, Germany

This chapter focuses on mendelian disorders with stroke as part of the clinical syndrome. Within recent years most of the major gene loci have been mapped. In some instances this has allowed a new nosologic classification. Many of the genes have been cloned, thus allowing a direct diagnosis in the index patient and its relatives. Moreover, the cloning of the genes has provided new insights into the molecular mechanisms underlying these disorders. Thus for example the identification of genes implicated in CADASIL and familial cavernoma revealed cell signalling pathways involved into angiogenesis.

In order to recognize mendelian stroke syndromes it is essential to perform a systematic family inquiry and to search for neurological and non-neurological signs and symptoms in index cases and relatives. The diagnosis may have implications both for therapeutic decisions and genetic counselling. At present, there is no uniform classification for mendelian stroke syndromes. Criteria that may be useful for clinical practice include the type of stroke, the presence or absence of associated symptoms, and the mode of inheritance. The chapter gives a summary of actual data regarding clinical, genetic and physiopathological aspects of these conditions.

Monogenic disorders with stroke as the prevailing manifestation

Conditions causing ischemic stroke

CADASIL

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is an autosomal dominantly inherited small vessel disease causing stroke in young adults. Previous descriptions of families with 'hereditary multi-infarct dementia', 'chronic familial vascular encephalopathy', and 'familial subcortical dementia' represent early reports of the same condition. In 1993, Tournier-Lasserve et al. mapped the gene on chromosome 19 and coined the acronym CADASIL (Tournier-Lasserve et al., 1993). Since then numerous families have been reported from all over the world.

Clinical manifestations include recurrent ischemic episodes (TIAs and strokes; 80%), cognitive deficits (50%), and migraine (40%) mostly with aura, as well as psychiatric disorders (30%) and epileptic seizures (10%) (Dichgans et al., 1998). Onset of ischemic symptoms is usually in mid-adulthood (mean age: 46.1 years). Magnetic resonance imaging reveals a combination of small lacunar lesions and diffuse white matter abnormalities (Fig. 85.1). The latter reflect varying degrees of demyelination, axonal loss, enlargement of the extracellular spaces and gliosis. There is evidence for additional subtle tissue alterations (both cortical and subcortical) outside T_2-visible lesions. Cerebral blood flow is reduced already within asymptomatic individuals. The underlying vascular lesion is a unique non-amyloid angiopathy involving small arteries (100–400 micrometres) and capillaries primarily in the brain but also in other organs. The diagnosis may therefore be established by skin biopsy. Ultrastructural examination reveals granular osmiophilic deposits within the vascular basal lamina (Fig. 85.2). These deposits are often seen in contact with degenerating smooth muscle cells. Yet they have not been characterized biochemically and their origin remains unresolved.

The disease is caused by mutations in *Notch3* (Joutel et al., 1996). *Notch* genes encode evolutionary conserved cell surface receptors that regulate cell fate choices in vertebrates and invertebrates during embryonic development. A constant feature of Notch receptors is a large number of

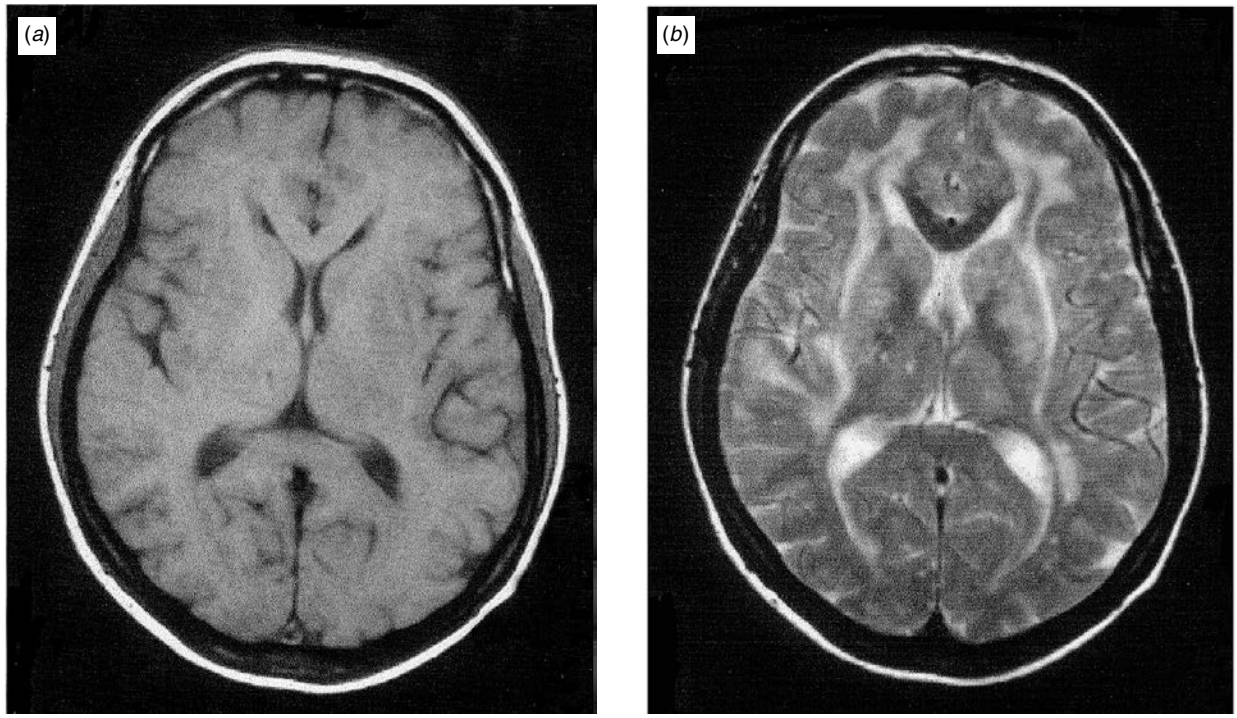

Fig. 85.1. Magnetic resonance images of a 48-year-old patient with CADASIL. (*a*) T_1-weighted image showing a small circumscribed lesion within the right thalamus as well as periventricular signal hypointensities; (*b*) T_2-weighted image showing diffuse signal-hyperintensities in the periventricular white matter and the external capsule.

tandemly arranged epidermal growth factor-like (EGF-like) repeat domains which account for most of the extracellular domains of these proteins. All CADASIL mutations are located in EGF-like domains of the Notch3 receptor with a strong cluster at the N-terminus. Mutations show a striking stereotyped nature: all mutations lead to the creation or loss of one cysteine residue. Since each wtEGF repeat domain contains six cysteines these mutations result in an odd number of cysteine residues within one EGF domain (Dichgans et al., 2000). Notch3 expression is restricted to vascular smooth muscle cells in human adult tissues. In CADASIL there is a dramatic accumulation of the ectodomain of the Notch3 receptor within blood vessels (Joutel et al., 2000). Accumulation takes place at the cytoplasmic membrane of vascular smooth muscle cells and pericytes, in close vicinity to but not within the granular osmiophilic deposits. These findings are in line with recent clinical studies evidencing vascular smooth muscle cell dysfunction in vivo.

There is no causative treatment for the disease. Management should focus on the control of symptoms such as headache, mood disturbances, urinary incontinence and sleep disturbances. Motor disabilities require formal rehabilitation. Forced crying and laughing may respond to selective serotonin reuptake inhibitors. When oral hydration and feeding become insufficient, the patient should receive additional tube feeding.

Conditions causing hemorrhagic stroke

Familial cerebral cavernoma

Cerebral cavernous malformations (CCM) are characterized by collections of large, abnormally dilated sinusoidal vascular spaces without intervening normal vessel wall elements or neural tissue. CCM usually present with seizures, headache, hemorrhagic stroke or focal neurologic deficits. Magnetic resonance imaging (MRI) demonstrates a characteristic lesion of variable signal intensity surrounded by a dark ring attributable to hemosiderin (Fig. 85.3). Gradient-echo sequences are particularly sensitive in displaying small lesions. Multiple lesions have been found in one-third of the sporadic cases and in up to 84% of the familial cases. The prevalence of CCM in the general population is close to 0.5%. A significant proportion of cases remain asymptomatic. CCM lesions are dynamic in time: subjects have been shown to acquire new lesions and lesions may undergo spontaneous involution. The risk of hemorrhage has been estimated at 0.7 to 1.1% per lesion per year.

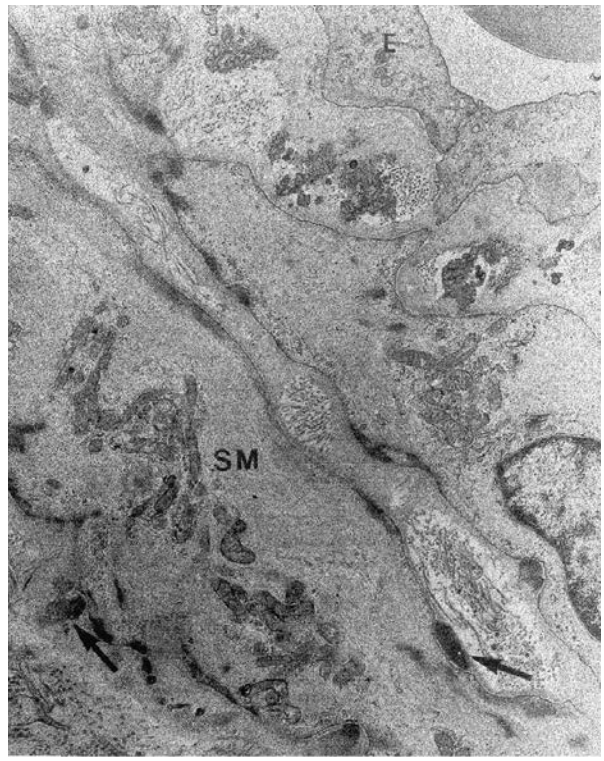

Fig. 85.2. Electron micrograph of a dermal vessel from a CADASIL patient: granular osmiophilic electron-dense material (arrows) within the vascular basal lamina (E = endothelial cell; SM = smooth muscle cell). Magnification ×16500. (Kindly provided by J Müller-Höcker, Munich.)

