Autism and autistic spectrum disorders

Barry Gordon

Division of Cognitive Neurology, Department of Neurology The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Autism is a neurodevelopmental disorder characterized by the early (before 3 years of age, if not earlier) presentation of deficits in social abilities (and in all abilities that depend upon social abilities) and language (delays and/or inappropriate use) and by repetitive behaviours or apparent obsessions. Approximately 70% of individuals with autism are mentally retarded, and nearly 50% of cases never develop useful speech. These disturbances are lifelong, although they may be modified by education, by circumstances, and perhaps by maturation. Autism is surprisingly common, with an incidence of approximately 1/1000. Although first described in 1943 by Kanner (1943) and in 1944 by Asperger (1944), it came under far more intense scrutiny and saw greater public awareness beginning in the 1970s. Milder forms have been recognized, other conditions (such as the general categories of 'developmental language delays' and 'mental retardation') are now being appreciated as frequently harbouring the diagnosis of autism, and individuals with autism are being more publicly visible, and even in some cases speaking out on their own behalf (e.g. Grandin & Scariano, 1996).

Nevertheless, autism is a confusing condition to many health care professionals. The term 'autism' is confusing partly because its characteristic deficits, in social abilities, communication and language use, and in the flexibility and spontaneity of behaviour, are all domains that are often difficult to assess without a detailed history from good observers, and in which a wide range of normalcy (in development tempo or degree of achievement) is generally allowed. The diagnosis of autism is also confusing to many because the term does not really apply to a single condition or even to a spectrum of severity along a single dimension of disease features. Instead, it describes a set of multidimensional clinical entities that differ in both their specific pattern of features and in the severity of each feature. The term can be used to characterize an award-winning mathematician (Baron-Cohen et al., 1999) as well as a mute, severely retarded child who spins in a corner by himself all day long. Whether such cases have a unifying neurobiologic basis is not yet known. Therefore, the diagnosis of autism is still based on an imperfect phenomenology, not on neurobiology. Because diagnostic standards have also varied over time and across different researchers and clinicians, older data on 'autism' have to be interpreted with caution, whereas information about conditions such as 'childhood schizophrenia' and many examples of 'mental retardation' and 'idiot savants' must now be reinterpreted as possible examples of autistic disorders. Therefore, there is less certain knowledge than one would like about such a relatively common, and frequently devastating, lifelong condition. This chapter will summarize what is reasonably well known or can be reasonably inferred about this condition or conditions, leaving many aspects of the controversies underlying these summaries to the more primary literature. Filipek et al. (1999) review the status of different diagnostic entities and diagnostic criteria and processes. Cohen and Volkmar (1997), Wetherby and Prizant (2000), and Accardo et al. (2000) are recent book-length treatments. Recent general reviews include those by Rapin (1997), Happé and Frith (1996), Minshew et al. (1997), and Bailey et al. (1996), with Ciaranello and Ciaranello (1995) focusing on neurobiology. Piven (1997) and Ingram et al. (2000) review the current knowledge of the genetics of autism. Recent reviews of treatment options include, for behaviour, Heflin and Simpson (1998), Howlin (1998), and Koegel and Koegel (1995), with Zimmerman et al. (2000) reviewing pharmacologic options. Gordon (2000) gives a theoretical overview of the strategies for behavioural treatments and possibly for pharmacological ones as well. Outcome studies have been summarized by Nordin and Gillberg (1998). Sperry (2001) presents the illustrative stories of ten autistic children, followed from childhood through adulthood.

Table 28.1. Diagnostic Criteria for 299.00 autistic disorder

A. A total of six or more items from (1), (2), and (3), with at least two from (1) and one each from (2) and (3)	(1) Qualitative impairment in social interaction as manifested by at least two of the following:	(a) Marked impairment in the use of multiple non-verbal behaviours such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction (b) Failure to develop peer relationships appropriate to developmental level (c) A lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g. by a lack of showing, bringing, or pointing out objects of interest) (d) Lack of social or emotional reciprocity
	(2) Qualitative impairments in communication as manifested by at least one of the following	(a) Delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication, such as gesture or mime) (b) In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others (c) Stereotyped and repetitive use of language or idiosyncratic language (d) Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
	(3) Restricted repetitive and stereotyped patterns of behaviour, interests, and activities, as manifested by at least one of the following	(a) Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus (b) Apparently inflexible adherence to specific, nonfunctional routines or rituals (c) Stereotyped and repetitive motor mannerisms (e.g. hand or finger flapping or twisting, or complex whole-body movements) (d) Persistent preoccupation with parts of objects
B. Delays or abnormal functioning in at least one of the following areas prior to age three years	(1) Social interaction (2) Language as used in social communication, or (3) Symbolic or imaginative play	
C. The disturbance is not better accounted for by Rett's syndrome or Childhood Disintegrative Disorder

Defining symptomatology

Terminology is confusing for autism and for the many named conditions that fall under the same term or that have apparent similarities with aspects of autism (autistic spectrum disorder, pervasive developmental disorder, high-functioning autism, Asperger's syndrome, non-verbal learning disability, Rett's syndrome, childhood disintegrative disorder, childhood schizophrenia). Some confusion has arisen because prior classification schemes were often based upon relatively small samples and were also somewhat prescriptive rather than data driven. More recent approaches have emphasized larger-scale surveys and classifications emerging from data clusters and correlations (e.g. Rapin, 1996).

The DSM–IV–TR (American Psychiatric Association and American Psychiatric Association: Task Force on DSM-IV, 2000) currently provides the most accepted definition and classification of autistic conditions; those definitions are reproduced in Table 28.1. (The ICD-10 [World Health Organization, 1993] definitions are very similar, although there are differences that may be important for research classifications.)

The DSM–IV–TR criteria incorporate three key features that define the condition and its relatives.

A defect in social awareness and understanding

Individuals with autism do not respond to other people the way that normal individuals do. Other people may be ignored or treated as though they were objects, or these individuals may fail to appreciate other people's emotional states, feelings, wants, or desires. While they may show some warmth and friendliness, particularly towards family members, even this is markedly reduced compared to normal. For many reasons, the social deficit seems to be a core characteristic of the condition.

A defect in communication

Individuals with autism frequently have delayed or absent speech or, if they have speech capabilities, often do not use these capabilities to communicate effectively. They appear to be unaware of the social uses of speech.

Repetitive and stereotypical behaviours, or fixed and unusual interests

These three characteristics do have a strong tendency to co-occur; they do not seem to be just an arbitrary collection. Some of the behavioural manifestations of autism do occur in other conditions but, in many ways, as Rutter and Bailey (1993) have pointed out, often appear to be more intrinsic to the autistic condition in affected individuals. Studies of children and adults (Wing & Gould, 1978, 1979; Shah et al., 1982; Rutter et al., 1992) and family studies (Bolton et al., 1994; Bailey et al., 1998b; Piven, 2000) have shown that these types of abnormalities tend to co-occur in the same individuals and in milder form in relatives. Nonetheless, these abnormalities still span a wide variety of individual presentations. Several subtypes of the autistic spectrum have either been identified in the literature or seen to be of practical or perhaps research significance (Zimmerman & Gordon, 2000).

Subtypes

Asperger's syndrome

Individuals whose only real deficits are 'qualitative impairments in reciprocal social interaction' with 'restricted, repetitive, and stereotyped patterns of behaviour, interests and activities' (World Health Organization, 1993), without any delays or impairments in language or cognitive development, are given this label. Frequently, these individuals also have a history of delayed motor milestones and motoric clumsiness. (In some classification schemes, these motor impairments are critical for the diagnosis, although it is not clear why they have to be.) In many ways, individuals with Asperger's syndrome can be considered almost the purest form of expression of an isolated defect in social awareness and interaction. As currently defined, the features of the syndrome of non-verbal learning disabilities have a high degree of overlap with those of Asperger's syndrome (Klin et al., 1995), probably representing a failure of precise differentiation. There are many reasons to believe that deficits in social awareness can exist in relatively pure form, apart from any deficits in other non-verbal domains, such as visuospatial functions.

High-functioning autism

Individuals with autistic features, but who have language capabilities and IQs$>$70 (sometimes, performance IQs$>$70), are in this category. The exact characterization of these individuals is controversial, and the upper boundary (with Asperger's syndrome) and lower boundary (with low-functioning autism) are not very distinct. High-functioning autism is now generally distinguished from Asperger's by a history of language delay, which individuals with Asperger's do not have. However, given that the pace of language development has a relatively wide range in normal individuals, the distinction between high-functioning autism and Asperger's may prove to be more of a quantitative difference in many cases than a qualitative one. Relative to individuals with Asperger's, individuals with high-functioning autism have lower verbal IQs and higher performance IQs (Klin et al., 1995).

Low-functioning autism

Generally, this category is reserved for individuals with autism who have low verbal IQs ($<$70). Fifty to 75% of individuals diagnosed as being autistic fall into this category. Approximately 50% of individuals with autism have not just low verbal IQs, but little or no speech. This category is also not precisely defined, partly because the spectrum of verbal abilities is relatively wide and often not easy to categorize in and of itself. For example, a fair percentage of individuals with autism demonstrate echolalia (Howlin, 1982; Roberts, 1989). Frequently, however, speech comprehension is impaired in such cases. IQ in autism is also not well defined (Lincoln et al., 1995), because these children do not necessarily cooperate on the tests, and because their pattern of disabilities prevents standard IQ tests from tapping more central functions.

Autism following regression

Approximately 20–25% of individuals with autism have a history of initially normal development followed by regression. Most often, the parent reports that the child had been developing words, then ceased to add new words and lost the words that he/she had acquired. This finding, most often reported between the age of 18 months and 3 years, has been difficult to study. To the extent that it has been (Rogers & DiLalla, 1990; Kurita et al., 1992; Tuchman & Rapin, 1997; Volkmar et al., 1997), evidence suggests that the actual phenomena may be more complex. Many, if not all, of these children were slower in word acquisition or had some other developmental abnormality or delay preceding the loss of words. In more than half of these children, the loss of words is accompanied by a change in social responsiveness. Regression does not necessarily predict autism, although the best clinical evidence suggests that the risk of autism with this pattern is quite high.

The reasons for this regression are even less clear than the existence of the phenomenon itself. However, a potentially significant possibility is that these cases represent secondary influences causing the autistic spectrum condition. As a result, this group of individuals is under intense scrutiny for possible immunologic and other exogenous etiologies for the autistic spectrum disorder. The best available current evidence has effectively ruled out an association between immunizations and autism in general (Afzal et al., 2000; DeStefano & Chen, 2000). However, the possibility remains that this group is enriched in secondary causes, for which the search continues.

It was once thought that children with regression otherwise followed the typical course of low-functioning individuals. However, there is now clinical evidence that at least some of these individuals can become higher functioning. Autism following regression is categorized here as a separate subtype not because its outcomes are not already categorized, but because its course may help to identify a different cause or causes than is true in other cases of autism.

Broader autism phenotype

The likelihood that autism does not have sharply defined boundaries and may have milder, fragmentary presentations is supported by the evidence for a broader autism phenotype in the relatives of autistic individuals (Bailey et al., 1998b; Piven, 2000). These relatives show a higher incidence of somewhat similar deficits in cognitive functions (relatively lower performance on verbal but not non-verbal IQ scores, poor performance on tests of reading comprehension, rapid automized naming, and executive function, and deficits in pragmatic language and speech), and problems with social cognition (difficulties in accurate interpretation of others' mental states). They suffer more frequently from affective disorders (major depression and anxiety). Relatives of autistic individuals also show a higher frequency of particular personality characteristics (aloofness, rigidity, hypersensitivity to criticism, and anxiety and a history of fewer close friendships) than do those from families without autism. This evidence suggests that there may be elements of autism that can occur in isolation and with less severity.

Autism likely to be secondary to other disorders

Autism has been reliably associated with several other conditions, such as tuberous sclerosis, and less reliably associated with many others (such as fetal alcohol syndrome) (see Table 28.2). Autism is a frequent consequence of tuberous sclerosis (Smalley, 1998). Sixty to 70% of mentally retarded individuals with tuberous sclerosis are autistic as well, and many of these individuals also have epilepsy (Curatolo et al., 1991; Smalley et al., 1992; Hunt & Shepherd, 1993; Gillberg et al., 1994). Particular involvement of the temporal lobes (Bolton & Griffiths, 1997) or of the cerebellum (Weber et al., 2000) has been claimed to be present in those individuals with autistic features. Autism or autistic-like features have also been reported to occur in 15–25% of individuals with Fragile X syndrome (Dykens & Volkmar, 1997; Bailey et al., 1998c). There are scattered reports of associations with other conditions, as noted in Table 28.2, although all have to be interpreted with extreme caution (Dykens & Volkmar, 1997). Severe physical and social deprivation has also been reported to cause autistic-like behaviours (Rutter et al., 1999).

What is also noteworthy about autism's associations is what it is not associated with. Autism has not been associated with focal lesions, even with perinatal focal lesions. Autism and autistic-like features are not seen in other neurodevelopmental conditions, even those with mental retardation. This relative rarity of autism as a secondary consequence of other conditions is part of the evidence for accepting it as an entity in its own right, as difficult as it may be to try to relate its various aspects.

Epidemiology

Prevalence

The prevalence of autism is approximately 1/1000 (Gillberg & Wing, 1999), although it may be as high as 1/500 or even greater, if relatively mild and more circumscribed deficits are included. The exact incidence and prevalence of

Table 28.2. Suspected etiologies or associations of autistic spectrum disorders

Presumed single gene deficit	*HOXA1*, *HOXB1* (Ingram et al., 2000)
Presumed polygenetic	(thought to be most common) (Szatmari et al., 1998; Piven, 2000)
In the context of otherwise known conditions	Fragile X syndrome (Bailey et al., 1998c) Tuberous sclerosis (Smalley, 1998) Phenylketonuria (?) (Dykens & Volkmar, 1997) Angelman syndrome Down's syndrome (rare; see Dykens & Volkmar, 1997) Turner's syndrome (Creswell & Skuse, 1999)
Structural brain anomalies (including those with known genetics)	Neural migration defects Moebius syndrome Joubert syndrome (Holroyd et al., 1991; Ozonoff et al., 1999) Duane syndrome
Toxins	Thalidomide (Stromland et al., 1994) Valproic acid (Williams & Hersh, 1997) Ethanol (Aronson et al., 1997)
Intrauterine infections	CMV (?) (Gillberg & Coleman, 1992) Rubella (?) (Gillberg & Coleman, 1992)
Perinatal cerebral injury	Anoxia–ischemia Hippocampal sclerosis Herpes simplex
Epileptic syndromes	Infantile spasms Lennox-Gastaut syndrome
Environmental (?)	Suspected, not established

Note:
For sources not otherwise referenced, see Dykens and Volkmar (1997), Ingram et al. (2000) and Rapin (2000).

autism are understandably not completely clear and are also controversial. Such estimates require both an appropriate set of screening criteria and a guarantee that all appropriate screening is performed to adequate standards in all of the potential population. Surveys coming closest to these ideals include those reported from Japan (Gillberg, 1995), Nova Scotia (Bryson et al., 1988), and Sweden (Gillberg & Wing, 1999).

In many school districts, the incidence of autism has given the appearance of rising, much to the concern of parents and school officials, probably not because of any change in the actual incidence of the condition (Fombonne, 2001), but instead because of greater awareness and, in some cases, to families moving into regions with allegedly better school systems.

Male predominance

Males are more commonly affected than females, by a ratio of approximately 4:1 overall (Gillberg & Coleman, 1992). This male predominance seems to be particularly true of Asperger's syndrome, where the male:female ratio has been reported to be as high as 10:1 (Gillberg, 1989). Skuse (Creswell & Skuse, 1999; Skuse, 2000) has suggested an explanation for the male predominance in autism; he has posited that a genetic factor that influences other genetic factors responsible for social behaviours is part of the X-chromosome. This factor is functional only on the paternally derived X-chromosome; it is imprinted on the maternal X-chromosome. The X-chromosome of boys can only come from the mother; hence, they become more susceptible to any other factors impairing the expression of genes related to social behaviour. Skuse and his colleagues (Creswell & Skuse, 1999; Skuse, 2000) have shown, in partial support of this hypothesis, that the individuals with Turner syndrome who show autistic features are those with maternal X-chromosomes.

Causative or risk factors

Genetics

The best available evidence is that most cases (if not all) of autism represent genetic disorders (or a genetic predispo-

sition coupled with as-yet-unknown non-genetic factors) (Bailey et al., 1998a; Szatmari et al., 1998; Maestrini et al., 2000; Piven, 2000). In a comparison of monozygotic twins vs. dizygotic twins, autism was present by strict definition in 36–91% of monozygotic twins but in 0% of same-sex dizygotic twins (Bailey et al., 1995). Using a broader definition of cognitive or social abnormalities, 92% of monozygotic twins were concordant compared to 10% of dizygotic twins. It has been suggested that anywhere from 2–20 interacting genes may be involved in the pathogenesis of autism. The strongest evidence for the identity of any one of these genes (which is also evidence that suggests that only one need be at fault) comes from the recent demonstration that the *HOXA1* gene, or perhaps the *HOXB1* gene, is abnormal in a large percentage of individuals with autism (with the frequency of specific mutations in the autistic group ranging from 21–35% (Ingram et al., 2000)). The *HOXA1* gene has been thought to be responsible for the developmental organization of the hindbrain. If this finding is confirmed, it would provide a clue as to why children with autism not infrequently appear to have motor abnormalities of the face and lower cranial nerves, and perhaps why the mental retardation and other defects associated with autism have a very different pattern from those occurring in most other conditions.

The risk to couples who already have one autistic child of having an additional autistic child has been estimated as anywhere from 1.5% to 10–20%, much greater than the general risk of approximately 0.1% (Piven et al., 1990; Jorde et al., 1990; Bolton et al., 1994). Families considering having more children obviously are interested in having a more precise estimate of risk within this almost tenfold estimated range, but it is difficult to refine the estimate more precisely, partly because of the different inclusion criteria used. Broader inclusion criteria are not necessarily incorrect, because of the existence of the broader autism phenotype referred to earlier. However, this broad autism phenotype does lead to an apparent overestimation of the chances of having a child with autism, because children with milder and/or less pervasive abnormalities are also included.

Non-genetic factors

These factors must exist, because the concordance rate even among identical twins is <100% (estimated at 60%, Bailey et al., 1998b). However, at the current time, there is no reliable understanding of what these non-genetic factors can be or how they may operate. Well-publicized cases of 'clusters' of autistic cases have not been proven to be due to any known environmental agent or combinations of agents. Immunization (Wakefield et al., 1998), and more recently, mercury exposure (Bernard et al., 2000) from the carrier used for immunization has been suggested as the 'cause' or contributors to autism. However, not only have these not been proven, there is considerable negative evidence against them (DeStefano & Chen, 2000).

There have been some promising laboratory models of how autism might be acquired. Pletnikov and his colleagues (1999) have shown deficits in social behaviour in juvenile rats who had neonatal infection with Borna disease virus. Bachevalier and colleagues (1994) have shown that some autistic-like behaviours can be seen in monkeys with neonatal injuries to the medial temporal lobes.

As a precaution to researchers in this area, it is perhaps well to keep in mind that, although autism is now known to be the most genetically determined of all the developmental neurobehavioural syndromes, as recently as 1976, genetics were not thought to have a role (Hanson & Gottesman, 1976). The biases and methodologic flaws that led to this erroneous conclusion need to be kept in mind.

Clinical presentation

Initial clinical presentation

Absent or below-average language development is the most common symptom prompting evaluation of these children, but retrospective clinical reports and research studies have suggested that disorders are apparent much earlier in infancy, perhaps as early as 12 months or even earlier. In research studies, the earliest definable feature separating children who will later be diagnosed as autistic from those who would develop normally has been failure of eye contact (based on retrospective review of videotapes of home movies and tapes) (Werner et al., 2000). In retrospect, parents will often note that the infant did not make normal eye contact, did not follow the parent's gaze or pointing (did not seem to have joint attention), and did not point himself.

Clinically, infants with autism are often reported to be irritable, 'colicky', and poor sleepers. Infants may seem to resist being touched, arching the back on contact, or may be unexpectedly passive to touching or holding, even by complete strangers. Early babbling is not abnormal but may not progress, and first words may be delayed, develop at a slower pace than normal, or even seem to be lost by age 2–2½ (see above, 'Autism following regression'). Gross motor development (sitting, crawling, and walking) is not necessarily delayed, although a minority of autistic children will show delayed gross motor development and, later, clumsiness.

The presentation of autism is dependent upon the severity of the defining autistic deficits themselves and

upon the severity of any other associated deficits in sensory function, motor function, or cognition. Many feel that autism can be reliably diagnosed before the age of 2 in most cases. However, it frequently takes much longer to recognize and to be actionable. In some cases, appreciation of autism is delayed until the child enters preschool or school, when more objective individuals can observe and compare behaviours. In fact, more recent awareness of the full diagnostic criteria has meant that some individuals have not been diagnosed until adulthood, when their pattern of social isolation, lack of social understanding, and inappropriate social behavioural responses are identified as being a manifestation of Asperger's syndrome. Social deficits might well be masked by achievement in other areas and by selective isolation and involvement that does not stress those areas of deficiencies.

Other associated findings or conditions

Although the defining symptoms of autism are behavioural, these individuals frequently have a number of other impairments or peculiarities. Many are listed in Table 28.3, although this is far from an exhaustive list; more complete tabulations and references can be found in the general reviews cited earlier and in Rapin (1996) and Leary and Hill (1996). One important limitation of such a list is that most of the available data cannot give individual correlations. Therefore, it is not known what features are related to other features and which are not. There may be clues to the neurobiology in those patterns, but these have not been studied systematically.

The seizures and EEG abnormalities noted in Table 28.3 deserve special mention. Two or more unprovoked seizures (epilepsy) occur in 20–40% of individuals with autism, particularly low-functioning, non-verbal individuals (Rapin, 1997). Seizures are most common in infancy and next most commonly occur in adolescence.

EEG abnormalities have been reported in even a larger proportion of individuals with autism, particularly when extended recordings are done (Tuchman, 2000). The clinical significance of these EEG abnormalities, in the absence of overt seizures, is unclear. Although aggressive antiepileptic treatment and even surgery have been used in such individuals, there is no compelling biological reason to believe that the EEG abnormalities are the primary cause of any of the symptomatology of autism, and there is no empirical evidence that treatment of these abnormalities *per se* actually results in improvement of autistic conditions. However, both of these possibilities are under continued investigation.

Neurobiology

A number of attempts have been made to identify a fundamental behavioural deficit that underlies the surface manifestations of autism. Suggestions include: 'mind-blindness', or a lack of awareness of other people (Baron-Cohen, 1995); executive disorders (Russell, 1997); failures of higher information processing (Minshew et al., 1997); and a failure of central coherence (Frith, 1989), the normal tendency to make consistent scripts for events and situations. Although each of these seems to explain large portions of the autistic disorder, no grand unified behavioural theory seems to be very plausible; the deficits in autism are too diverse and present at too many levels of the neuraxis (and perhaps somatically as well; see below).

Neuropathologic, structural imaging and functional imaging assessments of individuals with autism have been hampered by the relatively small numbers and, in some cases, atypical features of individuals who either are available for postmortem examination or are compliant with imaging studies. Several cooperating research efforts to collect the brains from individuals with autism and controls will undoubtedly help to correct this situation in the future. At the present time, available data have relatively little internal coherence or consistency. It does seem to be a reliable finding that the brains of autistic individuals are either normal sized or slightly larger than average. What elements of cerebral tissue are responsible for the increased size in these individuals is not known. Abnormalities have been reported by macroscopic and/or microscopic neuropathological studies and/or by imaging studies (structural or functional imaging) in the brainstem, cerebellar vermis, medial temporal lobes, and cortex and subcortical structures (e.g. Courchesne, 1997; Kemper & Bauman, 1998; Bailey et al., 1998a; Aylward et al., 1999; Ohnishi et al., 2000), although with considerable differences of opinion between investigators (see, for example, Courchesne, 1997 and Piven & Arndt, 1995). The variability and inconsistencies do suggest that either the reported abnormalities have nothing directly to do with autism itself or that autism may be a byproduct of damage or dysfunction of many different levels and sites in the nervous system. To the extent that autism is a neurogenetic condition, it is almost certain that the chain connecting expressed symptomatology with the underlying genetic defect or defects is likely to be extremely complex (Caviness, 2001).

What is clear about the neuropathology of autism is that no single focal lesion, or even currently used combination of lesions, can reproduce the symptomatology. Bachevalier et al. (1994) have created animal models for some aspects of autism in neonatal monkeys by bilateral ablation of the

Table 28.3. Autism and autistic spectrum disorders: other associated conditions/findings

Physical characteristics	Macrocephaly
	Mid-facial dysmorphic features (e.g. increased inter-pupillary distance) (Bailey et al., 1995)
	Other morphological abnormalities (Rodier et al., 1997; Walker, 1977)
Gastrointestinal disorders	Constipation and/or diarrhea
Sensory disorders	Apparent heightened sensitivity to sound (hyperacusis)
	Seemingly lowered sensitivity to pain
	Abnormal sensory response, increased to decreased (Rapin, 2000)
Motor disorders	Strabismus (Kaplan et al., 1999)
	Oromotor dyspraxia
	Hypotonia with increased joint mobility
	Dysmetria and intention tremor
	Awkward fine motor movements
	Limb apraxias
	Abnormal postures (hands, head, etc.)
	Toe walking
Other neurologic disorders	Sleep disorders with early night wakening (Hoshino et al., 1984)
	EEG abnormalities
	Seizures
	Impaired eye-blink conditioning
Cognitive/behavioural features	Smelling of food and people
	Gaze avoidance 'looking out of the corner of the eye'
	Spinning without dizziness
	Attentional disorders: difficulty holding attention, difficulty diverting attention (e.g. Courchesne et al., 1994)
	Apparent auditory processing deficits (Rapin et al., 1977)
	Apparent relative or absolute superiority (Happé & Frith, 1996) in:
	Visual perception
	WAIS Block design subtest
	Drawing
	Jigsaw puzzles
	Perfect pitch (Heaton et al., 1998)
	Music
	Rote memory
	Lightning calculations
	'Executive function' disorders: disorders of planning, strategy and attention (see above)
	Self-injurious behaviour
	Violence or aggression (goal-directed, or accidental)
	Repetitive, stereotypical behaviours

Notes:
For sources not otherwise referenced, see Happé and Frith (1996), Rapin (1997).

hippocampus, amygdala, or associated structures. This research is encouraging because it also begins to address the issue that lesions in early life may interrupt or redirect development, in addition to whatever deficits for which they may be directly responsible. Certainly, many individual components of the autistic condition can be seen behaviourally in focal brain lesions, even in adults, or seem to occur in other developmental disorders, such as attention–deficit–hyperactivity disorder or Tourette's syndrome, and severe learning disabilities. However, despite these superficial similarities, it remains to be seen whether the seemingly identical overt behavioural abnormalities are caused by the same underlying behavioural impairments or malfunctions.

Although many biochemical and neurotransmitter systems have been considered as possible causes or

contributors to the autistic deficit(s) (Cook, 1990), none have been reliably found to be abnormal, and no treatment of any putative transmitter system has yet been found to be of positive benefit.

Rett's syndrome (Bibat & Naidu, 2001), which has recently been identified as being caused by a mutation of a specific gene (Amir et al., 1999), the methyl-CpG-binding protein-2 gene (*MECP2*) on the X-chromosome, is an instructive example of the behavioural–neurobiologic correlations to be expected for autism. The condition primarily affects girls of all ethnic groups. Initially, there is stagnation of cognitive development, then profound motor and cognitive regression, then partial recovery and stability. Among the behavioural features that Rett's syndrome has in common with autism are loss of language functions, loss of fine motor functions, stereotypic hand movements, constipation, and seizures. (This list is selective; many somatic and neurologic features of Rett's syndrome are not typically seen in autism.)

The *MECP2* gene has been found to have 78 mutations so far in known Rett's syndrome cases (Shahbazian & Zoghbi, 2001). It is now appreciated that there are very mild cases as well as extremely severe cases (probably lethal in most hemizygous males) (Shahbazian & Zoghbi, 2001). Finally, even though the gene is widely expressed throughout the body, the bulk of pathology caused by the mutations seem to be confined to the central nervous system. Even more specifically, the neuropathologic abnormalities that have been described, selective vulnerability of the zona compacta of the substantia nigra, the nucleus basalis of Meynert, the caudate, frontal lobes, and cerebellum, and a distinctive pattern of cerebral cortical abnormalities (Bibat & Naidu, 2001), cannot be easily related to fairly prototypical signs of classic Rett's syndrome. Therefore, Rett's syndrome is further evidence that there must be a bidirectional perspective on these conditions, from the genes up to the neuropathology and behaviour, and from the behaviours and behavioural abnormalities down to the genes, if we are to hope to have a unified account of the neurobiology of these conditions (Caviness, 2001). The situation for autism is likely to be no less complex than that for Rett's syndrome.

Diagnosis

Guidelines for the diagnosis of autistic spectrum disorders have recently been accepted by a number of professional bodies (Filipek et al., 1999, 2000); guidelines are available on the Web (www.aan.com/public/practiceguidelines/autism.pdf). These guidelines divide the diagnosis into an initial screening phase, followed by more specific assessment for individuals identified as high risk for autism or related developmental disorders by the screen. The guidelines for screening reflect in part an increased awareness that developmental delays or idiosyncrasies need to be taken seriously in many cases; children do not necessarily 'grow out of them', as folklore may have taught. Moreover, earlier diagnosis needs to be encouraged because it is likely that, the earlier the intervention, the more positive the eventual outcome.

Several studies have demonstrated that, if a parent expresses concern about a child's development, they are almost always correct; such concerns need to be taken seriously. It is also the case, however, that many parents are not aware or concerned about even apparently obvious developmental delays. Therefore, the physician and health care provider need to have a high suspicion for such abnormalities, even in the absence of parental reports.

One practical problem in making a diagnosis is that the relevant information and assessments are not available at a single time but may be spread out over weeks to months. A related problem is that the relevant information is often in the possession of separate individuals and professions. A speech pathologist may note delayed speech. An occupational therapist may note clumsiness. Parents will realize that the child does not seem to play appropriately and does not have social contact, even with familiar family members. Often, these various observations are treated in isolation without realizing their common origin and interdependent significance.

One important diagnostic quandary is the child who has some features of autism or elements of autistic-like behaviour or dysfunction but does not meet full criteria for autism. Some such individuals seem to overcome these handicaps. Others will express them more persistently and more clearly, and will be more easily classified as autistic. However, regardless of the particular label, each of these elements or dysfunctions is itself a deficit that needs to be addressed by the child's medical and educational system.

Autism is a diagnosis that can be made with a fair amount of certainty, depending on the information base, the severity of the disorder and associated conditions, and the child's age. Moreover, in addition to the diagnosis itself, outcome predictions can be refined by observing the child's response to therapeutic intervention. Outcome itself is probably better, the earlier the intervention. Therefore, overall, it is better for a child to have suspicions aired and to have the appropriate medical and educational mechanisms engaged as early as possible.

Treatments

Autism cannot yet be 'cured' in the way that some other conditions can be cured and eliminated. Given the increasing evidence as to the fundamental nature of autism, it is unlikely that it will be possible to reverse the underlying neurobiologic deficits once they have had a pervasive influence on the developing brain. However, although features of the autistic spectrum disorders are essentially lifelong, this does not mean that they cannot be ameliorated in some way, either by treating the individual or by altering the individual's environment. Behavioural techniques and, to a lesser extent, pharmacological treatments, can improve some aspects of the functioning and adjustment of these individuals.

Behavioural treatments

Even though the basic neurobiologic deficit(s) in autism are not known, there are some basic principles that should guide behavioural treatment attempts (see also Gordon, 2000). Human beings normally have a variety of processes available to them for effecting change in the nervous system as a result of experience, existing at many different neural levels and time scales (Posner et al., 1997). One way of categorizing these processes of learning for behavioural purposes is as follows: at the most basic, least-demanding level, passive correlations can often extract considerable information from the environment, without the necessity for feedback, reward, punishment, or expectation. However, adding feedback, even in just basic rewards or punishments (e.g. food or the withholding of food) vastly increases the rate of learning. This reward/punishment feedback mechanism seems to be a fairly basic and pervasive one; it is evident in non-human animals, and in infants and young children. Some animals, and human children, also have the ability to learn through imitation. Finally, the most complex and subtle forms of learning are perhaps those which are accomplished by mental prediction, assessment of consequences, and selected actions, in essence, fast forwarding different scenarios and examining how they might turn out. The normally functioning human being has all of these mechanisms available to him or her, and all are typically used in almost every learned activity. For example, although learning to play video games involves conscious thought for tactics and strategy, winning or losing activates fundamental learning circuits, and basic perceptual and motor skills are more finely honed by practice, regardless of whether the game is won or lost.

From this perspective, individuals with autism may fail to learn for a large number of reasons: they may lack the perceptual, motoric, or conceptual abilities to understand basic functions and concepts; they may lack the executive abilities necessary to allocate their attention and their efforts; and they may lack the social awareness and needs that help motivate learning. To try to overcome these problems requires exactly the same types of strategies as are used for learning and teaching in general, except they have to be adapted to the narrower abilities of these children, the shorter conceptual leaps that they can take, and to their more constricted motivations. Behavioural treatments can, therefore, logically try to simplify the environment of the child on the one hand and increase the child's capabilities for dealing with that environment on the other.

Although these principles seem fairly straightforward, in the current educational environment, there have actually been a large number of different methods for teaching and training proposed, including Discrete Trial Training (the Lovaas method: Lovaas et al., 1971), the TEACCH method (Schopler et al., 1993; Schopler & Mesibov, 1994), pivotal behaviours (Koegel & Koegel, 1995), floor play (Greenspan, 1992; Greenspan & Wieder, 1998), the Eden method (Holmes, 1997), the Walden approach (McGee et al., 2001), and others (Handleman et al., 2001). There is evidence for the effectiveness of many if not all of these approaches (e.g. Helfin & Simpson, 1998; Howlin, 1998; Rogers, 1998; Sheinkopf & Siegel, 1998; Ozonoff & Cathcart, 1998). However, these various approaches do differ in a number of fundamental assumptions: in the level of functioning (or of functions) for which they are most appropriate; in their basic philosophies as to which are the core or fundamental deficits to be addressed first; and in their adopted methodologies for achieving behavioural changes in those particular functional deficits. Understanding these differences can help identify which approach is best for which child.

Assignment of fundamental deficits

As an example of philosophic differences, the explicit position espoused by Greenspan (1992) might be contrasted with the implicit positions of applied behavioural analysis and discrete trial training approaches (e.g. Lovaas & Taubman, 1981). For Greenspan, 'The primary goal of intervention is to enable children to form a sense of their own personhood, a sense of themselves as intentional, interactive individuals' (Greenspan, 1992). In the applied behavioural analysis tradition, these children have deficits in a number of specific skills. Training is, therefore, directed at improving the specific skills, presumably in the hope that they would coalesce into a better-functioning, complete human being. The evidence from neurobiology would seem

to lend more weight to the implicit applied behavioural analysis position, in that it is generally assumed, with much evidence supporting this, that our mental abilities (including perhaps even our sense of self) are, in fact, a collection of much more specific, discrete, and relatively independent underlying mental functions. If not all of those discrete abilities are present, then normal complete 'personhood' cannot be expected to be achieved. (Autism itself provides examples of how some specific functions can be impaired, while others can be relatively spared.) However, despite this seeming contrast in starting positions, Greenspan's own approach seems to also be focused upon specific functions and abilities (Greenspan & Wieder, 1998), albeit those thought to underlie the development of personhood, and those whose learning can be capitalized upon through special situations and interests in each particular child. This partial convergence of methodologies is perhaps another reason why a comparison of these methods is so confusing for parents and teachers alike.

Methods for achieving behavioural change

Specific methods that have been endorsed range from teacher-imposed, single-trial-at-a-time learning, with rewards (or withholding of rewards) (e.g. Lovaas & Taubman, 1981), to using the child's own spontaneous interests and actions as the basis for instruction (e.g. Greenspan & Wieder, 1998).

From the general perspective on learning discussed above, the ideal learning situation for each individual with autism is not so much a matter of a particular philosophy, but instead, identifying the particular pattern of abilities and disabilities that each individual exhibits at any one point in time, and of choosing the best methods for overcoming those disabilities at that time. For some deficits, in some children, trial-by-trial guidance and rewarding will be necessary (the discrete trial and Lovaas approaches). Other children may have fewer deficits and be more spontaneous and more capable of learning through their own intrinsic devices, with the proper guidance. For these children, approaches that capitalize on these features (such as pivotal behaviours (Koegel & Koegel, 1995) and floor play (Greenspan & Wieder, 1998) may be more appropriate.

A similar approach applies to the question of environmental adaptation. There is an ongoing debate as to whether the environment of these individuals should be simplified or not, to foster learning. For lower-functioning children, environmental adaptations consist of a routinized school environment and a simplified, routinized home environment. Each step involved in, for example, tooth brushing, may be indicated by picture icons as a constant reminder for the child of what is necessary after what. The number of choices may be reduced; commands and comments may be simplified to avoid confusion. For example, a low-functioning child may not apparently recognize that 'sit' and 'sit down' are meant to refer to the same thing.

There is a valid concern that simplification may be counterproductive, especially with higher-functioning children, leading to decreased motivation and to a decreased exposure to the natural variation and richness of a normal environment. This may reduce the child's ability to generalize to new materials or to respond to new situations. Achieving an adequate balance between adequate simplification and productive complexity is an ongoing debate in the teaching of such children. However, it remains the case that many children cannot begin to learn, or learn how to learn, unless they are started in a simplified, structured environment. Even in regular education, the learning environment is made more structured than outside reality usually is. For other children, less simplification and more variety are probably desirable.

In practice, it is often hard to tell many of these methods apart, despite their strong theoretical contrasts. Their goals and methods often seem to overlap and even blend. The overriding principles that need to be kept in mind are that the educational process, and the strategies for education, of any particular individual with autism can and must change with the individual's circumstances. Furthermore, no matter how successful the reported intervention is reputed to be, all interventional strategies must be tested by examination of the actual data for each individual.

Pharmacological treatments

Drugs have not yet been shown to produce improvement in any functions in these individuals. However, there are reasonable expectations, and some data exist that appropriate drug therapy can reduce problem behaviours in at least some individuals (Cook, 1990; Minshew, 2000; Zimmerman et al., 2000). Such behaviours and suggested drug treatment regimens are given in Table 28.4.

Treatment coordination

Regardless of whether behavioural treatments, drug treatments, or both, are used, the treatment of autistic individuals is a constantly changing process that requires different types of expertise at different points in time. Treatment plans must be adapted at any point in time to a particular individual's pattern of abilities and disabilities and to their family and school circumstances. Plans must have goals that are appropriate for that individual's

Table 28.4. Possible pharmacologic treatments for selected disorders in autism

Hyperactivity Distractibility Impulsivity	Stimulant medications	Methylphenidate, 5–60 mg/day in 3–5 divided doses Dextroamphetamine 5–40 mg/day in 3–5 divided doses Adderall, 5–30 mg/kg/day in two divided doses
	Clonidine, 0.1–0.4 mg/day in 2–3 doses or via transdermal skin patch	
	Naltrexone, 0.5–2.0 mg/kg/day in two divided doses	
Rituals Compulsions	Antidepressants SSRIs	Fluoxetine, 5–80 mg/day in 1–2 divided doses or 10–20 mg every other day Paroxetine, 2.5–50 mg/day in 1–2 divided doses Sertraline, 25–200 mg/day in 1–2 divided doses Fluvoxamine, 25–300 mg/day in 1–3 divided doses
	Tricyclic antidepressants	Citalopram, 5–40 mg/day in 1–2 divided doses Clomipramine, 25–200 mg/day in 1–2 divided doses
Aggression Irritability	Sympatholytic agents	Propranolol, 20–320 mg/day in 3–4 divided doses Naldolol, 40–100 mg/day in daily dose
	Anticonvulsants	Carbamazepine to a blood level of 8–12 micrograms/ml Valproate to a blood level of 50–125 micrograms/ml
	Naltrexone, 0.5–2.0 mg/kg in 1–2 divided doses Lithium to a serum level of 0.8–1.2 meq/litre	
	Neuroleptic agents	Risperidone, 0.5–4.0 mg/day in 1–3 divided doses Olanzapine, 2.5–20 mg/day in 1–3 divided doses

required functions, current status, and expected trajectory of change. Physicians are not typically involved in this therapeutic process, although their input is critical for justifying it. More typically, the educational process is in the hands of a varying combination of parents, educators, speech pathologists, physical therapists, behavioural psychologists, occupational therapists, and others. For most individuals with autism, it is critical that there be some strong coordinating individual or group that can help to identify goals, prioritize methods, and monitor the progress of any particular program that the child has, eliminating inconsistencies and redundancies, solving unforeseen problems, and trying to capitalize on successes.

Prospects

Although individuals with autism face a lifelong condition, it can be ameliorated in many cases and in many ways. Higher-functioning individuals in particular have a good chance of a successful life; indeed, some of the signature behavioural characteristics of autism can be positives in the right career or career niche. Success in many areas of life is determined less by weaknesses than by strengths, and these individuals may have many strengths. Meanwhile, autism has become an area of enormous interest, both in its own right and for what it can reveal about the mind and the brain and their pathologies and possible treatments.

Acknowledgements

Preparation of this chapter has been supported in part by an endowment and gifts from an anonymous family, by gifts from The Benjamin and Adith Miller Family Endowment on Aging, Alzheimer's and Autism Research, and by gifts in memory of Bernard Gordon.

The author's perspectives on autism have benefited from discussions with many individuals, including Drs Dana Boatman, Katharina Boser, Geraldine Dawson, Martha Denckla, Pauline A. Filipek, Rebecca Landa, Catherine Lord, O. Ivar Lovaas, William J. McIlvane, James L. McClelland, Ruth Nass, Isabel Rabin, Judith Rumsey, Tristram Smith, Paula Tallal, and Andrew Zimmerman. Most of all, the author has benefited from direct contact with individuals with autism and their schools, teachers, aides, and parents, including The Forum School (Wycoff, New Jersey; Dr Steven Krapes, Linda Edwards, and Brielle Boedart), the LEAP Program of the Kennedy Krieger School

(Baltimore, Maryland; Marilyn Cataldo, Keri Demos, and Melanie Wagner), the Mamaroneck Union Free School District (Mamaroneck, NY; Dr Sherry Parker King, Dr Fern Aefsky, and Jane Friedlander), and from teachers and therapists such as Maureen Boner, Anne Fetherston, and Jessica O'Grady, and many others. I particularly thank Nancy Cook, and also Maura Whelan and Renning Ji, for their help in the preparation of this chapter. None, of course, are responsible for any errors or omissions made here.

Attention deficit hyperactivity disorder: spectrum and mechanisms

Martha Bridge Denckla

Kennedy Krieger Institute, Baltimore, Maryland. MD, USA

Attention deficit hyperactivity disorder (ADHD) is among the most prevalent disorders (3 to 5% of school-age children) treated by physicians who manage children/adolescents, comprising as much as half of child psychiatric practice (Cantwell, 1996). Media attention has been inspired by the extension of the ADHD diagnosis to adults, acknowledgement of frequent comorbidity or antecedent status with respect to other conditions, and concern over the increase in stimulant prescriptions; it may appear that ADHD, or at least its importance, is a novelty. In truth, the essential description of the disorder has a 75-year-long history under a variety of names: 'incorrigibles', 'brain damaged', 'hyperkinetic', and 'Minimal Brain Dysfunction' (Barkley, 1990). Since 1980, the term 'attention' has been the initial and therefore most prominent feature of the names given to the syndrome, either 'attention deficit' alone or combined with 'hyperactivity' (and 'impulsivity') comprising the other central features defining the clinical category (American Psychiatric Association Diagnostic and Statistical Manual, 1994). The current *Diagnostic and Statistical Manual* (*DSM–IV*) lists three subtypes: a combined or full ADHD; a predominantly inattentive; and a predominantly hyperactive/impulsive subtype (*American Psychiatric Association Diagnostic and Statistical Manual*, 1994). Experts suspect that the predominantly hyperactive/impulsive subtype is most often seen in preschool children; there is more controversy about the predominantly inattentive subtype (except when it is only a residual form of the full syndrome, occurring in the adolescent and adult portions of the lifespan); controversial is whether those who present as children with the predominantly inattentive type have a disorder that is quite different. The heterogeneity of ADHD is one of the commonly documented but difficult characteristics of the disorder.

Diagnosis

Hyperactivity may be the first sign to be noticed, obvious in nursery school when not much sustained attention or independent self-control is expected. A small percentage of children diagnosed with ADHD are retrospectively described as difficult right from the moment of birth and as children who 'run rather than walk' as soon as they get up on their feet. Most children with the ADHD diagnosis are also impulsive, which can be in terms of 'on the mind, out the mouth' and is not necessarily gross physical activity or aggressivity. Impulsivity can take the form of not waiting one's turn or thinking before acting, interrupting, talking too much, talking too loud, blurting out whatever comes to mind. Impulsivity is more characteristic of ADHD than is true inattentiveness. Impulsive children may seem clumsy and accident prone because they are uninhibited when exploring the environment in a state of activation/excitation.

Time management, organization of possessions, and sustained on-task effort of any kind present difficulties at any age for people with ADHD. It is often stated that children with ADHD forget what they have for homework, forget to bring in what homework they have done, may bring their homework to school and forget to hand it in, fail to finish things, make careless mistakes, and appear to be in a kind of 'brownian motion' between activities, yet sustain attention on games/play of their own predilection.

Although they appear just 'immature for age' or 'exaggerated children', children with ADHD can make life difficult for everyone around them as well as for themselves, causing disruption and disorganization in homes and schools. Often, they experience social rejection by other children who find their behaviour somewhere between annoying and completely obnoxious, while teachers and parents may regard the children's deportment as belonging

to 'moral turpitude' categories such as irresponsibility, lack of motivation, or laziness. Secondary emotional overlay comes in the wake of rejection and the experience of negative reactions from others, so that anger and frustration may distort the psychosocial adjustment of children with ADHD; they can easily become oppositional, argumentative, and, while denying their own mistakes, attribute the causes of their actions to others. Because children with ADHD do not perform academically up to expectations based on their intellects or talents, because often and repeatedly they are subjected to negative comments, scolding, and punishments, they frequently suffer from poor self-esteem, generating still further disorders like depression and anxiety.

Adolescents and adults with ADHD are more likely to look like the 'predominantly inattentive type' even though, fulfilling full criteria for development of the full syndrome before the age of seven years, they have previously been hyperactive. What persists is a picture of fidgety restlessness, disorganization, forgetfulness, poor boredom tolerance, impatience and a generally 'immature'/disheveled lifestyle. As teenagers, they misplace their possessions, mismanage their time, neglect their homework, and do not achieve the level of self-control considered appropriate for the level of independence craved by most teenagers. Persisting in the adult picture is difficulty setting priorities, managing time, keeping track of possessions, and remembering an agenda. Adult 'hyperactivity' in a sense is persistent in the more time-stretched-out sense of moving frequently, changing primary relationships frequently and changing jobs more frequently than do others of their age.

ADHD is diagnosed at least three times more often in boys than in girls; and this difference, more boys than girls, is even more pronounced among those who are seen in psychiatric rather than pediatric settings. Boys appear more likely to be disruptive, hyperactive, overtly impulsive, and express the comorbidity of oppositional-defiant disorder. Girls are often diagnosed at a later age, and more often with the predominantly inattentive type; close clinical inspection of such girls, however, reveals considerable impulsivity in their leisure behaviours outside of school and a greater degree (than is obvious to the observer) of inhibitory insufficiency in the extent to which they are able to control their mental activities.

Diagnosis of ADHD is complicated by symptoms/signs suggestive of other psychiatric diagnoses and must be distinguished from these or declared comorbid with these. Common comorbidities in childhood are academic learning disabilities and developmental motor coordination disorder. The term minimal brain dysfunction was popular between 1968 and 1980 and was used to describe a mixture of attention deficit hyperactivity disorder symptoms, learning disabilities, and developmental motor coordination disorder (Barkley, 1990). More than 20% of children with ADHD have depressive or anxiety disorders; up to one-third of children with ADHD are aggressive and may receive a formal diagnosis of oppositional-defiant disorder. Some experts believe that the 'externalizing' or acting-out behaviours comprising so-called disruptive 'comorbidity' result from the same underlying failure of behavioural inhibition or impulse control that is fundamental to ADHD. Those whose profiles are complicated by the aggressive, oppositional-defiant, or misconduct symptomatology also have a high rate of alcoholism and drug abuse, sometimes because of antisocial personality, sometimes because of attempts towards self-medication for mood issues (Biederman et al., 1993; Mannuzza et al., 1993). Comorbidity with Tourette's syndrome is discussed in the chapter by Singer, this volume.

There are times when a 'secondary' ADHD gives clues as to the biological basis of the disorder in general; for example, the hyperactive/impulsive group called the 'incorrigibles' were children who suffered brain damage in the wake of the encephalitis lethargica epidemic in the 1920s after World War I. ADHD also occurs secondary to several genetic disorders, head injuries and toxic exposures such as lead poisoning and fetal alcohol syndrome (The Harvard Mental Health Letter, 2000). It is now widely accepted that the core of the disorder is a failure of self-control, most prominently in the sense of behavioural inhibition, inability to respond adequately to routine reward and punishment, and/or deficiencies in what is called 'executive function' (see below). So far, ADHD cannot be diagnosed by any form of neuroimaging, neuropsychological tests, or blood tests.

Differential diagnosis is complicated by the fact that circumstances and situations have to be taken into account in order to rule out that signs/symptoms resembling ADHD result from improper schooling/child rearing, or stress in the form of abuse or neglect. It is sometimes difficult to make a differential diagnosis between bipolar disorder and ADHD (The Harvard Mental Health Letter, 2000). The way in which the child is handled may make the child behave so markedly differently in one situation from another, contemporaneously, that it may be difficult to sort out whether or not the child has the fundamental biological disorder of ADHD; sometimes a child will be perfectly well behaved with a kind but firm teacher, but then be completely out of control in a daycare setting where there is a less structured approach to managing the room. In general, children with ADHD behave better one-to-one, in small groups, or in situations in which the adult management is kind but firm,

and the expectations are clear, as are the consequences of either positive or negative behaviours.

Diagnosis should require a thorough medical/psychiatric history and examination, a neuropsychological/psychoeducational evaluation, and use of questionnaires and rating scales in the context of careful clinical interviews with parents, teachers, and the children themselves. (Unfortunately, this is exceedingly time consuming, so that ideal diagnostic procedures are rarely feasible in today's medical care environment.) Information about family history and about the fine-grained details of home and school life are also important. There may need to be involvement beyond neurologists, psychiatrists, and teachers in the form of information from school counsellors and clinical child psychologists, as well. If there are learning disabilities or language disorders, special educators and language therapists will become participants in the process.

Much of the neurobiological thinking about the disorder has arisen from the fact that certain stimulant drugs in a majority of cases provide striking immediate improvement in the most troublesome and most disruptive symptoms of ADHD; however, response to stimulants is *not* diagnostic of ADHD.

A valid diagnosis of ADHD requires that the problems as quantified on rating scales must be a sufficient number of standard deviations from the mean for the behaviours exhibited by children at that age/level of development. The problems must have begun before the age of seven and must be persistent across time. The requirement that they be pervasive across situations runs into some of the difficulties noted above, but at least in settings similarly structured there should be pervasive problems. It is not that a high level of activity is considered intolerable as long as activity and impulse control are regulated; it is that the child cannot get along with others, obey reasonable requests from parents and teachers, and cannot progress academically because of impersistence. When clinicians follow established guidelines, the diagnosis of ADHD is reliable (NIH Consensus Statement, 1998).

Prognosis

Even the staunchest advocates of a biological interpretation of the basis for attention deficit hyperactivity disorder have been aware of the fact that there are major environmental interactions in the appearance and in the severity of the disorder. The increased demands for sustained attention, and self-control (at an earlier age than decades ago) due to patterns of parental employment, and even the burden of 'virtual reality' distractions may have profoundly influenced attentional and inhibitory capacities and accentuated the perception that a child is inadequate developmentally. Negative parenting practices predict more of the non-compliant and the externalizing behaviours, particularly those that go beyond the age inappropriate and are antisocial (Hinshaw et al., 1997). A persistent misconception is that a biological interpretation of ADHD leads to the conclusion that parenting and schooling do not matter; this prevails even among highly educated persons thinking about the controversies surrounding ADHD. Experience of clinicians is that the child's environment may powerfully influence the prognosis even when there are strong indicators of a biological set of predispositions of ADHD. How the family and the school react to the child, adolescent, and even young adult across the lifespan and how they cope with the problems, seek help and modify the environment for the person with ADHD may be crucial in shaping development; and for all we know, this may be in a very literal brain-development sense as well as the total adaptive sense. Underlying tendencies may be worsened by overly lenient, difficult, inconsistent, or hostile teaching and parenting. The most important complications of ADHD seem to emerge under the worst of circumstances, while optimal parenting and teaching promote strengths in children with ADHD, including positive peer relations (Tannock, 1998).

Neurobiology

Neuropsychology

Since 1980, contemporaneous with the emphasis upon the word 'attention' in the name of the disorder and also a general consensus that psychological processes should guide our understanding of the disorder, neuropsychologists have been struck by analogies between test/assessment behaviours seen in patients with 'frontal lobe' lesions and similar ones in children with ADHD. From this has come a large body of literature focused upon the frontal-lobe-associated construct of 'executive dysfunction' in children with attention deficit hyperactivity disorder, which has itself been the inspiration for a great deal more in the way of study of the normal development of the executive system in childhood. By 1991, a very influential textbook on learning disabilities was constructing a framework in which ADHD was affiliated with frontal lobe, particularly dorsolateral, dysfunction (Pennington, 1991). Executive functions are historically linked to prefrontal, especially dorsolateral, regions and their subcortical,

'domain-general' interconnected regions. The parallel circuits connecting corresponding subdivisions of the frontal lobes and various subdivisions of the basal ganglia have been scrutinized; there is now a general conceptual model to the effect that children with attention deficit hyperactivity disorder, particularly those with the frequent comorbidity of developmental motor coordination disorder, are deficient in one (or more) sectors of the frontal striatal circuitry involving control; there are seen various clinical combinations of motor control, cognitive control, and emotional control deviating from normal developmental attainments. Although there have been both positive and negative findings with respect to each of several tests of executive function in sampled populations with attention deficit hyperactivity disorder, examination of executive functions constitutes a major clinical advance and also inspires the focus of the anatomic imaging work, hypothesis-driven because it measures those structures that are reasonable frontal or basal ganglia 'candidates' implicated in the types of controlled processes on which ADHD-related failures are found (Tannock, 1998; Barkley, 2000).

The executive deficits found have largely been those that involve response inhibition and working memory. As for the adjacent 'motor' domain, there have been many publications on response inhibition in the context of behavioural neurology (Voeller et al., 1991). More recently, eye movements have been studied and a variety of different findings have been forthcoming with respect to antisaccades and remembered saccades (Mostofsky et al., 2000). Clinicians frequently see that tests of executive function, particularly in children, adolescents, and adults with the predominantly inattentive type of ADHD, successfully characterize young patients in a way that is instantaneously recognizable to their parents; however, it has not proven possible to turn around the diagnostic algorithm in such a way that one could classify persons as qualifying for the diagnosis of ADHD on the basis of their executive dysfunctions (Grodzinsky & Barkley, 1999). In his book on ADHD, which is subtitled *The Nature Of Self-Control* (Barkley, 1997), Barkley attempts a linear model explanation of executive function, whereby inhibition is the fundamental and driving precursor of all subsequent developmental executive difficulties, however multiple the manifestations. (Motor control enters into Barkley's thinking as he takes note of the disinhibition on motor examination in the form of overflow movements.) On the other hand, other researchers have suggested that a more pervasive cognitive dysfunction with more proactive organization of components, rather than a precursor deficit restricted to response inhibition, is characteristic of children with attention deficit hyperactivity disorder (Oosterlaan & Sergeant, 1998). Even tests previously thought of as completely within the linguistic domain, such as rapid automatized naming (considered to be one of the best predictors of reading disability) have been shown to be impaired in children with ADHD (Tannock et al., 2000). Furthermore, narrative language skills are not always normal in an ADHD group that is not clinically considered to have language deficits of a more basic nature, because higher order executive function deficits operating upon the domain of language emerge when important prewriting formulation skills are tested (Purvis & Tannock, 1997). Many professionals who specialize in evaluating school problems are now of the opinion, as is the writer of this contribution, that ADHD implies cognitive control issues that do constitute 'true learning disabilities'. The separation between 'learning disabilities' and 'ADHD' is increasingly untenable (Fischer et al., 1990; Cox et al., 1997; Denckla & Cutting, 1999).

On continuous performance tests, particularly of the go/no-go type, most patients with ADHD show prolonged reaction times and a high degree of variability (inconsistency) of their reaction times (Reader et al., 1994). Paradoxically, most patients with ADHD are slow on response preparation, so timed tasks are the most useful ones in corroborating the diagnosis of ADHD. Output under timed conditions with rule-governed control demands brings out deficits in ADHD, as on the letter-word fluency task aptly called Controlled Word Association. Clinicians have found it useful to look at the organizational scores, particularly in a developmental context, from the copying of the Rey Osterrieth complex figure. The California Verbal Learning Test for children also provides a useful opportunity to contrast the level of recall with the learning characteristics and error types. Children with ADHD, who have mainly proactive executive deficits, tend to be poor in strategy (clustering) and also respond less well under free recall conditions than they do when they are given by the examiner the explicit structure of category cues. Those with severe impulsivity make enormous numbers of intrusion errors. The occurrence of repetition errors may indicate poor working memory (Denckla, 1994, 1996).

Neurophysiology of ADHD

Although for many years de-emphasized, recently there has been reborn interest in the epileptiform EEG associated with attention deficit hyperactivity disorder. Epileptiform discharges were reported in a rather large study of children with ADHD, even after all patients with a history of clinical seizures were excluded from the study.

'Definite noncontroversial epileptiform activity' was present in 30%, with epileptiform spike discharges of a focal nature in 24% (temporal/occipital) and generalized spike/waves in 6%. Normal records were found in 47%, but only 28% were completely normal (Hughes et al., 2000). Transcranial magnetic stimulation, when used to study patients with ADHD, indicates immaturity (relative to age-matched peers) in the development of cortical inhibitory pathways; children with ADHD showed reduced intracortical inhibition relative to other children of their age (Moll et al., 2000). Functional magnetic resonance imaging has been used in order to demonstrate altered neuronal activity accompanying relevant response preparation/inhibition tasks; when tested without medication, boys with ADHD showed greater-than-normal activity in the frontal lobe during the more difficult of two tasks requiring response inhibition. Also, the ADHD group showed impaired inhibitory control on both 'easy' and 'hard' go/no-go tasks associated with reduced striatal activation; but they showed improved striatal function when given methylphenidate (Vaidya et al., 1998).

Neuroimaging

Over the past decade, there have been a dozen papers indicating significant regional brain differences in ADHD as determined by quantitative volumetric brain magnetic resonance imaging (MRI). Findings (smaller volumes) have always been more prominent in boys than in girls, but consistently across all studies from all groups is that boys with ADHD have reduced total cerebral volumes compared with controls (boys matched for age and intelligence). Girls with ADHD have not been shown to differ from controls in their total cerebral volume; however, as previously reported in boys with ADHD, girls with ADHD showed similar subtotal volume reductions in bilateral posterior prefrontal brain, bilateral caudate nucleus, left globus pallidus, and posterior inferior cerebellar vermis (F.X. Castellanos, personal communication, 1998). See also MRI volumetrics of Tourette/comorbid ADHD, reviewed by Singer, this volume.

Considerable consensus across studies from different centres reveals the following structures to be smaller in boys with ADHD: frontal regions, caudate, globus pallidus (Aylward et al., 1996; Castellanos et al., 1996; Filipek et al., 1997; Giedd et al., 1994), and posterior inferior cerebellar vermis (Berquin et al., 1998; Mostofsky et al., 1998b). Only one study differed from the majority's emphasis on the anterior structures, reporting additional parietal volume reductions in a group of 15 boys, one-third of whom were said to be stimulant non-responders (Filipek et al., 1997; Semrud-Clikeman et al., 1994). The symptom/sign of disinhibition in children with ADHD correlates with reversed asymmetry of the caudate; measures of attention correlate with right hemisphere white matter volumes (Semrud-Clikeman et al., 2000).

Neurotransmitters implicated in ADHD

Although most research has focused upon dopaminergic mechanisms, recent reviews related to the mechanisms underlying attention deficit hyperactivity disorder provide considerable evidence supporting a noradrenergic hypothesis of ADHD (Biederman & Spencer, 2000). Response to drugs with mixed noradrenergic and dopaminergic pharmacological loci of action have long been the starting point for this hypothesis, albeit the dopamine focus has been dominant. In addition (see genetics section below), although new and controversial, several research publications, with some degree of replication, have found associations between ADHD and two genes, the dopamine transporter and one particular dopamine receptor, D4 subtype (Swanson et al., 2000a). A recent PET study of children with ADHD using the tracer [^{18}F] DOPA indicates unusually high accumulation of that neurochemical in the dopamine-rich region of the high midbrain, while no other dopamine-rich regions significantly differed between groups with and without ADHD (Ernst et al., 1999); this recent PET study was considered to be suggestive of dysfunction at the level of the dopaminergic nuclei in children with ADHD. Noradrenergic activation is documented as essential to the normal operation of attention, especially the arousal infrastructure; the noradrenergic system is well known to be necessary for the modulation of higher cortical functions that include selective attention, vigilance, and executive function in general. Research based upon animal (including primate) models suggests that either too much $\mathcal{L}_1$ receptor or too little $\mathcal{L}_2$ receptor stimulation can impair prefrontal cortex (Arnsten, 2000). Epinephrine itself, linked to adrenomedullary functioning during cognitive testing in boys with diagnosed ADHD, has been reported to be correlated with both parent- and teacher-rated behaviours categorized under 'inattention'. Lower adrenomedullary epinephrine status in individuals with ADHD while they are performing the cognitive 'stress' of schoolwork appears to be associated with the inattentive subtype but not so much with the full syndrome (Anderson et al., 2000).

Serotonin is another neurotransmitter that may play a role, particularly among those children who are prominently aggressive from an early age. Serotonin activity has

also been implicated in working memory performance in some studies of children with ADHD (Gainetdinov et al., 1999; Spivak et al., 1999; Oades, 2000).

Providing transition to the subject of genetics, comparison of the effect of 20 genes that involve dopamine, serotonin, and neuroadrenergic metabolism on quantitative scores in a multivariate linear regression analysis predicting ADHD in a large population indicated that adrenergic genes accounted for more of the variance in ADHD than either the dopaminergic or serotonergic genes combined; but it must be noted that even the six adrenergic genes contributed only 6.9% of the variance, while all genes combined accounted for 11.6% of the variance (Comings et al., 2000).

Genetic basis of ADHD

Genes related to neurotransmitters and neurotransmitter receptors

Molecular genetic studies of ADHD have suggested the possible involvement of one or more dopaminergically relevant genes, either a dopamine transporter gene (associated with a mechanism of excess dopamine reuptake) or the 7-repeat allele of *DRD4* (associated with a reduced sensitivity of the receptor at the postsynaptic level) (Thapar et al., 1999; Swanson et al., 2000a). Neuropsychological tests of attention in those with the 7-repeat allele of *DRD4* gene contradicted the primary hypothesis of this study; those with the candidate abnormal gene (7-repeat allele *DRD4*) seemed to be free of difficulties on the neuropsychological tests, exhibiting average reaction times and consistent responses (Swanson et al., 2000a, b).

The *DRD4* gene and its relationship with ADHD remain controversial. Two negative studies from Israel concern the exon 3 repeat polymorphism (Eisenberg et al., 2000; Kotler et al., 2000) and a study from Ireland concerning the 7-repeat allele was similarly negative (Hawi et al., 2000). On the other hand, there have been several studies documenting *DRD4* variants conferring ADHD risk (McCracken et al., 2000; Barr et al., 2000; Muglia et al., 2000).

The human dopamine transporter gene was further analysed; gene variants that alter levels of DAT expression survive as excellent candidate mechanisms for underlying ADHD as well as, in a less specific fashion, other frequently comorbid associated neuropsychiatric disorders (Vandenbergh et al., 2000). Some evidence for the serotonin HTR 2 A receptor gene as relevant to ADHD opens an entirely new avenue of molecular genetics research on ADHD, leading to speculation that there is a complex interplay in ADHD among neurotransmitter systems rather than strictly emphasis upon the dopamine system (Quist et al., 2000).

Clarifying the genetic architecture of ADHD

Using a sophisticated statistical analysis called latent class analysis in a twin study of school-age children, only two subtypes emerged, one inattentive and the other combined, each of which is a dimensional domain (Neuman et al., 1999). Another twin study suggested that extreme hyperactivity/impulsivity might be genetically and etiologically separable from the usual moderate full syndrome and extrapolated without reservation to families with girls as ADHD probands (Faraone et al., 2000). A common genetic factor (revealed in a large twin pair study) underlies maternally reported and concordant maternal/teacher-reported ADHD; when teacher-only-ADHD is reported, weaker genetic influence is supported and environmental factors loom larger (Thapar et al., 2000).

In multiplex families with ADHD, the gender ratio appeared to be consistent with a genetic model in which a greater loading of familial influences was necessary for the girls to develop ADHD (Smalley et al., 2000).

Treatment

Most of the controversy about the diagnosis of ADHD has emanated from its almost complete identification (in the public mind) with treatment involving stimulant medication. In what is probably the most widely replicated body of literature on psychopharmacology dealing with the pediatric age group it has been shown that methylphenidate (Ritalin) and dextroamphetamine (Dexedrine) provide improvement for between 75 and 90% of children and adults with ADHD. Side effects are few and rarely serious, all being confined to observable effects upon the central nervous system (eating, sleeping, mood, tics). In 1998, the Council on Scientific Affairs of the American Medical Association conducted a 20-year review of the scientific literature and concluded that stimulant drugs were not being prescribed excessively or being misused (The Harvard Mental Health Letter, 2000). Stimulant treatment of ADHD in public schools in Maryland (mainly methylphenidate) is variably prescribed to students for school purposes, being fourfold greater for males than for females, twice as often for white as for minority students, and three times as often for elementary as opposed to high school students. The majority of the children taking stimulant medication had their medical supervision and prescriptions undertaken by pediatricians (63%); when medications other than methylphenidate (Ritalin) were

prescribed, the prescribing physician was a psychiatrist in 29% of such cases (Safer & Malove, 2000). Recent studies on the long-term risk of drug abuse and alcoholism among those who as children were treated with prescription stimulants reaches a conclusion opposite to that of increased risk; rather, the risk for drug abuse in adolescents is lessened by successful childhood stimulant medication treatment of ADHD (Degrandpre & Hinshaw, 2000).

A recent major clinical trial sponsored by the National Institute of Mental Health was conducted at several medical centres and universities for, so far, a 14-month period (MTA Cooperative Group, 1999a). Clear benefits of stimulant medication were documented for carefully diagnosed children with ADHD (who had their medication optimally managed by initial dosage adjustment, monthly family visits to the doctors, and mandatory contact with school personnel). Medication management of this high quality was superior in outcome, in terms of reducing signs/symptoms, to medication-free intensive psychosocial intervention (involving long-term parent training, school consultation, and summer programmes of contingency management/behaviour modification). The careful medication regimen was clearly superior to 'community' standards of stimulant medication treatment lacking the close monitoring and titrating. A lower dose of medication was effective in the group receiving the combined medical and behavioural treatment (MTA Cooperative Group, 1999b).

Medication alone is not even initially effective, when there are comorbid conditions, like learning disabilities, which require remediation. Cognitive interventions for non-academic behaviours are not as useful as contingency management techniques. Schools, following Federal law, must accommodate ADHD as a disability under the Section 504 of the American with Disabilities Act. This is a different law from the one that governs learning disabilities (P.L. 94–142). A 504 Plan for ADHD should feature the following: extended time on tests, frequent breaks on tests, close monitoring, predictable schedules, constant feedback, tangible rewards and response costs; and those with ADHD should be positioned in the classroom close to the teacher and as far as possible from sources of distraction. It appears that the main reason that non-pharmacological treatments do not receive as much focus as pharmacological ones is that they are very demanding of adult time, expertise and effort; and given that the ADHD is chronic, it appears likely that the psychosocial treatments need to be chronic, whatever the modality (Pelham & Gnagy, 1999).

In conclusion, despite fears that 'drugging children' into compliance is the motivation for making the diagnosis of ADHD, there is considerable clinical and research evidence supporting the view that ADHD represents a group of real neurological, mainly neurodevelopmental, disorders involving control processes (motor, cognitive, and emotional). This point of view acknowledges that 'the brain both shapes and is shaped by the environment; underlying psychobiological risk factors can be treated environmentally and some conditions resulting from stressful life events could be dealt with by biological intervention . . .' (Degrandpre & Hinshaw, 2000).

The neurobiology of drug addiction

Charles A. Dackis and Charles P. O'Brien

Treatment and Research Center, Department of Psychiatry, University of Pennsylvania, Philadelphia, PA, USA

Although neuroscientists have made considerable progress investigating and characterizing the brain regions that are involved in addiction, the integration of this information with clinical practice is still in its infancy. The neurobiology of addiction addresses the dynamic interaction between addictive drugs and the brain, ranging from drug intoxication to chronic neuroadaptations such as withdrawal, tolerance and craving. While psychological, psychosocial and environmental factors play important roles, addiction is primarily a brain disease (Leshner & Koob, 1999), and a greater understanding of its neurobiology should uncover new and effective treatments. Currently, there is an urgent need for medications capable of reducing craving and recidivism, perhaps by reversing brain disruptions associated with chronic substance abuse. Aside from refining treatment, addiction research has also shed light on the brain's reward centres that so dominate our lives. These centres have evolved over millions of years to reinforce feeding, mating, and other survival-related activities. Tampering with brain reward circuitry, through the process of addiction, produces many of the dangerous and lethal consequences that are associated with addictive illness.

Through the development of technological advances, scientists have developed sophisticated probes into the brain regions that are involved in drug reward. Addictive agents affect different neurotransmitter systems at various anatomical sites, creating distinct 'fingerprints' on the reward circuitry. However, the administration of all addictive substances increases extracellular dopamine (DA) levels in the nucleus accumbens (NAc), a location that has been named the 'universal addiction site'. This remarkable fact will be our starting point in a discussion of pathways that interconnect the midbrain, limbic system, and medial prefrontal cortex (PFC). Repeated administration of addictive drugs often produces opposite brain effects, and evidence of impaired DA neurotransmission has been reported with chronic cocaine, opiate, alcohol and marijuana exposure. Other neuroadaptations have also been identified and will be reviewed, by substance, in an attempt to integrate brain mechanisms with clinical phenomena such as drug withdrawal, craving and progression.

The nature of addiction

The hallmark of addiction is a progressive loss of control over drug intake, regardless of negative consequences. The willingness of drug addicts to risk death, disease, incarceration, job loss, financial ruin and family strife may seem counterintuitive. However, when the dynamics of addiction are understood, the lack of control exhibited by drug addicts becomes more comprehensible. A useful framework for conceptualizing addiction has been proposed by Wikler (Wikler & Pescor, 1967), based on classical and operant conditioning theory. In this construct, initial drug use may occur for a number of reasons, including boredom, curiosity, recreation and peer pressure. Drug euphoria, resulting from physiological effects on endogenous reward centres, 'positively' reinforces repeated drug use in the pursuit of pleasure. Over time, neuroadaptations affecting brain reward centres lead to phenomena such as drug withdrawal, craving and dysphoria. These unpleasant states, temporarily alleviated by drugs, 'negatively' reinforce repeated drug use. Craving and withdrawal symptoms can also be triggered by conditioned cues that are associated with drug procurement and drug use. Alternating negative and positive reinforcement drives a viscous cycle of addiction that becomes increasingly entrenched and uncontrollable. Since the cycle of addiction is essentially etched onto the brain's reward substrate, the compulsive drive to use drugs takes on the strength and characteristics of a primary survival drive.

Anatomy and circuitry of endogenous reward centres

Since 'pleasure centres' in the lateral hypothalamus were first discovered by Olds in the 1950s, brain regions supporting electrical and drug self-stimulation have been intensively researched (Bardo, 1998). However, much of what is known about these reward centres is based on animal experiments that may not be easily generalized to humans. Aside from cross-species differences in anatomical, neurotransmitter and molecular systems, it is a wide leap from animal behaviour to human subjective experience. With these caveats in mind, it is apparent that a number of structures with synaptic connections to the medial forebrain bundle are intrinsically involved in drug reward and natural reward states (Wise, 1996). These structures include the DA-rich ventral tegmentum (VTA), PFC, NAc, and elements of the limbic system.

Drugs as diverse as psychostimulants, opiates, alcohol, marijuana, nicotine and phencyclidine (PCP) acutely increase levels of extracellular DA in the NAc (Koob et al., 1998). The shell of the NAc shares embryological and cytoarchitectural similarities with the central nucleus of the amygdala and the bed nucleus of the stria terminalis, comprising what has been termed the extended amygdala (Heimer & Alheid, 1991). The extended amygdala has reciprocal connections with the forebrain, hippocampus, midbrain, ventral pallidum, mediodorsal thalamus and the lateral hypothalamus (Koob et al., 1998). The NAc can be functionally divided into its ventromedial shell, essentially a limbic structure, and its core that is associated with the ventral striatum. The shell is implicated in reward function and the core projects motor-related information to the substantia nigra. The proximity of predominately reward and motor structures within the NAc provides a direct anatomical interface between motivational and behavioural function (Pennartz et al., 1994).

The NAc shell region is composed primarily of medium-sized spiny cells. These neurons utilize GABA as their primary neurotransmitter but may also contain endogenous opioid peptide (EOP) neurotransmitters. EOP neurotransmitters such as dynorphin and enkephalin are contained primarily in output neurons within the NAc. All three classes of opiate receptors are found in the NAc. Agonists for the mu and delta receptors are rewarding in this region, whereas kappa agonists are aversive (Akil et al., 1998). In addition, the activation of mu and delta receptors releases DA, while kappa agonists inhibit DA release. There is evidence that separate populations of NAc neurons in the striatum contain either enkephalin or dynorphin, with enkephalin-containing neurons usually expressing D_2 receptors and dynorphin-containing neurons typically expressing D_1 receptors (Akil et al., 1998). Dynorphin and enkephalin projections are thought to be involved in compensatory actions in response to excessive DA neurotransmission, and alterations in these systems may underlie neuroadaptations associated with opiates, stimulants, and other addictive agents. The presence of opioids and opiate receptors in this universal addiction site is noteworthy.

The NAc receives 'reward circuit' DA projections from the VTA and returns inhibitory reciprocal fibres to this DA-rich centre. DA projections of the reward circuit have complicated actions on medium-sized spiny cells. D_2-mediated effects are inhibitory and reduce the formation of cAMP within NAc target cells (Self et al., 1998). D_1 receptors, on the other hand, stimulate cAMP formation and have a modulatory role that involves either inhibition or excitation, depending on the resting state of NAc target cells. Medium-sized spiny cells tend to be in either an active or inactive state, and D_1 activation causes a prolongation of the pre-existing state (Hernandez-Lopez et al., 1997). Therefore, while D_2 receptor activation inhibits medium-sized spiny cells, D_1 activation can either inhibit or stimulate the firing rates of these output neurons.

The NAc is stimulated by glutamate-containing axons that originate in the PFC, amygdala, hippocampus, and thalamus (Pennartz et al., 1994). The PFC sends massive descending fibres that actually join DA terminals of the reward circuit to form 'dual-synapses' on medium-sized spiny cells (Sesack & Pickel, 1992). Similar convergent DA and glutamate terminals in the NAc have been demonstrated with excitatory inputs from the hippocampus (CA3 area), amygdala and thalamus. Also, the NAc sends reciprocal fibres to each of these glutamatergic areas. Dense glutamate-containing fibres from the amygdala travel via the stria terminalis before converging on the spines and distal dendrites of NAc neurons. Hippocampal projections, possibly involved in reward memory, originate in the subiculum and pass through the fimbria-fornix to target cells in the NAc. Convergent synaptic input from glutamate and DA projections allows for the simultaneous processing of cortical and midbrain reward information by GABA\EOP-containing cells of the NAc.

Aside from glutamate and DA, the NAc is also influenced by other neurotransmitter systems. It receives serotonin terminals from the dorsal and median raphe, and norepinephrine projections from the locus coeruleus and the nucleus tractus solitarius. Cholinergic neurons intrinsic to the NAc synapse on the dendritic shafts of a population of medium-sized spiny cells that do not receive DA projections (Pickel & Chan, 1990). This finding provides evidence that discrete populations of medium-sized spiny cells in

the NAc have different functions. The convergence of DA, GABA, glutamate, EOP, serotonin, norepinephrine and acetylcholine-containing neurons in the NAc allows for complex interactions involving these critical neurotransmitter systems.

The NAc shell sends GABA and opioid-containing projections throughout the reward circuitry. NAc projections extend directly to the lateral hypothalamic and preoptic areas that are involved in the consummatory functions of feeding, drinking, and sexual activity. Morphine is self-administered directly into the lateral hypothalamus, suggesting a role for EOP systems in consummatory reward. Indirect outflow from the NAc passes through the ventral pallidum, a structure intrinsically involved in motivation and drug seeking behaviour (Bardo, 1998). In addition to serving as a relay point to other anatomical regions, the ventral pallidum processes reward information through opioid modulation (Napier & Mitrovic, 1999). The ventral pallidum conveys NAc projections to the pedunculopontine tegmental nucleus, a region composed of large cholinergic cells and smaller glutamate neurons. Cholinergic neurons of the pedunculopontine tegmentum project to the VTA and stimulate nicotinic receptors that are located on DA cell bodies. Implicated in the acquisition of drug-rewarded behaviour, the pedunculopontine nucleus also projects to the amygdala and lateral hypothalamus.

Another important NAc pathway traverses through the ventral pallidum to the mediodorsal thalamic nucleus, an area associated with feelings of fear and anxiety. The mediodorsal thalamus is generally viewed as limbic and has extensive connections to the PFC and anterior cingulate. The anterior cingulate, which also receives direct VTA projections, has numerous functions that include pain perception and the assignment of emotional valence to perceived stimuli. The pallidal–thalamocortical circuit has been termed the 'motive circuit' and is thought to initiate adaptive responses to reward information received from the NAc (Kalivas et al., 1999). The PFC (Grant et al., 1996) and cingulate area (Childress et al., 1999) are hypermetabolic in humans during cocaine cue craving, suggesting that the multisynaptic circuit connecting the NAc, ventral pallidum, mediodorsal thalamus, and cortical regions has an important role in the addictive process. As the neurobiology of craving is further unravelled by additional imaging studies, new treatments for this tenacious negative reinforcer may result.

The amygdala plays a role in reward and reward-related memory. The basolateral nucleus of the amygdala consists largely of glutamatergic pyramidal cells while the central nucleus is mainly populated by GABA-containing projection neurons. As with the NAc, the amygdala is rich in endogenous opioids. The central nucleus of the amygdala, NAc, and bed nucleus of the stria terminalis (extended amygdala) share many characteristics (Heimer & Alheid, 1991). The amygdala sends excitatory glutamatergic axons to the NAc and receives reciprocals from this important reward centre. Preclinical and imaging studies demonstrate that the amygdala is involved in the recognition of emotionally relevant stimuli. Imaging studies in humans have reported hypermetabolism in the amygdala during cocaine cue craving (Grant et al., 1996; Childress et al., 1999), and amygdaloid suppression during cocaine administration (Breiter et al., 1997). Animal studies report that lesions of the basolateral amygdala interfere with the process by which neutral stimuli become secondary reinforcers of cocaine administration and motivate drug-seeking behaviour and cue-induced relapse (Whitelaw et al., 1996). While the basolateral amygdala is involved in the acquisition of cocaine-seeking behaviour, the central nucleus of the amygdala is implicated in alcohol reward and withdrawal. This GABA/EOP-rich region may also be affected by CRF abnormalities that are associated with addiction. CRF is a centrally acting neuropeptide that, aside from its ability to activate the hypothalamic–pituitary–adrenal axis, also mediates behavioural responses to stress. Elevations in CRF are found during withdrawal from many substances (cocaine, opiates, THC, and alcohol) and CRF antagonists reverse aversive affects of alcohol and opiate withdrawal when administered into the central nucleus of the amygdala (Koob et al., 1998).

The VTA is the source of all mesocorticolimbic DA and serves a crucial role in drug reward and in natural drive states, including the procurement of food, fluid, and sex. DA neurons comprise about 85% of the cell bodies in the VTA and display either baseline pacemaker activity, or episodic burst firing when activated. Burst firing occurs during consummatory activity (such as feeding) and later upon exposure to cues associated with these behaviours, suggesting an interesting learning capability of mesocorticolimbic DA neurons (Schultz et al., 1997). The major projection bundles from the VTA extend to the NAc, the frontal lobe (prefrontal and anterior cingulate cortex), and the amygdala. It is not clear how these three important projections and their target sites interrelate on a functional basis through their extensive interconnections.

DA neurons in the VTA are under intensive local and distal regulation, receiving input from GABA, glutamate, acetylcholine, EOP, and serotonergic-containing neurons. Local inhibition is mediated through somato-dendritic D_2 autoreceptors and local GABA interneurons. Inhibitory fibres also project from the NAc (directly and via the ventral pallidum), amygdala and other limbic structures. Glutamatergic projections and cholinergic axons from the laterodorsal

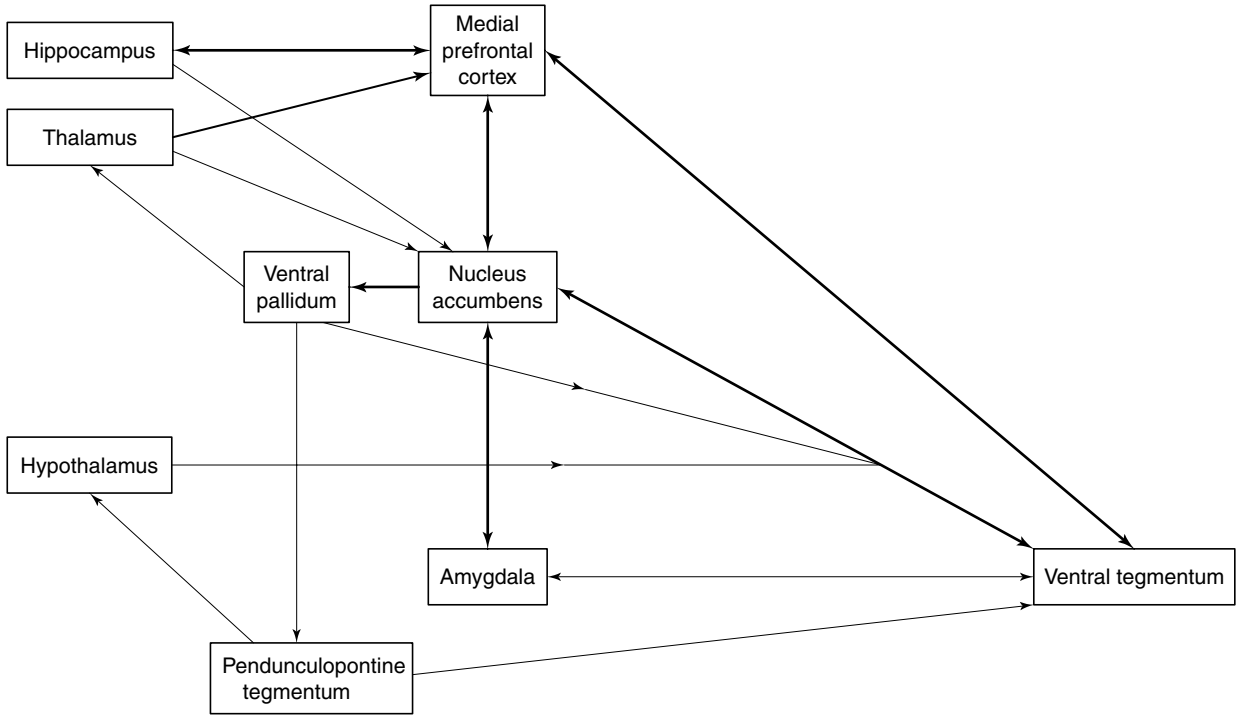

Fig. 30.1. Circuits of the reward centres are schematically represented. Attention is directed to the 'reward circuit' involving DA projections from the VTA to the NAc. The NAc, termed the 'universal reward site' contains GABA\EOP projection neurons and is implicated in all drug reward states. The 'motive circuit' connects the NAc and ventral pallidum with glutamatergic neurons of the thalamus and PFC. Cholinergic projections from the pedunculopontine tegmentum terminate on nicotinic receptors.

tegmental and pedunculopontine nuclei provide excitatory input to the VTA. The activation of inhibitory mu opioid receptors on GABA interneurons of the VTA (and GABA cells projecting to the VTA) releases DA neurons from tonic GABA inhibition (Leshner & Koob, 1999). DA neurons in the VTA also receive direct synaptic input from EOP-containing terminals, and are modulated by the raphe nuclei and the hypothalamus.

Glutamate-containing pyramidal cells in the PFC tonically stimulate VTA neurons, and thereby regulate the basal outflow of DA throughout the limbic system. Glutamatergic terminals synapse directly on DA neurons at the cell body level and activate NMDA and AMPA receptors. These cortical projections and reciprocal DA axons run through the medial forebrain bundle, a tract that has been intensely studied in reward, working memory, and schizophrenia research. DA projections to the PFC form synapses on the dendritic spines and shafts of cortical glutamatergic neurons, modulating their activity (Carr et al., 1999) and completing an interactive loop that is undoubtedly central to reward function. DA projections also modulate local inhibitory circuitry through synaptic connections on cortical GABA neurons. In addition to enhancing working memory, DA projections to the PFC appear to be involved in memory-guided goal-directed behaviour (Durstewitz et al., 2000). PFC pyramidal neurons that receive DA input are also innervated by glutamatergic projections from the hippocampus, a structure that is implicated in memory. The role of memory in the perpetuation of repeated drug use is an essential component of addiction.

The reward circuitry outlined in this discussion is summarized in Fig. 30.1. It is useful to note that there are three major VTA bundles projecting to the NAc, PFC, and amygdala. These structures are extensively interconnected and send reciprocal fibres back to the VTA to form a series of loops within the reward circuitry. The major neurotransmitter systems that comprise these circuits include DA, glutamate, GABA and EOP-containing neurons. Since these neurotransmitters are intimately involved in the acute and chronic actions of addictive substances, researchers have focused on therapeutic agents that directly or indirectly affect their associated neuronal pathways. Given the central modulatory role of mesocorticolimbic DA neurons, intact VTA function is probably crucial

in the normal orchestration of reward circuits. The dysregulation of DA neurons with chronic addiction, combined with target cell neuroadaptations, will be reviewed in the following sections, and may explain many of the clinical aspects of addiction. The next sections will focus on the major classes of addictive drugs with regard to their neurobiology and clinical characteristics.

Central stimulants: cocaine and amphetamine

Historically, central stimulants have caused a number of drug epidemics, especially when perceived to be safe. Stimulants are associated with intense euphoria, well outside the normal range of human experience, and their repeated use leads to rapidly progressive addiction in many individuals. The power of stimulant reward is illustrated by the fact that cocaine and amphetamine are readily self-administered by animals to the point of death, and preferred over sex, food and water (Dackis & Gold, 1985). Aside from producing euphoria, stimulants suppress hunger and food intake, reverse fatigue and increase psychomotor activity. Cocaine is often administered through the intrapulmonary route (as crack), which is the most rapid means of delivery to the brain. The relatively mild withdrawal seen with stimulants, characterized by depressed mood, hypersomnia, hyperphagia, anergia and psychomotor retardation, illustrates that severe physical withdrawal is not crucial in the perpetuation of drug addiction. There is significant evidence that repeated stimulant exposure disrupts the functional integrity of the brain's reward centres.

The rewarding effect of cocaine and amphetamine results from increased DA neurotransmission in reward circuits. Amphetamine promotes the presynaptic release of DA (through reverse transport) while cocaine blocks the dopamine transporter (DAT), a membrane-bound protein that regulates synaptic DA levels (see Fig. 30.2). There is a strong correlation between euphoria and the rate at which cocaine enters the brain and blocks the DAT (Volkow et al., 1999). Cocaine also blocks serotonin and norepinephrine reuptake, and has local anesthetic action on neurons. The acute administration of cocaine and amphetamine dramatically reduces DA neuronal firing in the VTA by activating D_2 autoreceptors. This finding demonstrates that increased DA neurotransmission, not increased DA burst firing, is an essential feature of stimulant euphoria. Also consistent with increased DA neurotransmission during stimulant reward are the findings that DA antagonists block self-administration and reduce euphoric effects (Koob et al., 1998).

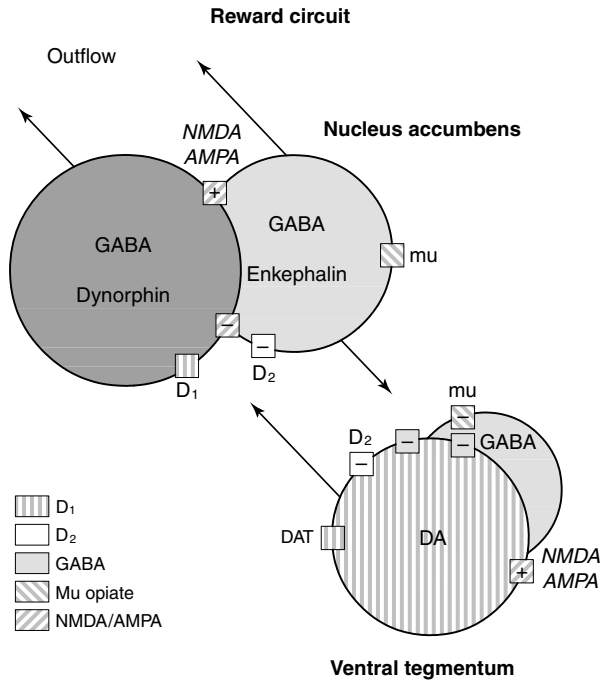

Fig. 30.2. 'Reward circuit' DA projections from the VTA stimulate D_1 and D_2 receptors on dynorphin and enkephalin-containing GABA neurons. Receptor effects (+ or −) are noted, and D_1 effects are modulatory. NMDA/AMPA receptors are excitatory, receiving glutamatergic projections from numerous cortical regions. Heroin acts on mu receptors, releasing DA from tonic inhibition. Cocaine acts on the DAT, increasing DA neurotransmission.

It has been suggested that increased DA neurotransmission cannot entirely explain stimulant reward because DAT knockout mice (lacking the DAT) self-administer cocaine, leading to the speculation that serotonin or norepinephrine systems are involved in stimulant reward. However, DAT knockout animals have high resting levels of extraneuronal DA and may have developed specific brain mechanisms to overcome their genetic deficit. For instance, the norepinephrine reuptake transporter has a high affinity for DA and may play a role in the self-administration of cocaine by these mice. Thus, the balance of evidence continues to support DA as the key neurotransmitter associated with stimulant reward.

Given the importance of DA neurotransmission in stimulant reward, attention is directed toward postsynaptic DA receptors. At least five distinct DA receptors ($D_{1–5}$) have been identified, although D_1 and D_5 receptors (often termed D_1) share many structural similarities, and $D_{2–4}$ receptors (often termed D_2) also have homologous residue sequences. Second messenger systems linked to DA receptors are intimately involved in the reinforcing action of

stimulants. D_2 receptor stimulation inhibits cAMP formation by activating the inhibitory guanine nucleotide binding protein (G_i-protein). If G_i-proteins in the NAc are inactivated with pertussis toxin, stimulant reinforcement is greatly reduced (Self et al., 1998). Therefore, stimulant reward is associated with D_2 inhibition of cAMP within medium-sized spiny cells in the NAc. Opiates also acutely inhibit cAMP in these neurons through mu and delta receptors coupled to G_i-proteins.

Opposing the action of G_i-proteins are G_s-proteins that increase cAMP levels and activate cAMP-dependent protein kinase. Activation of this pathway affects ion channels, neuronal enzymes and even nuclear transcription factors that can change long-term gene expression. It has been theorized that genetic changes are involved in the transformation from drug use to drug abuse. D_1 receptors are coupled to G_s-proteins and their stimulation increases cAMP levels. Therefore, D_1 and D_2 receptors have opposite effects on cAMP formation. Furthermore, cAMP inhibition enhances stimulant reward, while cAMP stimulation has the opposite effect (Self et al., 1998). Repeated cocaine administration increases cAMP levels in the NAc and upregulates D_1 receptors, resulting in a reduced capacity of DA to lower cAMP levels that could underlie tolerance (Self et al., 1998). Reduced D_2 receptors (associated with decreased metabolism in cingulate gyrus and orbitofrontal cortex) have been reported in human cocaine addicts although it is unclear whether these abnormalities are cocaine induced, or represent a pre-existing abnormality that may predispose certain individuals to cocaine dependence (Volkow et al., 1993). Anecdotal evidence from cocaine users suggests acute tolerance within a session and chronic tolerance to subjective effects over time. In a PET study of methylphenidate, another DAT inhibitor, less DA release was observed in cocaine abusers than in normal controls (Volkow et al., 1999). These findings indicate that repeated stimulant administration may render GABA\EOP neurons in the NAc less responsive to D_2-mediated inhibition and more responsive to D_1 effects.