In a significant proportion of cases CCM are inherited as an autosomal dominant condition (Labauge et al., 1998). In the Hispano-American population this proportion was reported to be close to 50%. Most patients with multiple cavernous lesions have a hereditary form of the disorder. Three chromosomal loci have been identified on 7q, 7p and 3q. A strong founder effect was observed among Hispanic–Americans of Mexican descent, all familial cases being linked to *CCM1* on chromosome 7q. *CCM1* is also a major locus in the non-Hispanic population. The gene has recently been cloned. *CCM1* encodes KRIT1 an ankyrin repeat domain-containing protein. KRIT1 interacts with RAP1A/KREV1, a member of the RAS family of GTPases. RAP1A is involved in cell differentiation and morphogenesis. Moreover, several lines of evidence indicate that RAS signalling is involved in angiogenesis. The *CCM1* mutations identified thus far predict truncated CCM1 proteins

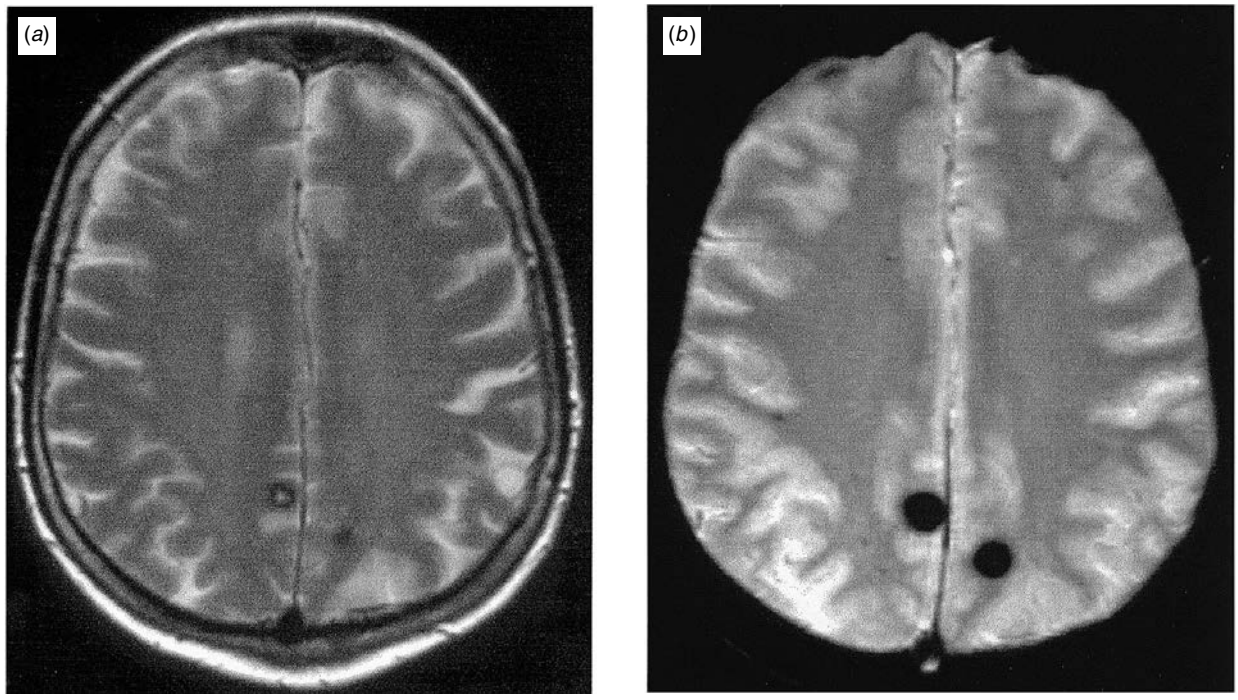

Fig. 85.3. Magnetic resonance images of a 69-year-old patient with multiple cerebral cavernous malformations. (*a*) T_2-weighted image, (*b*) gradient-echo image. For explanation see text.

completely or partially devoid of the putative RAP1A-interacting region. This points towards loss of function as the underlying mechanism. Laberge-le-Couteulx proposed a 'Knudson double hit mechanism' to explain the manifestation of sporadic forms of cavernomas as unique lesions and familial forms as multiple lesions (Laberge-le Couteulx et al., 1999). Following this hypothesis, a complete loss of CCM1 function would be required for the appearance of cavernous angiomas.

The primary therapeutic challenges in cavernous angiomas are: the management of the acute hemorrhage, the prevention of recurrent hemorrhages, and seizure control. Depending on the clinical situation pharmacological or surgical interventions may be necessary.

Conditions causing both ischemic and hemorrhagic stroke

Cerebral amyloid angiopathy

The cerebral amyloid angiopathies (CAA) encompass a heterogeneous group of disorders characterized by the deposition of amyloid in the walls of leptomeningeal and cerebral cortical blood vessels (Coria & Rubio, 1996). They are clinically characterized by recurrent or multiple lobar hemorrhages, cognitive deterioration, and ischemic strokes. MRI displays diffuse white matter abnormalities and focal lesions that can be ischemic or hemorrhagic. Apart from amyloid deposition vessel walls exhibit a number of changes such as cracking between single layers, microaneurysm formation, and fibrinoid necrosis. Rupture of such structurally weakened arteries eventually results in cerebral hemorrhage.

There are two autosomal dominantly inherited forms of CAA which can be differentiated based on clinical, biochemical and pathologic findings. Hereditary cerebral hemorrhage with amyloidosis-Dutch type (HCHWA-D) has been described in several large families from the Netherlands (Bornebroek et al., 1996). Stroke is usually the first clinical sign and occurs between age 45 and 60. Those who survive may experience multiple recurrences. The disease is biochemically characterized by deposition of β-amyloid in meningocortical blood vessels and cerebrocortical grey matter. β-amyloid refers collectively to a group of peptides, 38–42 amino acids in length, that arise from proteolytic cleavage of β-amyloid precursor protein (βAPP). HCHWA-D is caused by a mutation in the *APP* gene on chromosome 21. This mutation (Glu693Gln) has been shown to increase the aggregation of β-peptides into amyloid fibrils in vitro. Aggregation of normal β-peptide may further be enhanced by the presence of amyloid-binding proteins such as alpha1-antichymotrypsin or apolipoprotein E (apo E). Specific *APOE* alleles have been identified as important risk factors for the by far more common sporadic forms of CAA. The Flemish (A692G), Arctic (E693G), Italian (E693K) and Iowa (O694N) type of familial CAA represent allelic variants of the Dutch type.

Hereditary cerebral hemorrhage with amyloidosis-Iceland type (HCHWA-I) has been described in eight families of the same ethnic origin. Biochemically, this variant is characterized by vascular deposition of cystatin C, a cysteine protease inhibitor. The disease is due to a point mutation at codon 68 of the *CST3* gene. Mean age at onset for cerebral hemorrhage is considerably earlier than in HCHWA-D and most patients die before the age of 50. Genetic testing is feasible both for HCHWA-D and HCHWA-I. Several other hereditary amyloidoses show amyloid deposition within the central nervous system, but stroke has not been described as a major clinical feature of these diseases.

CAA also occurs in the context of Alzheimer's disease, Down's syndrome, and as a sporadic condition. Sporadic CAA may be suspected in patients aged 60 years or older with multiple hemorrhages confined to lobar brain regions and no other cause of hemorrhage. Gradient-echo MRI may be helpful to establish the presence of small previous hemorrhages. Whereas the biology of vascular damage in CAA appears to be distinct from other types of hemorrhage, there is no evidence for differences in the behaviour of the acute hematoma. Acute treatment may necessitate surgical intervention. Preventive treatment is limited to withdrawal of anticoagulant or antiplatelet agents.

Moyamoya disease

Moyamoya is a chronic progressive disease characterized by spontaneous bilateral stenosis or occlusion of the terminal carotid artery associated with telangiectatic vessels at the base of the brain (Ikezaki et al., 1997). Suzuki and Takaku observed that these collateral vessels give the appearance of a puff of smoke on arteriography and coined the name moyamoya (Suzuki & Takaku, 1969). Moyamoya occurs more frequently in females (male-to-female ratio 2:3) and is prevalent among patients $<$10 years of age, particularly of Japanese origin. Hemiplegia of sudden onset and epileptic seizures constitute the prevailing presentation in childhood. They are evoked by cerebral ischemia due to the narrowing or occlusion of the circle of Willis. Progressive narrowing of the carotid fork results in gradual development of collateral circulation. Eventual rupture of these abnormal vessels causes subarachnoid hemorrhage, the predominant manifestation of moyamoya disease in patients older than 30 years.

Most cases appear to be sporadic, but about 10% occur as familial cases. Linkage has been reported to loci on

chromosomes 3p24.2–26 and 17q25 reaching maximum lod scores of 3.46 and 4.58, respectively. Non-invasive diagnostic methods such as magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) have assisted in identifying asymptomatic family members thus increasing the number of familial cases. About 70% of cases of moyamoya disease among family members occur in siblings, whereas 24% occur in a parent and offspring.