In addition to changes in signal transduction, repeated cocaine exposure has been reported to produce DA depletion. DA depletion has been theorized to underlie the craving and dysphoria associated with cocaine dependence, and may result from the synaptic metabolism of DA during DAT blockade (Dackis & Gold, 1985). Consistent with DA depletion are reports of hyperprolactinemia (a marker for diminished DA tone) (Mendelson et al., 1989), reduced DA release (Volkow et al., 1999) and persistent reductions in DA activity in cocaine addicts (Wu et al., 1997). In addition, preclinical studies show low DA titres in the NAc (Robertson et al., 1991) and reductions in spontaneous VTA neuronal firing (Peoples et al., 1999) after chronic cocaine exposure. DA depletion, in combination with reduced D_2 receptor transduction, could explain the increases in reward thresholds that have been measured after repeated exposure to cocaine (Koob et al., 1998). If DA dysregulation contributes to the craving and dysphoria seen in stimulant addicts, its reversal could improve the recidivism that characterizes stimulant dependence (Dackis & Gold, 1985).

Cocaine craving, a major factor contributing to relapse, can be vigorously triggered by conditioned cues. While rehabilitative approaches advocate the avoidance of 'people, places and things' associated with drug use, this practice is seldom practical for patients immersed in the drug environments of our inner cities. Cue-induced craving has been reported to produce robust limbic activation in cocaine addicts (Grant et al., 1996; Childress et al., 1999), but not in cocaine naïve individuals (Childress et al., 1999), providing a graphic illustration of an acquired brain abnormality. Interestingly, preclinical studies have identified select NAc cells that actually fire in anticipation of cocaine, and this finding may have bearing on cue-induced craving mechanisms (Carelli, 2000). Also, the fact that specific NAc cells fire in anticipation of food and water (Miyazaki et al., 1998) suggests that cocaine has the capacity to recruit brain mechanisms that are normally activated in the presence of survival-related opportunities.

After repeated administration, sensitization develops to a number of toxic and behavioural effects of stimulants. This 'reverse tolerance' is exemplified by kindling in animals (sensitization to the convulsant effects of cocaine) and appears to involve glutamatergic mechanisms. In humans, clear evidence of sensitization is elusive although it has also been proposed to explain the clinical phenomenon of progressively worsening stimulant craving. Amphetamine and cocaine vigorously release glutamate into the PFC, NAc, and several other limbic regions (Reid et al., 1997) through the stimulation of D_1 receptors and, with repeated stimulant use, there develops an increased capacity of the D_1 receptor to release glutamate (Kalivas & Duffy, 1998) (see Fig. 30.3). Sensitization is also associated with D_2 autoreceptor downregulation in the VTA (Li et al., 1999) and supersensitivity of glutamate NMDA receptors (Itzhak, 1995). Stimulant sensitization can be prevented with NMDA antagonists and ablation of the PFC (Li et al., 1999), suggesting an important role for glutamate in this phenomenon. Glutamate depletion has been reported with chronic cocaine administration (Keys et al., 1998), and may result from the overstimulation of glutamatergic neurons.

Excessive brain levels of glutamate can produce neurotoxicity and cell death as a result of Ca^{2+} inflow through

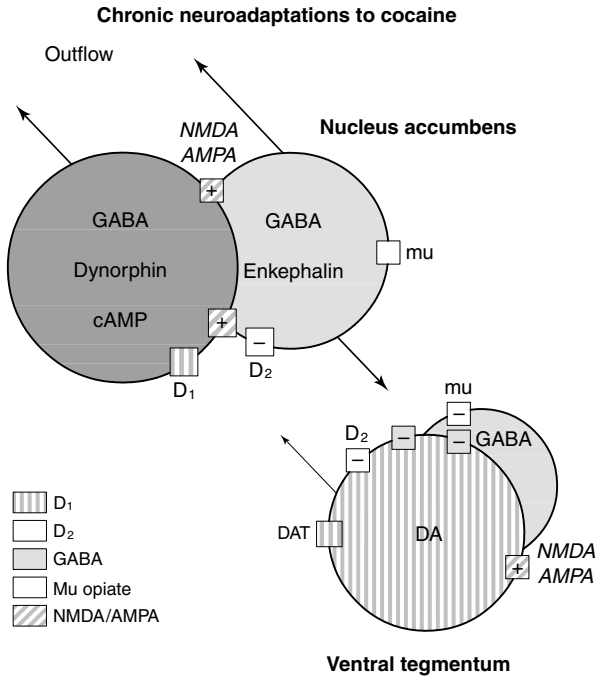

Fig. 30.3. Chronic cocaine exposure results in DA depletion and reduced outflow from the VTA. This effect is compounded by reduced D_2 and increased D_1 receptor transduction, increasing cAMP with NAc neurons. Up-regulation of NMDA/AMPA receptors in the NAc and down-regulation of D_2 autoreceptors contribute to sensitization. The NAc becomes increasingly resistant to VTA inhibition as levels of cAMP rise within GABA\EOP neurons. Over time, these changes may reduce hedonic function and contribute to clinical features of cocaine dependence.

NMDA-gated ion channels. Glutamate toxicity, in combination with focal defects of cerebral perfusion attributed to vasoconstriction (Holman et al., 1991), may account for longstanding neuropsychological impairment reported in some stimulant addicts. Reduced metabolism in the glutamate-rich orbitofrontal cortex has actually been reported during stimulant withdrawal (Volkow & Fowler, 2000). Alterations in glutamate-containing PFC neurons could adversely affect frontal lobe processing, including executive function and the ability to suppress limbic impulses.

Cocaine also affects serotonin, norepinephrine, and GABA-containing neurons. Repeated cocaine administration depletes norepinephrine and serotonin, possibly through increased synaptic metabolism during the blockade of associated membrane transporters. In addition, the stimulation of serotonin ($5\text{-}HT_{1b}$) receptors increases cocaine reward (Parsons et al., 1998). These and other findings may justify research of serotonergic agents in cocaine patients. Cocaine addicts also have benzodiazepine receptor upregulation, strengthening of GABA neurotransmission and enhanced sensitivity to benzodiazepine treatment (Volkow et al., 1998), suggesting likely research opportunities with GABA agents.

Unfortunately, there are no proven pharmacological treatments for stimulant dependence. Cocaine overdose can only be treated by supportive measures and prolonged elimination from the body can result from cocaine's nonlinear pharmacokinetics. The blockade of stimulant reward through neutralizing antibodies to cocaine has been demonstrated in animals and a cocaine vaccine study in humans is under investigation. DA antagonists reduce cocaine euphoria in humans but cause a number of side effects, may worsen craving (Dackis & Gold, 1985), and are unlikely to be acceptable to cocaine addicts. Also, reward blockade would not be expected to ameliorate neuroadaptations of chronic stimulant exposure. Effective detoxification and relapse prevention agents have yet to be identified for psychostimulants, although this is an area of intensive, government-sponsored research. As discussed, GABA/EOP-containing neurons in the NAc receive DA terminals from the VTA and convey reward-related signals to other structures, including regions of the thalamus, PFC, and hypothalamus. Disruption in DA neurotransmission, either through presynaptic DA depletion or postsynaptic transduction changes could drastically affect the orchestration of reward flow in the brain. Current research is being directed toward agents that might reverse DA, GABA, EOP and glutamatergic imbalances that are associated with stimulant addiction.

Opiates

Opiates produce their intensely rewarding effects by activating endogenous opioid receptors, the natural targets of endogenous endorphins, enkephalins, and dynorphins. The genes of mu, delta, and kappa receptors have been cloned, and the former two are involved in opiate reward while kappa receptors may contribute to aversion (Wise, 1996). Mu receptor agonists hyperpolarize medium-sized spiny cells, and this action contributes to their rewarding effect. GABA inhibition also results in DA burst firing with DA release into the NAc. Drug addicts frequently use heroin in conjunction with cocaine (speedballing), a combination that increases NAc extracellular DA by over 1000% (Gerasimov et al., 1999). Although GABA-mediated DA burst firing has been proposed as a mechanism of opiate reward, selective lesions of DA terminals within the NAc do not attenuate IV heroin self-administration (Pettit et al.,

Table 30.1. Intoxication and withdrawal signs and symptoms are listed for several classes of drugs

	Stimulants	PCP	Marijuana	Alcohol/Sedatives	Opiates
Intoxication	Tachycardia	Tachycardia	Tachycardia	Bradycardia	Bradycardia
	Hypertension	Hypertension	Hypertension	Hypotension	Hypotension
	Hyperthermia	Hyperthermia	Hyperthermia	Hypothermia	Hypothermia
	Arousal	Arousal	Paranoia	Sedation	Sedation
	Diaphoresis	Aggression	Diaphoresis	Hypokinesis	Hypokinesis
	Mydriasis	Psychosis	Mydriasis	Ataxia	Pinned pupils
	Hyperkinesis	Ataxia	Ataxia	Slurred speech	Slurred speech
	Euphoria	Salivation	Paranoia	Decreased respirations	Analgesia
	Psychosis	Rigidity	Dry mouth		Head Nodding
	Myoclonus	Red eyes			
	Nystagmus	Nystagmus			
Withdrawal	Bradycardia	Prolonged	Depression	Tachycardia	Tachycardia
	Hypersomnia	Psychosis	Insomnia	Insomnia	Insomnia
	Hyperphagia		Anxiety	Nausea	Nausea
	Depression		Irritability	Anxiety	Anxiety
	Hypokinesis		Anorexia	Hypertension	Hypertension
			Tachycardia	Tachycardia	
				Hyperreflexia	Hyperreflexia
				Diaphoresis	Diaphoresis

Notes:
Note the similarity among alcohol, sedatives, and opiates with regard to intoxication and withdrawal symptoms

1984). This finding demonstrates that opiate reward is not dependent on DA activation, and appears to include two separate (DA-dependent and DA-independent) components. Also consistent with DA-independent opiate reward is the fact that opiates are directly self-administered into a number of brain regions, including the NAc, lateral hypothalamus, amygdala, and the CA3 region of the hippocampus.

Opiates hyperpolarize neurons by increasing the outflow of K^+ through receptor-gated ion channels, and by closing Na^+ channels. As with stimulants, opiates also have the ability to acutely inhibit cAMP through mu and delta receptors coupled to G_i-proteins. Repeated opiate administration has the opposite effect of elevating cAMP levels within NAc cells, and increased cAMP has also been reported in the locus coeruleus, amygdala and thalamus after repeated opiate administration (Terwilliger et al., 1991). The activation of the cAMP pathway renders noradrenergic neurons less sensitive to opiate inhibition, resulting in rebound noradrenergic hyperactivity that has been hypothesized to underlie opiate withdrawal. Increased noradrenergic cAMP has also been reported with chronic stress, and there is an established relationship between stress and recidivism. In addition to noradrenergic effects, chronic exposure to opiates produces DA inhibition. During opiate withdrawal, extracellular DA is reduced in the NAc (Rossetti et al., 1992), and chronic opiate exposure leads to dramatically reduced DA firing rates that persist well beyond physical withdrawal (Diana et al., 1999). DA depletion may contribute to the reward inhibition and dysphoria that has been reported in opiate dependence (Dackis & Gold, 1992; Rossetti et al., 1992).

Opiate addiction has been a significant health problem in this country for many years, especially since the invention of the hypodermic syringe in the nineteenth century. Its poor prognosis is undoubtedly affected by the lure of opiate euphoria, a subjective and physiological state that differs greatly from psychostimulant intoxication (see Table 30.1). These drug states have opposite effects on vital signs, general arousal, libido, aggression, and vigilance. In addition, opiate use typically leads to a state of contentedness that lasts several hours, whereas cocaine use rapidly engenders additional cocaine craving (O'Brien et al., 1992).

A number of treatments are currently available for opiate dependence. Overdose is potentially lethal, usually due to respiratory inhibition, and can be reversed with naloxone, a mu receptor antagonist. Opiate withdrawal offers a classic example of how an understanding of brain mechanisms can uncover new treatments. A large body of clinical and preclinical research predicted the efficacy of clonidine,

an alpha-$_2$ adrenergic agonist, based on its ability to reverse noradrenergic hyperactivity associated with opiate withdrawal. Although alpha$_2$- agonists are effective for opiate withdrawal, patients usually prefer methadone. Heroin detoxification with methadone can be achieved with descending doses in about three days (Dackis & Gold, 1992) and dosing should be guided by clinical signs of withdrawal rather than patient-reported symptoms. Detoxification alone is seldom sufficient treatment and should be provided in concert with drug rehabilitation.

Even after detoxification and rehabilitative treatment, the majority of heroin addicts tend to relapse. Methadone maintenance, the transfer from intravenous heroin to a long-acting oral agonist, can achieve greater retention, reduced heroin use, and lower rates of HIV infection (Sees et al., 2000), viral hepatitis, and bacterial endocarditis. When combined with psychosocial treatment, an adequate dose of methadone can effectively stabilize many otherwise treatment refractory individuals. Two additional replacement agents are available to treat opiate addicts. Levo-alpha-acetylmethadol (LAAM), FDA approved since 1993, is a longer acting opioid that can be administered three times per week. Buprenorphine is a partial mu opiate agonist, an attribute that provides a 'ceiling' effect and diminishes lethality with overdose. Buprenorphine also attenuates the subjective effects of heroin. The availability of methadone, LAAM and buprenorphine provides the clinician with several options in treating these difficult patients.

A final treatment strategy for heroin dependence involves blocking heroin euphoria with naltrexone. Naltrexone has a high affinity for the mu and kappa receptors, and antagonizes neurotransmission by displacing opiate agonists such as morphine, heroin, and methadone. Since opiate receptor blockade produces acute withdrawal in dependent individuals, naltrexone should not be administered prior to the completion of detoxification. Special populations that may benefit from naltrexone are professionals with regular workplace exposure to drugs and probationers who are mandated to treatment (Cornish et al., 1997). Unfortunately, there has been little practitioner interest in this treatment, perhaps due to compliance issues. A long-acting depot form of naltrexone that provides clinically effective blood levels for 30–60 days is currently in clinical trials. It is hoped that this advance will improve medication adherence and reduce impulsive relapses.

THC and PCP

Marijuana is a widely abused substance, particularly by young people. Along with nicotine, another early exposure drug, marijuana has the potential to serve as a gateway to other drugs of abuse, perhaps due to its ability to activate reward circuitry and release DA into the NAc. Also, the persistence of marijuana's metabolites in the urine, combined with the widespread practice of pre-employment drug testing, can prohibitively affect the careers of both habitual and casual users. Marijuana produces drug seeking behaviour and addictive patterns, and its chronic use has been associated with withdrawal symptoms. As with alcohol, opiates, and stimulants, elevations in CRF occur during THC withdrawal (Rodriguez de Fonseca et al., 1997) and chronic exposure to marijuana reduces the firing rates of mesocorticolimbic DA cells (Diana et al., 1998). THC binds the cannabinoid receptor for which an endogenous ligand, anandamide, has been recently isolated (Devane & Axelrod, 1994). Cannabinoid receptors are found in the hippocampus, thalamus, cortex, and striatum, are coupled to G-proteins, and acutely inhibit cAMP levels. THC administration also reduces GABA output and releases DA into the NAc through a Ca^{2+}-dependent mechanism that can be blocked by naloxone (Chen et al., 1990). Therefore, THC appears to activate reward circuitry by stimulating DA and opiate systems. These actions of THC provide a neurochemical rationale for the well-established clinical prohibition of smoking marijuana when attempting recovery from other drugs of abuse.

Phencyclidine (PCP) exerts its rewarding effect through the blockade of NMDA receptors. Originally developed as an intravenous anesthetic, PCP ('angel dust') use was discontinued in humans due to the untoward effects of agitation, delusions, impaired judgment, and violent behaviour. PCP and other NMDA receptor antagonists have been proposed to have potential value in stroke models. The NMDA receptor is a complicated macromolecule that depolarizes neurons by opening gated Ca^{2+} channels, generally in the presence of both glutamate and glycine. This receptor is distinguished from two other glutamate receptor types, AMPA and KA, by its voltage-dependent characteristics, high permeability to Ca^{2+}, and activation of a nitric oxide cascade. PCP rewarding action may result, to some extent, from its ability to directly inhibit NAc medium spiny neurons. As previously discussed, these cells are normally activated by glutamatergic pyramidal neurons of the prefrontal cortex, and modulated by DA projections from the VTA. As a result of GABA inhibition, PCP has been reported to cause neurotoxicity through the release of excessive amounts of acetylcholine in the brain (Kim et al., 1999). Although PCP is not widely used at this time, a reduction in perceived risk could potentially lead to increased use of this dangerous agent. For example, MDMA ('ecstasy') has neurotoxic effects on serotonin neurons (Kosten, 1990) but

is currently popular and has low risk perception. The addictiveness of PCP, a specific NMDA antagonist, demonstrates the importance of glutamate pathways in the neurobiology of addiction.

Nicotine

Nicotine differs from previously discussed substances by its legality and the lack of functional impairment associated with its use. However, the tenacious quality of nicotine, combined with its extensive and serious medical complications, makes it arguably the most lethal of all addictive substances. Nicotine directly accounts for an estimated 400000 deaths per year (Epping-Jordan et al., 1998). Nicotine dependence involves reinforcement, tolerance, and withdrawal, and smokers often cite craving as the greatest impediment to quitting. Substitution therapy with a nicotine patch or nicotine gum has limited effectiveness, perhaps because these routes of administration do not provide the rapid delivery of nicotine seen with the intrapulmonary route. Encouraging results have been found with buproprion, an antidepressant that inhibits the DAT (O'Brien & McKay, 1998).

Nicotine stimulates nicotinic receptors that are located on DA cell bodies in the VTA and on DA terminals in the NAc (Dani & Heinemann, 1996), causing a release of DA into the shell of the NAc. In animal models, nicotine self-administration is reduced by destruction of mesocorticolimbic DA neurons (Corrigall et al., 1992) and by the administration of DA antagonists (Corrigall et al., 1994). Opiate antagonists also reduce nicotine self-administration, suggesting the involvement of both DA and EOP mechanisms. Nicotine withdrawal has been associated with changes in the distribution of nicotine receptors in the brain and with markedly reduced measurements of brain reward (Epping-Jordan et al., 1998). It is possible that a reduction in brain reward contributes to the intense craving characteristic of nicotine dependence. Since nicotine stimulates reward circuits it stands to reason that patients seeking recovery from other drugs might have more success if they quit smoking. Interestingly, 12-step self-help based approaches do not generally advocate nicotine avoidance and research is clearly needed to determine whether nicotine abstinence can improve recovery rates from other addictive agents.

Alcohol and sedative hypnotics

Alcohol has numerous actions on GABA, opiate, glutamate, DA, and serotonin neurotransmitter systems. Unlike other addictive agents with high affinity for membrane-bound proteins, alcohol mediates its effects on ion channels by disrupting the membrane lipid matrix. Alcohol facilitates GABA-mediated neurotransmission by promoting Cl^- influx through $GABA_A$-gated ion channels. This effect on Cl^- influx decreases with repeated alcohol administration, and may contribute to the development of alcohol tolerance (Koob & Weiss, 1992). A number of studies report that GABA neurotransmission is increased during alcohol intoxication and decreased during alcohol withdrawal. Consistent with these findings is the fact that alcohol withdrawal can be reversed with GABA agonists (such as benzodiazepines) and alcohol withdrawal seizures respond to GABAergic anticonvulsants.

The importance of opiate mechanisms in alcohol reward is illustrated by the fact that mu antagonists reduce alcohol consumption, especially when administered directly into the central nucleus of the amygdala (Koob & Weiss, 1992). Also, alcohol administration increases endorphin levels while alcoholics in withdrawal have reduced levels of beta-endorphin (CSF) (Koob & Weiss, 1992). Alcohol-induced DA release into the NAc is blocked by opiate antagonists (Acquas et al., 1993), suggesting an opiate mechanism of this phenomenon. Although the precise mechanism of alcohol's effect on opiate systems in the brain is not known, the appreciation of EOP involvement led to the landmark development of naltrexone as a treatment for alcoholism (Volpicelli et al., 1992).

DA mechanisms are also involved in alcoholism. Rats selectively bred for alcohol preference have an exaggerated DA response to alcohol, whereas D_2 receptor deficient (D_2 knockout) rats show a marked aversion to alcohol (Koob & Weiss, 1992). Alcohol directly and robustly excites DA neurons of the VTA (Brodie et al., 1999), increases DA synthesis and turnover, and releases DA into the NAc (Koob & Weiss, 1992). In addition, DA antagonists applied to the NAc reduce alcohol self-administration (Koob et al., 1998). These findings suggest an important role for DA in alcohol reward. However, the selective destruction of DA terminals in the NAc does not reduce alcohol self-administration (Koob et al., 1998), suggesting an additional DA-independent mechanism in alcohol reward.

Alcohol has chronic actions on DA neurons that are similar to those seen with cocaine and opiates. With chronic alcohol exposure, there is a reduction in DA release (Weiss et al., 1996) and a sustained inhibition of DA firing that persists well beyond the withdrawal state (Diana et al., 1996). This has led to the hypothesis that alcohol-induced DA depletion leads to hedonic inhibition, craving and relapse tendencies of alcoholics (Wise, 1996), as has been proposed with individuals addicted to opiates (Rossetti et

al., 1992), cocaine (Dackis & Gold, 1985), and marijuana (Diana et al., 1998). The high prevalence of depression and suicide in alcoholics and other substance abusers could also result, to some degree, from impaired hedonic function.

Alcohol has additional actions on serotonin, glutamate, and noradrenergic systems. Alcohol preferring rats have reduced levels of brain serotonin, and pharmacological enhancement of serotonin reduces alcohol intake (Koob & Weiss, 1992). However, serotonin depletion also reduces alcohol intake, and serotonergic agents have not been found effective in treating alcoholism (O'Brien & McKay, 1998). Additionally, alcohol reduces NMDA neurotransmission through allosteric blockade of Ca^{2+} and Na^{+} channels, resulting in a reduction of ion current that is linearly related to alcohol intoxication (Lovinger et al., 1989). Conversely, alcohol withdrawal is associated with increased NMDA neurotransmission (Fitzgerald & Nestler, 1995). Alcohol withdrawal may also involve noradrenergic hyperactivity as evidenced by the presence of hypertension, tachycardia, hyperreflexia, diaphoresis, insomnia, tremor, and anxiety (Koob & Weiss, 1992). Detoxification from alcohol is seldom a sufficient treatment for alcoholics and does not eliminate the protracted craving and recidivism that is characteristic of alcoholism. Rehabilitation through professional and self-help approaches should be strongly encouraged with these patients.

Medications currently available for treating alcoholism include detoxification agents, disulfiram, and naltrexone. Detoxification has been reviewed elsewhere (Dackis & Gold, 1992) and generally involves prescribing descending doses of benzodiazepines (or barbiturates) over 3–5 days. Disulfiram inactivates aldehyde dehydrogenase, resulting in high levels of the toxic metabolite, acetaldehyde, when alcohol is consumed. This results in aversive subjective effects that should theoretically discourage drinking. However, double-blind trials have not shown disulfiram to be better than placebo (O'Brien & McKay, 1998) and alcoholics tend to simply discontinue disulfiram and resume drinking. Also, disulfiram does not reverse chronic neuroadaptative changes caused by alcohol and is ineffective against alcohol craving.

Promising results in the treatment of alcoholism have been demonstrated with naltrexone. Naltrexone reduces alcohol consumption and ameliorates craving for alcohol, and its effectiveness may continue beyond the period in which the drug is taken (O'Brien & McKay, 1998). Naltrexone also reduces the rewarding effects of alcohol, presumably by blocking opiate-mediated reward. In spite of numerous studies confirming the efficacy of naltrexone in the treatment of alcoholism, its clinical use is not widespread. Acamprosate, a GABA receptor agonist, is currently under investigation and has been shown to be effective in five studies in Europe (O'Brien & McKay, 1998).

Sedative hypnotics, particularly benzodiazepines, are widely prescribed for anxiety, muscle tension, insomnia, and convulsions. Benzodiazepines, barbiturates, and alcohol produce a similar and characteristic state of reduced anxiety, disinhibition, euphoria, sedation, and hypnosis (Koob & Nestler, 1997). Sedatives facilitate GABA-mediated neurotransmission through allosteric actions on the GABA receptor complex, opening GABA-gated chloride channels. This action serves to inhibit target neurons and, in this regard, sedatives share effects and cross-tolerance with alcohol (Koob & Nestler, 1997). Unlike alcohol, sedatives have no effect on the NMDA receptor. Clinically, it is imperative to maintain a high degree of suspicion for sedative dependence since it is often covert, and withdrawal can be protracted. Successful detoxification from sedatives can be achieved by instituting a descending dose schedule of either phenobarbital (for barbiturates) or long-acting benzodiazepines like chlordiazepoxide (for benzodiazepines), and detoxification may require several weeks duration (Dackis & Gold, 1992). With the exception of treating withdrawal, sedatives should not normally be prescribed to alcoholics due to their addiction potential, similarity in brain action, and ability to reinstate alcohol intake.

In conclusion, extensive research into the neurobiology of addiction has yielded a number of interesting findings and some new treatments. It is evident that addictive drugs with diverse pharmacological and subjective effects activate common reward pathways (see Table 30.2). Increased DA neurotransmission is universally found during drug intoxication, while DA depletion and reduced DA neurotransmission appears to be a feature of chronic addiction. The NAc, thought to be a crucial target of DA projections, is largely composed of GABA/EOP-containing projection neurons. These medium-sized spiny cells convey reward-related information to a number of brain regions known to be associated with motivation and feeling states, including the thalamus, cingulate and frontal cortex, and the hypothalamus. The inhibition of GABA/EOP medium-sized spiny cells occurs in all intoxication states. While GABA/EOP neurons in the NAc are inhibited during drug intoxication, suppression may become increasingly difficult with repeated drug exposure due to molecular changes associated with the cAMP second messenger pathway. Neuroadaptations such as this may contribute to clinical phenomena associated with addictive illness, including tolerance, withdrawal, and hedonic inhibition

Table 30.2. Acute mechanisms of action of major addictive drugs

Alcohol	Facilitates GABA-mediated neurotransmission Antagonizes NMDA-mediated neurotransmission
Amphetamine	Releases DA through reverse transport Releases 5-HT, norepinephrine
Cocaine	Antagonist at DAT, local anesthetic action Antagonist at 5-HT and norepinephrine transporters
Heroin and opiates	Agonist at opiate receptors
Marijuana	Agonist at cannabinoid receptors
Nicotine	Agonist at nicotinic cholinergic receptors
Phencyclidine	Antagonist at NMDA receptors

(see Table 30.3). Since inhibition of medium-sized spiny neurons within the reward centres appears to be an important feature of drug reward, medications capable of altering GABA/EOP function should be high on the list of potential therapeutic agents to be investigated. Although pharmacological treatments for addiction are currently limited, additional treatments may result from a refined understanding of the neuronal and molecular aspects of addiction.

Several lines of evidence support the existence of two separate reward systems in the brain that are activated by different classes of addictive agents. Alcohol and opiates are self-administered even after the chemical ablation of DA terminals (Koob et al., 1998), strongly suggesting the existence of DA-independent reward mechanisms. Also, the intoxication produced by opiates, alcohol, and sedatives differs markedly from that of stimulants, also suggesting the activation of different brain mechanisms. Stimulants and opiates may act on different brain systems that have evolved to reward the procurement and consumption, respectively, of survival needs. Stimulants

Table 30.3. Acute and chronic neurotransmitter effects of addictive substances are indicated. Chronic neuroadaptations are often opposite to acute effects

	Acute actions	Chronic neuroadaptations
Stimulants	Increase DA levels in the NAc Reduce cAMP in the NAc Reduce DA and NE firing rates Decrease GABA firing rates	Deplete DA Increase cAMP in the NAc Increase CRF Increase NMDA receptor sensitivity Reduce D_2 autoreceptor sensitivity Decrease orbitofrontal metabolism Reduce brain reward
Opiates	Release DA into the NAc Reduce cAMP in the NAc DA burst firing Inhibit GABA neurons	Deplete DA Increase cAMP in the NAc NE hyperactivity Increase cAMP in the locus coeruleus Increase CRF
Alcohol	Releases DA into the NAc Decreases NMDA neurotransmission Increases GABA neurotransmission Increases EOP levels Produces DA burst firing	Depletes DA Reduces DA firing rates Increasees NMDA neurotransmission Decreases GABA neurotransmission Reduces EOP levels Increases CRF Reduces brain reward
Nicotine	Release DA into the NAc DA burst firing	Reduces brain reward
Marijuana	Releases DA into the NAc Reduces cAMP in the NAc Blocks GABA output	Depletes DA Increases cAMP in the NAc Increases CRF

promote vigilance, psychomotor and autonomic activation, environmental interaction, and intensification of craving. These activating effects would be desirable in the pursuit of survival goals. Opiates, on the other hand, produce euphoria, behavioural suppression, relaxation, and satiation, and may act on a system designed to punctuate consumption and provide consummatory reward.

Basic science research supports many clinical practices that are currently used in the treatment of addiction. Since all addictive drugs activate reward circuits, and appear to produce similar neuroadaptations with chronic use, reinstatement of addiction is a risk when any addictive agent is used. This notion supports the clinical principle that recovery from one class of addictive drugs is best achieved when all addictive drugs are avoided. The avoidance of cues associated with drug use, a central theme of drug rehabilitation, is strongly supported by PET studies showing limbic activation during cue-induced craving. Reliance on peers and professional caretakers during early recovery may be especially important to counter powerful limbic craving, and compensate for the lack of internal resolve that may result from impaired frontal lobe executive function. Genetic variations affecting the reward circuitry could explain why certain individuals are more likely to develop addiction. The possibility that nicotine use could undermine recovery, through its ability to stimulate the VTA–NAc pleasure circuit, warrants research. Given the biological underpinnings of addiction, clinicians should view addiction as a disease rather than a weakness, and maintain a compassionate and non-judgmental approach to their patients. In addition to being seriously afflicted with a brain disease, drug addicts and alcoholics are often victimized by prejudice and misunderstanding. Hopefully, further elucidation of the neurobiology of addiction will change perceptions, diminish prejudice, and reduce obstacles faced by afflicted individuals who are seeking acceptance and access to medical care.

Historical overview

The idea that the cortex of the brain could be responsible for the control of movement or indeed that any function could be localized to the cortex is a relatively new one. Until the middle of the nineteenth century it was generally thought that the cerebral cortex was the repository of thoughts and ideas. Nevertheless, Robert Boyle, one of the founders of the Royal Society and originator of the eponymous Boyle's Law, had suggested in 1691 that some aspects of motor function could be localized within the cerebral cortex. Franz Joseph Gall, the father of phrenology, had been a strong advocate of localized function within the cortex, and had suggested that the frontal lobes contained centres for speech some decades before Broca. Observations made by the British neurologist John Hughlins Jackson on patients with focal seizures convinced him that motor activity was localized within the surface of the brain. However, the first experimental demonstration of such localization came with the electrical stimulation experiments of Fritsch and Hitzig in 1870 (Fig. 31.1). They applied galvanic current to the brain of a dog and were able to elicit movements on the opposite side of the body. In 1875 David Ferrier (Ferrier, 1875) did similar experiments on the cortex of the monkey using faradic stimulation. Given the relatively crude methodology employed, the movements elicited by Ferrier through stimulation of different areas conform well to the somatotopic map currently accepted. Sherrington and his colleagues (Leyton & Sherrington, 1917) did a series of detailed experiments, using more refined stimulation methods, on the brains of anthropoid apes to more precisely define the motor and sensory areas of the cortex. Their findings were more detailed than those of Ferrier and not much different from the current standard maps of somatotopic distribution (Fig. 31.2).

Stimulation experiments were also done on the human brain. One of the most dramatic and earliest descriptions

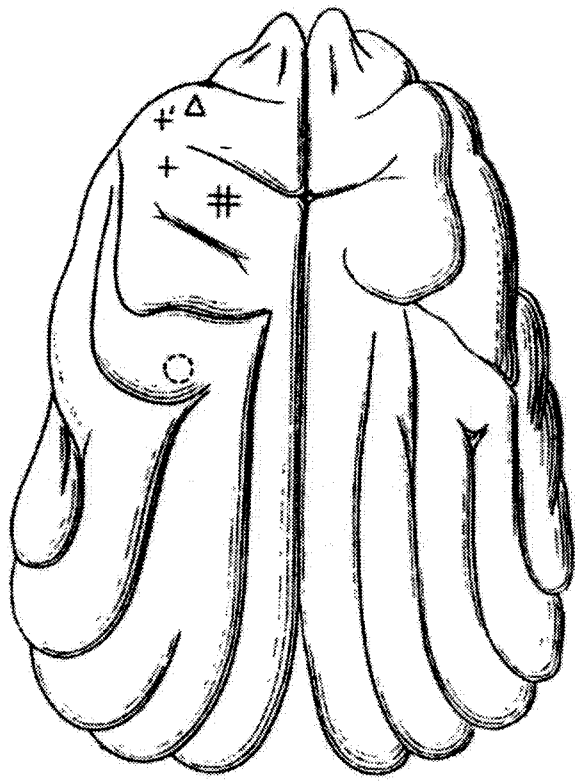

Fig. 31.1. Figure from the classic experiment of Fritsch and Hitzig in 1870. Shows the exposed cortical surface of the dog viewed from above. The symbols denote parts of the surface to which galvanic current was applied and the type of movement elicited in different groups of muscles on the opposite side of the body: # (hindlimb), + (forelimb), +′ (forelimb), △ (neck), ○ (facial). (From Fritsch and Hitzig, 1870, figure 2.)

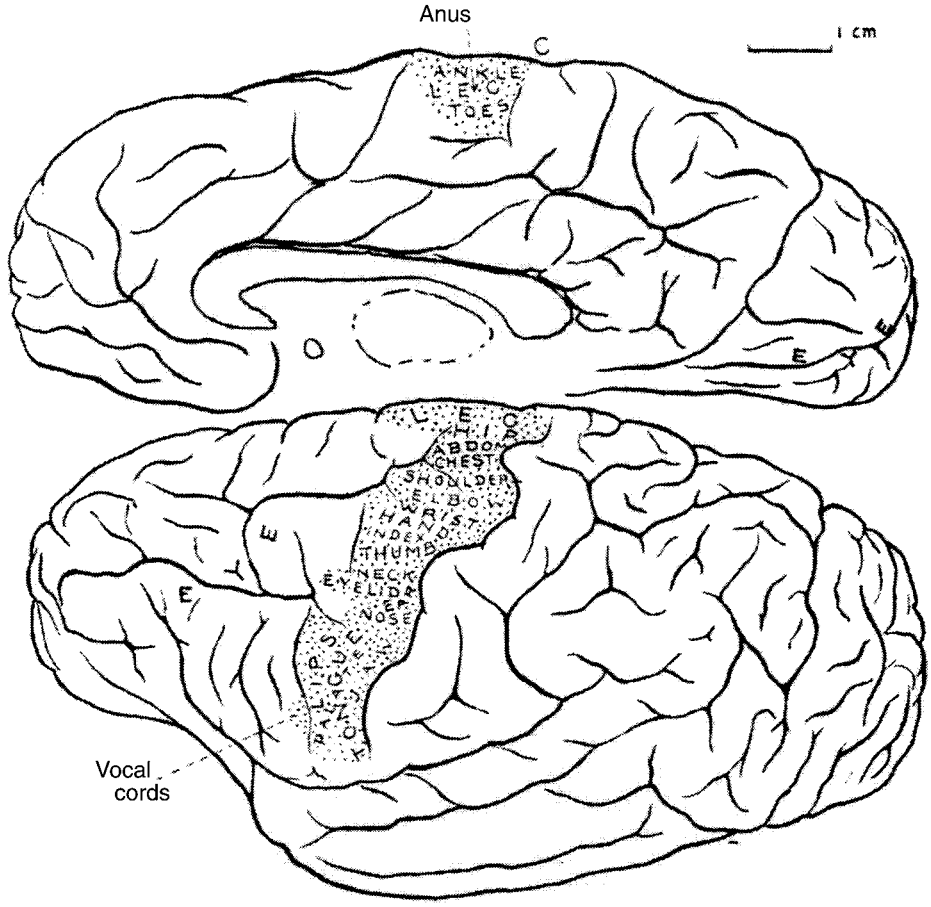

Fig. 31.2. Medial (above) and lateral view of the cortical surface of the brain of the gorilla. Points along the precentral gyrus where stimulation was applied are indicated by dots. The body parts in which movements were elicited following localized stimulation are also shown. (From Leyton and Sherrington, 1917, figure 10.)

of cortical stimulation in a human is to be found in an account by a Dr Bartholow of the Medical College of Ohio (Bartholow, 1874). He describes inserting a needle electrode into the parietal lobe of a patient through a defect in the skull. When current was passed through the electrode, movements were elicited on the opposite side of the body as well as pain and other sensations. Since these pioneering studies, we have gained a much clearer concept as to how the frontal lobes relate to the control of voluntary movement through the use of a variety of investigational techniques.

Investigating the functional properties of motor areas

The are a wide variety of methods that can be used to examine the functional properties of the different motor areas. As already mentioned, most of the earlier data came from electrical stimulation and lesion studies in animals, and from the observation of human subjects with brain lesions following trauma or stroke. After the introduction of extracellular neuronal recording in awake monkeys by Jasper (Ricci et al., 1957) it became possible to more precisely relate dynamic neural activity to aspects of motor behaviour. More recently, the use of functional imaging techniques (Ugurbil et al., 1999), such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), and other approaches such as transcranial magnetic stimulation (Hallett, 2000) has made it possible to study motor areas in the normal human brain in a relatively non-invasive way and at high spatial resolution. The techniques that may be used in the investigation of motor function differ as regards spatial resolution, temporal resolution, and invasiveness and

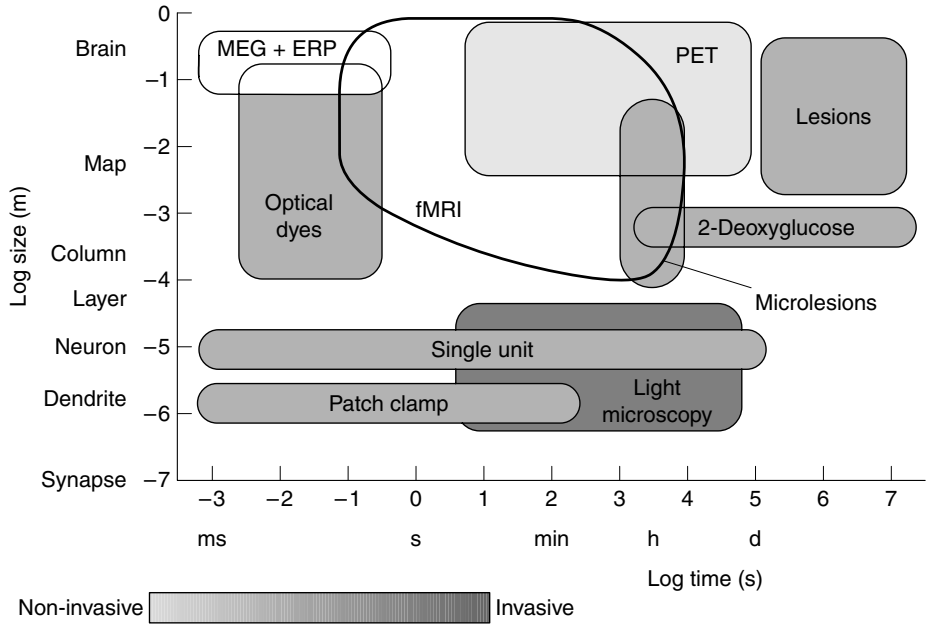

Fig. 31.3. The spatial resolution, temporal resolution, and invasiveness of different experimental techniques used to study the brain. (From Cohen and Bookheimer, 1994, figure 4.)

consequently provide very different types of information (see Fig. 31.3).

Motor cortex and other cortical motor areas

The results of early stimulation studies suggested that the motor portion of the frontal lobe was coextensive with the precentral gyrus, defined cytoarchitectonically as Brodmann area (BA) 4. However with the passage of time it became clear that this narrow view of what constituted 'motor cortex' was not consistent with data from lesion studies (Fulton, 1935) or stimulation experiments in both humans (Penfield & Welch, 1949) and monkeys (Woolsey et al., 1952). We now recognize that the cortical motor areas include both BA 4 and 6. The motor cortex proper or primary motor cortex is in area 4, while several distinct premotor areas, both functionally and anatomically, are located in area 6 (Geyer et al., 2000).

Motor cortex

The motor cortex in BA 4 is designated 'primary' because (i) historically it had been regarded as the only motor area, (ii) its neurons have the most direct and prominent connection to motor neurons in the spinal cord via the corticospinal tract, (iii) it is particularly important for the control of hand and finger movement, and (iv) lesions of this area or its projections frequently result in the most severe motor deficits.

A central question in motor physiology has been whether the motor cortex controls movement by specifying the activation of individual muscles or is primarily involved at a 'higher' level such as the control of whole movements or movement parameters like direction, force, velocity, acceleration etc? This issue of the 'representation' of movement within the motor cortex has been addressed using a variety of different approaches.

Clinical observation

Before the experimental studies of cortical stimulation of Frisch and Hitzig in the dog and Ferrier in the monkey, the neurologist John Hughlings Jackson in 1864 put forward an hypothesis about the cortical representation of movements based on his clinical observations in patients with stroke or convulsions (Jackson, 1864). He noted that, in patients with stroke, or other lesions of the cortex, the main deficit was an inability to perform certain movements rather than weakness in specific muscles and that, even with large lesions, many movements remained intact. There were several components to his hypothesis. He believed that the neural mechanisms of sensorimotor

processes, rather than muscles were represented in the motor cortex: 'The nervous centres represent movements not muscles; cords not notes'. He also believed that all the movements of which an individual is capable are represented in the motor cortex. A direct extension of this is that the hand, for example, a body part capable of a great variety of movements will be more widely 'represented' within the motor cortex, than the leg or the trunk. Jackson conceived of a pattern of overlapping representations of body parts within the motor cortex, the extent of any representation being determined by the repertoire of movements a particular body part possessed.

Cortical stimulation

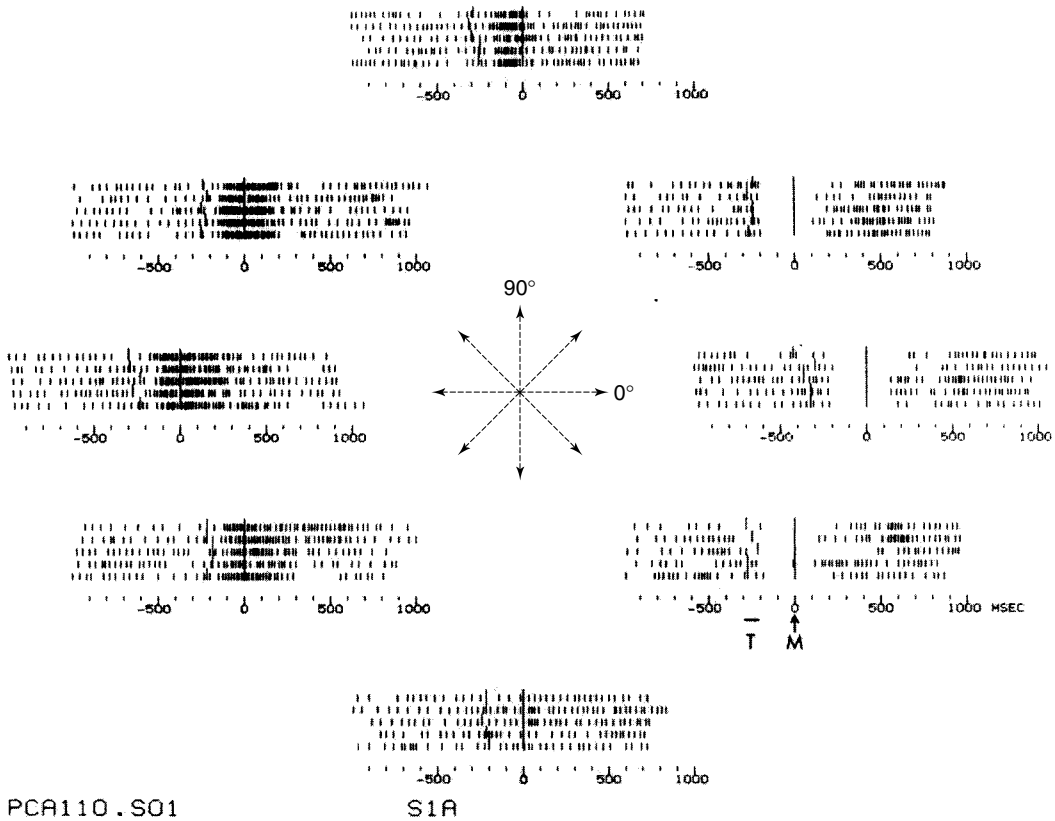
The first direct approach to the issue of representation as conceived by Jackson was through experiments using cortical stimulation, in which electrical stimulation was applied to the cerebral cortex and movements of limbs, joints, and muscles were observed (Penfield & Rasmussen, 1950). These studies showed that the principal body parts were represented separately though not equally, and that the order of this arrangement conformed in a general way to the body surface (somatotopy). However, these studies did not show how movements were represented, merely, that body parts were organized in an orderly way on the cortical surface and that there were direct excitatory connections between the motor cortex and motoneurons in the spinal cord.

Neural recording

The most detailed information to date about the representation of movement has come from neural recording from cells in the motor cortex of subhuman primates during the performance of movement under controlled conditions. Particular attention has been paid to whether the motor cortex plans and codes for movement in spatial terms such as direction and amplitude. In one experiment monkeys were trained to make arm movements from a central starting point to one of eight targets evenly spaced on a circle. During this task a large proportion of cells in the motor cortex were 'tuned' to the direction of movement (Fig. 31.4). Such cells had a preferred direction of movement in which the activity of the cell was highest and the activity decreased progressively as one deviated further from this direction. The interesting question is how cells in the motor cortex with these properties indicate or 'code' the direction of limb movement. Georgopoulos and colleagues (Georgopoulos et al., 1983) proposed, and subsequently demonstrated, that the coding of direction is actually done by a population of cells though the construction of a population vector which predicts the direction of an upcoming arm movement. The concept of the population vector is that for any movement each cell in the motor cortex which is directionally tuned, makes a contribution in its preferred direction, and the magnitude of this contribution is proportional to the angle between its preferred direction and the actual direction of movement. Figure 31.5 (see colour plate section) illustrates this concept for movement in one direction.

These and similar experiments (Alexander & Crutcher, 1990; Ashe & Georgopoulos, 1994; Kakei et al., 1999) suggest that the motor cortex represents movement in terms of the direction of the limb in space rather than on the basis of the activation of individual muscles. This raises the issue of how and at what level the activation of specific muscles, essential for goal directed movement, is achieved. It is likely that during infancy we learn the mapping between the spatial aspects of limb movements and the muscles that need to be activated for those movements to occur. Thereafter, spatial instructions from the motor cortex will automatically activate the appropriate muscles to execute the movement. Recent data which supports this intuitive conclusion comes from experiments in human subjects who were asked to make movements to targets in the presence of a complicated force field opposing the movement (Shadmehr & Mussa-Ivaldi, 1994). At first the movement trajectories were quite disrupted by the force field (Fig. 31.6(*a*)). However, over time, the movement trajectories reverted to those before the force field was imposed (Fig. 31.6(*b*)). The fact that the subjects adapted to the force field and produced smooth straight trajectories although they had received little instruction as to what movements to make suggests that movement is planned in terms of trajectory. To probe exactly how this adaptation was achieved, the force field was suddenly withdrawn (Fig. 31.6(*c*)). Subjects now produced movements with abnormal trajectories (almost the mirror image of the original perturbation) as if they were compensating for the forces they expected to experience. Therefore it is likely that the subjects built an 'internal model' of the forces which mapped the signals being produced by the motor cortex onto the forces being generated by the muscles. Whether one sees a reflection of this internal model in the activity of cells in the motor cortex during motor learning is currently being investigated in a number of laboratories (Gandolfo et al., 2000; Li et al., 2001). What is clear is that one does not see such activity once behaviours have been mastered.

If there is little evidence of a translation of a spatial signal to one indicating muscle activation in the motor cortex then where does this necessary transformation occur? Bizzi and colleagues (Bizzi et al., 1991; Gistzer et al., 1993; Tresch & Bizzi, 1999) have shown in experiments in the frog and rat



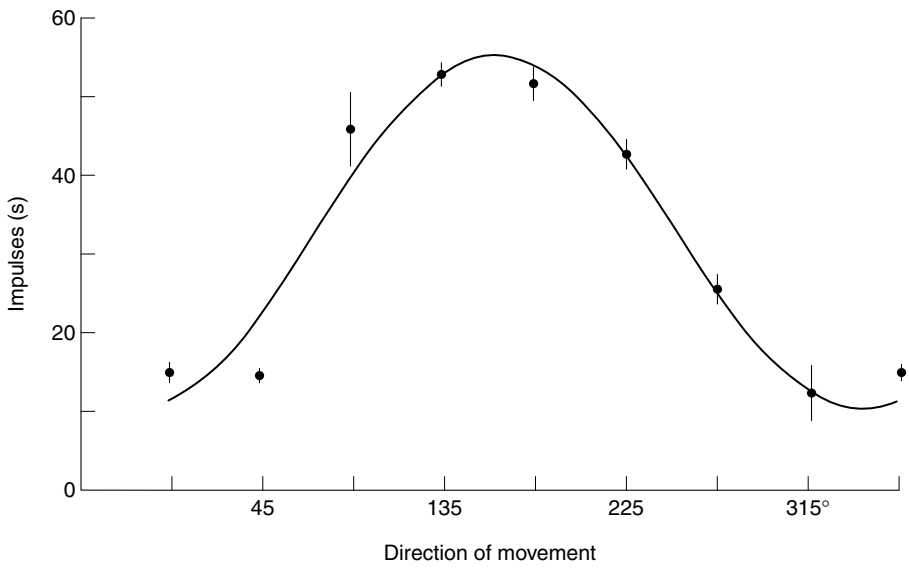


Fig. 31.4. Variation in the frequency of discharge of a single motor cortex cell during movement in different directions. *Upper half*, Each small tick indicates an action potential; the display shows impulse activity during five repetitions (trials) of movements made in each of the eight directions indicated in the centre diagram. Trials are oriented to the onset of movement *M. Lower half*, Direction tuning curve of the same cell; the average frequency of cell activity during the response time and movement time is plotted for each of the eight directions. (From Georgopoulos et al., 1982, figure 4.)

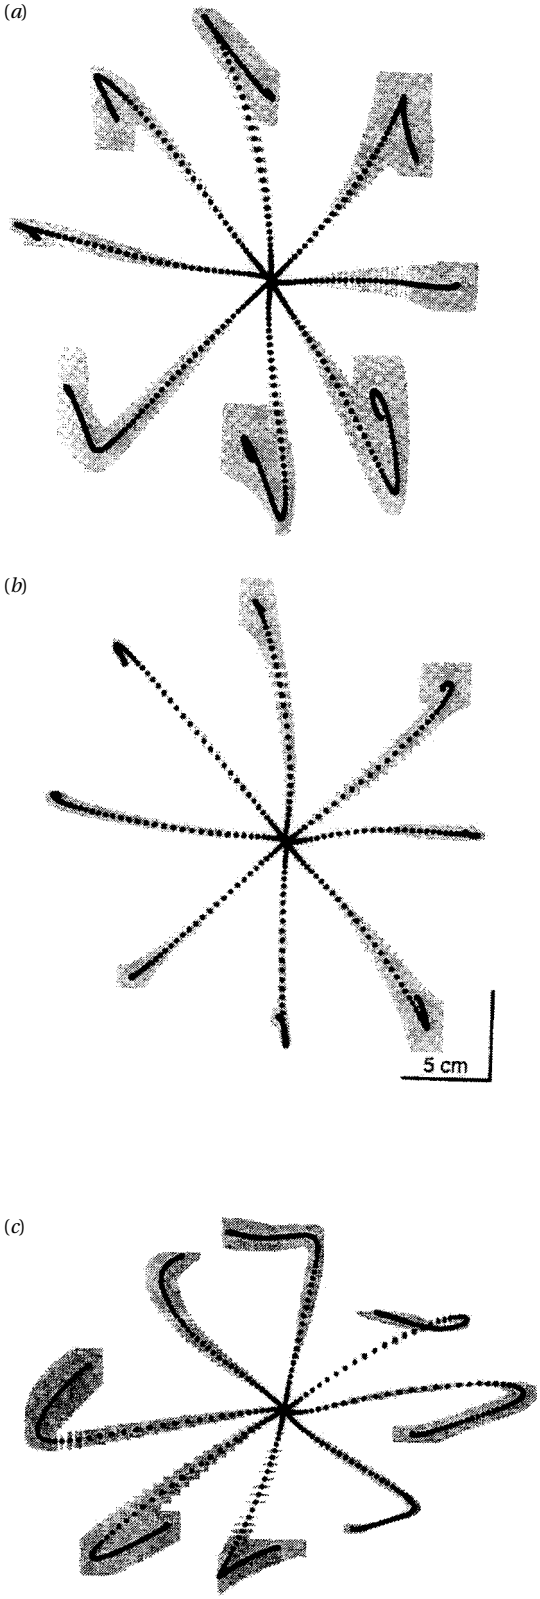

Fig. 31.6. Averages ± SD of hand trajectories during (*a*) the initial exposure to the force field, (*b*) following adaptation to the field and (*c*) after the force field was abruptly withdrawn toward the end of the training period. (From Shadmehr and Mussa-Ivaldi, 1994, modified from figures 9 and 13.)

that a set of 'motor primitives', which could form the basis of activating specific sets of muscles during multijoint movement, can be elicited through microsimulation of the spinal grey matter. These primitives may form the building blocks for voluntary movement by translating spatial signals from the motor cortex into appropriate muscle output. In addition, other spinal interneuronal systems such as the propriospinal system in the cat (Lundberg, 1979) have been shown to be important in the patterned activation of the different muscles required for reaching. Propriospinal neurons at the C3–C4 level in the cat have monosynaptic connections to motoneurons supplying proximal muscles. These propriospinal neurons, in turn, have monosynaptic connections to several supraspinal systems, including the corticospinal tract. Interruption of the projections from the interneurons results in abnormal reaching movements (Alstermark et al., 1981). These propriospinal interneurons may participate in the integration of reaching movements at a spinal level, and effectively translate signals from cells in the motor cortex that relate to the direction of force output of the whole limb (Georgopoulos et al., 1982) into appropriate patterns of muscle activation.

The premotor cortex

If the motor cortex is the most important area for the control of voluntary movement this inevitably raises the issue of the function of the other motor areas in the frontal lobe: the premotor areas (see Fig. 31.7). The functional division between the motor cortex and the other frontal motor areas is not strict nor is there the rigid hierarchy among them that had been previously thought (see Geyer et al., 2000). The motor cortex and premotor areas operate in parallel in the production of movement. Differences in the functional properties among these areas are relative rather than absolute.

Lateral premotor cortex

There are at least two distinct subareas within the lateral premotor cortex in humans: the dorsal (PMD) and ventral (PMV) premotor cortex, and there may be even more based on evidence from subhuman primates (Geyer et al., 2000). There has been a great deal of controversy about the consequences of lesions of the human lateral premotor area. Earlier workers noted a loss of skilled movements, forced

grasping, and spasticity, similar to those deficits seen with motor cortex lesions (Fulton, 1935); while others documented few if any adverse effects of lesions (Walshe, 1935). One consistent finding in humans has been prominent weakness in proximal muscles which led to the suggestion that an important function of the lateral premotor cortex was to place the limb in a position appropriate for action. More detailed work from neural recording in non human primates has pinpointed some clear functional divisions between the two major portions of lateral premotor cortex.

Neurons in the PMV can have both tactile and visual receptive fields (Rizzolatti et al., 1988; Graziano & Gross, 1998). The interesting feature, however, is that the visual receptive fields move with the arm and not with the eyes (Graziano & Gross, 1998). This feature enables the integration of somatosensory, visual and motor information and provides the substrate for the online visual guidance of movement which is now thought to be a prominent function of the PMV. Cells in the PMD show many of the same features as those in the motor cortex such as directional properties (Caminiti et al., 1990). This area may also be the site of the final step in the transformation of visual signals, which are initially coded in retinal coordinates, to a coordinate framework based on the arm (Johnson et al., 1996). The most compelling theory of PMD function is that it is involved in stimulus–response mapping. Neurons in this area integrate information about the properties of the stimulus, including its spatial location, with the attentional state of the subject, and the action or response required, so that we can more effectively interact with our environment.

Medial premotor areas

The medial premotor region contains both the supplementary motor area (SMA) and the cingulate motor areas. The SMA is further subdivided into two regions which are functionally and anatomically distinct, the SMA proper and the pre-SMA which is just anterior to it (Tanji, 1994). The cingulate motor areas in the human may contain up to three separate functional regions (Picard & Strick, 1996).

SMA

Data from subjects with lesions involving the SMA or medial premotor cortex have suggested that an important function of the SMA is in the temporal organization of sequences of movements, particularly when these sequences are produced from memory (Goldberg & Bruce, 1985; Halsband et al., 1993). For example, following a stroke in the medial premotor cortex a concert pianist was no longer able to make transitions smoothly from one note to the next or maintain the relative timing values of the notes although the actual spatial sequence was correct (Foerster,

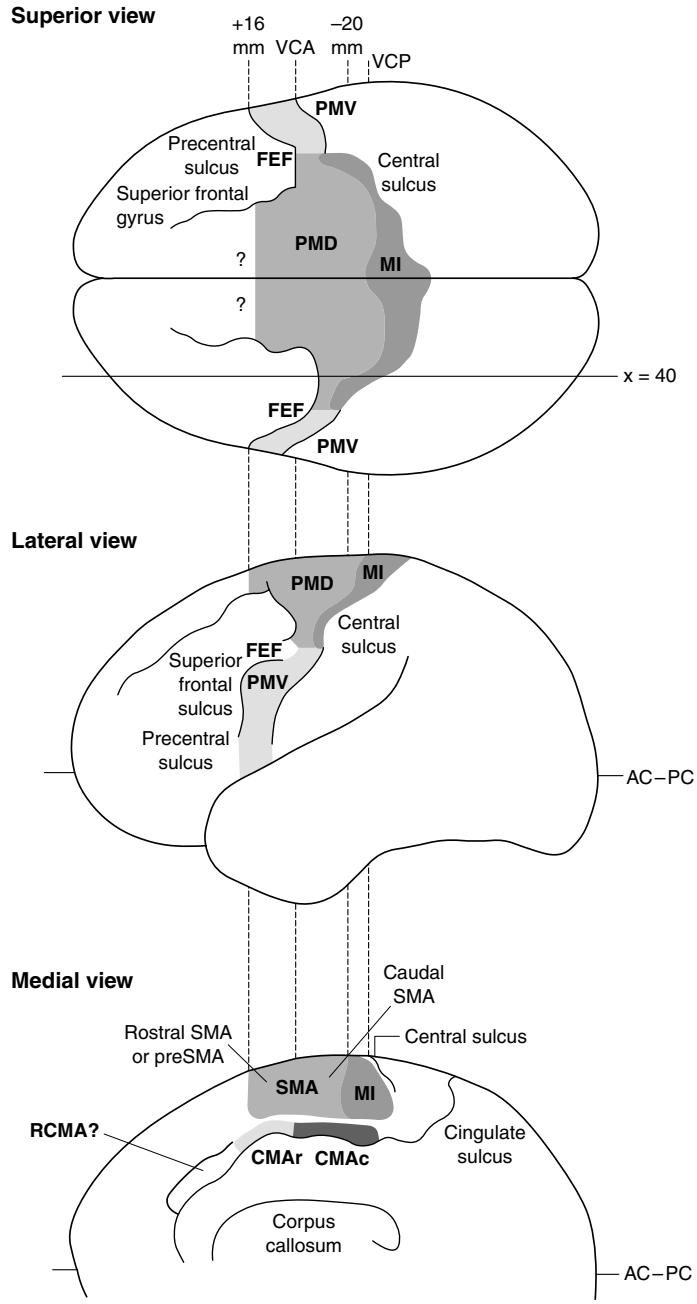

Fig. 31.7. Schematic diagrams of the proposed subdivisions of the cortical motor areas in humans from three different perspectives. AC-PC, anterior commisure–posterior commisure plane; CMAc, caudal cingulate motor area; CMAr, rostral cingulate motor area; FEF, frontal eye fields; M1, primary motor cortex; PMD, dorsal premotor cortex; PMV, ventral premotor cortex; RCMA, rostral anterior cingulate motor area; SMA, supplementary motor areas; VCA and VCP, coronal plane through the anterior and posterior commisure, respectively; $x = 40$, 40 mm from midline. (Adapted from Roland and Zilles, 1996, figure 1.)

1936). The Russian psychologist Luria noted that, although the ability to perform simple movements was preserved following lesions of the medial premotor cortex, there were impairments in complex sequences of movements, particularly when such movements had to be learned (Luria, 1966). In addition, the medial motor areas are involved in the control of bimanual movements; there is strong evidence for this, both from neural recording in monkeys and imaging in humans. The SMA has been subdivided on functional and anatomical grounds into the SMA proper, which has prominent connections to the motor cortex and projections to the spinal cord, and the preSMA which is more closely connected to the prefrontal cortex (Tanji, 1994). PreSMA is more active while learning novel motor behaviours, whereas SMA is prominently involved during the performance of previously learned sequential behaviours. The reports of akinetic mutism following medial premotor lesions in humans are almost certainly due to the involvement of the far anterior portions of the cingulate gyrus which do not have a prominent motor function.

Cingulate motor areas

Three distinct subregions have been defined within the cingulate motor area; all of which are buried in the cingulate sulcus (Picard & Strick, 1996). These comprise a rostral anterior cingulate motor area (RCMA) and two more posterior areas (see Fig. 31.7) divided into cingulate motor area rostral (CMAr) and caudal (CMAc). The RCMA has functions which appear little related to the control of action but is engaged in such operations as spatial attention, working memory, semantic and episodic memory (see Cabeza & Nyberg, 1997) and the online monitoring of performance (Carter et al., 1998). Nevertheless, there are direct projections from the cingulate motor areas to the spinal cord (Dum & Strick, 1991) and in the case of the more posterior areas a substantial number of the neurons project to motoneurons supplying the distal muscles of the upper limb (Dum & Strick, 1991; He et al., 1995). Therefore, these areas, like the motor cortex, may be involved in the control of distal movements. However, the specific function of the cingulate motor area is unclear. In imaging studies of the whole brain, activity within the most posterior cingulate motor areas seems to parallel that within the SMA. There have been few lesion studies restricted to this region, and comprehensive neural recordings have not been performed.

Motor deficits following stroke in humans

The constellation of motor symptoms resulting from stroke in humans seem to be primarily related to damage to the motor cortex or to its subcortical projection fibres (see Rondot, 1969; Rascol et al., 1982; Foix & Levy, 1927; Mohr et al., 1993). Given that vascular lesions generally do not respect cytoarchitectonic boundaries in the brain such statements are approximate at best. While it is not our purpose to treat the various stoke syndromes in any great depth, we can recognise two general types which primarily affect the motor system. The first is the result of infarction of the middle cerebral artery (MCA) or one of its principal branches, the second, the typical lacune, due to small vessel disease in or around the internal capsule.

MCA

Infarction of the main trunk of the MCA often leads to quite a profound deficit with contralateral hemiplegia, hemianesthesia and hemianopia in addition to deviation of the eyes and head toward the lesion. Lesser degrees of infarction such as from occlusion of the upper division of the MCA lead primarily to contralateral motor and sensory deficits which are less severe. There is some controversy as to the expected distribution of weakness in these cases. It has been generally held that the most severe weakness was in the distal arm and lower face and leg in keeping with the principles outlined by Broadbent in the nineteenth century (Broadbent, 1872) and consistent with the areal somatotopic distribution of these body parts on the precentral gyrus. However, this view has been recently challenged particularly by Mohr (Mohr et al., 1993) who maintains that usually proximal and distal movements are equally affected. Monoplegias are extremely rare and when present almost invariably indicate a cortical lesion.

Lacunes

Stroke due to small vessel ischemia in and around the internal capsule is perhaps the most common form of stroke seen clinically. The deficits associated with up to 70% of lacunar strokes are predominantly motor in character and have often been described as representing a form of pure motor stroke (Fisher & Curry, 1965; Rascol et al., 1982). However, it is pure only to the extent that there are not significant deficits in sensation, behaviour, language or vision. Although sensory symptoms may be frequent objective signs are rare. Face, arm and leg are generally equally affected. It has been commonly held that there was a fairly strict somatotopic distribution within the internal capsule. The results of studies correlating radiological lesions with deficits in humans would suggest that this is not the case.

Clinical–physiological interpretation

One of the more striking aspects of the deficits in patients following stroke is that, even in cases in which there is not profound weakness, there is poverty of movement. This seems to fit well with the concept of Jackson that the motor cortex is primarily concerned with movements rather than with muscles; when this representation is disrupted it is the movements rather than the muscles which are affected. The relative lack of correlation between weakness and the general impairment of motor function in patients with stroke has led neurologists to search for other causes. The standard explanation for this lack of correlation is that the motor impairment is primarily related to spasticity (Mizrahi & Angel, 1979; Dietz et al., 1991). Nevertheless, the weight of clinical evidence (Sahrmann & Norton, 1977), in addition to what we currently know about the physiology of motor control, would seem to go against this thesis. Obviously, extreme spasticity can further disrupt the ability to move but numerous studies have failed to find a quantitative relation between the extent of spasticity and the motor deficits.

Recovery of motor function following stroke

Some recovery of motor function is the rule after stroke. The extent and time course of recovery is quite variable and dependent on a host of factors which are not well understood (Twitchell, 1951; Bard & Hirschberg, 1965; Seitz, 1997). The natural history of the recovery from stroke has received less attention than it might have given the social and economic cost of the disorder. Recovery when it does occur generally begins early and is evident first in the proximal muscles (Twitchell, 1951). Patients who make a full recovery do so within the first month and it is not usual to find much additional improvement more than six months after the original stroke. There is controversy as to what constitute reliable prognostic indicators for motor recovery following stroke but prominent spasticity and a long interval from the onset of deficit to the first sign of recovery are not good signs. When recovery does occur, it is invariably associated with cortical reorganization.

Cortical reorganization is a well-described phenomenon following injury. It has been documented in animals following damage to, or disruption of, sensory input (Merzenich et al., 1983) and has been shown to occur in motor cortical areas of non-human primates after amputation, section of motor nerves (Donoghue & Sanes, 1988), or as a result of micro-infarction to adjacent areas of cortex (Nudo et al., 1996; Nudo & Milliken, 1996). Glees and Cole (1950, 1952) were the first to study reorganization in the motor system under controlled conditions. Following experimentally induced lesions of the motor cortex in the monkey, they found, on the basis of cortical stimulation, evidence of reorganization both in areas surrounding the cortical lesion (1950) and also in homologous regions in the other hemisphere (1952). The issue was re-examined more recently by Nudo and colleagues (Nudo et al., 1996; Nudo & Milliken, 1996) who showed that loss of hand and wrist representation after micro-infarcts in the motor cortex of the monkey was restored through reorganization following rehabilitation (Nudo et al., 1996, Fig. 31.8, see colour plate section). Without rehabilitation, although there was reorganization in the motor cortex, the representations in the areas damaged by infarction were not restored. Clearly, restoration of function is not dependent on motor cortex reorganization *per se* and presumably can be mediated by other cortical areas.

Functional imaging studies in humans following stroke have confirmed the suggestion of Glees and Cole (1952) that recovery of function is associated with a re-organization involving lateral premotor areas ipsilateral to the infarct and the motor cortex contralateral to the infarct (Chollet et al., 1991; Weiller et al., 1992; Cramer et al., 1997). Whereas there appears to be abundant data (Brodal, 1972; Kim et al., 1993) to support a role for the motor cortex (contralateral to the lesion) ipsilateral to the motor deficit in the control of movement and consequently its involvement in recovery of function, the evidence for significant reorganization in lateral premotor areas contributing to recovery is not nearly as strong. Recent data (Lewis et al., 1999) suggest that the medial premotor areas, which have prominent corticospinal projections, may make the largest contribution to recovery of function.

Effects of rehabilitation

Studies in normal subjects have shown that cortical motor areas can undergo reorganization on the basis of different patterns of limb or finger use. For example, there is an increased representation of left-hand digits in the motor cortex of string players and the extent of this increase is correlated with the age at which the subjects began to play the instrument (Elbert et al., 1995). The potential for use-dependent changes in cortical representation within the sensory motor system has obvious implications for rehabilitation in patients following stroke. Although spontaneous reorganization of the cortex does occur after experimentally induced cortical stroke in primates (Nudo & Milliken, 1996), this reorganization does not result in

restored movement capacity unless accompanied by specific rehabilitation (Nudo et al., 1996). The technique of constraint-induced movement therapy (or 'forced use'), in which the unaffected limb is restrained in a sling and the impaired one is trained in a series of motor tasks over a two week period, has been shown to lead to long-lasting improvement in function in patients with chronic stroke (Taub et al., 1993; Miltner et al., 1999), and is associated with concomitant changes in cortical excitability (Liepert et al., 2000). The encouraging preliminary results with the technique in both humans and subhuman primates offer hope that it will provide an efficacious form of rehabilitation of motor function in stroke patients when used on a larger scale.

The future: neural signals to control prosthetic devices

One of the more exciting developments for the future is that it may be possible to apply what has been learned about the neural control of movement to enable the use of signals from the intact motor cortex to control prosthetic devices. An even more ambitious project would be the use of neural signals to directly drive muscles, which would clearly be beneficial in patients with spinal cord injury and in a subgroup of patients following stroke.

The idea behind such a development is a relatively simple one and is based on a concept already discussed above: that many cells in the motor cortex are directionally tuned (Georgopoulos et al., 1982) and that a population of such cells can be used to predict the upcoming motor output under a variety of conditions (Georgopoulos et al., 1983, 1986). The issue is how one transforms such neural signals into a coordinated contraction of limb muscles to generate an appropriate motor output (Lukashin et al., 1996; Amirikian & Georgopoulos, 1999). This transformation can be carried out by an artificial neural network, using actual neural signals as an input, which it then recoded as graded muscle activation. For example, Fig. 31.9 shows neural data which were recorded while a monkey exerted force in a particular direction; these data were then used to instruct a model arm to produce the same behaviour.

Other recent experiments suggest that the goal of a neurally driven device is a realistic goal for the future. Chapin and colleagues have sampled neural signals in the cortex and thalamus of the rat and used them to control a relatively simple one-dimensional robot arm (Chapin et al., 1999). While the behaviour used in the experiment was relatively trivial compared to what might be required in real life, the authors also demonstrated that the animal could learn different strategies to control the neurons responsible for the movement of the robot arm. Such plasticity between neural activity in motor cortex and behaviour makes it more likely that patients could eventually learn to control prosthetic devices or even their own muscles. More recently, this work was expanded and extended to the monkey (Wessberg et al., 2000). Neural signals obtained from chronically implanted microwire electrodes in several cortical motor areas were used to predict hand trajectories in three dimensions, and more importantly, could be employed to control a robotic arm in real time. These approaches needs further modification and refinement so that they can be useful for application in humans. The work cited is best regarded as a promising start rather than a final solution.

The apraxias

Ramón C. Leiguarda

Raúl Carrea Institute of Neurological Research, FLENI, Buenos Aires, Argentina

Apraxia is a term used to denote a wide spectrum of higher-order motor disorders owing to acquired brain disease affecting the performance of skilled, learned movements with or without preservation of the ability to perform the same movement outside the clinical setting in the appropriate situation or environment. The disturbance of purposive movements cannot be termed apraxia, however, if it results from a language comprehension disorder or from dementia, or if the patient suffers from any elementary motor or sensory deficit (i.e. paresis, dystonia, ataxia) which could fully explain the abnormal motor behaviour (Heilman & Rothi, 1985; Roy & Square, 1985; De Renzi, 1989). The praxic disorder may affect various body parts such as the eyes, face, trunk, or limbs, and may involve both sides of the body (i.e. ideational and ideomotor apraxias), preferentially one side (i.e. limb-kinetic apraxia), or, alternatively, interlimb coordination, as in the case of apraxia of gait.

Apraxias are poorly recognized but common disorders that can result from a wide variety of focal (i.e. stroke, trauma) or diffuse brain damage (i.e. corticobasal degeneration, Alzheimer's disease) (Heilman & Rothi, 1985; Freund, 1992). There are two main reasons why apraxia may go unrecognized. Firstly, many patients with apraxia, particularly ideomotor apraxia, show a voluntary–automatic dissociation, which means that the patient does not complain about the deficit because the execution of the movement in the natural context is relatively well preserved, and the deficit appears mainly in the clinical setting when the patient is required to represent explicitly the content of the action outside the situational props. Secondly, although in apraxic and aphasic patients specific functions are selectively affected, language and praxic disturbances frequently coexist and the former may interfere with the proper evaluation of the latter (Freund, 1992).

Limb apraxias

Liepmann (1920) posited that the idea of the action, or movement formula, containing the space–time form picture of the movement, was stored in the left parietal lobe. In order to carry out a skilled movement, the space–time plan has to be retrieved and associated via cortical connections with the innervatory pattern stored in the left sensorimotorium that conveys the information to the left primary motor area. When the left limb performs the movement, the information has to be transmitted from the left to the right sensorimotorium through the corpus callosum to activate, thereafter, the right motor cortex. Liepmann conceived ideational apraxia as a disruption of the space–time plan or its proper activation, so that it was impossible to construct the idea of the movement; the patient does not know what to do. In contrast, in ideomotor apraxia, the space–time plan is intact but it can no longer guide the innervatory engrams which implement the movement because it is disconnected from them; the patient knows what to do but not how to do it. Finally, limb-kinetic apraxia appears when the disruption of the innervatory engrams interferes with the selection of the required muscle synergies to perform the skilled movement.

Heilman and Rothi (1985) and Rothi et al. (1991) proposed that the 'movement formulae' or 'visuokinesthetic motor engrams' were stored in the left inferior parietal lobule (IPL), and translated into an innervatory pattern in the supplementary motor area (SMA) rather than in the convexity of the premotor cortex (PM). A neuropsychological model was advanced involving specific dissociation of verbal, visual or tactile inputs into an action lexicon (represented in the parietal lobe) in which visuokinesthetic motor engrams programme skilled movements (Rothi et al., 1991).

Table 32.1. Assessment of limb praxis

Intransitive movements:	non-representational (e.g. touch your nose, wriggle your fingers) representational (e.g. wave good-bye, hitch-hike)
Transitive movements:	(e.g. use a hammer, use a screwdriver) under verbal, visual and tactile modalities
Imitation of meaningful and meaningless movements, postures and sequences.	
Multiple step tasks:	(e.g. prepare a letter for mailing)
Tool[a] selection tasks:	to select the appropriate tool to complete a task, such as a hammer for a partially driven nail
Alternative tool selection tasks:	to select an alternative tool such as pliers to complete a task such as pounding a nail, when the appropriate tool (i.e. hammer) is not available
Gesture recognition tasks:	to assess the capacity to comprehend gestures, either verbally (to name gestures performed by the examiner), as well as non-verbally (to match a gesture performed by the examiner with cards depicting the tool / object[b] corresponding to the pantomime)

Notes:
[a] Tool: implement with which an action is performed (e.g. hammer, screwdriver).
[b] Object: the recipient of the action (e.g. nail, screw).
Source: De Renzi (1989); Rothi et al. (1997).

In 1985, Roy and Square refined a praxis model into a conceptual system and a production system. The conceptual system was conceived to contain knowledge of object and tool use and organization of single actions into a sequence. On the other hand, the production system incorporates a sensori motor component of knowledge, as well as encompassing the perceptual motor processes for organizing and executing action. Dysfunction of the praxis conceptual system would give rise to conceptual or ideational apraxia, whereas impairment of the praxis production system would induce ideomotor and limb-kinetic apraxias. At present, however, it is possible to interpret the different types of limb apraxias, particularly ideomotor and limb kinetic apraxias, on the basis of our current knowledge of the modular organization of the brain (Leiguarda & Marsden, 2000).

Evaluation of limb praxis

A systematic evaluation of limb praxis is critical in order: (i) to identify the presence of apraxia; (ii) to classify correctly the nature of limb praxis deficit according to the errors committed by the patient; and (iii) to gain an insight into the underlying mechanism of the patient's abnormal motor behaviour (Table 32.1).

Several types of transitive movements are used in the evaluation of praxis and it is not an uncommon finding that apraxic patients perform some but not all movements in a particularly abnormal fashion and/or that individual differences appear in some but not all components of a given movement. Therefore, the dissimilar complexity and features of transitive movements should be considered in order to analyse and interpret praxic errors accurately. For instance: (i) movements may or may not be repetitive in nature (e.g. hammering versus using a bottle opener to remove the cap); (ii) an action may be composed of sequential movements (e.g. to reach for a glass and take it to the lips in drinking); (iii) a movement may primarily reflect proximal limb control (transport) such as transporting the wrist when carving a turkey, proximal and distal limb control such as reaching and grasping a glass of water, or primarily distal control as when the patient is asked to manipulate a pair of scissors; and (iv) movements may be performed in the peripersonal space (e.g. carving a turkey), in body-centred space (e.g. tooth-brushing), or require the integration of both, such as the drinking action.

Analysis of a patient's performance is based on both accuracy and error patterns (Table 32.2). Three-dimensional motion analysis of the spatio-temporal characteristics of gestural movements has provided an accurate method to capture objectively the nature of the praxis errors observed in clinical examination. Patients with ideomotor apraxia, due to focal left hemisphere lesions (Clark et al., 1994; Poizner et al., 1995), and different asymmetric cortical degenerative syndromes (Leiguarda & Starkstein, 1998), have shown slow and hesitant build-up of hand velocity, irregular and non-sinusoidal velocity profiles, abnormal amplitudes, alterations in the plane of motion and in the direction and shapes of wrist trajectories, decou-

Table 32.2. Types of praxis errors

I. Temporal
S = sequencing: some pantomimes require multiple positionings that are performed in a characteristic sequence. Sequencing errors involve any perturbation of this sequence including addition, deletion, or transposition of movement elements as long as the overall movemen structure remains recognizable.
T = timing: this error reflects any alterations from the typical timing or speed of a pantomime and may include abnormally increased, decreased, or irregular rate of production or searching or groping behaviour.
O = occurrence: pantomimes may involve either single (i.e. unlocking a door with a key) or repetitive (i.e. screwing in a screw with a screwdriver) movement cycles. This error type reflects any multiplication of single cycles or reduction of a repetitive cycle to a single event.

II. Spatial
A = amplitude: any amplification, reduction, or irregularity of the characteristic amplitude of a target pantomime.
IC = internal configuration: when pantomiming, the fingers and hand must be in specific spatial relation to one another to reflect recognition and respect for the imagined tool. This error type reflects any abnormality of the required finger/hand posture and its relationship to the target tool. For example, when asked to pretend to brush teeth, the subject's hand may close tightly into a fist with no space allowed for the imagined toothbrush handle.
BPO = body-part-as-object: the subject uses his/her finger, hand, or arm as the imagined tool of the pantomime. For example, when asked to smoke a cigarette, the subject might puff on his or her index finger.
ECO = external configuration orientation: when pantomiming, the fingers/ hand/arm and the imagined tool must be in a specific relationship to the 'object' receiving the action. Errors of this type involve difficulties orienting to the 'object' or in placing the 'object' in space. For example, the subject might pantomime brushing teeth by holding his hand next to his mouth without reflecting the distance necessary to accommodate an imagined toothbrush. Another example would be when asked to hammer a nail, the subject might hammer in differing locations in space reflecting difficulty in placing the imagined nail in a stable orientation or in a proper plane of motion (abnormal planar orientation of the movement).
M = movement: when acting on an object with a tool, a movement characteristic of the action and necessary to accomplish the goal is required. Any disturbance of the characteristic movement reflects a movement error. For example, a subject, when asked to pantomime using a screwdriver, may orient the imagined screwdriver correctly to the imagined screw but instead of stabilizing the shoulder and wrist and twisting at the elbow, the subject stabilizes the elbow and twists at the wrist or shoulder.

III. Content
P = perseverative: the subject produces a response that includes all or part of a previously produced pantomime.
R = related: the pantomime is an accurately produced pantomime associated in content with the target. For example, the subject might pantomime playing a trombone for a target of a bugle.
N = non-related: the pantomime is an accurately produced pantomime not associated in content with the target. For example, the subject might pantomime playing a trombone for a target of shaving.
H = the patient performs the action without benefit of a real or imagined tool. For example, when asked to cut a piece of paper with scissors, he or she pretends to rip the paper.

IV. Other
C = concretization. The patient performs a transitive pantomime not on an imagined object but instead on a real object not normally used in the task. For example, when asked to pantomime sawing wood, the patient pantomimes sawing on his or her leg.
NR = no response.
UR = unrecognizable response: the response shares no temporal or spatial features of the target.

Source: Rothi et al. (1997).

pling of hand speed and trajectory curvature, and loss of interjoint coordination (Figs. 32.1–32.3). All these studies have evaluated gestures, such as carving a turkey or slicing a loaf of bread, which mainly explore the transport or reaching phase of the movement. However, the majority of transitive gestures included in most apraxia batteries are prehension (reaching and grasping) movements which reflect proximal (transport) as well as distal limb control (grasping). The kinematic analysis of aiming movements in apraxic patients has demonstrated spatial deficits, in particular when visual feedback is unavailable, whereas the analysis of prehension movements has shown disruption of both the transport and grasp phases of the movements as well as transport-grasping uncoupling (Caselli et al., 1999;

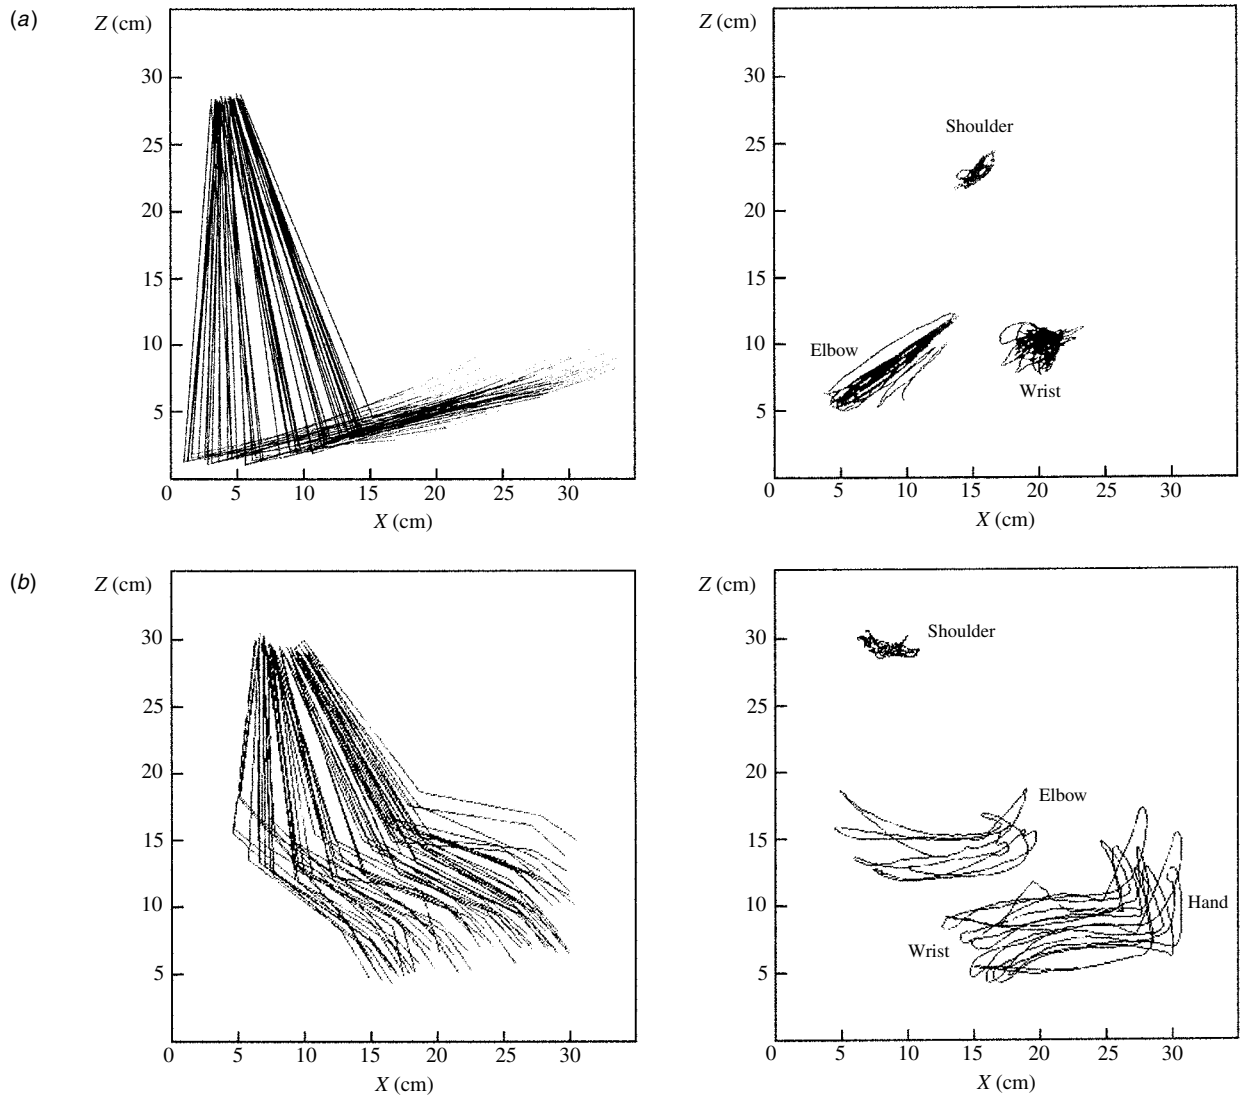

Fig. 32.1. Left: Lateral view of successive arm, forearm, wrist and hand positions during the performance of the bread-slicing gesture. Right: Frontal view of successive cycles of shoulder, elbow, wrist and hand trajectories. (*a*) Control subject. (*b*) Patient with ideomotor apraxia. Wrist trajectories in the control subject are located perpendicular to the goal object and aligned in the sagittal plane with slight vertical and horizontal displacement. The patient's wrist path showed abnormal horizontal displacement. Note also the incorrect orientation of movement axis.

Haaland et al., 1999; Leiguarda et al., 2000). Furthermore, the study of manipulating finger movements has disclosed abnormal workspace and breakdown of the temporal profiles of the scanning movements in patients with limb-kinetic apraxia (Leiguarda et al., 2000). Thus, exploration into the kinematics of reaching, grasping and manipulating provides information regarding the specific neural subsystems involved in patients with different types of limb praxic disorders.

Interhemispheric differences in the control of praxic skills

Apraxia as tested by the imitation of gestures and object use pantomime has been found in about 50% of patients with left hemisphere damage and in less than 10% of those with right hemisphere damage (De Renzi, 1989). Most of the errors exhibited by ideomotor apraxia patients are equally seen in left or right hemisphere-damaged patients

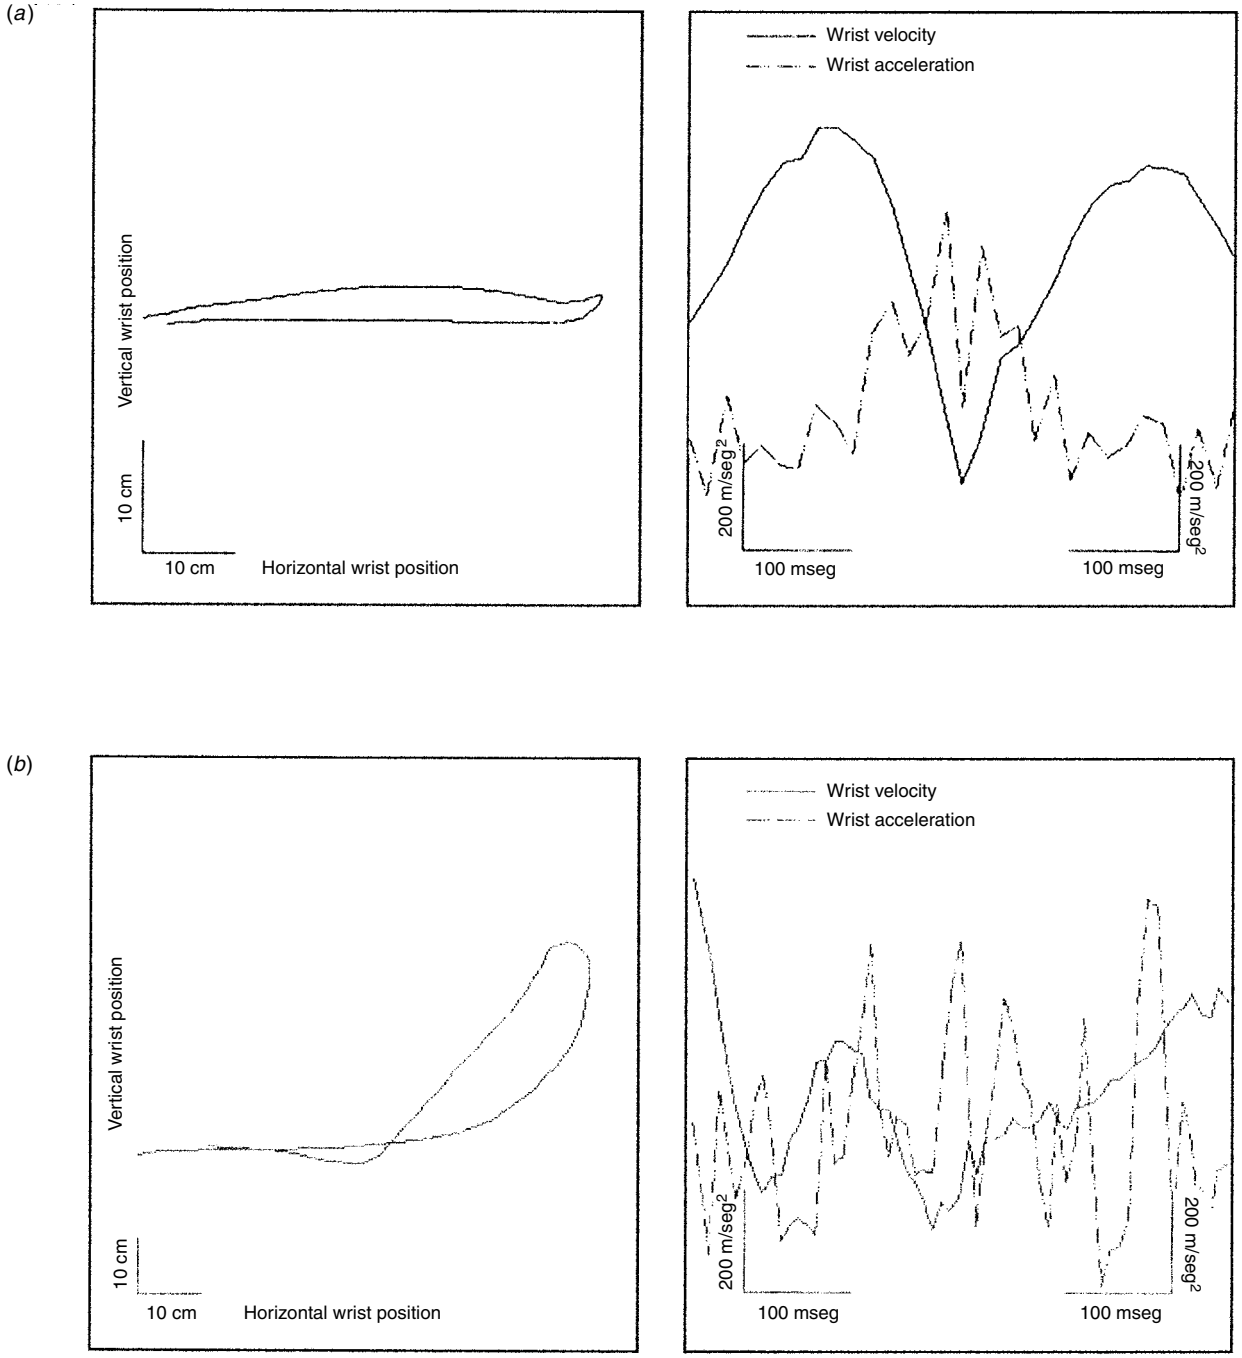

Fig. 32.2. Phase reversal in a control subject (*a*) and in a patient with ideomotor apraxia (*b*). The patient showed an abnormal widening of the wrist path during the reversal phase with a resulting spatial separation of irregular onward and outward path. The spatial distortion corresponds with a grossly disrupted relationship between wrist velocity and wrist acceleration.