Hypotheses concerning additional etiologies of moyamoya disease include infection with subsequent autoimmune response and environmental agents. So far, none of these hypotheses have been definitely confirmed. Instead, there is accumulating evidence that the condition is largely caused by genetic factors with multiple genes involved. Moyamoya-like vascular changes have been described in association with a variety of conditions such as von Recklinghausen disease, tuberous sclerosis, Marfan syndrome and pseudoxanthoma elasticum.

Histologically, there is a cellular fibrous thickening, or eccentric fibrosis, of the intima. The internal elastic lamina shows duplication and tortuosity, whereas the media shows atrophy and thinning. The adventitia is without major changes. The most severely affected site is confined to the carotid fork. However, similar vascular changes have been found in other organs. Recent studies on vascular smooth muscle cells derived from patients with moyamoya disease suggest an increase in elastin synthesis within arterial smooth muscle cells and elastin accumulation.

Patients have been treated with antiplatelet agents, rheologic therapy, corticosteroids and calcium-channel blockers, although the efficacy of these treatments has not been proven. Anticoagulants should be avoided because of the risk of bleeding. Good results have been reported with surgical revascularization such as superficial temporal artery to MCA anastomosis.

Monogenic disorders with stroke as part of a more complex syndrome

Hereditary hemorrhagic telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) or Osler–Weber–Rendu disease is an autosomal dominant vascular dysplasia. The condition is characterized by mucocutaneous telangiectasies, severe recurrent epistaxis, gastrointestinal hemorrhage, and a high incidence of vascular malformations in the lung and brain (Guttmacher et al., 1995). Telangiectasies tend to enlarge and multiply over time. Among patients with neurological deficits, about two-thirds have embolic complications of pulmonary arteriovenous malformations (AVM). The most common mechanism is paradoxical embolism. However, rarely a thrombus may form within the fistula itself. Transient ischemic attacks during hemoptysis may be caused by air embolism from a bleeding pulmonary arteriovenous fistula. Intracranial AVMs may cause intraparenchymal or subarachnoid hemorrhage. About 25% of unselected HHT cases have evidence for cerebrovascular malformations (CVM) on magnetic resonance images of the brain. HHT should always be considered in patients with multiple CVMs.

Most HHT families have mutations in one of two known genes. *HHT1* is the endoglin gene on chromosome 9q33. Endoglin is a homodimeric transmembrane receptor which is highly expressed on endothelial cells. Endoglin binds transforming growth factor-beta (TGFβ) isoforms 1 and 3 in combination with the signalling complex of TGFβ receptors types I and II. Its expression increases during angiogenesis, wound healing, and inflammation, all of which are associated with TGFβ signalling and alterations in vascular structure. Mouse embryos lacking both copies of the endoglin gene die due to defects in vessel and heart development. *HHT2* is the activin receptor-like kinase 1 (ALK1) gene on chromosome 12q13. Like endoglin, ALK1 is a cell-surface receptor for the TGFβ superfamily of ligands that is heavily expressed in endothelial and vascular smooth muscle cells. Mice deficient in ALK1 show severe vascular abnormalities characterized by fusion of capillary plexes into cavernous vessels. Thus both *HHT1* and *HHT2* highlight the role of receptors for TGFβ family members in the regulation of vascular differentiation.

The treatment of HHT is usually limited to the management of complications. In some cases resection or occlusion of pulmonary arteriovenous fistulas may be recommended. In patients with recurrent bleedings chronic iron administration and periodic transfusion may be necessary.

MELAS

Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS) is associated with several mutations in mitochondrial DNA (mtDNA). Most cases result from a point mutation (A3243G) in the $tRNA^{leucine\ (UUR)}$ gene which is associated with respiratory chain complex I deficiency. Muscle biopsy reveals ragged-red fibres.

The phenotype of MELAS is highly variable ranging from asymptomatic cases to severe childhood multisystem disease with lactic acidosis. Stroke-like episodes usually occur before age forty. The mechanisms underlying these episodes are incompletely understood. In many cases 'stroke' regions are not limited to vascular territories

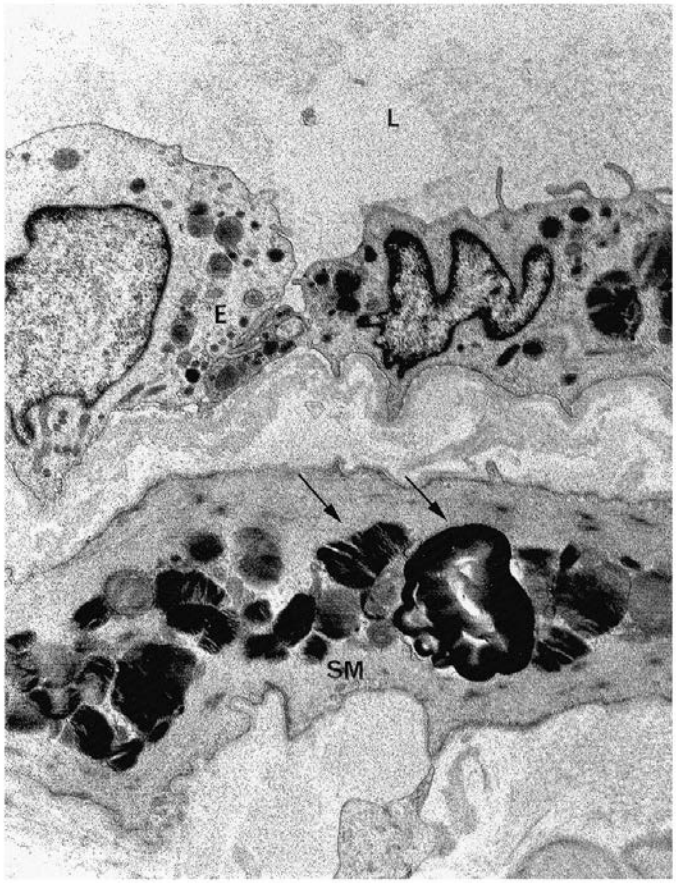

Fig. 85.4. Electron micrograph of a dermal vessel from a Fabry patient: Multilamellated zebra bodies (arrows) within vascular smooth muscle cells (L = vessel lumen; E = endothelial cell; SM = smooth muscle cell). Magnification ×16500. (Kindly provided by J Müller-Höcker, Munich.)

and cerebral angiography does not reveal embolic or stenotic lesions. These observations indicate that a mechanism other than cerebral infarction may be involved. Some authors have suggested a disturbance of the blood–brain barrier, presumably due to mitochondrial respiratory failure in the vascular endothelium (Yoneda et al., 1999). Others suspected an impaired autoregulation of cerebral blood supply secondary to metabolic abnormalities within precapillary sphincters. Both hypotheses are supported by studies that have indicated increased numbers of enlarged and structurally abnormal mitochondria in endothelial cells, pericytes, and vascular smooth muscle cells of capillaries and small arteries. In addition, primary defects in neuronal oxidative metabolism may be involved in the pathogenesis of stroke-like episodes in MELAS.

Several anecdotal reports have advocated the use of coenzyme Q, dichloroacetate, creatine, or vitamins in MELAS. However, in one of very few controlled trials there was no significant effect of coenzyme Q and multiple vitamins in mitochondrial diseases.

Fabry disease

Fabry disease (FD), is an X-linked recessive disorder due to alpha-galactosidase A deficiency. The deficiency of this enzyme results in progressive accumulation of glycosphingolipids in all areas of the body, but predominantly in the lysosomes of endothelial, perithelial and smooth muscle cells of blood vessels. Cerebrovascular symptoms are mediated both by large- and small-artery involvement (Mitsias & Levine, 1996). The latter is characterized by progressive occlusion of blood vessels, secondary to deposition of glycosphingolipid within the vessel wall (Fig. 85.4). The most frequent sign of large artery disease is dolichoectasia of the basilar and vertebral arteries. Large infarcts involving the cortex have been explained by artery-to-artery embolism from ectatic vessels. There is accumulating evidence for a prothrombotic state in Fabry disease. Some patients may develop intracranial hemorrhage (ICH). The latter may be caused by vessel degeneration as well as uncontrolled hypertension from renal failure. In hemizygous patients the penetrance for cerebrovascular involvement on MRI is complete by about age 54. In female heterozygotes the penetrance and expressivity of the phenotype is much lower. The diagnosis of Fabry disease may be suspected based on the typical skin changes that characterize the disease ('angiokeratoma corporis diffusum'): clustered non-blanching angiectases primarily over the lower part of the trunk, buttocks, and scrotum. Another frequent finding are painful paresthesias due to autonomic neuropathy (involvement of the vasa nervorum). The diagnosis is confirmed by skin biopsy (lipid inclusions in the vascular endothelium) (Fig. 85.4) and biochemical studies. Death usually occurs from systemic complications in particular renal failure and cardiac insufficiency. So far, there is no completely effective treatment. However, enzyme replacement therapy is under investigation. Carbamazepine or phenytoin may offer relief from the painful paresthesias.