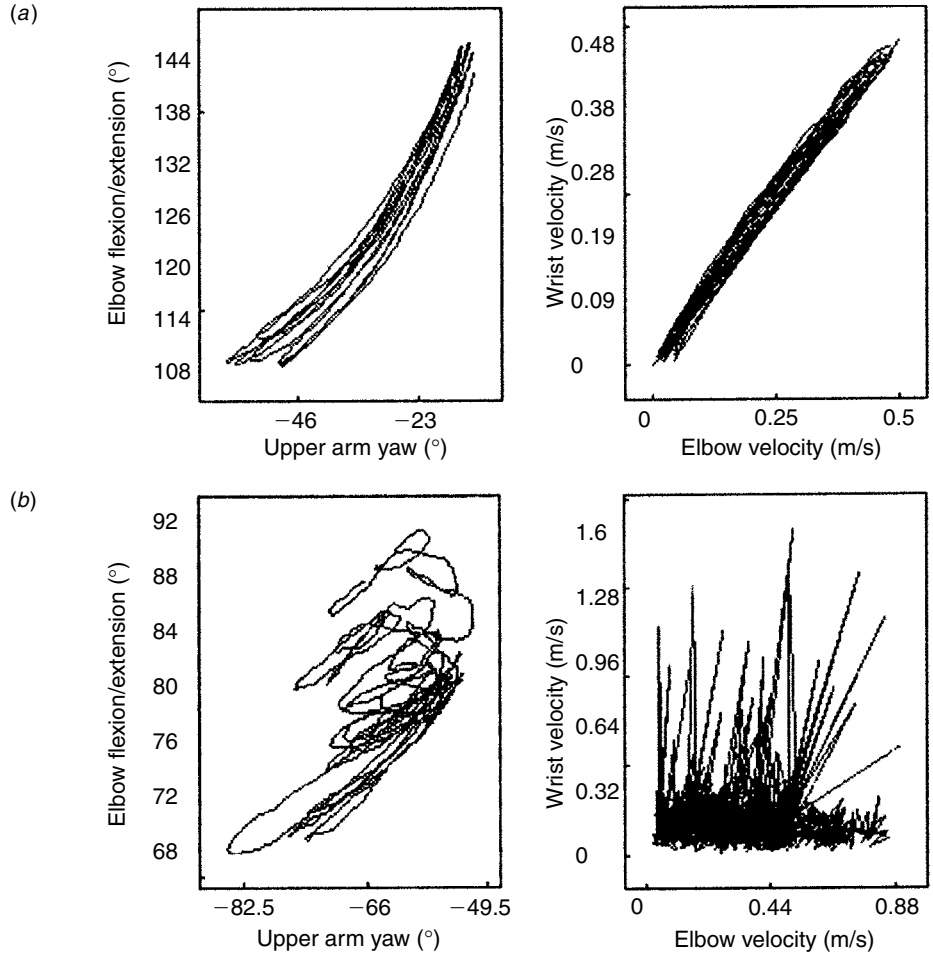

Fig. 32.3. Interjoint coordination (*a*) in a control subject and (*b*) in a patient with ideomotor apraxia. The control subject showed a smooth and linear relationship between elbow flexion–extension and upper arm yaw. As the elbow extended, the upper arm moved laterally across the body in a well-coordinated pattern. In contrast, the patient showed distorted angle–angle relationships owing to poor coordination between elbow flexion–extension and upper arm yaw as well as asynchronous intersegmental joint velocities.

when they pantomime non-representative and representative/intransitive gestures, but are observed predominantly in left hemisphere-damaged patients when they pantomime transitive movements, because it is this action which is performed outside the natural context (Haaland & Flaherty, 1984). Schnider et al. (1997) also emphasized that the left hemisphere motor dominance reflected by ideomotor apraxia refers to spatially and temporally complex movements carried out in an artificial context. Moreover, it has been suggested that, whereas either hemisphere would be able to process intransitive movements as well as transitive movements using tools/objects, the left hemisphere would be dominant not only for the 'abstract' performance (pantomiming to verbal command) of transitive movements but also for learning and reproducing novel movements such as meaningless movements and sequences (Rapcsak et al., 1993). Impairment in sequencing is apparent in left hemisphere-damaged patients when the tasks place demands on memory, but also when the temporal aspects of sequencing, reflecting response preparation and programming, are considered (Harrington & Haaland, 1992). Rushworth et al. (1998) have further proposed that the left hemisphere is not only dominant for learning to select movements in a sequence but also for learning to select a limb movement that is appropriate for the use of an object. Thus, is seems likely that the interhemispheric differences in the control of praxic skills would largely depend on the context in which the movement is performed and on the cognitive requirements of the task; that is, when a single and/or sequence of object-oriented

movements are performed outside the usual context and depend on higher-level cognitive abilities for planning and self-monitoring the action, the left hemisphere emerges as more dominant than the right (Haaland & Harrington, 1996).

Types of limb apraxia

Ideational or conceptual apraxia

In 1905 Pick described a patient who was unable to carry out a series of acts involving the utilization of several objects leading to an action goal (e.g. prepare a letter for mailing), although he was also able to use properly single tools and objects. Liepmann (1908) defined ideational apraxia as an impairment of tasks requiring a sequence of several acts with tools and objects. However, other authors use the term to denote a failure to use single tools appropriately (De Renzi, 1989). To overcome this confusion, Ochipa et al. (1992) have suggested restricting the term ideational apraxia to a failure to conceive a series of acts leading to an action goal, and introduced the term conceptual apraxia to denote deficits in the different types of tool-action knowledge as proposed by Roy and Square (1985). However, a strict difference between ideational and conceptual apraxia is not always feasible, since patients with ideational apraxia not only fail on tests of multiple object use, but may also perform abnormally when using a single object (De Renzi & Lucchelli, 1988).

Patients with ideational or conceptual apraxia exhibit primarily content errors in the performance of transitive movements (see Table 32.2), because they are unable to associate tools and objects with their corresponding action. They may also lose the ability to associate tools with the objects that receive their action; thus, when a partially driven nail is shown, the patient may select a pair of scissors rather than a hammer from an array of tools to perform the action. Not only are patients unable to select the appropriate tool to complete an action, but they may also fail to describe a function of a tool or point to a tool when the function is described by the examiner, even when the patient names the tool properly when shown to him/her. Patients with conceptual apraxia lose the mechanical advantage afforded by tools (mechanical knowledge). For example, when asked to complete an action and the appropriate tool is not available (e.g. a hammer to drive a nail), they may not select the most adequate tool for that action (e.g. a wrench) but rather one which is inadequate (e.g. a screwdriver) (Ochipa et al., 1992). These patients may also be impaired in the sequencing of tool/object use (Pick, 1905; Liepmann, 1920; Poeck, 1983). Patients with ideational or conceptual apraxia are disabled in everyday life, because they use tools/objects improperly, they misselect tools/objects for an intended activity, perform a complex sequential activity (e.g. make express coffee) in a mistaken order or do not complete the task at all (Foundas et al., 1995). Ideational apraxia has been traditionally allocated to the left parieto-occipital and parieto-temporal regions (Liepmann, 1920), although frontal and frontotemporal lesions may also cause ideational (De Renzi & Luchelli, 1988) or conceptual apraxia (Heilman et al., 1997).

Ideomotor apraxia

Ideomotor apraxia has been defined as 'a disturbance in programming the timing, sequencing and spatial organization of gestural movements' (Rothi et al., 1991). Patients with ideomotor apraxia exhibit mainly temporal and spatial errors (see Table 32.2). The movements are incorrectly produced but the goal of the action can usually be recognized. Occasionally, however, the performance is so severely deranged that the examiner cannot recognize the movement. Transitive movements are more affected than intransitive ones on pantomiming to commands and patients usually improve on imitation when performance is compared to responses to verbal commands (Heilman & Rothi, 1985). Acting with tools/objects is carried out better than pantomiming their use, but even so, movements may not be entirely normal. The improvement in performance observed when the patient actually uses the tool/object is due to the advantage provided by visual and tactile-kinesthetic cues emanating from the tool/object and by the fact that in this condition, the patient is performing the movement in a more natural context and therefore less dependent on the left hemisphere. Ideomotor apraxia is commonly associated with damage to the parietal association areas, less frequently with lesions of the PM cortex and SMA and usually with disruption of the intrahemispheric white matter bundles which interconnect them (Leiguarda & Marsden, 2000). Although small lesions of the basal ganglia and thalamus may cause ideomotor apraxia, in the majority of patients the pathology extends to the internal capsule and periventricular and peristriatal white matter (Pramstaller & Marsden, 1996). Most studies examining possible clinico-anatomical correlation for ideomotor apraxia have found a strong association of apraxia with large cortico-subcortical lesions in the suprasylvian, perirolandic region of the left dominant hemisphere, but no specific lesion site which correlated with apraxia. Disruption of cortico-cortical and cortico-subcortical connection due to white matter damage seems essential for the occurrence of apraxia (Kertesz & Ferro, 1984; Alexander

et al., 1992; Schnider et al., 1997; Leiguarda & Marsden, 2000).

Limb-kinetic apraxia

This type of apraxia was originally described by Kleist (1907), who called it 'innervatory apraxia' to stress the loss of hand and finger dexterity due to inability to connect and to isolate individual innervation. The deficit is mainly confined to finger and hand movements contralateral to the lesion, regardless of its hemispheric side, with preservation of power and sensation. Manipulatory finger movements are predominantly affected, but in most cases all movements, either complex or routine, independently of the modality to evoke them, are coarse, awkward, mutilated and 'amorphous' (Liepmann, 1908). Fruitless attempts usually precede wrong movements, which in turn are frequently contaminated by extraneous movements. Imitation of finger postures is also abnormal and some patients use the less affected or normal hand to reproduce the requested posture. The severity of the deficit is consistent, exhibiting the same degree in everyday activities as in the clinical setting; thus, there is no voluntary-automatic dissociation (Liepmann, 1908; Faglioni & Basso, 1985).

Limb-kinetic apraxia has been scantily reported with focal lesions (Faglioni & Basso, 1985); there are two potential explanations: first, most PM lesions also involve the precentral cortex, and, therefore, the contralateral paresis or paralysis precludes the expression of the praxic deficit; and, secondly, bilateral activation of the PM cortex and SMA are often observed with unilateral movements; thus, a unilateral lesion would not be enough for an overt deficit, since bilateral involvement would be most likely necessary. As a matter of fact, all recently pathologically confirmed cases of limb-kinetic apraxia suffered a degenerative process such as corticobasal degeneration and Pick's disease, involving frontal and parietal cortices or, predominantly, the PM cortex (Leiguarda & Marsden, 2000).

Callosal apraxia

Patients with damage to the body of the corpus callosum with or without genu involvement (Liepmann & Maas, 1907; Watson & Heilman, 1983; Graff-Radford et al., 1987; Leiguarda et al., 1989) may develop unilateral apraxia of the non-dominant limb whose characteristics vary according to the type of test given and the lateralization pattern of praxic skills in each patient. Some patients could not correctly pantomime to verbal commands with their left hand, but performed normally on imitation and object use (Geschwind & Kaplan, 1962), whereas others could not use their left hand on command, by imitation or while holding the object (Watson & Heilman, 1983; Leiguarda et al., 1989). Moreover, a few patients could not pantomime to verbal commands and while holding the object, but performed fairly well on imitation (Graff-Radford et al., 1987), or improved over time on imitation and object use (Watson & Heilman, 1983). Thus, the most enduring callosal type of praxic defect is demonstrated when verbal-motor tasks, such as pantomiming to command, are used (Graff-Radford et al., 1987).

Modality-specific or disassociation apraxias

The modality-specific (De Renzi et al., 1982) or disassociation apraxias (Rothi et al., 1991) refer to those types of praxic deficits exhibited by patients who commit errors only, or predominantly, when the movement is evoked by one but not all modalities. Thus, the impairment of patients who performed abnormally only under verbal commands has been attributed to a left hemispheric lesion most likely affecting the audio-verbal inputs to the parietal lobe (De Renzi et al., 1982) or a callosal lesion (Geschwind & Kaplan, 1962). Patients who performed poorly to seen objects, but were able to pantomime gestures normally to verbal command, have also been reported as having lesions interrupting the flow of visual information toward the parietal lobe. On occasion, praxic deficits may be confined to the tactile modality. Finally, patients have been reported who, unlike those with ideomotor apraxia improving on imitation, were more impaired when imitating than when pantomiming to command, or could not imitate but performed flawlessly under other modalities. Deficits may be restricted solely to the imitation of meaningless gestures with preserved imitation to meaningful gestures (De Renzi et al., 1982; Rothi et al., 1991; Ochipa et al., 1994; Goldenberg & Hagmann, 1997).

The anatomofunctional substrates of limb praxis

The fact that most studies exploring possible clinico-anatomical correlations for different types of limb apraxia have failed to unveil a consistent and specific lesion site for the disorder, strongly suggests that praxic functions are distributed across several distinct anatomofunctional neural systems, working in concert but with each one controlling specific processes (i.e. parieto-frontal systems and reaching/grasping, fronto-striatal system and sequential motor events). Damage to these systems would produce selective praxic-related deficits depending on the movement context and cognitive demand of the action.

Parallel parieto-frontal circuits for sensorimotor integration

Recent anatomical and functional studies have identified in primates a series of segregated parieto-frontal circuits,

working in parallel and each one involved in a specific sensorimotor transformation process; that is, their function is to transform the sensory information encoded in the coordinates of sensory epithelia (e.g. retina, skin) into information for movements (Rizzolatti et al., 1998). The transformation process involves parallel mechanisms that simultaneously engage functionally related parietal and frontal areas linked by reciprocal cortico-cortical connections. The posterior parietal cortex comprises a multiplicity of areas, each involved in the analysis of particular aspects of sensory information (i.e. somatosensory, visual, auditory, vestibular). The coordinate system may vary in different parts of the parietal cortex according to the nature of the actions evoked by sensory input. The motor cortex, in turn, is also made up by many areas, each containing an independent body movement representation, and playing a specific role in motor control, according to its afferent and efferent connections. The proposed functions of the main circuits originating from the superior parietal lobule (SPL) include: visual and somatosensory transformation for reaching (MIP-F_2), somatosensory transformation for reaching (PEc/PEip-F_2), somatosensory transformation for posture (PEci-F_3), and transformation of body part location data into information necessary for the control of body part movements (PE-F_1). The circuits originating in the IPL are devoted to visuomotor transformation for grasping and manipulation (AIP-F_5), the internal representation of actions (PF-F_5), coding peripersonal space for limb and neck movements (VIP-F_4), and visual transformation for eye movements (LIP-FEF) (Fig. 32.4) (Rizzolatti et al., 1998).

Selective apraxia-related deficits resulting from damage to the parieto-frontal circuits

Patients with lesions of the postero-superior parietal cortex develop a disorder of visually guided reaching called optic ataxia (Balint, 1909). Some of the patients not only misreach the target but also misshape the hand before grasping and on occasion commit errors in hand orientation (Jeannerod et al., 1994). Freund (1992) has suggested using the term 'visuomotor apraxia' rather than optic ataxia because inaccuracy of the movement (ataxia) is not the sole feature of the disorder, as performance is also misdirected, decomposed and faulty in the execution of its parts. Visuomotor apraxia most likely results from disruption of the parieto-frontal circuit devoted to visual and somatosensory transformation for reaching.

Lesions in the SPL involving circuits that subserve somatosensory transformation for reaching, somatosensory transformation for posture and transformation of body part location data into information for the control of body part movements would explain the external configuration and movement types of praxic errors such as faulty orientation and abnormal limb configuration. Heilman et al. (1986) described a right-handed patient with an apraxia due to a right superior parietal lesion; her performance with the left hand was characterized by minor temporal but gross spatial errors, particularly with the eyes closed; she erroneously moved the arm in space and abnormally oriented the limb in relation to the object. She failed to display visuomotor ataxia, and grasping appeared to be preserved. Selective deficits limited to the grasping phase of the movement that can mirror some of the internal configuration types of praxic errors have also been described in humans with damage to parieto-frontal circuits in the IPL. Jeannerod et al. (1994) reported a patient who, following a bilateral parieto-occipital infarction, showed a severe and bilateral grasping impairment; the hand was widely open, without correlation between grip and object size, and the grasp was awkward and inaccurate. Binkofski et al. (1998) studied patients with lesions involving the anterior bank of the intraparietal sulcus (IPs), possibly the human homologue of the anterior intraparietal area (AIP), who had selective temporal and spatial kinematic deficits in the coordination of finger movements required for grasping a switch with minor disturbances of the reaching phase of the movement. The report of Sirigu et al. (1995) clearly demonstrated the relationship between grasping and praxis. Their patient, with bilateral hypometabolism in the posterior parietal regions, showed a selective praxic deficit for hand postures during grasping objects in the context of utilization gestures, with apparently normal movement trajectories and accurate manual grasp scaling during simple reaching movements. Thus, object attributes are likely to be processed differently according to the task in which subjects are involved. When a subject is requested only to grasp an object but not to use it, the brain extracts the structural attributes of objects (i.e. form, size, orientation) relevant to action to generate the appropriate movement. However, during utilization gestures, in addition to data about object characteristics, prior knowledge about functional properties of objects needs to be integrated into the grasping subsystem to produce an accurate manual grasp (Jeannerod et al., 1995; Sirigu et al., 1995).

Lesions in animals and humans involving areas of the motor cortex making up the parieto-frontal circuits also cause distinct types of praxic-like deficits, though less selectively than those observed with damage to the parietal component of the circuits. Persistent impairment of skilled movement has been observed with damage to the PM cortex. Luria (1980) stressed the 'loss of the kinetic melody',

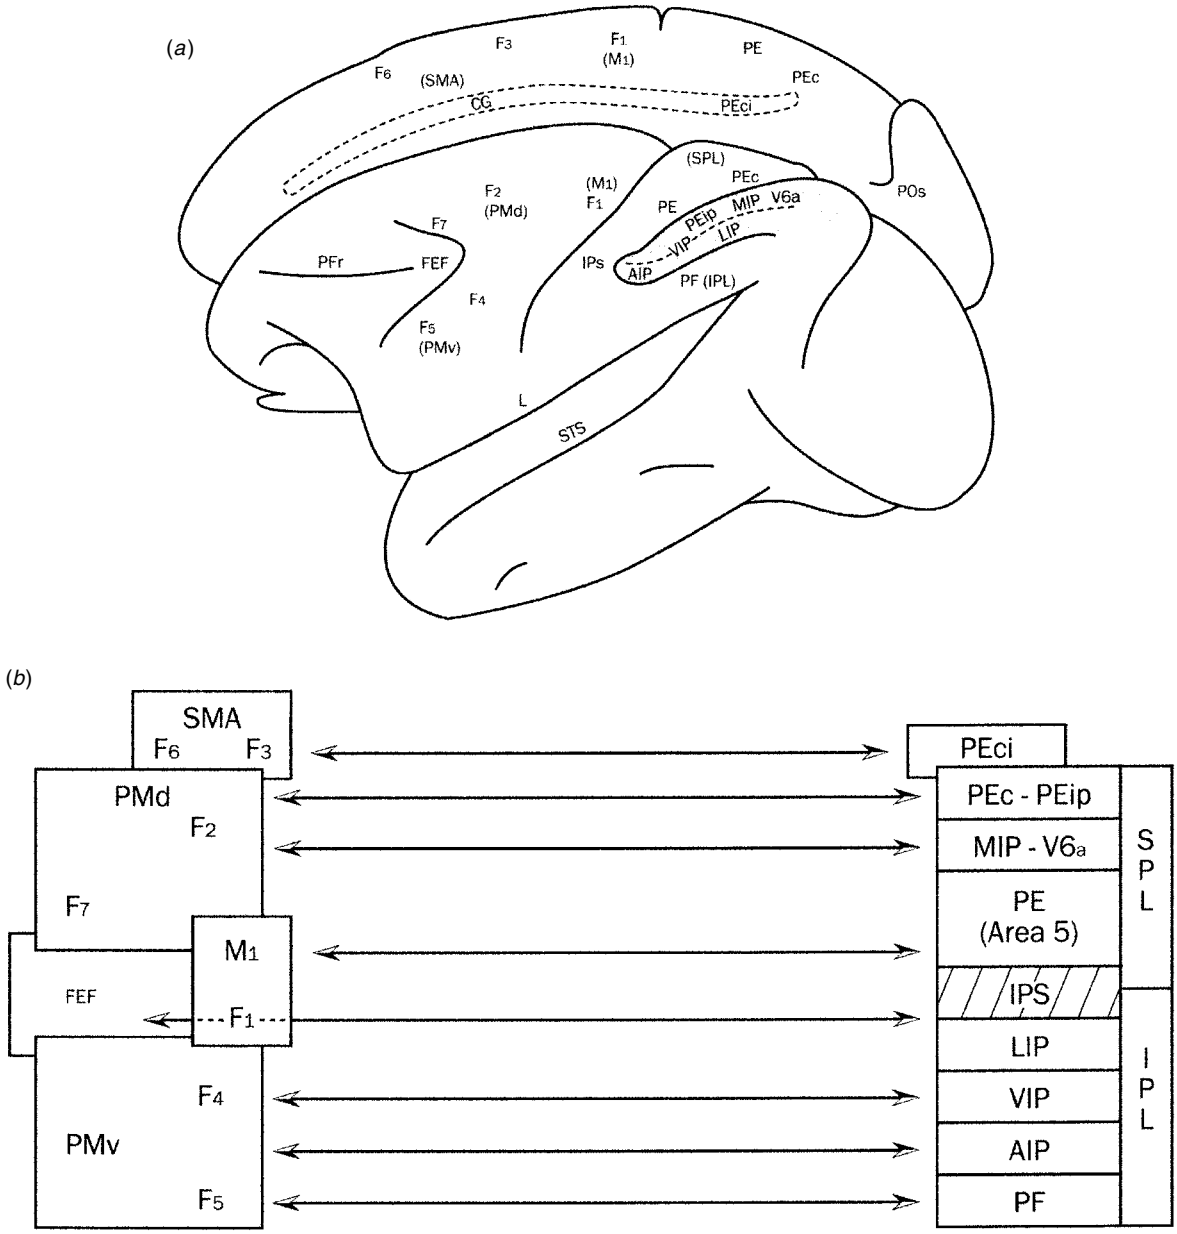

Fig. 32.4. (*a*) Lateral and medial views of the cerebral hemisphere of macaque monkey. The intraparietal sulcus has been opened (shaded grey) to show areas located in its medial and lateral bank. (*b*) Simplified diagram of the organization of the parallel parieto-frontal circuits for sensory-motor integration. The parcellation of the agranular frontal cortex is defined according to Matelli et al. (1985, 1991) studies in monkeys. F1 corresponds to primary motor cortex, F2 and F7 correspond to the dorsal premotor cortex (PMd) and F4 and F5 to the ventral premotor cortex (PMv). F6 and F3 correspond to the pre-supplementary motor area (SMA) and SMA proper, respectively. The arm is represented in F1, F2, F3, F4 and F5 whereas the leg only in F1, F2 and F3. F6 and F7 are almost devoid of corticospinal neurons. In the posterior parietal lobe there are also multiple representations of the arm, leg and face. All parietal areas are defined according to Pandya and Seltzer (1982), except those buried within the intraparietal sulcus (IPs) which are defined according to physiological data (Rizzolatti et al., 1998); AIP, anterior intraparietal area; CG, cingulate gyrus; FEF, frontal eye-field; L, lateral fissure; LIP, lateral intraparietal area; MIP, medial intraparietal area; PE, dorsal part of area 5; PEc, posterior part of PE; PEci, posterior part of cingulate sulcus; PEip, rostral part of the medial bank of IPs; PF, anterior part of the convexity of IPL; POs, parieto-occipital sulcus; PFr, prefrontal cortex; STS, superior temporal sulcus; VIP, ventral intraparietal area; V6a, visual area 6 in the rostral bank of the POs. Monkey IPL is not homologous to human IPL, since it is devoid of Brodmann areas 39 and 40. (Source: Leiguarda & Marsden, 2000.)

resulting in a disintegration of the dynamics of the motor act and of complex skilled movements in patients with PM lesions, which is mainly apparent when the task requires the learning of a new skilled movement. Patients with frontal lobe lesions may exhibit deficits in visually steering the arm accurately, particularly during rapid movements (catch a thrown ball) due to abnormal temporal sequencing of muscular activation (Freund & Hummelsheim, 1985). On the other hand, the cingulate and SMA seem to play a leading role in bimanual interaction since patients with damage to these areas show difficulties whenever the two hands must act simultaneously (i.e. buttoning, tying shoelaces) but experience no trouble with unimanual dexterity (Stephan et al., 1999). In addition, patients with PM lesions exhibit a deficit in conditional motor learning (Halsband & Freund, 1990) which may underlie the inappropriate selection of actions in relation to the context exhibited by apraxic patients (Passingham, 1993).

Fronto-striatal and fronto-parietal systems: sequencing of movements

Patients with apraxia exhibit several types of sequential errors, such as deletions, transpositions, additions, perseverations and non-related types of substitutions (Roy & Square, 1985; Rothi et al., 1997). Functional brain imaging studies have shown that different neural systems are actively engaged in the preparation and generation of a sequential action, depending on whether a sequence has been prelearned or is a new one, and contingent to the complexity of the attentional demands of the task (Grafton et al., 1995; Catalan et al., 1998).

The SMA, primary sensorimotor cortex, basal ganglia (mid-posterior putamen) and cerebellum would be mainly involved in the execution of automatic, overlearned, sequential movements, whereas the prefrontal, PM and posterior parietal cortices and the anterior part of the caudate/putamen would be particularly recruited, in addition to such areas engaged in the execution of simple movement sequences, when a complex or newly learned sequence, which requires attention, integration of multimodal information and working memory processes for its appropriate selection and monitoring, has to be performed (Grafton et al., 1995; Catalan et al., 1998.

Thus, different neural systems would be engaged depending on the type of movement sequence requested to be executed during praxis evaluation. When the sequence is well known or automated, or else performed from memory, the SMA-basal ganglion system would be preferentially recruited. However, most of the sequences used to test praxis are new (e.g. sequencing of movement in the movement imitation test for ideomotor apraxia); or, the content of an otherwise well learned goal-directed action (e.g. multiple sequential use of objects test for ideational apraxia) has to be explicitly represented. In any case, the system made up by the prefrontal, PM and parietal cortices, the striatum and white matter fascicles would be specifically engaged. In addition, it might be possible that within this system there are many different subsystems subserving functionally separate cognitive computations involved in motor sequencing (i.e. timing, motor attention, selection of limb movements and object-oriented responses) which may be selectively damaged by the pathological process and thus produce different types of sequencing impairment in apraxic patients (Harrington & Haaland, 1992; Rushworth et al., 1998).

The temporo-parieto-frontal system: recognition and imitation of actions

Action recognition deficits have been observed in patients with parietal, temporal, frontal and basal ganglion lesions predominantly in the left hemisphere (Ferro et al., 1983; Varney & Damasio, 1987). On the other hand, abnormal performance on imitation has been found in patients with parietal, frontal, temporal, subcortical and basal ganglion lesions (Hermsdöfer et al., 1996). Thus, recognition and imitation of actions seem to be subserved through distributed neural systems preferentially though not exclusively dependent on the left dominant hemisphere. These systems would be made up by several interconnected nodes mainly in the parietal and frontal cortices, but also in the temporal cortex and perhaps subcortical structures, each devoted to preferential functions within each system. Single-unit studies in monkeys and functional neuroimaging studies tend to support these assumptions.

Di Pellegrino et al. (1992) discovered a particular subset of neurones in F5 which discharge during the time a monkey observes meaningful hand movements made by the experimenter, in particular when interacting with objects; they called them 'mirror neurons' and speculated that they belonged to an observation/execution matching system involved in understanding the meaning of motor events as well as in action imitation (Rizzolatti et al., 1998). Neurons with properties similar to those of mirror neurons in F5 are also found in the superior temporal sulcus (STS) in monkeys (Carey et al., 1997). Two other types of neurons, which may contribute to the recognition and imitation of postures and actions, have also been found in the STS. One type encodes the visual appearance of particular parts of the body (i.e. fingers, hands, arms), which combine in such a way that the collection of components can specify a particular meaningful posture or action. The second type

encodes specific body movements, such as walking and turning (Carey et al., 1997). Cells responding to hand–object interaction might also be present in area 7b, located in the rostral part of the IPL, which sends its cortical output to the F5; in turn, area 7b receives projection from the STS region, and the latter is interconnected with the frontal lobe, thus closing a cortical circuit involved in the perception of hand–object interaction. The crucial cognitive role of the STS-7b-F5 network would be the internal representation of actions which, when evoked by an action made by others, would be involved in two related functions, namely, action recognition and action imitation (Rizzolatti et al., 1998).

PET studies in humans support neurophysiological findings in monkeys. Grasping observation markedly increased cerebral blood flow in the cortex of the STS, in the rostral part of Broca's area and in the rostral part of the left IPs on the left hemisphere of right-handed subjects (Rizzolatti et al., 1996; Grafton et al., 1996). Furthermore, the imitation of meaningful actions seems to be mediated by the implicit knowledge about the form as well as the meaning of the gesture, which is processed by regions involved in the planning and generation of actions plus the temporal cortex, whereas imitation of meaningless actions would depend on the decoding of their spatiotemporal layout in the occipito-parietal-PM cortex pathway (Decety et al., 1997), or on the analysis of arbitrary body movements or components (i.e. hand open, finger extended) by cells in the temporal cortex and their corresponding parietal and/or premotor connections (Carey et al., 1997).

Limb apraxias due to dysfunction of the parieto-frontal circuits: higher-order defects of sensorimotor integration

Disruption of parieto-frontal circuits and their subcortical connections, subserving the transformation of sensory information into action, would give rise to most of the praxic errors observed in ideomotor apraxia. Damage to circuits devoted to sensorimotor transformation for grasping, reaching and posture, as well as for transformation of body part location into information necessary for the control of body part movements, would produce incorrect finger and hand posture and abnormal orientation of the tool/object, inappropriate configuration of the arm and faulty orientation of the movement (both with respect to the body and the target of the movement in extrapersonal space), as well as movement trajectory abnormalities. These errors may be similarly observed in the limb contralateral to a left or right parietal lesion, if an associated elemental motor or sensory deficit does not preclude their proper interpretation. However, they would be particularly reflective of ideomotor apraxia, and then also observed in the limb ipsilateral to a left hemisphere lesion, when the patient pantomimes a transitive movement under verbal command. Thus, the praxic quality of the errors in ideomotor apraxia would be determined by the context in which the movement is performed and the cognitive requirements of the task.

Selective praxic deficits may be observed when specific circuits are involved in the parietal or frontal lobes. Damage to the SPL in circuits subserving somatosensory transformation for reaching, posture and movements would produce praxic errors, such as abnormal limb orientation and configuration, resembling those observed in patients with apraxia secondary to superior parietal lesions (Heilman et al., 1986). When the circuits subserving grasping mechanisms are damaged in the IPL, a praxic deficit characterized by a mismatch between finger and hand postures and the object to be grasped will be observed (Sirigu et al., 1995).

Lesions in the PM dorsal cortex and SMA involving the corresponding parieto-frontal circuits will most likely cause milder errors in limb position, configuration, orientation and trajectory than those observed with parietal lesions. These deficits will be more evident in the contralateral limb due to close interrelation between both premotor cortices during movements, although subtle abnormalities may be observed in the limb ipsilateral to a damaged left hemisphere, particularly when the subject pantomimes transitive movements to verbal command. Involvement of the circuits subserving sensorimotor transformation for grasping in the PM ventral cortex may produce some of the ideomotor type of praxis errors confined to hand movements. However, it seems possible that damage to this region of the premotor cortex, particularly when bilateral, would primarily disrupt particular segments of the action and the specificity for different hand and finger movements and configurations. The 'motor vocabulary' necessary for the proper selection of finger and hand movements (Jeannerod et al., 1995) would be impaired and a limb-kinetic type of praxis deficit would appear in the hand contralateral to the more affected hemisphere, regardless of the pattern of cerebral dominance (Leiguarda & Marsden, 2000).

Treatment of limb apraxia

Limb apraxia has a definitive ecological impact on patients' lives, since it interferes with activities of daily living. Patients may use and select tools/objects improperly and may be unable to perform a routine sequential

action. In addition, the presence of limb apraxia may negatively affect the acquisition and use of gestural communication in aphasic patients (Foundas et al., 1995). Furthermore, although the natural evolution of limb apraxia is still unknown, it seems that some aspects of the disorder improve over time, but others are persistent. Therefore, the praxic disorder should be correctly identified and treated together with associated neurological deficits.

Maher and Ochipa have suggested two strategies to manage patients' disability. One is to modify the environment in order to facilitate activities of daily living and to reduce the risk of injuries. The other would be to directly treat specific praxic deficits based on their functional relevance and patients' needs. Although still not well established, preliminary studies indicate that therapeutic gains are restricted to the specific defect or trained activity, and treatment is more effective when implanted into patients' natural environment (Maher & Ochipa, 1997; Goldenberg & Hagmann, 1998).

Distribution of the apraxias in other body parts

Spatial and temporal errors committed by patients with limb (ideomotor) apraxia are remarkably similar to those observed in patients with oral verbal (speech) and oral non-verbal (buccofacial) apraxias which may reflect some common disruption of motor control (Roy & Square-Storer, 1990). Apraxia of speech or verbal apraxia is defined as an articulatory prosodic speech disorder due to 'an impaired ability to program the positioning of the speech musculature . . . and the sequencing of muscle movements' (Darley et al., 1975). The disorder is distinct from aphasia and dysarthria, but often coexists with them, in particular with Broca's aphasia. Apraxic speech is characterized by articulatory errors of different types, slow rate and prosodic deviation or abnormalities of speech rhythm and stress patterns, becoming more evident on longer and phonetically more complex utterances. Frontal (PM), insula, anterior limb of the internal capsule, basal ganglion and parietal damage in the left hemisphere may cause apraxia of speech; the presentation of the motor speech disorder may differ according to lesion location. Both deficits of postural shaping and disruption for sequencing muscle contractions during speech seem to respond to therapy (Square-Storer & Apeldoorn, 1991). Buccofacial or oral non-verbal apraxia is a disturbance of voluntary facial acts; patients exhibit spatial and temporal errors of similar quality to those observed in limb and speech apraxia when performing movements such as sticking out the tongue, blowing out a match or sucking on a straw. Buccofacial apraxia often coexists with Broca's aphasia, but they can be completely dissociated. The disorder is more frequently observed with damage to the frontal and central operculum, insula, centrum semiovale and basal ganglia (Raade et al., 1991).

Apraxia of eyelid opening can be defined as a non-paralytic inability to open the eyes at will in the absence of visible contraction of the orbicularis oculi muscle. Many patients show a forceful contraction of the frontalis muscle and/or a backward thrusting of the head on attempting eyelid opening and use different types of manoeuvres to help open the eyes including opening the mouth, massaging the lids and manual elevation of the lids. Apraxia of eyelid opening can occur in isolation or associated with blepharospasm. Treatment with botulin toxin may be effective in patients with associated blepharospasm and when the disorder is due to a continuation of orbicularis oculi activity following voluntary closure of the eyes (pretarsal motor persistence) but not when it is only the result of involuntary palpebral levator inhibition (Goldstein & Cogan, 1965; Boghen, 1997).

Gerstmann and Schilder (1926) described apraxia of gait as a genuine disturbance of walking due to frontal lesions. However, it remains controversial whether it is a specific disorder or rather it represents a spectrum of higher-order walking syndromes (see Chapter 41). Apraxia of gait is defined as the loss of ability to use the lower limbs properly in the act of walking, which cannot be accounted for by demonstrable sensory impairment or motor weakness (Meyer & Barron, 1960). Gait is characterized by slowness of initiation, loss of balance, 'magnetic attraction of the foot to the ground', and inability to pedal, to kick or to trace a circle with the foot, as well as increased tone (Gegenhalten) and brisk reflexes in the lower limbs with grasping foot responses. The disorder is caused by bilateral damage to the frontal lobes or by white matter lesions interrupting the connections between premotor cortex, supplementary motor area and cerebellum and basal ganglia.

Parkinson's disease

Marian L. Evatt, Mahlon R. DeLong and Jerry L. Vitek

Department of Neurology, Emory University School of Medicine, Atlanta, Georgia, GA, USA

Clinical neuroscience

Movement disorders may be classified as hyperkinetic, characterized by excessive, involuntary movement or hypokinetic, characterized by decreased and slowed movement. First described by James Parkinson in 1817, Parkinson's disease (PD) is the archetypal hypokinetic disorder and the second most common neurodegenerative disorder after Alzheimer's disease. Though incidence and prevalence increase with age, the total estimated incidence is 20/100 000 and prevalence is 150/100 000 (Schapira, 1999). In the United States, approximately one million patients have PD. The estimated societal cost tops $25 billion (Scheife et al., 2000) and is expected to rise as the population ages.

Parkinsonism: classification/clinical symptoms

'Parkinsonism' is a term describing syndromes combining bradykinesia, tremor, muscle rigidity, gait and balance disturbances. The term 'idiopathic PD' traditionally referred to patients exhibiting two or more of the cardinal signs (rest tremor, rigidity and bradykinesia) who responded to levodopa replacement therapy and did not show evidence of other neurologic disease. Given the discovery of inherited dopa-responsive PD, parkinsonian syndromes with good, sustained clinical response to dopaminergic therapy are best termed 'primary PD' (PPD). Infection, drugs, metabolic abnormalities, or other disease states may cause symptomatic parkinsonism. 'Parkinson-plus' (PD-plus) or atypical parkinsonism includes such syndromes as multiple system atrophy (MSA), progressive supranuclear palsy (PSP), Lewy body disease (LBD), the tauopathies (corticobasalganglionic degeneration and frontotemporal dementias), as well as the amyloidopathies (Alzheimer's disease with parkinsonism). These conditions typically exhibit little or no response to levodopa therapy, prominent and early gait and balance disturbance, autonomic and cognitive symptoms (Table 33.1). Table 33.2 lists signs and symptoms occuring in PPD and parkinsonian syndromes. See Chapter 34 for further discussion of the atypical syndromes.

Diagnostic criteria and clinical features for primary Parkinson's disease (PPD)

Although James Parkinson published the first description of the 'shaking palsy' almost 200 years ago, we still have no standardized diagnostic test for PPD. Clinical criteria for PPD vary, but most movement disorders experts agree a patient must demonstrate at least two of the three cardinal signs and experience significant, long lasting (>5 years) improvement with dopaminergic therapy (Gelb et al., 1999). With these clinical criteria and experience, neurologists' diagnostic accuracy can approach 92% (Jankovic et al., 2000). Single photon emission tomography (SPECT) or ^{18}Fluoro-dopa scans may support the diagnosis, but these techniques are currently used largely in research studies and require clinical correlation for an accurate diagnosis (Staffen et al., 2000). Thus, history and clinical exam remain the primary determinants of diagnosis.

PD begins insidiously, often with non-specific complaints of malaise, fatigue or weakness. Since most patients manifest symptoms between ages 55 and 65, these symptoms are often attributed to aging or other disorders, particularly if the typical rest tremor is absent. The asymmetric 'pill-rolling' tremor typical of PPD appears at rest and/or with sustained posture, has a frequency of 4–7 hertz (Hz) and improves with movement of the affected limb. The tremor usually begins in the fingers or hand and spreads

Table 33.1. Classification of parkinsonism

Primary parkinsonism
Idiopathic ('sporadic') PD
Genetic primary PD
Identified mutations (rare)
PARK1 (α-synuclein)
– 2 mutations
PARK2 (Parkin gene mutation)
– multiple polymorphisms
PARK3
Symptomatic parkinsonism
Drugs
Antiemetics (e.g. compazine, metoclopramide)
Neuroleptics
Dopamine depleting agents (reserpine, tetrabenazine)
α-methyldopa
Lithium carbonate
Valproic acid
Fluoxetine
Vascular parkinsonism
Parkinson-plus sydromes
'Alpha-synucleopathies': Multiple systems atrophies and Lewy body dementia
'Tauopathies' (disorders with primary tau pathology): Progressive supranuclear palsy, Corticobasal degeneration, Fronto-temporal dementia
'Amyloidopathies' (disorders with primary amyloid pathology, secondary tau pathology and dementia): Alzheimer's disease with parkinsonism, (Sporadic, APP, PS1 and PS2 related)
Toxins
1-methyl-1, 2, 4, 6-tetrahydropyridine (MPTP)
Manganese
Cyanide
Methanol
Carbon monoxide
Carbon disulfide
Metabolic conditions
Hypoparathyroidism or pseudo-hypoparathyroidism with basal ganglia calcifications
Miscellaneous acquired conditions
Normal pressure hydrocephalus
Catatonia
Cerebral palsy
Repeated head trauma ('dementia pugilistica')
Genetic disorders with parkinsonian features
Wilson's disease
Hallervorden–Spatz disease
Chediack Hagashi disease
SCA-3 spinocerebellar ataxia
X-linked dystonia–parkinsonism (DYT3)
Huntington's disease (Westphalt variant)
Prion disease
Infectious and post-infectious diseases
Postencephalitic PD
Neurosyphilis

proximally, usually involving the opposite side within 1–2 years. Parkinsonian tremor may appear in the tongue, jaw or facial muscles, but titubation or voice tremor suggests essential tremor. However, in one familial form of PPD essential tremor may occur as an alternate phenotype (Farrer et al., 1999). Such observations have generated comment about the possible relationship between essential and parkinsonian tremor (Deuschl, 2000).

Patients may appear bradykinetic during both 'automatic' (e.g. walking) and 'commanded' tasks (e.g. rapidly alternating hand pronation/supination) as well as activities of daily living and fine motor tasks. Hypophonic speech is a particularly disabling manifestation of bradykinesia.

The rigidity seen in PPD presents as a uniform resistance to passive limb movement. Although subclinical tremor often imparts a 'cogwheel' quality to parkinsonian rigidity, the rigidity does not vary with velocity, thus differentiating it from spasticity. Patients may report 'heaviness' or 'weakness', but rarely complain of 'rigidity'.

Parkinsonian gait is narrow-based and slow, with short shuffling steps, diminished armswing, and *en-bloc* turning. With advancing disease, patients experience increased problems with initiating gait and 'freezing'. Predominant gait symptoms, ataxic gait and significant postural instability early in the course of the illness suggest atypical PD (Table 33.2).

Although PPD is considered a movement disorder, patients experience multiple associated non-motor signs, symptoms and syndromes (Table 33.3). Cognitive, behavioural and mood changes may reflect disruption of the non-motor circuits that parallel the motor circuits of the basal ganglia or involvement of other biogenic amine systems (Alexander et al., 1990).

Symptomatic PD

At one time, postencephalitic parkinsonism accounted for many of the symptomatic parkinsonian cases seen in clinics. However, after the 1918–1930 epidemic, encephalitis lethargica virtually disappeared. Drug-induced, dementia-associated and vascular parkinsonism are now the most common forms of symptomatic parkinsonism (Rajput et al., 1984; Baldereschi et al., 2000).

Dopamine(DA)-blocking and DA-depleting drugs are commonly associated with symptomatic parkinsonism. These include traditional neuroleptics, antiemetic medications (metoclopramide, promethazine, and prochorperazine) and some antihypertensive agents (reserpine and calcium channel blockers cinnarizine and flunarizine). The motor signs of drug-induced parkinsonism are generally symmetric. Rest tremor occurs less commonly than in PPD. The severity of drug-induced parkinsonism correlates with D2 receptor blocking in the basal ganglia. Newer, 'atypical' antipsychotic drugs differ from the traditional neuroleptics in their receptor binding characteristics. Though the

Excessive daytime somnolence (EDS)

mechanism of reduced extrapyramidal side effects (EPS) associated with atypical antipsychotics is uncertain, it seems related to a higher serotonin to DA blockade ratio and a relatively higher affinity for D3 receptors. Using 'atypical' neuroleptics (clozapine, quetiapine, olanzepine) reduces the risk of drug-induced parkinsonism, but even these atypical agents have been reported to cause parkinsonism (Glazer, 2000; Modestin et al., 2000). Multiple other drugs, including valproate, have been reported to induce parkinsonism, but the mechanism is unclear (Armon et al., 1996; Onofrj et al., 1998).

Although experts agree vascular parkinsonism exists, its precise phenotype is less clear. In general, affected patients have akinetic-rigid 'lower body' symptoms with prominent gait and balance problems. Action tremor is seen more commonly than in PPD. Associated findings include vascular risk factors, atherosclerotic disease, upper motor neuron signs, pseudobulbar palsy, and dementia. Dopaminergic therapy offers little benefit and anticholinergics and amantadine frequently induce hallucinosis or delerium. These clinical signs and evidence of diffuse white matter disease on imaging studies suggest vascular parkinsonism, but postmortem examination is necessary to exclude other causes of parkinsonism.

Etiology: pathology, genetics and pathogenic theories

Gross examination of the brainstem of a patient with PPD reveals the classic loss of pigmentation in the substantia nigra (SN). The basal ganglia (caudate, putamen, globus pallidus) appear normal. On microscopic examination, one sees loss of neuromelanin-containing neurons and gliosis in the substantia nigra pars compacta (SNc). This loss causes DA deficiency in the striatum and in extrastriatal nigral projections to the motor and limbic basal ganglia circuits (Braak & Braak, 2000). The motor portion of the striatum (the putamen) is the earliest and most severely depleted, most likely accounting for the early development of skeletal signs and symptoms.

Large, round, intracellular eosinophilic inclusions, named Lewy bodies (LB) after the neuropathologist who first described them in 1912, are seen in the nigral pigmented neurons as well as multiple other cortical and subcortical locations. These inclusions contain abnormally phosphorylated neurofilaments and have a halo surrounding a core that stains with antibodies to both ubiquitin and α-synuclein. Lewy bodies are found in the SN in about 75% of clinically diagnosed PPD cases and are considered a pathological hallmark for Parkinson's disease. However, LB have also been described in other neurodegenerative diseases including Alzheimer's disease, some prion diseases and diffuse Lewy Body disease (DLBD). They are not present in autosomal recessive juvenile parkinsonism (ARJP) and thus are sensitive, but not specific for PPD.

At least four different mutations (Park1, Park2, Park3, Park4, Table 33.4) have been described in families whose clinical course is consistent with PPD. Two of these mutations (Park1 and Park3) are in genes coding for α-synuclein and an enzyme involved in ubiquitin metabolism. Both ubiquitin and α-synuclein are major components of LB. Mutant proteins may self-aggregate and form the cores of LB or contribute to the selective vunerability of dopaminergic neurons to oxidant stress (Riess et al., 2000; Polymeropoulos et al., 1997). A third mutation, (Park2) (Matsumine et al., 1998) is found in ARJP patients who have not demonstrated LB when autopsied. This lack of LB in ARJP and the finding of DLBD pathology in a Park4

Table 33.4. Genetically mediated dopa-responsive parkinsonism

Gene	Chromosome	Inheritance	Gene product	Phenotype
Park1	4q21–23	AD	missense mutation in α-synuclein	onset <50 years old, rapid progressive, +Lewy bodies
Park2	6q25–27	AR	point mutation or deletion of parkin gene	onset <40 years, dopa-responsive; early motor fluctuations
Park3	2p	AD	?	40% penetrance
Park 4	4p15	AD	missense mutation of ubiqutin carboxy terminal hydrolase L1	PPD and essential tremor phenotypes

affected patient illustrates the difficulty of classifying parkinsonism solely on clinical or pathologic criteria.

Uncertainty surrounding genetic and environmental factors in PPD has been the rule. A small percentage of cases are familial, but the role of heredity in sporadic cases has been questioned. Early twin studies revealed conflicting concordance results and argued against heredity playing a significant role in PPD. However, monozygotic twins in these studies were prematurely classified discordant (Piccini et al., 1999), suggesting genetics may factor in development of some forms of parkinsonism. The 40% penetrance of the Park3 mutation makes it a target of investigation as a 'risk factor' for sporadic PPD.

Though it is not yet clear how mutations in these genes are related to the selective SN cell death seen in PD, other genetic polymorphisms or mutations may also play a role. Kruger et al., reported apolipoprotein E4 combined with a certain α-synuclein allele increases the risk of a person developing PD (Kruger et al., 1999). Furthermore, apoE genotype may modulate the age of PPD onset (Zareparsi et al., 1997).

Oxidative stress, along with mitochondrial dysfunction, excess nitric oxide formation, and inflammatory processes are all considered contributors to accelerated dopaminergic neuronal apoptosis and development of PPD. Increased glutamatergic output from the subthalamic nucleus (STN) may contribute to degeneration of SN_c neurons via excitotoxic mechanisms (Marsden & Olanow, 1998). Inflammatory responses have also been implicated as glial cells may accelerate DA cell loss via release of cytokines (Hirsch et al., 1998). The 30% decrease in mitochondrial complex I activity found in SN neurons in PPD may contribute to a lowered threshold for apoptosis or susceptiblity to environmental toxins (Schapira et al., 1998).

Langston's description of parkinsonism induced by 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP, a neurotoxic contaminant of synthetic heroin), suggested environmental toxins could precipitate PPD and lead to the development of the primate MPTP model of PD (Langston et al., 1983). MPTP is converted to MPP+ by monoamine-oxidase-B (MAO-B). MPP+, a mitochondrial complex I inhibitor, is concentrated in dopaminergic cells by the DA re-uptake system. Thus, MPP+ is selectively toxic to the striatal-nigral system, producing motor deficits in humans, non-human primates and a few other species that closely mimic the clinical signs of PPD. These motor symptoms respond to antiparkinson medications. In addition, MPTP-treated animals may develop dyskinesias and dystonic postures, though MPTP-induced tremor is usually seen with posture rather than at rest. As with motor symptoms, MPTP pathology varies from PPD pathology. Notably, LB are not seen (though older primates may show LB-like inclusions) and MPTP damage is selective for the SN_C. The first model to nearly replicate PPD motor signs, MPTP-parkinsonism is currently the standard to which other models are compared and by which new PPD treatments are tested.

Recently, Greenamyre et al. (1999) and Betarbet and Greenamyre (2000) described a new model of PPD based on chronic, low-level exposure of rats to rotenone, a mitochondrial respiratory chain inhibitor, an 'organic' pesticide used in gardening and aquamanagement. This model appears to more closely mimic the time course and neurobiology of PPD than the MPTP model, but its development in primates and confirmation of its validity awaits further study.

Pathophysiology circuit

The basal ganglia are viewed as components of multiple segregated circuits, including motor, oculomotor, associative, and limbic circuits (Alexander et al., 1990). The motor circuit is implicated in the pathophysiology of both hypo- and hyperkinetic movement disorders (DeLong, 1990). It originates from pre- and postcentral sensorimotor fields and includes specific portions of the putamen, the external

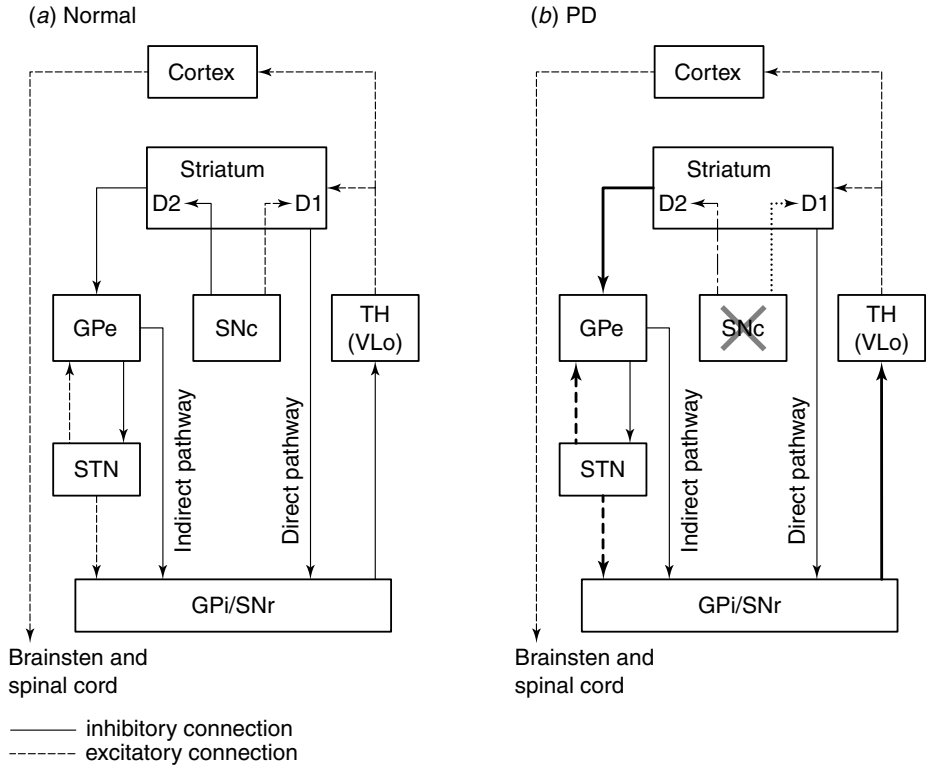

Fig. 33.1. Physiology model of PD. GPe = globus pallidus, external segment; SN_C = substantia nigra, pars compacta; TH = thalamus; VLo = ventrolateral nucleus; STN = subthalamic nucleus; GPi = globus pallidus, internal segment; SNr = substantia nigra, pars reticulata.

(GPe) and internal (GPi) segments of the globus pallidus, the substantia nigra pars reticulata (SNr), the subthalamic nucleus (STN) and portions of the motor thalamus (ventralis lateralis pars oralis, (VLo) and ventralis anterior, (VA)), and returns to the same precentral motor fields from which it originates (Alexander et al., 1990). The striatum (the major input structure of the basal ganglia), influences GPi and SNr (the major output structures), via two routes: a 'direct' pathway from striatum to GPi/SNr and an 'indirect' pathway from the striatum via the GPe and STN (Fig. 33.1).

All the intrinsic connections of the basal ganglia are inhibitory, except for the STN→GPi/SNr pathway, which is excitatory. The dopaminergic nigrostriatal pathway appears to modulate the activity of the two striato-pallidal pathways by activating different DA receptor subtypes (D1 and D2). Thus, DA appears to facilitate transmission in the 'direct' pathway via D_1 receptors and to inhibit transmission in the 'indirect' pathway via D_2 receptors (Albin et al., 1989; Gerfen et al., 1990). Output from GPi/SNr exerts a tonic inhibition on thalamocortical neurons (Yoshida et al., 1972).

Based on this model of intrinsic basal ganglia circuitry, putamenal DA depletion leads to increased mean discharge rates of GPi neurons, excessive inhibition of the thalamic pallidal receiving areas, and correspondingly reduced thalamocortical activity. Consistent with model predictions, single neuron recording studies in parkinsonian animals demonstrated increased tonic discharge rates of GPi neurons and reduced discharge rates in VLo (the pallidal receiving area) (Miller & DeLong, 1988; Filion et al., 1991; Vitek et al., 1994). The observed increases in tonic activity in GPi neurons indicate increased activity in the 'indirect' pathway and decreased activity in the 'direct' pathway in parkinsonian conditions. Increasing striatal inhibition leads to decreased GPe activity, which increases STN activity (Filion et al., 1989, 1991; Bergman et al., 1990). It is proposed that increased STN activity increases GPi output, which, in turn, suppresses thalamocortical activity and leads to dyskinesia and bradykinesia (DeLong, 1990). Consistent with these predictions, temporary or permanent inactivation of the GPi or STN, (in both animal PD models and patients with PPD) is associated with significant improvement in parkinsonian motor signs (Bergman et al., 1990; Wichmann et al., 1994; Lozano et al., 1995; Baron et al., 1996; Gross et al., 1997; Lang et al., 1997; Kumar et al., 1998; Vitek et al., 1998a, b; Volkmann et al.,

1998). Furthermore, this improvement in parkinsonian motor signs coincides with increased cortical metabolic activity (supplementary motor area and dorsolateral prefrontal cortex) (Grafton et al., 1995; Eidelberg et al., 1996; Davis et al., 1997; Samuel et al., 1997; Limousin et al., 1997).

However, this scheme of basal ganglia function (based solely on changes in discharge rate) has several problems. The model predicts that thalamotomy should worsen parkinsonian motor signs by further reducing thalamocortical activity. Contrary to these predictions, most studies report that thalamotomy causes little or no change in bradykinesia, but is highly effective in alleviating parkinsonian tremor and rigidity (Narabayashi, 1986; Montastruc et al., 1994). The model also predicts that pallidotomy should induce excessive involuntary movement (dyskinesias), by disinhibiting the thalamus and increasing thalamocortical activity. However pallidotomy is very effective in alleviating levodopa-induced dyskinesias in addition to improving rigidity, bradykinesia and tremor. These observations are difficult to reconcile with the hypothesis that rate changes alone account for the development of PPD. Many investigators have suggested the observed changes in the pattern of discharge and increased synchronization of neuronal activity reported in animal models and humans with PD play an important role in PPD motor symptoms (Hutchison et al., 1994; Nina et al., 1995; Wichmann & DeLong, 1996; Raz et al., 1997; Vitek, 1997; Vitek et al., 1998).

Changes in pallidal and thalamic receptive field characteristics and neuronal activity patterns (in addition to (or as well as) the levels of neuronal activity) likely provide a significant contribution to the development of parkinsonian motor signs. Disruption of the normal spatio-temporal pattern of cortical neuronal activity may disrupt thalamocortical signal transmission. In the MPTP rodent PD model, improvement of parkinsonian motor signs follows lesioning of the STN. The resulting normalization of pallidal and thalamic neuronal activity (Ryan & Sanders, 1993) coincides with normalization of cortical metabolic activity patterns and improvement in motor signs after stereotactic surgeries in humans with PPD (Grafton et al., 1995; Eidelberg et al., 1996; Davis et al., 1997; Limousin et al., 1997; Samuel et al., 1997). Thus, thalamotomy and pallidotomy are effective in alleviating parkinsonian motor signs because each removes or reduces abnormal neuronal activity that disrupts function in the motor circuit.

Therapeutic principles

The main treatment goals are controlling secondary disability and minimizing associated complications (deconditioning, joint contractures, fractures, etc.) with symptomatic therapy. For all patients, adjunctive therapies including daily stretching and regular physical activity are strongly recommended. Stretching helps maintain flexibility, decreasing the risk of injury from falls, and exercise training may decrease parkinsonian signs (Schenkman et al., 1998; Reuter et al., 1999). Several detailed algorithms for managing early and late PD have recently been published (Olanow & Koller, 1998; Silver & Ruggieri, 1998). The treatment options outlined below fall into three categories: symptom relief, prevention of l-dopa side effects and neuroprotective strategies.

Still considered the most potent symptomatic antiparkinson agent, l-dopa first became widely available in the early 1970s. Although initially administered in high doses without regard to long-term complications, dyskinesias and motor fluctuations were soon observed with chronic l-dopa treatment. Fifty percent of patients with PPD develop dyskinesias after 5 years of l-dopa therapy (Friedman, 1985; Blanchet et al., 1996; Denny & Behari, 1999) and current evidence suggests that the emergence and severity of dyskinesias depend on damaged nigrostriatum exposed to supraphysiologic pulsatile dopaminergic stimulation (Schuh & Bennett, 1993; Chase et al., 1994; Bedard et al., 1999). Younger patients appear more susceptible to motor fluctuations (Quinn et al., 1987; Gibb & Lees, 1988; Giovannini et al., 1991; Pantelatos & Fornadi, 1993; Friedman, 1994; Schrag et al., 1998), and it may be particularly important in younger patients to avoid l-dopa therapy as long as possible. Concerns over such l-dopa-induced side effects and neurotoxicity have led to an ever-increasing emphasis on l-dopa sparing and the early use of DA agonists (Montastruc et al., 1994; Rinne et al., 1998; Rascol et al., 2000; Shulman, 2000).

In addition to priming the basal ganglia for development of dyskinesias, l-dopa neurotoxicity could occur through oxidative stress. L-dopa metabolism generates free radicals, hydrogen peroxide and quinones, all of which can create oxidative stress in dopaminergic neurons. Administering supplemental l-dopa could accelerate or promote apoptotic death of dopaminergic cells. However, evidence from several studies suggests l-dopa delays death in elderly parkinsonian patients about 5 years (Clarke, 1995). Review of the l-dopa toxicity literature (including autopsy cases) found no evidence of l-dopa neurotoxicity in doses comparable to those used clinically (Agid et al., 1999; Weiner, 1999). More recently, Datla et al., provided evidence chronic l-dopa may be protective in 6-hydroxydopamine-lesioned rats (Datla et al., 2001).

The most common side effects of l-dopa are nausea, vomiting, orthostatic hypotension, and hallucinosis. L-dopa is converted to DA in both the periphery and the brain; while l-dopa crosses the blood–brain barrier, DA does not. Combining l-dopa with a peripheral decarboxylase inhibitor (carbidopa) increases the amount of available l-dopa for conversion to DA in the brain. Levodopa conversion to DA in the area postrema is decreased, thereby decreasing nausea and vomiting. Domperidone, a peripheral DA receptor antagonist, may be used as an antiemetic.

Several other agents commonly used for symptomatic management of PPD include DA agonists, anti-cholinergics, amantadine and catechol-*o*-methyl transferase (COMT) inhibitors. Dopamine agonists offer the advantage of directly stimulating postsynaptic DA receptors, thus bypassing the degenerating nigrostriatal nerve terminals. Other advantages include lack of competition with dietary amino acids for absorption and transport into the brain (Rabey, 1995), longer duration of action than standard carbidopa/l-dopa (thus providing more sustained DA receptor stimulation) and lack of auto-oxidation (thus reducing free radical generation and reducing oxidative stress) (Olanow, 1992).

The DA agonists currently used in the United States include ergotamine derivatives (bromocriptine and pergolide) and non-ergolines (pramipexole and ropinirole). Dopamine agonists vary in their affinity for dopamine receptor subtypes and 5-hydroxytryptiline (5-HT) receptors, but none of these compounds has shown clinical superiority in alleviating symptoms. Cabergoline is a long-acting agonist that is clinically available in Europe, but its use in the United States is limited to the treatment of hyperprolactinemia. Apomorphine and lisuride, also available in Europe, have the advantage of parenteral administration. Apomorphine, with its short half-life may be particularly helpful for patients with severe motor fluctuations. The nonergoline structure of ropinerole and pramipexole potentially could limit such side effects as orthostatic hypotension and should decrease the occurrence of pulmonary and retroperitoneal fibrosis associated with ergoline compounds.

Anticholinergic drugs, the first drugs shown to improve parkinsonian symptoms (Duvoisin, 1967), help balance the relative cholinergic excess caused by DA depletion. Though mildly beneficial for rigidity and bradykinesia, anticholinergics are now largely added to target tremor symptoms. Currently used anticholinergics include trihexyphenidyl (Artane), benztropine (Cogentin), and biperiden (Akineton). Ethopropazine (Parsitan) is no longer manufactured in the United States, but can be obtained from Canada and some compounding pharmacies in the United States. Neuropsychiatric and cognitive side effects limit anticholinergic usefulness.

Amantadine, an antiviral agent serendipitously discovered to have anti-parkinson activity, is thought to act by blocking the reuptake of DA into presynaptic neurons, directly stimulating postsynaptic DA receptors, and possibly inhibiting cholinergic activity (Bailey & Stone, 1975; Calne, 1993). More recently, Stoof, et al., recognized that amantadine may act as an NMDA receptor antagonist (Stoof et al., 1992). Amantadine can provide effective monotherapy in early PD, but more importantly provides significant (up to 60%) reduction in dyskinesias (Metman et al., 1999).

As PPD progresses, intracellular DA storage capacity declines and the DA availability becomes more closely tied to circulating blood levels. The COMT inhibitors entacapone and tolcapone have been studied as adjunctive therapy in PD and can extend the duration of l-dopa action by reducing the peripheral degradation of l-dopa. COMT catalyses the breakdown of l-dopa to 3-*o*-methyldopa (3-OMD). Tolcapone and entacapone both inhibit COMT peripherally, and tolcapone also inhibits COMT centrally. Both increase the fraction of l-dopa available to enter the brain. Thus, concomitant l-dopa and COMT inhibitor administration may provide more stable concentrations than can be achieved by fractionating the carbidopa/l-dopa dose or by using controlled release l-dopa formulations.

In addition to symptomatic treatment, neuroprotective strategies are receiving increasing interest. Several clinical trials are in progress to investigate whether DA agonists and such other medications as riluzole could slow PD progression (Dunnett & Bjorklund, 1999). Selegeline was one of the first drugs clinically studied for potential neuroprotection. In the DATATOP study, vitamin E (dosed at 400 IU/day) did not significantly delay the need for l-dopa initiation. Selegeline did delay initiation of l-dopa therapy, but its symptomatic benefit and long washout period confounded this endpoint. Whether selegiline slows the progression of PD remains an unanswered question.

The search for neuroprotection continues with DA agonists and other agents (Marsden & Olanow, 1998; Olanow et al., 1998; Schapira, 1999) Multiple lines of evidence suggest DA agonists may be neuroprotective. Dopamine agonists diminish the need for l-dopa and may therefore minimize the formation of toxic metabolites. In addition, recent evidence suggests that DA agonists have direct antioxidant effects possibly by acting as free radical scavengers (Yoshikawa et al., 1994).

Associated management issues

Coexisting illnesses (e.g. depression, dementia and manic-depressive disorder) can make patients more susceptible to medication side effects and may require the treating neurologist to manage more than the motor manifestations of PPD. Depression, occuring in up to 40% of PPD patients (Cummings & Masterman, 1999), may exacerbate parkinsonian signs and symptoms. Depressed PD patients may be managed similarly to other depressed geriatric patients. Many pharmacists are reluctant to dispense antidepressants to patients who are also taking selegeline, but concern regarding a potential 'serotonin syndrome' interaction is not generally warranted (Heinonen & Myllyla, 1998; Ahlskog, 1999). Patients should also be screened for other medical causes of depression (e.g. hypothyroidism, B12 deficiency).

Patients with cognitive impairment are particularly susceptible to delusions, frank hallucinosis and thought disruption from overstimulation of DA receptors. With a higher ratio of serotonin $5HT_{2a}$ to DA D_2 blockage, the newer atypical antipsychotics clozapine and quetiapine are particularly useful in managing such complications (Juncos, 1999). Electroconvulsive therapy may benefit both depression and parkinsonian symptoms (Anderson et al., 1987).

Along with neuropsychiatric issues, PD patients commonly suffer sleep disruption (Clarenbach, 2000; Larsen et al., 2000; Razmy & Shapiro, 2000). Restless legs syndrome (RLS), a common disorder, responds to DA agents but may be exacerbated by some of the antidepressants used to control depressive symptoms. REM behaviour disorder is a parasomnia commonly seen in PPD. Finally, excessive daytime somnolence and sleep attacks related to dopaminergic therapy are also common in PPD and can be extremely disabling and dangerous (Clarenbach, 2000).

Surgical therapy

Patients with PPD whose motor symptoms can no longer be adequately controlled by medical therapy or who develop intractable drug-induced side effects are candidates for surgical therapy (Fine et al., 2000). Surgical procedures for PD include restorative measures (transplantation using fetal, porcine or retinal tissue), ablative procedures (thalamotomy, pallidotomy and subthalamotomy) and chronic stimulation procedures (thalamic, pallidal, subthalamic).

Although the initial efforts to replace dying dopaminergic neurons with autologous adrenal transplants benefited some patients, such transplants do not offer enough benefit to justify such treatment routinely. Fetal cell transplants seem to offer the best results in animal models and have been tried in humans. Although patients have shown improved bradykinesia and rigidity, freezing and tremor was unaffected and some patients developed severe 'runaway' dyskinesias, even off medications (Fahn, 2000; Freed et al., 2001). Transplant clinical trials thus far have included only patients with advanced PPD, but these patients may not be the ideal candidates for a such a procedure. In the future, transplantation may be a standard therapy, but currently many issues limit it to experimental status.

Thalamotomy is effective for the treatment of Parkinsonian tremor (Tasker, 1998a, b; Linhares & Tasker, 2000). Lesions are generally placed in the cerebellar receiving area, (the ventralis intermedius (V_{im}) nucleus). If extended more anteriorly into the basal ganglia receiving areas (ventralis oralis posterior and ventralis oralis anterior), thalamotomy may also improve rigidity and drug-induced dyskinesias. Thalamotomy is not effective for bradykinesia, freezing, postural instability or the gait disorder associated with PD. Due to an unacceptably high incidence (30–50%) of aphasia, dysarthria or dysphonia, bilateral thalamotomy is not recommended.

A number of studies have demonstrated that pallidotomy is effective for PPD. Lesions within the posteroventral 'sensorimotor' portion of the GPi improve all the cardinal motor signs of PD including tremor, rigidity, bradykinesia, as well as motor fluctuations, drug-induced dyskinesias and dystonia. Although pallidotomy may also improve axial symptoms including gait, balance and freezing, such benefit following unilateral pallidotomy is less consistent than that for appendicular symptoms and many patients lose their benefit 6 months to 2 years postpallidotomy. Bilateral pallidotomy reportedly benefits axial symptoms, but is associated with an unacceptably high incidence of hypophonia. Urinary incontinence and cognitive decline have also been reported following bilateral pallidotomy, though these complications occur less commonly and may result from lesions that encroach on non-motor areas of GPi and/or the internal capsule. Lack of postpallidotomy improvement suggests the patient does not have idiopathic PD or was lesioned outside of the sensorimotor portion of the GPi (Vitek et al., 1998; Eskander et al., 2000).

In recent years, deep brain stimlation (DBS) via implanted electrodes has been employed in place of stereotactic ablation. An implantable programmable pulse generator activates the electrodes. Chronic DBS may reversibly suppress or normalize neuronal activity in neurons by activating an inhibitory interneurons, depolar-

ization block, interupting or normalizing irregular and abnormally bursting activity patterns.

Widely used in Europe, thalamic DBS is now FDA approved for tremor in the United States. Thalamic DBS is effective in the treatment of parkinsonian and other forms of tremor. However, since additional motor symptoms inevitably develop in PPD, pallidotomy or pallidal or subthalamic DBS, should be recommended for PPD patients. Bilateral DBS in the STN or GPi can be performed as a staged procedure or simultaneously. Although some centres support using STN DBS for midline symptoms and GPi DBS for dyskinesias, both procedures are effective in treating the cardinal motor signs of PD and may allow reduced dosing of antiparkinson medications (Burchiel et al., 1999; Krause et al., 2001). Kumar and others have reported benefit lasting 6 to 12 months though the long-term effect of DBS remains ill-defined (Krause et al., 2001).

Future directions: prevention and/or restoration

In the future, treatment strategies will likely provide neuroprotection and neurorescue in PPD (Schapira, 1999). Strategies which decrease iron, lipid peroxidation products and reactive oxygen species accumulation, increase antioxidant concentrations, and improve mitochondrial dysfunction may help accomplish these goals. Such anti-apoptotic agents as the neuroimmunophylins offer another potential avenue of rescue and protection and anti-glutaminergic drugs are being investigated as disease modifying agents. Lastly, transplant studies are currently under way with DA-producing human and pig mesencephalic tissue, genetically engineered dopaminergic cells, and cells expressing trophic factors (GDNF and BDNF). Recently, Kordower et al., successfully delivered glial cell line derived nerve growth factor (GDNF) via a lentiviral injection into the striatum and substantia nigra (Kordower et al., 2000) of rhesus monkeys. The implants successfully expressed GDNF, improved markers of dopaminergic function in MPTP-treated monkeys. Most importantly, the monkeys improved clinically and in quantitative motor testing.

Other extrapyramidal syndromes: parkinsonism-plus and other forms of secondary parkinsonism

Kailash P. Bhatia

Department of Clinical Neurology, Institute of Neurology, London, UK

There are numerous other causes of an extrapyramidal syndrome manifesting as parkinsonism apart from Parkinson's disease (see previous chapter). Traditionally, these are listed etiologically as shown in Table 34.1. In this list three broad groups emerge namely that referred to as the parkinsonism-plus syndromes (also called atypical parkinsonian syndromes), the symptomatic or secondary parkinsonian conditions and the hereditary/heredodegenerative disorders (Table 34.1). The parkinsonism-plus syndromes are so called because they are multisystem degenerations and have other features in addition to parkinsonism. This older classification, although useful, has its limitations because the divisions drawn are somewhat artificial and there is a fair amount of overlap in the disorders listed under the different subheadings. For example, additional clinical features can also be present in disorders in the two groups apart from the parkinson-plus disorders and it is being realized that a genetic basis may even underlie parkinsonian disorders thought to be sporadic like progressive supranuclear palsy (PSP). Great advances at the molecular, ultrastructural and genetic level are leading to a newer way of classifying many of these degenerative diseases affecting the basal ganglia causing extrapyramidal syndromes (Dickson, 1997; Spillantini, 1999). Many parkinsonian syndromes can now be viewed as being caused by the genetic or sporadic occurrence of diseases characterized on the basis of cytoskeletal pathology and staining of particular proteins, for example, alpha-synucleinopathies where alpha-synuclein is present (Spillantini, 1999; Goedert, 2001) or taupathies wherein there is deposition of tau protein (Morris et al., 1999a). This way, many of the disorders listed in Table 34.1 can now be reclassified as shown in Tables 34.2 and 34.3 on a molecular basis. Thus PSP and corticobasal degeneration and the inherited condition of frontotemporal dementia parkinsonism as well as dementia pugilistica or encephalitis lethargica from the secondary parkinsonism division are all grouped together as 'taupathies', while multiple system atrophy (MSA) and Parkinson's disease and dementia with Lewy bodies go together as 'alpha-synucleinopathies' (Spillantini et al., 1998a).

It is beyond the scope of this chapter to detail each of the conditions causing parkinsonism listed in Table 34.1, hence this chapter will focus on some of the conditions most likely to be confused with Parkinson's disease, namely progressive supranuclear palsy (PSP), corticobasal degeneration (CBD) and multiple system atrophy (MSA) among the parkinsonism-plus syndromes with a brief mention of other related conditions as well as some secondary or symptomatic parkinsonian disorders. The UK brain bank series study looking at a 100 cases diagnosed as having Parkinson's disease in life found that 25 of these had other diagnosis at pathology (Hughes et al., 1992). The most commonly misdiagnosed conditions were atypical parkinsonian disorders, namely progressive supranuclear palsy (PSP), multiple system atrophy (MSA), and vascular parkinsonism (CBD). It is important too for the clinician to recognize the parkinsonism-plus conditions as they usually have a poor response to levodopa replacement treatment and have a bleak prognosis with regard to survival.

Progressive supranuclear palsy (PSP)

Background

PSP is a progressive neurodegenerative condition with the anatomical pathology centred around the basal ganglia and brainstem accounting for its distinctive clinical features. PSP was first recognized as a distinct syndrome by Steele, Richardson and Olszewski in 1963 and their initial

Table 34.1. Classification of parkinsonism

Idiopathic (primary)
Parkinson's disease
Parkinsonism-plus
Progressive supranuclear palsy (PSP)
PSP of the French West Indies (Guadelope)
Multiple system atrophy (MSA)
Striatonigral degeneration (SND/MSA-P)
Shy–Drager syndrome (SDS)
Olivopontocerebellar degeneration (MSA-C)
Corticobasal ganglionic degeneration (CBD)
Dementia syndromes
Parkinsonism–dementia–ALS complex of Guam
Frontotemporal dementia parkinsonism–chromosome 17 (FTDP-17)
Dementia with Lewy Bodies (Diffuse Lewy body disease)
Creutzfeldt–Jakob disease
Alzheimer's disease
Hereditary/heredodegenerative disorders
Wilson's disease
Hallervorden-Spatz disease
Huntington's disease
Neuroacanthocytosis
SCA-3 (Machado–Joseph) and other spinocerebellar ataxias
Lubag (X-linked dystonia–parkinsonism)
Ceroid lipofuscinosis
Hereditary hemochromatosis
Hereditary ceruloplasmin deficiency (Apoceruloplasminemia)
Familial basal ganglia calcification (Fahr's syndrome)
Symptomatic (secondary)
Infectious and postinfectious
Postencephalitic (encephalitis lethargica)
Other encephalitides
Toxins – manganese, cobalt, MPTP, cyanide, CO, methanol, ethanol
Drugs
Dopamine receptor blockers (antipsychotics/antiemetics), dopamine storage depletors, α-methylparatyrosine, α-methyldopa, calcium channel blockers, SSRI's
Vascular–multi-infarct, Binswanger
Brain tumours
Head trauma – including dementia pugilistica
Vascular
Metabolic–hypoparathyroidism, hepatocerebral degeneration
Other – hemiparkinsonism/hemiatrophy, normal pressure hydrocephalus, paraneoplastic

Table 34.2. Conditions characterized by the deposition of tau containing neurofibrillary tangles (taupathies)

Progressive supranuclear palsy (PSP)
Corticobasal degeneration (CBD)
Frontotemporal dementia parkinsonism-chromosome 17 (FTDP-17)
Pick's disease
Post-encephalitic parkinsonism (encephalitis lethargica)
Post-traumatic parkinsonism
Parkinson dementia complex of Guam
Alzheimer's disease
Niemann–Pick type C
Subacute sclerosing panencephalitis

Table 34.3. Parkinsonian syndromes with alpha-synuclein accumulation (alpha-synucleinopathies)

Lewy body diseases
Idiopathic Parkinson's disease
Inherited Lewy body diseases (mutations of the alpha-synuclein gene, PARK3, PARK4)
Dementia with Lewy Bodies
Halloverden Spatz disease
Multiple system atrophy (MSA)
Striatonigral degeneration
Shy–Drager syndrome
Olivopontocerebellar atrophy

Source: From Goedert & Spillantini (2001).

description has proven to be remarkably accurate (Steele et al., 1964). Despite the distinctive clinical presentation, however, the condition is probably underdiagnosed (Nath et al., 2001).

Clinical aspects

PSP typically occurs late in life usually in the sixth decade with the median age at disease onset between 60 and 66 years (Nath & Burn, 2000). Onset below age 40 years is virtually unknown. A prevalence of 1.4/100 000 had been reported from New Jersey (Golbe et al., 1988) and 1 per 100 000 as per a more national survey from the UK (Nath et al., 2001). A recent cross-sectional study from the UK has shown that the age-adjusted prevalence for PSP was 6.4 per 100 000 (Schrag et al., 1999). There have been only two reported case control studies of PSP both by the same group. The first study sug-

gested that PSP patients were more likely to live in areas of relatively sparse population (Davis et al., 1988). However, a follow-up study failed to identify any particular risk factor except for the likelihood of having completed 12 years of education or more that differentiated PSP patients from matched controls (Golbe et al., 1996). Recently, one study reported a higher prevalence of presymptomatic high blood pressure in PSP patients (81%) compared to Parkinson's disease patients (15%) (Ghika & Bogousslavsky, 1997); however, another subsequent series could not replicate these figures and found this in a much smaller number (24%) of patients with PSP (Fabbrini et al., 1998) . PSP has been considered to be a sporadic condition and in one study of 104 patients, Jankovic et al. (1990) failed to find another affected person among 400 first-degree relatives. However, some reports of familial clustering have appeared in the literature from time to time (Brown et al., 1993; de Yebenes et al., 1995; Tetrud et al., 1996). Recently, 12 families were put together, 8 of whom with probable autosomal dominant inheritance with pathological confirmation in 4 probands (Rojo et al., 1999).

Most patients present with a gait disturbance with a tendency to fall backwards. Indeed 70% of PSP cases would have falls in the first year of the illness. Some may present with a complaint of visual disturbance, particularly when reading or walking downstairs due to lack of control of saccadic eye movements (see below). A growling gruff dysarthria and swallowing difficulty may be associated with presenting symptoms. Despite these disabling presenting features, surprisingly the mean interval from symptom onset to diagnosis of PSP is usually delayed even up to 3–4 years (Maher & Lees, 1986; Golbe et al., 1988). Thus, the average patient with PSP remains undiagnosed for approximately half of the natural history of their disease.

Clinically, most patients have an erect posture in contrast to the flexed posture of Parkinson's disease. Also, unlike Parkinson's disease most signs of parkinsonism in PSP are axial that is involving postural balance, gait and speech with less pronounced distal limb involvement. In contrast to PD, PSP patients have a stiff somewhat broad-based gait quite often marked by start hesitation, freezing and disequilibrium leading to a tendency to fall. There is early loss of postural reflexes as compared to PD (Litvan et al., 1997a). PSP patients, when asked to stand up from sitting, tend to jump up abruptly from the seated position, only to fall back immediately into the chair which has been called the 'rocket sign' and probably results from a combination of postural instability and frontal–subcortical disturbance (Litvan, 1997). Sitting 'en bloc', in which the patient's feet come high off the floor as they sit down, also tends to occur in 30% of cases (Collins et al., 1995). An increase of axial tone with rigidity of the trunk and neck rather than of the limbs is typical and rest tremor is uncommon or does not occur. Bradykinesia is common and affects nearly half the patients by the time of diagnosis and up to 95% of patients during the course of their illness (Verny et al., 1996). Striking frontalis overactivity with markedly reduced blink frequency and hypomimia produce the so-called 'reptilian' stare with regard to facial appearance (Verny et al., 1996). The characteristic feature from which the term 'progressive supranuclear palsy' is derived is the supranuclear gaze problem (Troost & Daroff, 1977). Typically, voluntary down-gaze is slow and incomplete but, when the oculo-cephalic manoeuvre is engaged, full down-gaze is possible. Because up-gaze may be restricted with ageing, and restriction in this direction can also occur with other disorders, downward gaze palsy is more specific for the diagnosis of PSP (Lees, 1987). Some other causes of vertical supranuclear gaze palsy include Whipple's disease (Averbuch-Heller et al., 1999), Niemann Pick type C (Shulman et al., 1995), and other conditions including CBD, prion disease (Brown et al., 1994) and spinocerebellar ataxia (SCA) including SCA2 and SCA3. Square wave jerks, saccadic intrusions when fixing gaze on a stationary object, can also be seen in PSP (Rascol et al., 1991). Unlike corticobasal degeneration, involvement of horizontal saccades occurs only later in PSP (Vidhailhet et al., 1994), a useful differentiating feature. In the late stages, complete supranuclear restriction of eye movements may be seen (Rivaud-Pechoux et al., 2000). Difficulty in eyelid opening may caused by blepharospasm and/or apraxia of eyelid opening. A pseudobulbar palsy occurs in 85–90% of cases, and a frontal lobe-like syndrome sometimes with marked emotional lability is present in 80% of cases with 52% developing this in the first year (Brusa et al., 1980; Verny et al., 1996). Speech and swallowing can be affected early and may be presenting features (Daniel et al., 1995). PSP patients may have stuttering, stammering hypophonic speech. Echolalia, pallilalia and pallilogia can be present. A poor or unsustained response to levodopa is characteristic of PSP (Litvan et al., 1997a). The condition is unfortunately relentlessly progressive with death from disease onset in about 5–6 years (Maher & Lees, 1986; Brusa et al., 1980). An early onset, presence of falls and early down-gaze palsy seems to be associated with a more rapid progression (Santacruz et al., 1998).

Pathology, clinicopathological correlation, tau ultrastructure and genetics of PSP

PSP is characterized pathologically by abundant neurofibrillary tangles (NFTs) which consist of hyperphosphorylated tau and neuropil threads in select basal ganglia and

brainstem regions (Fig. 34.1, see colour plate section). Thus PSP is one of group of tau neurofibrillary disorders (Table 34.2) (Dickson, 1997; Morris et al., 1999a). Tau is a microtubule binding protein which serves to promote and stabilize the polymerization of monomeric tubulin into microtubules. Tau is present mainly in axons and expressed also in glial cells, especially in pathological conditions. In PSP, for example, tau deposition is seen as tufted astrocytes (Fig. 34.2, see colour plate section). The tau protein itself is alternatively spliced from the tau gene with six different types of proteins (isoforms) appearing in normal adult human brain (Morris et al., 1999a). These isoforms differ in the presence of three or four repeated microtubule binding domains (three or four repeat tau) and the extra microtubule binding domain is determined by the inclusion of exon 10 of the tau gene. Tau deposition or dysfunction in these disorders is not thought to be an incidental finding but appears to be the pathogenic cause of neurodegeneration (Hutton et al., 1998; Goedert & Spillantini, 2001).

The main lesions in PSP are in the substantia nigra pars compacta, and reticulata, internal segment of the globus pallidus, subthalamic nucleus, midbrain and pontine reticular formation. Cortical damage and glial pathology is more variable and allows distinction between this disorder from CBD and Pick's disease which have distinctive cortical involvement. The most striking neurochemical abnormality is marked reduction in striatal dopamine, dopamine receptor density, choline acetyl transferase activity and loss of nicotinic cholinergic receptors in the basal forebrain (Young, 1985; Ruberg et al., 1985; Juncos et al., 1991). However, in contrast to the striatum the mesolimbic structures are relatively spared with normal dopamine levels in the nucleus accumbens.

There is a good correlation for PSP between the pathological anatomical substrate and the predominant clinical features. Postural instability is probably due to involvement of the dentate and pedunculopontine nucleus as well as bilateral globus pallidus. Involvement of the substantia nigra, medial pallidum and subthalamic nucleus (Feany & Dickson, 1996) may result in the bradykinesia and limb rigidity. The superior colliculus involvement may account for the increased axial tone. Impairment of vertical saccades is probably due to involvement of rostral interstitial nucleus of Cajal and nucleus of Darkshewitsch and the rostral interstitial nucleus of the medial longitudinal fasciculus (Juncos et al., 1991). Echolalia, pallilalia, grasping and groping behaviour arises from frontal lobe or frontal basal ganglia connections. PSP pathology may affect the spinal cord, and Onuf's nucleus in the sacral spinal cord has been shown to be affected and can result in loss of bladder control and abnormal sphincter electromyogram changes (Scaravilli et al., 2000; Valldeoriola et al., 1995)

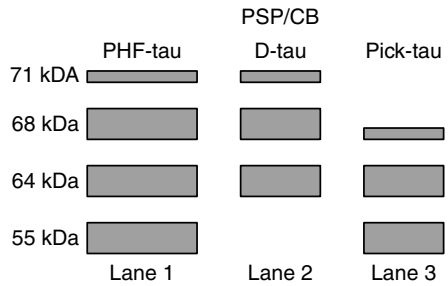

Fig. 34.3. Electrophoretic migration patterns in different taupathies. Lane 1 represents paired helical filament-tau (PHF-tau) characteristic of certain taupathies like Alzheimer's disease and certain forms of frontotemporal dementia linked to chromosome 17 (FTD-17). All six isoforms of tau contribute and a triplet pattern migrating at 68, 64 and 55 kilodaltons is observed. Lane 2 with a doublet pattern migrating at 68 and 64 kilodaltons is observed in conditions such as PSP and CBD. Abnormal tau in both these conditions is composed of four repeat isoforms. Lane 3 shows two bands migrating at 64 and 55 kilodaltons characteristic of conditions like Pick's disease. The tau in this condition is composed of three repeat isoforms. (Courtesy Dr Tamas Revesz, Dept. of Neuropathology, Institute of Neurology, London.)

These changes are associated with nerve cell loss, gliosis, and occasional granulovacuolar or ballooned argyrophilic neuronal degeneration (Jellinger et al., 1995). Ultrastructural and protein chemistry of neurofibrillary tangles allows subdivision of the different taupathies. In contrast to other neurodegenerative disorders with tau pathology like AD, Pick's disease and CBD which are characterized by flame-shaped NFTs, the NFTs of PSP are mainly of the globose type (Fig. 34.1, see colour plate section). They are made up of clusters of straight filaments arranged in circling and interlacing bundles, and have a diameter of 12 to 15 nm (Roy et al., 1974). This filamentous phenotype therefore differs from the paired helical filaments typically found in Alzheimer's disease (Dickson, 1997). Also, on electrophoresis the paired helical filaments of Azheimer's disease are made up of three distinct bands of 55, 64 and 68 kDa and they are composed of all six isoforms of the tau gene, containing both four and three repeat isoforms. In PSP the straight filaments are composed of only two bands at 64 and 68 kDa (Fig. 34.3) and the tau protein is made up only of a subset of tau isoforms consisting only of four repeat tau (Conrad et al., 1997; Morris et al., 1999a). Thus taupathies can be classified according to tau repeat isoforms deposited.

Most cases of PSP are isolated with no family history and it is considered to be a sporadic condition. However, a

number of families have been described with autosomal dominant PSP (Rojo et al., 1999), although neither a linked chromosomal locus nor a causative gene have been identified in any of these (Morris et al., 1999a). As a rare exception recently there has been report of a family with PSP pathology with a novel mutation of exon 10 of the tau gene (Stanford et al., 2000). However, no mutations were identified on sequencing exons 9–13 of the tau gene in over 60 patients with PSP (Baker et al., 1999). This is the area where most of the mutations causing frontotemporal dementia with parkinsonism linked to chromosome 17 had been detected. In fact, no mutations were found on sequencing the entire coding region of the tau gene in any of these PSP patients in whom this was carried out (Baker et al., 1999). Also there appears to be no effect of alpha-synuclein, synphilin, or APOE genotypic variability for the development of PSP (Morris et al., 2000). However, analysis of sporadic PSP cases has led to a suggestion of an association between a polymorphic dinucleotide marker within the tau gene and PSP (Conrad et al., 1997; Higgins et al., 1998, 1999, 2000; Baker et al., 1999; Morris et al., 1999b). In PSP there appears to be an over-representation of the more common allele A0 and the genotype A0/A0 which is not found in PD, MSA or CBD. This may be a predisposing factor to PSP in the same way as as apolipoprotein E e4 allele is in Alzheimer's disease.

Diagnostic tests, diagnostic criteria and differential diagnosis

CT or MRI brain scans of patienst with PSP may show generalized and/or brainstem atrophy mainly of the dorsal midbrain. The degeneration of the superior colliculus gives a flattened appearance of the third ventricle on MRI scans; aqueductal dilatation and increased olivary signal have also been noted (Savoiarda et al., 1994, Schrag et al., 2000). If midbrain atrophy is seen on MRI, differentiation of PSP from PD is possible as MRI is normal but not from other akinetic-rigid syndromes, for example MSA, where similar changes may be present. MR spectroscopy has shown reductions in *N*-acetylaspartate in the lentiform nucleus of PSP patients but not so in PD patients (Federico et al., 1997). Metabolic studies using PET have demonstrated global reduction in cerebral metabolism with particular affectation of the frontal and striatal regions using labelled oxygen or glucose markers (Brooks, 1994). ^{18}F-dopa PET uptake is reduced in the caudate and putamen thus discriminating from PD but not other akinetic-rigid syndromes like MSA which can have a similar picture. Ten to 25% reduction of uptake in caudate and putamen using ^{11}C-raclopride, a D2 receptor ligand, and also for ^{11}C-diprenorphine, an opoid receptor ligand, has been shown in PSP (Brooks, 1994).

Ideal diagnostic criteria for PSP would reliably separate the condition from other akinetic-rigid syndromes, notably Parkinson's disease and also other neurodegenerative disorders with parkinsonism and dementia (Lopez et al., 1999). Many different diagnostic criteria have been proposed to assist the clinician in making an accurate diagnosis of PSP (Lees, 1987; Collins et al., 1995; Tolosa et al., 1994; Litvan et al., 1996a). Of these the National Institute of Neurological Disorders and Stroke and Society for Progressive Supranuclear Palsy, Inc. (NINDS–SPSP) diagnostic criteria are shown in Table 34.4 (Litvan et al., 1996b) which have been validated and also evaluated and found to have good specificity (Lopez et al., 1999). A difficult problem can be with an early case of PSP, before the characteristic clinical features have emerged. The patient may not yet have the typical vertical supranuclear gaze paresis and it is clear that sometimes the development of 'core' diagnostic features may be delayed, or may not occur at all. Thus, in one series comprising 17 pathologically confirmed cases of PSP, 10 of the cases did not have a vertical supranuclear gaze paresis documented antemortem and all 10 of these were misdiagnosed (Daniel et al., 1995). Phenotypic variants for PSP can also cause diagnostic confusion. There have been unusual phenotypes of pathologically confirmed cases, for example, early and severe dementia or that with pure akinesia and unilateral limb dystonia or apraxia leading to a mistaken diagnosis of CBD (Matsuo et al., 1991; Davis et al., 1985; Pharr et al., 1999). PSP is most often clinically misdiagnosed as PD or as cerebrovascular disease (false-negative clinical diagnosis) (Litvan et al., 1996c). In the clinicopathological series of Hughes et al. (1992), mentioned earlier, 25% of the 24 cases clinically diagnosed as having PD, but without Lewy bodies at postmortem, were actually found to have PSP. Conversely, there are pathologically confirmed cases of corticobasal degeneration, multiple system atrophy, dementia with Lewy bodies, prion disease and Whipple's disease, that were clinically misdiagnosed as having PSP (false-positive clinical diagnosis) (Litvan et al., 1996c; Fearnley et al., 1991; Averbuch-Heller et al., 1999). Overall, looking at which factors best differentiate PSP from other related disorders, according to one study, postural instability, leading to falls (typically backwards) within the first year of disease onset, coupled with a vertical supranuclear gaze paresis have been shown to have good discriminatory diagnostic value when comparing PSP with other akinetic-rigid syndromes (Litvan et al., 1997a, b).