Cerebroretinal vasculopathy (CRV) and hereditary endotheliopathy with retinopathy, nephropathy and stroke (HERNS)

Cerebroretinal vasculopathy (CRV) is a rare condition characterized by a microangiopathy of the brain and retina

in conjunction with a cerebral pseudotumour typically located within the fronto-parietal white matter. Clinical symptoms include progressive visual loss, headache, seizures, focal neurologic deficits and progressive cognitive worsening. The few families reported so far suggest an autosomal dominant pattern of inheritance. Small intracerebral vessels exhibit amorphous thickening of their walls with adventitial fibrosis. Some of the vessels become necrotic and show thrombosis. Jen et al. (1997) described a large family in which multiple members from three generations had developed a syndrome consisting of retinopathy, nephropathy and stroke. In most cases the disease had started with visual disturbances ('blind spots') followed by focal neurologic deficits within a few years. On brain magnetic resonance images these individuals were shown to have contrast enhancing lesions with surrounding vasogenic edema most commonly in the frontoparietal region. Fluorescein angiograms demonstrated capillary obliteration with telangiectatic microaneurysms. Ultrastructural examination of microvessels from different organs including the brain, kidney and skin revealed multilayered capillary basal membranes. Based on these findings the authors suspected a primary endothelial injury and coined the acronym HERNS. Apparently, CRV and HERNS represent allelic disorders. Both conditions have recently been mapped to chromosome 3p21 (Ophoff et al., 2001). Although renal insufficiency has not been reported as a feature of CRV, evidence exists that CRV and HERNS may represent variants of the same condition (Weil et al., 1999). Corticosteroids have been advocated for the treatment of edema in the acute stage. Surgical resection of the pseudotumour has not helped those who underwent this procedure.

Connective tissue disorders

Ehlers–Danlos syndrome type IV

Vascular complications are the hallmark of Ehlers–Danlos syndrome (EDS) type IV, an autosomal dominant condition due to mutations in *COL3A1*, the gene for collagen type III. The clinical diagnosis is made on the basis of at least two of the following clinical criteria: easy bruising, thin skin with visible veins, characteristic facial features, and rupture of arteries, uterus, or intestines (Pepin et al., 2000). The diagnosis is confirmed by mutational screening or biochemical studies (cultured fibroblasts synthesize abnormal type III procollagen). Hyperextensibility of the skin and hypermobility of large joints are unusual in the vascular type of EDS. Neurovascular complications include intracranial aneurysms (IA), arterial dissection and spontaneous rupture of large- and medium-sized arteries. IAs may be saccular or fusiform, and they are commonly located in the cavernous sinus (Schievink, 1997). Rupture of these aneurysms results in carotid–cavernous fistula. Rupture of any artery into a free space such as the pleural cavity requires immediate intervention, even though the tissues are friable and repair may be difficult. In contrast, rupture into a confined space may be sealed by tamponade, and in such cases, surgery may be deleterious. Arteriography carries special risks and should be avoided if possible. Whether incidental aneurysms should be treated is still unclear. Prompt surgical intervention is crucial in the treatment of bowel rupture. Women with EDS type IV who become pregnant have to be considered at high risk for uterine and vessel rupture and should therefore be followed at specialized centres.

Marfan syndrome

Marfan syndrome (MFS) is an autosomal dominant disorder characterized by abnormalities of the skeleton, cardiovascular system and eye (Pyeritz, 2000). The condition is caused by mutations in the gene encoding fibrillin-1 (*FBN1*). Major diagnostic criteria include pectus carinatum or excavatum, reduced upper to lower segment ratio or arm span to height ratio >0.5 (Fig. 85.5), scoliosis $>20°$, ectopia lentis, and dilation of the ascending aorta with or without regurgitation. Molecular diagnosis is feasible though laborious since the majority of people with MFS have private mutations in a very large gene.

The most common cerebrovascular complication of MFS is extension of aortic dissection into the common carotid arteries. Aortic dissection may further cause spinal cord infarction. Spontaneous dissections limited to the cervical arteries are less frequent. An association between MFS and intracranial aneurysms (IA) has been repeatedly proposed but also challenged (Schievink, 1997). Many of the vascular complications of MFS are due to the changes in elastic arteries, which are age dependent and are localized primarily in the media. They include fragmentation and disarray of elastic fibres, degeneration of smooth muscle cells, and separation of muscle fibres by collagen and pools of mucopolysaccharide. As a result, the ascending aorta becomes less distensible and stiffer than usual.

Individuals with MFS should avoid intense physical or emotional stress. Patients should be considered for β-adrenergic blockade. Annual echocardiographic studies are recommended. In some cases, surgery may become necessary. Individuals with MFS should use routine antibiotic prophylaxis before dental and other procedures that carry a high risk of introducing bacteria into the bloodstream.

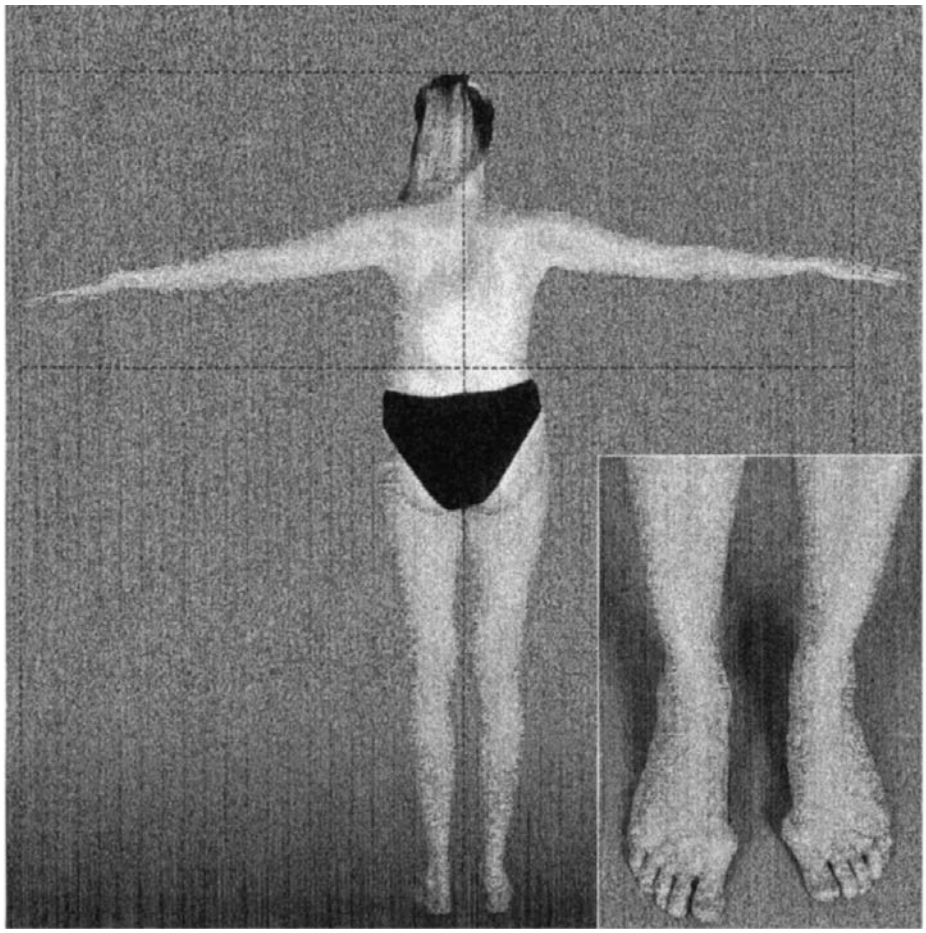

Fig. 85.5. Back view of a 33-year-old patient with Marfan syndrome and cerebrovascular complications. Note the characteristic skeletal abnormalities (reduced upper to lower segment ratio, arm span to height ratio >0.5, scoliosis, pes planus).

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum (PXE) is characterized by calcification of elastic fibres in the skin, eye and cardiovascular system. Typical skin changes consist in yellowish-grouped papules beginning on the lateral aspect of the neck. Ophthalmoscopic examination reveals mottled appearance of the retina as well as angioid streaks which are due to the breakdown of the elastic lamina of Bruch's membrane. The diagnosis may be confirmed by histologic examination of a skin biopsy. Recently, mutations in *ABCC6*, a member of the ATP-binding cassette (ABC) gene subfamily C have been shown to cause autosomal recessive and autosomal dominant variants of the disease (Ringpfeil et al., 2000). However, the mechanisms by which these mutations become pathogenic are still unknown. Cardiovascular complications are common due to calcification of the internal elastic lamina of mostly medium-sized arteries. Patients with PXE are at an increased risk of developing ischemic infarction. There are several case reports on a co-occurrence of PXE with intracranial aneurysms or spontaneous dissection of cervical arteries. However, these observations may be fortuitous. Platelet inhibitors, high systemic blood pressure and contact sports should be avoided because of an increased risk of bleeding. Patients should be followed by an ophthalmologist. Nutritional restrictions (calcium) are controversial.

Neurofibromatosis Type I

Neurofibromatosis Type 1 (NF1) is a progressive systemic disease involving tissues of meso- and ectodermal origin. Inheritance is autosomal dominant with a high rate of new mutations. The *NF1* gene codes for neurofibromin, a large tumour suppressor protein.

Cerebrovascular symptoms are a rare though accepted complication of the disease (Rizzo & Lessell, 1994). Stenosis, and eventually occlusion of the supraclinoid internal carotid artery is the most commonly reported abnormality. Intracranial arterial occlusions are often associated with a moyamoya-like pattern of collateral vessels which indicates that stenosis develops early in life. There have been a number of case reports on intracranial aneurysms (IA) in NF1 (Schievink, 1997). However, an association between IAs and NF1 has not been firmly established. The vascular pathology in NF1 includes concentric growth of the intima, disruption of the elastica, and nodular aggregates of proliferating smooth muscle cells. These findings are in agreement with studies that have demonstrated a vascular expression of NF1 within smooth muscle cells and vascular endothelium. The impact of *NF1* mutations on the vascular pathology is further corroborated by a mouse model of mutations in p120-rasGAP and *NF1* genes. Like p120-rasGAP, neurofibromin has been shown to act as a GTPase activating protein (GAP) on Ras. Disruption of p120-rasGAP in mice affects the ability of endothelial cells to organize into vascularised networks, and mutations in *GAP* and *NF1* genes have a synergistic effect on the observed phenotype which includes thinning and rupture of large and medium-sized arteries during embryonic development. There is no specific therapy for cerebrovascular complications in NF1.

Autosomal dominant polycystic kidney disease (ADPKD)

Patients with ADPKD may develop cysts not only in the kidney but also in other organs including liver, spleen, pancreas and subarachnoid space. The systemic nature of ADPKD is demonstrated by its associated cardiovascular abnormalities. Vascular complications include mitral valve prolapse, aortic root dilatation, aortic dissection, aortic aneurysm and coarctation. The association of intracranial aneurysms (IA) with ADPKD has been firmly established (Schievink, 1997; Chapman et al., 1992). IA (mostly saccular) are found in about one-fourth of autopsy cases of ADPKD and they are responsible for death in up to 20% of the cases. ADPKD is caused by mutations in one of two genes: *PKD1* (Chr 16p13.3) or *PKD2* (Chr 4q13–23). *PKD1* accounts for approximately 85% of pedigrees and is associated with a more severe phenotype. Polycystin-1, (the gene product of *PKD1*) and polycystin-2 (the gene product of *PKD2*) are transmembrane proteins that are coordinately expressed in vascular smooth muscle cells. It has been suggested that polycystin-1 preserves vascular integrity during angiogenesis by stabilizing the adhesion of cells to each other or to the extracellular matrix. This hypothesis is supported by recent animal data. Mice homozygous for targeted mutations in *PKD1* and *PKD2* exhibit focal hemorrhage, particularly in tissues undergoing angiogenesis. Patients with ADPKD may be at higher risk for invasive procedures, presumably because of increased vascular fragility.

Homocystinuria

Of the several autosomal recessive enzyme deficiencies that cause homocystinuria cystathionine beta-synthase deficiency, in which the conversion of homocysteine to cytstathionine is impaired is the most common form (Mudd et al., 1995). Homocystinuria may also result from disturbances in the conversion of homocysteine to methionine by a pathway that requires the formation of methylated derivatives of both folate and vitamin B12.

The disease should be considered in any child with stroke, mental retardation, or atraumatic dislocation of optic lenses. Other features include skeletal abnormalities (marfanoid habitus) and premature atherosclerosis and thrombosis. Cerebrovascular accidents account for about one-third of thromboembolic complications. Damage to the endothelium is suspected to be a critical step of the atherosclerotic process. Homocysteine has been shown to directly damage endothelial cells and increase smooth muscle cell proliferation in vitro. Putative factors whereby homocysteine may induce vascular injury further include extracellular matrix modification, lipoprotein oxidation and effects on platelet survival time and coagulation. Mild to moderate elevations of plasma homocysteine have been established as an independent risk factor for extracranial carotid artery stenosis and cardiovascular complications including stroke.

Early diagnosis of homocystinuria is critical, as the frequency of clinical complications can be minimized by instituting an appropriate diet and, in some forms of the disease, large daily doses of pyridoxine. Betaine, a methyl donor that recycles homocysteine to methionine, is recommended for those who do not tolerate a methionine-restricted diet and do not respond to pyridoxine. Folate is recommended because of a secondary deficiency. Antiplatelet agents are given to prevent thromboembolic complications. Patients with homocystinuria are at increased risk for surgery and need special perioperative care.

Miscellaneous

A large number of heritable hemoglobinopathies, coagulopathies, and platelet disorders are associated with an

increased risk for cerebrovascular complications. This also applies for heritable forms of cardiac arrythmia, cardiomyopathy, mitral valve prolapse, intracardiac myxoma and hypercholesterolemia. A detailed description of these disorders is beyond the scope of this chapter, but is covered by a number of excellent reviews (Natowicz & Kelley, 1987; Weksler, 1995).

Preventive management of stroke

Gillian E. Mead[1] and Charles P. Warlow[2]

[1] Department of Clinical and Surgical Sciences, University of Edinburgh, Edinburgh, Scotland, UK
[2] Department of Clinical Neurosciences, University of Edinburgh, Edinburgh, Scotland, UK

Stroke is the third most common cause of death worldwide after coronary heart disease and cancer, the most important single cause of severe disability in people living in their own homes in the UK, and consumes almost 5% of health service resources in Scotland. The overall burden of stroke disease could be reduced by improving the outcome of patients with acute stroke, and by preventing both first-ever-in-a-lifetime strokes (primary prevention) and recurrent strokes (secondary prevention).

There are three broad strategies to stroke prevention: reducing the average level of causative risk factors in the whole population (the 'mass strategy' for primary prevention), identifying and treating people at a particularly high risk of stroke (the 'high-risk' approach to primary prevention) and reducing the risk of recurrent stroke in patients with a previous transient ischemic attack (TIA) or stroke (secondary prevention) (Fig. 86.1). The 'mass strategy' will have very little effect on an individual's own risk of stroke, but the overall effect in population terms is large (Figs. 86.2 and 86.3). Conversely, the 'high-risk' and 'secondary prevention' strategies may reduce an individual's risk of stroke by a substantial amount, but will have rather little impact on the frequency of stroke in the population.

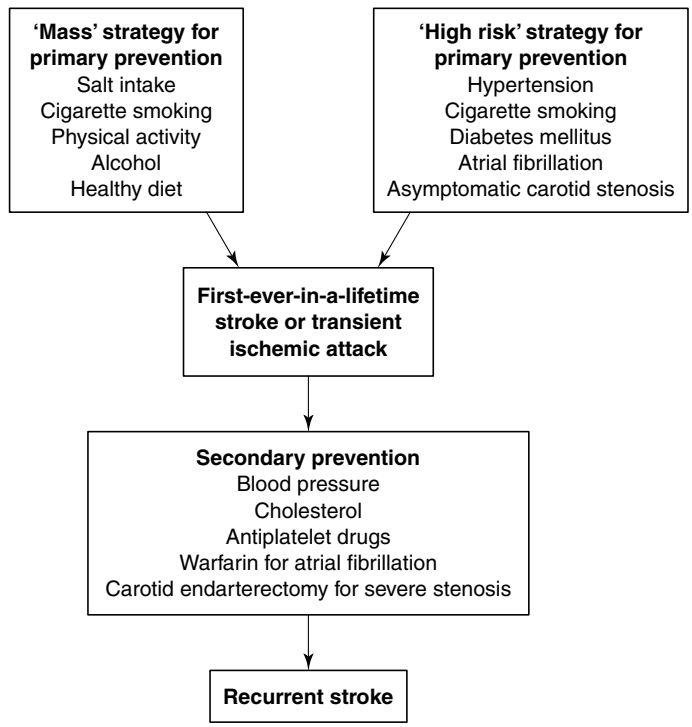

Fig. 86.1. Strategies for reducing the frequency of stroke.

The mass strategy for the primary prevention of stroke

Blood pressure and salt

A modest 5 mmHg reduction in mean population blood pressure could be achieved by reducing the mean daily salt intake in the population by 50 mmol, and this may reduce mortality from stroke by 22% (Law et al., 1991a,b). By reducing salt content of processed foods, a reduction in mean daily intake of 100 mmol could be achieved, which may further reduce the incidence of stroke.

Physical activity

Observational studies suggest that physical activity is associated with a lower risk of stroke, independent of other factors (Wannamethee & Shaper, 1999; Evenson et al., 1999). A systematic review, of largely non-randomized evidence, suggested that exercise programmes for people

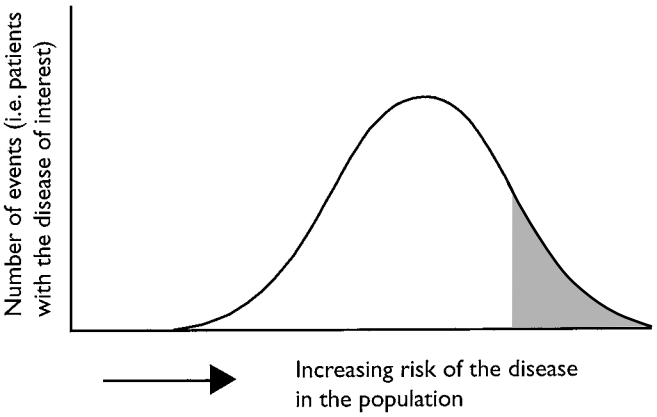

Fig. 86.2. Most cases of a disease occur in people at moderate risk, rather few (shaded) in people at the very highest risk in the right hand tail of a normal distribution.