Table 34.4. NINDS–SPSP Clinical criteria for the diagnosis of PSP

PSP	Mandatory inclusion criteria	Mandatory exclusion criteria	Supportive criteria
Possible	Gradually progressive disorder Onset age 40 or later Either vertical supranuclear palsy or both slowing of vertical saccades and postural instability with falls <1 year disease onset No evidence of other diseases that could explain the foregoing features, as indicated by exclusion criteria	Recent history of encephalitis Alien limb syndrome, cortical sensory deficits, focal frontal or temporoparietal atrophy Hallucinations or delusions unrelated to dopaminergic therapy Cortical dementia of Alzheimer type Prominent, early cerebellar symptoms or unexplained autonomic dysautonomia	Symmetric akinesia or rigidity, proximal more than distal Abnormal neck posture, especially retrocollis Poor or absent response of parkinsonism to levodopa Early dysphagia & dysarthria Early onset of cognitive impairment including >2 of: apathy, impairment in abstract thought, decreased verbal fluency, utilization or imitation behaviour, or frontal release signs
Probable	Gradually progressive disorder Onset age 40 or later Vertical supranuclear palsy and prominent postural instability with falls <1 year disease onset No evidence of other diseases that could explain the foregoing features, as indicated by exclusion criteria		
Definite	Clinically probable or possible PSP and histopathological evidence of typical PSP

Management

PSP patients usually do not have significant benefit from dopaminergic medication. In some there may be some initial improvement but this is not sustained. There have been some suggestions that amantadine may be useful with the motor features of PSP but this has not been formally tested in a randomized trial. Cholinergic drugs such as physostigmine have been said to be useful for certain aspects. Following physostigmine administration in PSP patients, a significant reduction in errors of performance was found in four out of seven on neuropsychological tests; however, motor disability was not significantly altered (Blin et al., 1995). Alpha-2 antagonist drugs like idaxozan and efaroxon have been mooted for motor symptoms; however, there is no clear evidence that these are useful (Ghika et al., 1991; Rascol et al., 1998). Botulinum toxin is useful for blepharospasm and less so for levator inhibition or apraxia of eyelid opening. Supportive therapy is the mainstay rather than drug treatment. Physiotherapy and occupational therapy are important to help balance with aids and avoid falls. Early speech therapy and assessment of swallowing function may be helpful in avoiding aspiration and its complications. In some instances feeding may have to be done by means of a percutaneous gastrostomy tube, but such an intervention should take into account the patients and the relatives' wishes with regard to quality of life and how advanced the disease process may be.

PSP in the French West Indies

Clues to the etiology of PSP may come from the recent observation of a large cohort of PSP patients in the small island of Guadelope in the French West Indies (Caparros-Lefebvre et al., 1999). Out of 87 consecutive patients with parkinsonism referred to a single neurological department, 31 had PSP which was a gross over-representation. A case control study established that a higher proportion of the PSP patients, but not the PD patients, consumed herbal teas and tropical fruits. As these are known to contain benzyltetrahydroisoquinolines, this is being considered as the possible exogenous environmental toxin in addition to a possible genetic susceptibility.

Corticobasal degeneration (CBD)

Background

Corticobasal degeneration (CBD), is a rare sporadic neurodegenerative disorder recognized relatively recently with the first description of three patients by Rebeiz, Kolodny and Richardson in 1967. These patients had an asymmetric onset of slow, awkward voluntary limb movement, tremor, dystonic posturing, stiffness, lack of dexterity, and 'numbness or deadness' of the affected limb. The gradual progression of symptoms included gait disorder, limb rigidity, impairment of position sense, and other sensory modalities (Rebeiz et al., 1967, 1968). Cognitive function was said to remain relatively intact (Rebeiz et al., 1967, 1968). A fairly characteristic clinical picture thus emerged. Pathology also was thought to be quite typical with asymmetric frontoparietal cortical atrophy, neuronal loss with associated gliosis, and swollen neuronal cell bodies which were devoid of Nissl substance, thus prompting the descriptive term 'achromatic'. There was considerable loss of pigmented neurons in the substantia nigra in all three patients, variable subcortical neuronal involvement, and secondary corticospinal tract degeneration. Different terms reflecting the cortical and subcortical pathology and the characteristic achromasia appeared in the literature describing clinically similar cases including corticonigral degeneration with neuronal achromasia (Rebeiz et al., 1967, 1968; Lippa et al., 1990), corticobasal ganglionic degeneration (Watts et al., 1985; Riley and Lang, 1988; Greene et al., 1990), corticobasal ganglionic degeneration with neuronal achromasia (Watts et al., 1989), syndrome of progressive rigidity with apraxia (LeWitt et al., 1989) and corticobasal degeneration (CBD) (Gibb et al., 1989; Thompson & Marsden, 1992; Rinne et al., 1994; Wenning et al., 1998), which is the term commonly used now for this condition.

Clinical features

CBD presents in mid to late adult life, with a mean onset of symptoms at 63 years (Wenning et al., 1998). However, cases of CBD have been reported as early as 40 years old and the youngest case with pathologic confirmation was 45 years old. Population prevalence is not known and although both sexes are affected, some have wondered about a slight preponderance of women (Rinne et al., 1994; Schneider et al., 1994; Watts et al., 1997). The clinical phenotype of CBD is well described most recently in three large series of patients (Rinne et al., 1994; Wenning et al., 1998; Kompoliti et al., 1998) one of them with postmortem confirmation (Wenning et al., 1998). The typical presentation is that of an asymmetric progressive akinetic-rigid syndrome poorly responsive to levodopa treatment. The most common initial symptom reported, limb clumsiness, has been observed in 50% of the patients at the first visit in some studies. Rinne et al. (1994) describing a large series of 36 patients with CBD outlined five common types of clinical presentation. The most common presentation was with a 'useless' arm which could be due to combined rigidity, dystonia, akinesia or apraxia, with or without myoclonus. A similar presentation but affecting a leg and presenting as a gait disorder was next most common. Other presentations included a sensory disturbance with pain, or 'clumsiness', or a speech disturbance. Only one patient in this series presented with behavioural changes, and cognitive problems were described as an uncommon presenting feature, being noted only later in the illness. However, of late it is becoming clear that many patients with pathologic findings of CBD may have dementia as the presenting and predominant feature (Grimes et al., 1999).

On examination, limb rigidity or dystonia and focal reflex myoclonus manifesting as an irregular action/postural tremor are the prominent clinical features. Asymmetric limb dystonia is observed in a vast majority of patients (Wenning et al., 1998; Vanek & Jankovic, 2000; Litvan et al., 1997b). The arm is the most frequently affected region and typically is held adducted at the shoulder with flexion of the forearm at the elbow. The fingers are flexed at the metacarpophalangeal joints, often digging into the palms of the hand, sometimes with associated contractures causing fixed posturing (Watts et al., 1997; Vanek & Jankovic, 2000). Akinesia, rigidity and apraxia are the most common findings during the course of CBD (Kumar et al., 1998; Riley & Lang, 2000). Typically, ideomotor and limb kinetic apraxia are seen in patients with CBD with ideational apraxia being less common (Leiguarda et al., 1994). Ideomotor apraxia is manifested by impairment of timing, sequencing, spatial organization, and in copying gestures made by the examiner. In limb kinetic apraxia there is a decrease in dexterity and fine movements. Ideomotor apraxia is usually bilateral and can be tested on the less affected side in advanced cases, as often the severe rigidity and dystonia of the more affected side make apraxia testing virtually impossible (Leiguarda et al., 1994). Orofacial apraxia with impairment of tongue and lip movements is also not infrequent in CBD (Ozsancak et al., 2000). Apart from apraxia, other cortical signs including cortical sensory loss or alien limb phenomenon are often present. The alien limb phenomenon is a failure to recognize ownership of a limb in the absence of visual cues. It is

Table 34.5. Clinical manifestations of CBD

Basal ganglia signs	Cerebral cortical signs	Other manifestations
Akinesia, rigidity	Cortical sensory loss	Postural-action tremor
Limb dystonia	Alien limb phenomenon	Hyperreflexia
Athetosis	Dementia	Impaired ocular motility
Postural instability, falls	Apraxia	Dysarthria
Orolingual dyskinesias	Frontal release reflexes	Focal reflex myoclonus
	Dysphasia	Impaired eyelid motion
		Dysphagia

Source: From Riley et al. (1990).

associated with autonomous activity of the extremity including posturing and levitation. About 40% or so of patients with CBD develop the alien limb phenomenon during the course of the illness, although it is rare on initial presentation (Kumar et al., 1998).

Eye movement abnormalities are also common in CBD and the extraocular movements appear slow and hypometric. Horizontal saccadic latencies are significantly increased in patients with CBD whereas vertical saccades are usually normal at least initially helping to differentiate CBD from PSP (Vidhailet et al., 1994; Litvan et al., 1997b). Slowness of speech production, and dysphonia, echolalia, and palilalia can be present as in PSP and also, like the latter, swallowing disorders are very common, especially in advanced stages.

Riley and colleagues suggested a set of diagnostic criteria for CBD (Table 34.5) (Riley et al., 1990; Riley & Lang, 1993). These consisted of unilateral onset and asymmetric course of an insidious and progressive disorder with the following clinical manifestations which were divided into three main groups: (i) those suggestive of dysfunction of the cerebral cortex namely cortical sensory loss, apraxia, alien limb, frontal release signs; (ii) those attributed to involvement of the basal ganglia namely akinesia, rigidity, limb dystonia, and postural instability and (iii) additional findings which did not localize to either cortex or basal ganglia such as action tremor, hyperreflexia, Babinski signs, oculomotor impairment, dysarthria and dysphagia.

Prognosis

The symptoms are progressive and death usually ensues 5 to 10 years after disease onset. Early onset of bilateral parkinsonism and the presence of a frontal lobe syndrome are associated with shorter survival in CBD patients (Wenning et al., 1998).

Pathology

Superior frontoparietal cortical atrophy in CBD is often asymmetrical and involves perirolandic cortex (Schneider et al., 1994). Microscopic examination reveals neuronal loss and gliosis in cortical and subcortical regions. Superficial spongiosis in atrophic cortical regions is common. Ballooned and achromatic neurons lacking Nissl substance, eosinophilic on H & E staining, and often vacuolar, observed in cortical and subcortical regions are a characteristic feature of CBD (Rebeiz et al., 1968; Watts et al., 1985; Smith et al., 1992). By immunochemistry ballooned neurons do not stain for alpha-synuclein and are sometimes positive for ubiquitin (Smith et al., 1992). However, focal tau immunoreactivity is detected in ballooned neurons as well as in neurofibrillary tangles, neuropil threads, grains, glial, and neuronal inclusions seen in this condition (Dickson, 1999; Feany & Dickson, 1996). They are frequently identified on silver stain preparations and on tau immunohistochemistry within cortical neurons, and subcortical structures including the basal ganglia, and brainstem nuclei. The locus ceruleus, raphe nuclei, tegmental grey matter, and substantia nigra have frequent neurofibrillary lesions that are tau immunoreactive (Feany & Dickson, 1996). Tau pathology in glial cells is also expressed in CBD (Dickson, 1999; Feany & Dickson, 1996). Tau-positive astrocytic plaques are argyrophilic structures identified in many cases of CBD. They are thought to be characteristic of CBD although they have also been observed in PSP (Dickson, 1999).

There appears to be considerable neuropathological overlap between Pick's disease, progressive supranuclear palsy (PSP), and CBD (Dickson, 1999; Gearing et al., 1994). All three conditions may have ballooned neurons along with variable degeneration of the substantia nigra, basal ganglia, and tau-positive inclusions (Gearing et al., 1994; Schneider et al., 1994). However, the temporal cortex as

well as the hippocampus that are usually involved in Pick's disease are spared in CBD and Pick bodies, which are characteristic of Pick's disease, are rarely observed in CBD. Also in CBD astrocytic tau plaques are seen, while in PSP there are tufted astrocytes (Fig. 34.2, see colour plate section) with tau within the distal and proximal processes (Dickson, 1999). Electrophoretic pattern of tau can separate Pick's disease from CBD, PSP (and frontotemporal dementia). Only Pick's disease has two bands migrating at 64 and 55 kdalton while in the others there are 60 and 64 kdalton bands (Fig. 34.3) (Dickson, 1999; Dickson et al., 2000). Both CBD and PSP have four repeat tau (Dickson et al., 2000).

It appears to be a sporadic condition, although rare familial cases have been reported and there is a suggestion that like PSP those with the specific tau haplotypes may be at risk factor for CBD (Di Maria et al., 2000; Houlden et al., 2001). Tau sequencing in 57 neuropathologically confirmed cases failed to reveal the presence of pathogenic mutations; however, analysing tau polymorphisms in CBD cases vs. controls the frequency of H1, H1/H1 was significantly increased. CBD and PSP thus seem to share a common genetic risk factor (Houlden et al., 2001).

Differential diagnosis

The characteristic features of CBD are so distinctive that it is often possible to make a confident clinical diagnosis (Feifel et al., 1994; Litvan, 1997). However, prototypic phenotypes may have atypical (non-CBD) pathology (Boeve et al., 1999; Bhatia et al., 2000). Examples of these CBD look-alikes include vascular lesions, leukodystrophies, Pick's and Alzheimer's disease, PSP and other etiologies (Bhatia et al., 2000). On the other hand, there are also examples of atypical phenotypes, for example presenting with early dementia, who have classic CBD pathology (Bergeron et al., 1996). CBD appears to be underdiagnosed, particularly in the early stages of presentation (Wenning et al., 1998; Litvan et al., 1997b). When it presents with the motor disorder phenotype, PSP is the commonest misdiagnosis (Litvan et al., 1997b). Differentiating the two can be difficult; however, CBD patients presented with lateralized motor (e.g. parkinsonism, dystonia or myoclonus) and cognitive signs (e.g. ideomotor apraxia, aphasia or alien limb), while PSP patients often had severe postural instability at onset, symmetric parkinsonism, vertical supranuclear gaze palsy, speech and frontal lobe-type features. Litvan et al. (1997b) have suggested that limb dystonia, ideomotor apraxia, myoclonus, and asymmetric akinetic-rigid syndrome with late onset of gait or balance disturbances were the best predictors for the diagnosis of CBD.

However, as mentioned recently, it has become clear that a fair proportion of patients with pathological proven CBD may have dementia as their presenting and/or as the main feature (Grimes et al., 1999). Thus conditions like Pick's disease, Alzheimer's disease and frontotemporal dementia which can have some extrapyramidal manifestations also come into the differential (Boeve et al., 1999; Litvan et al., 1997b).

Radiographic studies may help but are not by themselves diagnostic. Cortical asymmetry with fronto-parietal atrophy on CT or MRI may suggest CBD. Compared with CBD, MRI in patients with PSP shows atrophy in the midbrain (Schrag et al., 2000). AD, on the other hand, may be differentiated from CBD by recognizing diffuse temporal and hippocampal atrophy. CBD patients show a global reduction of oxygen and glucose metabolism demonstrated by FDG positron emission tomography (PET) scans most prominent in the cerebral hemisphere contralateral to the most affected limb (Brooks, 2000). There is a corresponding reduction of CBF most evident in the frontoparietal, medial frontal, and temporal cortical regions (Okuda et al., 1999; Laureys et al., 1999; Sawle et al., 1991). Dysfunction of the nigrostriatal dopaminergic system has been demonstrated by decreased ^{18}fluorodopa (F-Dopa) uptake in the striatum with PET, and reduced postsynaptic striatal D2 receptor binding of [^{123m}I]-iodobenzamide (IBZM) on SPECT scanning. Caudate and putamen are similarly affected in CBD, whereas in PD F-Dopa uptake is selectively reduced in the putamen (Brooks, 2000). The characteristic pattern of asymmetrically reduced frontoparietal cerebral cortical metabolism and/or CBF coupled with bilateral reduction of F-Dopa uptake in the caudate and putamen provides strong supportive evidence in a patient with a clinical diagnosis of possible CBD (Brooks, 2000).

Therapy

Pharmacotherapy for CBD has generally been of limited benefit. CBD patients show limited or no beneficial response to carbidopa/levodopa and other dopaminergic agents. However, these drugs are worth trying as some improvement in clinically diagnosed CBD occurred in 24% of patients receiving carbidopa/levodopa in one report (Kompoliti et al., 1998). Dopamine agonists provide less clinical improvement than carbidopa/levodopa and are more likely to produce side effects. Clonazepam can be beneficial for treatment of the action tremor and myoclonus. Baclofen and tizanidine may improve rigidity and tremor, but they have only a modest effect. Anticholinergics have been reported to yield benefit in a

small number of patients but their benefit wanes quickly and they are poorly tolerated (Kompoliti et al., 1998). Likewise, amantadine is of little or no benefit and may produce side effects. Botulinum toxin injections may be useful in the treatment of painful focal upper limb dystonia and blepharospasm (Vanek & Jankovic, 2000).

As for PSP, other aspects of patient care, not involving pharmacotherapy, are important for these CBD patients and their carers. Physiotherapy is useful for maintenance of mobility and may help prevent contractures. Speech therapy may help optimize speech function and guard against aspiration secondary to swallowing difficulty. Unfortunately, the disease is relentlessly progressive to a state of bilateral rigid immobility, and the patients usually die from aspiration pneumonia or urinary tract infection.

Frontotemporal dementia parkinsonism-chromosome 17

Frontotemporal dementia is a condition characterized by a behavioural disorder of insidious onset and variable progression. Clinically, its early features reflect frontal lobe dysfunction characterized by personality change, worsening memory and executive functions, and stereotypical and perseverative behaviour. Parkinsonism, postural instability and supranuclear gaze palsy are other characteristics showing similarities to other taupathies like PSP and CBD. Progressive dysphasia is prominent in some kindreds and signs of anterior horn disease may also be distinctive features. The condition can be rapidly progressive with the parkinsonism being unresponsive to levodopa therapy.

Pathologically, there is degeneration of the neocortex with marked frontal and temporal lobe atrophy and involvement of the subcortical basal ganglia and brainstem nuclei which led to the use of the term pallido-ponto-nigral degeneration (PPND) to describe some of these families (Wzolek et al., 1992). In cases where family aggregation is observed, it is inherited as an autosomal dominant, age-dependent disorder. Other terms for such families had included familial Pick's disease and disinhibition–dementia–parkinsonism–amyotrophy complex (Wilhelmsen–Lynch disease). However, there was linkage to chromosome 17q21 in many of the different kindreds (Lynch et al., 1994, Wilhelmsen et al., 1994; Wijker et al., 1996; Reed et al., 1998) described above, which led to the search of primary genetic etiology of these conditions. It became clear that, in all such families there was significant tau deposition in those where there was pathology, and they were all related disorders now called frontotemporal dementia parkinsonism-17 (FTDP-17). The link with tau was further established, as the tau gene was known to be located on chromosome 17q and it is clear tau gene mutations cause FTDP-17 (Poorkaj et al., 1998). Hutton et al. (1998) described three missense mutations and three mutations in the 5′ splice site of exon 10. Subsequently, many more different mutations have been found associated with FTDP (Dumanchin et al., 1998; Spillantini et al., 1998a, b; D'Souza et al., 1999). The location of most mutations in the microtubule binding region of the tau gene (Dumanchin et al., 1998) suggests that disruption of this process is likely to be central to the neurodegenerative process. It has also confirmed that abnormal tau deposition in this disorder leads to neurodegeneration (Spillantini et al., 2000). An other possibility is a proapoptotic effect by the tau mutations (Furukawa et al., 2000). Bird et al. (1999) in a clinical pathological comparison of three families with frontotemporal dementia and with an identical mutation in the tau gene (P301L) found marked clinical and pathological variabity in these families. This suggested that unidentified environmental and/or genetic factors were producing phenotypic variability on the background of an identical mutation. PET scanning in kindreds said to have pallido-ponto-nigral degeneration type of FTDP-17 showed a reduction of Fluoro-dopa uptake, which affected both caudate and putamen (Pal et al., 2001). 11C-Raclopride scans showed normal to elevated striatal D2-receptor binding and cerebral glucose metabolism globally reduced but with maximal involvement of frontal regions (Pal et al., 1999). The fact that there was severe presynaptic dopaminergic dysfunction with intact striatal D2 receptors in these patients suggested that the dopa unresponsiveness is probably a result of pathology downstream to the striatum. The pattern of presynaptic dysfunction contrasts with that seen in idiopathic parkinsonism, where the putamen is affected more than the caudate nucleus, but is similar to that in other atypical Parkinsonian conditions such as PSP. The differential diagnosis is from other conditions presenting with dementia and parkinsonism like Pick's disease, PSP, CBD and rarely Alzheimer's. A family history is usually lacking in these disorders compared to FTDP-17. However, rarely familial CJD or prion disease can present with a phenotype of FTDP-17. Recently, a family with CJD associated with a point mutation at codon 183 of the prion protein gene presented at median age of 44 years with behavioural disturbances as the predominant presenting symptom. Eight of the nine patients manifested parkinsonian signs and dementia thus resembling FTDP-17 (Nitrini et al., 2001).

Multiple system atrophy (MSA)

Background

Multiple system atrophy (MSA) is a sporadic progressive degenerative neurological disorder characterized clinically by the combination of varying degrees of parkinsonism, autonomic dysfunction and impaired cerebellar function (Quinn, 1989). Early descriptions focused on the most conspicuous clinical manifestation, so that it was variously described as striatonigral degeneration (SND), (predominant parkinsonism with a poor response to levodopa), Shy–Drager syndrome (SDS) (parkinsonism and/or cerebellar syndrome with predominant autonomic dysfunction) and sporadic olivopontocerebellar atrophy (sOPCA) (predominant cerebellar dysfunction). Although sOPCA was described in 1900 by Dejerine and Thomas, it was not until the 1960s that other presentations of MSA were documented by Shy and Drager (1960), Adams et al. (striatonigral degeneration, 1961) and Graham and Oppenheimer (1969). The term MSA thus describes a syndrome with features overlapping with SDS, SND and sOPCA (Quinn, 1989). The discovery of the characteristic histology marked by the glial cytoplasmic inclusions by Papp and Lantos in 1989 which are present in all these three types defined MSA as a clinico-pathological entity. MSA seems to be greatly under-recognized and, in one series of 35 pathologically proven cases of MSA, 30% had an incorrect diagnosis of Parkinson's disease (PD) at the time of death (Wenning et al., 1995).

The population prevalence of MSA has been estimated at 4.4 per 100 000, thus representing 2.4% of cases of parkinsonism (Schrag et al., 1999). The disease affects both men and women usually starting in the sixth decade, the median age at onset being 54 years. Onset before age 30 years has not been described and the incidence of the disease appears to decline after peaking in the early 50s. Median survival from first symptom to death was 9.5 years in one large clinical series (Wenning et al., 1994) but only 6.2 years in a large retrospective meta-analysis of pathologically proven cases from the literature (Ben Shlomo et al., 1997).

Clinical features

The clinical features and their frequency are listed, from a report of 203 pathologically verified cases of MSA, in Table 34.6 (Wenning et al., 1997). Bradykinesia, rigidity, and postural and rest tremor as well as dysequilibrium and gait unsteadiness characterize the parkinsonism associated with MSA. Although 67% of patients have resting tremor, a

Anisocoria	8	(5–12)
Contractures	7	(4–11)

Notes:

* Some patients had more than one type of tremor.

CI, confidence interval.

Source: From Wenning et al. (2001).

classic pill rolling rest tremor typical of PD is almost never or very rarely (8%) present in MSA patients. Up to 90% of patients with the parkinsonian presentation (MSA-P) treated with levodopa do not have a sustained response over the long term although there may be some initial benefit. Also unusual levodopa-induced dyskinesia often involving the orofacial region, as a dystonic grimacing of one side of the face, occur in MSA (Wenning et al., 1994). The cerebellar disorder consists of gait ataxia commonly leading to early falls when associated with the extrapyramidal loss of postural reflexes. Limb kinetic ataxia, scanning dysarthria and cerebellar oculomotor disturbances are other features of cerebellar dysfunction. Autonomic failure in MSA is manifested predominantly as symptomatic orthostatic hypotension which is defined as a 20 mm Hg fall of systolic or 10 mm Hg fall of diastolic blood pressure. Erectile disturbance is common and may be the earliest feature of MSA in males. Other features include increased constipation, hypohidrosis or anhidrosis. Urinary bladder disturbances are also common including urinary urgency, frequency, nocturia and urge incontinence.

Mild cognitive problems occur in about 22% of cases but moderate to severe dementia rules against the diagnosis of MSA. Apart from the main features mentioned above, softer signs or 'red flags' as they are called by Quinn (1995) often indicate the diagnosis. These include REM sleep behaviour disorder, inspiratory sighs, snoring, stridor, myoclonus, contractures and the so-called disproportionate anterocollis where the head is severely flexed forward with a fairly upright stance or/and the 'Pisa' syndrome where the patient leans to one side. Diagnostic criteria for MSA (Gilman et al., 1998) are shown in Tables 34.7, 34.8 and 34.9, which have to be used together.

Differential diagnosis

The difficulty most commonly faced is to differentiate MSA from PD or PSP. Colosimo et al., in 1995 attempted to identify factors that could assist in the early differentiation of MSA-P from PD and PSP and suggested that, in patients with symmetric onset, rapid progression, lack of tremor, orthostasis and little benefit from levodopa the diagnosis of MSA should be very carefully considered (Colosimo et al., 1996). Wenning et al. (2000) posing the same question developed a model based on the emergence of features within the first five years of the illness. The four features selected included: presence of autonomic features (2), poor initial response to levodopa (2), early fluctuations (2) and initial rigidity (2). Of note, 23% of PD subjects' initial response to levodopa was poor, while 58% of MSA cases had a poor response. Dementia and psychiatric symptoms were more common in PD than MSA. Speech impairment and axial instability were almost universal in the MSA cases. Autonomic failure occurred in 84% of the MSA cases but also in 26% of the PD cases. These findings should be considered when making the diagnosis in a given patient.

Diagnostic investigations

The diagnosis of MSA is thus largely clinical, based on the history and examination. No investigation is diagnostic by itself but diagnostic tests may help in supporting the clinical impression and help with excluding the differential diagnosis. In patients with urogenital complaints, external sphincter electromyography frequently shows prolonged and polyphasic muscle potentials consistent with deinervation and reinervation of voluntary sphincter muscles. However, sphincter EMG is a sophisticated technique that is not widely available. Also, because interpretation of the results requires great caution, since it may be affected by previous traumatic childbirth, abdominal, rectal, or retropubic prostatic surgery, and also since it is often abnormal in PSP (Valldeoriola et al., 1995) it is not particularly helpful in distinguishing between MSA and PSP. Nonetheless, if correctly undertaken and interpreted, the presence of an abnormal sphincter EMG can still be a useful ancillary investigation pointing away from idiopathic PD (Palace et al., 1997; Tison et al., 2000).

CT brain scans may show infratentorial atrophy in MSA patients. In almost 90% of patients with MSA brain, MRI shows characteristic changes in the striatum, brainstem and cerebellum (Schrag et al., 1998, 2000; Schultz et al., 1999). In T_2-weighted images there is frequently a hyperintense signal seen adjacent to the posterolateral putamen which itself displays a hypointense signal due to atrophic changes. What is the morphological basis of the hyperintense band is not entirely certain but it may be due to activated microglia seen adjacent to atrophic putamenal tissue. This appearance is a useful diagnostic marker with an estimated sensitivity of 93% and specifity of 88%. Another characteristic appearance is the so called 'hot cross bun' sign of MSA (Fig. 34.4); on T_2-weighted images of the brainstem, a hyperintense signal in the shape of a cross seen in the pons (Schrag et al., 1998). MR spectroscopy has shown reduced *N*-acetylcysteine as a metabolic correlate of neuronal cell loss in MSA (Davie et al., 1995) but, as yet, this has limited diagnostic value in a given patient. Functional imaging may be a useful adjuvant in support of the diagnosis but the changes are not specific

Table 34.7. Diagnostic categories of MSA

I. Possible MSA
One criterion plus two features from separate other domains. When the criterion is parkinsonism, a poor levodopa response qualifies as one feature (hence only one additional feature is required)

II. Probable MSA
Criterion for: autonomic failure/urinary dysfunction plus poorly levodopa responsive parkinsonsim or cerebellar dysfunction

III. Definite MSA
Pathologically confirmed by the presence of a high density of glial cytoplasmic inclusions in association with a combination of degenerative changes in the nigrostriatal and olivopontocerebellar pathways

Table 34.8. Exclusion criteria for the diagnosis of MSA

I. History
Symptomatic onset under 30 years of age
Family history of a similar disorder
Systemic disease or other identifiable causes for features listed in Table 34.7
Hallucinations unrelated to medication

II. Physical examination
DSM criteria for dementia
Prominent slowing of vertical saccades or vertical supranuclear gaze palsy
Evidence of local cortical dysfunction such as aphasia, alien limb syndrome, and parietal dysfunction

III. Laboratory investigation
Metabolic, molecular genetic, and imaging evidence of an alternative cause of features listed in Table 34.3

Source: From Gilman et al. (1998).

Table 34.9. Clinical domains, features and criteria used in the diagnosis of MSA

I. Autonomic and urinary dysfunction
A. Autonomic and urinary features
   1. Orthostatic hypotension by (20 mm Hg systolic or 10 mm Hg diastolic)
   2. Urinary incontinence or incomplete bladder emptying
B. Criterion for autonomic failure or urinary dysfunction in MSA
Orthostatic falls in blood pressure by (30 mm Hg systolic or 15 mm Hg diastolic) or urinary incontinence (persistent, involuntary partial or total bladder emptying, accompanied by erectile dysfunction in men) or both

II. Parkinsonism
A. Parkinsonian features
   1. Bradykinesia (slowness of voluntary movement with progressive reduction in speed and amplitude during repetitive actions)
   2. Rigidity
   3. Postural instability (not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction)
   4. Tremor (postural, resting or both)
B. Criterion for parkinsonism in MSA
   Bradykinesia plus at least one of items 2 to 4

III. Cerebellar dysfunction
A. Cerebellar features
   1. Gait ataxia (wide based stance with steps in irregular length and direction)
   2. Ataxic dysarthria
   3. Limb ataxia
   4. Sustained gaze-evoked nystagmus
Criterion for cerebellar dysfunction in MSA
Gait ataxia plus at least one of items 2 to 4

IV. Corticospinal tract dysfunction
A. Corticospinal tract features
   1. Extensor plantar responses with hyperreflexia
B. Corticospinal tract dysfunction in MSA: no corticospinal tract features are used in defining the diagnosis of MSA

Notes:
A feature (A) is characteristic of the disease and a criterion (B) is a defining feature or composite of features required for diagnosis.

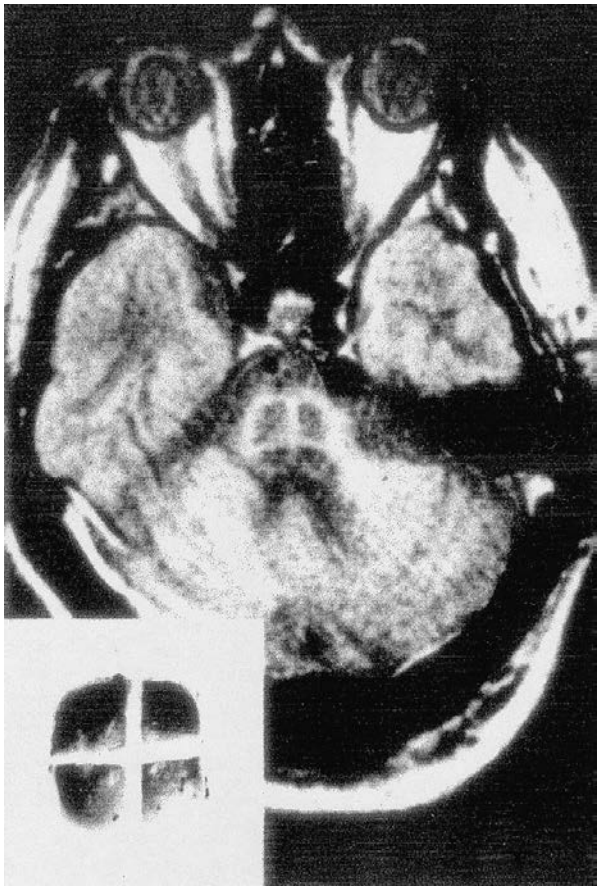

Fig. 34.4. MRI T_2-weighted image of the brainstem in a patient with multiple system atrophy showing infratentorial atrophy and typical signal change in the pons in the form of a cross resembling that seen on hotcross buns (inset) which are baked typically over Easter. (Courtesy Prof. Niall Quinn, Institute of Neurology, Queen Square, with permission from Journal of Neurology, Neurosurgery and Psychiatry.)

for MSA. IBZM SPECT shows reduced striatal dopamine D2 receptor binding in MSA and may predict l-dopa unresponsiveness with these patients turning out to have either MSA-P or PSP (Schulz et al., 1994; Schwarz et al., 1998). However, dopamine transporter ligands such as beta CIT so far are not particularly useful for the differential diagnosis (Brucke et al., 1997; Pirker et al., 2000). Fluorodopa PET scanning shows reduced uptake both in the putamen and caudate, a pattern different from PD but which may be seen with other atypical parkinsonian conditions like PSP or CBD. Increased striatal binding of both D2 and D1 receptor ligands (11C-SCH 23390) has been noted (Brooks et al., 1992; Momose et al., 1997; Shinotoh et al., 1993). On the other hand, there is decreased uptake in the putamen and caudate with opiod receptor ligand ^{11}C-diprenorphine (Burn et al., 1995). Specialized imaging can thus suggest that the patient has an atypical parkinsonian condition and not Parkinson's disease but cannot definitely differentiate between the different atypical parkinsonian disorders.

Pathology

Pathologically, there is neuronal loss and gliosis in substantia nigra, striatum (mainly posterior putamen), inferior olives, cerebellar Purkinje cells and pontine nuclei, and the intermediolateral cell columns and Onuf's nucleus of the spinal cord, to varying degrees according to clinical emphasis (Terao et al., 1994; Daniel, 1992). The current nomenclature is MSA-P, in which parkinsonism is more prominent, and MSA-C, in which cerebellar dysfunction is more prominent. The identification of a common pathology, the presence of glial cytoplasmic inclusions (GCIs) in oligodendrocytes (Papp et al., 1989), in these syndromes confirmed the suspicion that these disorders are manifestations of the same process. Glial inclusion formation which is thus characteristic of MSA has been added to the consensus diagnostic criteria of definite MSA (Gilman et al., 1998). GCIs are argyrophilic and half-moon, oval or conical in shape (Fig. 34.5, see colour plate section). They are distributed selectively in the basal ganglia, supplementary and primary motor cortex, reticular formation, bases pontis, the middle cerebellar peduncle and the cerebellar white matter (Lantos, 1998; Papp & Lantos, 1994). The origin of the GCIs is not known, but they are known to consist of filaments 20–30 nm in diameter and are antigenic for ubiquitin and tau (Lantos, 1998). The tau in MSA, however, resembles nomal adult tau (Cairns et al., 1997; Spillantini et al., 1998a, b; Takeda et al., 1997). Recently, alpha-synuclein has been observed in both neuronal and glial cytoplasmic inclusions in MSA brains (Fig. 34.3) (Wakabayashi et al., 1998; Arima et al., 1998; Tu et al., 1998). This has led to the notion that MSA belongs to the group of synucleinopathies like PD and DLB (Spillantini, 1999). What the role of alpha-synuclein is in the pathogenesis of MSA is not clear. Usually, this protein is found in the soluble fraction of neuronal cytoplasm, however in pathological states for example MSA, alpha-synuclein forms insoluble aggregates. Whether this is a primary event or a secondary epiphenomenon of MSA pathology remains to be discovered.

MSA is known to be a sporadic condition and abnormalities of alpha-synuclein gene causing autosomal dominant Parkinson's disease (A53T and A30P) have not been found in confirmed cases of MSA (Ozawa et al., 1999; Kruger et al.,

1998) suggesting that these mutations are not the pathogenic cause of MSA.

Therapy

Although MSA patients have a poor or unsustained response to levodopa almost 30% do have some benefit initially and hence it is worth trying (Wenning et al., 1994). In fact as per one report about 5% of cases still responded to levodopa after 5 years of treatment (Wenning et al., 1994). Patients with MSA also develop dyskinesias but unlike PD these are dystonic and often involve the face (Wenning et al., 1994). Dopamine agonists are generally not beneficial and poorly tolerated. Amantidine has not been found to be useful (Colosimo et al., 1996). The parkinsonian features of MSA are not helped by stereotactic surgery including pallidotomy and subthalamic nucleus stimulation and, in fact, the suspicion of MSA is a contraindication for these procedures. Management of orthostatic hypotension can be difficult. Increased salt intake, elastic stockings and head-up tilt of about 30 degrees are useful physical measures. Drugs like fludrocortisone, ephedrine and octreotide may be useful. For bladder urgency and urge incontinence, oxybutinin can be helpful. Physical therapy including use of walking aids and speech as well as occupational therapy can be very useful in these cases usually more so than drug treatments.

Dementia with Lewy bodies (DLB)

This condition which used to be called diffuse Lewy body disease has recently been defined as a clinical pathological entity (McKeith et al., 1996) in a consensus report of an international consortium. The syndrome is characterized by cognitive deficit and parkinsonism. Onset age is between 50 and 85 years. Cognitive impairment in DLB resembles that seen in Alzheimer's disease (AD), but memory loss is less marked early on; however, differentiation on clinical grounds alone may be difficult. Fluctuations in cognitive state often present as confusional states. Pathologically there are Lewy bodies, alpha-synuclein immunoreactive Lewy neuritis and neuronal loss in the neocortex and subcortical nuclei. Thus dementia with Lewy bodies is a synucleinopathy (Spillantini, 1999). Diffuse and neuritic amyloid plaques and neocortical neurofibrillary tangles can also be seen in about a quarter of cases. What is the relationship between Lewy bodies and the Alzheimer's type of change is still unresolved. However, it is clear that the clinical syndrome of dementia, psychosis and autonomic failure can occur with the presence of Lewy bodies alone (without significant Alzheimer's changes). Compared to Alzheimer's disease on formal neurospsychometry, attention and working memory appears to be disproportionately impaired in DLB, and these patients are worse off in visuospatial and constructional tasks and perception (Gnanlingham et al., 1997; Calderon et al., 2001). About 80% with DLB will develop extrapyramidal features in the course of the disease (McKeith et al., 1996). The parkinsonism in DLB may differ somewhat from PD, with symmetrical signs, uncommon resting tremor, frequent myoclonic jerks and an unpredictable response to levodopa. Recurrent visual hallucinations, depression and delusions are common, as is a REM sleep disorder which may precede the other features (Boeve et al., 1999). Autonomic dysfunction can be present leading to syncope and falls. The clinical criteria for the diagnosis of DLB have been suggested (McKeith et al., 1996). In addition to the progressive cognitive decline, two of the following are required for the diagnosis of 'probable' DLB (one for possible DLB): (i) Fluctuating course with pronounced variations in attention and alertness; (ii) recurrent, well-formed visual hallucinations and (ii) motor features of parkinsonism. Supportive features (not required for the diagnosis) include repeated falls, syncope, transient loss of consciousness, neuroleptic sensitivity, systematized delusions and hallucinations in other modalities. Clinically, differentiation from other Parkinsonian-plus syndromes can be difficult. Both MSA, if the autonomic features are present, and PSP, if there is dementia and supranuclear gaze palsy which can sometimes be seen in DLB (Lewis & Gawel, 1990), can come into the differential as can different dementing disorders including Alzheimer's and Pick's disease and corticobasal degeneration to name a few. However, as yet there are no specific antemortem biological markers for DLB and the clinical differentiation between these disorders remains a diagnostic challenge. Recent advances in structural and functional imaging can be useful but not definitive in making the diagnosis. Structural brain imaging shows generalized atrophy in DLB and in 50% or so the medial temporal lobe appears to be relatively preserved unlike Alzheimer's disease (Barber et al., 1999). Dopaminergic dysfunction in DLB can be shown by SPECT studies using dopamine transporter and this may help differentiate it from AD (Walker et al., 1999) but not from other parkinsonian syndromes.

Secondary/symptomatic parkinsonism

These are listed in Table 34.1 and some of them will be discussed in the section below.

Postencephalitic parkinsonism (PEP) and other infections

Encephalitis lethargica or postencephalitic parkinsonism (PEP) occurring after the pandemics of influenza beween 1918 and 1926 is well recognized (Calne & Lees, 1988). The parkinsonism in these cases usually occurred after a latent period, sometimes of many years. The presence of associated features such as oculogyric crises, blepharospasm and rarely, chorea, tic, and dystonia helped differentiate this disorder from PD. However, there appear to be many similarities between PEP and PSP and the Parkinson–dementia complex of Guam both clinically and pathologically (Geddes et al., 1993). Neuropathologists have great difficulty differentiating PSP and PEP on postmortem brains (Geddes et al., 1993). However, when clinical data is available, the sensitivity and reliability of diagnosis of PEP improves significantly (Litvan et al., 1996a, b). All three conditions display neurofibrillary tangles in subcortical and cortical areas and therefore a common etiology has been suspected but seems unlikely. New sporadic cases of PEP still occur rarely (Howard & Lees, 1987). However, other types of encephalitis such as Japanese B encephalitis in south east Asia, Western Equine encephalitis and others can also cause parkinsonism. Unlike encephalitis lethargica where there was a long latency period, in Japanese B and others, mentioned earlier the parkinsonism appears as the acute phase is resolving. Creutzfeldt–Jacob disease can present as a rapidly progressive parkinsonian syndrome with dementia and myoclonus associated (Brown et al., 1993). Parkinsonian signs and dementia resembling FTDP-17 have been described in a familial CJD with prion gene mutation (Nitrini et al., 2001).

Drug-induced parkinsonism

Perhaps the commonest secondary cause of parkinsonism is due to drugs. Neuroleptic drugs or dopamine receptor blockers are the usual culprit. Mostly, these drugs have been used to treat psychosis or other psychiatric disorders but it is important to remember that these drugs can be used for other indications, for example metoclopromide which is used to treat gastrointestinal symptoms and is a powerful D2 receptor blocking agent. The prevalence of neuroleptic-induced parkinsonism is estimated variably from 5% to 60% in those treated with these drugs. Female more than male, age, and possible genetic tendency are possible risk factors. Neuroleptic drug may be unmasking latent Parkinson's disease. One study by Rajput et al. (1982) showed that some patients who recovered from neuroleptic-induced parkinsonism had pathological changes of PD on postmortem.

Also, apart from neuroleptics, calcium channel blockers like cinnarazine and flunnarazine and even serotonin reuptake inhibitors (SSRIs) can induce parkinsonism.

Vascular parkinsonism

The clinical features here are fairly characteristic with gait difficulty freezing being the prominent feature as well as postural reflex impairment. Apart from that urinary and cognitive symptoms may be present. As there is no true bradykinesia involving the upper limbs some refer to this condition as a form of pseudo-parkinsonism (Quinn, 1995). There is usually no tremor and the response to levodopa is poor. Imaging will show multiple lacunes involving the basal ganglia. Rarely, a frontal tumour like a meningioma or other mass lesion may present with a similar clinical picture. Removal of the tumour can lead to resolution of the parkinsonian features, which must be caused by indirect pressure effects on the dopaminergic nigrostriatal pathway.

Toxins

A variety of toxins and heavy metals can cause parkinsonism. Exposure to manganese causing toxicity in miners without proper protective gear produces an atypical parkinsonian syndrome manifested as akinesia, postural reflex loss usually without tremor (Pal et al., 1999). There are dystonic features affecting the feet and legs and causing a peculiar gait with the patients walking on their toes, referred to as 'cock-walk'. The early phase of the intoxication may be characterized by psychic, non-motor signs. The neurological syndrome does not respond to levodopa. If these extrapyramidal findings are present, they are likely to be irreversible and even progress after termination of the exposure to manganese (Pal et al., 1999). Imaging of the brain may reveal MRI signal changes in the globus pallidus, striatum, and midbrain. Positron emission tomography reveals normal presynaptic and postsynaptic nigrostriatal dopaminergic function (Pal et al., 1999). Gliosis in the pallidal segments underlies the well-established phase of the intoxication. The mechanism of toxicity is not clear and oxidative stress is considered as a possibility.

Carbon monoxide, cyanide, MPTP, n-hexane and organophosphates (Bhatt et al., 1999) all can produce a parkinsonian syndrome. Bhatt et al. (1999) described five patients with exposure to organophosphates who acutely

developed an atypical parkinsonian syndrome poorly responsive to levodopa which reversed in four patients completely after withdrawal from exposure and one patient experienced repeated episodes of parkinsonism with inadvertent re-exposure.

Trauma

A direct link between trauma and parkinsonism has been long debated (Stern, 1991; Jankovic, 1994). However, it is widely accepted that repeated head injury for example in boxers leads to what is described as the chronic traumatic brain injury (CTBI) syndrome (Jordan, 2000). This presents with varying degrees of motor, cognitive, and/or behavioural impairments. Parkinsonism is a feature of the motor syndrome, along with gait imbalance and loss of postural reflexes. The severe form of CTBI is referred to as 'dementia pugilistica'. The diagnosis of CTBI is dependent upon documenting a progressive neurological condition that is consistent with the clinical symptomatology of CTBI attributable to brain trauma and unexplainable by an alternative pathophysiological process (Jordan, 2000). Pathologically, CTBI shares many characteristics with Alzheimer's disease (i.e. neurofibrillary triangles, diffuse amyloid plaques, acetylcholine deficiency, and/or tau immunoreactivity) (Jordan, 2000). The mainstay of treatment of CTBI is prevention; however, medications used in the treatment of Alzheimer's disease and/or parkinsonism could be tried, although no controlled trials have been done.

More contentious is the notion that head injury can cause or precipitate Parkinson's disease. Although trauma is mentioned in epidemiological studies, there is only a weak causal relationship between trauma and PD as a result of recall bias, time between injury and onset of the condition and other factors. Long-term prospective data fail to corroborate an increased incidence of PD among a cohort of head injury patients (Williams et al., 1991). There are some exceptions. Recently, Bhatt et al. (2000) reported three patients who developed a rapidly evolving post-traumatic akinetic-rigid syndrome following head injury, the clinical manifestations of which were similar to parkinson's disease, including response to levodopa. In all three cases imaging studies showing traumatic damage to the substantia nigra; however, the parkinsonian syndrome appeared only after a delay of 1–5 months after the injury. However trauma remains a rare cause of parkinsonism. Cardoso & Jankovic (1995), have proposed that even peripheral injury can result in movement disorders including parkinsonism. However, not all agree with this assumption. For example, recently there was a report of parkinsonism following electric injury to the hand (Morris et al., 1998) but this claim was refuted by Quinn and Marganore (2000), who suggested that this was a coincidence.

Hereditary/heredodegenerative disorders

These have been listed in Table 34.1 and many of these disorders are detailed elsewhere in other chapters. A few conditions will be mentioned briefly here. About 10% or 50 of patients with Huntington's disease present with an akinetic rigid syndrome rather than chorea and this is often referred to as the Westphal's variant. This presentation is more common in the juvenile onset cases who are more likely to have inherited the CAG triplet repeat disorder from their fathers.

Wilson's disease usually presents with dystonia, imbalance, dysartria, and psychiatric or cognitive disturbances. Sometimes they may manifest with parkinsonism and all juvenile onset parkinsonian patients must have serum copper and ceruloplasmin assay and a slit-lamp examination for presence of Kayser–Fleischer rings. It is important not to miss this potentially treatable disorder. Copper chelating agents like D-penicillamine can be very effective.

Neuroacanthocytosis mostly occurs as a neurological syndrome with chorea, personality change, orofacial dyskinesias or dystonia causing feeding difficulty and self-mutilation, and often absent tendon reflexes due to an axonal peripheral neuropathy (Hardie et al., 1991). Rarely, parkinsonism may be the predominant feature rather than the chorea (Peppard et al., 1990) and sometimes there can be progression from an earlier hyperkinetic disorder to a later parkinsonian state (Stevenson & Hardie, 2001). Diagnosis requires the demonstration of acanthocytes in a peripheral blood smear and serum creatine kinase is frequently elevated.

Hallervorden–Spatz syndrome usually presents in childhood predominantly as a dystonic syndrome often with associated dementia, psychiatric disturbances and retinal pigmentary changes. Rarely, onset in adolescence or adulthood may be with predominant parkinsonism. Pathologically there are spheroids seen and there is deposition of iron in the globus pallidus and zona reticulata of the substantia nigra. The diagnosis may be indicated by MRI changes due to the iron deposition producing the typical 'eye of the tiger' sign with a zone of decreased intensity (due to iron) with hyperintensity on T_2-weighted images. Treatment is only symptomatic and not usually beneficial.

Tremors

Jyh-Gong Hou and Joseph Jankovic

Parkinson's Disease Center and Movement Disorders Clinic, Department of Neurology,
Baylor College of Medicine, Houston, Texas, USA

Tremor, the most common movement disorder, is defined as a rhythmic, oscillatory movement of a body part produced by alternating or synchronous contractions of agonist and antagonist muscles. It ranges from a normal, barely noticeable, physiologic phenomenon to a severe, disabling movement disorder. Tremors can be classified according to their phenomenology, distribution, frequency, amplitude or etiology (Deuschl et al., 1998). Phenomenologically, tremors are subdivided into two major categories: rest tremors and action tremors. Rest tremors occur when the body part is fully supported against gravity and not actively contracting. In contrast, action tremors manifest during voluntary muscle contraction on an antigravity posture (postural tremor) or a goal-directed movement (kinetic tremor) (Table 35.1). This phenomenologic classification is far from ideal since there are many overlapping features among different tremors, but it remains the most widely accepted classification.

Rest tremor is present predominantly in Parkinson's disease (PD). It may also occur in other conditions such as different forms of parkinsonism, severe essential tremor (ET) and midbrain lesions. Postural tremors are typical of physiologic tremor, enhanced physiologic tremor, and ET. Task- or position-specific tremors are action tremors that occur only during specific motor activities, such as writing ('primary writing tremor') or maintaining at a certain posture. Kinetic tremors exist in cerebellar or midbrain disorders. Isometric tremor is seen during a voluntary isometric contraction, such as making a tight fist or contracting abdominal muscles. Tremors associated with dystonia, myoclonus, tardive dyskinesia, and other movement disorders may exhibit mixed phenomenology. Other disorders that produce rhythmic, but not necessarily oscillatory movements include segmental myoclonus, myorhythmia, asterixis, fasciculations, clonus, epilepsia partialis continua, shivering, head bobbing, and titubation. In this chapter we will first review the current notions of the tremor pathophysiology and then discuss the clinical features and treatment of the different types of tremors.

Pathophysiologic mechanisms of tremors

The broad clinical spectra of tremors suggest that different pathophysiologic mechanisms underlie various forms of tremors. Based on a large body of evidence from experimental and clinical physiologic studies, tremors originate from two types of mechanisms: (i) central and (ii) peripheral. The central oscillators consist of neuronal networks with auto-rhythmic properties and spontaneous bursting propagated through central nervous system (CNS) motor pathways. The peripheral components of tremors are influenced by mechanical characteristics of the affected body parts (muscles, tendons, and joints) and sensorimotor reflex mechanisms (Hallett, 1998). With the development of novel electrophysiologic and functional imaging techniques, the knowledge of mechanisms of tremors has been significantly advanced in recent years.

Intracellular recordings of certain neurons reveal autorhythmic (pacemaker) properties. Studying neurons of the inferior olive, Llinas and colleagues (Llinas, 1988) demonstrated that, as a result of low-threshold Ca^{2+} conductance, these neurons generate action potentials (low-threshold spike or LTS) at subthreshold depolarization. A fast action potential, generated by Na^{+} current into the cell body, is followed by a slow, high-threshold Ca^{2+} spike that activates prolonged (80–100 ms) K^{+}-mediated hyperpolarization. This is followed by an abrupt rebound response mediated by a low-threshold Ca^{2+} conductance large enough to generate a second Na^{+}-dependent action potential. The cycle then repeats, resulting in rhythmical bursting. Other CNS regions besides inferior olivary also

Table 35.1. Classification and differential diagnosis of tremors

Rest tremors (Typical 3 to 6 Hz)	Action tremors
Parkinson's disease	*Postural tremor*
Other parkinsonian syndromes	*Physiologic tremor*
Multiple system atrophies (SND, SDS, OPCA)	*Enhanced physiologic tremor*
Progressive supranuclear palsy	(Typical 8–12 Hz)
Cortical–basal–ganglionic degeneration	(a) Stress-induced: emotion, exercise, fatigue, anxiety, fever
Parkinsonism–dementia–ALS of Guam	(b) Endocrine: hypoglycemia, thyrotoxicosis, pheochromocytoma, adrenocorticosteroids
Diffuse Lewy body disease	(c) Drugs: beta agonists (theophylline, terbutaline, epinephrine, etc), dopaminergic drugs (levodopa, dopamine agonists), stimulants (amphetamines), psychiatric drugs (lithium, neuroleptics, tricyclics) methylxanthines (coffee, tea), valproic acid, cyclosporin, interferon
Progressive pallidal atrophy	(d) Toxins: Hg, Pb, As, Bi, Br, alcohol withdrawal
Heredodegenerative disorders	
Huntington's disease	*Essential tremor*
Wilson's disease	(Typical 4–8 Hz)
Neuroacanthocytosis	(a) Autosomal dominant
Hallervorden–Spatz disease	(b) Sporadic
Gerstmann–Strausler–Scheinker disease	
Ceroid lipofuscinosis	*Postural tremor associated with*
Secondary parkinsonism	(a) Dystonia
Toxic: MPTP, CO, Mn, methanol, cyanide, CS_2	(b) Parkinsonism
Drug-induced: dopamine receptor blocking drugs (neuroleptics, the 'rabbit syndrome'), dopamine depleting drugs (reserpine, tetrabenazine), lithium, flunarizine, cinnarizine	(c) Myoclonus
	(d) Hereditary motor–sensory neuropathy (Roussy–Levy)
	(e) Kennedy's syndrome (X-linked spino–bulbar atrophy)
Vascular: multi-infarct, Binswanger's, 'lower body parkinsonism'	*Task- or position-specific tremors*
Trauma: pugilistic encephalopathy, midbrain injury	(a) Handwriting
Tumour and paraneoplastic	(b) Orthostatic
Infectious: postencephalitic, fungal, AIDS, SSPE,	(c) Other (e.g. occupational) task-specific tremors
Creutzfeldt-Jakob disease	
Metabolic: hypoparathyroidism, mitochondrial	*Kinetic (intention, terminal) tremors*
Cytopathies, chronic hepatic degeneration	(Typical 2.5–4 Hz)
Normal pressure hydrocephalus	(a) Cerebellar disorders (cerebellar outflow): multiple sclerosis, trauma, stroke, Wilson's disease, drugs, toxins
Spasmus nutans	(b) Midbrain lesions
	Isometric tremor
	Muscular contraction during sustained exertion
Tremors with mixed phenomenology	*Miscellaneous tremors and other rhythmic movements*
A Parkinson's disease and other parkinsonian syndromes (rest and postural)	A Myoclonus: rhythmical segmental myclonus (e.g. palatal), oscillatory myoclonus, asterixis, mini-polymyoclonus
B Essential tremor (postural and kinetic) Severe essential tremor (postural and rest)	B Dystonic tremors
	C Cortical tremors
C Midbrain (rubral) tremor (postural, kinetic and rest)	D Epilepsia partialis continua
D Tardive tremor (rest, postural and kinetic)	E Nystagmus
E Myorhythmia (rest and kinetic)	F Clonus
F Neuropathic tremor (postural or rest)	G Fasciculations
G Psychogenic tremor (rest, postural or kinetic)	H Shivering
	I Shuddering attacks
	J Head bobbing (3rd ventricular cysts)
	K Aortic insufficiency with head titubation

contain neuronal networks with self-generating bursts of activities. For example, high-frequency oscillations are induced in local cortical circuits from cortex-striatum-mesencephalon organotypic cultures (Plenz & Kitai, 1996). Neurons from the subthalamic nucleus and external globus pallidus generate synchronized oscillating bursts at 0.4, 0.8 and 1.8 Hz in cell cultures.

Different types of tremors originate from different central oscillators. By studying awake decerebrate monkeys, Lamarre (1984) found two different types of rhythmic discharges from two different regions: 3 to 6 Hz spontaneous rhythmic discharges in the ventral thalamus and 7 to 12 Hz discharges in the olivo-cerebellar system. The 3 to 6 Hz thalamic neuron discharges were facilitated by a lesion in the ventromedial tegmentum of the midbrain. Such thalamic deafferentiation was thought to express parkinsonian rest tremor.

Central mechanisms

Central oscillators are thought to play a major role in the generation of rest tremor in PD, with only minimal contribution from the peripheral mechanical-reflex mechanisms. Rest tremor can be produced in a monkey treated with the neurotoxin 1-methyl-4-phenyl-1, 2, 3, 6- tetrahydropyridine (MPTP) which damages dopaminergic neurons in SN pars compacta (SNpc) (Bergman et al., 1994). The investigators demonstrated that subthalamic nucleus (STN) and globus pallidus interna (GPi), the outflow nucleus from the basal ganglia, were overactive in the monkeys with MPTP-induced parkinsonism (Blandini et al., 2000). According to a model of the basal ganglia circuitry, the degeneration of SNpc and reduced striatal dopamine (DA) result in excessive inhibition from striatal neurons that project to globus pallidus externa (GPe) and consequent disinhibition of the subthalamic nucleus (STN) via indirect pathway (Obeso et al., 2000). The nigrostriatal denervation decreases inhibition of globus pallidus interna (GPi) via the direct pathway. The combined effects of increased activity of the indirect pathway and decreased activity of the direct pathway result in increased activity of the STN and GPi. Since the outflow pathway from the GPi to the thalamus is mediated by the inhibitory neurotransmitter gamma-amino-butyric acid (GABA), the increased GPi activity in PD results in overinhibition of the thalamo-cortical-spinal pathway, clinically expressed as bradykinesia and tremor. The latter is presumably due to an inhibition of those thalamic neurons that normally suppress the oscillators in the ventral thalamus 'unmasking' the normally suppressed pacemakers. The 3 to 6 Hz spontaneous bursts from ventral thalamus are transmitted via the thalamo-cortical-spinal circuitry to the spinal motor neurons leading to synchronization of motor unit discharges, manifested as tremor. This model is used to explain the physiologic basis of surgical treatment of PD by thalamotomy, pallidotomy and deep brain stimulation (DBS).

Unlike PD, there are no morphologic or biochemical abnormalities found in autopsied brains of patients with ET (Rajput et al., 1991). Clinical physiologic studies demonstrate that the frequency of ET is not affected by mass loading to the studied limb. This indicates that central oscillators but not stretch reflex or limb mechanics play a major rolesin ET (Hallett, 1998). Tremorgenic oscillators in the CNS, possibly in those brainstem nuclei projecting to the cerebellum, are believed to be responsible for the tremor of ET. This is supported by the finding that harmaline, a monoamine oxidase inhibitor that causes tremor similar to human ET in animal models, induces rhythmic activities in the olivo-cerebellar system (Wilms et al., 1999). Metabolic PET studies (Wills et al., 1994) and functional MRI (Bucher et al., 1997), however, suggest that the tremor generators for ET reside in bilateral cerebellum and red nucleus. Cerebellar involvement in ET is also supported by subtle signs of cerebellar dysfunctions, impaired tandem gait, postural instability, kinetic tremor in advanced stage of ET, and disappearance of ipsilateral ET after cerebellar infarct (Deuschl et al., 2000). Alcohol reduces the amplitude of ET possibly by inhibiting cerebellar hyperactivity, as demonstrated by PET studies during tremor (Boecker et al., 1996). However, some argue that cerebellar dysfunction is not specific for ET since other forms of tremors such as PD, neuropathic tremor, and orthostatic tremor (see below) are associated with an increase in cerebellar blood flow on PET (Boeker & Brooks, 1998). Thalamus has been also postulated to play a role in ET either because it contains populations of pacemaker neurons or because it simply relays rhythmic discharges from the cerebello-olivary pathway to the motor cortex and then to the spinal cord, synchronizing the motor neuron pool and thus producing the oscillatory movement (Hua et al., 1998). The involvement of thalamus in ET is supported by the observation that thalamotomy and thalamic stimulation improve ET (Ondo et al., 1998).

Ever since the classic descriptions by Holmes (1917) that cerebellar injuries cause hypotonia, ataxia, and kinetic tremor, this form of tremor has been related with dysfunctions of cerebellum and its outflow pathways. Lesions in the midbrain (red nucleus) are associated with a slow, 2 to 3 Hz frequency tremor, sometimes referred to as myorhythmia. Higher brain stem (midbrain, pons) lesions lead to tremor at 5–7 Hz, and lower brainstem lesions produce a faster frequency at 8–11 Hz. Several anatomic–

physiologic studies have demonstrated that disruptions of the dentatorubrothalamic outflow pathway induce kinetic tremor. Such lesions result in error timing on contractions of the agonist and antagonist muscle groups.

Peripheral mechanisms

The limb muscle coupled with bones, tendons and joints is virtually a mechanical spring system that resonates and vibrates at its natural frequency. The resonant frequency varies from different joints and is inversely related to the mass of the body part. Walsh (1992) formulated an equation to calculate this frequency of vibration (f_0): $f_0 = 1/(2\pi)(K/J)^{1/2}$, where K is the stiffness exerted on a structure and J is the moment of inertia. Several factors may modify the resonance. Ballistocardiac effect influences the frequency and amplitude of peripherally generated tremors. Loading the extremity with weight mass reduces the resonant frequency. This oscillation of the muscle–joint coupling is the major contributor to physiologic tremor with typical frequency at 8 to 12 Hz. Muscle spindle primary afferent ending receptors are very sensitive, particularly in contracting muscles with α-γ co-activation, sending signals to the spinal cord and eliciting a stretch reflex. With appropriate timing, the stretch reflex produces synchronization of spinal motor neurons and generation of muscle contraction. The contraction induces another stretch reflex, and the cycle repeats itself, resulting in an oscillatory movement (McAuley & Marsden, 2000). The stretch reflex–muscle spindle feedback is controlled and modified by central oscillators and other supraspinal influences. The presence of stretch reflex loop is essential for enhanced physiologic tremor; tremors of PD and ET are much less dependent on the peripheral stretch reflex.

Clinical features and treatments of tremors

Rest tremors

Rest tremor is an oscillatory movement of a body part when that part is supported against gravity. By definition, rest tremor disappears or diminishes during voluntary muscle contraction or movement. It is difficult, however, to apply this definition to certain body parts such as lips, chin and face that are often involved in rest tremor. It should also be emphasized that all tremors, including rest tremors, disappear when the body part is at a complete rest state or during sleep and hand rest tremor is typically exacerbated when a patient with PD walks. The classical clinical picture of PD rest tremor is an asymmetric onset of 3 to 6 Hz supinating-pronating (pill-rolling) hand oscillation. Other body parts frequently involved by PD tremor include individual fingers, lips, jaw, tongue, legs and feet. Head tremor, which is typical for ET, however, is rarely seen in PD. About 70% of PD patients present with rest tremor and nearly all patients with PD manifest tremor some time during the course of their illness (Hughes et al., 1993). Patients with tremor-dominant form of PD generally have a younger age at onset, relative sparing of cognition, slower progression and more favourable prognosis than PD patients with postural instability and gait difficulty, or PIGD (Jankovic et al., 1990). The amplitude varies between different patients and may vary from minute to minute in the same patient. When PD patients hold their arms outstretched horizontally in front of their body, the rest tremor usually disappears. In some patients the tremor reappears after a latency of several seconds (up to a minute). Although this tremor occurs during maintenance of a posture, this 're-emergent tremor' shares the same mechanisms with rest tremor because its amplitude and frequency are both similar to those of rest tremor (Jankovic et al., 1999).

While PD is the most common cause, there are many other etiologies including secondary parkinsonism and parkinsonism-plus syndromes presenting with rest tremor (Table 35.1). Advanced ET can also cause rest tremor. Although some authors argued that the coexistence of PD and ET simply represents a chance of occurrence of two common diseases (Pahwa & Koller, 1993), there is a growing body of evidence that the presence of ET is a risk factor for later development of PD (Jankovic, 2000). Several autosomal dominant families have been described in which some members have ET and others have PD (Jankovic et al., 1995; Findley, 2000).

Treatment

The discussion of treatment of rest tremors is beyond the intended scope of this chapter, but it is essentially the same as treatment of PD (Jankovic & Marsden, 1998). For a summary of treatment options on different types of tremors, please refer to Table 35.2. The choices of medical treatment of PD rest tremor include dopamine replacement with levodopa, dopamine receptor agonists, amantadine, and anticholinergic agents. Clozapine, an atypical neuroleptic (Ceravolo et al., 1999) and mirtazapine, an antidepressant with both noradrenergic and serotoninergic properties (Pact & Giduz, 1999) have been also found effective. Local injections of botulinum toxin (BTX) into the affected muscles reduce the tremor amplitude (Jankovic et al., 1996). The antitremor action of BTX is not well understood, but has been attributed to the action of BTX on the extrafusal and intrafusal motor fibres, reducing

Table 35.2. Medical treatment of tremor variants

Variant	Treatment		
Rest tremor	T, L, PH	BTX	DBS
Postural hand/arm tremor	P, PRI, A, PH	BTX	DBS
Head tremor	C, PRI, P	BTX	
Voice tremor	P	BTX	
Facial/tongue tremor	P, PRI, L	BTX	
Task-specific tremor	T, P, PRI	BTX	
Orthostatic tremor	G, C, PRI, PH, L		
Kinetic hand/arm tremor	C, P, PRI, BU, PH	BTX	DBS

Notes:
A = Alprazolam.
BTX = Botulinum toxin.
BU = Buspirone.
C = Clonazepam.
DBS = Deep brain stimulation.
G = Gabapentin.
L = Levodopa.
P = Propranolol.
PH = Phenobarbital.
PRI = Primidone.
T = Trihexyphenidyl.

spindle afferent input to the spinal cord. This restores presynaptic inhibition between antagonist muscles and reduces tremor (Modugno et al., 1998). While BTX injections may be quite effective in the treatment of parkinsonian rest tremor, it is particularly useful in ET and in dystonic tremor (see below).

For drug-resistant and disabling tremors, several surgical treatment options include thalamotomy, pallidotomy and high frequency deep brain stimulation (DBS) of the STN or GPi (Jankovic, 1999; Lang, 2000). Ventral lateral thalamotomy involving the nucleus ventralis intermedius (VIM) used to be the most popular choice of surgical options, but now VIM DBS (in ET), GPi DBS and STN DBS (in PD) are far more common. Patients can turn the pulse generator (stimulator) on or off by applying a magnet over the area where the stimulator is subcutaneously implanted, usually in the upper chest. These procedures have the advantage over the ablative procedures because the stimulating parameters can be customized to each patient and they are safer and more effective than the traditional thalamotomy (Schuurman et al., 2000). While VIM DBS reduces contralateral tremor in about 46–92% of patients (Ondo et al., 1998; Koller et al., 1999), GPi or STN DBS offers the possibility of improvement on tremor and other parkinsonian features as well, including levodopa-induced motor complications (Krack et al., 1998; Krauss et al., 2001). Rare complications of DBS are hemorrhage, seizures, contralateral hemiparesis, dysequilibrium, and infection due to foreign bodies (stimulating electrode, the pulse generator and their connections).

Action tremors

Physiologic tremor

Physiologic tremor is universally present in all people, but it is not considered pathological, until it interferes with social or occupational (fine motor) activities. Many factors may exacerbate the amplitude of physiologic tremor, including endogenous factors such as emotional stress, anxiety, fatigue, hypoglycemia, endocrine effects (e.g. hyperthyroidism, hyperadrenergic states in response to hypoglycemia); exogenous CNS stimulants such as caffeine, amphetamines, beta-agonists, lithium, neuroleptics, anticonvulsants, and tricyclic antidepressants (Diederich & Goetz, 1998). Delirium tremens, the tremor induced by acute alcohol withdrawal, is a variant of enhanced physiological tremor. Enhanced physiologic tremor is usually reversible after causative agents are removed. Chronic use of certain drugs, such as the neuroleptics, however, can produce persistent parkinsonian or tardive tremor. Tardive tremor is manifested by a mixture of rest, postural and kinetic tremor with a frequency of 3 to 5 Hz (Stacy & Jankovic, 1992). In contrast to parkinsonian tremor, tardive tremor improves rather than worsens with anti-dopaminergic agents such as tetrabenazine, a dopamine depleting and dopamine receptor blocking drug.

Several studies have demonstrated an overlap in physiologic characteristics between physiologic and isometric tremors. Isometric tremors usually do not require treatment with the exception of orthostatic tremor (Deuschl et al., 1998) (see below).

Treatment

In most cases, enhanced physiologic tremors are reversible and the treatment strategies should focus on elimination of the triggering factors such as anxiety, caffeine, drugs (e.g. lithium), hyperthyroidism, pheochromocytoma, and hypoglycemia. If tremor is embarrassing or troublesome, beta adrenergic blockers (propranolol or nadolol) and benzodiazepines may be useful (Wasielewski et al., 1998).

Essential tremor

ET is characterized by postural or kinetic tremor with frequency usually at 4 to 8 Hz, but sometimes may be as high as 12 Hz (Jankovic, 2000b). Head tremor has a slower frequency at 2 to 8 Hz. The amplitude and frequency of ET are less dependent on position of the limb or mass loading, different from those of physiologic tremor. Although the term 'benign essential tremor' is still used in the literature,

it is important to recognize that ET can be very disabling. The tremor may interfere with eating, speaking, writing, daily activities and cause social embarrassment leading to social withdrawal.

Various epidemiologic studies show prevalence rates ranging from 0.4 to 5.6%, depending on different methodologies, diagnostic criteria and study populations (Louis et al., 1998). The age at onset appears to be a bimodal distribution, with peaks at the second and sixth decades (Lou & Jankovic, 1991). Since there are no physiologic, genetic or biological markers for ET, the diagnosis is based on clinical criteria. According to one set of criteria, definite ET is a bilateral postural tremor, with or without kinetic component, involving hands or forearms persistent for more than 5 years (Jankovic, 2000b). The tremor may be asymmetrical and other body parts may be affected. Other causes of tremor must be excluded. Probable ET includes the same criteria as of definite ET, but tremor may be confined to one body part and the duration is greater than 3 years. Primary orthostatic tremor, isolated voice, tongue, chin tremors, position- and task-specific tremors must be excluded. There are two types of possible ET. Criteria for type 1 possible ET are the same as of probable ET, but patients may exhibit other neurologic disorders (parkinsonism, dystonia, myoclonus, peripheral neuropathy, restless legs syndrome, or mild extrapyramidal signs). Type 2 possible ET consists of a monosymptomatic and isolated tremor of uncertain relationship to ET. It includes position- and task-specific tremors such as occupational tremors (primary writing tremors), primary orthostatic tremor, isolated voice, chin, tongue, leg tremor and unilateral postural hand tremor. Core and secondary criteria were proposed to facilitate a practical approach to the diagnosis of ET (Elble, 2000). Core criteria include bilateral action tremor of the hands and forearms (but not rest tremor), absence of other neurologic signs (except for the Froment's sign), and isolated head tremor without signs of dystonia. Secondary criteria include long duration (>3 years), positive family history, and beneficial response to alcohol. There are diagnostic red flags which indicate diagnoses other than ET, such as unilateral tremor, leg tremor, rigidity, bradykinesia, rest tremor, gait disturbance, focal tremor, isolated head tremor with abnormal posture (head tilt or turning), sudden or rapid onset, and on drug treatment that may cause or exacerbate tremor.

Upper extremities are involved most frequently in ET, typically manifesting a 4 to 8 Hz symmetrical hand tremor. Similar to enhanced physiologic tremor, emotion, stress and fatigue make ET worse. Head is another body part frequently affected, either in a form of anterior–posterior oscillation (yes–yes nodding) or lateral, side-to-side (no–no shaking) oscillation at 2–8 Hz. Body parts also affected by ET include larynx (voice), jaw, lips, face and tongue. The lower extremities are rarely involved (Lou & Jankovic, 1991; Elble, 2000). ET often develops insidiously and progresses slowly, becoming more severe over years. The prevalence increases with age, affecting 5% to 14% of people above 65 years old (Brin & Koller, 1998). Older patients tend to have lower frequency (4–12 Hz) than younger patients (8–12 Hz) (Elble, 2000). Because the frequency of physiologic tremor is similar to ET, it may be difficult to differentiate mild ET from enhanced physiologic tremor. The way to differentiate is that mass loading of the limb decreases the frequency of physiologic tremor, but not ET.

ET is a genetic disorder inherited as an autosomal dominant pattern. The frequency of positive family history among first-degree relatives ranges from 17% to 100%. These wide variations in reported family histories are mostly due to different methodologies used to ascertain ET among family members and different characteristics of study populations (Findley, 2000). Based on studies of large ET families, Higgins et al. (1998) found a marker on chromosome 2p22–p25, termed *ETM*. The ET gene locus, *FET1*, on chromosome 3q13 (Gulcher et al., 1997), was mapped in other families with ET. Although classic ET is a monosymptomatic disorder without other neurologic signs and symptoms, in some patients and families ET is associated with parkinsonism, dystonia and other neurologic disorders. In one such family, the disorders (ET, parkinsonism, or both) were linked to chromosome 4p14–16.3 (Farrer et al., 1999). It is anticipated that there will be more gene loci and mutations identified in tremor families which will eventually lead to a genetic classification of ET.

Task- or position-specific tremors represent either variants (forme fruste) of ET or dystonia (Jankovic, 2000). The patients experience tremor when performing fine-coordinated motor activities, such as writing, playing a musical instrument, golfing or holding objects in certain positions (Bain et al., 1995). The pathophysiology of these tremors is not clear. One possibility is an abnormal CNS response to muscle spindle input from forearm muscles. Isolated voice, tongue and chin tremors also have features that seem to overlap with focal dystonia (Deuschl et al., 2000). Although many patients with dystonia have a postural tremor that is phenomenologically identical to ET, this tremor does not appear to be associated with the known GAG deletion in the *DYT1* gene (Dürr et al., 1993). Orthostatic tremor, another position-specific tremor, is characterized by a rapid (14–16 Hz) frequency tremor present in the legs while standing or during isometric contraction of trunk muscles. It is associated with 'vibration' in the legs, calf cramps and a feeling of unsteadiness after

standing for a few minutes (Heilman, 1984). Jaw and other cranial muscles may occasionally be involved. Electrophysiologic recordings from the legs show bilateral coherence supporting the notion that this type of tremor is generated from a single central oscillator (McAuley et al., 2000).

Treatment

The choice of treatment for ET largely depends on the severity of the tremor and how it interferes with patient's daily activities. The antitremor medications decrease tremor amplitude but not frequency. In addition to medical treatment, factors affecting tremor such as drugs, alcohol, caffeine, anxiety, or temperature should be eliminated or minimized whenever possible. The main therapeutic options for ET include beta-adrenergic blockers and primidone (Koller et al., 2000). The beta-adrenergic blockers, especially propranolol, have been considered the treatment choice since the early 1970s. The other beta-blockers (metoprolol, nadolol and timolol) seem to be less effective than propranolol. The pharmacological mechanism of beta-blockers in the treatment of ET is not clear. Since there is no direct correlation between lipid solubility (and consequent ability to cross the blood brain barrier) and their efficacy, peripheral mechanisms seem to play a key role in reducing tremor (Guan & Peroutka, 1990). Beta-blockers are generally well tolerated, but may cause excessive daytime drowsiness, fatigue, erectile dysfunction and depression. They should not be prescribed in patients with diabetes, asthma or congestive heart failure. The efficacy of primidone in reducing tremor amplitude is about 40–50%, similar to that of propranolol. The drug is metabolized into phenylethylmalonamide (PEMA) and phenobarbital. Neither PEMA nor phenobarbital seem to have an independent antitremor activity, suggesting that the parent compound is the active drug (Sasso et al., 1991). The most common side effect is excessive daytime drowsiness, and up to 25% of patients, particularly the elderly patients, experience an acute reaction that is manifested by nausea, vomiting, sedation, confusion and ataxia. This idiosyncratic reaction may be prevented by initiating the drug with a very low dose (e.g. 25 mg at bedtime) followed by a slow and gradual titration over several weeks (up to 750 mg per day in 3 divided doses).

Many patients with ET report transient improvement of tremor after alcohol ingestion. Some use alcohol (often not judiciously) at social events to ameliorate tremor (Koller et al., 2000). Benzodiazepines, especially clonazepam, are also used to reduce ET. Other drugs with antitremor effect include the antiepileptic drugs gabapentin and topiramate (Ondo et al., 2000). Orthostatic tremor responds well to clonazepam, gabapentin and perhaps levodopa (Wills et al., 1999). BTX injections into the muscles involved in the generation of tremor have been found to be beneficial (Jankovic et al., 1996). BTX is particularly useful in controlling head tremor, which usually does not respond well to other medical therapies. Vocal and palatal tremors are also effectively treated with BTX injections. Kaji et al. (1995) showed that local injection of lidocaine into the target muscle produced peripheral deafferentiation and transient reduction in the amplitude of postural tremor (as well as focal dystonia, such as writer's cramp).

Neurosurgical intervention should be reserved only for those patients with severe ET who are disabled or functionally impaired despite optimal medical therapies. While thalamotomy was the surgical treatment of choice in the past, in recent decades DBS of the ventral intermediate (VIM) nucleus of the thalamus has become the surgical treatment of choice because it is safer and more effective (Schuurman et al., 2000). Besides VIM, chronic cortical stimulation may improve contralateral action tremor, but this is not a practical treatment modality (Nguyen et al., 1998). Subthalamic nucleus is currently being investigated as a target for refractory proximal ET (Kitagawa et al., 2000).

Kinetic tremor

Kinetic tremor, formerly named 'intention' tremor, is a form of action tremor in which the oscillation occurs when voluntary contraction of muscles produces a goal-directed movement (e.g. finger-to-nose). This tremor has been referred as 'midbrain' or 'rubral' tremor although CNS areas, especially thalamic lesions, may present a similar clinical picture (Vidailhet et al., 1998). Diseases affecting the cerebellum or the cerebellar outflow pathways cause not only kinetic tremor, but also ataxia, dysmetria and other cerebellar signs (Deuschl et al., 2000). 'Titubation', which is a slow rhythmic oscillation of whole body or head with increasing amplitude on movement, is associated with cerebellar dysfunction (San Pedro et al., 1998). Kinetic tremor is often unilateral, present on the side ipsilateral to the cerebellar lesion, with a slow frequency raging between 2 and 5 Hz. Amplitude is medium to coarse, and is more robust when approaching the target (terminal tremor). Disorders commonly causing kinetic tremor include multiple sclerosis (MS), Friedreich's ataxia, stroke, trauma, and Wilson's disease. Alcohol abuse and toxicity due to various anticonvulsants (phenytoin and valproic acid) may also induce kinetic tremor.

Myorhythmia is a special type of tremor that is characterized by a slow 1 to 3 Hz frequency, continuous or intermittent rhythmic movement existing at rest and persisting during activity. It has irregular presentations mixed with

rest, kinetic and postural tremors and is not as rhythmic as other tremors (Deuschl et al., 1998). It is often accompanied by ataxia and ipsilateral 3rd nerve palsy. This slow tremor arises from lesions in the red nucleus, midbrain, cerebellum or thalamus with secondary interruption of various pathways. It is also associated with palatal myoclonus due to an interruption of the dentato-rubro-olivary pathway (Yanagisawa et al., 1999). Etiologies of myorhythmia include cerebellar degeneration, ischemic or hemorrhagic lesions, Whipple's disease and Wilson's disease. Autopsy and PET studies suggest that the combination of rest and kinetic tremors is typically associated with disruptions in both cerebello-thalamic and nigrostriatal systems (Remy et al., 1995).

Treatment

Before selecting a symptomatic therapy for the kinetic tremor, it is important to thoroughly evaluate the patient in search of an etiology-specific treatment. Of all different tremors, kinetic tremor is the most resistant to symptomatic pharmacologic therapy. No drug has been found to provide a reliable benefit (Wasielewski et al., 1998). Clonazepam, which works on both serotoninergic and GABA systems, is used frequently for symptomatic relief. Buspirone, a 5-HT1A agonist and odansetron, a 5-HT3 antagonist were reported effective in improving cerebellar tremor (Lou et al., 1995; Rice et al., 1997). Tetrahydrocannabinol and cannabinoids may improve spasticity and tremor in patients with multiple sclerosis (Baker et al., 2000). Surgical treatment is less effective in kinetic tremor, but for some incapacitating kinetic tremors, surgical intervention, such as VIM DBS, may be the only option (Schulder et al., 1999; Taha et al., 1999).

Miscellaneous tremors

Tremors associated with peripheral neuropathy

Tremors often accompany peripheral neuropathies, particularly the dysgammaglobulinemic neuropathies, and hereditary motor–sensory neuropathies (Cardoso & Jankovic, 1993). Since the amplitude of tremor in patients with hereditary motor–sensory neuropathy does not directly correlate with the severity of motor weakness, sensory loss, or slowing of nerve conduction, the mechanism of the tremor may be pathophysiologically independent of the neuropathy. Peripheral injuries induce tremor, whether or not associated with reflex sympathetic dystrophy or the complex regional pain syndrome (Cardoso & Jankovic, 1995). There is growing evidence of central reorganization in response to altered peripheral input that may underlie peripherally induced tremors (Jankovic, 2001).

Psychogenic tremor

Psychogenic tremor sometimes can be difficult to differentiate from neurologic ('organic') tremor, but several series have provided useful diagnostic criteria (Deuschl et al., 1998). These include: (i) sudden onset, (ii) spontaneous remission, (iii) various combinations of different types of tremors, (iv) changing amplitude and frequency, (v) tremor increases with attention and decreases with distraction, (vi) poor response to antitremor drugs, (vii) selective disability, (viii) entrainment of the tremor with voluntary repetitive movement, (ix) absent finger tremor, and (x) remission with psychotherapy. Many patients with psychogenic tremor not only have abrupt onset but also present with maximal disability at onset (Kim et al., 1999). Some additional or associated features may help diagnose psychogenic tremor, such as false weakness, false sensory symptoms, multiple somatizations, self-inflicted injuries, bizarre movements or pseudoseizures, and subtle or obvious psychiatric illness. The management of patients with psychogenic tremor is often challenging and should include careful exploration of psychological as well as physical factors that may be contributing to the tremor. By helping the patient provide insight into the psychodynamics of the tremor, the physician may successfully treat not only the tremor, but also the underlying psychological disturbance. Antidepressant medications often play an ancillary role. Prognosis varies from poor to complete remission, largely depending on the insight of the patient and the family.

Myoclonus

Peter Brown

Sobell Department of Motor Neuroscience, Institute of Neurology and National Hospital for Neurology and Neurosurgery, London, UK

Myoclonus is defined as shock-like involuntary movements. Most often these are due to brief bursts of muscle activity, resulting in positive myoclonus. Jerks, however, may also result from sudden short inhibitions of ongoing tonic muscle activity, termed negative myoclonus or asterixis. Myoclonus may be physiological, such as hiccups, or due to a variety of hereditary or acquired conditions. In particular, it may be seen in primary generalized epilepsy, but as this syndrome is dominated by epilepsy rather than myoclonus, it will not be considered further here.

Clinical overview of physiologically based classification

Although etiological classifications have not proven very useful in predicting the response to drugs, electrophysiological investigations have been able to distinguish several different pathophysiological mechanisms with therapeutic implications. To a large degree, the pathophysiological type of myoclonus can be suspected on clinical grounds. The most useful clinical distinction is between generalized, multifocal and focal/segmental jerks. Generalized myoclonus involves the majority of the body in a synchronous jerk. It may spare the face and be predominantly axial, as in propriospinal myoclonus, or include the face, as in brainstem myoclonus. The latter may only consist of reflex jerks, as in exaggerated startle/hyperekplexia, or may also involve prominent spontaneous jerks as in brainstem reticular reflex myoclonus. A useful confirmatory sign of a brainstem origin is the presence of jerks in response to auditory stimulation, particularly unexpected sounds. Multifocal myoclonus involves different parts of the body at different times. There may also be the occasional generalized jerk, but the clinical picture is dominated by multifocal jerks. Such patients may be divided into those in whom the distal limbs are especially involved, and are likely to have cortical myoclonus, and those in whom the jerks are most noticeable proximally, particularly round the shoulders. These are likely to have essential myoclonus. Helpful confirmatory signs of cortical and essential myoclonus are an exacerbation of jerking upon voluntary action and the presence of dystonic posturing, respectively. Focal/segmental jerks are the most obscure as they may arise at virtually any level of the nervous system, including the spinal cord.

Clinical suspicion of particular pathophysiological types of myoclonus can be supported by simple investigation. Epileptic EEG abnormalities are suggestive of a cortical origin, as are giant cortical SEPs following median or tibial nerve stimulation. EMG studies are useful in focal myoclonus as signs of segmental denervation often accompany spinal segmental myoclonus. Similarly, imaging of brain and spinal cord can be very helpful in demonstrating the structural lesion that often accompanies generalized or focal myoclonus.

Cortical myoclonus

Pathophysiology

Cortical myoclonus is the result of an abnormal discharge in the sensorimotor cortex, and rapidly conducting corticospinal pathways. It may consist of reflex myoclonus, spontaneous jerks or myoclonus elicited by voluntary action, and tends to be focal or multifocal. It is characterized by brief bursts of electromyographic activity (EMG), usually less than 70 ms in duration. EMG bursts are preceded by pathological enlargement of the cortical components of the sensory evoked potential in reflex jerks, or a time-locked cortical correlate in the electroencephalographic activity (EEG) in action or spontaneous myoclonus

(Fig. 36.1). In each case the relevant EEG wave precedes the EMG burst by an interval more or less appropriate for conduction in the fastest corticospinal pathways. For the intrinsic muscles of the hand, this interval is about 20 ms. Although the EEG waves prior to the jerks are often several tens of microvolts in amplitude, averaging techniques, such as backaveraging, are usually necessary to identify their morphology and distribution.

Some patients may also have cortical negative myoclonus, either action induced or reflex. In this a brief silencing of muscle activity occurs preceded by a cortical wave. Sudden lapses in posture result, particularly noticeable during gait, and tend to be more resistant to drug treatment than positive reflex or action myoclonus. In addition, in some patients with multifocal myoclonus, myoclonic activity spreads within and between the sensorimotor cortices, so that bilateral or generalized jerks also occur. Spread is somatotopic, and cranial nerve innervated muscles are activated rostro-caudally, unlike the caudo-rostral activation seen in hyperekplexia.

The cortical inhibitory processes, which would normally keep spread in check, are deficient in cortical myoclonus. This can be shown in vivo using the technique of transcutaneous stimulation of the motor cortex (Brown et al., 1996). A conditioning magnetic shock to either the ipsilateral or contralateral motor cortex normally inhibits the response to a succeeding test shock, demonstrating the presence of both cortico-cortical and transcallosal inhibition in healthy subjects. Both types of inhibition are severely impaired in patients with cortical myoclonus and evidence of cortical spread of myoclonic activity.

Etiology and clinical features

Cortical myoclonus is most marked in the distal limb, and in focal forms is usually confined to this site. If widespread, myoclonus is multifocal, with or without additional bilateral or generalized jerks. The latter are associated with more marked disability. Reflex jerks may be elicited by touch and tap, or visual stimuli. Marked sensitivity to photic stimulation suggests Unverricht–Lundborg disease. Sensitivity to auditory stimuli suggests a startle syndrome, although some patients may have a combination of cortical myoclonus and pathological startle. Multifocal jerks occurring with voluntary action are very suggestive of a cortical origin for the myoclonus. As well as involving arm function, jerks may affect speech and gait. Extraocular muscles are spared.

Focal cortical myoclonus is usually due to vascular or neoplastic lesions of the sensorimotor cortex. When spontaneous jerks are frequent, focal cortical myoclonus is

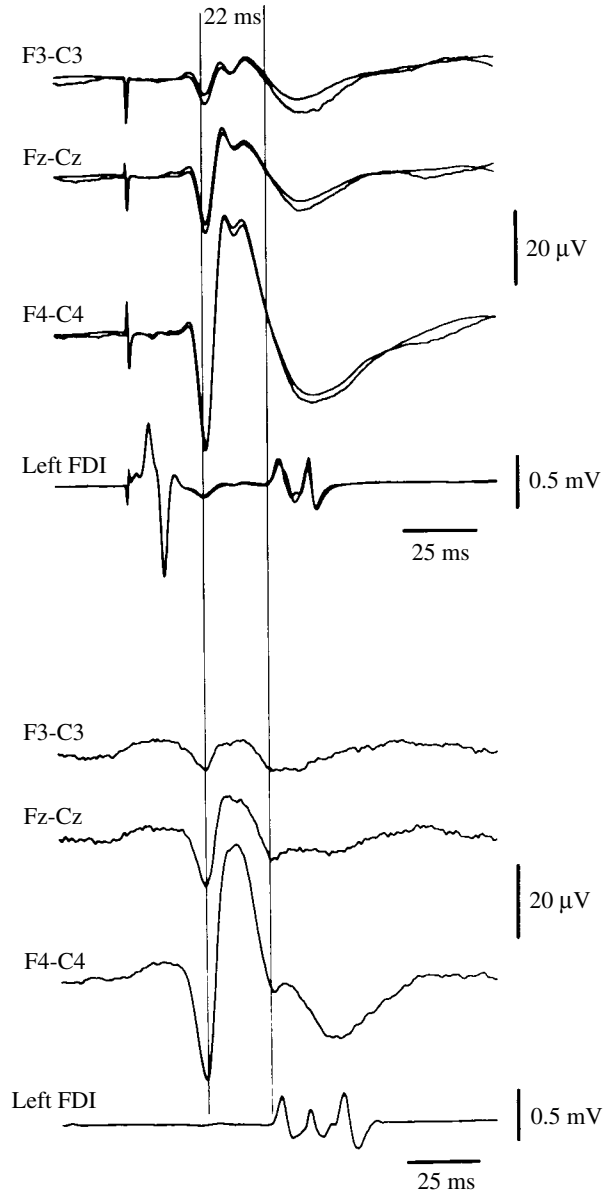

Fig. 36.1. (*a*) Cortical sensory evoked potentials to electrical stimulation of the left ulnar nerve at the wrist. (*b*) Backaveraged EEG activity preceding voluntary action jerks in a patient with coeliac disease and cortical myoclonus. A giant EEG wave is recorded, largest contralateral to the stimulated or moved hand. The positive (downgoing) component of the wave precedes the reflex response (*a*) or action jerk (*b*) by 22 ms, an interval appropriate for conduction from motor cortex to hand via the fastest pyramidal pathways. (Reprinted from Bhatia et al., 1995, with permission.)

often called epilepsia partialis continua. Multifocal myoclonus may occur in posthypoxic encephalopathy, as first described by Lance and Adams (1963), or as part of a progressive illness, as in the syndromes of progressive myoclonic ataxia and progressive myoclonic epilepsy. Causes with a genetic basis usually have an onset before the age of 20. Progressive myoclonic ataxia describes those patients with prominent myoclonus and ataxia, but little in the way of epilepsy or progressive dementia. The term encompasses the Ramsay Hunt syndrome. Progressive myoclonic ataxia is most commonly due to Unverricht–Lundborg disease, mitochondrial encephalopathy or coeliac related encephalopathy. The latter usually comes on in middle-age or later and enteric coeliac disease may be asymptomatic (Bhatia et al., 1995). The diagnosis is confirmed by small bowel biopsy. Unverricht-Lundborg disease is due to mutations in the gene on chromosome 21q that codes for cystatin B, an inhibitor of cysteine protease. The mitochondrial encephalopathy associated with myoclonus is usually the MERRF syndrome of myoclonus, epilepsy and ragged red fibres. This is typically due to point mutations in the mitochondrial gene that codes for tRNA (Lys). An elevated CSF lactate level is suggestive of the diagnosis, which can often be confirmed by mitochondrial DNA analysis of blood.

Progressive myoclonic epilepsy describes those patients with myoclonus, severe epilepsy and relentless cognitive decline. The commonest causes are sialidosis, Lafora's disease, lipidosis, neuronal ceroid lipofuscinosis, dentato-rubro-pallido-luysian atrophy and Huntington's disease, although mitochondrial encephalopathy can also be responsible. Dentato-rubro-pallido-luysian atrophy and Huntington's disease are due to CAG triplet repeat expansions on chromosome 12p and 4, respectively. Sialidosis is due to mutations in the sialidase gene and confirmatory tests include assays for urine oligosaccharides and fibroblast α-neuraminidase. Juvenile neuronal ceroid lipofuscinosis is caused by mutations in the CLN3 gene, a gene of unknown function that encodes a 438-amino acid protein of possible mitochondrial location. The remaining forms of neuronal ceroid lipofuscinosis and Lafora disease have been mapped by linkage analysis but the corresponding gene defects are still unknown. Lafora disease is an autosomal recessive storage disease characterized by polyglucosan acid-Schiff positive inclusions (Lafora bodies) in cells of brain, liver, muscle and skin, in sweat gland ducts.