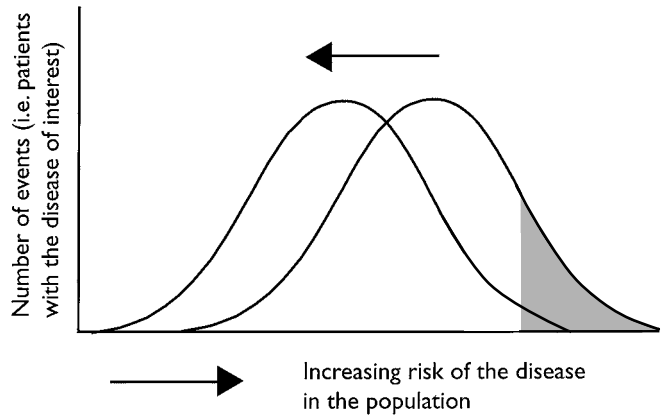

Fig. 86.3. The 'mass' strategy of disease prevention involves a small left shift in the risk distribution, by for example, moving the average blood pressure for the population. This not only reduces the number of people at high risk in the (shaded) tail of the normal distribution but also reduces the number events in the much larger number of people at moderate risk in the middle of the normal distribution.

aged 45 and over might be effective in primary stroke prevention (Nicholl et al., 1994). The benefits are probably mediated by a reduction in blood pressure, weight loss, a change in lipid profile, improved glucose tolerance, and by promoting a lifestyle conducive to other 'healthy' activities (such as reducing cigarette smoking).

Alcohol

High levels of alcohol consumption are associated with high blood pressure, and are also a risk factor for stroke and vascular dementia in a number of observational studies. However, people who drink no alcohol at all are at a slightly higher risk of cardiovascular events (possibly including stroke) than people who drink a modest to a moderate amount of alcohol regularly (Hillbom et al., 1999). Therefore, it is probably sensible to avoid heavy alcohol consumption, but whether this will reduce the risk of stroke or vascular dementia is not known (Hillbom et al., 1999; Mulrow & Jackson, 2000). Complete abstinence may not necessarily be a good idea.

Cigarette smoking

Cigarette smoking increases the risk of stroke by about 50%; and the risk increases with the number of cigarettes smoked per day (Shinton & Beevers, 1989). Cessation of smoking is associated with a reduced risk of stroke, and after five years, the risk of stroke is similar to that of people who have never smoked. Randomized trial evidence of stopping smoking has been impractical to obtain, but the observational studies are reasonably convincing.

Healthy diet and weight reduction

Observational epidemiological studies show that a diet rich in fresh fruit and vegetables is associated with a lower risk of stroke (Ness & Powles, 1999). The average Westerner must make several changes to achieve a healthier diet: reduce the total fat content to no more than 30% of calorie intake; switch from saturated animal fat to unsaturated vegetable fats; increase the intake of vegetables and fresh fruit and dietary fibre; and reduce the consumption of low-residue processed foods. Such a diet is also likely to reduce blood pressure slightly (Mulrow & Jackson, 2000). However, it is unclear whether or not a healthy diet reduces the risk of stroke and other vascular disease; and the role of increased vitamin C and fish consumption is also uncertain.

Long-term aspirin

The risk of stroke and other vascular events in healthy middle-aged people is so low that the risk of serious intra- and extracranial hemorrhage with aspirin may outweigh the potential benefits. Hence, people would get all the (small) risk of treatment and almost no benefit (Sudlow & Baigent, 2000a).

Evaluation and implementation of the 'mass strategy'

The benefits of the 'mass strategy' cannot be evaluated by a randomized controlled trial because it would be impractical to apply the intervention to a random 50% of the population; but the strategy is worth pursuing because it is prob-

ably effective, sensible and presumably safe. Politicians have much more influence than doctors in ensuring that the population adopts a healthy lifestyle (e.g. a ban on tobacco advertising, a reduction in the salt content of processed foods, facilitation of physical exercise, e.g. provision of cycle paths, and a reduction in social deprivation and poverty).

Primary prevention in high-risk individuals

Principles

The 'high-risk' strategy requires the identification and treatment of people at particularly high risk of stroke, e.g. hypertensives, smokers, diabetics, and those in atrial fibrillation or with severe carotid stenosis, by screening everyone in the community or by opportunistic 'case-finding' (for example, by measuring the blood pressure of all adults attending a doctor or nurse for whatever reason). However, even if all 'high-risk' individuals were identified, not all are prescribed treatment, and even if treatment is prescribed, compliance is often poor in people who feel well. A further problem with the 'high-risk' approach is that it is unethical to identify an individual as 'high risk' unless their risk of stroke can be reduced; because the individual will have gained nothing and may even have lost something as a result of being labelled 'sick' (Rose, 1991).

The 'high-risk' strategy is harder to sustain as one attempts to identify and treat people at moderately high risk as well as those at very high risk. The number of people at moderately high risk who would need to be treated to prevent one event is substantially larger than the number of very high-risk individuals who would need to be treated, which means that the treatment becomes less cost-effective. For example, the absolute risk of stroke is higher in elderly hypertensive people than in middle-aged hypertensive people. This means that treatment of elderly hypertensive people saves both strokes and money, whereas it costs several thousand US dollars to avoid one stroke in a middle-aged women with mild hypertension (Asplund et al., 1993).

Blood pressure lowering and primary stroke prevention

Antihypertensive drugs for primary stroke prevention amongst patients with moderate to severe hypertension have been evaluated in trials which have recruited almost 50 000 individuals. Conventional antihypertensive drugs reduced the relative risk of stroke by about 38%, with most of the benefit becoming apparent within a year or two of starting treatment (Collins & MacMahon, 1994; MacMahon & Rodgers, 1994a,b).

However, even if treatment were given to all those people with a systolic blood pressure of 160 mmHg or more, irrespective of their absolute risk of stroke, then stroke incidence would be reduced by only 15%. In practice, the actual effect of blood pressure lowering on stroke incidence will be far less, because of practical difficulties in identifying and treating all hypertensive people in the community and lack of compliance by people who feel well without treatment. It has been suggested that only about half of all people with hypertension in the community are identified; of those identified, only half are treated, and of those who are treated, only half have well-controlled hypertension (Bannan et al., 1991).

Reduction in dietary salt has substantial promise as an effective means of blood pressure control in 'high-risk' individuals as well as populations (Frost et al., 1991; Law et al., 1991a,b). It therefore seems reasonable to advise hypertensive people to reduce their dietary salt intake.

Aspirin for individuals with symptomatic vascular disease

Antiplatelet drugs reduce the relative risk of stroke and other 'vascular events', e.g. myocardial infarction or vascular deaths, by about 25% in patients with a history of symptomatic vascular disease such as myocardial infarction, angina, or intermittent claudication, even if they have not had a previous stroke or TIA (Antiplatelet Trialists' Collaboration, 1994; Antithrombotic Trialists Collaboration (ATT), 2001) (Fig. 86.4) (see p. 1418).

Atrial fibrillation and primary stroke prevention

Non-rheumatic atrial fibrillation (AF) is associated with an increased risk of stroke by a factor of five and is present in about 15% of patients with acute stroke (Wolf et al., 1978, 1991). Its prevalence increases with age, so that almost 9% of people between the ages of 80 and 89 are in AF (Wolf et al., 1991). A meta-analysis of all the available data from five randomized trials demonstrated that, after exclusion of the small number of patients who had suffered a previous stroke or TIA, oral anticoagulation (International Normalised Ratio, INR between 2.0 and 2.6) reduced the risk of ischemic stroke, all stroke, all disabling or fatal stroke and the combined endpoint of all stroke, myocardial infarction and vascular death by between one-half and two-thirds (Benavente et al., 2000a) (Fig. 86.5). The observed rates of intracranial and extracranial hemorrhage were not significantly increased by oral anticoagulants, but confidence intervals were wide.

There are people with AF who are at particularly high risk from stroke, e.g. those with a history of hypertension, diabetes mellitus, coronary heart disease, congestive cardiac

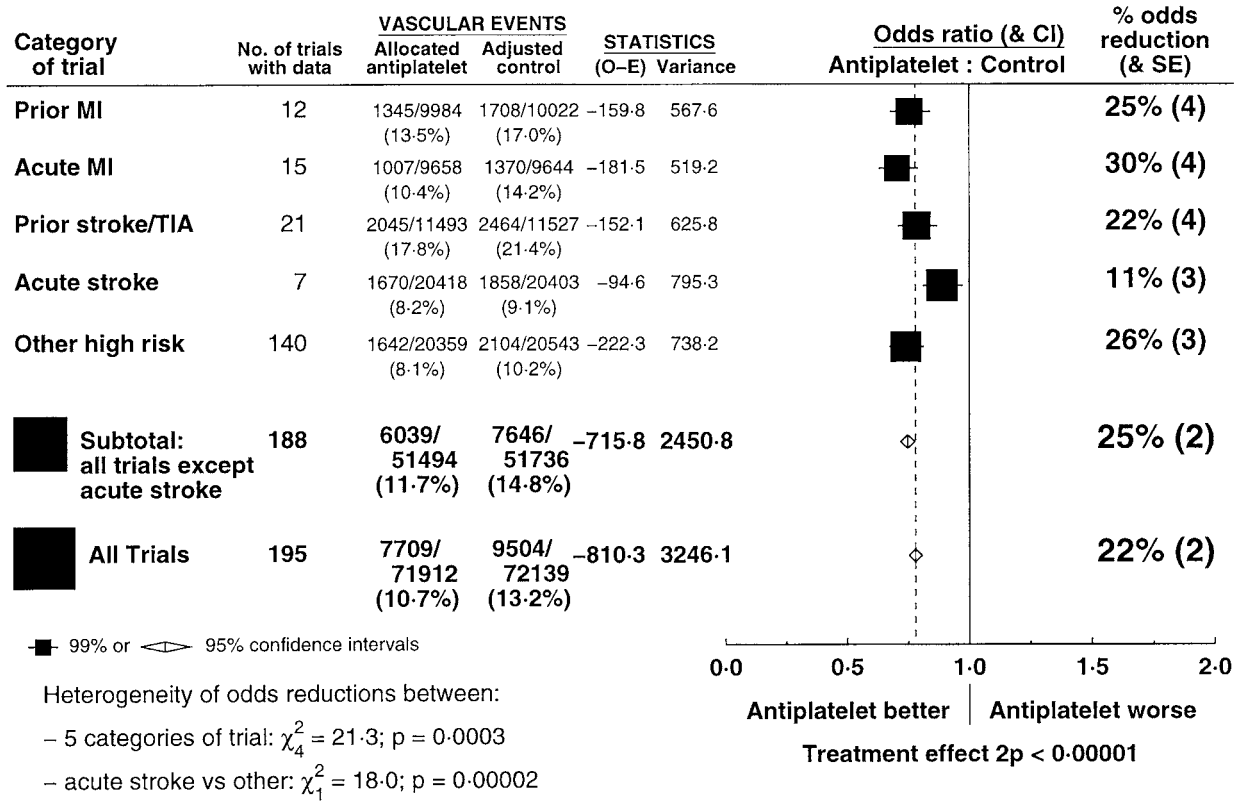

Fig. 86.4. Proportional effects of antiplatelet therapy on serious vascular events in 198 trials of antiplatelet therapy vs. control subdivided by type of patient; MI, myocardial infarction. In most trials, patients were allocated roughly evenly between treatment groups, but in some, more were deliberately allocated to active treatment; to allow direct comparisons between percentages having an event in each treatment group, adjusted totals have been calculated after converting any unevenly randomized trials to even ones by counting control patients more than once. Statistical calculations are, however, based on actual numbers from individual trials. The ratio of the odds of an event in the treatment group compared with that in the control group is plotted for each type of patient (black square: area proportional to amount of statistical information contributed by trials) along with its 99% confidence interval (horizontal line). Stratified overview of results of all trials (and 95% confidence interval) is represented by open diamond, indicating an odds ratio of 0.78 (SD 0.015) or, equivalently, an odds reduction of 22% (SD 1.6%) (With permission from Antithrombotic Trialist's Collaboration, 2000 and the *British Medical Journal*).

failure and age >75 (Hart & Benavente, 1999) (Table 86.1). 'High-risk' patients with AF have more to gain in absolute terms from anticoagulation compared with 'low-risk' patients such as young people with lone AF, i.e. without underlying heart disease. Therefore, the absolute risk of stroke should be taken into account when deciding which individual patients to anticoagulate.

Despite the evidence that anticoagulation reduces stroke risk, not all eligible patients receive it (Bath et al., 1993; Sudlow et al., 1997). The reasons are complex, but include concerns about the applicability of the trial results to patients in the community, the feasibility of monitoring anticoagulation in such a potentially large number of patients, and the long-term safety of warfarin (Sweeney et al., 1995).

The role of aspirin in primary prevention for AF

A systematic review of trials comparing antiplatelet drugs with placebo (1680 patients) in patients with non-rheumatic AF and no previous stroke or TIA found that aspirin resulted in a non-significant reduction of about 20% in the risk of ischemic stroke, all strokes, all disabling/fatal strokes and the combined endpoint of stroke, MI or vascular death. (Benavente et al., 2000b). About 10 strokes would be prevented annually for every 1000 patients given aspirin. Hence,

Table 86.1. Annual risk of stroke in patients with non-valvular atrial fibrillation

Risk group	Untreated (%)	Aspirin (%)	Warfarin (%)	Number-needed-to-treat[a]
Very high				
Previous ischemic stroke or transient ischemic attack	12	10	5	13
High				
Age over 65 and one other risk factor:	5–8	4–6	2–3	22–47
Hypertension				
Diabetes mellitus				
Heart failure				
Left-ventricular dysfunction				
Moderate				
Age over 65, no other risk factors	3–5	2–4	1–2	47–83
Age under 65, other risk factors				
Low				
Age under 65, no other risk factors	1.2	1	*ca.*0.5	200

Notes:
[a] Number-needed-to-treat with warfarin instead of aspirin for one year to prevent one stroke.

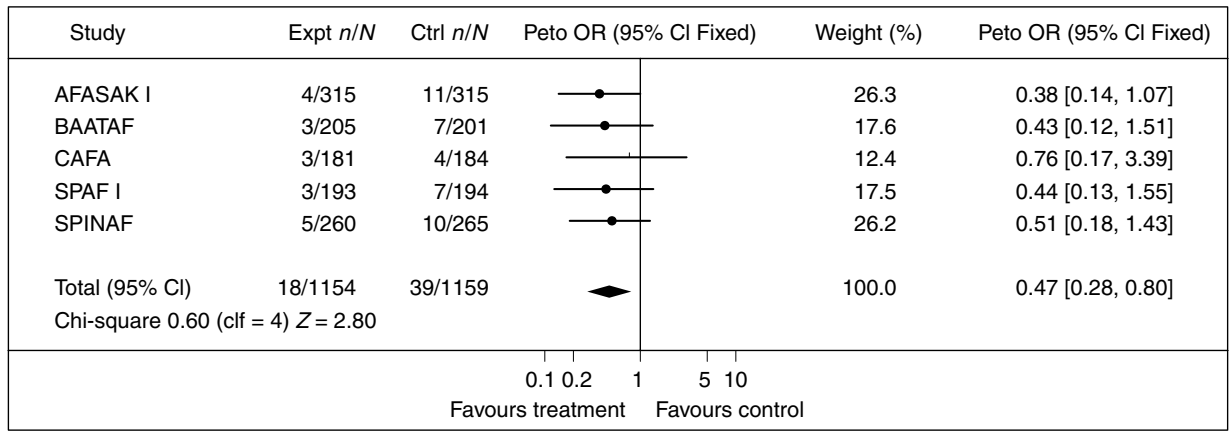

Fig. 86.5. Oral anticoagulants for preventing stroke in patients with non-valvular atrial fibrillation and no previous stroke or transient ischemic attack. The outcome is all disabling or fatal ischemic stroke or intracranial hemorrhage. Each trial result is illustrated by a horizontal line (95% confidence interval) and a box (estimated relative reduction in odds of disabling or fatal stroke). The pooled odds ratio of 0.47 and its confidence interval are represented by a black diamond. (With permission from Benavente and Update Software 2000a.)

aspirin is less effective than warfarin, but is worth prescribing to patients where warfarin is contraindicated (Table 86.1).

Lowering plasma cholesterol and primary stroke prevention

Prospective observational studies among healthy middle-aged western populations have shown no overall association between blood total cholesterol and stroke risk (Prospective Studies Collaboration, 1995), but the lack of an overall association may conceal a positive relationship with ischemic stroke and a negative relationship with hemorrhagic stroke. Non-statin drugs do not reduce the risk of fatal or non-fatal stroke, but statin drugs (which cause a much larger reduction in plasma cholesterol) do reduce the risk of non-fatal stroke. However, they increase the risk of

fatal stroke by 17% (non-significant), perhaps a surrogate marker that statins increase the risk of hemorrhagic stroke which is more likely to be fatal than ischemic stroke (Hebert et al., 1995, 1997; Sudlow & Baigent, 2000a).

We tend to prescribe statins to patients with symptomatic coronary heart disease who have a total cholesterol of >5 mmol/l, as this will certainly reduce the risk of future cardiovascular events, and will probably reduce the overall risk of stroke as well.

Diabetes mellitus

Diabetes mellitus is associated with an increased risk of stroke. The final results of a multicentre study of over 4000 patients with type II diabetes demonstrated that 'intensive blood–glucose control', with sulphonylureas or insulin therapy to maintain a median HBA_{1C} of 7.0%, reduced the risk of any diabetes-related endpoint, including both microvascular and macrovascular complications (relative risk 0.88 (95% CI 0.79–0.99) compared with 'conventional treatment' (diet only) (UKPDS Group 1998a). However, there was no effect on the incidence of stroke (relative risk 1.11, 95% CI 0.81–1.51). A separate publication described the effect of tight blood pressure control (target level <150/85mmHg) with captopril or atenolol in the 1148 patients with hypertension (UKPDS Group, 1998b). There was a reduction in the risk of diabetes-related endpoints (RR 0.76, 95% CI 0.62–0.92) and the risk of stroke (RR 0.56, 95% CI 0.35–0.89) in patients randomized to 'tight blood pressure control'. Therefore, controlling blood pressure in patients with type II diabetes is probably more important than 'tight glucose control' in the prevention of diabetic complications and stroke.

Endarterectomy for asymptomatic carotid stenosis

Carotid endarterectomy reduces the risk of stroke (plus all perioperative strokes or deaths) in patients with a >50% asymptomatic carotid stenosis by almost two-thirds (Benavente et al., 1998). This relative risk reduction sounds impressive, but the annual risk of stroke without surgery in people with severe stenosis is only around 2% (Warlow, 1995); therefore the absolute risk reduction is only about 2% in 3 years (Benavente et al., 1998). It follows that the cost-effectiveness of surgery for asymptomatic carotid stenosis is highly questionable; about 50 patients must be operated on to prevent one having a stroke in 3 years. Nonetheless, some advocate screening for asymptomatic carotid stenosis and then offering surgery to those fit for surgery (perhaps under the age of 80 years). However, this would be extremely expensive, and even if surgery was done on all those aged 50–79 years, stroke incidence would only be reduced by about 6% in the next year, and maybe by a similar amount in each subsequent year.