Cortical myoclonus may also be a relatively minor aspect of several degenerative diseases, where the clinical picture is dominated by other features. Examples are multiple system atrophy and Alzheimer's disease. Multifocal myoclonus, particularly of the hands, may be present in corticobasal degeneration, but it seems likely that the myoclonus in this condition is subserved by different pathways to classical cortical myoclonus. In particular, cortical sensory evoked potentials are not giant, and the latency of reflex responses is very short, raising the possibility of a direct relay of somatosensory afferent input to the motor cortex without involvement of the sensory cortex. Patients with Creutzfeldt–Jacob disease usually have myoclonus, which at least in some cases has a cortical origin.

Pharmacology and treatment

Drug treatment is primarily aimed at bolstering deficient inhibitory processes. In particular, a reduction of 25 to 50% of GABA levels has been reported in the cerebrospinal fluid of patients with posthypoxic myoclonus and progressive myoclonic epilepsy, and GABAergic drugs form the cornerstone of treatment. Of these sodium valproate is the most effective, and increases cortical GABA levels as well as potentiating GABA postsynaptic inhibitory activity. The drug is introduced slowly, with most patients needing doses of 1200 to 2000 mg/day. Transient gastrointestinal upset may occur during initial treatment, usually with nausea and vomiting, but sometimes with abdominal pain and diarrhea. Hair loss, tremor, hepatotoxicity and drowsiness may also occur.

Benzodiazepines and barbiturates facilitate GABAergic transmission by effects on the GABA receptor–ionophore complex. Clonazepam is the most useful antimyoclonic agent. Large doses of clonazepam are often necessary (as much as 15 mg/day). Undue drowsiness and ataxia are the only major side effects and can be largely overcome by gradually increasing the dosage. Abrupt reductions and withdrawls can result in a marked deterioration in myoclonus and withdrawal fits. Tolerance may develop over a period of several months in some patients. Primidone and phenobarbital are occasionally useful.

Piracetam is structurally similar to GABA, but it does not elicit specific GABAergic effects nor modify GABA levels in the brain, and its mechanism of action remains unclear. The drug's effectiveness is largely limited to cortical myoclonus, regardless of aetiology. This suggests that, where possible, electrophysiological assessment of the physiological type of myoclonus should be undertaken before considering treatment with the drug. Piracetam is well tolerated and does not alter blood levels of other anticonvulsants. In particular, it is non-sedating. It is usually prescribed as add-on therapy, but can be effective when given alone. Therapeutic dosages range between 2.4 g and 21.6 g. Abrupt withdrawal of piracetam has been associated

with a severe worsening of myoclonus and seizures in a minority of patients.

Disturbances of serotoninergic function have also been incriminated in cortical myoclonus. CSF concentrations of the principal metabolite of serotonin, 5-hydroxyindoleacetic acid, are reduced in these patients. However, treatment with serotonin precursors like 5-hydroxytryptophan, is poorly tolerated and, nowadays, only used as a last resort.

Phenytoin and carbamazepine are rarely helpful. In some patients, particularly those with Unverricht–Lundborg disease, phenytoin may exacerbate myoclonus. Carbamazepine may worsen myoclonic seizures. Vigabatrin, an irreversible inhibitor of GABA transaminase, surprisingly does not seem very useful. It may lead to a paradoxical increase in myoclonus in some patients, or, occasionally, myoclonus in its own right.

In summary, the treatments of first choice in cortical myoclonus are sodium valproate and clonazepam. However, most patients only gain adequate relief from their myoclonus when drugs are used in combination (Obeso et al., 1988). Gait disturbance tends to be the most resistant feature and a bouncy unsteady gait with frequent falls may persist despite control of action and reflex myoclonus in the upper limbs. The combination of clonazepam, primidone and either sodium valproate, piracetam or both may be necessary to provide substantial relief of myoclonus. Polytherapy is generally well tolerated, but doses may be limited by ataxia and drowsiness. Piracetam has particular advantages in these circumstances, as its addition to existing treatments is rarely accompanied by sedation.

Prognosis

Prognosis is dictated by the underlying condition. However, two conditions merit particular comment. The progressive myoclonic ataxia associated with coeliac disease often starts in the foot, slowly spreading to the other foot and upper limbs. Most patients become wheelchair bound or die within 2 years, regardless of dietary restriction (Bhatia et al., 1995). In posthypoxic myoclonus the disability following the hypoxic event is often severe, but it has recently been realized that late improvement in the myoclonic syndrome and the level of disability can occur years after onset (Werhahn et al., 1997). Some patients are eventually able to discontinue antimyoclonic medication and to walk unaided. Cognitive deficits are found in about half, but are usually mild. Epilepsy may be a problem in the first year, particularly during the initial period of posthypoxic coma, but thereafter only persists in the minority of cases. Other neurological deficits are rare.

Table 36.1. Diagnostic criteria for hereditary essential myoclonus

Onset under 20 years old
Males and females equally affected
Myoclonus with a benign course, compatible with a life of normal span
Dominant mode of inheritance, but with variable severity
Absence of seizures, dementia, gross ataxia and other neurological deficits
Normal EEG

Myoclonus in association with dystonia

Essential myoclonus

Essential myoclonus is commonly inherited as an autosomal dominant trait with variable penetrance and expression, when it is termed hereditary essential myoclonus (the terms essential familial myoclonus, familial myoclonia, ballistic overflow myoclonus and benign essential myoclonus have also been used). The diagnostic criteria for this condition have been set out by Mahloudji and Pikielny (1967), and are summarized in Table 36.1. The jerks are present at rest, but become more marked with action. They are worst around the neck and proximal arms, and may dramatically improve with alcohol. In many cases there is also evidence of dystonic posturing or a family history of dystonia. Sporadic cases are very similar and may be examples of hereditary essential myoclonus with incomplete penetrance, new mutations or truly sporadic phenocopies.

Myoclonic jerks arise from a distortion of the normal reciprocal activation pattern of ballistic movements, so that muscle activity is no longer restricted to appropriate muscles. EMG activity may also be prolonged, with conspicuous cocontraction. Stimulus sensitivity is not a prominent feature, although jerks can sometimes be provoked by unexpected loud noises. Cortical somatosensory evoked potentials are normal. Back-averaging of the EEG activity preceding jerks reveals no cortical correlate or an unusual generalized wave preceding the jerks by a longer interval than seen in cortical myoclonus.

The available but limited pharmacological evidence suggests a cholinergic–serotoninergic imbalance. Thera-

peutic trials have shown moderate benefit from benztropine mesylate and 5-HTP, although the latter is poorly tolerated. The deterioration of the myoclonus following parenteral physostigmine also supports a relative cholinergic overactivity. Antiepileptic treatments are not helpful, with the possible exception of clonazepam. Drug treatments generally fail to match the amelioration seen with alcohol, and as a result there is a real danger of alcoholism in this condition. Deep brain stimulation of the globus pallidus interna may be considered in intractable cases.

Myoclonic dystonia

Some families with idiopathic dystonia may have family members with jerks (termed myoclonic dystonia), but myoclonus is not found in the absence of dystonia and does not show a dramatic response to alcohol, distinguishing these families from those with hereditary essential myoclonus (Quinn, 1996).

Brainstem myoclonus and the startle syndrome: segmental

Brainstem myoclonus usually leads to generalized myoclonic jerks, as in brainstem reticular reflex myoclonus and hyperekplexia. Focal forms are rare, although diaphragmatic myoclonus may arise in the rostral medulla. Palatal myoclonus is best considered as a form of tremor.

Hyperekplexia/startle syndrome

The most striking clinical characteristic of the generalized forms of brainstem myoclonus is the exaggerated motor response to unexpected auditory and, sometimes, somesthetic and visual stimuli. Hyperekplexia is the commonest cause of the startle syndrome. It may be idiopathic, inherited as an autosommal dominant condition, or symptomatic. There is now general agreement that the response in hereditary and symptomatic hyperekplexia is a pathological exaggeration of the normal startle reflex (Brown et al., 1991b; Matsumoto et al., 1992). Both types of response are the result of activity in a common reflex centre in the lower brainstem. Thus (when allowance is made for the blink reflex which is usually elicited concurrently) the first EMG activity in the startle is recorded in sternocleidomastoid, with other cranial, trunk and limb muscles following in an orderly fashion, as myoclonic activity spreads up the brainstem and down the spinal cord (Fig. 36.2). Caudal muscles are recruited relatively slowly, and involvement of the

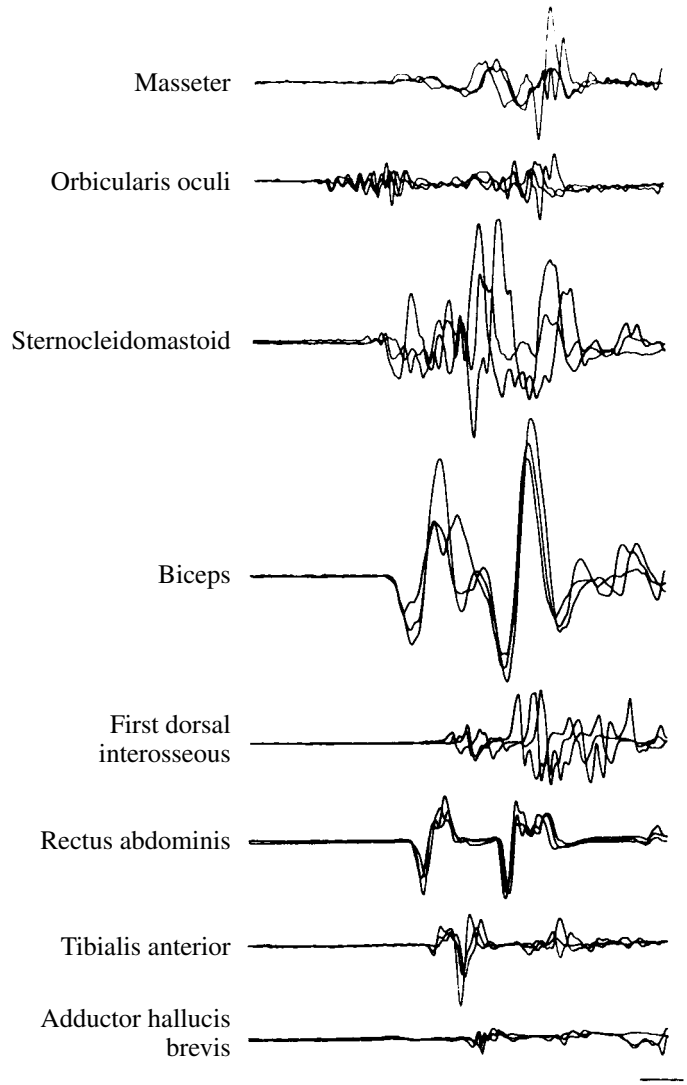

Fig. 36.2. The EMG activity in the abnormal startle response elicited by auditory stimulation in a patient with symptomatic hyperekplexia. The unrectified EMG activity in three single trials is superimposed. Each trial was started at the point of presentation of a 124 dB tone. Following the normal auditory blink reflex, EMG activity was recorded first in sternocleidomastoid, and then later in masseter and trunk limb muscles. The latencies to the intrinsic hand muscles of the hand and foot were disproportionately long. The horizontal calibration line represents 20 ms. The vertical calibration line represents 0.5 and 4.0 mV for the upper three channels, and the lower five channels, respectively. (Reprinted from Brown et al., 1991a, with permission.)

intrinsic hand and foot muscles is disproportionately delayed.

The reflex jerks to auditory, somesthetic or visual stimuli involve many muscles, both proximal and distal, bilaterally and synchronously to produce a sudden shock-like movement usually involving a grimace, abduction of the arms, and flexion of the neck, trunk, elbows, hips and knees. Thus the reflex jerks resemble the normal startle reaction in general character, although, clinically, they are greatly exaggerated in amplitude, more extensive in distribution and habituate poorly. Somesthetic stimuli are most effective when applied to the mantle area; that is the head, face and upper chest.

Many patients also exhibit generalized tonic spasms with unexpected stimuli, and it is these that lead to frequent injury and which are the most disabling feature of the condition. The pathophysiology of these tonic spasms is not known. They may be a brainstem phenomenon or the result of activity in the motor and supplementary motor cortex, as in startle epilepsy. Tonic spasms consist of generalized stiffening, lasting a few seconds, usually in response to unexpected somesthetic or acoustic stimuli. During these tonic spasms patients are unable to take any protective action and, if erect, fall stiffly to the ground, without losing consciousness. When present, tonic spasms tend to dominate the clinical picture. The tonic episodes are quite different to the brief, generalized startle reflexes seen in these patients and occur less frequently than the latter. They are also distinct from the tonic spasms of multiple sclerosis, which are usually painful, unilateral and rarely stimulus sensitive.

In addition, patients may experience excessive jerking, particularly during or going off to sleep. These paroxysms of jerking involve repetitive flexion of all four limbs, especially the legs. They are usually spontaneous. Consciousness is preserved in diurnal attacks, although jerking may be severe enough to cause incontinence of urine. The pathophysiology of the episodes of jerking, like that of the tonic spasms, is unclear.

Carbamazepine, phenytoin and the benzodiazepines, particularly clonazepam, form the mainstay of treatment, which is directed at the disabling tonic spasms rather than the exaggerated startle responses.

Hereditary hyperekplexia

Hereditary hyperekplexia is due to a mutation in the alpha$_1$ subunit of the glycine receptor, which may lead to altered ligand binding or disturbance of the chloride ion-channel part of the receptor (Shiang et al., 1993). Gycine receptors are widely distributed within the central nervous system, and this change in the alpha$_1$ subunit may account for the range of abnormalities which can be present in this condition. Stiffness and apneic attacks as a baby, hyperreflexia, a hesitant wide-based gait, epilepsy, and low intelligence may occur in addition to an exaggerated startle, tonic spasms and paroxysms of jerking.

The clinical and electrophysiological findings vary between members of the same family, and many relatives may only have an excessive startle reaction, without other neurological abnormalities. The mutation in the glycine receptor is rarely found in these minor forms, despite its presence in more affected relatives and it is possible that these minor forms represent a normal variant or 'copied' behaviour.

Acquired hyperekplexia

Clinically, idiopathic and symptomatic hyperekplexia are usually only distinguished from hereditary hyperekplexia by the absence of a family history and the presence of any signs attributable to the underlying disease in symptomatic forms. Patients have an exaggerated startle reflex, with or without tonic spasms and paroxysms of jerking. Tonic spasms are occasionally complicated by laryngeal spasm, with the risk of respiratory arrest. So far, sporadic cases have not been found to have mutations in the glycine receptor. Symptomatic hyperekplexia is usually due to brainstem disease, such as infarct, hemorrhage or encephalitis.

Startle epilepsy

Startle epilepsy can readily be distinguished from hyperekplexia, although similar pathophysiological mechanisms may operate in the tonic episodes of each condition. Startle epilepsy is seen in the setting of early brain damage, usually perinatal anoxia (Chauvel et al., 1992). Most patients have a hemiparesis, and mental retardation is common. Seizures begin in childhood or adolescence, and tend to be frequent. They consist of tonic spasms, lasting up to 30s, with preservation of consciousness. The spasms are typically asymmetrical and predominatly involve the paretic limbs. They may be elicited by unexpected auditory, visual or somesthetic stimulation, or occur spontaneously. Other seizure types occur in about a quarter of patients. Cranial imaging is abnormal in the majority of cases, usually showing unilateral atrophy involving the lateral central and pericentral cortex. The interictal EEG is generally abnormal with localized or diffuse slow waves and spikes. Ictal scalp-recorded EEG shows a fast low amplitude discharge often preceded by a high voltage spike at the vertex. Using depth electrodes the tonic seizures have been shown to originate in the motor or supplementary motor cortex.

Brainstem reticular reflex myoclonus

This rare form of generalized myoclonus may occur in posthypoxic encephalopathy, brainstem encephalitis and uremia. It responds to anticonvulsant drugs, particularly clonazepam and sodium valproate. Clinically, it is distinguished from hyperekplexia by the frequent occurrence of spontaneous, as well as reflex jerks to auditory and somesthetic stimulation. The latter is most effective over the distal limbs, rather than the mantle area typical of hyperekplexia. The basic pattern of muscle recruitment in the jerks is similar to that recorded in hyperekplexia in so far as activity seems to spread from the caudal brainstem (Hallett et al., 1977). EMG activity is recorded first in trapezius and sternocleidomastoid, and later in other cranial, trunk and limb muscles. The relative latencies to onset of reflex EMG activity in these muscles increases with the distance of their respective segmental innervations from the lower brainstem.

These generalized jerks are therefore believed to arise in the reticular formation of the caudal brainstem. Despite this, several important electrophysiological distinctions exist between brainstem reticular reflex myoclonus and hyperekplexia, making it likely that their origins within the bulbopontine reticular formation are different. The difference between the relative latencies of trunk and limb muscles is small in the jerks of brainstem reticular reflex myoclonus, indicating that the spinal motor pathways are rapidly conducting, with velocities comparable to those of rapidly conducting pyramidal pathways. This is in contrast to the findings in hyperekplexia. Also, in reticular reflex myoclonus the relative latencies of the intrinsic hand and foot muscles are not disproportionately prolonged, as in hyperekplexia.

Startle responses with unknown physiology

There remain several other conditions in which an exaggerated startle is a prominent feature, but the physiology of the motor response is unclear. Infantile GM2 gangliosidosis (Tay–Sachs and Sandhoff's diseases) is characterized by hypotonia, irritability and abnormal startle responses in infancy. Developmental regression, progressive blindness with a cherry red macular spot, deafness, seizures and spasticity ensue. Death usually occurs before the third year. The physiology of the abnormal startle is unknown in this condition, but a relationship to the normal startle or Moro response seems unlikely as the motor response consists of a sudden extension of the arms, head and trunk.

Tics in Gilles de la Tourette's syndrome usually are spontaneous, but sometimes may be triggered by external stimuli and may have the appearance of an exaggerated startle response. They rarely represent a diagnostic problem as the other clinical features of Gilles de la Tourette's syndrome are distinctive. In jumping, latah and myriachit unexpected sensory stimulation leads to an initial violent start followed by automatic speech or behaviour, such as echolalia, echopraxia or the assumption of a defensive posture.

Spinal myoclonus

The spinal cord possesses both local segmental organization and long propriospinal pathways linking activity across many segments. Pathological activity in either system can lead to myoclonus. Very rarely, focal myoclonus may be due to a lesion of the spinal root, plexus or peripheral nerve.

Propriospinal myoclonus

In this form of myoclonus a spinal myoclonic generator recruits axial muscles up and down the spinal cord via long propriospinal pathways (Brown et al., 1991a; Schulz-Bonhage et al., 1996). The disorder generally develops in middle age, and follows cervical trauma, albeit mild, in about half of cases. Its course is relatively benign, with a history of involuntary jerking stretching back up to 25 years. Spontaneous remission is unusual. Myoclonus usually takes the form of axial flexion jerks involving the neck, trunk, and hips, although a minority of patients may have truncal extension jerks. It may occur spontaneously, particularly on lying flat, or be precipitated by somesthetic stimuli. Myoclonic EMG activity usually consists of repetitive bursts with a frequency of 1–7Hz. EMG bursts can be quite long, lasting several hundred milliseconds. The jerks may be stimulus sensitive, particularly to taps to the abdomen, biceps or patella tendons. The orderly recruitment of rostral and caudal segments from a given spinal focus often confirms a spinal origin for the myoclonus (Fig. 36.3), although it is not always possible to distinguish such a pattern of activation. Clonazepam has proven the most effective treatment for propriospinal myoclonus, and leads to partial improvement in over half of patients. Other anticonvulsants have been largely unhelpful.

Segmental spinal myoclonus

Segmental spinal myoclonus is often symptomatic of an underlying structural lesion, such as an intrinsic or extrinsic

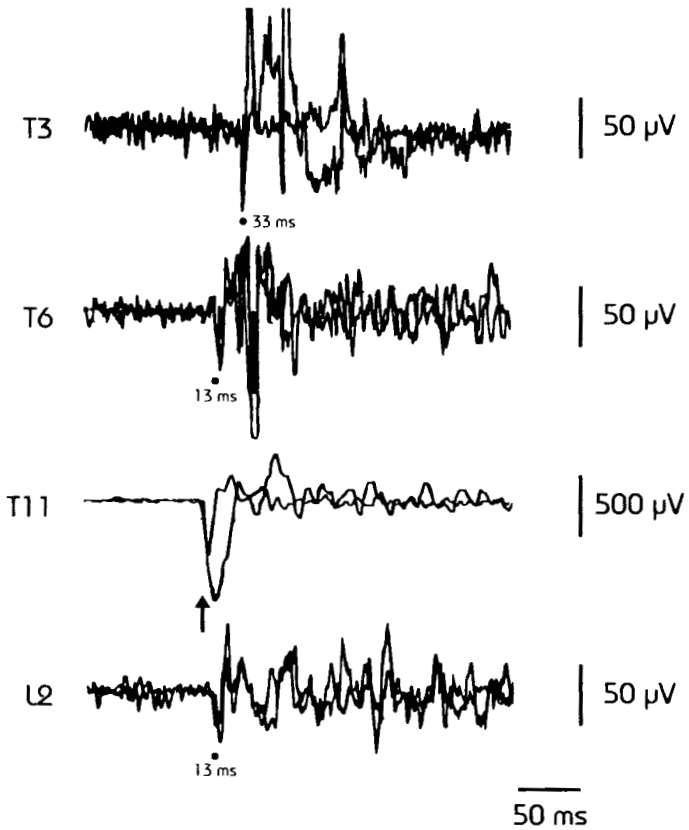

Fig. 36.3. EMG recordings from erector spinae at various vertebral levels from the second lumbar vertebra (L2) to the third thoracic vertebra (T3) in a patient with stimulus-sensitive propriospinal myoclonus. Two recordings are superimposed. Jerks were elicited by tapping the electrode overlying T11 (arrowed). Latencies are given with respect to the stimulus artefact at T11. Propagation occurs away from the lower thoracic level. (Reprinted from Schulze-Bonhage et al., 1996, with permission.)

malignancy or syringomyelia, or of viral or paraneoplastic myelitis (Brown, 1994). It is confined to one or a few contiguous myotomes, and is most often rhythmic, the frequency of the jerks varying between 1 and 2 per minute to 240 per minute. EMG bursts may be up to 1000 ms in duration. Clues to a spinal origin are the independence from supraspinal influences and persistence of myoclonus in sleep. The condition may or may not be stimulus sensitive.

Segmental spinal myoclonus is believed to result from the isolation of spinal motoneurones from inhibitory influences or from direct cellular injury. Treatment is that of the underlying cause, where this is possible. Symptomatic treatment is only moderately effective. Clonazepam is the drug of first choice and, in dosages of up to 6 mg daily, may diminish or abolish myoclonus.

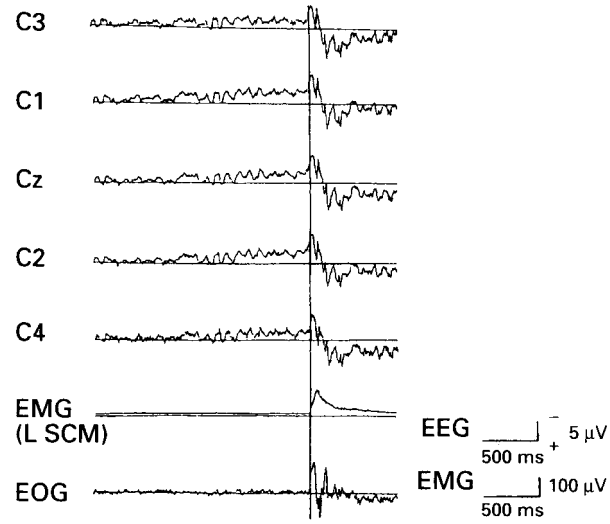

Fig. 36.4. Records from a patient with psychogenic myoclonus. EEG activity has been realigned to the onset of the jerk recorded in left sternocleidomastoid (L SCM) and then averaged to give the 'backaveraged EEG'. This shows a slow negative wave (the Bereitschaftspotential) starting 1.3 seconds before the EMG onset. Compare this wave to the brief, giant wave, which precedes cortial myoclonus by 20 or so milliseconds in Fig. 36.1. (Reprinted from Terada et al., 1995, with permission.)

Diazepam, carbamazepine and tetrabenazine have been useful in occasional cases.

Psychogenic myoclonus

Clinical features suggestive, but not diagnostic, of a psychogenic origin are the sudden onset of an inconsistent and variable movement disorder, which does not overly trouble the subject. Additional clues are the lessening of movements when distracted and, conversely, a dramatic increase in severity and complexity of movements during direct observation, settling again when no longer under direct observation. The absence of signs of organic neurological disease and the unusual nature of the movements are also suggestive, but not necessarily diagnostic of a psychogenic etiology. More convincing is the disappearance of the movement disorder when supposedly unobserved or following suggestion and placebo. The typical indicators of a conversion disorder, such as psychological precipitants, multiple somatizations and secondary gain may or may not be present.

The electrophysiological pattern of psychogenic jerks is indistinguishable from that of voluntary movements. In particular, EMG burst duration is almost always longer

than 70ms (unlike cortical myoclonus) and may involve a triphasic activation of agonist and antagonist muscles. The pattern of recruitment of muscles with different segmental origins is variable, and the latencies of reflex jerks are long. In patients with spontaneous jerks good electrophysiological evidence in favour of psychogenic myoclonus is the presence of a slow negative wave (Terada et al., 1995), the Bereitschaftspotential, in the EEG backaveraged from the jerks (Fig. 36.4).

Dystonia

Barbara Illowsky Karp, Susanne Goldstein and Mark Hallett

Office of the Clinical Director and Human Motor Control Section NINDS, NIH, Bethesda, Maryland, USA

Dystonia is a movement disorder characterized by sustained involuntary muscle contraction causing abnormal twisting, repetitive movements or posturing that tend to have a directional predominance. Descriptions of dystonic patients, who were often believed to be hysterical, first appeared at the beginning of the twentieth century (Zeman & Dyken, 1968). In 1908, Schwalbe ascertained the hereditary nature of the illness and its variable expression (Schwalbe, 1908). The term 'dystonia musculorum deformans' was first used by Oppenheim (1911), while Mendel and Flateau, emphasizing the twisted posture, called the disease 'torsion dystonia' or 'torsion spasm' (Flateau & Sterling, 1911; Zeman & Dyken, 1968).

After a period of relative inattention, interest in dystonia revived in the 1970s with a fuller delineation of the symptomatology allowing the recognition of focal forms. More recent technological developments have culminated in the identification of genetic mutations underlying generalized torsion dystonia, dopa-responsive dystonia, and some focal dystonias. New therapies have been developed including botulinum toxin injections, stereotactic surgery, and deep brain stimulation.

Classification

Dystonia can be classified by etiology, by the body area involved, and by the age of onset. The division by etiology into primary (idiopathic) and secondary (symptomatic) dystonia provides a schema for evaluating the patient. The classification by affected region is especially useful for the primary dystonias, where the epidemiology, prognosis, treatment and genetics differ by dystonia type. Classifying dystonia by age of onset is also most applicable to primary dystonia, where it serves to separate idiopathic generalized torsion dystonia of childhood onset from the focal dystonias which typically present in adulthood.

A classification suggested by Fahn et al., divides dystonias into primary dystonia, 'dystonia-plus' syndromes in which dystonia combines with other neurological symptomatology, secondary dystonia where an underlying pathological process causing dystonia can be identified, and heredofamilial dystonia in which there is an underlying neurodegenerative disorder (Fahn et al., 1998).

Signs and symptoms

Idiopathic dystonia often first manifests as a feeling of discomfort or stiffness in the affected body part. Abnormal movement ensues and initially may only be apparent when performing specific acts, interfering with smooth and accurate performance. As it progresses, dystonia occurs with other voluntary movements and may eventually be present even at rest. Dystonic muscles may hypertrophy; fixed contractures and deformity occur in severe cases. Dystonia disappears during sleep. Prolonged muscle spasm can lead to aching, but severe pain is generally absent except in cervical dystonia.

Dystonia may be the sole movement disorder present or it may be accompanied by postural or action tremor (Cohen et al., 1987; Jedynak et al., 1991; Lou & Jankovic, 1991; Dubinsky et al., 1993). As shown in the Fig. 37.1, some patients have 'gestes antagonistes' or tricks whereby a simple touch or movement temporarily relieves the dystonia. Primary sensory function assessed by routine neurologic examination, strength, muscle tone, and reflexes are normal in idiopathic dystonia. The presence of such neurologic signs should therefore suggest another diagnosis.

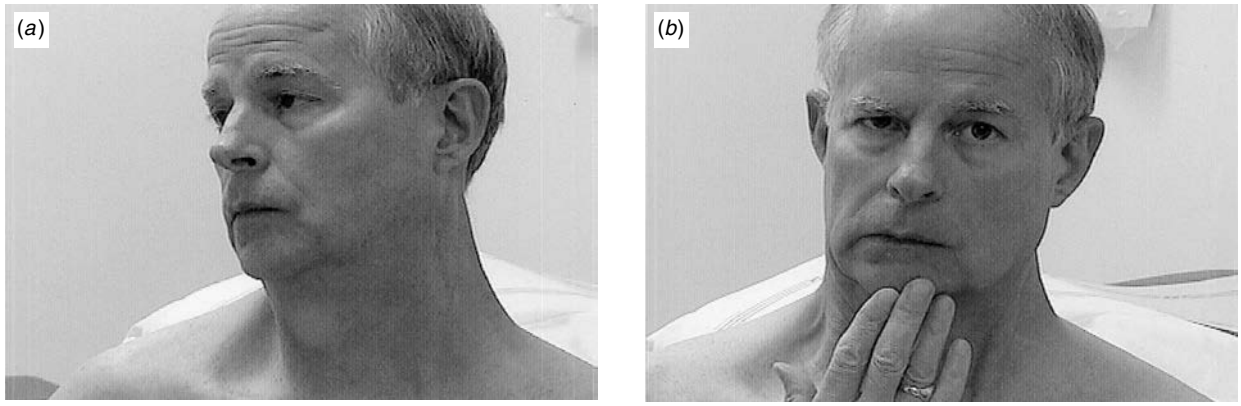

Fig 37.1. (*a*) Resting position of the head in a patient with torticollis. (*b*) Resting position of the head during the geste antagoniste. A light touch to the chin allows the head to return to a forward position.

Primary dystonias

The generalized dystonias include idiopathic torsion dystonia (formerly called 'dystonia musculorum deformans') and 'dystonia-plus' syndromes such as dopa-responsive dystonia, paroxysmal choreoathetosis/dystonia, rapid onset dystonia/parkinsonism and myoclonic dystonia.

Idiopathic generalized torsion dystonia (early-onset torsion dystonia) typically presents between ages 6 and 12, almost always before age 24 (Marsden & Harrison, 1974; Bressman et al., 2000). The first sign in many patients is limb involvement (Bressman et al., 2000), such as gait impairment due to foot flexion and inversion. When dystonia presents with early onset and limb involvement, it is especially likely to progress and become generalized, but affects the cranial muscles in only 11% of patients. Symptoms usually stabilize after 5–10 years. While patients often become wheelchair bound, lifespan is nearly normal. Remissions lasting hours to years occur in up to 20% of patients.

Early-onset generalized torsion dystonia is most frequently an autosomal dominant disease with a reduced penetrance. In the most common form, DYT1, the clinical expression is highly variable and members of the same family may have focal rather than generalized symptoms. The gene underlying this disorder has been identified and will be discussed below.

Dopa-responsive dystonia (DRD) is a less common form of generalized dystonia characterized by childhood-onset, diurnal variation and exquisite sensitivity to low doses of l-dopa (Segawa et al., 1976; Nygaard et al., 1990). In this disorder, dystonic symptoms progressively worsen during the day and improve with sleep. The presence of spasticity and mild hyperreflexia in some patients may lead to the mistaken diagnosis of cerebral palsy. Parkinsonism may develop later in the course. Genetic mutations underlying both autosomal dominant and autosomal recessive forms of DRD have been identified and will be discussed below.

In paroxysmal dystonic choreoathetosis (PDC), attacks of generalized dystonia sometimes accompanied by choreoathetosis begin in infancy or childhood. In kinesigenic dyskinesia, brief attacks follow exercise or movement. In the rarer non-kinesigenic PDC, episodes are precipitated by alcohol, stress or caffeine and last minutes to hours (Bhatia, 1999). Patients are asymptomatic between attacks.

Myoclonic dystonia is an autosomal dominant disease with myoclonus and dystonia beginning in adolescence (Quinn et al., 1988; Klein et al., 1999). Both symptoms may respond dramatically to alcohol ingestion. Unlike early-onset idiopathic generalized torsion dystonia, it typically spares the legs.

Focal dystonias

Focal dystonias are named by the predominant site of involvement. The extent to which the various forms of focal dystonia share genetic or physiological underpinnings is unknown. Focal dystonia can be the presenting feature of generalized dystonia, but especially in later-onset cases, tends to remain focal.

Cervical dystonia (spasmodic torticollis) is the most common focal dystonia with approximately 9 cases/100 000 population (Nutt et al., 1988). Women are more often affected than men and the usual age of onset is 40–60 years (Jankovic et al., 1991). Cervical dystonia is named by the direction of head movement. The most common pattern is torticollis, where the head turns to one

side due in part to overactivity of the opposite sternocleidomastoid muscle. In retrocollis, the head tilts backward due to over-contraction of neck extensors such as splenius capitus. In anterocollis the neck is flexed due to hyperactivity of the anterior scalenes and sternocleidomastoids. Laterocollis, head tilt, and other patterns are less common. Cervical dystonia is often accompanied by tremor and shoulder elevation. Unlike other focal dystonias, cervical dystonia is often painful.

Patients with blepharospasm often first complain of uncomfortable sensations in or around the eyes. Bilateral involuntary eye closure ensues leading to visual impairment, and, at worst, functional blindness. In Meige syndrome, blepharospasm combines with oromandibular dystonia where the abnormal movements encompass the jaw, face, and neck.

Dystonia of the vocal cords is called spasmodic dysphonia. The most common form is adductor spasm, in which dystonia of the thyroarytenoid muscles produces a hoarse, choked voice. The less common abductor spasm is due largely to cricoarytenoid dystonia and leads to an intermittent soft, whispery voice.

Focal hand dystonia often arises in those whose work entails repetitive small hand movements or following a period of particularly excessive hand use. The initial sign may be a feeling of tightness or stiffness in the affected limb. As the dystonia develops, abnormal hand posture may become apparent accompanied by loss of speed, impaired movement fluency, and inaccurate motor control. At its onset, limb dystonia may be task-specific, i.e. present only during a particular action such as writing or playing a musical instrument. Other movements, even those utilizing the same muscles, can be performed normally. In some patients, the dystonia progresses to include other activities and at times, may become obvious even at rest. When limb dystonia involves the contiguous proximal limb girdle musculature, it is called segmental dystonia.

Hemidystonia, in which only half of the body is affected, is often secondary to structural brain damage (Marsden et al., 1985).

Secondary dystonia

Dystonia can be part of the symptomatology of a wide range of metabolic and degenerative diseases, can accompany or follow brain damage, or be caused by medications (Table 37.1). When identifiable brain lesions are present in patients with symptomatic dystonia, the basal ganglia, especially the putamen, are likely to be involved (Marsden et al., 1985; Bhatia & Marsden, 1994; Kostic et al., 1996; Lehericy et al., 1996). Conversely, dystonia is the most common movement disorder associated with basal ganglia damage (Bhatia & Marsden, 1994). Dystonia can occasionally arise from damage in the thalamus, subthalamic area, brainstem, or with posterior fossa or cervical lesions (Jankovic & Patel, 1983; Lee & Marsden, 1994; Cammarota et al., 1995; Jho & Janetta, 1995; Krauss et al., 1997).

Dystonia is part of the symptomatology of several known basal ganglia diseases. It is seen with Parkinson's disease and other parkinsonian and degenerative disorders such as X-linked dystonia/parkinsonism (Lubag), rapid-onset dystonia–parkinsonism, and corticobasal ganglionic degeneration. In Wilson's disease, dystonia may arise before tremor or cerebellar signs. Neuroleptic medications are a common cause of both acute dystonic reactions and tardive dystonia, especially in the psychiatric population.

Table 37.2. Genetics of dystonia

Genotype	Location	Mutation	Phenotype
DYT1	9q34	GAG deletion in Torsin A	Early-onset generalized dystonia
DYT2	Unknown	Unknown	Autosomal recessive dystonia in Gypsies(Gimenez-Roldan et al., 1988)
DYT3	Xq13.1	Unknown	X-linked dystonia/parkinsonism (Lubag)
DYT4	Unknown	Unknown	Hereditary whispering dystonia in an Australian family (Parker, 1985)
DYT5	14q22.1-22.2	GTP cyclohydrolase I	Dopa-responsive dystonia-autosomal dominant
	11p15.5	Tyrosine hydroxylase	Dopa-responsive dystonia-autosomal recessive
DYT6	8p21-q22	Unknown	Phenotype intermediate to early- and late-onset dystonia in Mennonites
DYT7	18p	Unknown	Adult-onset torticollis and spasmodic dysphonia
DYT8	2q33-35	?channelopathy	Paroxysmal non-kinesigenic dystonic choreoathetosis
DYT9	1p	Unknown	Paroxysmal choreoathetosis with episodic ataxia
DYT10	16p11.2-q12.1	Unknown	Paroxysmal kinesigenic dystonic choreoathetosis
DYT11	11q23	Dopamine receptor D2	Myoclonic dystonia
DYT12	19q13	Unknown	Rapid onset dystonia-parkinsonism

Post-hemiplegic dystonia follows ischemic brain damage or trauma and is probably due to aberrant cerebral reorganization. Extrapontine myelinolysis, a neurologic disorder caused by rapid correction of hyponatremia, frequently affects the basal ganglia and dystonia often develops weeks to months after the initial brain insult (Wu & Lu, 1992; Seiser et al., 1998).

Dystonia, especially hemidystonia, can follow head trauma with a latency of months to years (Krauss et al., 1992, 1996). The contralateral basal ganglia and thalamus are the most frequent lesion sites in post-traumatic dystonia (Lee et al., 1994).

There is also an association between peripheral trauma and the development of dystonia (Schott, 1985; Jankovic & Van Der Linden, 1988). Bhatia et al. reported a history of trauma to the dystonic body part within 3 months preceding the onset of dystonia in 39% of patients with primary axial dystonia (Bhatia et al., 1997). Similarly, peripheral trauma appeared to trigger the onset in up to 20% of cases with idiopathic generalized torsion dystonia reported by Fletcher et al. (1991). Tarsy identified differences in cervical dystonia developing immediately after trauma from that developing later and from idiopathic torticollis (Tarsy, 1998). Acute onset torticollis reached maximal intensity within days of the injury, had a more fixed posture, no relief with sensory tricks, and poorer response to botulinum toxin injection.

Dental procedures and facial trauma can trigger oromandibular dystonia, even in areas of the face and oropharynx not directly traumatized. These patients often have pain and dysesthesia as well as dystonia (Sankhla et al., 1998; Schrag et al., 1999).

Dystonia is no longer considered a hysterical disorder, but can be psychogenic in some patients. Psychogenic dystonia should be suspected when there is no identified underlying cause, abrupt onset, rapid progression to fixed posture, prominent pain, other psychogenic neurologic signs, and multiple somatizations (Lang, 1995).

Secondary dystonias can be recognized by the clinical setting and by the presence of neurological signs other than dystonia. Evaluation for treatable form of dystonia, such as Wilson's disease, should be undertaken in all patients in whom an etiology is not apparent.

Epidemiology

Nutt et al. (1988) found a prevalence of generalized dystonia of 3.4/100000 and focal dystonia of 29.5/100000 in Rochester, Minnesota in 1980. The European Dystonia Study Group found that, except for writer's cramp, segmental and focal dystonias are more common in women, but that men tend to have an earlier age of onset (Epidemiologic Study of Dystonia in Europe Collaborative Group, 1999).

Genetics

Table 37.2 summarizes the identified dystonia genes.

Idiopathic torsion dystonia

Early-onset idiopathic torsion dystonia is most often an autosomal dominant disorder with 30–40% penetrance.

Ozelius et al., first reported the localization of the gene (DYT1) for this disorder to chromosome 9q34 in 1989 (Ozelius et al., 1989). In 1997, the same group identified the gene itself (Ozelius et al., 1997). Early-onset torsion dystonia is caused by a GAG deletion in the DYT1 gene resulting in the loss of a glutamine residue from a conserved region of an ATP binding protein, Torsin A. Although the function of Torsin A is not known, it is structurally related to heat shock proteins. Torsin A is expressed in the substantia nigra pars compacta, the major source of dopaminergic neurons projecting to the basal ganglia (Augood et al., 1999).

The DYT1 mutation is present in 2.7/100000 Ashkenazi Jews but only in 0.5/100000 of the general population. Early-onset idiopathic torsion dystonia in Ashkenazi Jews appears to have arisen from a single founder mutation (Risch et al., 1995). The GAG deletion in the Torsin A gene is responsible for 60–75% of cases of early-onset idiopathic dystonia. The DYT1 mutation can be associated with atypical phenotypes in different members of the same family, such as postural hand tremor or stuttering (Slominsky et al., 1999).

Less is known about the genetics of adult-onset idiopathic dystonias. Up to 25% of patients with focal dystonias have other affected family members and these disorders may also be autosomal dominant with incomplete penetrance and variable phenotypic expression (Waddy et al., 1991; Stojanovic et al., 1995; Leube et al., 1997). The DYT1 mutation is not involved (Valente et al., 1998). There is similarly no evidence that the DYT1 founder mutation plays a role in the development of secondary dystonia (Bressman et al., 1997).

Dopa-responsive dystonia

Dopa-responsive dystonia (DRD) can be an autosomal dominant or recessive disorder. Autosomal dominant DRD is caused by mutations on chromosome 14q22.1–22.2 in the gene for the tetrahydrobiopterin (BH4) biosynthetic enzyme, GTP cyclohydrolase I (GCH1). BH4 is a required cofactor for tyrosine hydroxylase, the first enzyme in the synthesis of dopamine from tyrosine. These patients therefore have low basal ganglia neopterin and biopterin levels. Putaminal tyrosine hydroxylase levels may also be low (Furukawa & Kish, 1999; Furukawa et al., 1999; Ichinose & Nagatsu, 1999). More than 30 mutations have been reported in the GCH1 gene, but the specific mutation does not predict the clinical picture. As with idiopathic early-onset dystonia, there is marked phenotypic variation even in the same family. Mutations in the tyrosine hydroxylase gene itself have been found in patients with autosomal recessive DRD (Nygaard et al., 1990; Ichinose & Nagatsu, 1999).

Other dystonias

Almasy et al. (1997) identified DYT 6 in the pericentromeric region of chromosome 8 in 2 Mennonite families with a phenotype intermediate to that of early and late-onset dystonia. Leube et al. (1996) identified DYT7 on chromosome 18p in a single pedigree from northwest Germany with adult-onset spasmodic torticollis and spasmodic dysphonia.

Autosomal dominant paroxysmal non-kinesigenic dystonic choreoathetosis has been mapped to chromosome 2q31–36 and, similar to other paroxysmal movement disorders, may be a channelopathy (Fink et al., 1997; Jarman et al., 1997; Matsuo et al., 1999). Paroxysmal kinesigenic dystonic choreoathetosis appears to localize to chromosome 16 (Bennett et al., 2000). Myoclonic dystonia is associated with a mutation in the dopamine D2 receptor on chromosome 11 (Klein et al., 1999). The area of the X-chromosome linked to the DYT3 gene associated with X-linked dystonia/parkinsonism is being narrowed (Nemeth et al., 1999). Rapid onset dystonia-parkinsonism is a rare autosomal dominant disease in which dystonia and parkinsonism evolve over hours or days. This disorder has been linked to chromosome 19q13 (Brashear et al., 1998; Kramer et al., 1999). Despite the progress made to date, idiopathic dystonias appear to have wide genetic heterogeneity and the presently identified genes cannot account for most cases (Jarman et al., 1999).

Pathology

While isolated cases of neuronal loss and gliosis have been reported (Zeman & Dyken, 1968; Zweig et al., 1988), routine pathological examination is generally unrevealing in idiopathic dystonia (Zeman, 1970; Hornykiewicz et al., 1986; Gibb et al., 1988; Furukawa et al., 2000). X-linked dystonia–parkinsonism, however, has been associated with a mosaic pattern of striatal gliosis (Altrocchi & Forno, 1983; Gibb et al., 1992; Waters et al., 1993), and hypopigmentation of dopaminergic cells in the substantia nigra may be seen in dopa-responsive dystonia (Rajput et al., 1994).

Becker et al. (1999) recently reported increased copper and a trend towards increased manganese in the globus pallidus and putamen in idiopathic adult-onset dystonia. These changes in metal deposition may explain the increased basal ganglia echogenicity on transcranial sonography in patients with idiopathic dystonia reported

by Naumann and Becker (Naumann et al., 1996; Becker et al., 1997). Naumann et al. (1998c) failed to find changes in *N*-acetyl aspartate/creatine-lactate/creatine ratio in focal hand dystonia, suggesting no neuronal loss or change in aerobic metabolism.

Neurochemistry

Although a unifying neurochemical abnormality has not been identified in dystonia, dopamine is likely to be involved. Dystonia is part of the symptomatology of other disorders with dopaminergic dysfunction such as Parkinson's disease, myoclonus-dystonia, dopa-responsive dystonia, rapid-onset dystonia parkinsonism, and X-linked dystonia–parkinsonism. Dystonia also arises with l-dopa treatment in Parkinson's disease patients. Neuroleptic medications, which are dopamine antagonists, can cause both acute and tardive dystonia.

Direct measurement of neurotransmitters and their metabolites in cerebrospinal fluid (CSF) or pathological specimens have given inconsistent results. Low CSF levels of homovanillic acid (HVA), the major metabolite of dopamine, have been found in isolated cases of idiopathic dystonia (Tabaddor et al., 1978; Ashizawa et al., 1980), but are usually normal (Marsden & Harrison, 1974). CSF HVA is low in dopa-responsive dystonia, and rapid-onset dystonia–parkinsonism (Nygaard et al., 1990; Brashear et al., 1998). Hornykeiwicz also found decreased striatal dopamine in a single patient with idiopathic dystonia (Hornykiewicz et al., 1986). In contrast, striatal dopamine and HVA concentrations were normal in a single patient with the DYT1 mutation reported by Furukawa et al. (2000).

In vivo positron emission tomography (PET) and single photon emission tomography (SPECT) studies have similarly given inconsistent results. Kishore et al., found elevated D2 receptor binding in the striatum in both patients and asymptomatic gene carriers of dopa-responsive dystonia (Kischore, 1998), and Leenders et al. (1993) found increased striatal uptake of C11-methyl-spiperone contralateral to dystonia in 6 focal dystonia patients. Perlmutter et al. (1997a), however, found decreased F18-spiperone binding in the putamen in idiopathic blepharospasm and oromandibular dystonia, and Naumann et al. (1998a) found decreased D2 receptor binding in the striatum of patients with torticollis. In the same study, Naumann found normal presynaptic tracer uptake; however, Playford et al. (1993) reported decreased F18-dopa uptake in the putamen in idiopathic dystonia. Vidailhet et al. (1999) found decreased F-dopa uptake in the striatum of patients with dystonia secondary to midbrain strokes that paralleled the severity of the dystonia.

Animal studies have also implicated dopamine. In MPTP-poisoned animals, dystonia appears before the onset of parkinsonian symptoms. In these animals, Perlmutter et al. (1997b) found that the dystonic phase was associated with a 98% decrease in dopamine in the ipsilateral caudate and putamen and decreased D2 receptor number bilaterally, which increased as the dystonia improved. In the spontaneously dystonic hamster, D1 and D2 binding are decreased in the dorsomedial striatum as well as in limbic structures (Nobrega et al., 1999).

Although the strongest evidence is for dopaminergic dysfunction, other neurotransmitters may be involved. Jankovic and Patel (1983) and Hornykiewicz et al. (1986) found abnormalities of several neurotransmitters, especially norepinephrine, in patients with idiopathic dystonia. The dystonic dt rat has more marked changes in norepinephrine than dopamine (Richter & Loscher, 1998). The response of some dystonia patients to anticholinergic medications raises the possibility of an abnormality in acetylcholine function or in interactions between dopaminergic and cholinergic pathways.

Both decreased activity in the D2-mediated indirect pathway (Perlmutter et al., 1997a; Todd & Perlmutter, 1998) and increases in the D1-direct pathway (Eidelberg et al., 1995; Karp et al., 1999) in the basal ganglia have been proposed as underlying dystonia. Either condition would lead to impaired thalamic inhibition by the globus pallidus and thus to excess thalamic stimulation of the cerebral cortex. Rather than being due to an absolute underactivity or overactivity in either pathway, dystonia may arise from an imbalance between the two.

Animal models

There are two animal lines with spontaneously-arising dystonia. The dt rat develops generalized dystonia after a period of normal motor development which worsens with stress and disappears during rest (Richter & Loscher, 1998). Similar to human idiopathic dystonia, cerebral gross and microscopic pathology are normal. Studies in these rats have suggested cerebellar and noradrenergic dysfunction. In the dystonic hamster (dt^{SZ}), dystonia is precipitated by stress and worsened by selective dopamine uptake inhibitors and intrastriatal injection of dopamine agonists (Rehders et al., 2000). During dystonic attacks, dopamine transporter binding is decreased in the nucleus accumbens and ventral tegmental area (Norbrega, 1999).

Dystonia can be induced in otherwise normal animals. Matsumura et al. (1991) showed that local application of bicuculline, a GABA antagonist, onto motor cortex caused disordered movement and changed the EMG pattern from reciprocal activity of antagonist muscles to co-contraction. At the cellular level, there was a loss of cell directionality and conversion of silent cells into active ones (Matsumura et al., 1992). Guehl et al., used bicuculline injections into the ventrolateral (VL) thalamus to produce dystonia (Guehl et al., 2000). In these animals, injections into the rostral VL thalamus caused severe dystonic posturing, difficulty performing a sequential motor task, and, by EMG, prolonged muscle bursts with co-contraction of antagonist muscles. Injection into the caudal VL thalamus led to dystonia with myoclonus. Byl et al. (1996) showed that repetitive hand movements in monkeys could induce a motor dysfunction similar to dystonia associated with enlargement and overlap of somatosensory neuron receptive fields for the fingers in primary sensory cortex (Topp & Byl, 1999). A role for aberrant plasticity in the development of dystonia is also supported by studies in rats, where facial palsy coupled with mild dopamine deficiency induced by unilateral injection of 6–OH-dopamine caused blepharospasm with increased excitability of the blink reflex (Schicatano et al., 1997).

Physiology

Dystonic movements have been studied electromyographically since the mid-twentieth century (Herz, 1944; Tournay & Paillard, 1955). They are characterized by cocontraction of agonist/antagonist muscles with loss of normal alternation, prolonged duration of muscle bursts with superimposed shorter, repeated bursts of activity, lack of selectivity for individual movements, overflow of contraction to muscles not normally activated by the task being performed, and failure of some muscles to activate voluntarily (Cohen & Hallett, 1988; Berardelli et al., 1998). The time needed to switch between components of a voluntary complex motor task is increased (Agostino et al., 1992). Using cross-correlational analysis, Farmer et al. (1998) showed that dystonic cocontraction is distinct from voluntary cocontraction and is due to abnormal presynaptic synchronization of antagonistic motor pools.

Reciprocal inhibition is a process by which activation of a muscle suppresses activity in its antagonist. Deficient reciprocal inhibition, which could result in co-contraction of antagonist muscles, has been demonstrated in patients with generalized dystonia, writer's cramp, spasmodic torticollis, and blepharospasm (Rothwell et al., 1983; Nakashima et al., 1989a; Panizza et al., 1989, 1990; Deuschl et al., 1992; Chen et al., 1995; Valls-Sole & Hallett, 1995). Deficient inhibition can also be demonstrated in the blink reflex in blepharospasm, generalized dystonia, spasmodic torticollis, and spasmodic dysphonia, in some cases even in the absence of clinical eyelid involvement (Berardelli et al., 1985; Cohen et al., 1989). Similar abnormalities are seen in perioral reflexes (Topka & Hallett, 1992) and exteroceptive silent periods (Nakashima et al., 1989b). Although reduction of spinal cord and brainstem inhibition are present in dystonia, the fundamental physiological disturbance is more likely to be in supraspinal commands.

Several lines of evidence point to dysfunction of the cortical motor system in dystonia. Movement-related cortical potentials with self-paced finger movements in patients with arm dystonia show a diminished amplitude of the NS component, thought to be generated in the motor cortex (van der Kamp et al., 1995; Deutschl, 1995). Changes both in premotor potential peak amplitude and in localization were found by Feve et al. (1994) in more severely affected secondary and idiopathic dystonia patients. Yazawa et al. (1999) found that the premotor potential preceding voluntary wrist relaxation was also decreased in amplitude. The contingent negative variation, an EEG potential generated in a warned, reaction time task, is similarly deficient with head turning in patients with torticollis (Kaji et al., 1995b) and with hand movement in patients with writer's cramp (Ikeda et al., 1996; Hamano et al., 1999). A localized deficiency of event-related desynchronization in the beta frequency range of the EEG before unilateral movement in patients with writer's cramp confirmed a focal abnormality of the contralateral sensorimotor regions (Toro, 1993). These studies demonstrate abnormalities in cerebral preparation for movement in dystonia (Berardelli et al., 1998).

Other evidence of cerebral dysfunction in dystonia comes from cerebral blood flow studies. Ceballos-Baumann et al. (1995) found depressed activity of the caudal SMA and bilateral sensorimotor cortex, with overactivity of the contralateral lateral premotor cortex, cingulate, dorsolateral prefrontal cortex, and lentiform nucleus with self-paced movements and handwriting in patients with dystonia (Ceballos-Baumann et al., 1997). Magyar-Lehmann et al. (1997) found increased glucose metabolism bilaterally in the lentiform nucleus in patients with torticollis. Ibanez et al. (1999) found deficient activation of somatosensory cortex, premotor cortex, cingulate, and SMA during writing and with sustained hand muscle contraction in patients with writer's cramp. Eidelberg et al. (1995) found increased metabolic activity of contralateral lentiform nucleus, pons, and midbrain which was dissociated from thalamic activity and correlated with symptom severity in patients with unilateral dystonia.

Hyperexcitability of motor cortex can be demonstrated by transcranial magnetic stimulation (TMS). Ikoma et al., showed that motor threshold and motor evoked potential (MEP) amplitude were normal; with increases in the level of background contraction, however, there was an abnormal increase in MEP size with increasing stimulus intensity in writer's cramp (Ikoma et al., 1996). They and Byrnes et al. (1998) also found enlarged motor maps for dystonic muscles suggesting cortical reorganization. Hyperexcitability of the motor cortex may arise from deficient intracortical inhibition. Ridding et al. (1995) and Siebner et al. (1999) demonstrated less inhibition of MEPs elicited by dual stimulus and repetitive TMS in patients with focal hand dystonia. Chen et al. (1997) found similar defective inhibition at long interstimulus intervals with sustained background contraction only in the symptomatic hand in writer's cramp. A shortening of the silent period elicited by TMS in dystonia patients also indicated defective inhibition (Ikoma et al., 1996; Chen et al., 1997; Filipovic et al., 1997; Rona et al., 1998; Curra et al., 2000). Taken together, these results suggest relative overactivation of prefrontal motor planning areas and underactivation of inhibitory sensorimotor areas in dystonia (Berardelli et al., 1998).

Although dystonia is a movement disorder, abnormalities of sensory systems may contribute (Hallett, 1995). While the routine sensory examination is normal, subtly abnormal kinesthesia may be present (Grunewald et al., 1997). In some cases, ill-defined abnormal sensations may elicit or accompany dystonic movements, as in patients with blepharospasm who have photophobia or eye irritation (Ghika et al., 1993). Sensory gestes can temporarily relieve dystonia. Aberrant sensory feedback may contribute to the development of dystonia following peripheral trauma. Sensory dysfunction in dystonia may arise at the level of the processing of muscle spindle input. Kaji et al. (1995b) found that vibration induced dystonia in patients with hand cramp, which could be reversed by cutaneous stimulation similar to the sensory geste or by lidocaine block. PET and evoked potential studies have detected abnormal brain responses to somatosensory input in dystonia (Tempel & Perlmutter, 1990; Reilly et al., 1992; Tempel & Perlmutter, 1993; Tinazzi et al., 1999, 2000). Cortical sensory maps for individual fingers may be distorted and temporal discrimination impaired (Bara-Jimenez et al., 1998, 2000). Intracerebral recordings have shown expanded thalamic sensory receptive fields (Lenz et al., 1999).

Basal ganglia dysfunction may underlie the cortical abnormalities. Direct recording from neurons in patients with primary dystonia undergoing neurosurgical procedures have found lowered firing rates, enlarged sensory receptive fields, and irregular discharge patterns in the basal ganglia (Vitek et al., 1998a). Defects in the TMS-elicited silent period have been found in diseases known to involve the basal ganglia, such as Parkinson's disease and Huntington's chorea (Roick et al., 1992; Priori et al., 1994). Bromocriptine can increase intracortical inhibition in normal subjects, demonstrating dopaminergic influences on cortical function (Ziemann et al., 1997).

Although most evidence points to the basal ganglia as the fundamental site of dysfunction in dystonia, abnormalities can also be found the thalamus, an area where sensory and motor functions converge. As noted above, bicuculline injections into the thalamus can produce dystonia (Guehl et al., 2000). Recordings made during thalamic surgery in patients with secondary dystonia show sensory reorganization (Lenz & Byl, 1999; Lenz et al., 1999). Thalamotomy lesions in the Vim or Vop nuclei can treat dystonia in some patients.

Treatment

Since the etiology of dystonia is not yet known, its treatment remains symptomatic. Current therapeutic options include oral medications, chemodenervation, peripheral nerve or muscle surgery, and brain neurosurgical procedures. Often despite optimal management, there are residual dystonic symptoms. Oral medications are most useful in generalized, hemi-, segmental, and severe cervical dystonia. Focal dystonias are often well controlled with botulinum toxin injections. This approach is less successful in the treatment of widespread dystonic symptoms because toxic doses would be required. Surgery is reserved for medication-refractory dystonia. Physical therapy, occupational therapy and alternative treatments can be combined with pharmacotherapy or surgery. The management of secondary dystonias is similar to that of primary dystonias, except where specific treatment is available for an underlying disorder such as Wilson's disease.

Pharmacotherapy

Dopaminergic agents

Although dopamine dysfunction likely plays a role in the etiology of dystonia, neither dopaminergic agonists nor antagonists are generally effective treatments. An important exception is dopa-responsive dystonia (DRD), in which symptoms are well-controlled with low doses of l-dopa. The response of DRD is also remarkable in that it can be sustained for years without the medication side effects

common in Parkinson's disease patients. Although DRD usually presents in childhood with lower limb involvement, atypical presentations during adulthood have also been described (Steinberger et al., 1998, 1999). Patients with idiopathic dystonia should therefore have a trial of L-dopa treatment (Bandmann et al., 1998; Jankovic, 1998).

Antidopaminergic medications

While dopamine receptor antagonist medications, such as the conventional neuroleptics may be particularly useful in suppressing tardive dystonia (Kang et al., 1986), they may also benefit patients with idiopathic generalized or focal dystonia (Fahn, 1987; Lang, 1988). Their use, however, is often complicated by significant side effects such as parkinsonism, which may require the concomitant use of anticholinergic drugs. Sedation and depression are also common. More seriously, typical neuroleptics can cause neuroleptic malignant syndrome or permanent tardive dyskinesia. The efficacy of newer neuroleptics, such as risperidone, has not yet been fully evaluated. Clozapine, an atypical neuroleptic agent, is useful in treating tardive dystonia (Trugman et al., 1994; Wolf & Mosnaim, 1994; Adityanjee & Estrera, 1996; Raja et al., 1996) and, in a small open-label trial, also helped patients with idiopathic generalized and focal dystonia (Karp et al., 1999).

Approximately 25% of dystonia patients benefit from dopamine depleting agents such as reserpine or tetrabenazine (Greene et al., 1988; Jankovic & Beach, 1997). These drugs, however, can cause intolerable sedation and depression, limiting their use.

Anticholinergic agents

Although their mechanism of action in treating dystonia is not known, anticholinergic medications are often the most effective oral drugs. Approximately 50% of children and 40% of adults with idiopathic dystonia benefit from trihexiphenidyl, although high doses may be required (Fahn, 1983). The use of anticholinergic medication is limited by side effects, many of which are dose-related. Systemic side effects include blurred vision, dry mouth and constipation. The elderly are particularly susceptible to central side effects such as sedation, confusion and short-term memory loss.

Muscle relaxants and antispasmodics

Clonazepam and other benzodiazepines are rarely adequate to treat dystonia when used as sole agents (Greene et al., 1988), however they are often used as adjunctive therapy. There have been no controlled trials of clonazepam as an antidystonic agent, but some anecdotal evidence supports its efficacy in dystonic tremor (Davis et al., 1995). Side effects of benzodiazepines include sedation, depression, and drug dependence.

Muscle relaxants and antispasmodics such as baclofen or possibly tizanidine may also help patients with severe or generalized dystonia. Similar to benzodiazepines, they are not very effective when used alone, but may contribute to dystonia relief when combined with other medications (Greene et al., 1988). Side effects of oral baclofen and tizanidine include sedation, dizziness, weakness, and fatigue.

Baclofen can also be administered as a continuous intrathecal infusion via an implanted pump, which delivers a high dose directly into the spinal fluid, thereby limiting systemic adverse effects. This approach improves spasticity and there is some evidence of efficacy in dystonia, although higher doses may be required (Penn et al., 1995; Albright et al., 1996; Ford et al., 1996, 1998a; Siebner et al., 1998). Ford et al. (1996) retrospectively reviewed 13 patients undergoing baclofen pump implantation. After a mean of 21 months, 55% patients had continued benefit, but only 27% had sustained improved function. Thirty-eight per cent had severe, treatment-related complications. Penn et al. (1995) tried intrathecal baclofen in five patients who had failed oral baclofen. Three patients with generalized or secondary dystonia had mild or brief improvement, while two with focal leg dystonia had marked improvement. Unfortunately, some patients who initially respond become tolerant to intrathecal baclofen and lose benefit over time. Because pump implantation is associated with significant morbidity, including infection, CSF leaks, baclofen over-infusion, meningitis, lethargy and skin erosion, it should only be undertaken if there is a good response to a test drug infusion before pump insertion and after carefully weighing the risks and benefit (Ford et al., 1998a).

Botulinum toxin

Dr Alan Scott pioneered the use of intramuscular injection of small doses of botulinum toxin to treat strabismus (Scott, 1981). Its success in treating ocular disorders associated with muscular overcontraction led to successful trials in dystonia. Botulinum toxin has become the first line of treatment for focal dystonia.

Botulinum toxin is the most potent biological toxin known. It acts presynaptically, blocking the release of acetylcholine at the neuromuscular junction, thereby chemically denervating the muscle. There are seven distinct botulinum toxin serotypes which cleave SNAP-25, a protein needed for acetylcholine vesicle fusion with the presynaptic membrane, synaptobrevin-2/VAMP, a compo-

Table 37.3. Botulinum toxin serotype sites of action

Serotype	Site of Action
Type A	SNAP-25
Type B	VAMP/ synaptobrevin
Type C	Syntaxin 1A, 1B
Type D	SNAP-25; VAMP/synaptobrevin
Type E	SNAP-25
Type F	VAMP/ synaptobrevin
Type G	VAMP/ synaptobrevin

nent of the synaptic vesicle membrane or syntaxin, a plasma membrane-associated protein (Table 37.3) (Tsui, 1996). Since type A has been the only form commercially available until recently, the discussion below centres on clinical experience with this serotype. Type B toxin, recently marketed, differs in dosage and possibly duration of action and frequency of adverse effects. Although type F has been studied in limited clinical trials, it will not be commercially developed.

During preparation for clinical use, botulinum toxin is precipitated with hemaglutinin and other proteins. The weight of the drug therefore does not correlate well with clinical potency. Botulinum toxin dose is, rather, quantified in terms of the mouse unit (MU) defined as the LD50 for 18–20 gram female Swiss-Webster mice injected intraperitoneally. Extrapolating from data on intramuscular injection in monkeys, the human LD50 is estimated to be 40 MU/kg for type A toxin (Scott & Suzuki, 1988). When used to treat dystonia, benefit from botulinum toxin becomes apparent within 2 weeks, peaks between 2 and 6 weeks, and wears off about 10–12 weeks after injection, although the time course varies widely. Regardless of the response duration, repeated injections are needed to maintain benefit. There are presently two commercially available preparations of botulinum toxin type A, Botox®(Allergan, Inc, USA), and Dysport® (Speywood Pharmaceuticals, England). The doses of these two products are not equivalent. Due to differences in preparation, Botox® is approximately 3–5 times as potent as Dysport® (Tsui, 1996). Botulinum toxin can effectively treat all forms of focal dystonia including blepharospasm (Scott et al., 1985), cervical dystonia (Jankovic & Schwartz, 1990), oromandibular dystonia (Hermanowicz & Truong, 1991), and limb dystonia (Karp et al., 1994), but is less successful if large muscles or many body areas are involved.

Up to 10% of patients receiving the original type A botulinum toxin preparations develop clinical resistance due to the formation of blocking antibodies. The incidence of antibody formation in patients receiving the newer toxin preparations is not yet known. Sensitization is especially likely in patients who receive large doses and frequent injections. Patients who lose response to repeated injections should be tested for the presence of antibodies. The currently available immunoassay has high specificity, but variable sensitivity; a rabbit bioassay correlates better with clinical resistance (Borodic et al., 1996). The absence of weakness following a trial injection into a non-dystonic muscle, such as the frontalis, can also be used to demonstrate loss of toxin efficacy (Hanna & Jankovic, 1998).

There is little immune cross-reactivity between botulinum toxin types. Therefore, in the face of antibody development, patients may be switched to another serotype. Resumption of clinical benefit has been demonstrated in patients with antibodies to type A toxin who are switched to type F or type B (Tsui et al., 1995; Borodic et al., 1996; Chen et al., 1998; Sankhla et al., 1998a). Plasmapharesis was used in a single patient with botulinum toxin resistance to decrease antibody burden (Naumann et al., 1998c). The patient was able to benefit from a subsequent injection. Duane et al. (2000) used mycophenolate, an immunosuppressant, to maintain non-detectable antibody titers and botulinum toxin responsivity in three patients with cervical dystonia and previous loss of response. It is not yet known if either of these latter approaches to botulinum-toxin resistant patients will be practical for long-term management.

The most common side effect of botulinum toxin injections is greater weakness than intended in the injected or contiguous muscles. To help avoid spread, small volume injections into multiple sites are preferable to a single large injection. Weakness is always transient, typically resolving in a matter of weeks. Dysfunction due to excessive weakness depends on the location of injection. For example, injection of the anterior neck muscles may lead to dysphagia. Ptosis and diplopia may result from injections around the eyes. Weakness is rarely a problem with lower limb injections. Although electrophysiological changes in neuromuscular junction function in muscles remote to the injection site can be demonstrated (Girlanda et al., 1992), there are few clinically significant systemic side effects. Transient low-grade fever, malaise, fatigability and flu-like symptoms have been noted (Tsui et al., 1986). Other rare adverse reactions to botulinum toxin include allergic reactions and a Guillain–Barré-like syndrome (Haug et al., 1990; LeWitt & Trosch, 1997). Neuromuscular disorders, such as myasthenia gravis, Eaton–Lambert syndrome, amyotrophic lateral sclerosis and the concomitant use of aminoglycosides are relative contraindications to using botulinum toxin. The safety of botulinum toxin in pregnancy and during nursing has not been evaluated.

Neuroablative drugs

Intramuscular injection of phenol permanently destroys the surrounding peripheral nerve and muscle tissue (Gracies et al., 1997). Although phenol is less expensive than botulinum toxin, its use requires additional precautions. Phenol injection is painful. It can only be used on motor nerves, as destruction of sensory nerves can lead to severe, persistent dysesthesia. Two pilot studies showed benefit in three of five patients with torticollis (Massey, 1995; Garcia Ruiz & Sanchez Bernardos, 2000). Although effects were longer lasting than those of botulinum toxin, repeated phenol injections were sometimes necessary.

Doxorubicin is an antimitotic drug that destroys muscle. Wirtschafter et al., injected this medication to treat 18 patients with blepharospasm (Wirtschafter, 1991; Wirtschafter & McLoon, 1998). Of ten patients able to complete a series of up to ten injections, nine had remission lasting longer than one year. Caution is warranted, however, because of significant adverse effects including skin ulceration, pigmentary changes, urticaria and diplopia.

Local anesthesia

Noting the possible sensory contributions to dystonia discussed above, Kaji et al. (1995b) injected lidocaine at doses that blocked muscle spindle afferents. Thirteen of 15 patients had clinical improvement lasting up to 24 hours. Benefit was prolonged up to 21 days if 10% ethanol was injected at the same time. The utility of oral mexiletine for the treatment of dystonia is currently being explored (Ohara et al., 1997, 1998).

Peripheral surgery

Dystonia surgery is usually reserved for those patients who are refractory to medical management, develop antibodies to botulinum toxin, or desire a more permanent solution.

Several techniques have been employed to treat cervical dystonia, including rhizotomy, peripheral denervation of the spinal accessory nerve, ramisectomy and myectomy (Lang, 1998). An early surgical approach combined anterior cervical rhizotomy with selective resection of the spinal accessory nerve (Hamby & Schiffer, 1969; Gauthier et al., 1988). Hernesniemi et al. reported 23 patients with spasmodic torticollis, 11 of whom underwent SCM myotomy and 12 of whom had cervical rhizotomy (Hernesniemi & Keranen, 1990). Only two of the myotomy patients reported subjective improvement lasting up to 4 years after surgery. The remainder of the patients had poor response. Complications of both procedures were significant, including neck and shoulder weakness, neck instability, pain and dysphagia (Horner et al., 1992; Lang, 1998). Myectomy or myotomy of the trapezius muscle similarly achieved only moderate improvement (Hernesniemi & Keranen, 1990; Krauss et al., 1999).

Peripheral denervation and selective sectioning of the spinal accessory nerve are more successful in treating cervical dystonia, but also entail significant complications including sensory loss or hyperesthesia, weakness of the trapezius, and dysphagia (Bertrand et al., 1987; Bertrand, 1993). Ford et al. (1998b) conducted a retrospective study of selective ramisectomy in botulinum toxin-resistant cervical dystonia patients. One-third of 16 patients had at least moderate benefit, but all except one remained unable to work. Given the limited benefit and the high frequency of adverse effects and dystonia recurrence, such procedures should be reserved for patients with severe, refractory cervical dystonia.

Peripheral nerve surgery, such as carpal tunnel release, is generally not helpful in limb dystonia. Ulnar nerve transposition, however, may benefit the occasional patient whose hand dystonia may be secondary to an occult ulnar neuropathy (Ross et al., 1995; Charness et al., 1996). Tendonotomy or even limb amputation have been performed for severe, disabling limb dystonia (Moberg-Wolff, 1998).

Myectomy of the orbicularis oculi and neurectomy of the facial nerve have been used for blepharospasm. Up to 90% of patients initially have improved visual function with such procedures, but blepharospasm recurrence is common. Forty-six per cent of the patients reported by Chapman et al. (1999) who benefited from myectomy required botulinum toxin injections within 5 years of surgery. Side effects of myectomy include forehead numbness, chronic periorbital lymphedema, keratitis, ptosis, and lid retraction (Lang, 1998).

Sectioning of the recurrent laryngeal nerve benefits many patients with adductor spasmodic dysphonia (Schiratzki & Fritzell, 1988; Fritzell et al., 1993). Symptom recurrence, often attributed to nerve fibre regeneration, is common after surgery, and may require an additional procedure or botulinum toxin injections (Ludlow et al., 1990).

Thalamotomy, pallidotomy and deep brain stimulation

Stereotactic neurosurgery was used to treat dystonia as early as the 1950s. In 1979, Cooper reviewed his 20-year experience with thalamotomy for primary and secondary generalized dystonia (Cooper, 1979). Most patients had bilateral procedures. Seventy per cent had subjective improvement. In the series reported by Andrew et al. (1983), 64% of 55 patients with focal or generalized dystonia improved after thalamotomy, but benefit persisted

longer than a year in only 25%. Lesioning the contralateral thalamus was especially helpful in hemidystonia. Bilateral thalamotomy was more successful than unilateral in patients with torticollis. In Tasker's review of 56 patients with lesions in either the ventral intermediate or posterior ventral oral nucleus of the thalamus operated on between 1961 and 1985, 34% of those with secondary dystonia and 32% with primary generalized dystonia had at least 50% improvement in their symptoms (Tasker et al., 1988). Unfortunately, symptoms recurred in most patients following surgery; the longest remission was six years. Thalamotomy complications were frequent and included hemiparesis, numbness, dysarthria and dysphagia. Adverse effects were more common with bilateral procedures. Overall lack of uniformity in technique, target and patient selection led to a wide range of outcomes and the procedures were largely abandoned.

Recent stereotactic advances have led to a revival in neurosurgical approaches to treating dystonia. Surgical targets for dystonia are largely the thalamus and internal globus pallidus (GPi), components of the fronto-basal ganglionic-thalamo-cortical circuit that appears to be involved in the generation of dystonia (Lenz et al., 1998; Vitek, 1998; Vitek et al., 1998a, b).

Initially shown beneficial in Parkinson's disease, pallidotomy has more recently been applied to the treatment of dystonia. Ondo et al. (1998) reported improvement lasting up to 9 months in 8 patients with primary and secondary generalized dystonia. The patients with idiopathic dystonia had greater benefit than those with secondary dystonia. Lozano et al. reported improvement in single cases of patients with idiopathic or symptomatic childhood-onset dystonia with bilateral GPi procedures (Lozano et al., 1997; Lin et al., 1998, 1999; Lai et al., 1999). Complications from pallidotomy including hemiparesis, hemianopsia, dysarthria, dysphagia, cognitive and mood disorders were more common with bilateral procedures.

Ablative techniques such as pallidotomy and thalamotomy leave permanent lesions in the target structure. Many physicians therefore now prefer deep brain stimulation (DBS), which entails the implantation of electrodes in the same brain targets. Activation of the electrodes suppresses neuronal firing. The electrodes are controlled by a stimulator implanted under the skin which can be turned on or off at will. Stimulus parameters can be adjusted to those providing maximal relief of symptoms with minimal adverse effects. If needed, the electrodes and stimulator can be repositioned or removed.

Kumar et al., used bilateral GPi DBS to treat generalized dystonia and found significant improvement that was sustained for at least one year (Kumar et al., 1999). Interestingly, PET scanning 1 year after surgery showed a decrease in previously hyperactive motor cortex activity. Tronnier et al., reported GPi DBS in three patients with generalized dystonia, two with idiopathic and one with secondary dystonia (Tronnier & Fogel, 2000). Both patients with idiopathic dystonia had marked improvement, while the patient with secondary dystonia had only moderate improvement. Symptomatic dystonia may however also respond to DBS. Loher reported a single patient with post-traumatic hemidystonia who had improvement in dystonic symptoms sustained for at least four years (Loher et al., 2000).

Deep brain stimulation can also target the thalamus. A case study of hemidystonia secondary to a thalamic lesion reported marked benefit from ventroposterolateral nucleus stimulation (Sellal et al., 1993). Benabid et al., however, found only mild improvement with nucleus ventralis intermedius stimulation in two patients with idiopathic dystonia (Benabid et al., 1996).

There is more limited experience with stereotactic procedures for focal dystonia. Individual case reports have shown mixed results in treating limb dystonia and blepharospasm with thalamotomy (Goto et al., 1997; Iacono et al., 1998).

Ancillary therapies

Ancillary non-pharmacological, non-surgical therapies such as physical and occupational therapy help many dystonic patients maintain as much function and mobility as possible. Splints and neck braces in patients with limb or cervical involvement may be helpful. Biofeedback benefited a single patient with writer's cramp reported by O'Neill et al. (1997). Specific large muscle EMG biofeedback eased writing in 10 of 13 writer's cramp patients with proximal muscle involvement reported by Deepak et al. (Deepak & Behari, 1999). Biofeedback, acupuncture, massage and other alternative therapies may increase patient comfort, but their use in dystonia has not been studied systematically. Our patients have had mild relief of dystonia-associated pain, but no sustained benefit from acupuncture. Since these therapies may offer some relief to individual patients and since they can be safely combined with medical or surgical treatment, physicians should consider their use.

Conclusions

Dystonia is a hyperkinetic movement disorder characterized by sustained or tremulous twisting or turning postures. Physiologic and pharmacologic data suggest dopaminergic dysfunction of the basal ganglia and

defective cerebral inhibition at several levels. Optimal management takes advantage of oral medications, chemodenervation, and ancillary, non-pharmacologic therapies. Surgery and deep brain stimulation are currently reserved for medically refractory dystonia. As our understanding of the genetic, physiologic, and biochemical bases of dystonia grows, more specific, curative therapies may well become available.

Tourette syndrome

Donna J. Stephenson and Harvey S. Singer

Department of Neurology, Johns Hopkins University, Baltimore, Maryland, USA

In 1885 George Gilles de la Tourette, a Parisian neuropsychiatrist, described nine patients with a chronic disorder characterized by the presence of multiple motor and vocal tics. He recognized many of the salient clinical features of the syndrome that today bears his name, including its onset in childhood, the tendency of tics to wax and wane, and the presence of a variety of comorbid neurobehavioural problems such as obsessive–compulsive symptoms, anxieties, and phobias. Nevertheless, Gilles de la Tourette (1885) and his mentor Charcot attributed this disorder to a form of 'hereditary insanity' and felt it was a degenerative disorder with 'no hope of a complete cure'. Today, Tourette syndrome (TS) is considered a complex neuropsychiatric disorder with a wide spectrum of behavioural manifestations and psychological comorbidities.

Clinical features

Tics are the cardinal feature of TS. They encompass a wide variety of involuntary movements and sounds and are formally defined as involuntary, sudden, rapid, brief, repetitive, non-rhythmic stereotyped movements or vocalizations. Motor tics consist of involuntary movements and are subdivided into simple and complex subtypes. Simple motor tics are movements of single muscle groups. Examples include eye blinking, head jerking, and facial twitching. Complex motor tics consist of a coordinated pattern of movements that may be non-purposeful (facial or body contortions) or appear to be more purposeful but actually serve no purpose (touching, smelling, jumping, obscene gestures). Copropraxia describes the presence of obscene gestures, whereas echopraxia is the imitation of the gestures of others as a tic manifestation. Phonic (vocal) tics involve the production of sound. Simple phonic tics include sniffing, grunting, and throat clearing. Complex phonic tics involve the production of partial or complete words, phrases, or sentences. Palilalia is the repetition of one's own words and echolalia is the repetition of words of another person. Coprolalia is a dramatic type of tic that consists of the involuntary utterance of obscene words and phrases. Although once considered necessary for the diagnosis of TS, coprolalia occurs in only a small minority of patients with TS (Goldenberg et al., 1994). Tics are commonly misdiagnosed as other problems such as chronic respiratory symptoms, visual problems, asthma, allergies and anxiety.

Several features differentiate tics from other movements, including their variability, duration, exacerbating factors, supressibility, diminution during sleep, subjective perceptions and associated disturbances. Tics typically wax and wane in severity and may not be apparent during a routine office visit. As one tic fades, another may take its place. Several tics may occur at one time, or there may be a quiescent period with no tics noticed. A videotape of the movements is often helpful when the diagnosis is in question. Tics evolve over time and vary in their temporal pattern. Often exacerbated by fatigue, anxiety, and stress, tics may lessen during periods of relaxation. Although they are not usually evident on casual observation during sleep, they are present on polysomnograms. Most individuals are able briefly to suppress their tics. During the period of voluntary suppression, patients frequently describe a build-up of 'inner tension' that is relieved when the tic occurs or the effort to suppress the tics is discontinued. Tics are often preceded by a 'feeling' or sensory phenomenon, labeled a premonitory urge or sensory tic.

Infrequently tics can be mistaken for other movements or disorders. Stereotypies are involuntary, patterned, purposeless, repetitive, rhythmic movements that can be simple or complex. They often occur in the setting of

mental retardation, pervasive developmental disorders, and other syndromes of brain dysfunction, but can also occur as a normal developmental feature of childhood. Mannerisms are an individual's embellishments of otherwise intentional normal movement patterns (e.g. baseball player at bat). Compulsions are behaviours that are experienced as alien but necessary to fulfil an inner 'need.' There is significant comorbidity of obsessive–compulsive disorder with TS, and sometimes it may be difficult to distinguish between compulsive movements and tics (Miguel et al., 1995). Seizures are occasionally confused with complex motor tics, but are distinguished from them by non-suppressible prolonged movements, loss of awareness, postictal state, and abnormal electroencephalogram. Myoclonus, tremor, dystonia, and chorea are usually clearly distinguishable from tics by observation. Sydenham's chorea (SC), which occurs in the same age group as TS, can have tics as part of the presenting motor disorder. A wide range of conditions, drugs and toxins have been associated with tics (Table 38.1). A spectrum of movements that are not tics may also occur in patients with TS. For example, it is possible that some movements may be drug-induced (akathisia, dystonia, chorea, parkinsonism) or associated with comorbid conditions such as obsessive–compulsive disorder (OCD), attention deficit hyperactivity disorder (ADHD), or antisocial behaviour (Kompoliti & Goetz, 1998).

Although the diagnosis of a tic disorder typically requires an age of onset before 18 to 21 years, the mean age of onset for tics in TS is between 6 and 7 years (Shapiro & Shapiro, 1982). Seventy-five per cent of patients have symptoms by 11 years. Infrequent cases of adult-onset tics have been reported (Chovinard & Ford, 2000). Often tics come to attention gradually, but on occasion there is an apparently explosive onset (Singer et al., 2000). Boys are three times as likely as girls to be diagnosed with TS. The most common presenting tics are those classified as simple motor tics, e.g. eye blinking, facial and head movements. Vocal tics are uncommon as a presenting symptom (Shapiro & Shapiro, 1982). Tics are usually most severe during late childhood and early adolescence (8 to 12 years). More complex tics, including coprolalia, may develop several years after the initial tic appeared (Shapiro & Shapiro, 1982). About one-third of patients with TS will have complete remission of their tics during late adolescence, and a significant improvement in tic severity is seen in an additional third of patients (Erenberg et al., 1987; Bruun, 1988; Bruun & Budman, 1993). The remaining one-third will continue to have significant tics into adulthood. Childhood tic severity is not a good predictor of tic severity later in life.

Table 38.1. Conditions in which tics may be seen

Chromosomal abnormalities	9p mosaicism
	XXX
	Fragile X
	XXY
	XYY
Developmental disorders	Static encephalopathies
	Cerebral palsy
	Autistic spectrum disorders
Neurodegenerative disorders	Huntington's chorea
	Lesch–Nyhan syndrome
	Hallovorden–Spatz
	Neuroacanthocytosis
	Subacute sclerosing panencephalitis
	Wilson's disease
	Primary dystonia
Drugs	Tardive dyskinesia (tardive Tourette)
	Dopaminergic drugs
	CNS stimulants
	Carbamazepine
	Phenobarbital
	Phenytoin
	Lamotrigine
	Clomipramine
	Wellbutrin

Table 38.2. Diagnostic criteria for Tourette syndrome (TS Classification Group)

(i)	The presence of multiple motor and at least one vocal (phonic) tics
(ii)	A waxing and waning course with tics evolving in a progressive manner
(iii)	The presence of tic symptoms for at least 1 year
(iv)	Onset before age 21
(v)	Absence of a precipitating illness, e.g. encephalitis, stroke or degenerative disease
(vi)	Observation of tics by a knowledgeable individual

Diagnostic criteria

Tic disorders are classified into transient and chronic forms. Transient tic disorder is quite common, affecting 5–24% of school children. By definition, the disorder lasts less than 1 year and typically involves only a few motor or vocal tics. Chronic tic disorders (CTD) are diagnosed after a duration of at least 1 year and include chronic motor tic disorder, chronic vocal tic disorder, Tourette syndrome, and Tourette disorder. To meet the diagnosis of chronic motor (or phonic) tic disorder an individual must have either several motor (or several phonic tics), but not both. Chronic motor/phonic tic disorder is a heritable trait (often occurring in families with TS) and responds similarly to TS therapies. Non-specific tic disorder is a category in the DSM IV that encompasses chronic tic disorders that do not meet criteria for CTD or TS (APA, 1994). Terms often used for this category include Tourettism, Tourette-like, or secondary tic disorder.

Criteria for *Tourette syndrome* have been developed by the Tourette Syndrome Classification Group and are set out in Table 38.2 (1993). The DSM IV criteria for Tourette disorder (TD) are similar to those for TS, with several additions including an 'impairment' criterion requiring that 'marked distress or significant impairment in social, occupational, or other important areas of functioning' be present (APA, 1994). Furthermore, the DSM IV requires an age of onset before 18 years and a tic-free interval that is not longer than 3 months. Coprolalia, echolalia, and copropraxia are not inclusion criteria in either TS or TD, nor is there a requirement for coexisting comorbid features. Since the duration of tics is an essential criterion for tic disorder diagnosis, individuals presenting with a brief history of tics are called 'tic disorder-diagnosis deferred' while awaiting further temporal observation. Accurate distinction of a chronic tic disorder into CTD, TS, or non-specific tic disorder is important for research investigations, but has little relevance for discussion of outcome or treatment.

Rating scales

Although the diagnosis of tics is generally straightforward, it is challenging to rank tics objectively in terms of symptom severity and their impact on quality of life. Several questionnaires and rating scales have been developed for this purpose. Self-report checklists such as the Tourette Syndrome Questionnaire (TSQ) (Jagger et al., 1982) and the Tourette Syndrome Symptom List (TSSL) (Cohen et al., 1980) are easy to administer. The Tourette Syndrome Severity Scale (TSSS) (Shapiro & Shapiro, 1984; Shapiro et al., 1988), the Hopkins Motor and Vocal Tic Scale (Walkup et al., 1992), and the Yale Global Tic Severity Scale (YGTSS) (Lechman et al., 1989) are three different scales that are based on patient observation and historical information. The TSSS and YGTSS take into account not only the phenomenology of tics but also their impact on quality of life. Video-based rating systems offer the advantage of video replay for reliable tic assessment, but may be difficult to obtain in a busy office setting. The Rush Video-based Tic Rating Scale is a 10-minute film protocol that includes near and far body views obtained with the patient relaxed with and without the examiner present. It has recently been suggested that videos obtained in the home environment, rather than the physician's office, may be more accurate indicators of tic severity (Goetz et al., 1999). Other common questionnaires used to assess neuropsychiatric comorbidities include the Child Behaviour Checklist (Achenbach, 1991), Parent Symptom Questionnaire for ADHD (Conners, 1970), and the Child Yale-Brown Obsessive Compulsive Scale (CY-BOCS) (Goodman et al., 1989a, b).

Associated behaviours and psychopathology

Individuals with TS frequently manifest other behavioural and psychiatric problems. The most common comorbidities are attention deficit hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD) and this diagnosis is often referred to as the 'TS triad.' In addition to these typical findings, the scope of comorbidity includes anxiety disorders, bipolar and non-bipolar mood disorders, and episodic behaviour disorder (Table 38.3). In several studies, severely ill patients with tic disorders have been shown to be more impaired by their non-tic

Table 38.3. Frequency of comorbid conditions in TS

OCD	30–70%
ADHD	50–75%
Anxiety disorders	20–80%
Mood disorders	20–80%
Episodic control disorders	25%
Sleep problems	12–62%
Academic difficulties	50%

symptoms than by their tics (Coffey et al., 2000; Robertson, 2000). Rates of comorbidity vary depending on the clinical setting in which individuals are seen, i.e. patients seen in a psychiatry clinic are more likely to be diagnosed with comorbid psychiatric conditions than if they are seen in a neurologist's office.

Obsessive–compulsive disorder

Obsessions are defined as recurrent ideas, thoughts, images, or impulsions that intrude upon conscious thought and are persistent and unwelcome (ego-dystonic). Compulsions are repetitive, seemingly purposeful, behaviours usually performed in response to an obsession, or in accord with certain rules, or in a stereotyped fashion. Obsessive–compulsive behaviours (OCB) become a disorder (OCD) when activities are sufficiently severe to cause marked distress, take up more than 1 hour of the day, or have a significant impact on normal routine, function, social activities, or relationships. The incidence of OCB in TS is typically reported to be from 30–70% (Frankel et al., 1986; Comings & Comings, 1987d; Kano et al., 1997; King et al., 1999). Obsessive behaviours generally emerge several years after the onset of tics, usually during early adolescence. Comorbidity with OCD is associated with a more severe tic phenotype (de Groot et al., 1997). In one study, subjects with more severe tics, notably coprolalia, were more likely to have OCB (Kano et al., 1997). Studies comparing OCB in persons with and without TS have suggested clinical differences. In patients with TS, obsessions may have sexual, violent, religious, and/or aggressive themes, and compulsions include a need for order or routine and a requirement for things to be symmetrical or 'just right.' Hence, compulsions typically involve arranging, ordering, hoarding, touching, tapping, rubbing, counting, checking for errors, and 'evening-up' rituals. In contrast, in pure OCD, obsessions are predominantly concerned with contamination, dirt, germs, being neat and clean, fear of errors, bad happenings, or illness, and compulsions tend to involve cleaning and washing (Robertson, 2000). Biological differences have reported between pure OCD and TS–OCD groups based on levels of CSF oxytocin (Leckman et al., 1994). Patients from both groups, however, have premonitory sensations and urges. Obsessive–compulsive behaviours are associated with a preceding trigger of anxiety or fear rather than a true sensation (itch, tightening, tingling) or a feeling of tension before a tic. After the action is performed, there is a brief relief from the trigger. Despite these differences, it may be difficult to distinguish whether actions such as touching, tapping, and picking represent tics or compulsions. Because of similarities in features, many investigators believe complex tics and compulsions represent a clinical spectrum of symptoms with many overlapping features. The concept that tics and obsessive–compulsive symptoms represent a continuum is supported by evidence that there is a genetic association between OCD and TS. Nevertheless, OCD is etiologically heterogeneous and not all cases are associated with a chronic tic disorder. The pharmacologic treatment of tics and OCD is distinctly different.

Attention deficit hyperactivity disorder (ADHD)

ADHD (see also Chapter 29) is characterized by impulsivity, hyperactivity, and a decreased ability to maintain attention. The disorder is common in TS probands and is reported to affect about 50–75% of referred TS cases (Golden, 1984; Comings & Comings, 1987a; Matthews, 1988; Comings, 1990; Walkup et al., 1999). Often children are diagnosed with ADHD before the onset of tics. ADHD typically begins about age 4–5 years and in TS patients, usually precedes the onset of tics by 2 to 3 years. Its appearance is not associated with the concurrent severity of tics, although ADHD is common in patients with more severe tic symptoms. Associated ADHD appears to be the most important contributing factor to poor school performance in a child with TS (Park et al., 1993; Abwender et al., 1996). Comparisons between children with ADHD-only and TS+ADHD have suggested that mood and anxiety problems were associated with ADHD and not the presence of tics (Spencer et al., 1998). Investigators have also suggested that some of the apparent increases in personality disorders in adults with TS are secondary to the presence of childhood ADHD (Robertson, 2000). Impairments in TS patients with ADHD appear to differ quantitatively and qualitatively from those observed in patients with primary ADHD without tics: those with primary ADHD have significantly more impairment on tests that measure visual search and mental flexibility, have slower reaction times, and make fewer correct

responses on both simple and choice reaction time tasks (Silverstein et al., 1995). Whether a genetic relationship exists between TS and ADHD remains controversial. Pauls and colleagues have suggested that there may be two distinct populations of TS patients with comorbid ADHD: (i) those with onset of ADHD before the onset of tics; and (ii) those, possibly genetically associated, with onset after, or in concert with, the onset of tics (Pauls et al., 1993).

Other psychopathologies

Several studies have shown an increased incidence of anxiety and depression in patients with TS (Comings & Comings, 1987a, b; Robertson, 1989; Coffey et al., 1992; Robertson et al., 1993). Although the incidence of generalized anxiety disorder in TS subjects (range 19 to 80%) exceeds that in controls, some investigators believe that symptoms, especially separation anxiety, may be secondary to moderate or severe TS (Coffey et al., 1992; Robertson, 2000). TS patients also have a higher prevalence of depression than do controls. Some investigators believe that depression correlates positively with earlier onset and longer duration of tics, whereas others find no correlations between depression and the number of tics. Genetic studies show that major depressive disorder is genetic but that TS and this disorder are unrelated (Pauls et al., 1994). Personality disorders are more common in TS, but this increase has been attributed to long-term outcome of childhood ADHD (Robertson et al., 1997). Sudden, unpredictable, explosive outbursts of anger, irritability, temper, and aggression have been reported in about 25% of clinically referred patients with tic disorders (Comings et al., 1989; Wand et al., 1993; Budman et al., 2000). These explosive outbursts occur more frequently in children and resemble intermittent explosive disorder. Their presence appears to correlate highly with the combined comorbidity of ADHD and OCD (Santangelo et al., 1994; Park et al., 1996). A variety of other behavioural/emotional problems have been identified, including aggressiveness, immaturity, withdrawal, conduct disorder, oppositional defiant disorder, and somatic complaints (Singer & Rosenberg, 1989; Walkup et al., 1992, 1995). Whether these disorders are related to tic severity, are secondary to the presence of ADHD, or are the result of having a stigmatizing disorder is unclear.