Unless subgroups of particularly 'high-risk' patients can be identified, we would not recommend screening for asymptomatic carotid disease, because there is so little benefit of surgery for individual patients, and because surgery will have so little impact on the incidence of stroke in the population. Also, there are not enough resources to operate on everyone with an asymptomatic stenosis.

Other interventions

A systematic review of all epidemiological studies investigating the relationship between homocysteine and the risks of cardiovascular and cerebrovascular disease found that elevated total homocysteine levels were associated with an increased risk of coronary artery and cerebrovascular disease in cross-sectional population and case-control studies, but most prospective studies found a smaller or no association (Christen et al., 2000). Hence, it is uncertain whether or not elevated homocysteine levels cause cardiovascular and cerebrovascular disease. Further studies are required to investigate whether or not a reduction of total homocysteine levels is followed by a reduction in the risk of atherothrombotic vascular disease; and randomized trials of multivitamin therapy (to reduce homocysteine levels) are in progress (Hankey & Eikelboom, 1999).

Secondary prevention of stroke

Principles

Stroke physicians and neurologists regularly see patients in clinics and hospital wards who have already had TIAs and strokes. Their role is to ensure that these patients receive the best possible advice and treatment to minimize their risk of recurrent events.

The risk of recurrent stroke after a TIA or ischemic stroke is about 10% in the first year, and then about 5%/year. The risk of recurrent stroke following primary intracerebral hemorrhage is uncertain as it has not been well studied. There are some patients who are at particularly high risk from further events following their TIA or stroke, so it is important to ask the question 'What is the risk of another important vascular event in this particular patient?' Prognostic models have been developed to identify which particular patients are at highest risk from recurrent stroke and other vascular events, but these models have yet to be properly validated in independent cohorts of patients (Table 86.2).

Table 86.2. Prediction equation for survival free of stroke, myocardial infarction or vascular death in a patient with transient ischemic attacks

Age in years	Minus 60	Multiplied by 6
Female		Subtract 68
Transient ischemic attack of the eye (amaurosis fugax) only		Subtract 56
Number of transient ischemic attacks in the last 3 months (n)		Add $1.5 \times (n-1)$
Carotid and vertebrobasilar transient ischemic attacks		Add 71
Peripheral vascular disease		Add 84
Residual neurological signs		Add 66
Left-ventricular hypertrophy (ECG)		Add 54
		Total score = y

Divide y by 100 and exponentiate ($e^{y/100}$) = x

Probability of survival free of stroke, myocardial infarction or vascular death:

at 1 years = 0.95^x

at 5 years = 0.79^x

Notes:

Example: 65-year-old woman with five episodes of amaurosis fugax only in last 3 months and ECG shows left ventricular hypertrophy.

	Cumulative score
65–60 years = 5 multiplied by 6	30
Female: subtract 68	−38
Transient ischemic attack of the eye (amaurosis fugax) only: subtract 56	−94
Five transient ischemic attacks in the last 3 months: add $(1.5 \times [5-1])$	−88
Left-ventricular hypertrophy (ECG): add 54	−34
	Total score = −34

Divide −34 by 100 and exponentiate ($e^{-0.34}$)

$= 1/(e^{0.34})$

$= 1/1.4$

$= 0.7$

Probability of survival free of stroke, myocardial infarction or vascular death:

at 1 year = $0.95^{0/7} = 0.96$ or 96%

at 5 years = $0.79^{0.7} = 0.85$ or 85%.

The most common cause of death following a TIA is coronary heart disease rather than recurrent stroke; and patients are also at risk of developing cognitive impairment and vascular dementia. Hence, a physician must also consider how to prevent vascular disease in general as well as stroke, although in practice, broadly similar interventions are usually appropriate.

The risk of recurrent stroke is highest early after the initial event, which means that early assessment and intervention are important. This has implications for adequate provision of outpatient services, including prompt access to carotid Doppler studies.

Treat any specific underlying cause

If a treatable cause for cerebral ischemia is identified, e.g. vasculitis, endocarditis, then specific treatment should be given. In practice, though, this only applies to a very small proportion of patients with ischemic stroke.

Strategies for secondary stroke prevention

These can be divided into two broad categories: risk factor modification which applies to patients with both ischemic and hemorrhagic stroke, e.g. control of blood pressure, and specific interventions, e.g. antiplatelet drugs, anticoagulants and vascular surgical procedures, which apply only to patients with ischemic events.

General risk factor modification

The same advice about 'healthy lifestyles' should be given to patients who have had a previous stroke or TIA as to those who have not experienced vascular events. Because

patients who have had a stroke are at much higher risk of another one compared to the risk of a first stroke in the general population, their absolute benefit from risk factor control is considerably higher. The effect of exercise on the risk of recurrent events is uncertain, but it is reasonable to suggest that, after a stroke, patients should be encouraged to return to normal physical activities. Even though the levels of physical activity likely to reduce the risk of further vascular events may not be achievable, exercise may bring other benefits such as reducing the risk of falls (Campbell et al., 1998; Gillespie et al., 2000).

Blood pressure reduction

Although the role of blood pressure reduction in the primary prevention of stroke is well established, its effect on reducing the risk of recurrent stroke is less clear. A systematic review of the data from 2742 patients from the two trials of blood pressure reduction in patients with ischemic stroke, and the two trials where beta-blockers were used to prevent recurrent events, found a relative reduction in the risk of stroke of 19%, which was not statistically significant (MacMahon & Rodgers, 1994a,b, PROGRESS Management Committee, 1996). Since then, a large placebo-controlled trial in China of blood pressure reduction with the diuretic indapamide in 5665 stroke survivors (some of whom were 'normotensive') published a preliminary report suggesting that the treatment achieved a reduction of 2 mmHg in diastolic blood pressure over two years which was associated with a 29% reduction in stroke risk (PATS Collaborating Group, 1995).

Long-term blood pressure reduction after stroke may not be beneficial because in theory this may precipitate a further stroke. A large trial evaluating the balance of risks and benefits of blood pressure reduction in TIA and stroke survivors is attaining completion, the Protection against Recurrent Stroke Study (PROGRESS) trial (PROGRESS Management Committee, 1996). Until the results are available in 2001, we tend not to treat patients unless their blood pressure exceeds about 160/90 mmHg. We usually delay initiation of treatment after stroke for at least one or two weeks as drops in blood pressure shortly after a TIA or stroke may have adverse effects on cerebral blood flow.

Cholesterol

In patients with and without a history of ischemic heart disease, statins reduce the risk of stroke (Hebert et al., 1997). However, it is unclear whether cholesterol reduction in patients following a TIA or ischemic stroke is also beneficial: ongoing trials will provide further information. In the meantime, we prescribe statins to patients with an elevated cholesterol who also have a history of ischemic heart disease.

Antiplatelet drugs

In patients with a history of past ischemic stroke or TIA, antiplatelet drugs reduce the risk of vascular events from about 22% to about 18%, equivalent to the avoidance of 38 serious vascular events per 1000 patients treated over about 3 years (Antiplatelet Trialists' Collaboration, 1994). In an overview of the long-term trials, hemorrhagic strokes occurred in 0.5% of controls and 0.6% of treated patients (Antithrombotic Trialists' Collaboration, 2000), but this small but definite hazard is outweighed by the reduction of recurrent ischemic stroke, both in the acute phase of stroke, and in long-term secondary prevention.

In the Antithrombotic Trialists' (ATT) review, aspirin was the most extensively tested drug. The data suggest that doses of less than 75 mg may not be as effective as doses of between 75 mg and 300 mg. Our preferred dose of aspirin is 75 mg daily, which probably minimizes the risk of adverse effects and is as effective as higher doses. Most of the trials evaluating aspirin in high-risk patients lasted only 2 or 3 years (Antiplatelet Trialists' Collaboration, 1994). The benefits of continuing aspirin beyond this period have not been evaluated formally, but it seems sensible to suggest that individuals who are at continuing high risk because of past stroke or TIA should probably continue aspirin lifelong, provided there are no adverse effects.

If a patient continues to have vascular events while on aspirin, it is worth checking whether the clinical diagnosis is correct, e.g. are these events really TIAs, or could they be focal seizures, whether other vascular risk factors are being optimally managed, and whether the patient is complying. If all these have been checked, some clinicians increase the dose of aspirin, whilst others change to a different antiplatelet drug or add another one. At present, there is no evidence that, for patients in sinus rhythm, anticoagulation is better than aspirin alone, but in patients who are having very frequent TIAs on aspirin, we tend to use heparin, then warfarin, at least for a few weeks.

The thienopyridines, ticlopidine and clopidogrel, inhibit the binding of adenosine diphosphate (ADP) to its receptor on platelets. Forty-five trials comparing ticlopidine with control, recruiting 7600 patients, have been completed. Ticlopidine reduced the relative odds of a serious vascular event by 31% (95% CI, 18%–42%) (Antithrombotic Therapy Trialists' Collaboration, 2000). Although there are no trials comparing clopidogrel with control, the data are consistent with both drugs being effective (Hankey et al., 2000).

Four trials (22 656 high vascular risk patients) have compared ticlopidine or clopidogrel with aspirin. There was an overall reduction in the relative odds of a serious vascular event of 9% (95% CI 2–16%) (Hankey et al., 2000). The *Drug and Therapeutics Bulletin*, an independent UK publication which reviews new treatments, concluded 'clopidogrel appears to offer little or no advantage over aspirin' (Anon, 1999). Furthermore, clopidogrel is very much more expensive than aspirin. The role of adding clopidogrel to aspirin is uncertain, but further trials (if performed) may resolve this issue.