Sleep problems

Sleep disturbances, including somnambulism (sleep walking), night terrors, nightmares, talking in sleep, restlessness, and difficulty falling asleep, have been reported in 12 to 62% of patients with TS (Comings & Comings, 1987f; Allen et al., 1992). Studies with polysomnographs have revealed decreased rapid eye movement sleep, but have not shown consistent abnormalities in delta sleep (Mendelson et al., 1980; Glaze et al., 1983). The use of sleep behaviour questionnaires has confirmed that patients with TS have an increased incidence of insomnia, dreams, required bedtime rituals, and parasomnias (Allen et al., 1992). This study found that the incidence of sleep problems was significantly increased in patients with comorbid ADHD, however, suggesting that ADHD may be a significant determinant for sleep problems in TS. Overlapping clinical and pathologic features have been proposed to exist between individuals with TS and the restless legs syndrome. Both groups have excess periodic leg and arm movements during sleep (Voderholzer et al., 1997).

Academic difficulties

Several studies have shown that learning problems are common in children with TS (Hagin & Kugler, 1988; Burd et al., 1992) and that TS is more prevalent in children in special education classes (Comings et al., 1990; Kurlan et al., 1994b). Individuals with TS typically have normal levels of intellectual functioning, although there may be a discrepancy between performance and verbal IQ, an impairment of visual perceptual achievement, or a decrease in visual–motor skills. Learning difficulties have been reported in up to 51% of children with TS, but are most common in those with both TS and ADHD. Several studies have identified differences in neuropsychological and neuromotor capabilities between children with TS only and those with TS + ADHD. For example, children with TS only had higher full scale IQ scores than did children with TS + ADHD (Faraone et al., 1993; Schuerholz et al., 1996). In a study designed to determine whether a discrepancy-based learning disability was associated with a specific subset of TS patients, results showed that comorbid ADHD accounted for the increased incidence of learning disabilities (Schuerholz et al., 1996). Children without ADHD also performed better on tests of executive function. Nevertheless, individuals with TS, irrespective of the presence of ADHD, often require extra time to complete their assignments. This difficulty has been associated, in part, with a linguistic executive dysfunction that affects the speed and efficiency of memory search. For example, a group of bright children with TS only and no learning disabilities had slowed responses on measures of executive function, especially those that were timed. Most notable was slowing on the Letter Word Fluency Task, which

requires the ability to search memory efficiently. TS boys, compared to age-matched controls, had slowed reaction time during a continuous performance test (Shucard et al., 1997), but the effect of comorbid variables was not measured. In patients with TS without ADHD, school difficulties may be related to tic severity, the use of tic-suppressing medicine, executive dysfunction, a direct consequence of having a stigmatizing disorder, or other psychopathologies (Singer et al., 1995).

Epidemiology

Tourette syndrome occurs worldwide, with increasing evidence of common features in all cultures and races. The true incidence and prevalence of TS have yet to be accurately determined. Among the multiple factors accounting for inconclusive estimates are the following: mildly affected individuals do not seek medical care; the diagnostic criteria have evolved over time; TS symptoms vary in their intensity and severity; misdiagnosis of TS by practitioners; and estimates are influenced by selection and attribution bias. In a retrospective review of medical records in Rochester, Minnesota over 12 years, the calculated incidence from identified cases was 0.46 per 100 000 or 1000 new cases annually in the United States (Lucas et al., 1982). The estimated prevalence of TS has varied greatly in individual studies; estimates of 49.5 (65), 23 (72), 5.2 (73), 2.9 (9), and 0.7 (10) per 10 000 in school age children and adolescents. More recent studies, however, have suggested a prevalence rate of approximately 1% of school-age children. A study of 13- to 14-year-old mainstream British students revealed a prevalence of 299 per 10 000 children with mild to severe tics. The validity of this study has been questioned, however, because this population was not reassessed or formally diagnosed by an expert (Shapiro & Shapiro, 1982). In Houston, Texas, investigators found a prevalence rate of definite TS or TS by history in 0.7% of students (Kadesjö & Gillberg, 2000), in Sweden the prevalence was estimated at up to 1.1% of school-aged children (Hanna et al., 1999) and in Rochester NY up to 3.5% of school-aged children (Kinlan et al., 2001). All authors suggest that mild TS is more common than was previously recognized. In adult populations, prevalence estimates have been much lower (Coffey et al., 1992), presumably because the natural history is that tics become less severe after adolescence. Investigators have also shown that children in special school populations have an increased prevalence of tic disorders (Comings et al., 1990), as do children with autism, Asperger syndrome, and autistic spectrum disorders (Baron-Cohen et al., 1999).

Genetics

Although Georges Gilles de la Tourette suggested that TS is an inherited disorder, the precise pattern of transmission and the identification of the gene remain elusive. Strong support for a genetic disorder is provided by studies of monozygotic twins, which show an 86% concordance rate with TS as compared to 20% in dizygotic twins (Price et al., 1985; Hyde et al., 1992). Earlier proposals suggesting a sex-influenced autosomal dominant role of inheritance with variable expressivity as either TS, chronic tic disorder, or OCD (Pauls & Leckman, 1986) have been seriously questioned. Other investigators have proposed hypotheses of a single major locus in combination with a multifactorial background, i.e. either additional genes or environmental factors (Walkup et al., 1996). The search for a genetic site is being actively pursued, but to date no reproducible locus has been identified. In a systematic genome scan of 76 affected sib-pair families with a total of 110 sib pairs, the multipoint maximum likelihood scores for two regions (4q and 8p) showed a trend, but did not reach acceptable statistical significance (The Tourette Syndrome Association, 1999). Linkage analysis in a large French Canadian family showed a LOD score of 3.24 for chromosome 11 (11q23), which replicated findings described in a South African population (Simonic et al., 1998; Merette et al., 2000). A region on chromosome 19p has also been implicated in a genome scan of multigenerational families and three of five patients with a fragile site at 16q22–23.37 had TS. Linkage studies to candidate genes associated with specific synaptic markers, including dopamine D1–5 receptors, have not found a consistent linkage to a large variety of factors (Barr et al., 1997, 1999a; Brett et al., 1997; Hebebrand et al., 1997; Devor et al., 1998; Thompson et al., 1998; Stober et al., 1999). Several variables have been proposed to explain the unsuccessful genome search, including problems defining the phenotype, inaccurate diagnostic assessment, improper ascertainment methods, and problems with genetic modelling and data analysis. Nevertheless, some investigators have suggested that TS is not genetic, but rather represents a common disorder in the general population (Kurlan, 1994). Further complicating our understanding of TS genetics is the controversial issue of genomic imprinting (sex of the transmitting parent may affect the clinical phenotype) (Furtado & Suchowersky, 1994; Lichter et al., 1995; Eapen et al., 1997) and bilineal transmission (genetic contribution from both sides of the family (Comings et al., 1989; Kurlan et al., 1994a; McMahon et al., 1996; Hanna et al., 1999; Lichter et al., 1999). For example, it has been shown that paternal transmission of the affected gene leads to increased vocal

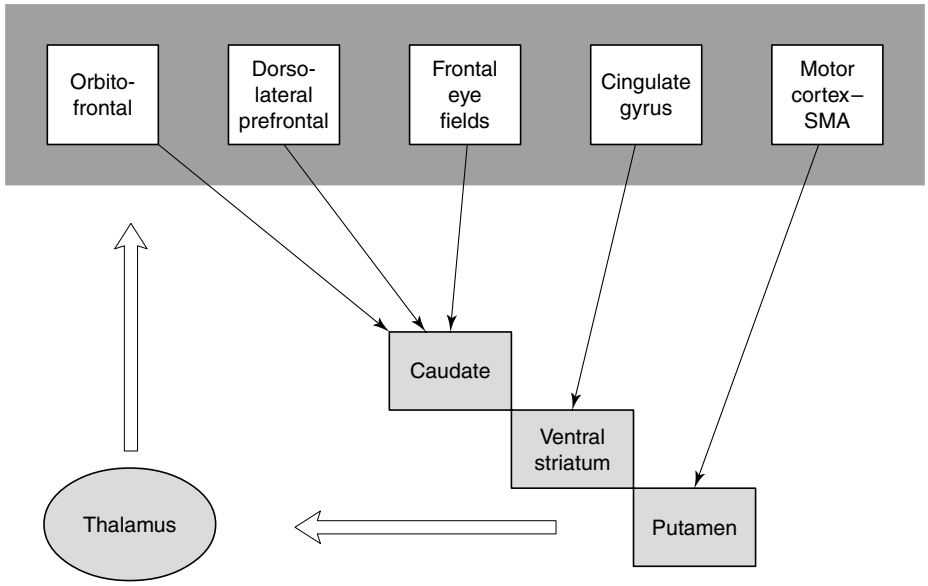

Fig. 38.1. Postulated frontal–subcortical pathways involved in Tourette syndrome.

tics and ADHD, whereas maternal transmission is linked to greater motor tic complexity and obsessive compulsive symptoms (Lichter et al., 1995). Additionally, one study estimates bilineality for tics, OCD, and ADHD to be 26% in TS families, further complicating interpretation of genetic data (Hanna et al., 1999). Studies also emphasize that factors other than genetic dose effects, such as genetic heterogeneity, epigenetic factors, and gene-environment interactions, may play an important role in determining tic severity in TS. A hypothesized role for environmental factors, especially infections, in the presentation or exacerbation of tics and OCD (Swedo et al., 1998) remains a controversial issue awaiting more definitive evidence (Kurlan, 1998).

Pathophysiology

Neuroanatomy

The exact neuroanatomic localization of TS remains unknown. Published postmortem studies are limited to seven cases; one suggested arrested development of the striatum and four showed a reduction in dynorphin-like immunoreactivity in the striatal projections to the globus pallidus and ventral pallidum (Richardson, 1982; Haber & Wolfer, 1992). Routine non-invasive neuroradiographic studies (CT and MRI) have identified only isolated defects that are considered to be incidental non-specific findings, unrelated to the basic pathology. Nevertheless, several publications have described localized lesions in the striatum, globus pallidus, and gyrus rectus of the left frontal lobe associated with clinical tics (Singer & Walkup, 1991). Neuropathologic and radiographic investigations have shown abnormalities in persons with secondary tics (Tourettism). For example, in a postmortem study of encephalitis lethargica, subjects with acquired tics had an array of small focal lesions in the central grey matter that extended into the midbrain tegmentum (Wohlfart et al., 1961; Sacks, 1982). Tourette-like symptoms also appear in association with a variety of acute and chronic neurologic disorders (see Table 38.1).

Although the exact neuroanatomic localization for tics has yet to be established, a series of parallel frontal subcortical circuits that link specific regions of the frontal cortex to subcortical structures (Alexander et al., 1986; Alexander & Crutcher, 1990; Cummings, 1993) provide a unifying framework for understanding the interconnected neurobiologic relationships that exist between ADHD and movement disorders (see Fig. 38.1). In brief, the striatum is distinguished by the presence of several structurally and functionally distinct subcortical and cortical circuits that are shared by the frontal lobe, striatum, globus pallidus, and thalamus. Each of these circuits has been associated with a behavioural abnormality seen in TS. The motor circuit, a potential site for generation of tics, originates primarily from the supplementary motor cortex and projects to the putamen in a somatotopic distribution. The

oculomotor circuit, a potential site of origin for ocular tics, begins primarily in the frontal eye fields and connects to the central region of the caudate. The dorsolateral prefrontal circuit links Brodmann's areas 9 and 10 with the dorsolateral head of the caudate and appears to be involved with executive function and motor planning. Dysfunction of this pathway could lead to attentional difficulties such as ADHD. The lateral orbitofrontal circuit originates in the inferolateral prefrontal cortex and projects to the ventromedial caudate. Orbitofrontal injury is associated with OCD, personality changes, disinhibition, irritability and mania. Lastly, the anterior cingulate circuit arises in the anterior cingulate gyrus and projects to the ventral striatum (olfactory tubercle, nucleus accumbens, and ventral medial aspect of the caudate and putamen) which receives additional input from the amygdala, hippocampus, and entorhinal and perirhinal cortex. Mutism, apathy and OCD are associated with this circuit. An important aspect of a circuit hypothesis is that lesions in one part (e.g. globus pallidus) of the circuit could produce signs and symptoms similar to those caused by a lesion in another region of the circuit (e.g. prefrontal cortex).

Direct evidence for pathophysiologic involvement of frontal subcortical circuits, especially the basal ganglia, in TS is derived from volumetric MRI studies (Peterson et al., 1993; Singer et al., 1993), area measurements of the corpus callosum (Peterson et al., 1993; Baumgartner et al., 1996), functional imaging of glucose metabolism and blood flow (Riddle et al., 1992; Baxter & Guse, 1993), oculomotor paradigms (Farber et al., 1999; Dursun et al., 2000; Mastofsky et al., 2001), and neuroimaging studies in subjects with ADHD and OCD (Aylward et al., 1996; Trivedi, 1996). For example, volumetric MRI studies in TS have shown significant differences in the symmetry of the putamen and lenticular region in boys (Singer et al., 1993) and a reduction in the size of these structures in adults (Peterson et al., 1993). On the basis of a quantitative MRI study of monozygotic twins, other investigators have suggested that, rather than an abnormality of the lenticular region, the caudate may be the important site (Hyde et al., 1995). A recent study in girls, however, showed no significant differences in basal ganglia or corpus callosum size between those with and without TS, suggesting that there may be gender differences in the neurobiologic manifestations of TS (Mostofsky et al., 1999; Zimmerman et al., 2000). Functional imaging studies have identified abnormalities in glucose metabolism and perfusion of the basal ganglia, especially on the left (Riddle et al., 1992; Stoetter et al., 1992; Baxter & Guse, 1993). In the HMPAO SPECT study of Riddle et al. (1992), TS was associated with a 4% reduction of blood flow to the left putamen and globus pallidus. In a small number of TS patients, event-related $[^{15}O]H_2O$ PET combined with time-synchronized audio and videotaping, identified aberrant activity in interrelated sensorimotor, language, executive, and paralimbic circuits (Stern et al., 2000). Transcranial magnetic stimulation (TMS) in children with tic disorders identified a shortened cortical silent period (Ziemann et al., 1997), suggesting a reduced motor inhibition believed to be at the level of the basal ganglia. In preliminary functional MRI studies, Peterson et al. (1998) compared images acquired during periods of voluntary tic suppression with those acquired when subjects were allowed spontaneous expression of their tics. Significant changes in signal intensity were seen in the basal ganglia and thalamus, as well as in connected cortical regions. Lastly, functional MRI imaging of five patients with TS during finger tapping showed an increased area of cerebral activation in both sensorimotor cortex and supplementary motor area as compared to these areas in healthy subjects (Biswal et al., 1990).

Neurochemistry

The distribution of classical neurotransmitters within the basal ganglia's frontal–subcortical circuits raises the possibility that a variety of transmitters are involved in the pathobiology of TS (Graybiel, 1990; Graybiel et al., 1994). In general, current hypotheses are based on extrapolations from clinical trials evaluating the response to specific medications; from studies of CSF, blood, and urine in relatively small numbers of patients; from SPECT and PET investigations; and from neurochemical assays on a limited number of postmortem brain tissues (Singer, 1997; Singer & Wendlandt, 2001). Genetic linkage analyses have also been performed in an attempt to identify specific candidate genes that are associated with components of neurotransmission. To date, the dopaminergic, GABAergic, cholinergic, serotoninergic, noradrenergic, and opioid systems have all been implicated. Which, if any, of these systems is the primary pathologic factor remains to be determined. Since many transmitter systems are interrelated in the production of complex actions, it is indeed possible, if not probable, that imbalances exist among several transmitter systems. Moreover, investigators must vigorously pursue mechanisms that could unify findings of alterations within multiple transmitter systems, i.e. such possibilities as second-messenger pathways, vesicle release proteins, channel abnormalities, or synaptic membrane dysfunction. Furthermore, any hypotheses about specific neuro-

transmitter deficiencies must account for variability in tic manifestations, fluctuating symptoms, and potential resolution in adulthood.

Neurochemical studies on postmortem tissues are limited to four TS cases. Singer et al. (1991) found a significant elevation of striatal [^{3}H]mazindol binding suggesting an elevation of dopamine transporter sites. Additionally a reduction in cyclic AMP was observed in cerebral cortex (Singer et al., 1990), but subsequent investigations identified no specific abnormality within several second messenger pathways (Singer et al., 1995a). Anderson et al. (1992) evaluating the same cases, compared levels of catecholamines, serotonin (5-HT), amino acids, and metabolites in 13 brain regions. Results showed reductions of 5-HT, tryptophan, and 5-hydroxyindoleacetic acid in subcortical structures, decreased glutamate levels in the globus pallidus and substantia nigra pars reticulata, and diminished glycine levels in substantia nigra pars reticulata. These data would suggest the possibility of altered serotoninergic transmission in the striatum and a reduced influence of glutamate in subthalamic efferent pathways. Because of the small number of available postmortem samples, emphasis has shifted to studies by in vivo neurochemical imaging. Dopaminergic hypotheses, including abnormalities of both pre- and postsynaptic function (supersensitive postsynaptic dopamine receptors, dopamine hyperinnervation, abnormal presynaptic function, or excessive release of dopamine) have been studied by PET and SPECT techniques. Overall, studies of D2 dopamine receptors have not consistently shown significant differences between TS patients and controls. Nevertheless, several investigations have supported the hypothesis that the dopamine receptor is involved in the neurobiology of TS (Wolf et al., 1996; Wong et al., 1997; Muller-Vahl et al., 2000). Similarly, attempts to provide support for a postulated dopamine hyperinnervation hypothesis by PET or SPECT binding have resulted in contradictory reports (Maison et al., 1995; Heinz et al., 1998). Studies evaluating dorsal striatal dopaminergic innervation by use of in vivo measures of vesicular monoamine transporter type 2 (VMAT2) binding, however, do not support the concept of increased striatal innervation. The possibility that deficits in a variety of presynaptic dopamine functional elements play a role has been supported by higher accumulations of [^{18}F]fluorodopa in the left caudate nucleus and right midbrain compared with levels in control subjects (Ernst et al., 1999). Lastly, increased intrasynaptic dopamine release from the putamen has been proposed, based on kinetic modelling of [^{11}C]raclopride binding after pretreatment with a central stimulant (Singer et al., in press). A [^{125}I]-CIT SPECT binding study has reported a negative correlation between overall tic severity and binding in the midbrain (serotoninergic) and thalamus (serotonin or noradrenergic) (Heinz et al., 1998). The authors suggest that serotoninergic transmission is a modifying, but not causal, factor in the pathogenesis of tics. In summary, available data have not confirmed a definite consistent abnormality of synaptic neurotransmission.

Neuroimmunology

Recently it has been proposed that TS, like Sydenham's chorea (SC), may be part of an immune-mediated neurologic response to a Group AB-hemolytic streptococcus infection (GABHS). SC is a major manifestation of rheumatic fever, along with carditis, migratory polyarthritis, erythema marginatum, and subcutaneous nodules. Typically, systemic manifestations of rheumatic fever occur 1–5 weeks after a GABHS pharyngitis, whereas chorea, which may be the sole manifestation, occurs from 2–6 months after antecedent infection. The pathophysiology responsible for the chorea has been speculated to be autoimmune, probably due to 'molecular mimicry,' i.e. shared antigens by the bacteria and host organs (Cairns, 1988; Stollerman, 1991).

The proposed spectrum of neurobehavioural disorders associated with GABHS infection has been expanded to include some children with TS and/or OCD termed 'pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection' (PANDAS) (Swedo et al., 1997, 1998). A possible association between GABHS and tics was initially proposed in case reports describing the explosive onset of tics after a preceding streptococcal infection (Kondo & Kabasawa, 1978; Matarazzo, 1992; Kiessling et al., 1993). More recently, Swedo and colleagues proposed diagnostic criteria that include: the presence of OCD and/or tic disorder; prepubertal age at onset; sudden, 'explosive' onset of symptoms and/or a course of sudden exacerbations and remissions; a temporal relationship between symptoms and GABHS; and the presence of neurologic abnormalities, including hyperactivity and choreiform movements. Volumetric MRI analysis in 34 children with PANDAS showed that the average size of the caudate, putamen, and globus pallidus, but not thalamus or total cerebrum, was significantly greater in the affected group than in 82 healthy children (Gredd et al., 2000). In a study of first degree relatives of children with PANDAS, the rates of tic disorders and OCD were similar to those published for tic disorders

and OCD (Lougee et al., 2000). The authors suggest that this supports the hypothesis of an environmental trigger in a genetically vulnerable population. An immune-mediated mechanism involving molecular mimicry has been proposed for PANDAS (i.e. antibodies produced against GABHS cross-react with neuronal tissue in specific brain regions), similar to the Sydenham's chorea model. Indirect support for this hypothesis is derived from the response of a small number of patients with PANDAS to two forms of immunotherapy, intravenous immunoglobulin (IVIG) and plasmapheresis (PEX) (Perlmutter et al., 1999); the documentation of antineuronal antibodies in patients with TS (Singer et al., 1998); and the development of dyskinesias (paw- and floor-licking, head- and paw-shaking) and phonic utterances in rodents after the microinfusion of dilute IgG from TS subjects into their striatum (Hallett et al., 2000).

The existence of PANDAS, however, remains controversial (Kurlan, 1998). For example, no prospective epidemiologic study has confirmed that an antecedent GABHS infection is specifically associated with either the onset or exacerbation of tic disorders or OCD. Subjects with PANDAS lack other stigmata of streptococcal infection, such as rash, arthritis, or valve disease. Diagnostic criteria established for PANDAS are also potentially confounded by the phenotypic variability commonly associated with tic disorders: a normal fluctuation in the frequency and severity of symptoms; exacerbation of tics by stress, anxiety, fatigue, and illness; the occurrence of 'sudden, abrupt' onset and/or recurrence of tics in non-PANDAS subjects (Singer et al., 2000); a variable response to pharmacotherapy; and the lack of a precise definition for choreiform movements. Additionally, longitudinal laboratory data, rather than studies that utilize only a throat culture or only a single antistreptolysin O (ASO) or antideoxyribonuclease B titre, are necessary to confirm the presence of a prior GABHS infection.

Evidence to support an immune-mediated hypothesis for PANDAS also remains largely circumstantial. For example, although plasmapheresis was claimed be beneficial, the therapeutic response did not parallel to the rate of antibody removal, it is unclear how peripheral changes affect events across the blood–brain barrier, and the mechanism for the beneficial response remains undetermined. Additionally, despite reported higher antineuronal antibody values in children with neurobehavioural problems and/or movement disorders including tics (Husby et al., 1976; Kiessling et al., 1992; Singer et al., 1998), the sensitivity and specificity of these studies remain a major issue. Antineuronal antibodies are present in control groups and Western blot analyses suggest that there are multiple differences in antibody repertoires in children with TS (Wendlaudt et al., 2001). Longitudinal studies will be required to clarify the current controversies.

Treatment

Treatment of TS must take into account not only the severity of tics but the significance of comorbid academic, social, and neuropsychiatric problems. The symptom causing the most difficulty for the patient must be targeted first. The mere presence of tics does not in itself justify initiation of pharmacotherapy (Table 38.4). Medications should be targeted and reserved only for those problems that are functionally disabling and not remediable by non-drug interventions.

Patients with tics that are not causing any psychosocial or physical problems (i.e. no loss of self-esteem, no peer problems, no difficulty participating in academic, social, and after-school activities, no disruption of classroom setting, and no musculoskeletal problems) should be counseled and observed for the progression of symptoms. A variety of behavioural treatments including conditioning techniques, relaxation training, biofeedback, and hypnosis have been utilized as alternative therapeutic approaches for tics with variable short- and long-term success (Turpin, 1983; Bergin et al., 1998).

Tic-suppressing medications can be broadly divided into a 'mild' (non-neuroleptic) group and the neuroleptics (typical or atypical). Initial treatment of tics generally begins with non-neuroleptics. This category includes clonidine, guanfacine, baclofen and clonazepam. Clonidine can be especially effective in individuals with relatively mild tics who also have ADHD with aggressive features or poor impulse control. There is some suggestion that motor tics are more effectively suppressed with clonidine than are vocal tics (Leckman et al., 1985, 1991; Goetz et al., 1987). For tics alone, a BID dosing schedule is often adequate. For patients with comorbid ADHD, a QID schedule is often necessary for a consistent therapeutic effect. Common side effects include drowsiness, dry mouth, itchy eyes, postural hypotension, bradycardia and headaches. Clonidine should be tapered gradually to avoid rebound tic exacerbation and hypertension.

Individuals who fail initial therapy or who present with severe tics may benefit from neuroleptic or atypical neuroleptic medications. Neuroleptics, D2 dopamine receptor antagonists, are the most effective tic-suppressing agents (about 70–80% effective), but side effects may limit their usefulness. Side effects include weight gain, dysphoria, movement abnormalities (acute dystonic reactions, bradykinesia, akathisia, tardive and withdrawal dyskinesias), depression, and poor school performance. Haloperidol has historically been the most frequently used neuroleptic in this class, but more recently it has been replaced by pimozide because of greater tolerability (Shapiro et al., 1989; Sallee et al., 1997). Before initiating treatment with pimozide, an ECG should be obtained in order to identify a prolonged Q–T_c interval, a contraindicating factor. Other neuroleptics used in TS include fluphenazine and trifluoperazine.

The atypical neuroleptics were designed to decrease the extrapyramidal side effects common to most D2 receptor antagonists. As a group, risperidone, olanzapine, ziprasidone, clozapine, and quetiapine all have greater affinity for 5-HT2 (serotonin) receptors than for D2 receptors. Of these, risperidone and olanzapine have been used most extensively in TS. Risperidone may be most beneficial when tics occur with comorbid OCD (Robertson et al., 1996). A recent study has identified equal efficacy in the suppression of tics with use of either risperidone or pimozide (Beuggeman et al., 2001). In several studies olanzapine has been shown to be generally well tolerated and beneficial for tics (Bengi & Semerci, 2000; Onofrj et al., 2000; Stamenkovic et al., 2000).

Several additional pharmacotherapies have been proposed as tic-suppressing agents. Tetrabenazine, a dopamine antagonist that depletes presynaptic storage of dopamine and blocks postsynaptic dopamine receptors, has effectively suppressed tics (Jankovic et al., 1984; Jankovic & Beach, 1997). Dopamine agonists, such as pergolide, somewhat unexpectedly improved tics at approximately one-tenth the dose used for treatment of Parkinson's disease (Lipinski et al., 1997). Nicotine, in gum or patch form, has been shown to have brief beneficial effects when used in conjunction with neuroleptics (Dursun & Reveley, 1997; Sanberg et al., 1988, 1989, 1997). In uncontrolled trials, marijuana and delta-9-tetrahydrocannabinol, the major psychoactive component of marijuana, have been reported to be beneficial (Muller-Vahl et al., 1999, 2000). Botulinum toxin, which reduces muscle activity by inhibiting acetylcholine release at neuromuscular junctions, has been shown not to only reduce tics but also the premonitory urge associated with the tics (Kwak et al., 2000). Suggestions that Botox® produces a universal improvement in simple tics (Trimble et al., 1998; Awaad, 1999) have not been supported in all studies (Marras et al., 2000). Several patients with coprolalia have been successfully treated with injections either into a single vocal cord or both thyroarytenoid muscles (Scott et al., 1996; Trimble et al., 1998). Penicillin and immune therapies including IVIG and plasmapheresis for PANDAS are currently under investigation. Neurosurgical interventions for severe intractable tics are rarely indicated. Procedures used have included focal lesions of frontal, cingulate, thalamic, and cerebellar areas (Rauch et al., 1995). Thalamic deep brain stimulation, a modern stereotactic treatment proposed for use in other movement disorders, has been suggested as a potential therapy for the control of tics.

ADHD

Although psychostimulant medications are generally regarded as the treatment of choice for ADHD, their use in children with TS was controversial because of their proposed potential to provoke or intensify tics in a substantial minority. Several new reports providing additional information on the question of the role of stimulants in worsening tic disorders can be summarized as follows: there is strong evidence that stimulants have a beneficial effect on ADHD and, in most children receiving low-moderate doses of methylphenidate, there appears to be no clinically significant effect on tics (Lowe et al., 1982; Castellanos et al., 1997; Gadow et al., 1999; Nolan et al., 1999; Law & Schachar, 1999). Tics may fluctuate but usually do not require pharmacologic adjustments. Other medications suggested for the treatment of ADHD symptoms in children with TS include clonidine, guanfacine, desipramine, deprenyl, and nortriptyline. In the occasional situation where a stimulant is required for attendance in school or

performance at work and tics remain constant, stimulants and tic-suppressing medications are given simultaneously.

OCD

Over the past decade the treatment of OCD has expanded, with the addition of a variety of serotonin reuptake inhibitor antidepressants including fluoxetine, fluvoxamine, clomipramine, paroxetine, and sertraline. These medications, also effective in anxiety disorders, can sometimes be helpful in addressing the stress associated with the stigma of a chronic tic disorder.

In conclusion, although much is known about TS and related disorders, much remains to be done. Tourette syndrome is a chronic neuropsychiatric disorder that has been recognized for well over a century. Although defined by the presence of vocal and motor tics, comorbidities, such as OCD and ADHD, often cause more significant impairment than the tics. TS is considered to be an inherited disorder, although the precise pattern of transmission and the identification of the gene remains elusive. Genetic heterogeneity, epigenetic factors and gene–environmental interactions may play an important role in phenotypic expression. Evidence supports involvement of frontal–subcortical circuits and synaptic neurotransmission. Nevertheless, the precise localization and specific subcellular mechanism have yet to be determined. Pharmacotherapy is available for tic suppression, but is strictly symptomatic, not universally effective, and often limited by side effects.

Cerebral palsy

Alexander H. Hoon, Jr[1] and Michael V. Johnston[2]

[1] Department of Pediatrics, Johns Hopkins University School of Medicine and Kennedy Krieger Institute, Baltimore, MD, USA
[2] Departments of Neurology and of Pediatrics, Johns Hopkins University School of Medicine and Kennedy Krieger Institute, Baltimore, MD, USA

Cerebral palsy (CP) is a clinical diagnostic term referring to a group of upper motor neuron syndromes secondary to disorders of early brain development (Johnston, 1998a). In addition to primary impairments in motor function, there may be associated problems with speech, cognition, epilepsy, visual impairment seizures and orthopedic deformities. Although CP is considered non-progressive, neurological findings may change or progress over time (Saint Hilaire et al., 1991; Scott & Jankovic, 1996).

CP is the most prevalent and costly form of chronic motor disability that begins in childhood. Although comprehensive longitudinal studies are limited, the majority of affected children live into adulthood (Crichton et al., 1995). In the United States, financial costs of care are estimated to be in the billions of dollars (Kuban & Leviton, 1994). The non-economic impact on affected individuals and their families is substantial (Murphy et al., 2000).

At the end of the nineteenth century, William Osler published his lectures on *The Cerebral Palsies of Children,* with a CP classification based on neuroanatomy, etiology and extremity involvement. 'Dividing the motor path into an upper corticospinal segment, extending from the cells of the cortex to the grey matter of the cord, and a lower spinomuscular, extending from the ganglia of the anterior horns to the motorial end plates, the palsies which I propose to consider have their anatomical seat in the former, and may result from a destructive lesion of the motor centres, or of the pyramidal tract, in hemisphere, internal capsule, crus or pons' (Osler, 1987). The current concept of CP is built on Osler's description, using imaging techniques, molecular genetic probes and measurement tools to further etiological understanding, improve classification and refine treatment options (Hoon & Melhem, 2000; Brunstrom et al., 2000).

Several strongly conflicting theories of causation have been proposed. In the mid-1800s, Sir William Little suggested that most CP was related to difficulties with delivery, a view which has had legal ramifications extending to the present time (Little, 1861). Approximately 50 years later, Sigmund Freud offered an alternative hypothesis that cerebral palsy reflected 'symptoms of deeper underlying influences which have dominated the development of the fetus' (Freud, 1968). Recent epidemiological studies indicate that most cases are related to prenatal disorders of genetic and environmental origin (Hagberg et al., 1996; Palmer et al., 1995). A small but distinguishable group results from perinatal hypoxic–ischemic insults, and a third group from injury in early childhood.

Modern neuroimaging techniques, including cranial ultrasound, computerized tomography (CT) and magnetic resonance (MR) imaging, provide clues to the timing and pathogenesis in 70–90% of patients (Truwit et al., 1992; Hoon, 1995). The ongoing development of advanced nuclear magnetic resonance methods, including diffusion-weighted imaging (Inder et al., 1999a; Johnson et al., 1999), diffusion tensor imaging (Mori et al., 1999) and MR spectroscopy (Shu et al., 1997; Novotny et al., 1998), hold promise to further etiological understanding.

Neuroimaging studies, including brain MR imaging, have demonstrated links between specific CP syndromes and patterns of selective vulnerability of specific components of developing motor systems (Dammann & Leviton, 1997; Nelson et al., 1998). These patterns are related to age-dependent changes in cellular metabolism, neuronal connectivity and circulation (Johnston, 1998b). Important examples readily seen with MR imaging include white matter vulnerability between 24 and 34 weeks, termed periventricular leukomalacia (PVL), as well as neuronal vulnerability at term (Okumura et al., 1997; Menkes & Curran, 1994).

Effective management of patients with CP requires the participation of a team of physicians, clinicians and thera-

pists that provides careful, continuing neurodiagnostic evaluation along with therapeutic intervention to manage tone and other rehabilitative needs. Coordination of services with community based clinicians is also required to ensure that affected individuals have full opportunities to learn in school and participate in society.

Epidemiology

The overall prevalence of CP in developed countries is 2–3/1000 (Murphy et al., 1993; Hagberg et al., 1996). This figure has remained relatively constant over the last two decades, despite dramatic improvements in obstetrical and neonatal intensive care. This suggests that obstetrical interventions such as tocolysis (medication to slow or stop labour, eg, ritodrine, magnesium), the increased rate of Caesarean section and fetal heart rate monitoring have had little impact in reducing the incidence of CP (Canadian Preterm Labor Investigators Group, 1992; Scheller & Nelson, 1994; Parer & King, 2000).

Prematurity is strongly associated with CP (Surveillance of Cerebral Palsy in Europe, 2000). The improved survival of very low birthweight infants has led to an absolute increase in the number of children with the disorder. A second related factor is the recent increase in multiple births; there is a tendency for these infants to be low in birthweight, with a consequent increased risk of developing CP (Grether et al., 1993). Overall, while most premature infants develop normally, concerns have been expressed that one undesirable result of the success of neonatal medicine is the increased survival of children with severe neurodevelopmental handicaps, including CP (Hack & Fanaroff, 1999; Colver et al., 2000).

However, births at term are far more numerous than premature births and the majority of children with CP are born full term. Studies based on the NIH Perinatal Collaborative Project indicate that in more than 80% of cases, CP is associated with disorders of prenatal origin (Nelson & Ellenberg, 1986). Major risk factors for CP, in addition to low birthweight and prematurity, include maternal infections and/or fever at term, endocrine disturbances such as hypothyroidism and other factors listed in Table 39.1.

Table 39.1. Epidemiological factors associated with cerebral palsy

Maternal	Fetal/neonatal
History of fetal loss	Congenital malformations
Long interval between menstrual cycles	Fetal growth retardation
	Twin gestation
Low socioeconomic group	Abnormal fetal presentation
Mental retardation	Nuchal cord
Fever in labour	Prematurity
Chorioamnionitis	Premature separation of placenta
Febrile urinary tract infections	
Thrombophilic disorders	Newborn encephalopathy
Thyroid disorders	

Table 39.2. Common cerebral palsy syndromes

Bilateral spasticity	Extrapyramidal (dyskinetic)
Spastic diplegia	Bradykinesia
Spastic quadriplegia	Dystonia
Unilateral spasticity	Choreoathetosis
Spastic hemiplegia	Hemiballismus

Cerebral palsy syndromes

CP can be classified into four broad groups based on differences in tone and limb involvement: bilateral spasticity, unilateral spasticity, extrapyramidal (dyskinetic) and hypotonia/ataxia, and further subcategorized into clinically recognizable syndromes such as spastic diplegia (Table 39.2). These syndromes often have differing etiological antecedents (Table 39.3) and relatively distinct clinical features (Table 39.4).

The majority of patients with CP have relatively symmetric upper motor neuron involvement, with spasticity being the primary neurologic abnormality. Most of these individuals have either spastic diplegia or spastic quadriplegia depending on whether the lower limbs are preferentially involved (diplegia) or whether all four extremities are heavily involved (quadriplegia). A smaller group with unilateral spasticity is referred to as hemiplegic CP.

Patients with abnormalities of tone and posture associated with basal ganglia involvement are classified as extrapyramidal (dyskinetic) CP. They usually have rigidity rather than spasticity, variability in truncal and appendicular tone, and additional manifestations of basal ganglia involvement including bradykinesia, dystonia, choreoathetosis or hemiballismus.

A small group of patients with atypical features such as hypotonia and or ataxia are classified with hypotonic/ataxic CP. Many patients with this type of congenital motor disorder, along with a substantial portion of the extrapyramidal

Table 39.3. Common causes of cerebral palsy by syndrome

Spastic diplegia	Spastic quadriplegia	Hemiplegia	Extrapyramidal
PVL[a]	PVL[a] (Severe)	Stroke[d]	Near-total asphyxia
Hereditary spastic paraparesis	Multicystic encephalomalacia[b]	Periventricular hemorrhagic infarction[e]	Kernicterus
HIV	Genetic-developmental[c]	Genetic-developmental[f]	Genetic-metabolic[g]
	Hydrocephalus		Hypothermic circulatory arrest (heart surgery)

group, have undiagnosed genetic/metabolic disorders including disorders of mitochondrial energy metabolism.

Spastic diplegia

Spastic diplegia is the clinical syndrome with spasticity greater in the legs than the arms, seen most commonly in children born prematurely. As premature infants usually receive careful developmental follow-up after discharge from the NICU, those with spastic diplegia are often identified during the first 6–12 months of life with signs of delayed motor development.

Spastic diplegia is primarily a disorder of developing white matter and is nearly always associated with neuropathological and neuroimaging findings of PVL. PVL is characterized by destruction of cerebral white matter in regions near the lateral ventricles. It consists of areas of focal necrosis with complete cellular loss, and surrounding regions with selective glial cell injury. PVL is easily demonstrated on MR imaging either as characteristic 'squared off', enlarged ventricles or as moderate ventricular enlargement with periventricular gliotic scarring, as seen on T_2-weighted sequences (Fig. 39.1). PVL is typically more prominent in the posterior ventricular system, particularly in the periatrial area, and is associated with thinning of the corpus callosum.

PVL is strongly associated with premature birth, with the highest incidence at 28 weeks gestation; later in gestation the incidence markedly declines, becoming far less frequent after 32 weeks gestation. While most children with PVL are born prematurely, a few are born at term. It is very likely that most of these children acquired PVL earlier

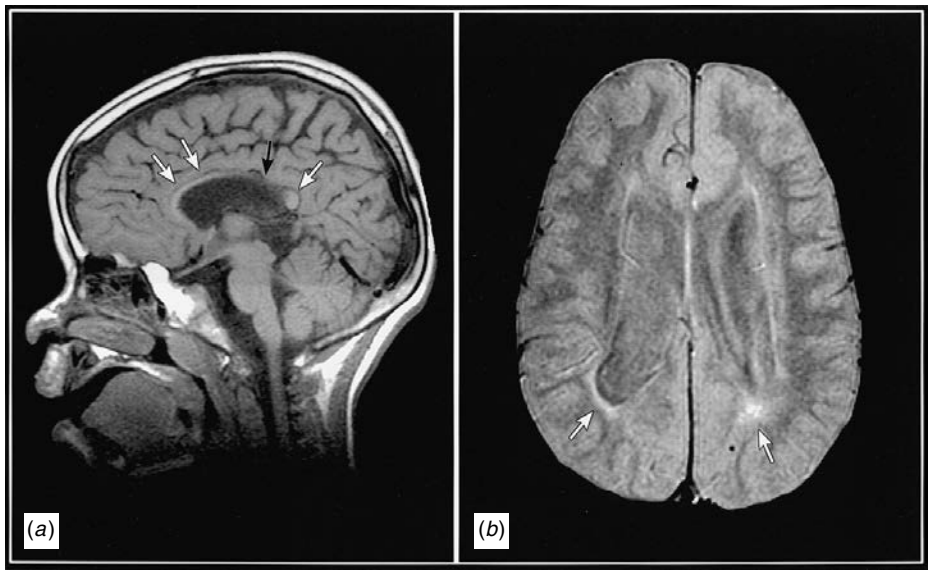

Fig. 39.1. These MR images obtained in childhood show the MR imaging findings of PVL. (*a*) Marked thinning of the corpus callosum (white arrows) with area of complete loss (black arrow); (*b*) Ventriculomegaly with scalloped irregular borders and periventricular gliosis (white arrows). Clinically the child had severe motor and cognitive impairments. (These images were previously published in Hoon & Melhem, 2000.)

during gestation (Miller et al., 2000). Preferential involvement of myelinating corticospinal fibres closest to the ventricles, which control the lower extremities, explains the greater involvement of the legs than the arms in spastic diplegia.

Considerable clinical and experimental evidence indicates that PVL and associated spastic diplegia reflect the selective vulnerability of immature oligodendroglia to stressors such as hypoxia–ischemia or infection at a critical period in their development (Dammann & Leviton, 1997). In many premature infants, PVL is probably produced by reductions in blood flow to marginally perfused periventricular regions as a result of dysfunctional vascular regulatory mechanisms related to prematurity and other contributing factors, including respiratory distress syndrome/prolonged mechanical ventilation, sepsis and necrotizing enterocolitis (Volpe, 1997). Experimental evidence suggests that glutamate released during ischemic episodes may trigger excitotoxic injury in immature oligodendroglia, in part because these cells are less protected from oxygen free radical damage than more mature oligodendroglia (Oka et al., 1993).

Infection, especially gram-negative infection, in either the mother or infant has also been associated with PVL based on clinical and experimental evidence. PVL has been reported to be more frequent in infants whose mothers had febrile urinary tract infections during pregnancy and in infants with sepsis related to necrotizing entercolitis. PVL may also be associated with thyroid or other endocrine metabolic disturbances.

In contrast, low grade (I–II) intraventricular bleeding does not appear to be a strong predictor of motor disability or PVL (Paneth, 1999). However, periventricular hemorrhagic infarction associated with grade IV hemorrhage is often associated with unilateral white matter destruction and asymmetric spasticity (Volpe, 1995).

MR imaging is quite sensitive and specific for PVL associated with spastic diplegia, and is useful for ruling out other causes of motor dysfunction. MR imaging is useful even in older patients with PVL since the changes appear to be permanent. Evidence from quantitative brain MR studies suggests that ventricular enlargement with PVL correlates with greater motor and cognitive impairment related to loss of white matter connections among different regions of the cerebral cortex (Melhem et al., 2000). Quantitative MR imaging is also useful for detecting neuronal abnormalities that may coexist with PVL (Inder et al., 1999b). By contrast, CT scanning is relatively insensitive to PVL, showing only the most severe involvement as enlargement of the ventricles with the characteristic 'squared-off' ventricular profile.

Cranial ultrasound is often informative in the newborn period when the anterior fontanel remains open. Cranial ultrasound can often detect the progression from

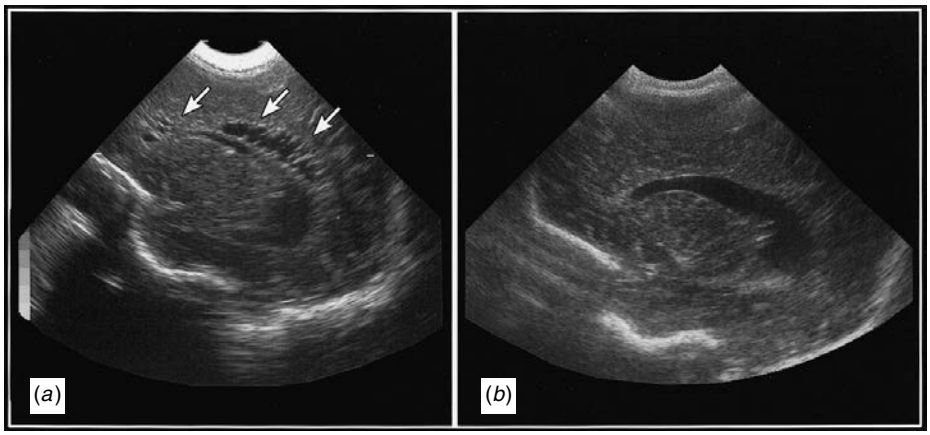

Fig. 39.2. These images show the evolution of cystic PVL on sagittal cranial ultrasound images in a 27 week infant. (*a*) Hypoechoic areas corresponding to cystic degeneration in periventricular white matter at 2 months of age (white arrows); (*b*) Resolution of the cysts with compensatory ventriuculomegaly at 6 months of age. The findings in Panel A carry a risk for CP which approaches 100%. (These images were previously published in Hoon & Melhem, 2000.)

periventricular enhanced signal intensity to cyst formation to ventricular enlargement that can occur during the postnatal period in premature infants (Fig. 39.2). Persistent ventriculomegaly seen on ultrasound in premature infants is a strong risk factor for CP, probably because it reflects loss of periventricular white matter (Paneth et al., 1994).

Spastic quadriplegia

Spastic quadriplegia is the pattern of bilateral spasticity affecting all four extremities. It is the result of a broader range of pathological insults than spastic diplegia, including severe PVL, multicystic encephalomalacia, genetic/developmental brain malformations and hydrocephalus. As with other forms of CP, low birthweight, prematurity and complicated neonatal course are important risk factors. Delayed motor development in the first year is usually more prominent than in spastic diplegia.

In the subgroup with severe PVL, extensive white matter involvement leads to disruption of arm as well as leg fibres as they descend from the motor cortex. These children are often born very prematurely. Some may have also sustained posthemorrhagic hydrocephalus with pressure-related disruption of white matter.

Patients in a second major subgroup have relatively symmetric destructive lesions of the cerebral cortex. One important type of destructive lesion is multicystic encephalomalacia, which refers to multiple cystic cavities in the cortex separated by glial septations. It results from diffuse insults occurring from late gestation through infancy (Barkovich, 2000). It can be produced by intrauterine infections, partial prolonged hypoxia–ischemia, perinatal herpes simplex, bacterial meningitis, or non-accidential trauma during infancy. Parasagittal watershed infarctions associated with hypotension in sick term infants may present as quadriplegia with more weakness in the shoulders and upper extremities (Pasternak, 1987).

A third subgroup includes patients with genetic/developmental brain malformations, such as holoprosencephaly, lissencephaly, pachygyria and agenesis of the corpus callosum which commonly lead to microcephaly and spastic quadriplegia. TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes, and other bacterial and viral) can also result in pachygryria, with similar clinical findings. Brain MR imaging is very useful for distinguishing these disorders, some of which have specific recurrence risks (Hoon & Melhem, 2000). CT is still useful for detecting intracranial calcifications.

A final common subgroup includes those with fetal or neonatal hydrocephalus, reflecting a variety of pathologies affecting the development and maintenance of CSF pathways, including aqueductal stenosis and Dandy Walker syndrome. Outcome is related to the presence and severity of associated anomalies (Pretorius et al., 1985) as well as the need for multiple shunt revisions.

Hemiplegic cerebral palsy

One-third of patients with CP have unilateral spasticity, termed hemiplegic CP, which usually affects the arms more than the legs. A higher proportion of these infants are born at term than in groups of patients with diplegia or quadri-

plegia. Several studies indicate that most term infants with hemiplegic CP sustained cerebral infarctions or strokes prior to birth (Scher et al., 1991; Nelson, 1991). Neuropathological and neuroimaging studies demonstrate the presence of wedge-shaped lesions suggesting vascular infarctions or irregularities in the periventricular white matter (Taudorf et al., 1984). In a large postmortem study of cerebral infarctions in neonates, arterial vascular occlusions were found to be the most common lesion, and the most common associated cause was sepsis with or without disseminated intravascular coagulation (Barmada et al., 1979). Venous sinus thrombosis is probably also a significant cause of hemiparesis, though it has been difficult to identify until the era of modern neuroimaging.

In a study of focal white matter necrosis in infants, markers for infection are prominent risk factors as are congenital malformations, placental vascular malformations, multiple births and maternal and intra-amniotic infections (Leviton & Paneth, 1990). Prenatal white matter necroses and hemipareses have also been found to be associated with polyhydramnios, and the in utero death of one twin. In premature infants, hemiparetic CP can be produced by Grade IV intraventricular hemorrhages with periventricular white matter infarction due to venous infarction. Overall, hemiparetic CP is far more likely than other syndromes to be caused by infarctions secondary to vascular occlusions.

Recently, inherited thrombophilic disorders such as Factor V Leiden have been recognized to be a significant cause of vascular occlusions in fetuses and infants, and may be nearly as frequent as infection as a precipitating cause of hemiparetic CP (Thorarensen et al., 1997) (Table 39.5). Recent studies suggest that Factor V leiden may be responsible for obstetrical complications in mothers such as preeclampsia, as well as for bleeding disorders and strokes in infants (Harum et al., 1999). In one study of mothers with complicated pregnancies, acquired or inherited thrombophilic disorders were diagnosed in more than half of these women (Kupferminc et al., 1999). These studies suggest that patients with hemiparetic CP should be evaluated carefully for possible thrombophilic disorders, which may carry a recurrence risk in subsequent pregnancies.

A third group of disorders which may cause hemiplegia is schizencephaly, some forms of which may have a genetic etiology (Brunelli et al., 1996). Unilateral schizencephaly is associated with hemiplegic CP, while bilateral schizencephaly results in spastic quadriplegia.

Brain MR imaging is the most useful diagnostic modality in patients with hemiplegia. It provides clear distinction between vascular insults which are lined with gliotic white matter and the grey matter lining seen in schizencephaly (Candy et al., 1993).

Extrapyramidal cerebral palsy

Approximately 20% of patients with CP have a prominent extrapyramidal syndrome with rigidity more than spasticity and involvement of the upper extremities more than lower extremities. It is usually associated with a marked reduction in speech production but relatively preserved intelligence. Most of these individuals have an overall reduction and slowing of movement (bradykinesia), but some have hyperkinetic disorders including chorea, athetosis, dystonia and hemiballismus. (An additional group of children have spastic diplegia or quadriplegia associated with extrapyramidal signs, and are referred to as having a 'mixed' CP.)

The entire group of patients with extrapyramidal CP is quite heterogeneous because of the wide spectrum of acquired and inherited disorders of the basal ganglia responsible for the syndrome (Hoon et al., 1997). In some patients the motor disability remains stable over time, while in others there is progressive neurological decline. This important distinction may require careful, repeated neurological examinations to establish.

One important subgroup of extrapyramidal CP patients results from selective injury to the basal ganglia, especially the putamen and thalamus, occurring in acute near-total asphyxia in the last few weeks of a term gestation (Johnston & Hoon, 1998). Several authors have reported the neuroimaging picture of basal ganglia injury in these patients, with MR imaging proving to be particularly helpful (Menkes & Curran, 1994; Pasternak & Gorey, 1998). Early MR imaging, within a few weeks of injury, often shows increased signal on T_1-weighted images in the caudate, putamen and thalami while follow-up is more likely to show enhanced T_2-weighted signal in the posterior portion of the putamen and lateral thalami. The peri-rolandic cerebral cortex is sometimes involved as well. The selective vulnerability of these regions may reflect hyperactivity of prominent excitatory glutamate-containing neurons that

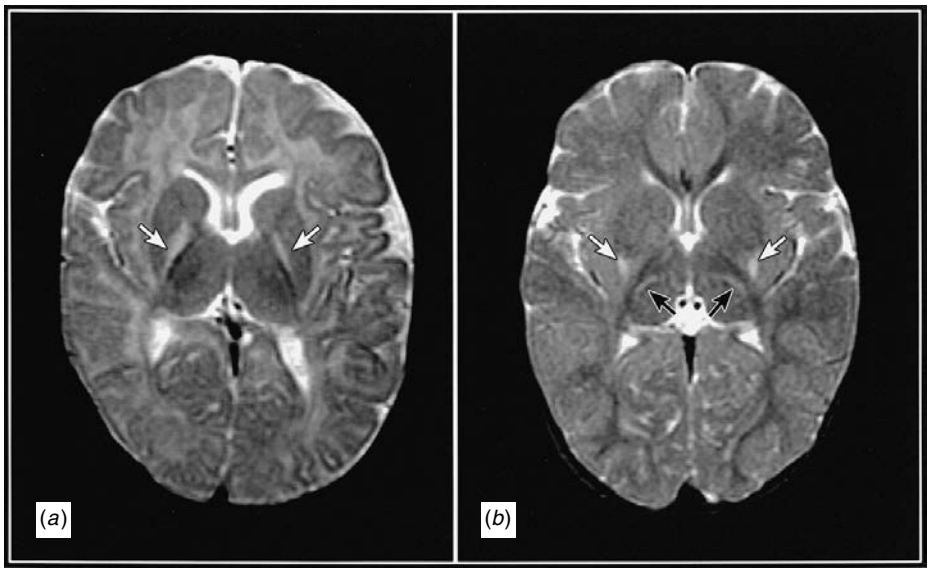

Fig. 39.3. MR images from two infants with clinically similar neonatal encephalopathies, including seizures and ventilatory failure. (*a*) Globus pallidus hyperintensities (white arrows) seen in bilirubin encephalopathy; (*b*) Putaminal (white arrows) and thalamic (black arrows) hyperintensities seen in perinatal hypoxic–ischemic encephalopathy. Both result in extrapyramidal CP.

connect these regions with the cerebral cortex in reciprocal circuits. This pattern of selective vulnerability has also been reproduced in animal models of hypoxia–ischemia. MR imaging can provide strong evidence that hypoxic–ischemic injury to the basal ganglia from asphyxia is responsible for extrapyramidal CP in some patients.

Other patients with extrapyramidal CP may have heterogeneous disorders that require careful diagnostic evaluation. This subgroup of patients is most likely to contain undiagnosed metabolic–genetic disorders, where careful follow-up is important to detect changes that may reflect a progressive disorder. MR imaging can readily distinguish patients with extrapyramidal CP associated with lesions in the globus pallidus from those with putaminal injury in asphyxia. Pallidal injuries are common in kernicterus from hyperbilirubinemia (Fig. 39.3), but may also be caused by mitochondrial disorders with or without lactic acidosis. Some patients with extrapyramidal CP may have pallidal injury after heart surgery as infants (Kupsky et al., 1995). These patients are more likely than others to have hyperkinetic disorders such as chorea or hemiballismus.

Patients with degenerative disorders that affect the globus pallidus, such as Hallervorden–Spatz disease, may progress at such a slow rate initially that they appear to have idiopathic extrapyramidal CP. Other disorders that can present as undiagnosed CP include glutaric aciduria Type I and juvenile Huntington disease, both of which have prominent basal ganglia lesions on MR imaging (Morton et al., 1991; Lenti & Bianchini, 1993). Methylmalonic aciduria can also present with prominent lesions of the globus pallidi after metabolic 'strokes' (Heidenreich et al., 1988). Patients with other, more obscure disorders of intermediary or neurotransmitter metabolism, or of idiopathic or genetic dystonia, may present initially as extrapyramidal CP. Rarely, patients with a defect in GTP cyclohydrolase (Segawa's disease or dopa-responsive dystonia) may present with severe idiopathic extrapyramidal CP early in life (Korf, 1998).

Because of the diverse nature of disorders that can present as extrapyramidal CP, this group of patients requires careful diagnostic evaluation. The etiological evaluation should include brain MR imaging, urine organic acids, plasma amino acids, lactate and chromosomes. Evaluation of CSF biopterin, neurotransmitter and amino acid metabolism is often indicated, especially in patients with idiopathic extrapyramidal CP with normal MR scans. Careful follow-up is important as many of these patients progress or change over time. Furthermore, patients with extrapyramidal CP secondary to acquired lesions such as asphyxia may progress or display new movement disorders including dystonia in teenage or adult years, probably due to continuing reorganization of the nervous system.

Hypotonic/ataxic cerebral palsy

A few patients with congenital motor disorders present predominantly with hypotonic truncal tone, delayed

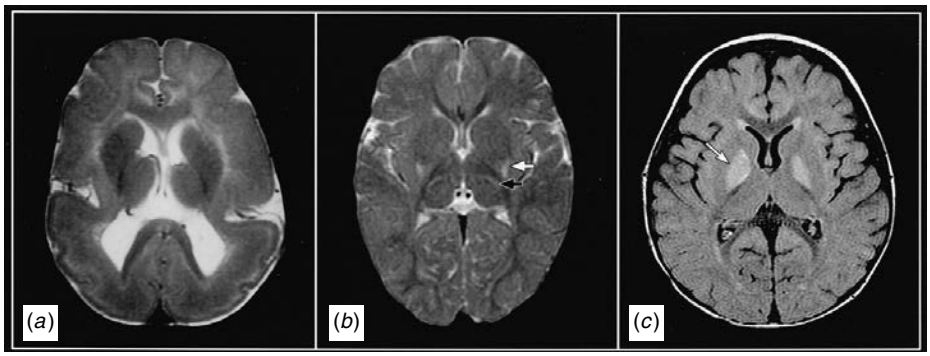

Fig. 39.4. MR images from three children presenting with severe CP. (*a*) Lissencephaly in Miller–Dieker syndrome; (*b*) perinatal hypoxic–ischemic encephalopathy (from Fig. 39.3), and (*c*) methymalonic acidemia with globus pallidus hyperintensities (white arrows).

motor milestones and an abnormal gait with an ataxic appearance (Dubowitz, 1980). These patients are distinguished by the lack of lower motor neuron signs, suggesting a disorder of upper motor neurons. Like extrapyramidal CP, this is a very heterogeneous group, which probably contains many patients with undiagnosed genetic-metabolic disorders. This group is probably the least likely of all the cerebral palsy syndromes to be caused by an acquired condition such as asphyxia. Careful neurodiagnostic evaluation of these patients is also indicated with MR as well as metabolic testing. Recognized disorders include congenital malformations of the cerebellar vermis with mega-cisterna magna, mitochondrial disorders, carbohydrate-deficient glycoprotein disorder, disorders of neurotransmitter metabolism, and Joubert's syndrome. Periodic re-evaluation of these children is indicated.

Diagnostic evaluation

The evaluation of patients with motor delay should begin with a careful history, including details of the prenatal, perinatal and postnatal course. Maternal perception of decreased fetal movement is an important sign of prenatal onset. If there is no history of an acute neonatal encephalopathy, then the etiology is not related to perinatal events. Family history is important to identify those with potential genetic disorders. The review of systems should include questions about vision, hearing, snoring, feeding, bowel and bladder function as well as any cardiac and pulmonary problems. The neurological examination should be comprehensive, including careful observation for adventitious movements, including chorea, athetosis, hemiballismus and dystonia.

An assessment of functional abilities should be obtained, and measures of cognitive function whenever possible. The functional assessment of children with CP is best done in conjunction with skilled physical and occupational therapists. Children may be classified both by the extent of mobility aids required (from point canes to wheelchairs), as well as by their ability to ambulate independently in various settings (from home to gymnasium to community). Physical therapists can be of great benefit here, recommending appropriate aids to mobility as well as setting functional goals for the child, which will foster independence. The cognitive evaluation should be done by a neuropsychologist experienced in the assessment of intelligence in motor impaired patients to provide an accurate reflection of abilities.

The diagnostic evaluation should commence with an MR imaging study (Fig. 39.4). Findings from this study can often be used to determine the need for additional testing. For example, in a child with extrapyramidal CP and imaging abnormalities in the globus pallidus, a comprehensive evaluation for genetic–metabolic disorders should be completed. In those with developmental brain malformations including neuronal migration disorders such as lissencephaly and schizencephaly, specific molecular testing may be important to identify an etiology and to determine recurrence risk (Gleeson et al., 2000).

Depending on the clinical setting, there are a number of other diagnostic modalities. All children with CP should have an ophthalmological evaluation by a specialist experienced in CP. This is important both because of the large number who have refractive errors as well as the potential diagnostic clues which can be identified from a dilated examination of the optic nerve and retina.

Based on clinical examination, if there is evidence to suggest a genetic etiology, a karyotype as well as specific molecular probes should be obtained. If there is evidence of rigidity on examination, a disorder of energy production involving mitochondrial function should be considered,

with a lactate, plasma amino acid and urinary organic acid profile obtained. If there is significant ataxia, the cerebellum should be carefully assessed on MR imaging, with testing to include various forms of SCA as well as carbohydrate deficient glycoprotein disorders; Angelman syndrome should also be considered.

If the initial diagnostic work-up is unrevealing, ongoing clinical follow-up may reveal further information that will assist in diagnosis and clinical care. While many parents seek 'closure' of the search for cause so that they can proceed with rehabilitation, most nevertheless remain interested in establishing the cause, and will continue with a carefully orchestrated ongoing diagnostic search.

Associated impairments

While CP refers primarily to the motor involvement, affected individuals frequently have a range of associated impairments (Table 39.3). Up to half of children with CP have mental retardation. A third have seizure disorders. Learning disabilities are also linked with CP. Impairments in hearing and vision should also be considered, as well as disorders of speech, swallowing and feeding.

Furthermore, for the affected child, there may be social and emotional limitations. These children often have a difficult time once they become aware of differences from their peers. It is important for families to encourage them to develop skills in other areas, which may include horseback riding, and in other forms of therapeutic recreation. This will promote a sense of confidence and self-esteem.

While educational opportunities are often available until age 21 under the provisions of the Individuals with Disabilities Education Act (IDEA), rehabilitative and supportive services are less well organized in adulthood. Despite the American with Disabilities Act, barriers to employment continue to exist.

Rehabilitation

There are a number of rehabilitative motor interventions for individuals with CP. Depending on the clinical situation, the rehabilitative goals may be ease of care, preventing orthopedic deformities or facilitating function. The specific goals of affected individuals and their families should be carefully considered in formulating rehabilitation plans.

In young children, the mainstays of rehabilitation are occupational and physical therapy (Bartlett & Palisano, 2000). These techniques serve to lessen the effects of inhibitory reflexes and to facilitate the acquisition of gross and fine motor skills. They may also have benefit in other areas of development including language, and the promotion of confidence and self esteem.

In children with spasticity, there may be progressive orthopedic deformities. In the past, surgeries were done in a sequential fashion, one at a time. However, more recently, multiple soft tissue and/or bone procedures have been conducted simultaneously (Fabry et al., 1999). Initially, soft tissue releases are usually employed for those with contractures. Bony procedures to the leg, hip and spine may also be required. Whether pharmacological interventions will lessen the need for orthopedic surgery is unclear at this time.

For patients with localized spasticity, botulinum toxin has been effectively utilized to improve gross and fine motor abilities (Wissel et al., 1999; Koman et al., 2000). Beneficial effects are related to the temporary weakening of specific muscle groups interfering with function. Botulinum injections are extremely safe, with effects lasting up to three to four months.

A range of oral pharmacological agents has been effectively utilized to diminish spasticity (Pranzatelli, 1996). Diazepam has been employed in the past, although concerns over cognitive side effects limited its use. More recently, baclofen has been preferentially used, recognizing that there are less cognitive side effects from this drug. However, patients should be cautioned against abruptly discontinuing baclofen, which can precipitate hallucinations or seizures. Depending on the clinical situation, other antispasticity agents such as dantrolene and tiazadine can be used.

For patients with extrapyramidal CP, pharmacological agents modulating dopamine action in the striatum have been effectively utilized. For those with chorea, drugs to deplete dopamine such as reserpine, tetrabenazine, clonzapam and carbamazepine have been used. For patients with dystonia, athetosis or bradykinesia, drugs to increase dopamine flux including trihexyphenidyl and levodopa (usually administered with carbidopa) have been effectively employed.

Recently, intrathecal baclofen, delivered by a programmable pump placed in the abdomen connected to a catheter ending in the intrathecal space, has been employed for patients with spasticity of spinal as well as cerebral origin (Penn & Kroin, 1985; Albright et al., 1993). Studies have indicated that intrathecal baclofen effectively reduces spasticity (Gilmartin et al., 2000), and may be of benefit in improving function (Latash & Penn, 1996). Intrathecal baclofen has also been reported to be of benefit in dystonic CP (Albright et al., 1996). Complications of this

therapy include catheter kinking as well as infection, possibly requiring replacement of the catheter or pump.

Selective dorsal rhizotomy, a neurosurgical procedure in which a percentage of sensory rootlets in the LS spine are cut, is felt by some groups to be an effective intervention for spastic diplegia (Park & Owen, 1992). In carefully chosen patients with relatively pure forms of spastic diplegia, this procedure reduces spasticity and improves function (Steinbok et al., 1997). However, other groups have reported no benefit from this procedure over intensive physical therapy (Graubert et al., 2000). Furthermore, there may be both short- and long-term complications from this procedure (Abbott, 1992; Tuir & Kalen, 2000).

Recently, there has been interest in stereotactic neurosurgical procedures similar to those performed for Parkinson disease (De Salles, 1996). Preliminary work indicates that in carefully selected patients, the severity of dystonia and hemiballismus may be decreased. Depending on the clinical setting, both ablative as well as neural stimulation procedures may be done.

Because therapies have not achieved all the goals that families want for their children or for themselves, parents and those affected may seek alternative therapies. Such therapies are wide ranging, from herbal remedies to hyperbaric oxygen. While some may be beneficial, each should be carefully considered. Care should be taken as some herbs may have significant toxicities, and with regard to hyperbaric oxygen tanks, there have been concerns that high oxygen tension may damage developing white matter pathways (Huang et al., 2000).

Prognosis

Families as well as affected individuals often seek information about long-term prognosis so that appropriate medical, financial and life care plans can be made. They may also worry about whether other family members are at risk. The key step to providing information in these matters is to conduct a comprehensive etiological evaluation at the time that the diagnosis of CP is made. Such a work-up can provide specifics of prognosis and recurrence risk when a recognized genetic or metabolic disorder is identified, as well as reassurance when a sporadic cause is identified.

Given the progressive nature of some CP syndromes, ongoing medical follow-up is required both for the individual patient, as well as to establish guidelines for groups of patients. For example, some adults with extrapyramidal CP are at risk for progressive cervical spine disease, which if untreated can lead to sudden quadriplegia (Harada et al. 1996) (Fig. 39.5). Others may develop progressive neurological symptoms necessitating new treatment modalities (Scott & Jankovic, 1996).

Fig. 39.5. MR image from an adult with extrapyramidal CP, who sustained cord compression (white arrow) from repetitive head movements used to control a communication system.

In conclusion, advances in neurobiology, as well as brain imaging, have expanded the understanding of the pathogenesis of CP. Combining imaging techniques with clinical examination can refine classification and establish homogeneous groups so that rehabilitative interventions can be more effectively assessed.

Gait and balance disorders

John G. Nutt[1] and Fay B. Horak[2]

[1] Department of Neurology and Department of Pharmacology and Physiology, Oregon Health Sciences University, USA
[2] Neurological Sciences Institute and Department of Pharmacology and Physiology, Oregon Health Sciences University, USA

Walking requires two capabilities: maintenance of balance (protection of upright stance via anticipatory and reactive postural mechanisms) and movement through the environment via locomotion. Postural responses and locomotion are dependent upon all levels of the nervous and musculoskeletal systems. Consequently, gait and balance disorders are common manifestations of many diseases.

The clinician commonly thinks of gait disorders in terms of walking pattern, emphasizing the movements of the legs. And literally this is correct; 'gait' is defined by Webster's *Third International Dictionary* as the 'manner of walking' or 'sequence of foot movements.' Accordingly, the neurological exam emphasizes evaluation of strength, tone, coordination, sensation and reflexes of the limbs. The result is that clinical neurology focuses on locomotion.

The importance of balance or equilibrium to walking is not recognized or explicitly acknowledged. Yet balance is the key and critical element in safe ambulation. Many so-called gait disorders are in reality balance disorders, not disorders in the sequence of foot movements. For example, Bruns' 'frontal ataxia' (Bruns, 1892) and van Bogart and Martins' 'apraxia of gait' (1929) are descriptions of patients who could not even stand independently. Although impairments of gait or locomotion can sometimes be separated from impairments of balance or postural equilibrium, locomotion and balance are more often inextricably intertwined (Mori, 1987). Thus, classifications need to consider disorders of both gait and balance.

The aim of this chapter is to present a classification scheme for gait and balance disorders. We first consider a classification based on neurological functions required for purposeful ambulation using Hughlings Jackson's hierarchical scheme of lower, middle and higher functions. This classification suggests the range of neurological impairments that can disrupt ambulation and the relationships among various gait and balance disorders.

Patients' walking and balance patterns do not necessarily reflect impairments in neural functioning but rather the patient's compensatory strategies for coping with the impairments. Different impairments may elicit common compensatory strategies. For this reason, classification by impairments is inadequate for clinical diagnosis. The second portion of our classification scheme considers the common compensatory strategies as clinical patterns or syndromes for which there are differential diagnoses. Problems with ambulation are separated into clinical patterns or syndromes that are predominantly disorders of balance and those that are predominantly disorders of locomotion, recognizing that in most diseases, both postural control and locomotion are affected to some extent. Because falls are a common presenting complaint, we offer a separate classification for fall patterns.

Physiology of locomotion and postural control

The temporal and spatial sequence of contractions of leg muscles for locomotion are programmed at the spinal cord level by central pattern generators (CPGs) (Grillner & Wallen, 1985). Well-patterned hind leg stepping responses can be elicited by treadmill stimulation in cats with total thoracic cord transection (Grillner & Wallen, 1985) and in the legs of humans with paraplegia and quadriplegia (Dietz et al., 1994). This spinal stepping can be activated by sensory stimulation resulting from treadmill motion and by non-specific dorsal root sensory stimulation. The CPGs are normally activated by descending pathways arising in brainstem locomotor centres (Orlovsky & Shik, 1976). Electrical stimulation of the brainstem locomotor centres will produce stepping and, at higher intensity, trotting and running movements of the legs of cats and monkeys (Eidelberg et al., 1981). Cerebellum, basal ganglia and

primary motor areas refine and adapt locomotion to varying conditions such as for precision walking on the rungs of a horizontal ladder (Armstrong, 1988). Other cortical areas coordinate locomotion with the individual's voluntary or purposeful actions.

The neuroanatomical control of posture is less well understood than is locomotion. The isolated spinal cord does not have postural responses. The hindlimbs of paraplegic cats can support the weight of the trunk with background muscle tone but do not respond to postural perturbation to prevent a fall (Macpherson & Fung, 1999). Postural support must be provided for the spinal cats walking on a treadmill (Grillner & Wallen, 1985) indicating that postural responses must be mediated through centres above the spinal cord. Coordinated postural responses can be elicited from brainstem. Evidence for brainstem programming of postural control comes from the studies in intact cats with implanted electrodes in dorsal and ventral tegmental regions of the pons. Stimulation of the ventral tegmental region would make a lying cat stand up and then begin walking. Stimulation of the dorsal tegmental region reversed this effect; a walking cat would first stop and then would lie down (Mori, 1987). Thus, at least some postural responses appear to arise from the brainstem.

Higher centres are presumed to adapt postural control to the environment and to the individual's needs. For example, frontal cortical areas coordinate anticipatory postural adjustments that precede and accompany any voluntary movement to protect postural stability. These adaptations require accurate neural maps of the body in relation to the earth's gravitational field, the support surface and the immediate environment as well as the relation of various body segments to each other. These maps are synthesized from information obtained from a variety of sensory modalities (Horak & Macpherson, 1996). Somatosensory information from proprioceptors in muscles and joints is the most important for coordination of posture and gait, including triggering rapid postural responses. Cutaneous information provides information about the contour and characteristics of surfaces, the pressure under the feet in contact with support surfaces, and a stable reference for posture. Vestibular information helps control trunk and head orientation in space, as well as stable gaze during locomotion. Vision is primarily used in a predictive manner to avoid obstacles and plan trajectories and step placement during gait. In addition to online sensory information, postural responses are modified and adapted to behaviour goals by context, previous experience and expectation.

Systems classification of gait and balance syndromes

A hierarchical classification, modelled after Hughlings Jackson's approach, considers three levels of neural function controlling gait and balance; lower, middle and higher levels (Table 40.1). 'Lower' to 'higher' correlates with 'simpler' to 'more complex' neural processing. It will be apparent that clinicians are most comfortable diagnosing disorders caused by neurological dysfunction arising at lower levels and motor dysfunction at the middle level of this classification. The effects of sensory disorganization and higher neurological dysfunction on balance and gait are less well defined clinically. We emphasize these less recognized and problematic disorders in the text and references. It is important to note that a given disorder may produce balance and gait dysfunction by effects at several levels. For example, mild to moderate parkinsonism is envisioned as causing mid-level dysfunction by reducing the force generation for balance and locomotor synergies. More severe parkinsonism may also affect higher level functions such as adaptation of balance synergies to environmental conditions and coordination of synergies.

Lower level

The lower level has three components. The first component consists of the intrinsic locomotor synergies (CPGs) programmed in the spinal grey matter and the postural responses programmed in the brainstem. These locomotor and postural synergies are the building blocks of successful ambulation. A patient with complete spinal cord section may have no behavioural evidence of locomotor synergies because they lack the necessary facilitation to elicit them. Spinal lesions may also injure CPGs disrupting spinal locomotor synergies and thereby timing of muscle contractions required for locomotion although frequently other neurological dysfunctions from higher spinal and brainstem lesions complicate interpretation. Lower level synergies may be disinhibited by higher lesions so that spinal stepping (Dietz et al., 1994) and decerebrate, tonic neck and perhaps grasp responses may emerge. Another possible abnormal postural response in humans resulting from disinhibition is the involuntary hyperextension or pushing the centre of mass behind the base of support seen in some patients upon standing.

The second component of the lower level is the primary sensory modalities with which the person locates themself with respect to the support surface, the gravitational field, and the immediate environment and also senses the relative

Table 40.1. Neural systems/anatomical classification

I. LOWER LEVEL

A. Spinal locomotor and brainstem postural synergies

1. Absence of synergies
2. Abnormal spatial–temporal organization of synergies
   a. Spinal cord lesions disrupting CPGs
3. Disinhibition of synergies with higher lesions
   a. Spinal stepping
   b. Decerebrate posturing, tonic neck responses
   c. Hyperextension, pushing backwards

B. Primary Sensory Input (vestibular, visual, somatosensory)

1. Absent or distorted input
   a. Veering ataxia of acute vestibular lesions
   b. Sensory ataxia with loss of proprioception from peripheral nerve or posterior column lesions
   c. Veering, careful gait of newly blind

C. Force Production (muscle and nerve)

1. Weakness
   a. Steppage gait (foot drop) of peripheral nerve lesions
   b. Waddling gait of muscular dystrophies and polymyositis with involvement of proximal muscle
   c. Hyperextended knees with quadriceps weakness

II. MIDDLE LEVEL

A. Perception/Orientation (organization of primary sensation into spatial maps of body in gravitational field by parietal cortex, putamen, premotor cortex and their subcortical connections)

1. Distorted spatial maps
   a. Central vestibular lesions of brainstem and thalamus
   b. Parietal lesions and 'pusher syndrome'
2. Distorted maps or neglect of spatial information
   a. Thalamic astasia
   b. Putaminal astasia
   c. Progressive supranuclear palsy?
   d. Non-dominant parietal lesions?

B. Force Scaling (modulation of force for optimization of postural and locomotor synergies by basal ganglia, cerebellum and primary motor cortex)

1. Movement disorders
   a. Hypo- and hyperkinetic disorders of basal ganglia origin
   b. Hypermetric and dysmetric disorders of cerebellar origin
   c. Spasticity and clumsiness from corticospinal system damage

III. HIGHER LEVEL

A. Synergy selection, coordination and adaptation of locomotor and postural responses (less conscious functions) mediated by frontal lobe and subcortical connections.

1. Dyscoordination of voluntary movement and postural responses
   a. Reduction or loss of anticipatory responses with frontal lobe lesions
2. Altered inhibition or excitation of lower postural and gait synergies
   a. Hyperextension and pushing centre of mass behind support
   b. Freezing with frontal, subcortical and basal ganglia lesions
3. Adaptation of postural synergies to conditions
   a. Postural inflexibility of advanced parkinsonism
   b. Inability to use experience to anticipate appropriate magnitude of postural responses in cerebellar disease
   c. Appropriate slowing, shortening of stride and en bloc turns with perceived postural instability
4. Inappropriate sequencing of postural synergies
   a. 'Apraxia' of postural shifts as from lying to sitting and sitting to standing

Table 40.1 (*cont.*)

B. Cognitive (attention and insight for adaptation to person's goals and limitations (more conscious functions) mediated by all cortical regions
1. Impaired attention
a. Falls related to centrally active medications, delirium and dementia
2. Imparied insight
a. Falls related to inappropriate behaviour in dementia
b. Psychogenic gait disturbances

positions of various limb segments, trunk and head. Under most conditions, the information from the visual, vestibular and proprioceptive sensory systems is redundant so that an accurate spatial sense is possible with input from just one or two of the sensory systems. The disequilibrium of acute and chronic vestibular dysfunction and the sensory ataxia associated with proprioceptive dysfunction are examples of gait and balance disorders associated with reduced, unbalanced and disordered sensory input.

The third component of the lower system is the musculoskeletal system and peripheral motor nerves connecting it to the CNS. These tissues are responsible for generating forces to preserve balance and to move in space. Damage or disease affecting these structures, the effectors of postural and locomotor strategies, will obviously alter the execution of the strategies. Skeletal deformities, arthritis, muscle disease and peripheral motor neuropathies will affect gait and postural responses. For the neurologist, the waddling gait and locked knees of muscular dystrophies and polymyositis and the steppage gait of peripheral neuropathies such as Charcot Marie Tooth disease are prime examples of this type of dysfunction.

Middle level

At the middle level there are two components. The first component is composed of the neural structures that integrate sensory information into spatial maps. This function probably takes place in many areas of the brain. Spatial maps concerned with motor function have been identified in the putamen and premotor cortex. Maps concerned with visual function exist in frontal eye fields and the superior colliculus. Surprisingly, the parietal lobes appear to be more important in creating the spatial maps which may actually reside elsewhere in the brain (Gross & Graziano, 1995). Distorted maps can result in body tilt or lean or inappropriately asymmetrical postural responses. Examples of this type of disorientation are the altered perception of visual and postural verticality that may accompany lesions of central vestibular connections (Dieterich & Brandt, 1993; Bisdorff et al., 1996) and parietal lesions (Karnath, 1994; Karnath et al., 2000). Other candidates for this type of dysfunction in orienting in space are progressive supranuclear palsy, thalamic astasia (Marsden & Gorelick, 1988) and putaminal astasia (Labadie et al., 1989) syndromes in which patients appear to be either unaware of postural vertical or indifferent to this information. As patients with these clinical syndromes have not been studied carefully, it is not known if these syndromes are attributable to lack of synthesizing information into maps or to sensory neglect, motor neglect, or other types of dysfunction.

The second component of the middle level function is the precise modulation of force for optimal locomotor and postural control. The central motor system has this role. Basal ganglia, cerebellum and cortical motor areas sharpen and adapt locomotor and postural coordination but do not create the synergies. The clinical manifestations of dysfunction at this level are parkinsonism (slow/bradykinetic and stiff/rigid postural and locomotor synergies), hyperkinetic movement disorders (involuntary movements superimposed on normal strategies), ataxia (hypermetric and dysmetric synergies) and spasticity (slowed, stiff and imprecise synergies). These clinical syndromes are a distortion, not loss, of appropriate postural and locomotor synergies caused by the imprecise execution of appropriate synergies. Skilled and precise voluntary stepping are impaired; walking a line or performing a dance step become challenging.

Higher level

At the higher level, two components are hypothesized. The first largely operates at an unconscious level. It is responsible for selecting, accessing and coordinating the appropriate brainstem and spinal synergies for balance and walking. The selection of synergies is based on the information about the body, its location in space and the goals

of the individual. Sensitivity to context is an important component of this function. For example, balance and locomotor synergies should be different for walking on a slick versus a non-slippery surface and for responding to a postural perturbation when holding onto a support versus when standing without a handhold. Anticipatory postural responses that accompany voluntary movements to prevent postural perturbations caused by the voluntary movements may be impaired by lesions of premotor or supplementary regions (Massion, 1992).

A second group of higher level problems is with disinhibition of inappropriate postural responses and inability to elicit appropriate locomotor synergies. The tendency for some patients to push their centre of mass behind their support base may be an example of disinhibition of an inappropriate postural tone. It may be seen with frontal lesions, deep white matter lesions and severe parkinsonism (which may induce frontal dysfunction). Freezing appears to be disturbed access to locomotor synergies and is associated with the same array of frontal, subcortical white matter and basal ganglia lesions (Yanagisawa et al., 1991; Achiron et al., 1993; Giladi et al., 1997).

A third group of higher level problems relates to the ability to adapt to changes in environmental conditions and to predict appropriate responses. Subjects with basal ganglia disease have difficulty adapting postural synergies to changes in support surfaces (Horak et al., 1992) and subjects with cerebellar disease have difficulty adapting postural synergies based on prior experience (Horak & Diener, 1994). A gait that is often considered as abnormal and variously termed senile, elderly or cautious gait, is the slowed, short stepped gait with *en bloc* turns. However, this gait pattern is an appropriate response to perceived instability and shows that at least some of the higher level function is intact.

A fourth group of higher level problems is totally deranged synergies that may fit the concept of apraxia. Although the term 'apraxia of gait' is in common use, its appropriateness and clinical definition are problematic (Nutt et al., 1993). However, the term 'apraxia of balance' may be justified for righting responses that are entirely disrupted and ineffective. Inappropriate righting responses such as trying to arise from a chair without bringing the feet underneath the seated body, and bizarre postural responses upon standing may be associated with frontal lobe lesions and deep white matter lesions (Bruns, 1892; van Bogart & Martin, 1929; Meyer & Barron, 1960; Petrovici, 1968; Thompson & Marsden, 1987; Nutt et al., 1993). What is commonly termed apraxia of gait is subsumed under freezing and apraxia of balance in our classification.

A second component of the highest system operates at a more conscious level to modify locomotor synergies. It is responsible for precision stepping such as on stepping stones or performing unfamiliar dance steps. If there are lower and middle level postural and locomotor difficulties, this higher level compensates as best it can to allow ambulation within the constraints imposed by the lower level dysfunction. Under these circumstances, walking and balance are elevated from operation at the largely unconscious level to operation at a conscious level. The more balance and gait are under conscious control, the more attention is required. In this situation, balance and gait deteriorate when attempting a simultaneous, cognitive task such as conversation, searching for keys in a pocket or carrying a fragile object (Wright & Kemp, 1992). Falls occur in older patients who do not direct sufficient attention to walking and balance or who do not have the insight to avoid posturally challenging situations. This may be the reason that dementia and centrally active drug use in the elderly emerge in epidemiological studies as predisposing factors to falls (Tinetti et al., 1988; Salgado et al., 1994).

Psychogenic gait disorders would also be seen as representative of dysfunction at this higher level (Keane, 1989; Lempert et al., 1991).

Classification of balance and gait disorders by clinical patterns

The postural responses and locomotor patterns that the clinician observes are not the direct consequence of the neurological impairments but instead reflect the compensatory strategies the patient uses to cope with the impairments. Impairments at different levels may invoke clinically similar compensatory postural and gait patterns. For example, a hyperextended, locked knee to prevent knee buckling in stance may be a compensatory strategy for weak quadriceps muscles, hypermetric synergies from a cerebellar disorder or lack of proprioceptive feedback in an individual with profound somatosensory loss.

The pattern classification assumes that there are gait and balance features that define different strategies for which there is a limited differential. The patterns or syndromes are not exclusive; a patient may demonstrate more than one abnormal pattern.

The classification is based on the history and observation of gait and postural responses. History is particularly important for patients with falls, as they are generally not directly observed. Gait and balance features are observed not only during stance and gait, but also during transitions from sit to stand and turning, when balance is challenged by walking in tandem with a narrow base of support, and responding to postural perturbations such as the 'pull test.'

Table 40.2. Fall patterns

1. Collapsing (akinetic seizures, syncope, orthostatic hypotension)
2. Toppling
   a. Drifting into a fall while standing
   b. While changing position/posture
   c. Weaving from side to side or in all directions until falling
3. Tripping
4. Freezing
5. Falling in specific situations or with concurrent sensory symptoms
6. Non-patterned

The perceived limits of stability can also be evaluated by examining how far the subject can lean forward and backwards in standing and laterally in sitting. Ability to maintain orientation with limited somatosensory information can be evaluated by standing on compliant foam with eyes open and closed. These features will describe gait and balance patterns. Each pattern will have a differential. Other clinical features derived from the neurological exam, imaging and laboratory testing will help differentiate between causes of a given pattern but are not used to define the pattern. The proposed pattern classification has three categories; fall patterns, disequilibrium patterns and gait patterns.

Fall patterns

Fall patterns (Table 40.2) are based on history. The first distinction is between falling because of loss of postural tone and falls with retained tone. 'Collapsing in a heap' is a common description of falls from loss of postural tone. Akinetic seizures, negative myoclonus, syncope, otolithic crises and orthostatic hypotension cause collapsing falls. The recognition of the collapsing fall syndrome is an important distinction as the differential, diagnostic tests and treatments are very different from the other falls to be considered below.

In falls with retained muscle tone, the patient falls in some direction and does not just collapse. It may be helpful to distinguish whether the patient actually falls to the ground or has 'near-falls.' 'Near-falls' suggest that the patient recognizes when they are out of equilibrium and performs a late or inadequate postural response. In contrast, patients who consistently fall to the ground clearly have grossly inadequate postural control or are unaware, until too late, that equilibrium has been compromised. Patients and their caregivers can often provide helpful information regarding the environmental situation, task attempted and type of fall pattern. It is also useful to re-enact the circumstances that led to a fall during the clinical exam.

Toppling falls are falls where the patient 'topples like a falling tree.' They may occur when the subject is just standing as seen in progressive supranuclear palsy or thalamic and putaminal astasia (Masdeu & Gorelick, 1988; Labadie et al., 1989) or when the subject is changing position as is characteristic of parkinsonism. In these disorders there is often inadequate or no effort to arrest the fall. Patients with cerebellar disease may weave about when standing and fall in any direction but have protective responses.

Tripping falls occur because the feet do not clear the support surface adequately. The falls are generally forward. Foot drop, spasticity and parkinsonism are common causes of tripping falls.

Freezing falls occur when the feet do not move quickly enough to stay under the falling forward centre of mass. The patients typically fall forward on to their knees and outstretched arms.

Falls that occur only when the patient is experiencing vertigo, in the dark, or in sensory conflict situations such as when surrounded by moving objects, suggest a peripheral or central vestibular deficit. Falls when walking on uneven surfaces suggest inadequate sensory information for control of balance, especially somatosensory loss as occurs with peripheral neuropathy and dorsal column disease. In these sensory type falls, patients generally recognize their spatial disorientation and attempt to use their arms to grab onto stable objects or voluntarily sit down to prevent injury.

Finally, non-patterned falls, falls that do not seem to fit a consistent pattern, may represent failure of attention and insight producing carelessness as can occur in dementia.

Disequilibrium syndromes

Disequilibrium syndromes (Table 40.3) are characterized by impairments of balance that markedly impede or preclude locomotion. They are identified by inspection of arising, standing with eyes open and closed, standing on foam, walking, tandem walking, turning, response to postural perturbation and limits of stability while standing and sitting.

Disequilibrium can result from dyscoordination within postural synergies; the relative timing of postural muscle contractions is inappropriate. The clinical consequence is buckling and excessive motion of joints. Cortical lesions and partial spinal cord lesions can produce abnormal timing of postural responses. An example of a dyscoordi-

Table 40.3. Disequilibrium patterns

1. Dyscoordination: excessive motion, buckling, etc. of limb segments caused by disordered timing affecting temporal patterns of body segment movements
2. Dysmetric (hypermetric): excessive sway and over-reaction to postural disturbance caused by correct timing but inappropriately large movements
3. Hypometric: postural responses are too small because force develops slowly
4. Sensory deprivation: situation-dependent disequilibrium related to circumstances that limit sensory input
5. Sensory disorganization: apparent disregard for postural vertical leading to drifting off balance or distorted perception of verticality causing active moving into unstable postures
6. Apraxic: completely abnormal or inappropriate postural responses

nated pattern is the delayed onset of postural responses in gastrocnemius such that the hamstrings muscle activation that normally follows gastrocnemius, comes earlier than it, resulting in knee buckling (Nashner et al., 1983).

In dysmetric disequilibrium, there is increased postural sway while standing still. The postural responses are appropriately organized but improperly scaled and often are hypermetric (Horak & Diener, 1994). Postural pertubation often elicits a response that is too large and causes the body to be thrown into another unstable position. Dysmetric, often hypermetric, postural responses are characteristic of cerebellar disorders, the prototype for dysmetric disequilibrium. However, the involuntary movements of chorea can also produce the dysmetric disequilibrium syndrome. High anxiety, fear of falling and suggestibility can also produce hypermetric postural responses. Distraction by another task, such as testing stereognosis, will often reduce sway in patients with anxiety and suggestibility.

Hypokinetic or bradykinetic postural responses are frequent in parkinsonism. The development of force is slow so that the execution of postural responses is slow and may not be sufficiently timely or forceful to maintain upright balance. Recovery from the pull test is noticeably slow, the upper body moving back over the centre of support over a few seconds or longer. Sometimes the patients fall without an apparent effort to resist the perturbation. Despite responses that clinically appear delayed, weak or even absent, the latency of postural responses measured by surface EMG electrodes are not prolonged, but amplitude is reduced (Horak et al., 1992).

Disequilibrium resulting from sensory deprivation is characteristic of vestibular disorders, severe peripheral neuropathies and posterior column disease. Disequilibrium occurs because there is inadequate sensory information to trigger and modify postural responses. These disorders are revealed by situations that deprive the patients of other sensory input such as standing with eyes closed or standing on foam (Horak et al., 1990).

Disequilibrium from sensory disorganization appears to be the cause of falls with thalamic, putaminal, and cortical, particularly parietal and possibly frontal lesions. Primary sensory input is intact but the synthesis of the information into spatial maps is disturbed or there is inattention to the spatial information. Falls are characterized by drifting off balance with no apparent effort to correct balance in thalamic (Masden & Gorelick, 1988) and putaminal astasia (Labadie et al., 1989) progressive supranuclear palsy and advanced parkinsonism. Parietal lesions may be associated with actively pushing the centre of mass toward the lesioned side secondary to a distorted sense of body vertical (Karnath et al., 2000).

Apraxic disequilibrium is the disorganization of arising and standing because the righting and standing synergies are completely inappropriate. The most common example is patients who try to arise from sitting without bringing the feet under the chair but other mechanically impossible strategies for righting and standing may be seen. These types of disequilibrium disorders are commonly associated with frontal lobe dysfunction (Nutt et al., 1993) but may also be seen with advanced parkinsonism.

Gait syndromes

Gait syndromes are based on abnormalities that are apparent while the patient is walking. Waddling and foot drop gait patterns identify weakness. The distance between the feet (base) may be widened or, less commonly, narrowed while standing or walking. Gait speed and stride length are reduced with any gait disorder or perceived risk to upright balance and are therefore of no diagnostic assistance. The cadence or regularity of steps, both length and base, may vary during walking. Deviation or veering from intended direction of travel may be observed. Stiffness or rigidity of the legs or trunk may be apparent by the loss of the normal fluidity of gait. Difficulty initiating or maintaining gait (freezing) is one of the more striking abnormalities of gait. Adaptability may be estimated by the patient's ability to modify walking speed, avoid obstacles, perform precision walking or turn about.

Eight gait patterns are proposed (Table 40.4). The proposed gait patterns are not exclusive; patients may show elements of more than one pattern. Also, gait patterns are not fixed but may change or progress across time in conjunction

Table 40.4. Gait patterns

1. Ataxic: irregular cadence and progression
   a. Cerebellar ataxia
   b. Sensory ataxia
   c. Chorea
2. Stiff/rigid: loss of fluidity, stiffness of legs and trunk
   a. Spasticity
   b. Parkinsonism
   c. Dystonia
   d. Diffuse cortical and subcortical diseases, such as multi-infarct state
3. Weakness: waddling and foot drop
   a. Muscle disorders
   b. Peripheral neuropathies
   c. Corticospinal tract lesions
4. Veering: deviation of gait to one side
   a. Vestibular disorders
   b. Cerebellar disorders
5. Freezing: start and turn hesitation
   a. Parkinsonism
   b. Multi-infarct state
   c. Normal pressure hydrocephalus
6. Wide-based: widened base with standing and walking
   a. Midline cerebellar disorders
   b. Multi-infarct state
   c. In conjunction with ataxic syndromes
7. Cautious: slowing, short steps and *en bloc* turns
   a. Non-specific, multifactorial
8. Psychogenic: bizarre, inconsistent, distractible

with the evolution of the neurological problems. Many gait syndromes begin as a cautious gait and evolve into other syndromes. Finally, gait pattern classification is not to say that the patients have no balance disorders; most do, and the abnormal gait pattern may be a compensatory response to the balance difficulties.

Ataxic gaits are a result of uncertainty when and where the feet will make contact with the support surface with each step. This can be a consequence of dysmetric control of the centre of mass and leg movements as in cerebellar disorders, superimposed involuntary movements as in chorea, impaired proprioception in the feet and legs as in sensory ataxia and a moving support surface as on a ship deck. Ataxic gaits are characterized by irregular, excessive centre of mass motion and disorderly progression (locomotion). Typically, these abnormalities are associated with a widened base and shorter stride. Cadence is also irregular.

Stiff/rigid gaits are gaits in which the usual fluidity of walking is lost. Rotation of trunk is reduced or absent. The range of motion at the knees and hips is reduced, as is arm swing. Base may be abnormally narrow or wide; stride is shortened. Examples are spasticity, parkinsonism, dystonia, multi-infarct states (vascular parkinsonism) and musculoskeletal disorders. The stiffness may be unilateral as in spastic hemiparesis or hemidystonia.

Gaits disturbed by proximal or distal weakness are well recognized. Proximal weakness prevents fixation of the pelvis during single support portions of gait. Myopathies and dystrophies that typically affect proximal muscles commonly produce waddling gaits although occasionally multiple root and peripheral nerve lesions are responsible. Hyperextension of the knee may also occur with proximal weakness. Distal weakness generally affects dorsiflexors of the ankle, requiring the leg to be lifted higher for the toe to clear the ground. Peripheral neuropathies are the common cause of this problem. Corticospinal tract lesions affect the distal leg muscles more than proximal muscles but stiffness and circumduction of the leg differentiate this from weakness caused by peripheral nerve lesions.

Veering gaits are those in which the patient tends to lean, fall or deviate in one direction while walking. Peripheral and central vestibular disorders are the common cause but other brainstem and thalamic lesions may cause similar patterns.

Freezing gaits are those characterized by difficulty initiating (start hesitation and 'slipping clutch' phenomena) and maintaining locomotion while maneuvering in tight quarters, passing through doorways and turning (turn hesitation). There appear to be at least two distinguishable patterns of the freezing gait. Most commonly freezing is associated with a stiff/rigid gait and a narrow base. These patients may have no or reduced lateral sway when trying to initiate walking. Idiopathic parkinsonism, parkinsonism plus syndromes, normal pressure hydrocephalus and vascular parkinsonism are common diagnoses (Giladi et al., 1997). A less common form of freezing is associated with widened base and often exaggerated truncal sway and arm swing to initiate gait. It is this pattern to which 'slipping clutch' is an apt description. It has been associated with multi-infarct state.

Wide based gaits indicate problems with lateral stability. In isolation, that is without dysmetria of the legs and with normal cadence, wide based gaits are seen in midline cerebellar syndromes such as alcoholic cerebellar atrophy and in multi-infarct states.

Cautious gait is marked by mild to moderate slowing, shortening of stride and *en bloc* turns with only minimal widening of the base. Other gait abnormalities are absent. It is termed cautious because it is the gait pattern assumed by a normal person who is concerned about their balance

such as when walking on a slippery surface. Cautious gait is an appropriate response to perceived threats to postural balance. As such, cautious gait is non-specific and may be associated with a variety of problems that impact a person's ability to walk safely. Cautious gait may also be of multifactorial etiology.

A final category is psychogenic gait disorders. Although balance may be disturbed in patients with a psychogenic origin for the problem, most can ambulate as well and therefore are considered as gait disorders. A variety of bizarre patterns that fit none of the above descriptions are possible. Distractibility, inconsistencies and other non-physiological signs are common tip-offs to the diagnosis Keane, 1989; Lampert et al., 1991). Because some of the apraxic disequilibrium syndromes and dystonic gaits may be very bizarre, they can be easily confused with psychogenic gaits.

An 'over cautious' pattern sometimes termed space phobia or fear of falling occurs in some older people with mild, multisystem impairments, generally in response to a fall or some other event arousing their anxiety about falling. Gait is slow, often wide-based, staggering and with prolonged double stance duration. The person must hold on to another person, furniture or the wall to walk (Murphy & Isaacs, 1982). The clinician needs to be 'cautious' about this syndrome and not make the diagnosis without thorough evaluation, including a MRI to look for silent infarcts.

Diagnosis of balance and gait disorders

The remainder of the neurological exam will direct the workup of fall, balance and gait disorders. For unexplained balance and gait disorders, a MRI is indicated and may reveal unexpected infarcts, hydrocephalus, atrophy and particularly subcortical white matter ischemic lesions (Baloh et al., 1995). Vitamin B12 deficiency is another rare cause of unexplained balance and gait disorders.

Treatment of balance and gait disorders

If a treatable lesion is discovered as a cause of imbalance or gait disorders, this is obviously the target of therapy. In many cases there is no single abnormality that is responsible for gait and balance abnormalities and a multifactorial etiology is likely. This is particularly true in the elderly where mild sensory and motor deficits may produce a cautious or pathological gait syndrome. Attempts to improve as many of these factors as possible, even seemingly inconsequential factors, may improve gait and reduce falls (Tinetti et al., 1994). Assessment of home safety to remove hazards, optimize lighting and instal hand-holds is an important method of reducing falls. Strengthening and balance exercises, even in the elderly, reduce risks for falls (Province et al., 1995).

Rehabilitation of balance and gait disorders

The goal of rehabilitation is to eliminate impairments if possible and, if not, to facilitate the most optimal compensatory strategies given the constraints imposed by the impairments. Some impairments, such as weakness and poor range of motion can be readily improved. The extent to which higher level neurological problems affecting balance and gait can be remediated is less clear. However, even if the specific impairments, such as sensory loss, dysmetria, and distorted internal body maps may not be readily improved with exercise and experience, studies have shown that functional balance and gait can be successfully trained (Woollacott & Moore, 1992). Not only can sway area and gait speed improve with training, the use of sensory information for postural orientation can improve and the incidence of falls can be significantly reduced.

The particular therapeutic goal and approach to treatment of balance and gait disorders must be specific to the underlying physiological constraints or impairments. Thus, balance and gait problems due to abnormal timing and scaling of postural synergies would be treated differently from problems due to loss of sensory information and from adaptation and cognitive problems. For example, abnormal synergies for controlling postural sway could be retrained using kinematic biofeedback and functional electrical stimulation during postural sway activities. In contrast, balance and gait in an individual without vestibular information for postural orientation should be retrained by focusing on sensory substitution and increase sensitivity of the remaining visual and somatosensory senses. Patients who compensate poorly for lack of joint coordination by co-contracting the neck or increasing limb spasticity, can be exposed to alternative, less energy inefficient movement patterns, with or without prosthetic or assistive devices. Patients with Parkinson's disease who have difficulty initiating a step, can be shown how to use external cues or imagined cues to trigger a step. In general, rehabilitation of balance and gait should involve exposing subjects to particular tasks and environments that allow the nervous system to discover the most optimal and effective strategies available for their specific functional goals.

In conclusion, this chapter proposes two new classifications that would serve different purposes. The systems

oriented balance and gait disorders classification is intended to provide a logical hierarchy and indicate interrelations of balance and gait disorders. It is partially hypothetical because higher level disorders have received less attention in clinical and laboratory investigations and the proper places for some disorders in the classification are unproven. The pattern or syndrome classification is intended to help the clinician consider the diagnostic possibilities for falls, abnormal postural responses and abnormal gait patterns.

Safe, efficient ambulation is a wonderful attribute of health. Understanding the many ways in which it may be disturbed by neurological disease should lead to better methods to treat or cope with dysfunction.

Part IV

Disorders of the special senses

41

Smell

Richard L. Doty[1] and Steven M. Bromley[1,2]

[1] Smell and Taste Center, University of Pennsylvania Medical Center, Philadelphia, PA, USA
[2] Neurological Institute of New York, Columbia-Presbyterian Medical Center, New York, NY, USA

Possibly owing to the fact that, historically, most disorders of smell function have been difficult to diagnose and treat, physicians often downplay this sense in the routine neurological examination. This is unfortunate when one considers that olfactory disorders are relatively common and profoundly effect a patient's quality of life. Along with its sister sense of taste (see Chapter 42), olfaction determines, among other things, the flavour of foods and beverages, and provides an early warning system for detecting leaking natural gas, spoiled food, fire and other adverse environmental situations. Importantly, olfactory disturbances can be an early sign of such serious diseases or anomalies as Alzheimer's disease, idiopathic Parkinson's disease, epilepsy, multiple sclerosis, and schizophrenia. Although some patients initially present with a frank complaint of a smell disturbance, others are unaware of their dysfunction, pointing out the need for routine quantitative olfactory assessment, which is now easily performed in the office.

In this chapter, we (a) summarize key aspects of olfactory anatomy and physiology, (b) present up-to-date practical techniques for the management and quantitative evaluation of the olfactory system, and (c) describe basic olfactory disorders commonly encountered in the neurological setting.

Anatomy and physiology

Olfactory neuroepithelium: a portal to the central nervous system

The olfactory receptors are located within a ~ 2 cm^2 neuroepithelium lining the cribriform plate and regions of the superior turbinate, middle turbinate, and septum. The neurologist should be aware of the fact that, in addition to the main olfactory system (CN I), other specialized neural systems are present in the nose. These include (a) trigeminal (CN V) afferents responsible, for example, for the coolness of menthol vapours (Doty, 1995a), (b) a rudimentary and non-functional vomeronasal organ (VNO) near the base of the septum (Bhatnagar & Meisami, 1998; Smith & Bhatnagar, 2000), and (c) the poorly understood nervus terminalis or terminal nerve (CN O). CN O, a highly conserved neural plexus that ramifies throughout the nasal epithelium, is distinguished by ganglia at nodal points and a high gonadotropin content, and presumably plays no role in human odour perception (Schwanzel-Fukuda & Pfaff, 1995). Throughout life, islands of respiratory-like epithelial metaplasia appear within the epithelium, presumably as a result of cumulative viral, bacterial, and other insults Among the cells within the neuroepithelium (see Fig. 41.1) are (a) the *bipolar sensory receptor neurons* which harbour the seven domain transmembrane odorant receptors on multiple cilia extending from each dendritic knob, (b) the *supporting or sustentacular cells*, which have microvillae and serve structural and metabolic functions, (c) the poorly understood *microvillar cells* located at the surface of the epithelium, (d) the *cells that line the Bowman's glands and ducts*, and (e) the *globose (light)* and *horizontal (dark) basal cells* – cells located near the basement membrane from which most of the other cell types arise (Huard et al., 1998).

Olfactory nerve cells, as well as the proximal extraneural spaces, are well-established conduits for the movement of viruses and exogenous agents from the nasal cavity into the brain. In the case of viruses, transit times occur at rates usually intermediate between slow and fast axonal transport, e.g. around 3 mm/day for rabies virus, 8–16 mm/day for herpes simplex virus, and 14 mm/day for retrovirus (Stroop, 1995). This pathway has been recognized for some time (e.g. Clark, 1929; Hurst, 1936), as has the knowledge that chemical cauterization of the olfactory mucosa protects against viral-related CNS infection (Armstrong & Harrison, 1935; Burnet & Lush, 1938). Such knowledge led to

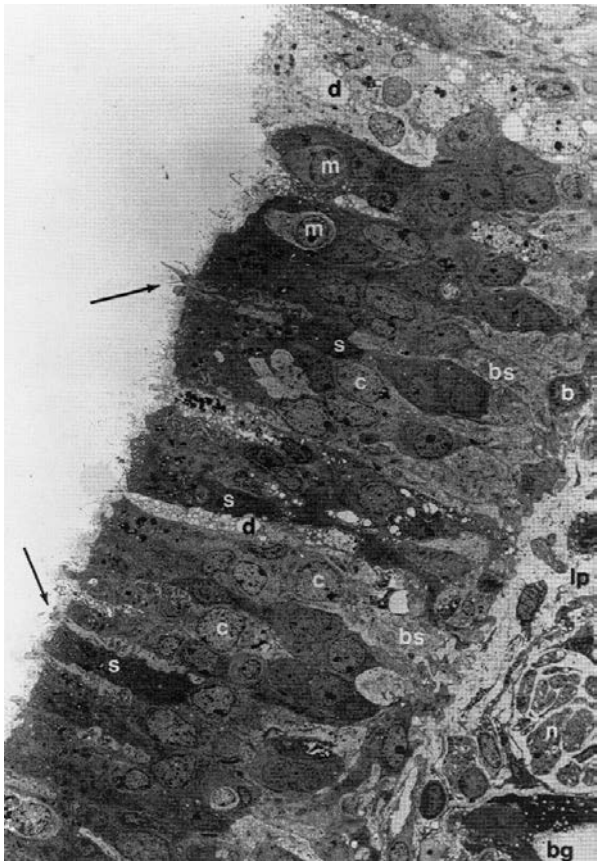

Fig. 41.1. Low-power electron micrograph (×670) of a longitudinal section through a biopsy specimen of human olfactory mucosa taken from the nasal septum. Four cell types are indicated: ciliated olfactory receptors (c), microvillar cells (m), supporting cells (s), and basal cells (b). The arrows point to ciliated olfactory knobs of the bipolar receptor cells. d = degenerating cells; bs = base of the supporting cells; lp = lamina propria; n = nerve bundle; bg = Bowman's gland. a prophylaxis movement in the late 1930s to spray noses of school children with zinc sulfate during poliomyelitis outbreaks (Peet et al., 1937; Schultz & Gebhardt, 1937; Tisdall et al., 1937). More recently, the 'olfactory vector hypothesis' has been proposed to explain both the olfactory loss and the etiology of several common neurodegenerative diseases (Doty, 1991; Doty et al., 1992a; Ferreyra-Moyano & Barragan, 1989; Roberts, 1986; Hawkes et al., 1999).

Olfactory neural transduction

Once odorants traverse the olfactory mucus and reach the cilia, they contact and bind to receptors which initiate the transduction cascades that ultimately result in action potentials. Around 1000 olfactory receptor types are believed to exist, and a given receptor cell contains only one type of receptor (Buck & Axel, 1991). Neurons expressing the same gene seem to be randomly distributed, at least in the mouse, within one of four segregated strip-like 'spatial zones' of the neuroepithelium, and olfactory neurons expressing a given gene seem to project to the same glomeruli within the olfactory bulb (Ngai et al., 1993). A given odorant activates an idiosyncratic pattern of activity across the population of receptors: a pattern that serves as the initial basis for odour perception and discrimination (Shepherd & Firestein, 1991).

Despite the fact that, under normal circumstances, there is continuous neurogenesis within basal segments of the epithelium, many receptor cells are long-lived and become replaced only after damage (Hinds et al., 1984). Both endogenous and exogenous factors promote receptor cell death and replenishment from the basal progenitor stem cells (Mackay-Sim & Kittel, 1990).

The olfactory bulb

The neural components of the olfactory bulb, the first neural processing station in the olfactory pathway, are arranged in six concentric layers: the olfactory nerve layer, the glomerular layer, the external plexiform layer, the mitral cell layer, the internal plexiform layer, and the granule cell layer (Fig. 41.2). The axons of the olfactory nerve cells synapse, within the glomeruli of the glomerular layer, with the dendrites of mitral and tufted cells, the major second order neurons of the olfactory system. The latter cells, in turn, send collaterals that synapse within the periglomerular and external plexiform layers, resulting in 'reverberating' circuits in which negative and positive feedback occur. For example, mitral cells modulate their own output by activating granule cells (which are inhibitory to them). Reciprocal inhibition between neighbouring mitral or tufted cells presumably sharpens the contrast between adjacent channels, perhaps analogous to what occurs among visual receptors within the retina.

The mitral and tufted axons project ipsilaterally to the primary olfactory cortex via the lateral olfactory tract without synapsing in the thalamus. However, some projections from primary to secondary (e.g. orbitofrontal) cortex do relay through the thalamus (see Fig. 41.3). Furthermore, contralateral projections also occur via the anterior commissure, largely from pyramidal cells of the anterior olfactory nucleus (AON).

The primary olfactory cortex

In addition to the AON, the mitral and tufted cells target (from rostral to caudal) (a) the piriform cortex, (b) the

olfactory tubercle, (c) the entorhinal area, (d) the periamygdaloid cortex, and (e) the corticomedial amygdala (Fig. 41.3). Most of the olfactory cortical structures have three distinct layers. The superficial segment of layer 1 contains synapses between (a) the incoming mitral and tufted cell axons and (b) the apical dendrites of the pyramidal cells, the principal olfactory cortical neurons. The deeper segments of layer 1 contain connections among intracortical association areas. Layers 2 and 3 are made up of cell bodies and processes of the pyramidal cells. Small populations of intrinsic short axon cells are present within all three layers. The axons of the pyramidal neurons project reciprocally, via layer 2 and 3 connections, to numerous regions, including the anterior commissure, the mediodorsal thalamus, the posterior hypothalamus, and the medial hypothalamus and hippocampus. Centrifugal fibres richly project from sectors of the olfactory cortex and other central structures to the olfactory bulb, presumably modulating the incoming flow of olfactory sensory signals (Kratskin, 1995) (Fig. 41.4).

Olfactory cortical regions: functional anatomy

While lesions of the olfactory neuroepithelium, the olfactory fila, or the olfactory bulbs and tracts rostral to the olfactory trigone can produce *total anosmia* on the affected side, lesions within olfactory structures more posterior to the olfactory trigone do not typically cause *complete* loss (Gloor, 1997). Orbitofrontal cortex lesions produce difficulties in discriminating or identifying odours, and odour discrimination is reportedly impaired following amygdalotomy (Zatorre and Jones-Gotman, 1991; Jones-Gotman et al., 1997a). In multiple sclerosis, the number of plaques within the inferior medial temporal and inferior frontal lobes correlates strongly ($r = -0.94$) with odour identification test scores (Doty et al., 1997a, 1998). Recent functional imaging studies have reported greater right than left orbitofrontal cortex activation by odorants, suggesting some hemispheric specialization (Malaspina et al., 1998; Yousem et al., 1997a; Zatorre et al., 1992). Olfactory stimulation reliably and significantly activates posterior lateral cerebellar areas, whereas sniffing alone activates mainly anterior central cerebellar regions (Sobel et al., 1998a, b; Yousem et al., 1997).

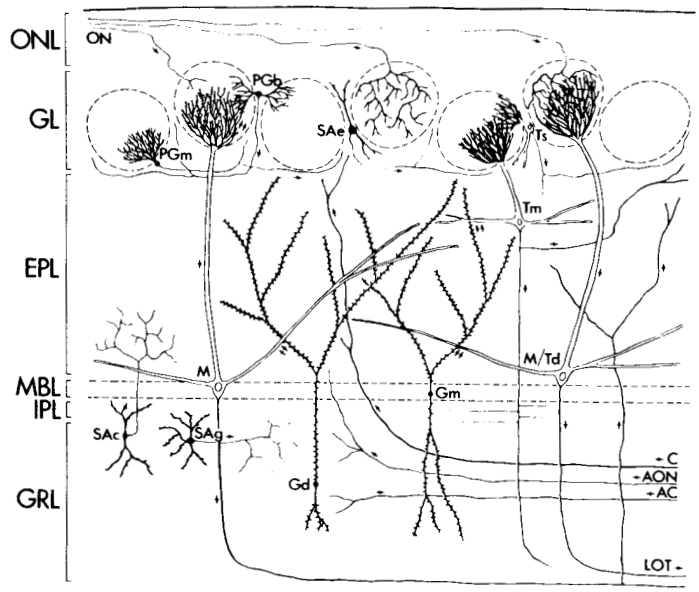

Fig. 41.2. Diagram of major layers and types of neurons in the mammalian olfactory bulb, as based on stained Golgi material. Main layers are indicated on the left as follows: ONL = olfactory nerve layer; GL = glomerular layer; EPL = external plexiform layer; MBL = mitral cell body layer; IPL = internal plexiform layer; GRL = granule cell layer; ON = olfactory nerves; PGb = periglomerular cells with biglomerular dendrites; PGm = periglomerular cell with monoglomerular dendrites; SAe = short-axon cell with extraglomerular dendrites; M = mitral cell; M/Td = displaced mitral or deep tufted cell; Tm = middle tufted cell; Ts = superficial tufted cell; Gm = granule cell with cell body in mitral body layer; Gd = granule cell with cell body in deep layers; SAc = short-axon cell of Cajal; SAg = short-axon cell of Golgi; C = centrifugal fibres; AON = fibres from anterior olfactory nucleus; AC = fibres from anterior commissure; LOT = lateral olfactory tract. Classification of olfactory disorders

Olfactory disorders can be reliably classified as follows: *anosmia*: inability to detect qualitative olfactory sensations (i.e. absence of smell function); *partial anosmia*: ability to perceive some, but not all, odorants; *hyposmia* or *microsmia*: decreased sensitivity to odorants; hyperosmia: abnormally acute smell function; *dysosmia* (sometimes termed cacosmia or parosmia): distorted or perverted smell perception to odorant stimulation; *phantosmia*: a dysosmic sensation perceived in the absence of an odour stimulus (a.k.a. olfactory hallucination); and *olfactory agnosia*: inability to recognize an odour sensation, even though olfactory processing, language, and general intellectual functions are essentially intact, as in some stroke patients. Presbyosmia is sometimes used to describe smell loss due to ageing, but this term is less specific than those noted above (e.g. it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age per se that is causing the age-related deficit.

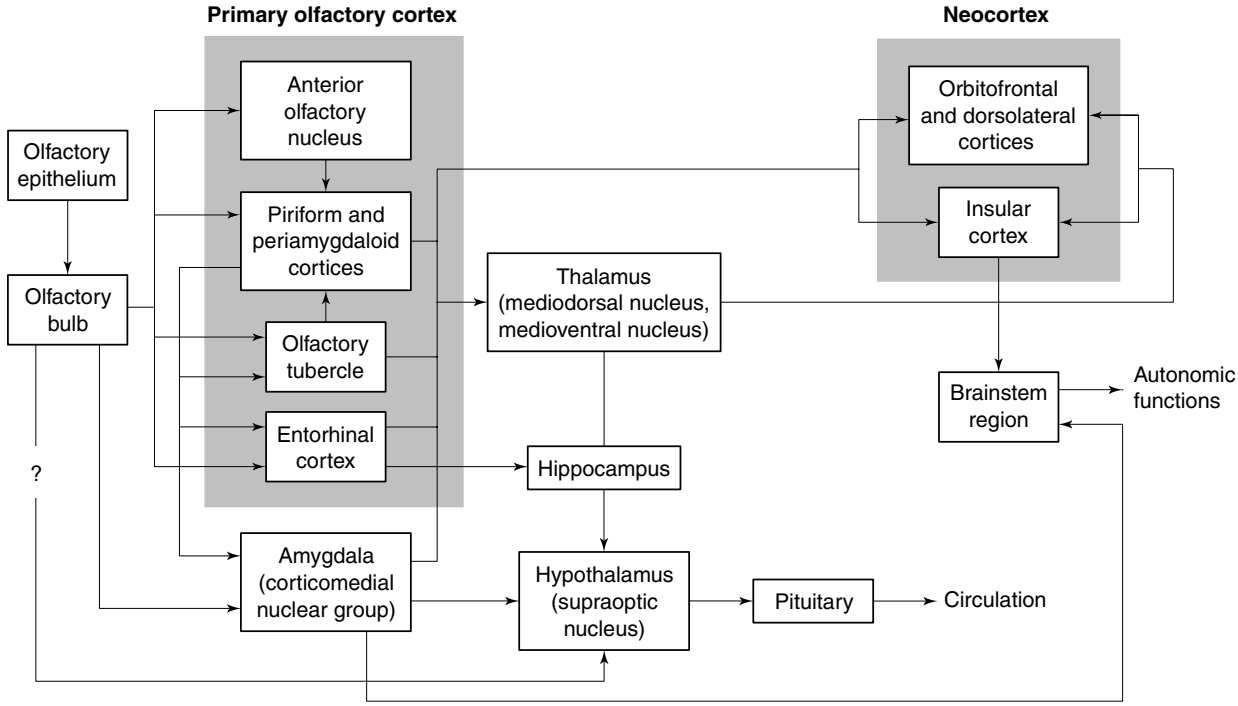

Fig. 41.3. Major afferent neural connections of the olfactory system. Structures common to both the olfactory and limbic systems include the olfactory tubercle, the entorhinal cortex, the amygdala, the hippocampus, and the hypothalamus. Although it is well established that the olfactory fibres project from the amygdala to the 'feeding centre' of the hypothalamus (especially the ventromedial and ventrolateral nuclei), it is unclear whether direct olfactohypothalamic routes exist in humans, as may be the case in some other vertebrates. (Copyright © 2001, Richard L. Doty.)

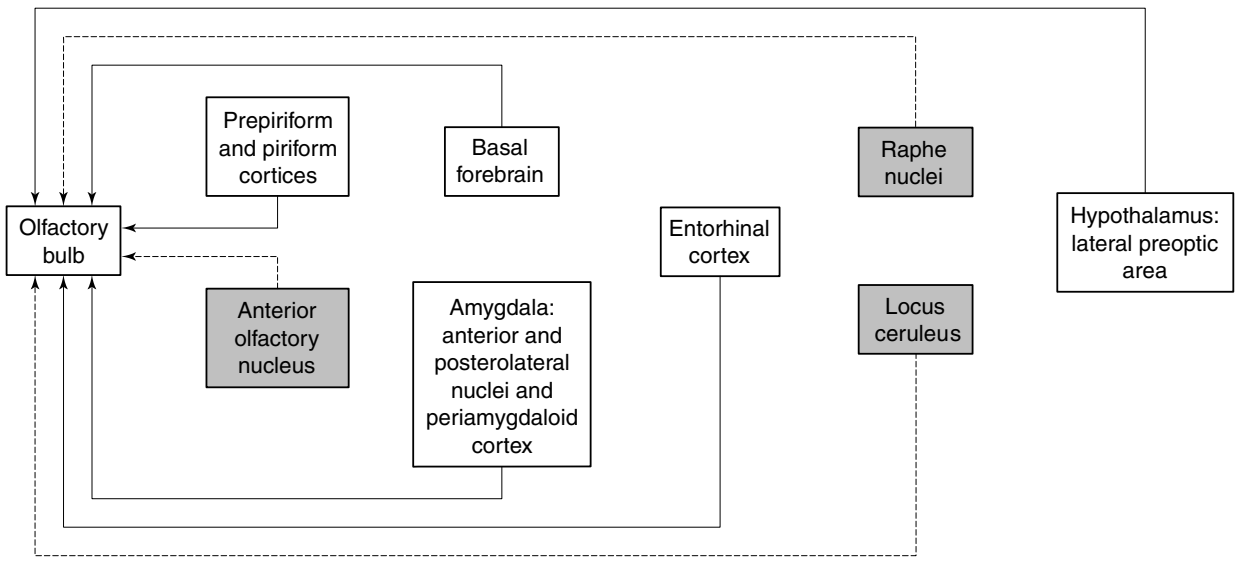

Fig. 41.4. Major neural structures from which centrifugal fibres project to cells within the olfactory bulb. The anterior olfactory nucleus, locus ceruleus, and raphae nuclei are known to have projections to both olfactory bulbs. The other depicted structures are presumed to have primarily, if not solely, ipsilateral projections to the bulbs. (Copyright © 2001, Richard L. Doty.)

Clinical evaluation of olfactory function

History

Details concerning the nature, timing of onset, duration and pattern of fluctuations, if any, of the patient's chemosensory problem are all very important. Discovery of precipitating antecedent events, such as head trauma, viral upper respiratory infections, toxic exposures, and nasal surgeries is critical. A history of allergy should be sought. The use of drugs (e.g. intranasal cocaine), alcohol (e.g. chronic alcoholism in the context of Wernicke and Korsakoff syndromes), and smoking tobacco are also important given the association between smell loss and such factors. A determination of the medications that the patient is or was taking is needed, as some drugs, such as angiotensin-converting enzyme (ACE) inhibitors, often have distinct influences on olfaction. It is critical to be aware that while patients often complain of problems with smell and taste, quantitative testing usually reveals only an olfactory problem, reflecting decreased retronasal stimulation of the olfactory receptors during deglutition (Burdach & Doty, 1987).

The examiner should ascertain whether the patient has any other medical conditions potentially associated with smell impairment (e.g. renal failure, liver disease, hypothyroidism, diabetes, or dementia). Questions regarding epistaxis, discharge (clear, purulent or bloody), nasal obstruction, allergies and somatic symptoms, including headache or irritation may have localizing value. A family history of smell dysfunction may suggest a genetic etiology. Subtle symptoms of central tumours, dementia, parkinsonism, and seizure activity (e.g. automatisms, occurrence of black-outs, auras, and *déjà vu*) should be sought. Delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann's syndrome or some variant thereof.

Physical examination and laboratory tests

The neurological component of the evaluation should focus on cranial nerve function, with particular attention to possible skull base and intracranial lesions. Visual acuity, visual field, and optic disc examinations aid in the detection of possible intracranial mass lesions and in the detection of the Foster Kennedy syndrome (ipsilateral anosmia, ipsilateral optic atrophy, and contralateral papilledema secondary to raised intracranial pressure) (Watnick & Trobe, 1989). The otolaryngological examination should employ nasal endoscopy, both flexible and rigid, to ensure thorough assessment of the olfactory meatal area. Appropriate medical imaging should be employed to assess sinonasal tract inflammation (e.g. computerized tomography), as well as brain lesions and the integrity of the olfactory bulbs, tracts, and cortical parenchyma (e.g. magnetic resonance imaging). Some laboratory tests (e.g. blood serum tests) may be helpful in detecting underlying medical conditions suggested by history and physical examinations, such as infection, nutritional deficiencies (e.g. B6, B12), allergy, diabetes mellitus, and thyroid, liver, and kidney disease (Bromley, 2000).

Quantitative olfactory testing

A number of practical standardized clinical smell tests are now commercially available (for review, see Doty, 2001a), providing the neurologist with the ability to (a) determine of the validity of patients' complaints (including the detection of malingering), (b) characterize the exact nature of the problem, (c) reliably monitor changes in function over time (including those of iatrogenic etiology), and (d) accurately establish compensation for permanent disability. The most widely used of these tests are self-administered 'scratch and sniff' tests, ranging from the 3-item Pocket Smell Test™ to the 40-item University of Pennsylvania Smell Identification Test (UPSIT; commercially termed the Smell Identification Test™ or SIT) (Doty, 1995b; Doty et al., 1996). Available in English, Spanish, French, and German language versions, the latter test can be self-administered in 10 to 15 minutes by most patients in the waiting room, and scored in less than a minute by non-medical personnel. Results are expressed in terms of a percentile score of a patient's performance relative to age- and sex-matched controls, as well in categories of function: normosmia, mild microsmia, moderate microsmia, severe microsmia, anosmia, and probable malingering. Malingering is inferred from improbable responses in the forced-choice setting.

Although olfactory event-related potentials (OERPs) are available in some specialized medical centers, including our own, their general practicality is limited. They require expensive equipment capable of delivering well-delineated 'square wave' odorant pulses to the olfactory receptors within a background of continuously flowing warmed and humidified air (Doty & Kobal, 1995). Unlike their visual and auditory counterparts, OERPs are unable to discern where in the pathway the anomaly exists.

Causes of olfactory dysfunction

In general, olfactory dysfunction is due to one of three causes: (a) conductive or transport impairments from

obstruction of the nasal passages (e.g. by chronic nasal inflammation, polyposis, etc.); (b) sensorineural impairment from damage to the olfactory neuroepithelium (e.g. by viruses, airborne toxins, etc.); and (c) central olfactory neural impairment from CNS damage (e.g. tumours, masses impacting on olfactory tract, etc.). These categories are not necessarily mutually exclusive. For example, both damage and blockage of airflow to the receptors can occur from chronic rhinosinusitis.

As seen in Table 41.1, there are a number of known etiologies for olfactory disturbance. Nearly two-thirds of cases of chronic anosmia or hyposmia (i.e. those which are presumably permanent) are due to prior upper respiratory infections, head trauma, and nasal and paranasal sinus disease, and most reflect permanent damage to the olfactory neuroepithelium (Deems et al., 1991). Other causes include iatrogenic interventions (e.g. septoplasty, rhinoplasty, turbinectomy, radiation therapy, medications), intranasal neoplasms (e.g. inverting papilloma, hemangioma, and esthesioneuroblastoma), intracranial tumours or lesions (e.g. Foster Kennedy Syndrome, olfactory groove meningiomas, frontal lobe gliomas), neurodegenerative diseases, toxic exposures (which includes smoking), epilepsy, psychiatric disorders, and various endocrine and metabolic disorders. Details regarding some of the more common entities associated with smell loss are discussed below.

Ageing

In later life, decreased smell function is the rule, rather than the exception, and is largely responsible for the well-documented age-related increases in accidental gas poisonings and explosions, as well as weight loss, malnutrition, impaired immunity, and worsening of some medical illnesses (Doty et al., 1984a, Miletic et al., 1996; Mattes & Cowart, 1994). In contrast to the ~ 1% of persons under the age of 65 years with major smell loss, about half of the population between 65 and 80 years of age has such loss (Fig. 41.5). Over the age of 80, this figure rises to nearly 75% (Doty et al., 1984a). Often an accumulation of damage over the years is the culprit and a single event, such as a bad cold, can be the precipitating factor. In some cases, the olfactory loss may reflect, as a result of age-related appositional bone growth, the pinching off of the olfactory fila as they traverse the ethmoid bone (Kalmey et al., 1998). In general, the number olfactory receptors and olfactory bulb glomeruli decrease markedly with age (Smith, 1942; Meisami et al., 1998).

Post-upper respiratory infections

The most common cause of *permanent* smell loss in the adult human is that induced by upper respiratory infections

(URIs), such as those associated with the common cold, influenza, and pneumonia. Often the respiratory illness is described as being more severe than usual. Exactly what predisposes someone to viral- or bacterial-induced smell dysfunction or the mechanisms underlying it remains unclear. Direct insult to the olfactory neuroepithelium is likely, but central structures may also be affected. In general, patients with URI-related anosmia have markedly reduced numbers of receptors and when receptors are present, they appear abnormal compared to those patients with hyposmia (Jafek et al., 1990). Although spontaneous recovery in

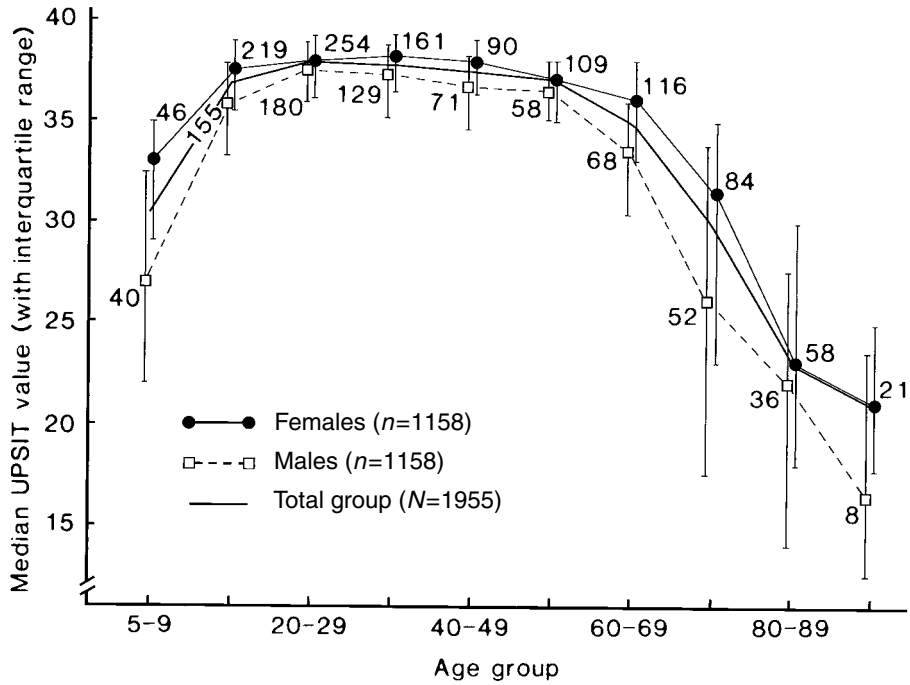

Fig. 41.5. Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age and gender in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. (From Doty et al., 1984b; Copyright © 1984, American Association for the Advancement of Science.)

these patients is theoretically possible given the propensity of olfactory neurons to regenerate, meaningful recovery is unlikely when marked loss has been present for a period of time.

Head trauma

Smell disturbance following head trauma is common, particularly where rapid acceleration/deceleration of the brain occurs (i.e. coup contra coup injury). On average, blows to the occiput have been found to produce greater olfactory loss than blows to the front of the head (Doty et al., 1997b). The most common mechanisms include disruption of the sinonasal tract from shearing forces, and direct contusion and ischemia to the olfactory bulb and frontal and temporal poles (Fig. 41.6). The prevalence of olfactory dysfunction in patients with head trauma is typically below 15% (Yousem et al., 1999), and is proportional to the severity of the injury (Doty et al., 1997b). Dysosmia, when present, typically decreases significantly over the post-trauma period (Doty et al., 1997b). In severe cases, MRI images reveal damage to the olfactory bulbs, tracts, and areas of the temporal and frontal lobes (Yousem et al., 1996). Animal studies show that intracranial hemorrhage and ischemia can lead to degeneration of the olfactory epithelium without transection of the olfactory nerves (Nakashima et al., 1983).

Nasal and sinus disease

Unlike the sensorineural dysfunction that can follow a viral syndrome or head trauma, olfactory impairment that accompanies nasal or sinus disease has been traditionally viewed as being solely conductive. However, empirical data suggest that surgical (e.g. excision of polyps) or medical (e.g. administration of topical or systemic steroids) treatment rarely returns function to normal levels, implying that blockage alone cannot explain the olfactory loss (Doty & Mishra, 2001). Recently it has been shown that the severity of histopathological changes within the olfactory mucosa of patients with chronic rhinosinusitis is positively related to the magnitude of olfactory loss (Kern, 2000). Furthermore, biopsies from the neuroepithelial region of patients with nasal disease are less likely to yield olfactory-related tissue than biopsies from controls (Feron et al., 1998). The same is true for anosmic vs. non-anosmic rhinosinusitis patients, the former of whom exhibit a generally more pathological epithelium (e.g. disordered arrangement of cells, more islands of respiratory-like epithelium) (Lee et al., 2000).

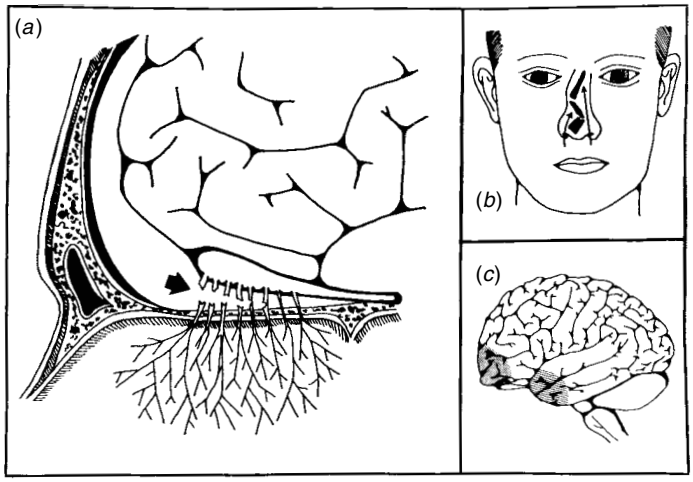

Fig. 41.6. Mechanisms of post-traumatic olfactory dysfunction. (*a*) Shearing or tearing of the olfactory fila. (*b*) Injury to the sinonasal tract (*c*) Cortical contusions and brain hemorrhage. (From Costanzo & Zasler, 1991; Copyright © 1991, Raven Press, Ltd.)

CNS neoplasms

According to Finelli and Mair (1991), the single most egregious error of neurologists is failure to recognize the symptom of anosmia as the principal or sole feature of an olfactory groove neoplasm. Tumours impinging on the olfactory bulbs or tracts, such as olfactory groove meningiomas, frontal lobe gliomas, and suprasellar ridge meningiomas arising from the dura of the cribriform plate, have been associated with olfactory disturbance, as have tumours on the floor of the third ventricle, pituitary tumours that extend above the sella turcica, and tumours in the temporal lobe or uncinate convolution.

Neurodegenerative and other neurological diseases

Olfactory deficits have been described in such neurological disorders as Alzheimer's disease, idiopathic Parkinson's disease, Huntington's disease, alcoholic Korsakoff's syndrome, Pick's disease, the parkinson dementia complex of Guam, amyotrophic lateral sclerosis, schizophrenia, and multiple sclerosis (Mesholam et al., 1998; Doty, 1991; Doty et al., 1998; Moberg et al., 1997a; b). Importantly, olfactory dysfunction may be the first clinical sign of Alzheimer's disease (AD) and idiopathic Parkinson's disease (PD) (Doty et al., 1987, 1988b). Although not classically considered a neurodegenerative disease, schizophrenia also is associated with smell loss that appears to be correlated with disease duration, suggesting a possible progressive or degenerative component to this disorder in olfaction-related pathways (Moberg et al., 1997b). The olfactory bulbs and tracts of patients with schizophrenia are markedly smaller than those of controls (Turetsky et al., 2000).

Two studies have recently demonstrated that smell testing is useful in identifying persons at risk for later significant cognitive decline or AD. Graves et al. (1999) tested 1985 Japanese–American people around the age of 60 with cognitive tests and an abbreviated version of the UPSIT, and then rescreened 1604 of these people after two years. They also genotyped 69% of the follow-up participants for apolipoprotein E (apoE). Overall, olfactory dysfunction in the presence of one or more APOE-e4 alleles was associated with a very high risk of subsequent cognitive decline, and smell testing identified persons who came to exhibit later cognitive decline better than did a global cognitive test. More recently, Devanand et al. (2000) administered the UPSIT to 90 outpatients with mild cognitive impairment at 6-month intervals, along with matched healthy controls. Patients with mild cognitive impairment scored lower on the UPSIT than did the controls. Most importantly, patients with low UPSIT scores ($<$34) were more likely to develop AD than the other patients. Low UPSIT scores, combined with lack of awareness of olfactory deficits on the part of the patients, predicted the time to development of AD. UPSIT scores from 30–35 showed moderate to strong sensitivity and specificity for diagnosis of AD at follow-up.

The underlying physiological basis of the olfactory loss in patients with AD is not yet clear, although this disorder is associated with a profound loss of neurons in the anterior olfactory nucleus, olfactory bulb, and layer II of the entorhinal cortex (Doty, 1991; Gomez-Isla et al., 1996). Limbic brain regions which receive olfactory bulb mitral and tufted cell projections are disproportionately laden with neurofibrillary tangles and neuritic plaques (Delacourte et al., 1999). Deficits in the neurotransmitter acetylcholine may somehow relate to this problem, as it is well established that (a) individuals with no history of cognitive loss that are in the early histopathologic stages of AD exhibit a cholinergic deficit within the inferior temporal lobe and (b) drugs that alter cholinergic function alter the ability to smell. For example, scopolamine, a muscarinic cholinergic antagonist, reportedly decreases olfactory sensitivity (Serby et al., 1990), whereas physostigmine, a cholinesterase inhibitor, improves odour discrimination performance, at least in rats (Doty et al., 1999a).

In idiopathic PD, bilateral olfactory deficits occur before the onset of most of the classical neurological signs and symptoms (Doty et al., 1988b). The PD-related olfactory impairment is unrelated to disease stage, use of anti-parkinson medications, duration of the illness, and severity of the symptoms, such as tremor, rigidity, bradykinesia

or gait disturbance (Doty et al., 1992b). Since olfactory loss is pervasive and marked in PD, as well as in AD, and is absent or not present to the same degree in a number of other neurological disorders, it can be used to distinguish among disorders that share many symptoms and signs with PD (Doty, 1991). For example, while patients with essential tremor, progressive supranuclear palsy, multiple system atrophy and parkinsonism induced by the proneurotoxin 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP) share a number of motor symptoms with idiopathic PD, they have little or no olfactory dysfunction (Doty, 1991). Like idiopathic PD, familial PD is also associated with olfactory impairment, and this heritable defect occurs independently of the parkinsonian phenotype (Markopoulou et al., 1997).

In multiple sclerosis, olfactory loss is directly proportional to the number of MS-related plaques in central brain regions associated with olfactory processing (e.g. inferior middle temporal lobe and periorbital frontal cortex) (Doty et al., 1997b, 1998). A 1:1 longitudinal association is present between UPSIT scores and changes in plaque load over time (Doty et al., 1999b), implying that olfactory function increases and decreases as the plaque numbers increase and decrease. In effect, knowledge of a patient's UPSIT score largely predicts the plaque load in the olfaction-related regions.

Other causes

A number of environmental and industrial chemicals have been linked to olfactory dysfunction, including acrylates, cadmium, benzene, formaldehyde, solvents, and nickel dust, although few well-controlled studies exist in this area and most reports are largely anecdotal (Doty & Hastings, 2001). With regard to cigarette smoking, olfactory ability decreases as a function of cumulative smoking dose and cessation of smoking can result in improvement in olfactory function over time (Frye et al., 1990). Medications commonly affect smell function and should be considered early in an evaluation, especially in the context of a new drug therapy (Table 41.2). Olfactory hallucinations occur in mesial temporal lobe seizures and migraine. Hyperosmia is classically associated with pregnancy and hyperemesis gravidarum, although objective evidence of true hypersensitivity, rather than hyperreactivity, is still lacking. Despite the fact that some patients with apparent multiple chemical hypersensitivity syndrome (MCS) report heightened ability to smell, olfactory thresholds are not meaningfully altered (Doty et al., 1988a). Hyperosmia reportedly occurs in some cases of epilepsy during the interictal period, although, as noted above, most patients with long-term epilepsy and intractable seizure activity, such as candidates for temporal lobe resection, are hyposmic.

Treatment of olfactory disorders

As alluded to earlier, meaningful treatments are available for some, but not all, patients whose olfactory dysfunction is conductive; i.e. resulting from blockage of airflow to the olfactory neuroepithelium. Such therapies include allergy management, topical and systemic corticosteroid therapies, and surgical procedures to reduce inflammation or obstructions (e.g. polyps). A brief course of systemic steroid therapy can be useful in distinguishing between conductive and sensorineural olfactory loss, as patients with the former will often respond positively to some extent to the treatment, although longer term systemic steroid therapy is not advised. Topical nasal steroids are often ineffectual in returning smell function because the steroid fails to reach the affected regions in the upper nasal passages. Increased efficacy presumably occurs when the nasal drops or spray are administered in the head-down Moffett position.

Patients with sensorineural causes of olfactory disturbance are difficult to manage, and the prognosis for patients suffering from long-standing total loss due to upper respiratory illness or head trauma is poor. Most patients who recover smell function subsequent to trauma do so within 12 weeks of injury (Costanzo et al., 1995). Although there are no verified treatments for trauma-related olfactory loss, anti-inflammatory agents may minimize post-traumatic sequelae in some cases. Recent rat research suggests that application of nerve growth factor onto the olfactory epithelium may alleviate axotomy-induced degenerative changes in the olfactory receptor neurons, although it is not known whether this has any functional consequence or if such a procedure in humans would be efficacious (Yasuno et al., 2000).

Tobacco smoking by itself rarely causes complete loss of the sense of smell, although patients who quit smoking typically have dose-related improvement in olfactory function and flavour sensation over time (Frye et al., 1990). Central lesions, such as CNS tumours that impinge on olfactory bulbs and tracts and epileptogenic foci within the medial temporal lobe that result in olfactory seizures, can often be resected in a manner that allows for some restoration of olfactory function. Medications that induce distortions of olfaction can often be discontinued and replaced with other types of medications or modes of therapy. Importantly, dopaminergic and cholinergic therapies do not improve the olfactory dysfunction seen in Parkinson's disease, and there is no evidence that neuroleptics alter the

Clarithromycin (Biaxin)
Enalapril (Vaseretic)
Griseofulvin (Grisactin)
Metronidazole (Flagyl)
Ofloxacin (Floxin)
Terbinafine (Lamisil)
Ticarcillan (Timentin)
Tetracycline

Anticonvulsants
Carbamazepine (Tegretol)
Phenytoin (Dilantin)

Antidepressants
Amitriptyline (Elavil)
Clomipramine (Anafranil)
Desipramine (Norpramin)
Doxepin (Sinequan)
Imipramine (Tofranil)
Nortriptyline (Pamelor)

Antihistamines and decongestants
Chlorpheniramine
Loratadine (Claritin)
Pseudoephedrine

Antihypertensives and cardiac medications
Acetazolamide (Diamox)
Amiodarone (Pacerone)
Amiloride (Midamor)
Amiodarone (Cordarone)
Betaxolol (Betoptic)
Captopril (Capoten)
Diltiazem (Cardizem)
Enalapril (Lexxel, Vasotec, Vaseretic)
Hydrochlorothiazide (Esidix)
Nifedipine (Procardia)
Nitroglycerin
Propafenone (Rythmol)
Propranolol (Inderal)
Spironolactone (Aldactone)
Tocainide (Tonocard)

Anti-inflammatory agents
Auranofin (Ridaura)
Beclomethasone (Beclovent, Beconase)
Budesonide (Rhinocort)
Colchicine
Dexamethasone (Decadron)
Flunisolide (Nasalide, Aerobid)
Fluticasone (Flonase)
Gold (Myochrysine)
Hydrocortisone
Penicillamine (Cuprimine)

Antimanic drugs
Lithium

Antimigrane agents
Dihydroergotamine (Migranal)
Naratriptan (Amerge)
Rizatriptan (Maxalt)
Sumatriptan (Imitrex)

Antineoplastics
Cisplatin (Platinol)
Doxorubicin (Adriamycin)
Levamisole (Ergamisol)
Methotrexate (Rheumatrex)
Vincristine (Oncovin)

Antiparkinsonian agents
Levodopa (Larodopa; with carbidopa: Sinemet)

Antipsychotics
Clozapine (Clozaril)
Trifluoperazine (Stelazine)

Antithyroid agents
Methimazole (Tapazole)
Propylthiouracil

Antiviral agents
Ganciclovir (Cytovene)
Interferon (Ruferon-A)
Zalcitabine (HIVID)

Bronchodilators
Biotolterol (Tornalate)
Pirbuterol (Maxair)

Lipid-lowering agents
Atorvastatin (Lipitor)
Fluvastatin (Lescol)
Lovastatin (Mevacor)
Pravastatin (Pravachol)

Muscle relaxants
Baclofen (Lioresal)
Dantrolene (Dantrium)

Pancreatic enzyme preparations
Pancrelipase (Cotazym)

Smoking cessation aids
Nicotine (Nicotrol)

olfactory loss of patients with schizophrenia. Despite the fact there are advocates for zinc and vitamin therapies, there is no compelling evidence that these therapies work except in cases where frank zinc or vitamin deficiencies exist.

Prognosis for recovery seems to be better for patients with not too severe microsmia (e.g. UPSIT scores above 25) than for those with anosmia or severe microsmia. In some etiologies, this reflects the less extensive damage into the basal cell layer of the epithelia and possibly less fibrosis around the foramina of the cribriform plate through which the olfactory nerve axons pass. An important component to therapy for many patients is the quantitative establishment of the true degree of olfactory loss. This places the patient's problem into overall perspective; thus, it can be therapeutic for an older person to learn that, while his or her smell function is not what it used to be, it still falls above the average of his or her peer group.

Taste

Steven M. Bromley[1, 2] and Richard L. Doty[1]

[1] Smell & Taste Center, University of Pennsylvania Medical Center, Philadelphia, PA, USA
[2] Neurological Institute of New York, Columbia-Presbyterian Medical Center, New York, NY, USA

Taste modifies the act of eating, and subsequently has a tremendous impact on one's behaviour and well-being. The physiologic role of the gustatory system is multifold and includes: (a) triggering ingestive and digestive reflex systems that alter the secretion of oral, gastric, pancreatic, and intestinal juices (Schiffman, 1997; Giduck et al., 1987), (b) reinforcing the ingestive process by enhancing the feelings of pleasure and satiety (Warwick et al., 1993), and (c) enabling the individual to determine the quality of sampled foodstuffs and distinguish nutrients (which usually taste 'good') from potential toxins (which usually taste 'bad') (McLaughlin & Margolskee, 1994; Scott & Giza, 1995). Although rarely appreciated, gustatory dysfunction can alter food choices and patterns of consumption, resulting in weight loss, malnutrition, and possibly impaired immunity (Schiffman & Wedral, 1996; Mattes & Cowart, 1994). Increased sensitivity and aversion to bitter-tasting substances on the part of the pregnant mother during the first trimester presumably reflects the need to detect and avoid bitter tasting poisons and teratogens during this critical phase of fetal development. Similarly, increased preferences for salty and bitter tasting substances during the remainder of pregnancy likely encourage the eating of a varied diet and the ingestion of much needed electrolytes to expand fluid volume (Duffy et al., 1998). In someone who is hypertensive or diabetic, taste loss can lead to a dangerous tendency to over-compensate for the loss by adding additional salt or sugar to the food.

In this chapter, we review clinically important aspects of the anatomy and physiology of the gustatory system, describe approaches for quantitatively evaluating this system, and present examples of common types of gustatory dysfunction, along with means for their management or treatment.

Anatomy and physiology

Taste buds, papillae, and initiation of taste transduction

The ~4600 goblet-shaped taste buds are located on the tongue's dorsal surface, the tongue–cheek margin, the base of the tongue, the soft palate, the pharynx, the larynx, the epiglottis, the uvula, and the first third of the esophagus (Miller, 1995). Most are found on the surface of the tongue within the protruding papillae. The fungiform, foliate and vallate (also called circumvallate) papillae harbor most of the taste buds; filiform papillae do not (Fig. 42.1).

Each taste bud contains between 50 and 150 slender epithelial cells arranged in a manner similar to the segments of a grapefruit. The taste pore opens into the centre of the bud, the taste pit, into which microvillae of sensory cells project. Each bud contains not only sensory and supporting cells, but progenitor cells from which the other cell types arise. Light, dark, and intermediate cells can be identified on the basis of their ultrastructural appearance and the presence or lack of dense granules in their apical portion (Farbman, 1980). Taste bud cells have the propensity to replace themselves ('turn over') periodically, with a time course of around two weeks (Beidler & Smallman, 1965).

A tastant initiates gustatory transduction and ultimately action potentials in one of two ways: by directly gating apical ion channels on microvillae of taste bud cells (a process that probably occurs with sour- and salty-tasting substances) or by activating receptors coupled to G-proteins that, in turn, are coupled to various second messenger systems (a process that probably occurs for sweet- and bitter-tasting agents; for review, see Margolskee, 1995). The

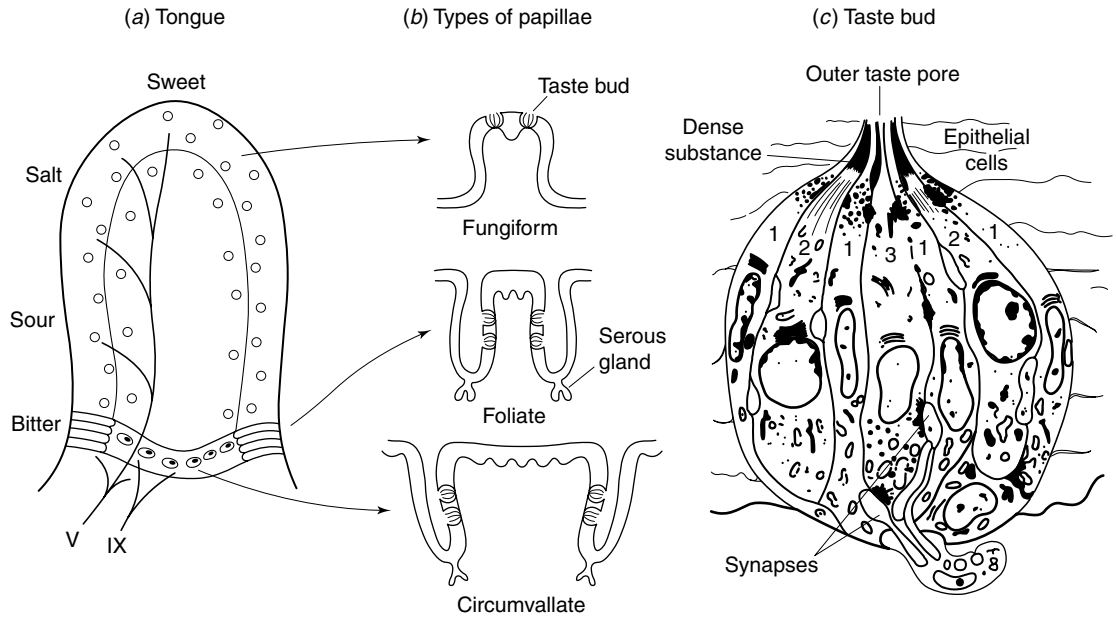

Fig. 42.1. (*a*) Lingual distribution of (*b*) types of papillae that harbour (*c*) taste buds. In (*c*), 1 and 2 are presumably supporting cells, which secrete materials into the lumen of the taste buds; 3 is a sensory receptor cell; and 4 is a basal cell from which the other types of cells arise. (Modified from Shepherd, 1994.)

full range of primary taste sensations may be broader than simply sweet, sour, salty, and bitter, including 'metallic' (iron salts), 'umami' (monosodium glutamate, disodium gluanylate, disodium inosinate), and 'chalky' (calcium salts) (Schiffman, 1997; Kurihara & Kasiwayangi, 2000). The olfactory and trigeminal systems contribute to overall flavour perception by providing aroma, texture, temperature and spiciness.

Saliva and its role in taste function

Saliva contains dozens of different proteins and peptides (Table 42.1) and is secreted into the oral cavity by numerous glands, most importantly the paired parotid, submandibular, and sublingual salivary glands. Saliva is involved in the taste process, *per se*, in at least four ways. First, before tastants can enter the taste buds, they must be solubilized, and tastants dissolve or mix with saliva before entering the taste pore. Secondly, saliva serves as a filter to influence the concentration of tastants that enter the taste buds. For example, when bitter-tasting tannin-containing foods are ingested, there is an increase in the amount of proline-rich salivary proteins that bind tannins (Beidler, 1995). Such binding decreases the amount of tannins available to the taste buds, thereby increasing the taste threshold to the tannins. Third, saliva rinses away tastants and other materials that are introduced into the mouth, decreasing their tendency to linger in the oral cavity. Finally, saliva appears to play a role in taste bud maintenance. For example, taste buds within the fungiform papillae of rats disappear following removal of the submandibular and sublingual salivary glands: disappearance that can be reversed by adding epidermal growth factor to their drinking water (Morris-Witman et al., 2000).

Multiple peripheral pathways to the gustatory nucleus

The taste buds are innervated by branches of several cranial nerves which, unlike CN I, are mixed motor and sensory nerves transmitting multiple forms of information. The facial nerve (CN VII) supplies the taste buds within the fungiform and filiform papillae on the anterior two-thirds of the tongue (via the chorda tympani) and those on the soft palate (via the lesser palatine nerve branch of the greater petrosal nerve). The cell bodies of these afferent gustatory fibres are located in the geniculate ganglion. A short distance of the CN VII taste fibres is shared with the lingual nerve (CN V3) proximal to the tongue. The glossopharyngeal nerve (CN IX) supplies the circumvallate and most foliate taste buds within the posterior third of the tongue via its lingual–tonsillar branch. The

Table 42.1. Proteins and peptides in mammalian whole saliva

N-Acetyl-D-glucosaminidase	IgA
Agglutinagen A	IgG
Agglutinagen B	IgM
Agglutinagen C	Kallikrein
Albumin	Lactoferrin

Antitrypsin	Mesodermal growth factor
Aproerytherin	Metalloprotease
Biopterin	Monopterin
Bone marrow colony-stimulating factor	Mucins
	Neopterin
Calmodulin	Nerve growth factor
Carbonic anhydrase	Neural tube growth factor
Cathespin	Parotid glycoprotein family
Collagenase	Peroxidase
Cystatin family	Plasminogen activator
Elastase	Platelet-activating factor
Endothelial growth-stimulating factor	Proline-rich proteins
	Prostaglandins
Esterase	Pterin
Esterase B	Renin
Esteropeptidase	Sialomucin
Ferritin	Sialotonin
Fibronectin	Somatostatin
Fucosyltransferase	Statherin
Gastrin	Tissue plasminogen activator
Glucagon	Tonin
Glutamine-glutamic acid protein family	Transferrin
	VEG protein
Granulocytosis-inducing factor	Vitamin B-binding proteins
	Wound contraction factor
5-Hydroxymethylpterin	Xanthopterin

Notes:
If individual protein family members and isoenzymes are included separately, the total number approaches 200.

Table 42.2. Relative potency, in terms of taste thresholds, among different chemical compounds that have primarily sweet, sour, salty, or bitter tastes

Salty-tasting substances	*Index*	*Sour-tasting substances*	*Index*
Sodium chloride	1	Hydrochloric acid	1
Ammonium chloride	2.5	Formic acid	1.1
Sodium fluoride	2	Chloracetic acid	0.9
Calcium chloride	1	Lactic acid	0.85
Potassium chloride	0.6	Tartaric acid	0.7
Sodium bromide	0.4	Malic acid	0.6
Lithium chloride	0.4	Acetic acid	0.55
Sodium iodide	0.35	Citric acid	0.46
Sweet-tasting substances	*Index*	*Bitter-tasting substances*	*Index*
Sucrose	1	Quinine	1
Sucrononic acid	200,000	Denatonium	1000
Saccharin	675	Strychnine	3.1
Aspartame	150	Nicotine	1.3
Chloroform	40	Brucine	1.1
Fructose	1.7	Phenylthiourea	0.9
Alanine	1.3	Caffeine	0.4
Glucose	0.8	Morphine	0.02

Notes:
The thresholds can vary as much as several thousand-fold from one compound to another, even within the same class.

pharyngeal branch of this nerve innervates taste buds in the nasopharynx. The nerve cell bodies of these visceral gustatory afferent fibres are located immediately outside the jugular foramen in the petrosal ganglion. The vagus nerve (CN X) innervates the taste buds on the epiglottis, aryepiglottal folds, and esophagus (via the internal portion of the superior laryngeal branch).

Gustatory cortical regions: functional anatomy

All the peripheral gustatory fibres enter the brainstem and project to the nucleus of the tractus solitarius (NTS), which begins in the rosterolateral medulla and extends caudally along the ventral border of the vestibular nuclei. From this structure, connections are made to higher processing centres described below. The cells of the NTS also make reflexive connections, via the interneurons of the reticular formation, with cranial nuclei that control (a) muscles of facial expression, (b) taste-mediated behaviours such as chewing, licking, salivation and swallowing, and (c) pre-absorptive insulin release (Smith & Shipley, 1992).

In primates, the projections from the NTS to higher centres likely ascend ipsilaterally within the central tegmental tract, to synapse ultimately within the parvicellular division of the ventroposteromedial thalamic nucleus

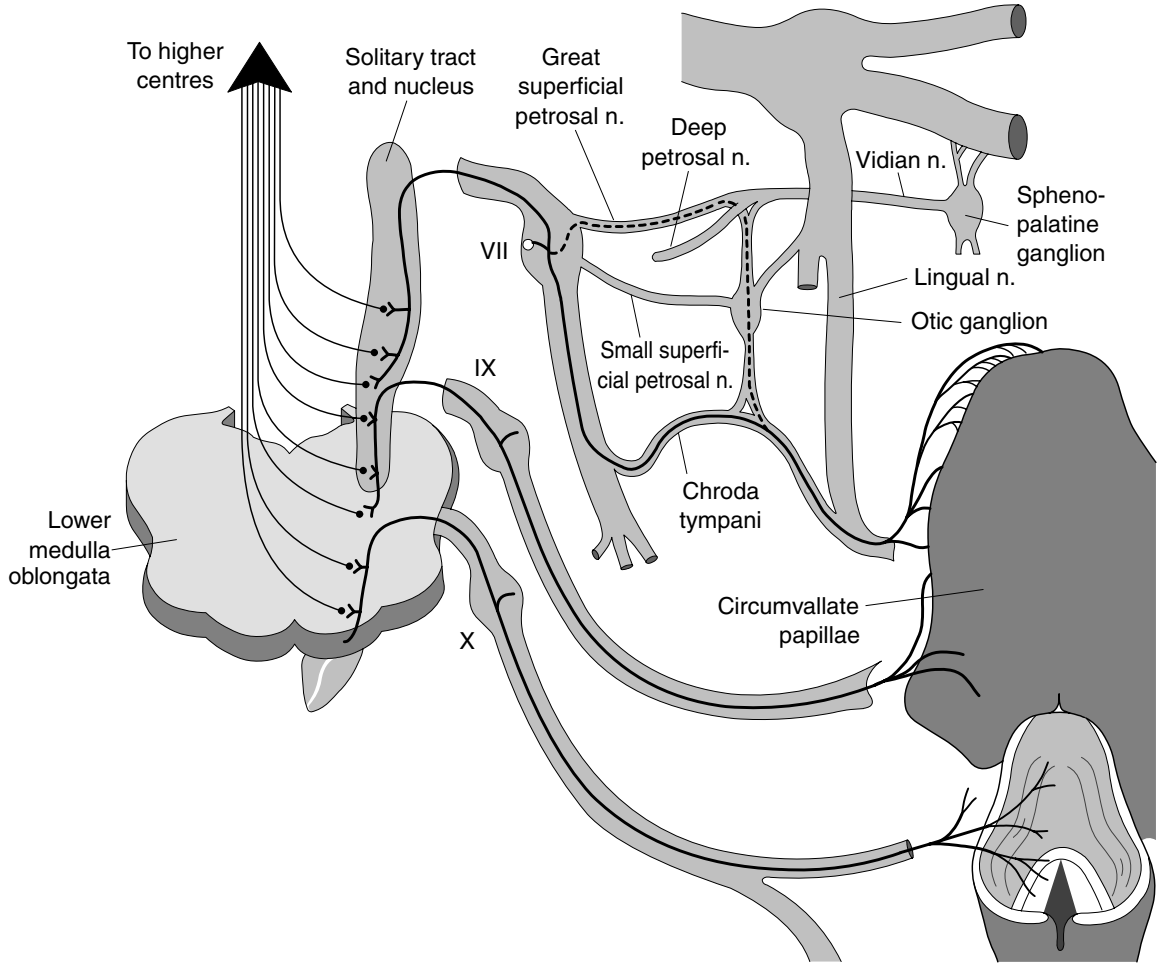

Fig. 42.2. Distribution of cranial nerves to gustatory regions. CN VIII fibres from the geniculate ganglion innervate taste buds on the anterior portion of the tongue and on the soft palate. CN IX fibres from cell bodies within the petrosal ganglion innervate taste buds on foliate and vallate papillae of the tongue, as well as pharyngeal taste buds. CN X fibres from cell bodies in the nodose ganglion innervate taste buds on the epiglottis, larynx and esophagus. (Modified and adapted from Netter, F.H. The CIBA Collection of Medical Illustrations, Vol. 1. Nervous System. Ciba Pharmaceutical Corporation, New York, 1964.)

(termed the thalamic taste nucleus or TTN) (Beckstead et al., 1980; Onoda & Ikeda, 1999). From the TTN, fibres then project to the primary taste cortex, which is located deep in the parietal operculum and adjacent parainsular cortex near somatosensory centres for oral sensation and motor centres for the control of jaw and tongue movement (Pritchard et al., 1986). Functional imaging studies suggest tastants activate insular and perisylvian regions, including the frontal operculum, superior temporal gyrus (opercular part), and inferior parts of the pre- and postcentral gyrus (Gloor, 1997; Faurion et al., 1998). A secondary cortical taste region is located in the caudomedial/caudolateral orbitofrontal cortex, extending several millimetres in front of the primary taste cortex (Rolls, 1995).

Little is known about the role the gustatory cortical regions in the processing of taste information, although none are purely gustatory, as they also contain neurons responsive to touch and temperature (Pritchard, 1991). The orbitofrontal cortex processes information from several sensory pathways (including olfactory, gustatory, and visual), and has been linked to emotion, feeding and social behaviour (Rolls & Baylis, 1994; Rolls et al., 1998). The degree to which taste function is represented on each side of the brain is also poorly understood. In an fMRI study, Cerf et al. (1998) found the superior part of the insula is likely bilaterally innervated; however, significant lateralization of taste function was present in the inferior insula, such that in right-handed subjects there was relatively

more left inferior insula activation, whereas in left-handed subjects the reverse was true.

Classification of gustatory disorders

The classification of gustatory disorders follows a schemata similar to that of olfactory disorders: ageusia: inability to detect qualitative gustatory sensations; i.e. absence of taste; hypogeusia: decreased sensitivity to tastants; dysgeusia: distortion in the perception of a normal taste (e.g. the presence of an unpleasant taste when a normally pleasant tastant is presented); gustatory agnosia: inability to recognize a taste sensation, even though gustatory processing, language, and general intellectual functions are essentially intact.

Clinical evaluation of gustatory function

History

The clinical history for taste dysfunction largely overlaps that described in Chapter 41 for olfactory dysfunction. It is especially important to distinguish alterations in sweet, sour, bitter, and salty perception from changes in the perception of such sensations as chocolate, lemon, chicken, spaghetti, etc., since most 'taste' complaints reflect loss or distortions of the latter sensations which depend upon retronasal stimulation of CN I. Problems with speech articulation, salivation, chewing, swallowing, oral pain or burning, dryness of the mouth, periodontal disease, bruxism and foul breath odour should be noted, along with hearing and balance problems (since previous ear infections and surgery can alter chorda tympani function and produce taste loss or distortions). A determination of recent dental procedures and the patient's history of radiation exposure should also be made. Stomach problems may also be relevant, since acid reflux can damage or irritate taste buds. A careful assessment of medication usage is critical since, as described in detail later in this chapter, a number of drugs, including lipid-lowering agents, antibiotics and antihypertensives, produce significant taste disturbances.

Physical examination and imaging

In the evaluation of the oral cavity, particular attention should be directed towards the teeth and gums, since dysgeusia may result from exudates commonly found in gingivitis or pyorrhea. Inspection of fillings, bridges and other dental work should be made along with inspection of the mucosal surfaces, which may show signs of scarring, inflammation, or atrophy. A whitish lingual plaque can reflect candidiasis, lichen planus, leukoplakia, or food products. Local causes of glossitis include (a) mechanical trauma (e.g. tongue biting, jagged teeth, ill-fitting dentures), (b) irritation (e.g. that due to excessive use of alcohol, tobacco, O_2-liberating mouthwashes or peroxides), and (c) burns. Systemic causes of glossitis include (a) vitamin deficiencies (e.g. B vitamins, C, zinc), (b) anemia (e.g. pernicious, iron-deficiency), and (c) dermatologic syndromes (e.g. Behcet's syndrome, lichen planus, erythema multiforme, aphthous lesions, and pemphigus). Palpation should be performed to detect masses, neoplastic lesions or collections deep in the tongue's musculature. Neurologically, the integrity of CN VII, IX, and X can be evaluated by screening for deficits in non-gustatory functions of these nerves (e.g. facial musculature, swallow, salivation, gag, voice production).

Quantitative gustatory testing

Regional taste testing is needed to establish the function of each of the nerves innervating specific taste bud fields, as whole-mouth tests are insensitive to even complete dysfunction of one or several of the nerves that innervate the tongue. Two general stimulus presentation approaches can be employed. In c*hemical testing*, liquid stimuli are presented to target regions of the tongue or oral cavity via pipettes, Q-tips, or filter paper disks. In e*lectrical testing* (also termed electrogustometry), low levels of electrical current are presented to taste bud fields via small electrodes (Frank & Smith, 1991).

Accurate quantitative taste testing can be quite time consuming, more so for chemical than for electrical testing because of rinsing and stimulus delivery (e.g. intertrial interval) issues. In chemical testing, for example, stimuli representing each of the four basic tastes are typically administered to each side of the anterior (CN VII) and posterior (CN IX) tongue, with rinsing and expectoration following. Thus, a minimum of 16 trials (4 tastants $\times$ 4 tongue regions), as well as 16 rinses and expectorations, are needed to provide a single trial of each taste quality stimulus within the back and front hemilingual surfaces. If a paired blank in a forced-choice trial (e.g. water) is to be presented, then an additional 16 trials are needed. Since multiple stimuli are required to produce reliable responses, a typical taste test requires a considerable number of trials. The regional test used by us employs a micropipette to present 15μl aliquots of suprathreshold tastants (sucrose, citric acid, sodium chloride, and caffeine) that are equated in viscosity to left

and right anterior and posterior tongue regions. A single concentration of each stimulus is presented to each of the four target tongue regions six times, in counterbalanced order, along with a subsequent water rinse. Thus, 96 stimuli and 96 rinses are presented.

Gustatory dysfunction: causes and treatments

Although total loss or markedly diminished whole-mouth gustation exists, such changes are rarely produced by non-metabolic diseases or disorders unassociated with central ischemic or other damage, since regeneration of taste buds can occur and peripheral damage would have to involve multiple pathways to induce taste loss. Thus, while 433 of 585 patients (74%) studied at the University of Pennsylvania with verifiable olfactory loss complained of both smell and taste disturbance, less than 4% had verifiable whole-mouth gustatory dysfunction, and even that dysfunction was limited (Deems et al., 1991).

Regional deficits in taste dysfunction are much more common. For example, in one study sensitivity to three relatively low concentrations of NaCl was measured on the tongue tip and 3 cm posterior to the tongue tip in 12 young (20–29 years of age) and 12 elderly (70–79 years of age) subjects. On average, the young subjects were more sensitive to NaCl on the tongue tip than on the more posterior stimulation site and exhibited, at both tongue loci, an increase in detection performance as the stimulus concentration increased. The elderly subjects, who would be expected to exhibit, at worse, moderate deficits on whole-mouth testing, typically performed at chance level (Matsuda & Doty, 1995).

Most people, including older persons, are unaware of regional taste deficits, despite their wide prevalence. Patients rarely recognize their loss of taste sensation on half of the anterior tongue following unilateral sectioning of the chorda tympani in middle ear surgery. This lack of awareness reflects, in part, the redundancy of the multiple taste nerves, as well as possibly compensatory mechanisms. Anesthetizing or lesioning the chorda tympani (CN VII) unilaterally reportedly enhances taste perception on the rear of the tongue (CN IX), particularly on the side contralateral to that of the anesthesia or lesion (Kveton & Bartoshuk, 1994). The latter phenomenon, which has been interpreted as release of inhibition, probably occurs centrally, since the taste pathways are generally believed not to be crossed until the level of the thalamus.

A wide range of disorders and interventions have been associated with at least some loss of taste function. Mechanisms can include: (a) the release of bad-tasting materials from oral medical conditions (e.g. gingivitis, sialadenitis, oral infections), (b) transport problems of taste chemicals to the taste buds (e.g. caused by excessive chronic dryness of the oral cavity or damage to taste pores from a burn), (c) destruction or loss of taste buds themselves (e.g. from radiotherapy of the oral cavity), (d) damage to one or more neural pathways innervating the taste buds (e.g. Bell's palsy, trauma, dental or surgical procedures), and (e) involvement of central neural structures (e.g. tumour, stroke, multiple sclerosis, epilepsy).

Damage to brainstem structures that subserve taste may produce dysgeusia, although usually not without significant impairment of other cranial nerves or long tracts. Notable brainstem areas involved in taste that are susceptible to injury include the tractus solitarius and its nucleus (where injury produces ipsilateral ageusia) and the pontine tegmentum which involves both gustatory lemnisci (where injury produces bilateral ageusia). Bilateral injury to the thalamus can result in ageusia, although unilateral lesions above the brainstem do not usually cause complete loss of function (likely due to the multiple areas involved in processing taste information). Gustatory disturbance as a result of stroke (either ischemic or hemorrhagic) or demyelination (as seen in multiple sclerosis) (Catalanotto et al., 1984) commonly involve lesions in the gustatory pathway that can be discerned by MRI (Onoda & Ikeda, 1999; Yabe et al., 1995). An example of a stroke-related ischemia in a region of the upper medulla near the right nucleus tractus solitarius that produced altered taste ability is shown in Fig. 42.3 (note that, in this image, the left and right sides are reversed). Taste identification scores and a localized complaint of dysgeusia was greater in the right than in the left CN VII and CN IX lingual fields.

It is noteworthy that gustation may also be affected by injury to cortical association areas outside of the primary gustatory pathways. The concept of left unilateral neglect, typically resulting from contralateral injury to the right hemisphere (e.g. parietal lobe, thalamus, basal ganglia), appears to exist for taste in a manner similar to the visual, auditory, tactile, and olfactory sensory systems (Bellas et al., 1988). A specific syndrome of buccal hemineglect may exist in which patients neglect mouth and food products in the left half of the mouth and are unable to initiate chewing and swallowing when food is in this location (Andre et al., 2000). This syndrome can result in choking or a socially-embarrassing tendency to drool and regurgitate unnoticed food.

Bell's palsy

Although Bell's palsy is frequently associated with ipsilateral loss of taste over the anterior two-thirds of the tongue,

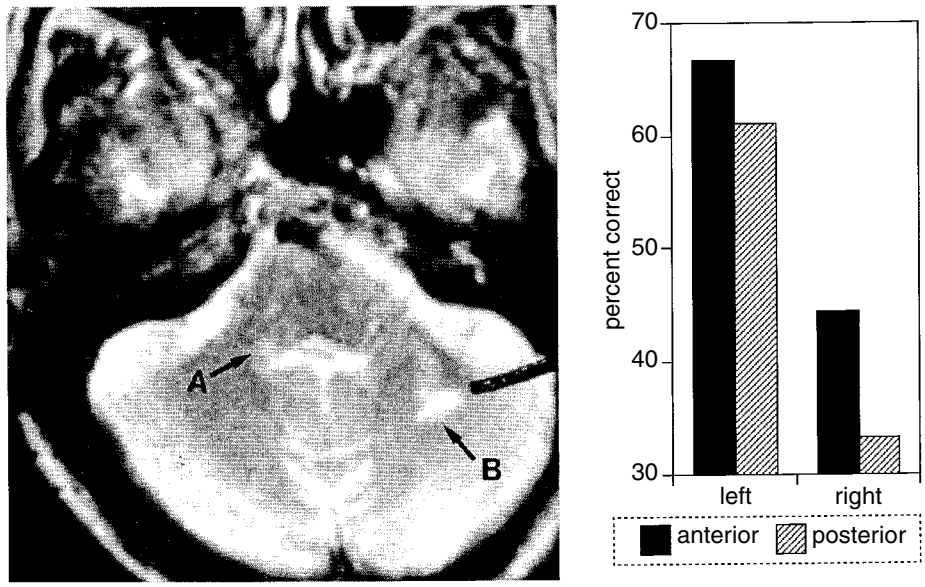

Fig. 42.3. L: Axial T2 (2500/90) MR scan through the upper brain stem reveals a hyperintensive infarct lesion (4×3 mm) in the right medulla (Arrow A). Note also large infarct (15×8 mm) inside the white matter of the left cerebellum (Arrow B). R: Identification scores on the University of Pennsylvania Taste Assessment Test (UPTAT) showing relative decrement on right side of tongue. From a 65-year-old woman with a history of ministrokes who developed a persistent salty/metallic dysgeusia and soreness on the right side of the tongue following a severe 2-day bout of emesis accompanied by marked dehydration and increased blood pressure but unaccompanied by fever. (Copyright © 2001, Richard L. Doty.)

the patient may not recognize this loss. Taste loss in Bell's palsy reflects a lesion somewhere in the neural pathway extending from the pons, along the nervus intermedius portion of the facial nerve (CN VII), through the geniculate ganglion, to the point where the chorda tympani joins the facial nerve in the facial canal. In addition to ipsilateral taste loss and commonly recognized facial weakness, hyperacusis (due to weakness of the stapedius muscle) and impairment of the taste-salivary reflex are present in many cases.

Trauma

Post-traumatic ageusia, as a result of peripheral or central injury, is much less common than post-traumatic anosmia, with solitary ageusia of one or more primary taste modalities occurring in less than 1% of persons with major head injury (Sumner, 1967; Deems et al., 1991). However, the prognosis for post-traumatic ageusia is far better than for post-traumatic anosmia, and recovery from ageusia, when present, usually occurs over a period of a few weeks to months. The etiology of post-traumatic taste dysfunction varies. Head trauma that results in injury to the middle ear, a finding encountered with basilar temporal bone fractures, can potentially result in both ipsilateral impairment of taste and salivary function (by damaging the chorda tympani nerve *and* preganglionic parasympathetic fibres). Trauma to the jaw (e.g. from a punch with a fist) or to the mouth (e.g. from difficult orotracheal intubation, aggressive dental procedures) can result in numbness and taste loss over the anterior two-thirds of the ispilateral tongue, since the chorda tympani-lingual nerve carries both taste and touch information. Compression injury to this nerve may have a greater effect on taste than on fine-touch sensory components, since the chorda tympani fibres of the conjoined nerve are more superficial and posterolateral, and therefore more susceptible to partial transection or pressure on the side of the nerve (Wantanabe et al., 1995). Although presently there are no well-validated treatments for trauma-induced gustatory dysfunction, early steroidal intervention may minimize damage due to inflammatory sequelae in some cases.

Surgical iatrogenesis

A number of surgical procedures have been associated with taste dysfunction. Ear surgery, including tympanoplasty, mastoidectomy, and stapedectomy can damage CN VII (Bull, 1965; Moon & Pullen, 1963; Kveton & Bartoshuk,

1994). The chorda tympani nerve fibres are often stretched or sectioned during surgery for otosclerosis, resulting in taste loss or dygeusia. Such aberrations can last long after the operation (Bull, 1965). Damage to the glossopharyngeal nerve is not uncommon as a result of tonsillectomy, bronchoscopy, or laryngoscopy (Ohtuka et al., 1994; Donati et al., 1991; Arnhold-Schneider & Bernemann, 1987), reflecting the close proximity of the muscle layer of the palatine tonsillar bed to the lingual branch of CN IX (Ohtsuka et al., 1994). Third molar extraction, a very common dental procedure, can damage the lingual nerve and its coexisting chorda tympani fibres, as they lie in close proximity to the mandibular third molars. Such damage is very common; recently the taste function of 17 patients was quantitatively evaluated before third molar extraction, and at 1 month and 6 months thereafter (Shafer et al., 1999). Measurable taste deficits were found in most of these patients that persisted for at least 6 months after surgery, even though complaints of the deficits were rare. Patients with the most deeply impacted teeth exhibited the most severe loss. The chorda tympani nerve may also be injured by the injection of local anesthesia, either by direct contact with the needle or as a result of neurotoxic effects of the anesthetic compound (typically lidocaine and epinephrine) (Shafer et al., 1999; Nickel, 1993). While it is generally assumed that most cases of iatrogenic damage to nerves subserving gustatory function resolve spontaneously over time (reflecting the ability of nerves to regenerate), the limited data available suggest that complete recovery is, in fact, the exception (Bull, 1965; Shafer et al., 1999).

Infections

Local infections have the potential to disturb or impair taste. Important anatomical regions include (a) the teeth and periodontal tissue, (b) the salivary glands, (c) surfaces of the tongue, mouth, and oropharynx, and (d) the middle ear. Importantly, the use of appropriate doses of antibiotic medications may, in and of themselves, have detrimental consequences on taste function (Morris & Kelly, 1993; Schwartz et al., 1996; Adelglass et al., 1998; Magnasco & Magnasco, 1985). Proper oral hygiene and routine dental care should be emphasized to patients as a way of protecting themselves against oral infections.

Medications

Pharmacological agents appear to result in taste disturbances much more frequently than olfactory disturbances. Over 250 medications have been noted in the literature to alter the sense of taste, including antiproliferative drugs, antirheumatic drugs, antibiotic drugs, psychotropic drugs and drugs with sulfhydryl groups, such as penicillamine and captopril (Ackerman & Kasbekar, 1997; Doty et al., 1991; Deems et al., 1991; Bromley, 2000; Schiffman et al., 1998; Schiffman, 1997). Angiotensin-converting enzyme inhibitors are commonly associated with taste disturbance, such as hypogeusia, or excessive metallic, bitter, or sour dysgeusic tastes (Ackerman & Kasbekar, 1997). Such psychotropic medications as amytriptyline, clomipramine, desipramine, imipramine, doxepin, and trifluoperazine as well as protease inhibitors used in the treatment of HIV and AIDS, not only have a taste of their own, but can significantly alter the intensity of other tastants, such as salt and sugar (Schiffman et al., 1998, 1999). Drug-induced taste disorders can, in some instances, be reversed by discontinuance of the offending drug, by employing alternative medications, or by changing drug dosage. However, many pharmacological agents appear to induce long-term alterations in taste that may take months to disappear even after discontinuance of the drug. In situations where xerostomia and excessive dryness occurs as a result of a drug (e.g. an anticholinergic agent), a physician can offer artificial saliva (e.g. Xerolube) to improve comfort, particularly if alternative medications are not available and drug dose cannot be decreased. However, if specific salivary proteins are needed for taste bud maintenance, saliva substitutes may not completely alleviate the chronic effects of lack of saliva on the taste buds.

Although various carcinomas apparently can alter taste function, it is important to recognize that conditioned taste aversions commonly occur among cancer patients undergoing chemo- or radiation therapy. In effect, malaise from the therapy becomes conditioned to the taste of foodstuffs, even if the malaise occurs hours after the intake of the food. In some cases, such conditioned aversions are transient, but in other cases they can be relatively long lasting and can lead to generalized anorexia and cachexia. A strategy for minimizing such aversions is to have the patient consume a novel food immediately before the initiation of therapy. Somehow subsequent conditioned aversions become focused primarily on the novel food, protecting against the formation of conditioned aversions to preferred food items (Chambers & Bernstein, 1995).

Epilepsy

Taste function can be altered by seizure activity, and on occasion gustatory auras appear. Like olfactory auras, gustatory auras usually represent seizure activity predominately within the temporal lobes, although on rare

occasion such activity arises from the orbitofrontal region (Hausser-Hauw & Bancaud, 1987; Acharya et al., 1998; Roper & Gilmore, 1995). Sensations have been reported to include 'peculiar', 'rotten', 'sweet', 'like a cigarette', 'like rotten apples', and 'like vomitus' (for review, see West & Doty, 1995), although many of these 'tastes' likely represent smell sensations miscategorized as tastes by both the patients and their physicians. Usually, taste auras produced by simple partial seizures disappear after the use of antiseizure medications, although this may not be the case with intractable epilepsy. Surgery, e.g. temporal lobe resection, successfully halts most gustatory auras (Acharya et al., 1998).

Other medical causes

There are a number of other causes of gustatory disturbance, including diabetes (where there can be a progressive loss of taste beginning with glucose and extending to other sweeteners, salty stimuli, and then all stimuli), familial dysautonomia (a genetic disorder with lack of taste buds and papillae), hypothyroidism, myasthenia gravis, and Guillain-Barré syndrome. In cases of taste loss secondary to hypothyroidism, thyroxin replacement can normalize taste sensitivity (Mattes & Kare, 1986). In newly diagnosed non-insulin dependent diabetics (based on plasma glucose concentration and glycosolated hemoglobin percentage), quantifiable taste impairment not only exists, but may be somewhat reversible with correction of the hyperglycemia (Perros et al., 1996). Both chronic renal failure and end-stage liver disease have been associated with alterations in taste function, and in some circumstances, transplantation may improve detection thresholds (Bloomfield et al., 1999). It is not clear whether the prodrome or acute headache phase associated with migraine involves definable gustatory phenomena as seen with olfaction. Certain tastes may, however, induce a migraine (Blau and Solomon, 1985). A distinct entity from glossopharyngeal neuralgia, Burning Mouth syndrome (BMS), often referred to as glossalgia or glossodynia, is the subjective sensation of intense burning in the mouth without obvious physical cause that may respond to tricyclic antidepressants (for review, see Tourne & Fricton, 1992). BMS is sometimes associated with dysgeusia.

Fortunately, most cases of idiopathic dysgeusias spontaneously resolve within 2 years (Deems et al., 1996). In some cases, antifungal and antibiotic treatments have been reported to be useful in resolving dysgeusias, although double blind studies of the efficacy of such treatments are lacking. Chlorhexidine, which has a strong positive charge, has been suggested as having possible efficacy for mitigating some salty or bitter dysgeusias when used as mouthwash (Helms et al., 1995).

Disorders of vision

Antony Morland[1] and Christopher Kennard[2]

[1] Department of Psychology, Royal Holloway College, Egham, Surrey, UK
[2] Division of Neuroscience and Psychological Medicine, Imperial College School of Medicine, Charing Cross Campus, London, UK

Vision is the primary sensory input to the brain in terms both of the number of sensory fibres and in the amount of cortical processing area devoted to its analysis. As a consequence there is a protean number of disorders, which range in their pathophysiological mechanisms from disturbed axon conduction, as in optic neuritis, to the abnormal cortical sensory processing apparent in the generation of visual hallucinations. The localization of visual disturbances is often assisted by appropriate analysis and interpretation of visual field defects (Fig 43.1).

Anterior visual pathway

Disorders of the optic nerve

Optic neuritis

Optic neuritis (ON) is a term used to describe an idiopathic optic neuropathy or one resulting from inflammatory, infectious or most commonly demyelinating etiology. In the majority of cases the optic disc is normal on ophthalmoscopy and the term retrobulbar neuritis is used. In those cases in which the optic disc is swollen then the terms papillitis or anterior ON are used.

Clinical features

In typical ON there is usually acute unilateral loss of visual acuity and visual field, which may progress over hours or a few days, reaching its maximal impairment within 1 week. Ninety per cent of cases complain of ocular pain which is noted especially with eye movement, and which may precede the visual impairment by a few days (Lepore, 1991). The visual loss may range from contrast defects with maintained acuity to no light perception. A defect of colour vision is almost universal. Although ON is generally associated with a central scotoma a wide variety of field defects may be found ranging from a central scotoma to altitudinal and nerve fibre layer defects (Keltner et al., 1993). An afferent pupillary defect is present in over 90% of patients with acute ON. The patient is usually aged under 40 years, although ON may occur at any age, and improvement takes place in most patients (90%) to normal or near normal visual acuity over several weeks. There may be persistent subtle residual defects of colour vision, depth perception and contrast sensitivity, which may continue for several months. Subsequent disc pallor may occur but does not correlate closely with the level of visual recovery (McDonald & Barnes, 1992).

ON exemplifies a number of the pathophysiological consequences of axonal demyelination, which may be partial or complete. These include slowed conduction (indicated by the delay in the P100 of the visual evoked potential), and susceptibility of partially demyelinated axons to small increases in local temperature (Uhtoff's phenomenon in which patients with ON become aware of increased visual impairment during exercise), and to mechanical distortion (visual phosphenes on eye movement).

Atypical ON may be unilateral or involve bilateral simultaneous onset of ON in an adult patient. There is often lack of pain and there may be other ocular findings suggestive of an inflammatory process, such as an anterior uveitis. Other features include a worsening of visual function beyond 14 days of onset, in a patient outside the 20–50-year age span. They may also have evidence of other systemic conditions, particularly inflammatory or infectious diseases.

A number of disorders may be associated with typical or atypical ON (Table 43.1).

The evaluation of patients with ON rather depends on whether or not it is a typical or atypical case. Typical ON probably does not necessitate any additional laboratory

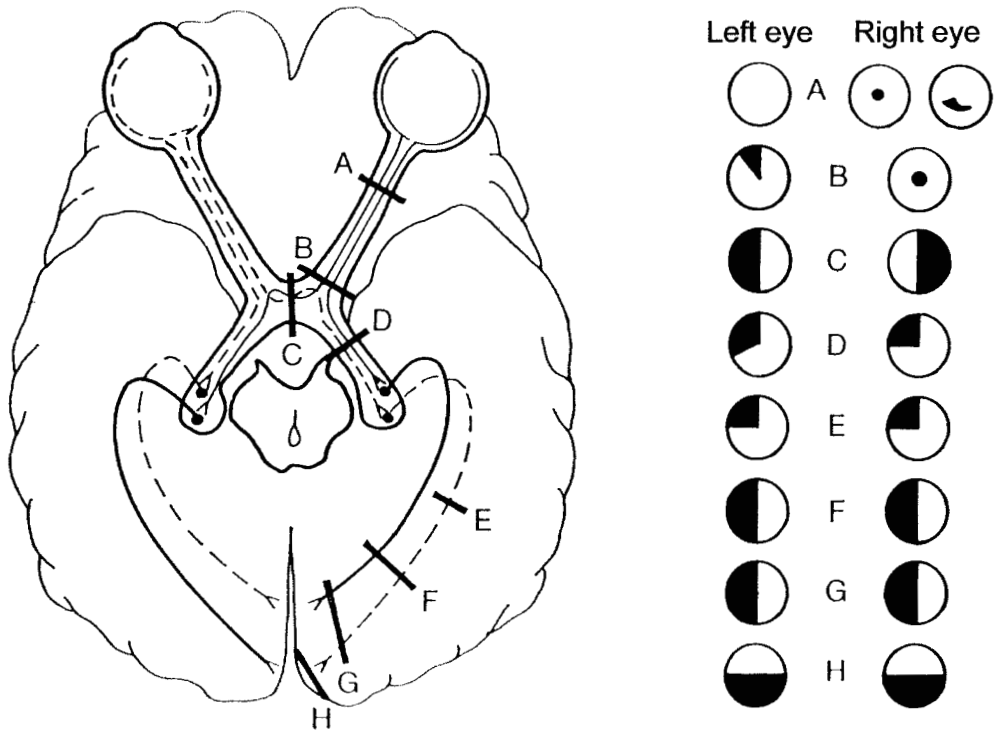

Fig. 43.1. Patterns of visual field loss: (*a*) Optic nerve lesions result in a central scotoma or arcuate defect. (*b*) Optic nerve lesions just prior to the chiasm produce junctional scotoma due to ipsilateral optic nerve involvement with the inferior contralateral crossing fibres (dotted line). (*c*) chiasm lesions produce a bitemporal hemianopia. (*d*) Optic tract lesions result in an incongruous hemianopic field defect. (*e*), (*f*) Lesions of the optic radiation result in either homonymous quadrantanopia or hemianopia depending on the extent and location of the lesion (upper quadrant, temporal lobe; lower quadrant, parietal lobe). (*g*) Lesions of the striate cortex produce a homonymous hemianopia, sometimes with macular sparing, particularly with vascular disturbances. (*h*) Partial lesions of the superior or inferior bank of the striate cortex cause inferior or superior altitudinal field defects, respectively.

investigations, although an abnormal MRI brain scan significantly increases the likelihood of developing multiple sclerosis (Morrisey et al., 1993).

Those patients with atypical ON should have a chest X-ray, laboratory tests including a blood count, biochemistry, and tests for collagen and vascular disease and syphilis serology. Examination of the spinal fluid (CSF) is probably justified in this group of patients.

Management

Although IV methylprednisolone leads to a more rapid visual recovery, at the end of 6 months the visual acuity is no better than without the treatment (Beck et al., 1992). Therefore, steroid treatment of patients with typical ON is unnecessary, unless there is severe ocular pain which cannot be managed with analgesics, or if there is already poor vision in the fellow eye due to some other disease process. The role of beta interferon in preventing the development of multiple sclerosis after a single attack of ON in a patient with an abnormal MRI scan is still unclear.

Ischemic optic neuropathy

Ischaemic optic neuropathy is due to infarction of the optic nerve head, and can be either the more common non-arteritic (idiopathic ischemic neuropathy, anterior ischemic optic neuropathy, AOIN) or arteritic type, when it is usually associated with giant cell arteritis.

Non-arteritic ischemic optic neuropathy

This is characterized by abrupt, painless and generally non-progressive visual loss, associated with an arcuate or altitudinal visual field loss, and tends to occur in patients aged between 45 and 80 years. In nearly all cases, there is optic disc edema, often associated with one or more splinter hemorrhages at the disc margin. Optic atrophy rapidly ensues after the ischemic event. Although previously considered irreversible, as many as 40% of patients may show

Grave's disease
Atypical glaucoma
Macular dystrophies

some improvement, and there is a 40% chance of involvement of the fellow eye within 5 years (Ischemic optic neuropathy decompression trial research group, 1995).

The cause of AION remains obscure, although it has been associated with small optic discs (Burde, 1993). The most important aspect of management, since there is no treatment of proven benefit, is to exclude the possibility of the arteritic form, when the fellow eye is particularly vulnerable to similar involvement.

Arteritic ION

The arteritic form of ION usually occurs in giant cell (cranial, temporal) arteritis (GCA), but also rarely occurs in lupus and polyarteritis nodosa. Anyone with AION over the age of 50 should be suspected of having GCA. This often occurs in the context of headache, malaise, weight loss, anorexia, anemia, proximal muscle ache or stiffness, temporal artery tenderness, jaw claudication and fever. These symptoms and signs usually precede the visual loss. The disc infarction is similar to that seen in non-arteritic AION.

A high index of suspicion is required for GCA, and if suspected an urgent erythrocyte sedimentation rate (ESR) and temporal artery biopsy should be arranged. At the same time as the blood for the ESR is taken, the patient should be immediately started on systemic steroids (prednisolone 80 mg daily, plus 200 mg i.v. hydrocortisone immediately). In most patients the ESR is markedly elevated, as is the C-reactive protein. Occasionally the ESR may be normal. A biopsy of the superficial temporal artery should be obtained as soon as possible after the diagnosis has been considered. The biopsy will not be affected by the use of corticosteroids for at least 48 hours. A positive temporal artery biopsy confirms the diagnosis of giant cell arteritis, but in 25% of patients skip areas are found in biopsy specimens, and therefore a negative biopsy may sometimes be obtained.

Steroid treatment should not be tapered or withdrawn too early, since a relapse of symptoms is common. The dose of prednisolone can be gradually tapered after 2–3 weeks to maintain a normal ESR and the patient asymptomatic. Treatment should be continued for at least 6–12 months.

Optic atrophy

Optic atrophy is the final result of a variety of disturbances to the optic nerve or retina. The disc appears pale, which is due to death of the retinal ganglion cells with a dying back of their nerve fibres. This can, therefore, result from diseases which directly involve the ganglion cells themselves or from damage to the axons in the pregeniculate visual pathway, resulting in retrograde atrophy. The development of optic atrophy is usually slow, dependent on its cause. In most instances the optic atrophy is bilateral, the disc appearing chalky-white in colour with clearly defined margins and an absence of disc vasculature and retinal nerve fibres. The differential diagnosis of optic atrophy is considered in Table 43.2.

Heredo-familial optic neuropathies

The hereditary optic neuropathies can either be those which are autosomal dominant or recessive, or those which are due to point mutations in mitochondrial DNA.

The autosomal conditions usually present in childhood with impaired vision and pale optic discs, and due to space restrictions will not be considered further.

Leber's hereditary optic neuropathy (LHON)

This mitochondrial disorder develops primarily in males (approximately 14% women) in the second to third decade of life. It is characterized by an abrupt loss of central vision in one eye usually followed by a loss of vision in the remaining eye which may occur weeks, months or sometimes years later. Occasionally visual loss may occur simultaneously in the two eyes. There is no associated pain on eye movement in contrast to acute ON, and the visual loss is usually permanent with optic atrophy and large absolute central scotomas. However, the fundoscopic picture in the acute phase often shows swelling of the papillary nerve fibre layer, circumpapillary telangiectatic microangiopathy and tortuosity of the retinal vessels (Riorden-Eva et al., 1995).

There is a maternal pattern of inheritance and a number of point mutations in mitochondrial DNA have been identified, particularly at the 11778 location and less frequently at 3460 and 14484 (Mackey, 1994). Patients with the point mutation at 14484 are more likely to show some visual recovery when compared with patients who have a defect at the 11778 (37% as opposed to 4%). It is appropriate, therefore, to carry out genetic testing in those individuals presenting with atypical ON of the appropriate sex and age, even if a positive family history is not available. There is no effective treatment for this condition.

Nutritional and toxic optic neuropathies

Bilateral, slowly progressive central visual loss with centrocaecal scotomas, and usually normal or mild temporally atrophic optic discs characterizes optic nerve failure due to either nutritional deficiency or a toxic cause. Once a family history of one of the hereditary familial diseases has been excluded, this condition should be considered, and is usually due to a combination of alcohol abuse, deficiencies within the B vitamin complex and a frequently high tobacco consumption. With treatment by abstinence of the likely toxic agents and vitamin supplementation, recovery of vision usually occurs, unless the condition is so long standing that optic atrophy has intervened. Recent epidemics of optic neuropathy in Cuba (Sadun et al., 1994), and in West Africa have probably been related to multiple dietary deficiencies.

A wide variety of instances have been cited as causing toxic optic neuropathy which include ethambutol, chloramphenicol, halogenated hyroxyquinolones, lead, isoniazid and vincristine.

Tumours of the optic nerve

Optic nerve sheath meningiomas

Primary optic nerve sheath meningiomas, most frequently found in middle-aged women, are usually unilateral but if bilateral raise the possibility of central neurofibromatosis (NF2). Although most patients will have mild (2–4 mm) proptosis at the time of their initial consultation, patients complain of dimming of vision and decreased colour vision. Visual loss progresses over years with optic disc swelling gradually being supplanted by optic atrophy, with or without the evolution of optociliary venous (retinochoroidal anastamoses) shunt vessels (Dutton, 1992).

The CT picture in patients with these tumours is most often one of diffuse narrow enlargement of the optic nerve, with bulbous swellings of the nerve in the region of the globe and orbital apex. 'Railroad-track' calcification of the optic nerve sheath in the orbit is a characteristic feature. Use of MRI has enabled optic nerve sheath meningiomas to be distinguished from optic nerve gliomas, where the former but not the latter shows that the nerve is readily distinguished from the optic nerve sheath (Lindblom et al., 1992).

Management of patients with optic nerve sheath meningiomas is controversial. While there is general agreement that nerve sheath tumours are most aggressive in children and become progressively more indolent with advancing age, there is no consensus as to the best way to treat these lesions. Clinical resection, particularly when there is intracranial spread, is usually incomplete. These patients rarely die from the meningioma and it is probably best to observe. In some instances radiotherapy has been shown to result in some visual improvement.

Optic nerve gliomas

Optic nerve gliomas, which may also involve the chiasm, are of two distinct types. By far the commonest is the benign glioma of childhood, and the other the malignant glioblastoma in adults (Dutton, 1994). Approximately a quarter of cases occur in the setting of NF-1.

Benign optic nerve gliomas usually present within the first two decades of life, with a peak incidence at 1–6 years of age. The usual presenting manifestations are proptosis and visual loss. The fundus may show either papilledema or optic atrophy. The clinical course of childhood optic nerve gliomas is highly variable. In some tumours enlargement proceeds slowly for a time but then reaches a plateau, while in others the enlargement proceeds unabated (Hoyt & Bagdassarian, 1969). Necropsy has suggested that these tumours are in fact hamartomas rather than true neoplasms. Optic nerve gliomas are generally managed conservatively, although some favour radiation therapy for

lesions with chiasmal involvement and surgery for at least those tumours restricted to the orbit.

Optic nerve gliomas of adulthood are malignant gliomas which usually arise in males aged 40–60 years. These patients often present with a rapid onset of visual failure, which on some occasions may mimic acute ON. The tumour rapidly progresses and the patient usually dies within a short period.

Disorders of the optic chiasm

Approximately 25% of all brain tumours occur in the chiasmal region and since half of these cases initially present with visual loss, an appreciation of the various field abnormalities is important. Although there are a number of other causes for the chiasmal syndrome, eg trauma and demyelination, these are rare. The neuro-ophthalmological signs of a compressive optic chiasm lesion are primarily a field defect and deterioration of visual acuity, which depend on the relationship of the chiasm to the pituitary. The classical field defect of a chiasmal lesion is a bitemporal hemianopia, since pituitary tumours first affect the medial aspect of the chiasm (Holder, 1991). Damage to the lateral aspects of the chiasm due to aneurysm result in nasal field defects. These two observations indicate that the human chiasm is organized in an orderly fashion with medial and lateral aspects of the chiasm comprising fibres originating from the nasal and temporal retinal fibres respectively, which was first anatomically observed by Hoyt and Luis (1963). Hemianopic field defects associated with a compressive optic chiasm lesion may be complete or incomplete and may or may not be symmetrical. Due to the optic nerve being compromised in addition to the chiasm it is unusual to have a bitemporal hemianopia without some reduction in central visual acuity in at least one eye.

The main symptom resulting from the chiasmal syndrome is usually a progressive deterioration of vision, often with associated dimming of the visual field, particularly temporally. A fairly frequent symptom in patients with the chiasmal syndrome is diplopia. This may be a vertical or horizontal separation of images, which usually occurs in the absence of a demonstrable ocular motor paresis. An explanation for this hemifield slide phenomenon is the absence of the temporal field in each eye, which normally acts as a physiological linkage for the two nasal fields. Minor ocular motor imbalance, which does not normally affect binocular fusion, now results in an inability to maintain the two fields in juxtaposition. Some patients will also complain of a disturbance of depth deception, experiencing problems with such tasks as sewing, threading needles or using precision tools. This phenomenon, called chiasmic postfixation blindness, is due to the presence of a blind area beyond the fixation point. The image of objects located in this area falls on the nasal retina which is blind (Kirkham, 1972).

Abnormalities in decussation at the chiasm can also result from congenital disorders. In albinism, in addition to nasal fibres, some temporal fibres also cross at the optic chiasm. The additional crossed fibres result in a systematic shift of the line of decussation into the extra foveal temporal retina. Albinism has many phenotypes and is expressed as a hypopigmentation of the skin, hair and eyes in oculocutaneous albinism (OC) and of the eyes only in ocular albinism (OA). Oculocutaneous albinos can be either tyrosinase positive or negative and further phenotypic subdivisions have been documented (Abadi & Pascal, 1989). There is considerable variability in the visual disorders suffered by albinos. All patients suffer loss of visual acuity, which is invariably associated with foveal hypoplasia. Albinos can also suffer photophobia and nystagmus, the latter contributing to reduced acuity (Abadi & Pascal, 1991). It should be noted, however, that acuity is also reduced in the rare cases where patients are able to fixate, showing that nystagmus alone does not underlie the acuity loss (Abadi & Pascal, 1991). Usually, albinism can be readily diagnosed with fundoscopy and iris transillumination, but some cases can be more difficult to detect. The most reliable measurement that detects the albino aberrant visual projections is the VEP, which has been shown to diagnose patients in 97/98 cases. As nystagmus is often present, however, pattern-onset VEP has revealed the most reliable results in adults (Apkarian, 1992). Appropriate stimulus selection has also proved effective in detecting albino pathway 'misrouting' in infants, so early detection is possible with VEPs (Apkarian et al., 1991). Visual stimulation during fMRI has also proved effective in documenting the albino visual projections (Morland et al., 2001).

Stereopsis was thought to be absent in all patients with congenital chiasmatic abnormalities because fibres representing the central visual field from both eyes project to different hemispheres. There has been one report, however, that documents stereopsis in approximately 10% of albinos, who also had reasonably stable fixation and ocular alignment. This interesting observation implies that adaptive mechanisms involving interhemispheric communication must develop to mediate this aspect of binocular vision (Apkarian, 1996; Zeki & Fries, 1980).

Disorders of the optic tract, radiation and occipital lobe

Optic tract lesions

Lesions of the optic tract, although rare (less than 3% of visual field defects in a series of 100 homonymous hemianopias), often produce specific signs and visual field

abnormalities which allow definitive diagnosis (Newman & Miller, 1983). The optic tract is the first point in the visual pathways where the ipsilateral temporal and contralateral nasal retinal nerve fibres come together, and so the field defect is usually a partial or complete homonymous hemianopia. When partial there is often gross incongruity between the visual field defects found in each eye, which may also be found with lesions of the lateral geniculate nucleus and more rarely the optic radiations. Ophthalmoscopically optic pallor due to retrograde degeneration may be observed. This takes a characteristic form with band or 'bow tie' atrophy in the eye opposite to the lesion due to loss of nasal retinal fibres. Ipsilateral to the lesion, temporal pallor is observed.

Occipital lobe

On reaching the occipital lobe there is a high degree of order in the fibres of the optic radiation and lesions, which are usually due to infarction, trauma or tumour, produce congruent field defects which are homonymous. The only features of the field defect which help localize the lesion to the occipital lobe, rather than the anterior optic radiation, is the presence of macula sparing or a temporal crescent in a homonymous hemianopia.

In macula sparing there is preservation of the visual field within a region of 1–2° up to 10° around the fixation point in the hemianopic field. In the more usual situation the hemianopic field is split along the vertical meridian through the fixation point (macula splitting). Although it has been argued that macula sparing is a result of poor fixation during visual field testing, this would only account for about 1–2° of sparing (Bishoff et al., 1995). Despite the continued controversy concerning the cause of macula sparing there appear to be two main anatomical factors which may explain this phenomenon. Firstly, there is evidence that there is a vertically orientated median strip centred on the fovea in which retinal ganglion cells project either ipsilaterally or contralaterally (Fukuda et al., 1989). The macula, therefore, is bilaterally represented but since this strip is at most responsible for 2° of the central field this is insufficient to explain many cases of macula sparing. The second more probable explanation is the rich anastomotic network between terminal branches of the middle cerebral artery and the posterior cerebral artery which supply the area of the striate cortex containing the macula representation in the occipital pole (Sugishita et al., 1993).

Lesions at the pole of the occipital lobe result in small homonymous central scotomas, which may lead the patient to present with reading difficulties and may be missed if only the peripheral field is examined to confrontation. The central 10° of the primary visual cortex (Horton & Hoyt, 1991). More anterior lesions of the occipital lobe involving the more anterior part of the calcarine fissure, which contains the representation of the unpaired peripheral nasal retina, results in a monocular defect in the peripheral temporal field, called the 'temporal crescent', 60–90° from the fixation point. However, it should be remembered that the most common cause for such unilateral peripheral visual field defects is a retinal lesion rather than an intracranial one. The converse of this defect may be found in which there is sparing of the temporal crescent in a homonymous hemianopia. This usually occurs with a vascular lesion affecting the more posterior striate cortex (Benton et al., 1980).

Bilateral lesions of the occipital lobes may result in varying degrees of homonymous hemianopia, ranging from small bilateral central homonymous scotomas to complete blindness. The extent of the abnormality may vary between the two halves, being partial or complete, hemianopic or quadrantic. Sometimes restricted bilateral lesions of the occipital lobes may result in small bilateral homonymous central scotomas. Altitudinal field defects usually occur as a result of trauma (rarely tumours or vascular events) involving upper or lower occipital poles bilaterally (Holmes, 1918).

fMRI, which can spatially localize brain blood oxygenation accurately, can be used to investigate the effect of lesions of the radiation on cortical activity. It is possible, therefore, to use fMRI during visual stimulation to determine the reason for visual field loss, when damage to the cortical grey matter is absent. Retinotopic mapping fMRI methods, that have become commonplace in the research of normal visual function (DeYoe et al., 1996), may become increasingly useful in investigating visual field defects resulting from occipital damage (Baseler et al., 1999).

Cortical blindness

Cortical blindness usually indicates selective involvement of the occipital visual cortex. The essential features are (i) complete loss of all visual sensation, (ii) loss of reflex lid closure to threat, (iii) normal pupillary light reactions, (iv) normal retina and full extraocular eye movements. The commonest etiology is hypoxia of the striate cortex. Patients with cortical blindness may sometimes be unaware of their visual defect (anosognosia) and vigorously deny it, known as Anton's syndrome. This may occur with lesions elsewhere causing total blindness. There is no satisfactory explanation for this syndrome and the various hypotheses are discussed by Lessell (1975). Several hypotheses have been proposed to explain this syndrome including an alteration in emotional reactivity,

'psychiatric' denial as an accentuation of a common response to illness, a memory disorder for example in Korsokoff's syndrome, and associated lesions elsewhere in areas of the brain responsible for the recognition and interpretation of visual images.

Disorders of higher visual processing

Residual visual function in hemianopias

In his classic work Holmes (1918) showed that the striate cortex damage results in a complete hemianopia. However, incomplete damage to the occipital lobe may result in retention of some aspects of visual perception, the most commonly observed being the ability to perceive small moving objects in the homonymous hemianopia (Riddoch, 1917; Zeki & ffytche, 1998). Riddoch's phenomenon may be the first evidence of recovery of a homonymous hemianopia. This is then usually followed by perception of static targets and finally colour perception returns. Unfortunately, the Riddoch phenomenon is not only found in occipital lesions, but has been reported in patients with lesions in the anterior visual pathways (Safran & Glaser, 1980).

The retention of the ability to localize objects in space and limited pattern discrimination in monkeys in whom both striate cortices had been removed, led to interest in the possible visual functions in the hemianopic field of human patients (Weiskrantz, 1986). Since these patients are unaware of any residual visual capacity and appear blind by standard clinical perimetric methods this visual capacity has been termed 'blindsight' (Weiskrantz et al., 1974; Weiskrantz, 1986). Using forced-choice discrimination methods such patients have revealed their ability to locate stimuli both by saccadic eye movements and by pointing (Cowey & Stoerig, 1991). The extent of the residual visual capacity is varied amongst the patients so far reported, and as yet there is poor correlation with the precise location of lesions in the occipital lobe.

Residual visual function also extends the ability to discriminate between stimuli on the basis of their motion (Barbur et al., 1980; Blythe et al., 1986a, 1987; Morland et al., 1999; Zeki and ffytche, 1998), orientation (Morland et al., 1996; Weiskrantz, 1986), spatial periodicity (Weiskrantz, 1986), and spectral content (Blythe et al., 1987; Morland et al., 1999; Stoerig & Cowey, 1989, 1992). The extent to which different patients have conscious experience of such visual abilities is variable (Weiskrantz, 1986; Weiskrantz et al., 1974) and in individual patients is dependent on the characteristics of the visual stimulus (Morland et al., 1999; Zeki & ffytche, 1998). In one patient with damage to striate cortex, stimulation with visual motion activates extrastriate cortical areas (Barbur et al., 1993; Zeki and ffytche, 1998). However, a general consistency between activity in extrastriate cortex and residual motion processing in hemianopes has yet to be revealed in studies of more than one patient (Barton & Sharpe, 1997).

Reports have documented a reduction in the size of scotomata in patients with cortical lesion following training (Zihl & von Cramon, 1979). Patients were trained to detect targets present within, but near, the boundary of their scotomata. This resulted in an increased visual sensitivity within the trained region that transferred interocularly and to different stimulus attributes such as colour (Zihl & von Cramon, 1979). Further studies also revealed that scotomata could be reduced when patients are trained to saccade to targets in their blind visual fields (Zihl, 1981; Zihl & von Cramon, 1985). Recent work has revealed that hemianopic patients visually scan natural images differently from normal (Pambakian et al., 2000). The degree of abnormality in the scan paths was greatest for patients with the longest period between the lesion onset and time of testing, which suggests development of coping strategies. In addition to the training implemented by Zihl's group (Zihl, 1981; Zihl & von Cramon, 1979, 1985) it may also be possible to train patients to scan scenes so the effects of the visual field defects may be minimized and adaptive strategies may be enhanced (Zihl, 2000; Pambakian et al., 2000).

Functional visual loss in prestriate lesions

There is increasing evidence from electrophysiological studies in primates that once initial processing of visual information has occurred in the striate cortex, segregation of different properties of the visual stimulus occurs in the prestriate cortex (Zeki & Shipp, 1988; Zeki, 1993). This cortical region contains a number of individual representations of the contralateral hemifield, each containing neurons with a particular response characteristic. For example, some areas contain neurons which are selective for colour (V4), and another for motion (V5, middle temporal gyrus, MT). There appears, therefore, to be parallel processing of different aspects of visual information in these various cortical areas before an organized synthesis of the visual scene can be generated. Specific lesions in one or other of these areas might be expected to give rise to an appropriate specific loss of a visual modality. In this section such specific losses are described for colour (achromatopsia), movement (akinetopsia) and faces (prosopagnosia).

Colour

Acquired disorders of colour vision due to lesions of the central nervous system are of two types. In one the colour sense is normal but the naming and recognition of colour is impaired. This can occur as part of an aphasia e.g. Wernicke's or anomic, in the syndrome of alexia without agraphia or as one feature of visual agnosia (see below). In the second type there is an inability to see colours (dyschromatopsia or achromatopsia) (Zeki, 1990).

Patients with lesions in the region of the lingual and fusiform gyri, which lies in the anterior inferior region of the occipital lobe and is considered to be the human homologue of the monkey visual area V4, complain that they cannot see colours and that everything looks grey or in varying shades of black and white (Meadows, 1974a). They are unable to identify the figures on pseudoisochromatic test plates, although able to correctly name the colours of brightly coloured objects. In addition they are unable to perform normally on the Farnsell–Munsworth 100-hue test. Patients with cerebral dyschromatopsia may or may not realize that their colour sense is impaired. Other functions such as visual acuity, object recognition and depth perception are all normal, but there is often an associated visual field defect, usually a bilateral superior homonymous quadrantanopia sometimes also associated with prosopagnosia.

There is good evidence that cortical lesions disrupt selective aspects of colour processing. One patient with reduced colour discrimination appeared to have colour naming responses that were consistent with a lack of colour constancy (Kennard et al., 1995). Colour constancy describes the ability to perceive an object colour as constant when illumination changes to cause a change in the spectral distribution of light reflected from that object. Neurons in the macaque visual area V4 exhibit colour-constant responses, whereas those in V1 do not (Zeki, 1980). This evidence suggests that the lesions of the lingual and fusiform gyri in the patient documented by Kennard et al. (1995) included the human homologue of V4. Functional imaging experiments on normal observers have also implicated the same cortical regions as colour selective (McKeefry & Zeki, 1997; Zeki et al., 1991). Other patients have also been shown to lack colour constancy, some of them with lesions to putative V4 (Clarke et al., 1998), while in other patients lesions appeared exclusive of this cortical area (Ruttiger et al., 1999).

Movement

A case has been reported of a woman who exhibited a selective deficit of movement perception (Zihl et al., 1983). She had no impression of movement in depth and could only discriminate between a stationary and a moving target in the periphery of her otherwise intact visual fields. The patient had bilateral lesions involving the lateral occipito-parieto-temporal junction, which PET has revealed is specifically activated during motion perception and, therefore, appears to be the human homologue of the monkey visual area V5 (Zeki, 1991).

Moving boundaries that are defined by second order features (as opposed to luminance boundaries) are not discriminated normally in patients with lesions in lateral occipital regions (Plant & Nakayama, 1993). A more recent study, however, appears to indicate a considerable overlap in the cortical areas responsible for processing first and second order motion (Greenlee & Smith, 1997).

Visual associated agnosia

The term visual agnosia refers to a rare condition in which there is an inability to recognize and name or demonstrate the use of an object presented visually, in the absence of a language deficit, general intellectual dysfunction or attentional disturbances. The patient is, however, able to name the object when using other sensory modalities such as touch or sound. Teuber (1965) described visual agnosia as a 'percept stripped of its meaning'.

Visual agnosia has been classified in a number of different ways. One classification depends on the specific category of visual material which cannot be recognized, for example a disturbance of recognition of objects (object agnosia), faces (prosopagnosia) and colour (colour agnosia) which may occur in isolation or in various combinations. Lissauer's (1890) classic dichotomous classification of visual agnosia is, however, still relevant today. When a patient is able to copy and match-to-sample objects that he fails to name or recognize visually, his agnosia is termed associative; if he fails on all these tasks or demonstrates perceptual abnormalities his agnosia is termed apperceptive (Tranel & Damasio, 1996).

Apperceptive visual agnosia

Well documented cases of apperceptive visual agnosia are rare (Warrington & James, 1988). They show an inability to copy or match-to-sample drawings which they cannot recognize, and recognition and matching of all other stimuli which demand shape or pattern perception is also affected. Most cases have been associated with cerebral damage due to cardiac arrest, carbon monoxide poisoning or bilateral cerebrovascular infarction. Less severe apperceptive disorders are associated with unilateral and generally right cerebral damage.

Associative visual agnosia

Unlike apperceptive agnosia there is no doubting the existence of associative agnosia as a definite neuropsycholog-

ical syndrome since a number of well-documented cases have been reported (Humphreys & Riddoch, 1993).

These cases exhibit the ability to copy and/or match-to-sample items which they fail to identify visually, without any evidence of primary sensory or sensory motor disturbance. The syndrome is commonly associated with colour agnosia, prosopagnosia and alexia in various combinations. This may reflect task and processing similarities between recognition of faces and objects, resulting in defects of both. Alternatively, lesions giving rise to object agnosia may involve adjacent areas specific for colour or face processing.

Patients with associative visual agnosia show an increasing difficulty in identifying an object when presented as the object itself, as a picture or a line drawing. Auditory and tactile recognition is usually intact. There is no uniformity about the field defects which are often present. A further commonly found feature is the strong tendency these patients have to perseverate either previously viewed objects or, more commonly, the verbal response to them.

A number of hypotheses to explain visual agnosia have been proposed. Geschwind (1965) suggested that agnosia was not a defect of a unitary process of recognition, but rather a special form of a modality-specific naming defect. Using a disconnection explanation similar to that given for dyslexia without dysgraphia and colour agnosia, he suggested that the confabulatory verbal responses are due to a pathological disconnection of the intact speech area from the intact sensory area. Ratcliff and Newcome (1982) have argued, however, that since object recognition, as opposed to naming, is mediated by the semantic system, disconnection must be a visual-semantic one and not merely visual–verbal. However, patients with surgically sectioned cerebral commisures are able to extract meaning from words and pictures when visual input is restricted to the right hemisphere, making it unlikely that this disconnection of an intact right hemisphere would be sufficient to cause agnosia.

A second hypothesis, proposed by Warrington (1975), suggests that the disorder is due to a disturbance of access to visual semantic information itself, since in her patient 'all links of associations were lost, not just verbal' and hence a visual–verbal disconnection was not a sufficient explanation. She regarded preservation of the ability to make same/different judgements with respect to photographs of objects taken from different angles as evidence of preserved 'perceptual classification'. However, other authors have suggested a defect of visual categorization in their patients (Albert et al., 1975). It has to be concluded that both the anatomical basis and clinical criteria for associative visual agnosia are still uncertain, but excellent reviews are available by Farah (1990) and Tranel and Damasio (1996).

Prosopagnosia

Prosopagnosia is a specific inability to recognize familiar faces despite a normal ability to recognize everyday objects, and is therefore, different from visual agnosia (Meadows, 1974b). Although facial recognition is a visual pattern discrimination of great complexity patients with prosopagnosia have no difficulty in discriminating unfamiliar faces and matching faces correctly. Indeed there appears to be no disturbance of visual perception, patients being able to accurately recognize many stimuli which are visually more complex than human faces. It appears that the disorder is not specific to faces but to complex non verbal visual stimuli that belong to a group where individual members are visually similar and yet individually different. For example, prosopagnosics cannot recognize their own car and do not recognize different makes of car; however, they can distinguish different classes of vehicle, e.g. ambulance or fire engine. Similarly a case has been reported of a farmer suddenly becoming unable to distinguish individual animals within his herd and of a bird watcher developing an inability to recognize different species of birds.

Prosopagnosics appear, therefore, to be unable to match a current visual stimulus within a class such as faces, with the memory traces of other members of this specific class which have been built up from past experience (De Renzi, 1997). Pathophysiologically there is disorder of visually triggered contextual memory. Under normal circumstances after multiple exposures to a stimulus, a template of the stimulus is stored, perhaps at several levels, but in prosopagnosics there is a defect in activating this template. Recent brain imaging studies have suggested that these processes involve the inferior temporal lobe and also the ventrolateral frontal cortex (Haxby et al., 1996). Electrophysiological recordings from superior temporal sulcus in monkeys have identified neurones which are specifically responsive to faces, cells which may well be involved in the facial recognition process (Perrett et al., 1984).

Most cases of prosopagnosia are due to infarction, head injury or hypoxia resulting in bilateral lesions in the ventromedial aspects of the occipitotemporal region (Damasio et al., 1982).

Visual illusions

Visual illusions occur when the visually perceived target appears altered in size, shape, colour, position in space and in number of images (Kölmel, 1993). The illusory type of

defects may occur in the entire field of vision, or may effect only the object or the background. The term 'dysmetropsia' indicates the apparent smallness (micropsia), largeness (macropsia) or irregularity of shape (metamorphopsia) of objects. Dysmetropsia usually occurs as a result of retinal disease due to distortion of the relative distance between rods and cones. However, these distortions can also occur as a result of cortical dysfunction, for example in the aura of migraine or epilepsy, chiasmic compression or focal cerebral lesions. Visual allesthesia is a transfer of visual images from one half field to the other (Jacobs, 1980). There may also rarely be an inversion of the visual scene or tilting of the environment in patients with the lateral medullary syndrome (Wallenberg's syndrome) (Hornstein, 1974) . This relates to a disturbance of the vestibular inputs required for normal visual perception.

Visual hallucinations

Visual hallucinations occur under many circumstances, eg drug withdrawal, anoxia, migraine, infection and schizophrenia in addition to those related to focal neurological disease. Those in the latter category may be unformed, consisting of flashes of light (coloured or white), lines, simple shapes or they may be complex highly organized hallucinations of people, objects, etc. (Kölmel, 1993).

Although it is considered that simple visual hallucinations signify involvement of the occipital lobe and complex ones involvement of the temporal lobe this is not always the case, for example complex hallucinations have been observed by patients with hemianopias due to occipital lobe lesions (Kölmel, 1985).

It has long been considered that visual hallucinations could result from irritative foci analogous to epileptic discharges, and certainly electrical stimulation of the occipital and temporal lobes (Penfield and Perot, 1963) supports this suggestion. Other mechanisms in some cases may be a release phenomenon to be found in the context of sensory deprivation (Charles Bonnet syndrome), in which visual cortical areas are deprived of normal visual impulses so releasing cortical activity which normal visual inputs keep suppressed (ffytche et al., 1998) This is the explanation usually given to hallucinations occurring in elderly patients who have impaired vision (Teunisse et al., 1995). However, the term 'peduncular hallucinations' was first described by L'Hermitte (1922) to describe visual hallucinations which appear animated, slow moving, cartoon-like and are usually frightening for the patient. This type of hallucination is usually associated with inversion of the sleep–wake cycle, with diurnal somnolence and nocturnal insomnia, and occurs with lesions in the upper brainstem (McKee et al., 1990).

Palinopsia

Palinopsia is a rare disorder in which there is persistence (perseveration) or recurrence of visual images after the exciting stimulus has been removed (Bender et al., 1968). Although in the literature both perseveration and recurrence of visual images have been lumped together under the term palinopsia it has been argued that they may be distinct (Blythe et al., 1986b). It most commonly occurs during the progressive evolution or resolution of a homonymous hemianopic field defect, usually resulting from a posterior cerebral hemisphere lesion due to neoplasia (Bender et at, 1968), vascular disease or trauma.

Bender et al. (1968) suggested four possible mechanisms for this phenomenon: sensory seizures, psychogenic elaboration or fantasies, visual after-images or hallucinations. Although some patients with palinopsia have had seizures, most have no evidence of seizure activity on the electroencephalogram and the palinopsia does not respond to treatment with anticonvulsants. Patients with palinopsia show no signs of psychopathology and, therefore, it is unlikely that they are due to psychogenic collaborations. Similarly, there is no evidence that visual after-effects in patients with palinopsia are enhanced and such an explanation would not explain the late recurrence of the image (by some several minutes) which occurs in some patients. However, palinopsia may be a type of release phenomenon as described for visual hallucinations. In favour of this possibility is a fact that formed release hallucinations can occur in patients with palinopsia and that in both conditions there is evidence of an interruption of cortical visual processing.

Specific types of palinoptic phenomena are illusory visual spread and polyopia. In illusory visual spread (Critchley, 1951) there is an extension of visual perception over an area greater than that excited by the object presented to the observer. In the time domain visual perseveration of moving objects has also been reported and one patient experienced accelerated movement of a perseverated image.

In instances of usually right-sided occipital lesions patients may experience monocular diplopia or more commonly polyopia (the seeing of multiple images) which persist whichever eye is closed. Rare cases of cerebral induced monocular diplopia emphasize the importance of ensuring that this phenomenon is not present in patients complaining of diplopia. Other causes for monocular diplopia include ocular causes such as corneal irregularities, iris lesions and retinal detachment.

Certain cases of polyopia may be due to epileptic phenomena (Bender & Sobein, 1963) but Bender (1945) in a description of four cases tried to explain the phenomenon as a result of impaired fixation.

Oculomotor control: normal and abnormal

David S. Zee[1] and R. John Leigh[2]

[1]Department of Neurology, Johns Hopkins Hospital, Baltimore, MD, USA
[2]Department of Neurology, University Hospitals of Cleveland, OH, USA

An approach to understanding eye movements best begins by considering how they serve vision (Leigh & Zee, 1999). One class of eye movements brings objects of interest onto the fovea and includes saccades and quick phases of nystagmus, which are the fastest of eye movements and allow us to rapidly change our line of sight. A second class of eye movements holds images steady on the fovea and includes pursuit, which allows us to track small objects moving across our visual environment, and vestibular slow phases, which hold images steady on the fovea during head motion. Optokinetic slow phases (OKN, full-field visual following) also help stabilize gaze during head rotation. Vergence eye movements rotate the eyes in opposite directions; they bring the images of an object of interest onto both foveae at once, and then keep them there.

Head motion is of two types: angular (rotations), sensed by the semicircular canals, and linear (translations) sensed by the otoliths. For head rotations, horizontal (yaw), vertical (pitch) and, roll (ear to shoulder), compensatory slow phases in the orbit must be equal and opposite to the angular motion of the head. For head translations, fore–aft, up–down or side-to-side, slow phases must be scaled to the location of the point of regard; the closer the target the greater the amplitude of the compensatory slow-phase for a given amount of translational motion. During natural movements of the head, rotational and translational vestibular reflexes work together with the visual-following reflexes, OKN, pursuit and vergence, so that subjects can maintain their line of sight on the particular location of interest in three-dimensional space.

Oculo-motor control signals

To interpret abnormal ocular motility it is helpful to understand the way the central nervous system controls eye movements under normal circumstances (Leigh & Zee, 1999). Here, we review the normal patterns of innervation for moving the eyes to change gaze accurately, and for holding the eyes steady to maintain gaze on a stationary object of interest. The major hindrance to rotation of the globe is orbital viscosity because the moment of inertia of the globe is relatively small. For rapid eye movements (saccades and quick phases of nystagmus), a powerful contraction of the extraocular muscles is necessary to overcome viscous drag. This is accomplished by a phasic increase in the frequency of neural discharge called the pulse of innervation. Once the eyes are brought to their new position they must be held there against elastic-restoring forces of the orbital tissues, which would return the globe to the primary position. Preventing this centripetal drift requires a sustained contraction of the extraocular muscles. This is produced by a tonic level of neural activity called the step of innervation. The oculomotor control signal for saccadic eye movements is this pulse-step of innervation (Fig. 44.1). This pattern of activity is reflected in the discharge of both ocular motoneurons and the eye muscles themselves.

The immediate premotor command for the saccadic pulse is generated by burst neurons, which for horizontal saccades lie within the pontine paramedian reticular formation (PPRF) and for vertical saccades lie in the prerubral fields of the mesencephalon in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). Burst neurons discharge at high frequencies beginning just before and time locked to the saccade itself. Otherwise they are silent because of inhibitory inputs from omnipause neurons, which are located between the rootlets of the abducens nerve in the nucleus raphe interpositus. Omnipause neurons discharge tonically except during saccades in any direction, when they pause and allow burst neurons to generate a saccade. A separate class of saccade-related neurons, inhibitory burst cells, are located in the

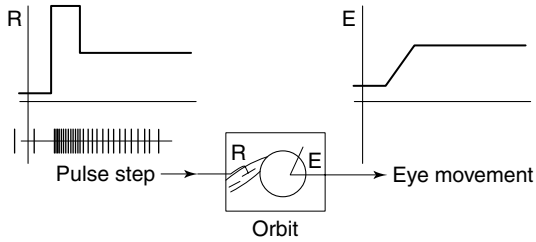

Fig. 44.1. Neural signal for a saccade. (Right) Eye movement; E is eye position in the orbit, and the abscissa scale represents time. (Left) Neural signal sent to the extraocular muscles to produce the saccade. The vertical lines indicate the occurrence of action potentials of an ocular motoneuron. The graph above is a plot of the neuron's discharge rate (*R*) against time. It shows the neurally encoded pulse (velocity command) and step (position command). (From Leigh & Zee, 1999.)

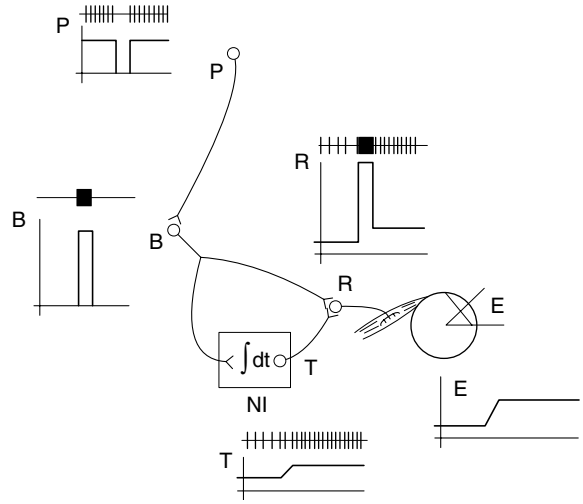

Fig. 44.2. Relationship between pause cells (P) and burst cells (B) during saccades. Pause cells cause discharging just before each saccade, allowing the burst cells to generate the pulse. The pulse is integrated by the neural integrator (NI) to produce the step. The pulse and step combine to produce the innervational change on the ocular motor neurons (OMN) that produces the saccadic eye movement (E). Vertical lines represent individual discharges of neurons. Underneath the schematized neural (spike) discharge is a plot of discharge rate versus time. (From Leigh & Zee, 1999.)

medulla, they act as a brake, and help stop saccades so that they do not overshoot the target.

The step of innervation is created by a neural gaze-holding network or neural integrator that integrates, in the mathematical sense, the saccadic eye velocity command to produce the appropriate position-coded information for the ocular motoneurons. The medial vestibular nucleus and the adjacent nucleus prepositus hypoglossi are important for the neural integration of horizontal oculomotor signals (Arnold et al., 1999). For integration of vertical oculomotor signals the interstitial nucleus of Cajal, coupled with activity in the vestibular and prepositus nuclei (Helmchen et al., 1998) are important. The flocculus of the cerebellum also contributes to the integration of both vertical and horizontal eye movements (Zee et al., 1981); its input is in part from cell groups that lie in the paramedian tracts (PMT) adjacent to the MLF along its extent from the rostral medulla to the caudal midbrain (Büttner-Ennever & Horn, 1996; Nakamagoe et al., 2000). All types of versional eye movements require a step component of innervation to hold gaze at the end of a movement; they share a common neural integrator. Fig. 44.2 shows the relationship between burst neurons, pause neurons, and the neural integrator for the generation of saccadic commands.

Control of horizontal conjugate gaze

The abducens nucleus itself is the site of assembly of the premotor commands for horizontal conjugate eye movements (Büttner-Ennever & Büttner, 1988). The nucleus contains two main types of neurons: abducens motor neurons, with axons that innervate the lateral rectus muscle; and abducens internuclear neurons, with axons that project, via the contralateral medial longitudinal fasciculus (MLF), to the medial rectus subdivision of the contralateral oculomotor nucleus (Fig. 44.3). Lesions of the abducens nucleus, therefore, cause a conjugate gaze palsy, an inability to move the eyes beyond the midline with any type of ipsilaterally-directed versional eye movement (saccadic, pursuit, optokinetic or vestibular). There may also be some horizontal gaze-evoked nystagmus on looking contralateral to the side of the lesion, probably due to involvement of fibres of passage crossing to the contralateral abducens nucleus from the ipsilateral medial vestibular nucleus, or the involvement of the PMT cell group (Müri et al., 1996). Lesions of the MLF, on the other hand, deprive the ipsilateral medial rectus of its innervation during versional eye movements. This leads to paresis of adduction during conjugate gaze but with intact adduction during convergence: internuclear ophthalmoplegia (INO) (Gamlin et al., 1989). There is often a nystagmus in the abducting eye, which may reflect involvement of the PMT cell group adjacent to the MLF, or commissural pathways connecting the two neural integrators on either side of the brain stem. In some cases of INO the abducting nystagmus reflects an adaptive response to the patient habitually fixing with the paretic eye. If a 'conjugate' gaze palsy is not perfectly conjugate, a coexisting abducens nerve lesion

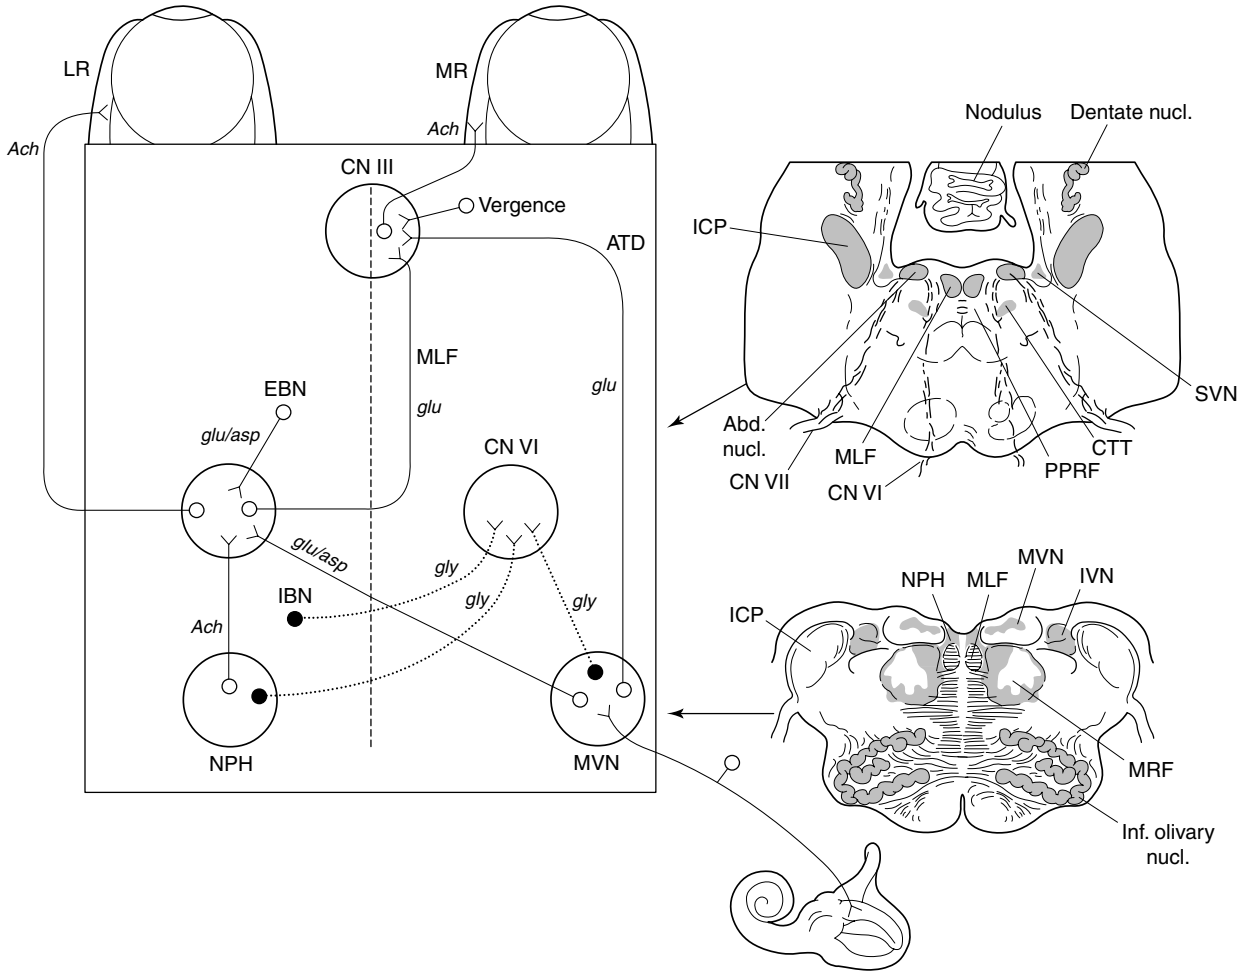

Fig. 44.3. Anatomic scheme for the synthesis of signals for horizontal eye movements. The abducens nucleus (CN VI) contains abducens motoneurons that innervate the ipsilateral lateral rectus muscle (LR) and abducens internuclear neurons that send an ascending projection in the contralateral medial longitudinal fasciculus (MLF) to contact medial rectus (MR) motoneurons in the contralateral third nerve nucleus (CN III). From the horizontal semicircular canal, primary afferents on the vestibular nerve project mainly to the medial vestibular nucleus (MVN), where they synapse and then send an excitatory connection to the contralateral abducens nucleus and an inhibitory projection to the ipsilateral abducens nucleus. Saccadic inputs reach the abducens nucleus from ipsilateral excitatory burst neurons (EBN) and contralateral inhibitory burst neurons (IBN). Eye position information (the output of the neural integrator) reaches the abducens nucleus from neurons within the nucleus prepositus hypoglossi (NPH) and adjacent MVN. The medial rectus motoneurons in CN III also receive a command for vergence eye movements. Putative neurotransmitters for each pathway are shown: Ach, acetylcholine; asp, aspartate; glu, glutamate; gly, glycine. The anatomic sections on the right correspond to the level of the arrowheads on the schematic on the left. Abd. nucl., abducens nucleus; ATD: ascending trait of Deiters; CN VI, abducens nerve; CN VII, facial nerve; CTT, central tegmental tract; ICP, inferior cerebellar peduncle; IVN, inferior vestibular nucleus; Inf. olivary nucl., inferior olivary nucleus; MRF, medullary reticular formation; SVN, superior vestibular nucleus. (From Leigh & Zee, 1999.)

(abduction affected more than adduction) is suggested. A brainstem lesion affecting one abducens nucleus and the adjacent MLF causes paralysis of both ipsilateral conjugate gaze and adduction of the ipsilateral eye. The only remaining movement during attempted conjugate gaze is abduction of the contralateral eye. This is the 'one-and-a-half' syndrome (Wall & Wray, 1983).

How do saccadic, pursuit, and vestibular commands reach the abducens nucleus? The velocity commands for horizontal saccades come from the burst cells located in the pontine paramedian reticular formation (PPRF) adjacent to the abducens nucleus. Lesions here impair ipsilateral saccades, but vestibular slow phases and smooth pursuit may be spared (Johnston & Sharpe, 1989; Kommerell et al., 1987; Horn et al., 1997). This is because vestibular inputs and pursuit commands reach the abducens nucleus by direct projections from the vestibular nuclei; only if these pathways are involved will vestibular or pursuit movements also be affected. The output of the neural integrator (the step (tonic) component for versional eye movements) appears to reach the abducens nucleus via projections from the nucleus prepositus hypoglossi and the medial vestibular nucleus (see Fig. 44.3). Mesencephalic lesions, too, may affect horizontal eye movements, presumably by interrupting descending pathways carrying higher-level commands. A deficit in contralateral saccades and ipsilateral pursuit is the usual finding (Zackon & Sharpe, 1984).

The excitatory command for the horizontal vestibulo-ocular reflex comes from the contralateral vestibular nuclear complex. When the head is still, neurons in the right and left vestibular nuclei discharge tonically at the same rate. During horizontal head rotation the lateral semicircular canal in one labyrinth is stimulated and the lateral canal in the other is inhibited. This creates an imbalance between the discharge rates of the right and left vestibular nuclei; activity increases on one side and decreases on the other. The difference encodes head velocity and provides the command that generates the slow phase of vestibular nystagmus.

Control of vertical conjugate gaze

The midbrain is important for vertical eye movements (Fig. 44.4) (Horn & Büttner-Ennever, 1998; Bhidayasiri et al., 2000). The vertical premotor saccadic command arises in burst cells located in the riMLF. This structure lies ventral to the sylvian aqueduct in the prerubral fields at the junction of the midbrain and thalamus. Each burst neuron projects to motoneurons in a manner such that the eyes are tightly coordinated (yoked) during vertical saccades. Saccadic innervation from riMLF is unilateral to depressor muscles but bilateral to elevator muscles, with axons crossing within the oculomotor nucleus. Thus, riMLF lesions may cause conjugate saccadic palsies that are either complete or selectively downwards (but not upwards). The riMLF on each side of the midbrain contains burst neurons for both up and down saccades, but only for ipsilateral torsional saccades. Therefore, unilateral riMLF lesions can be detected at the bedside if torsional quick phases are absent during ipsidirectional head rotations in roll (ear to shoulder). There also may be a spontaneous torsional nystagmus with quick phases directed with the top poles beating toward the side opposite to the lesion (Helmchen et al., 1996). Bilateral lesions of the riMLF in monkeys and in humans produce a predominantly downward deficit for saccades or paralyse all vertical saccades. Bilateral experimental lesions of the riMLF in monkeys abolish vertical and torsional saccades (Suzuki et al., 1995) but vertical gaze-holding, vestibular eye movements, and pursuit are preserved, as are horizontal saccades.

The interstitial nucleus of Cajal (INC) is important for holding the eye in eccentric gaze after a vertical saccade, and coordinating eye-head movements in roll. Bilateral INC lesions limit the range of vertical gaze, but vertical saccades are not slowed (Helmchen et al., 1998). The posterior commissure (PC) is the route by which INC projects to ocular motoneurons. Inactivation of the PC causes vertical gaze-evoked nystagmus, but destructive lesions cause a more profound defect of vertical gaze, probably due to involvement of the nucleus of the PC.

Unilateral lesions of the INC cause a spontaneous torsional nystagmus with quick phases directed such that the top poles of the eyes beat toward the side of the lesion. There may be a 'see-saw' component to this nystagmus. There also is an ocular tilt reaction (OTR) with contralateral head tilt, skew deviation with hypertropia of the ipsilateral eye, and ocular counterroll with extorsion of the contralateral eye, and intorsion of the ipsilateral eye. This pattern of ocular tilt reaction is similar to that produced by a lesion of the contralateral utricular nerve (Riordan-Eva et al., 1997) and is encountered clinically with a variety of brain stem lesions that involve central otolithic pathways (Brandt & Dieterich, 1994). Lesions in the vestibular periphery or vestibular nuclei (as occurs with Wallenberg's syndrome) usually produce an ipsilateral pattern of ocular tilt reaction, with an ipsilateral head tilt, skew deviation with hypertropia of the contralateral eye, and extorsion of the ipsilateral and intorsion of the contralateral eye. Lesions in the MLF produce a contralateral pattern of ocular tilt reaction similar to that produced with lesions in the INC. Lesions in the MLF also produce an asymmetry in the vertical

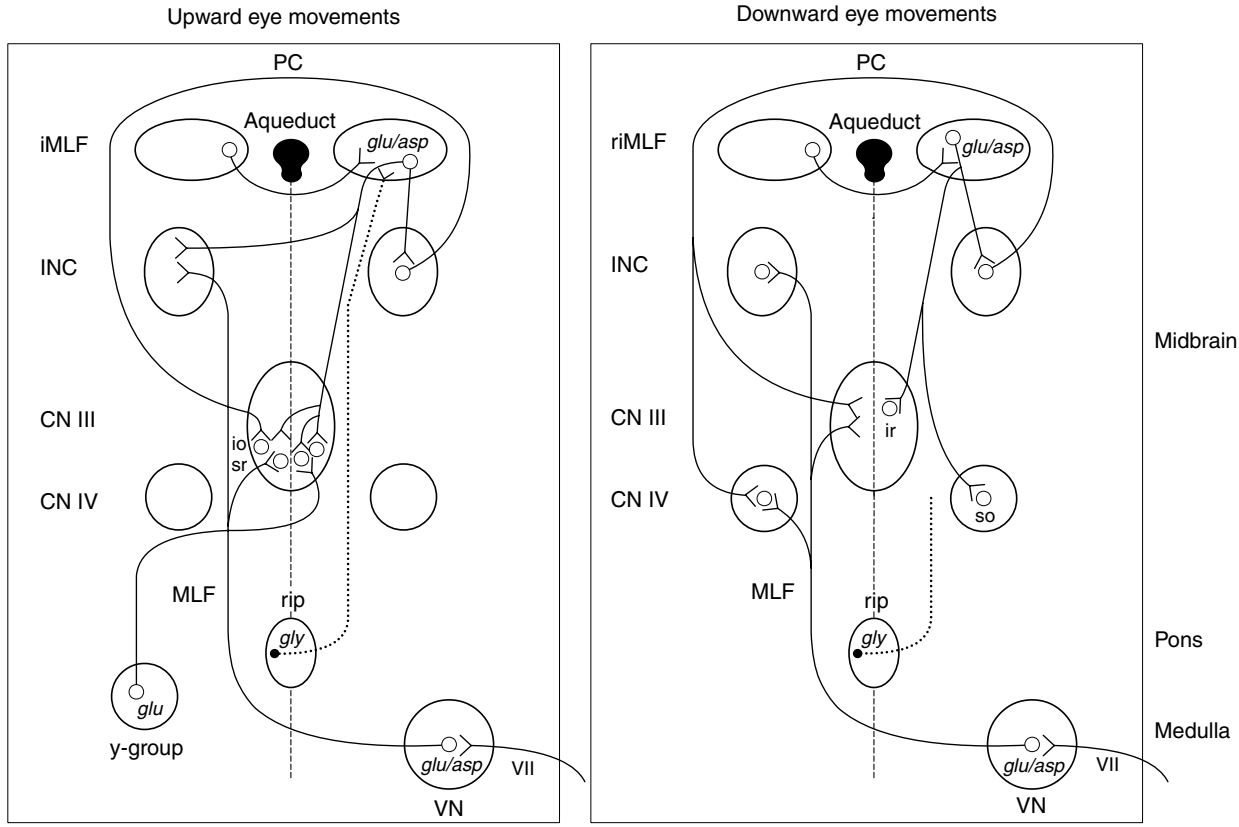

Fig. 44.4. Anatomic schemes for the synthesis of upward, downward, and torsional eye movements. From the vertical semicircular canals, primary afferents on the vestibular nerve (VN) synapse in the vestibular nuclei (VN) and ascend into the medial longitudinal fasciculus (MLF) and brachium conjunctivum (not shown) to contact neurons in the trochlear nucleus (CN IV), oculomotor nucleus (CN III), and the interstitial nucleus of Cajal (INC). (For clarity, only excitatory vestibular projections are shown.) The rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), which lies in the prerubral fields, contains saccadic burst neurons. It receives an inhibitory input from omnipause neurons of the nucleus raphe interpositus (rip), which lie in the pons (for clarity, this projection is only shown for upward movements). Excitatory burst neurons in riMLF project to the motoneurons of CN III and CN IV and send an axon collateral to INC. Each riMLF neuron sends axon collaterals to yoke-pair muscles (Hering's law). Projections to the elevator subnuclei (innervating the superior rectus and inferior oblique muscles) may be bilateral because of axon collaterals crossing at the level of the CN III nucleus. Projections of inhibitory burst neurons are less well understood, and are not shown here. The INC provides a gaze-holding signal, and projects to vertical motoneurons via the posterior commissure. Signals contributing to vertical smooth pursuit and eye-head tracking reach CN III from the y-group via the brachium conjunctivum and a crossing ventral tegmental tract. Neurotransmitters: asp, aspartate; glu, glutamate; gly, glycine. (From Leigh & Zee, 1999.)

vestibulo-ocular reflex (better response with slow phases upwards) due to the sparing of fibres mediating anterior semicircular canal reflexes, which run in part outside the MLF (Cremer et al., 1999).

Higher-level control of saccades

The brainstem circuits that generate the premotor commands for saccades are triggered by inputs both directly from the cerebral hemispheres, and indirectly from the cerebral cortex and the basal ganglia via the superior colliculus (SC). The cerebellum is also an important circuit for generating saccades and receives inputs from the cerebral hemispheres via the pontine relay nuclei. Recent research has emphasized the role of the SC in saccade generation. Although pharmacological inactivation of the SC in experimental animals severely disrupts normal saccadic programming (Lee et al., 1988), destructive lesions in the SC do not permanently abolish voluntary saccades (Albano et

al., 1982). So the cerebral projections to the brainstem, and to the cerebellum via the nucleus reticularis tegmenti pontis (NRTP) also seem important. Lesions restricted to the superior colliculus in humans are rare and are reported to cause relatively minor changes in the triggering of saccades (Pierrot-Deseilligny et al., 1991). A crucial finding is that bilateral lesions of the frontal eye fields and the superior colliculus cause an enduring, severe deficit of voluntary saccades (Schiller et al., 1987). A similar defect occurs with combined bilateral lesions of the frontal and parietal eye fields (Lynch, 1992). Thus, parallel descending pathways are involved in generating voluntary saccades, and it appears that each is capable of triggering saccades.

The frontal lobes contain three major areas that contribute to the control of saccadic eye movements: frontal eye fields (FEF), supplementary eye fields (SEF), and dorsolateral prefrontal cortex. The cingulate cortex and the intralaminar thalamic nuclei, with which the frontal and supplementary eye fields have reciprocal connections, are also important in the control of saccades. Recent studies in normal humans using functional imaging and transcranial magnetic stimulation, combined with studies in patients with focal cerebral lesions, have allowed a more precise understanding of the contribution of the different cerebral areas to the control of saccades (e.g. Gaymard et al., 1998; O'Driscoll et al., 2000; Connolly et al., 2000).

In humans, the FEF is located around the lateral part of the precentral sulcus, involving adjacent areas of the precentral gyrus, the middle frontal gyrus, and the superior frontal gyrus, and corresponding to confluent portions of Brodmann areas 6 and 4, but not area 8 (Blanke et al., 2000). The supplementary eye field (SEF) lies on the dorsomedial surface of the hemisphere, in the posterior–medial portion of the superior frontal gyrus. The dorsolateral prefrontal cortex occupies the middle frontal gyrus and adjacent cortex, corresponding to Brodmann areas 46 and 9.

Acute inactivation of the frontal eye fields in monkey (and presumably in humans), causes an 'ocular motor scotoma', so that all voluntary contralateral saccades with sizes and directions corresponding to the injected site are abolished. Such animals also have a pronounced gaze preference towards the side of the lesion, which is also the case for humans with acute frontal lobe lesions. In humans with chronic frontal eye field lesions there are increases in the reaction time of saccades, especially to remembered target locations, and to imagined targets during the 'antisaccade' task in which patients are required to look in the direction opposite to that of a suddenly-appearing target (Ploner et al., 1999). Other findings include hypometria of saccades made to visual or remembered targets located contralaterally to the side of the lesion, a reduced ability to make saccades in anticipation of predictable stepping movement of a target, when the target moves away from the side of the lesion, and an impaired ability to inhibit inappropriate saccades to a novel visual stimulus. Patients with lesions in the supplementary eye fields have an impaired ability to make a remembered sequence of saccades to an array of visible targets and also have some difficulty with memory-guided saccades. Patients with lesions in the dorsolateral prefrontal cortex show defects in predictive saccades, memory-guided saccades and antisaccades.

The parietal lobe also plays an important role in the control of saccades. Its influence is largely through projections to the superior colliculus, though there are also reciprocal projections between the frontal eye fields and more posterior structures. The parietal eye field (PEF), which in humans lies close to the horizontal portion of the intraparietal sulcus, projects directly to the superior colliculus. The PEF seems important for triggering visually-guided saccades to explore reflexively the visual environment. Patients with unilateral and especially right-sided parietal lesions may show contralateral inattention, ipsilateral gaze deviation or preference, and increased latency for visually- and memory-guided saccades. Bilateral parietal lobe lesions can lead to Balint's syndrome: peripheral visual inattention (simultanagnosia), inaccurate arm pointing ('optic ataxia'), and difficulty in making visually-guided saccades. If all voluntary eye movements are affected, involvement of both frontal and parietal lobes is likely, and the term 'ocular motor apraxia' has been used.

All three frontal areas project to brain stem structures important in saccadic programming via parallel descending pathways. Although direct projections from frontal cortex to the pontine reticular formation do exist, at least in monkeys, the indirect projections via the superior colliculus seem more important.

The frontal eye fields send a direct projection to the superior colliculus but also an indirect projection to the superior colliculus via the caudate nucleus and the pars reticulata of the substantia nigra. The latter, indirect pathway is composed of two serial inhibitory links: a phasically active caudate-nigral inhibition and a tonically active nigrocollicular inhibition (Hikosaka & Wurtz, 1989). If the frontal eye fields cause caudate neurons to discharge, the nigrocollicular inhibition is removed and the superior colliculus is able to activate a saccade. Thus, disease affecting the caudate could impair the ability to make saccades in complex tasks, often related to memory, expectation and reward (Vermersch et al., 1999). Conversely, disease affecting the pars reticulata of the substantia nigra might disinhibit the superior colliculus and so cause excessive, inappropriate saccades. Such a combination of deficits is

encountered in patients with disease of the basal ganglia, such as Huntington's disease (Lasker & Zee, 1997). The subthalamic nucleus, too, has a role for the generation of saccades. Stimulation here in patients with Parkinson's disease leads to an improvement in the generation of memory-guided saccades (Rivaud-Pechoux et al., 2000a).

To summarize, the influence of frontal and parietal cortex on the control of saccades appears to be via two parallel descending pathways. One pathway is via the frontal eye field to the superior colliculus (directly, and indirectly via the basal ganglia). This pathway appears to be more concerned with self-generated changes in gaze, related to remembered, anticipated, or learned behaviour and potential reward. The other pathway is directly from posterior parietal cortex to the superior colliculus. This pathway is more concerned with reorienting gaze to novel visual stimuli and in particular with shifting visual attention to the location of new targets appearing in extrapersonal space. There are, however, strong interconnections between, and common projection sites of, the parietal and the frontal lobes, which precludes a strict separation of function between the two pathways (Chafee & Goldman-Rakic, 2000).

Control of smooth pursuit

In monkeys, a subdivision of the visual system is concerned with the perception of motion. It starts with retinal ganglion cells that project to the magnocellular layers of the lateral geniculate nucleus. Some striate cortex neurons respond to moving visual stimuli, but most information processing occurs in the middle temporal visual area (MT), to which striate cortex projects (Komatsu & Wurtz, 1988). Discrete lesions of the middle temporal area in monkeys produce a scotoma for motion in the affected visual field (Dürsteler & Wurtz, 1988). The consequences are that saccades can still be made accurately to stationary targets in the affected visual field, but moving stimuli cannot be tracked accurately by saccades or smooth pursuit.

The middle temporal visual area projects to the adjacent medial superior temporal visual area (MST); neurons here not only encode moving visual stimuli but also carry an eye movement signal (Newsome et al., 1988). Lesions of the medial superior temporal area cause a deficit of horizontal smooth pursuit for targets moving toward the side of the lesion. Human homologues of the MT and MST are in the occipito-temporo-parietal junction, where Brodmann areas 19, 37, and 39 meet.

Signals about target motion are also passed from posterior structures to frontal areas, which also have neurons that discharge in relation to pursuit and in which areas lesions create abnormalities of pursuit tracking (Shi et al., 1998). Functional imaging studies, too, implicate both posterior and anterior cerebral regions in control of pursuit eye movements (Berman et al., 1999; Petit & Haxby, 1999). Both the frontal and extrastriate visual areas project to the pontine nuclei, especially the dorsolateral pontine nuclei (DLPN) with further relay onto the paraflocculus, flocculus, and dorsal vermis of the cerebellum (Fig. 44.5). The nucleus of the optic tract (NOT) within the midbrain, which receives inputs from areas MT and MST, may be important in the initiation of pursuit by virtue of its projections to the pontine nuclei (Yakushin et al., 2000). The cerebellum plays a critical role in synthesizing the pursuit signal. The dorsal vermis and fastigial nucleus may contribute mainly to the onset of pursuit, whereas the paraflocculus and flocculus mainly sustain the pursuit response. The output of the flocculus and paraflocculus is primarily through the vestibular nuclei and y-group (for vertical responses), but it remains unclear how the fastigial nucleus effects its control of pursuit.

Like the control of saccades there may be a dichotomy between the frontal and parietal contributions to smooth pursuit, the former being associated with more voluntary, internally generated aspects and the latter with more reflexive, externally triggered tracking (Petit & Haxby, 1999; Berman et al., 1999). Similar considerations apply to vergence and changing our line of sight in depth; frontal areas may be more important for generating volitional changes, posterior structures for more reflexive responses (Gamlin & Yoon, 2000).

Cerebellar influences on eye movements

The cerebellum plays an important role in both immediate on-line and long-term adaptive oculomotor control (Walker & Zee, 2000; Dieterich et al., 2000; Demurget et al., 2000). The latter refers to the mechanisms that ensure that eye movements remain appropriate to their stimulus in normal development and aging as well as disease. Three distinct cerebellar syndromes have been identified as the result of studies of discrete lesions.

First, lesions of the flocculus and paraflocculus impair smooth visual tracking – both smooth pursuit with the head still and steady fixation of a target rotating with the head (Zee et al., 1981). The latter, called cancellation of the vestibulo-ocular reflex, is comparable to fixation suppression of caloric nystagmus. Floccular lesions also cause horizontal gaze-evoked nystagmus, which implicates the vestibulocerebellum in the normal function of the neural

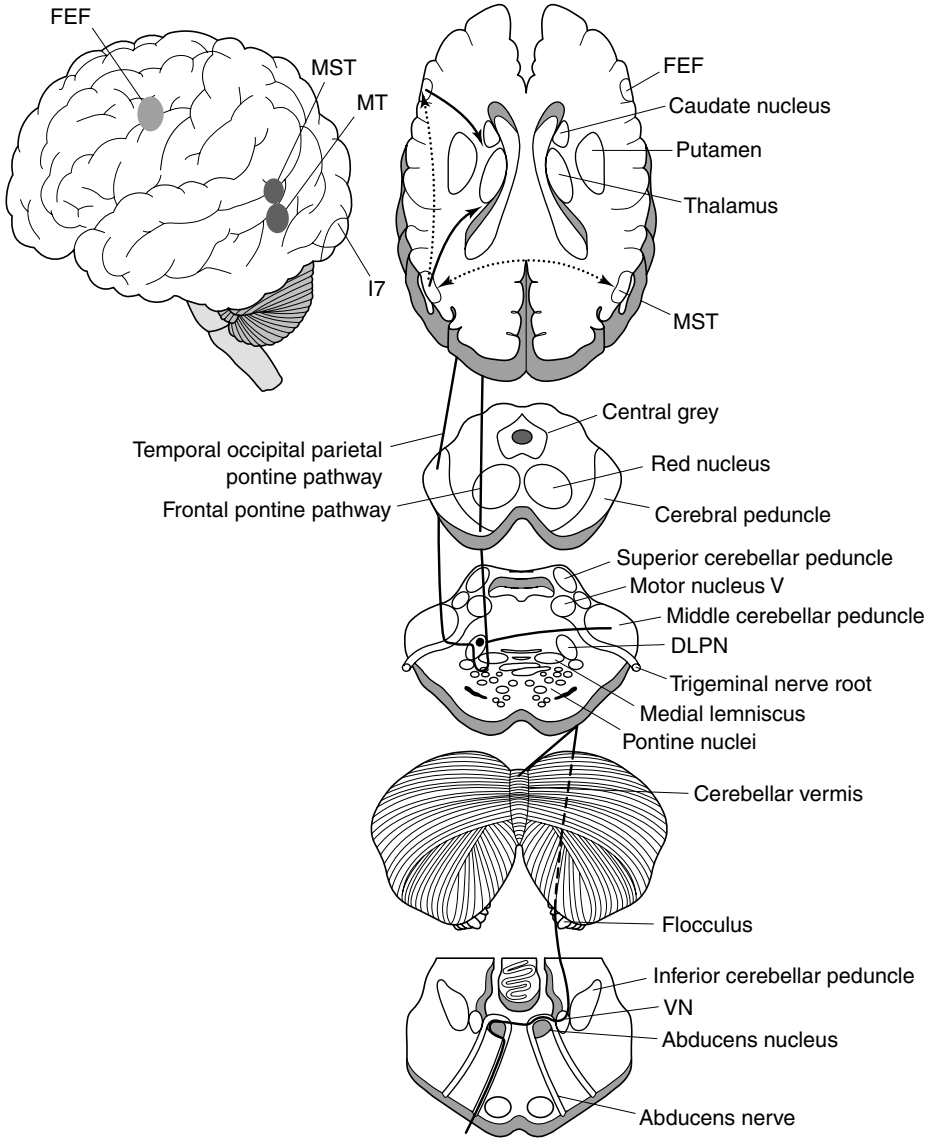

Fig. 44.5. A hypothetical scheme for horizontal smooth pursuit. Primary visual cortex (V1) projects to the homologue of the middle temporal visual area (MT) that in humans lies at the temporal–occipital–parietal junction. MT projects to the homologue of the medial superior temporal visual area (MST) and also to the frontal eye field (FEF). MST also receives inputs from its contralateral counterpart. MST projects through the retrolenticular portion of the internal capsule and the posterior portion of the cerebral peduncle to the dorsolateral pontine nucleus (DLPN). The DLPN also receives inputs important for pursuit from the frontal eye field; these inputs descend in the medial portion of the cerebral peduncle. The DLPN projects, mainly contralaterally, to the flocculus, paraflocculus, and ventral uvula of the cerebellum; projections also pass to the dorsal vermis. The flocculus projects to the ipsilateral vestibular nuclei (VN), which in turn project to the contralateral abducens nucleus. Note that the sections of brain stem are in different planes from those of the cerebral hemispheres. (From Leigh & Zee, 1999.)

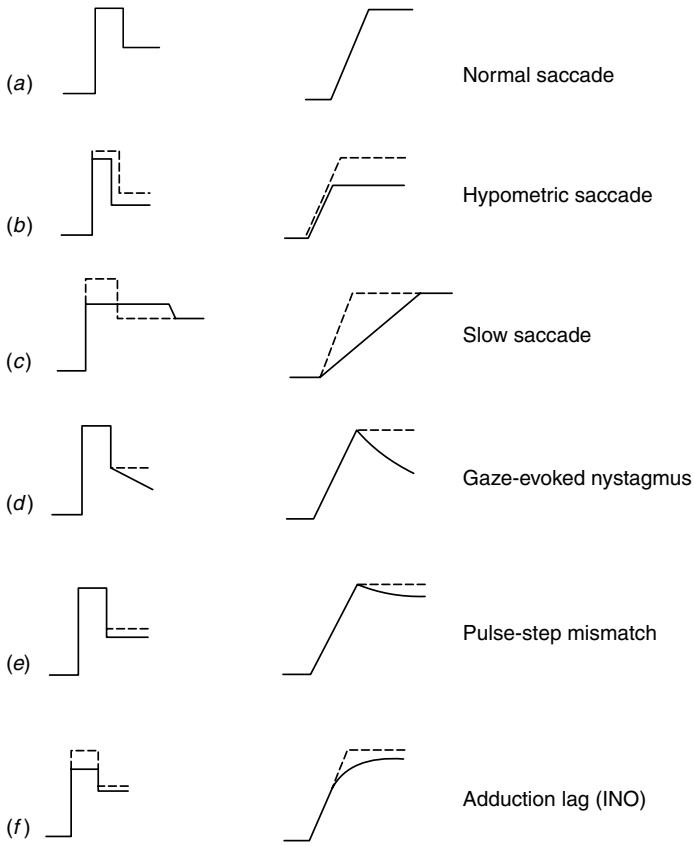

Fig. 44.6. Disorders of the saccadic pulse and step. Innervation patterns are shown on the left, eye movements on the right. Dashed lines indicate the normal response. (*a*) Normal saccade. (*b*) Hypometric saccade: pulse amplitude (width × height) is too small but pulse and step are matched appropriately. (*c*) Slow saccade: decreased pulse height with normal pulse amplitude and normal pulse-step match. (*d*) Gaze-evoked nystagmus: normal pulse, poorly sustained step. (*e*) Pulse-step mismatch (glissade): step is relatively smaller than pulse. (*f*) Pulse-step mismatch due to internuclear ophthalmoplegia (INO): the step is larger than the pulse, and so the eye drifts onward after the initial rapid movement. (From Leigh & Zee, 1999.)

gaze-holding integrator. Other signs of flocculectomy are downbeat nystagmus, rebound nystagmus, and postsaccadic drift or glissades (see under 'Disorders of saccadic eye movements').

Secondly, lesions of the nodulus and adjacent uvula cause a prolongation of vestibular responses as well as periodic alternating nystagmus (Waespe et al., 1985). There also is a failure of tilt-suppression of post-rotary nystagmus (Wiest et al., 1999).

Thirdly, lesions of the dorsal vermis (lobules V–VII) and the underlying fastigial nuclei cause both pursuit abnormalities and saccadic dysmetria. Vermal lesions produce hypometric saccades and impaired pursuit, especially when the eyes initiate their smooth tracking response. Fastigial nuclei lesions produce predominantly hypermetric saccades with relative preservation of pursuit.

The cerebellum also plays an important role in mediating the adaptive capabilities of the oculomotor system. Floccular lesions interfere with the adaptive capability of maintaining the accuracy of vestibular eye movements as well as preventing postsaccadic drift (Yagi et al., 1981; Lisberger et al., 1984; Optican et al., 1986). Lesions in the dorsal vermis produce abnormalities of adaptation for saccades and pursuit (Takagi et al., 1998, 2000).

Disorders of saccadic eye movements

Abnormalities of saccades can be divided into disorders of accuracy, velocity, latency, and stability. Furthermore, they can be analysed as disorders of the saccadic innervational commands: the pulse, the step, and the match between the pulse and the step (Fig. 44.6). For optimal performance the saccadic pulse must be the appropriate amplitude (approximately height × width) to ensure that the saccade is accurate, and of the appropriate height to ensure that the saccade is of high velocity. The saccadic pulse and step must be perfectly matched to prevent drift of the eyes after the saccade. A change in amplitude of the pulse creates saccadic overshoot, saccadic dysmetria. This sign is characteristic of disorders of the dorsal vermis or the fastigial nuclei of the cerebellum, although it appears with lesions in other parts of the nervous system. In Wallenberg's syndrome, for example, a specific pattern of saccadic dysmetria occurs. Saccades overshoot to the side of the lesion and undershoot away from the side of the lesion, and with attempted purely vertical saccades there is an inappropriate horizontal component toward the side of the lesion; this is called 'ipsipulsion' of saccades. With lesions of the superior cerebellar peduncle, the opposite pattern, 'contrapulsion', occurs: saccades overshoot opposite to the side of the lesion (Ranalli & Sharpe, 1986).

A decrease in the height of the saccadic pulse causes slow saccades. Normally, saccades follow a relatively invariant relationship between peak velocity and amplitude, called the 'main sequence'. Slow horizontal saccades usually imply disease affecting the horizontal burst cells in the pons, such as olivopontocerebellar atrophy (e.g. spinocerebellar ataxia types 1 and 2 (SCA1 and 2)). Slow vertical saccades usually imply disease affecting the vertical burst cells of the midbrain, such as progressive supranuclear palsy (Rivaud-Pechoux et al., 2000b) or Neimann–Pick

disease (Rottach et al., 1997). A mismatch in size between the pulse and the step produces brief (several hundred millisecond) postsaccadic drift or glissades. Postsaccadic drift occurs with disease of the vestibulocerebellum. The combination of slow, hypometric saccades and postsaccadic drift also occurs with internuclear ophthalmoplegia (INO), ocular motor nerve palsies, myasthenia gravis and ocular myopathies.

Disorders of saccadic initiation lead to an increase in saccadic latency (the normal saccadic latency is 200 ms). Often an associated head movement or a blink is needed to help initiate the saccade. Impaired saccadic initiation has been reported in patients with a variety of conditions including frontal or parietal lobe lesions, congenital or acquired 'oculomotor apraxia', Huntington's disease, Parkinson's disease and Alzheimer's disease. In patients with Parkinson's disease the saccade initiation deficit is often most obvious when they are instructed to voluntarily make repetitive saccades back and forth between two stationary targets.

Inappropriate saccades disrupt steady fixation, so called saccadic intrusions (Fig. 44.7). They include square-wave jerks, small-amplitude (up to 5°) saccades that take the eyes off target and are followed within 200 ms by a corrective saccade. Square-wave jerks may occur in normal, elderly subjects or in patients with cerebral hemisphere lesions, but they are especially prominent in progressive supranuclear palsy and in cerebellar disease. Square-wave jerks may be an exaggeration of the microsaccades that occur in normal individuals during fixation and can be most easily detected by ophthalmoscopy when the patient is instructed to fixate a target seen with the other eye. Macro-square-wave jerks (10–40° in amplitude) have been observed in multiple sclerosis and olivopontocerebellar atrophy. Macrosaccadic oscillations consist of sequences of markedly hypermetric saccades, separated by a normal intersaccadic interval (several hundred milliseconds), that continually overshoot the target. This causes a prominent back-and-forth oscillation about the point of fixation. Macrosaccadic oscillations reflect an increase in saccadic system gain (the saccade amplitude-target displacement relationship). They are typically found in patients with lesions in the midline deep cerebellar nuclei (Selhorst et al., 1976) but may be found with lesions in the pons (Averbuch-Heller et al., 1996).

Saccadic intrusions should be differentiated from excessive distractibility, in which novel visual targets that are behaviourally irrelevant evoke inappropriate saccades. Excessive distractibility can be demonstrated in the antisaccade task. When instructed to make a saccade in the direction opposite that of a visual stimulus (antisaccade paradigm), patients with Huntington's disease, Alzheimer's disease, schizophrenia, and frontal lobe lesions make an inappropriate saccade to the visual target.

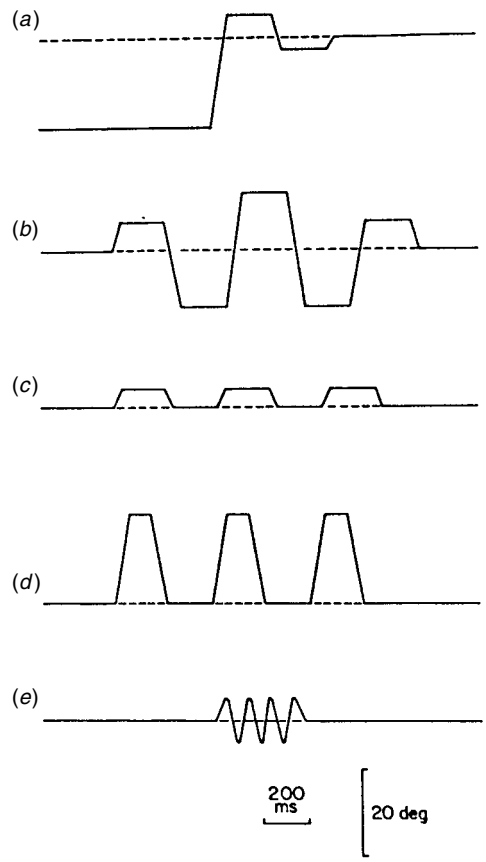

Fig. 44.7. Schematic of saccadic intrusions and oscillations. (*a*) Dysmetria: inaccurate saccades. (*b*) Macrosaccadic oscillations: hypermetric saccades about the position of the target; (*c*) Square-wave jerks: small, uncalled-for saccades away from and back to the position of the target; (*d*) Macrosquare-wave jerks: large, uncalled-for saccades away from and back to the position of the target; (*e*) Ocular flutter: to-and-fro, back-to-back saccades without an intersaccadic interval. (From Leigh & Zee, 1999.)

Saccadic oscillations without an intersaccadic interval (back-to-back, to-and-fro saccades) are called ocular flutter when they are limited to the horizontal plane and opsoclonus when they are multidirectional (horizontal, vertical, and torsional). Either type of oscillation may occur in patients with various types of encephalitis, as a remote effect of neuroblastoma or other tumours, and in association with toxins. An immunological basis is suggested (Connolly et al. 1997). Such oscillations are typically brought out by a change in gaze, eye closure, an associated

blink, or combined saccadic-vergence eye movements (Bhidayasiri et al., 2001). Flutter and opsoclonus may reflect a disorder of saccadic omnipause neurons (Zee & Robinson, 1979), although other explanations are possible (Leigh & Zee, 1999; Ridley et al., 1987). Voluntary nystagmus is another example of saccadic oscillations without an intersaccadic interval.

Disorders of smooth pursuit

Smooth pursuit eye movements that cannot keep up with the moving target, and require 'catch-up' saccades to keep the fovea on target are a common clinical finding. Impaired pursuit is often a side effect of medications such as sedatives and anticonvulsants. It also occurs with disease of the cerebellum or of the brainstem in, for example, progressive supranuclear palsy. Smooth pursuit capability also decreases with age. With lesions of the cerebral hemispheres typically pursuit is impaired for tracking directed toward the side of the lesion.

'Reversal' of smooth pursuit may be seen in some patients with congenital nystagmus: the smooth eye movements are directed opposite to the motion of the target.

Abnormalities of smooth pursuit are usually accompanied by commensurate disturbance of tracking of smoothly moving targets with combined movements of eye and head. This is tested by asking the patient to fixate a target rotating with the head. If cancellation (fixation suppression) of the vestibulo-ocular reflex is intact, no nystagmus is seen and the eyes remain stationary in orbit. When pursuit is defective, cancellation is also impaired and a nystagmus appears. Only when the vestibulo-ocular reflex is abnormal will noticeable discrepancies between smooth pursuit and eye–head tracking be evident.

Mechanisms of nystagmus

Nystagmus is a repetitive, to-and-fro movement of the eyes. When pathologic, it reflects abnormalities in the mechanisms that hold images steady on the retina: visually mediated eye movements (fixation), the vestibulo-ocular reflex, and the neural integrator which makes it possible to hold eccentric gaze (Stahl & Leigh, 2001). A disturbance of any of these mechanisms may cause drifts of the eyes (the slow phases of nystagmus) during attempted steady fixation. Corrective quick phases of saccades then rest the eyes.

Constant-velocity drifts of the eyes (Fig. 44.8(*a*)) with corrective quick phases produce jerk nystagmus, which is usually caused by an imbalance of vestibular or possibly optokinetic or pursuit drives. Lesions of the peripheral vestibular apparatus (labyrinth or nerve VIII) usually cause a mixed horizontal–torsional nystagmus with slow phases directed toward the side of the lesion. Because visually mediated movements are preserved, peripheral vestibular nystagmus is suppressed during fixation. This visual suppression of vestibular nystagmus may be evaluated at the

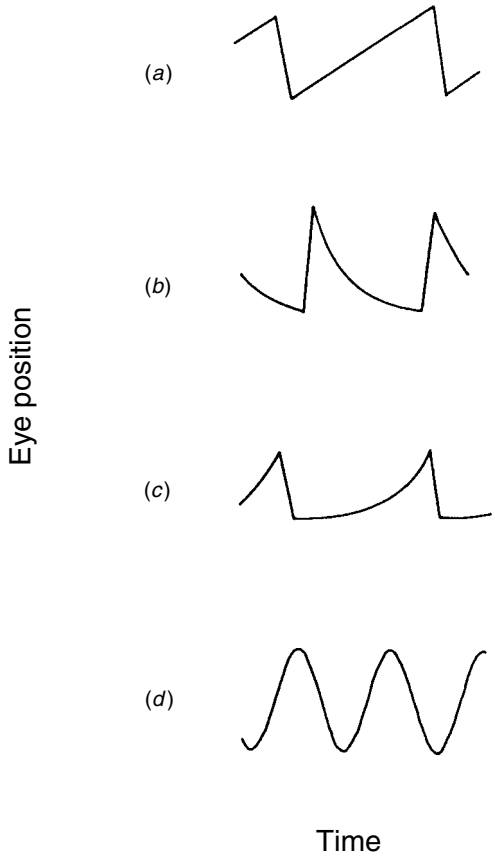

Fig. 44.8. Four common slow-phase waveforms of nystagmus. (*a*) Constant velocity drift of the eyes. This occurs in nystagmus caused by peripheral or central vestibular disease and also with lesions of the cerebral hemispheres. The added quick phases give a 'sawtooth' appearance. (*b*) Drift of the eyes back from an eccentric orbital position toward the midline (gaze-evoked nystagmus). The drift shows a negative exponential time course, with decreasing velocity. This waveform reflects an unsustained eye position signal caused by an impaired neural integrator. (*c*) Drift of the eyes away from the central position with a positive exponential time course (increasing velocity). This waveform suggests an unstable neural integrator and is encountered in the horizontal plane in congenital nystagmus and in the vertical plane in cerebellar disease. (*d*) Pendular nystagmus, which is encountered as a type of congenital nystagmus and with acquired disease. (From Leigh & Zee, 1999.)

bedside by using the ophthalmoscope; when the fixing eye is transiently covered, drifts of the optic disc and retinal vessels may appear or increase in velocity if there is an underlying vestibular imbalance. Frenzel goggles can also be used to remove fixation and bring out nystagmus. Nystagmus induced by a change in head position is frequently due to free-floating otoconia that have become trapped in one of the semicircular canals, benign positional vertigo, but may also be due to central disease. In particular, purely vertical positional nystagmus is suggestive of a posterior fossa lesion.

Nystagmus caused by disease of central vestibular connections may be purely torsional, purely vertical (downbeat or upbeat), or purely horizontal (i.e. without the torsional component that is usually seen with peripheral lesions). Smooth pursuit is usually also affected, so the velocity of slow-phase drift of central vestibular nystagmus does not diminish with fixation. Downbeat nystagmus in primary position usually reflects disease at the craniocervical junction, such as the Arnold–Chiari malformation or degenerative lesions of the cerebellum. Downbeat nystagmus is usually increased by convergence or lateral gaze. Patients with episodic ataxia (EA1) often have interictal downbeat nystagmus; they can be treated with diamox (Brandt & Strupp, 1997). Upbeat nystagmus in primary position occurs with lesions at the pontomedullary or pontomesencephalic junction or in the fourth ventricle. In the medulla it often involves the nucleus intercalatus, one of the perihypoglossal nuclei. Purely torsional nystagmus usually reflects intrinsic brain stem involvement in the vestibular nuclei or lesions in the vestibulocerebellum. Periodic alternating nystagmus (horizontal jerk nystagmus that changes direction every 2 minutes) is a form of central vestibular nystagmus (Leigh et al., 1981) and can be created experimentally by removing the cerebellar nodulus (Waespe et al., 1985). It can be successfully treated with Baclofen (Halmagyi et al., 1980).

Nystagmus on attempted eccentric gaze and with slow phases that show a declining exponential time course (see Fig. 44.8(*b*)) is due to an unsustained eye position command. This is gaze-evoked nystagmus, and it commonly occurs as a side effect of certain medications, especially anticonvulsants, hypnotics, and tranquillizers; with disease of the cerebellar flocculus; or, in the brainstem, with lesions in the paramedian tracts, the nucleus prepositus hypoglossi, and the medial vestibular nuclei. These last structures are frequently involved in Wernicke's encephalopathy and account for the gaze-evoked nystagmus and vestibular paresis in this condition. With prolonged eccentric gaze, gaze-evoked nystagmus may damp and actually change direction, so-called centripetal nystagmus. Following eccentric gaze, a rebound nystagmus occurs when the eyes return to the primary position; slow phases are directed toward the prior position of eccentric gaze. Rebound nystagmus usually coexists with other cerebellar eye signs.

Latent nystagmus also has slow phases with exponentially decreasing velocity (Abadi & Scallan, 2000). Latent nystagmus appears when one eye is occluded; then both eyes drift conjugately with slow phases of the viewing eye directed toward the nose. Latent nystagmus is commonly associated with strabismus (usually an esotropia) and dissociated vertical deviations (DVD) in which the eye under cover is higher. Latent nystagmus is acquired early in life but does not imply any underlying neurologic disease.

Nystagmus with slow phases that show an increasing exponential time course (see Fig. 44.8(*c*)) are typical of congenital nystagmus and may be due to instability of smooth pursuit or gaze-holding mechanisms. Congenital nystagmus is usually horizontal, accentuated by attempted fixation, diminished by convergence or active eyelid closure, associated with a head turn, and sometimes accompanied by 'reversed' smooth pursuit in which slow phases are directed oppositely to that of the target. Occasionally, acquired lesions of the cerebellum produce nystagmus with slow phases that have increasing exponential waveforms; this is usually vertical.

Pendular nystagmus consists of a slow phase that is a sinusoidal oscillation (see Fig. 44. 8(*d*)) rather than a unidirectional drift. Quick phases may be superimposed. Congenital nystagmus often appears pendular, although the slow-phase waveform of the nystagmus is usually not a true sinusoid and the nystagmus becomes jerk at extremes of horizontal gaze. Acquired pendular nystagmus may be a manifestation of multiple sclerosis or a sequel to brainstem infarction with inferior olivary hypertrophy (the syndrome of palatal tremor) (Deuschl et al., 1994). It has recently been proposed that pendular nystagmus in patients with multiple sclerosis may be caused by an instability in the neural integrator that normally guarantees steady gaze (Das et al., 2000). Acquired pendular nystagmus may have both horizontal and vertical components, and the amplitude and phase relationships of the two sine waves determine the trajectory taken by the eyes. For example, the trajectory is oblique if the sine waves are in phase and, more commonly elliptical (or circular) if they are 90° out of phase. Acquired pendular nystagmus is frequently disconjugate and may even be horizontal in one eye and vertical in the other. Gabapentin and memantine often diminish the intensity of acquired pendular nystagmus (Starck et al., 1997; Averbuch-Heller et al., 1997).

Convergence-retraction nystagmus, which occurs with midbrain lesions and usually coexists with upgaze paralysis

Table 44.1. Pulling actions of the extraocular muscles with the eye in primary position

Muscle	Primary action	Secondary action	Tertiary action
Lateral rectus	Abduction	–	–
Medial rectus	Adduction	–	–
Superior rectus	Elevation	Intorsion	Adduction
Inferior rectus	Depression	Extorsion	Adduction
Superior oblique	Intorsion	Depression	Abduction
Inferior oblique	Extorsion	Elevation	Abduction

(Parinaud's syndrome), actually consists of asynchronous adducting saccades (Keane, 1990). Cocontraction may also occur, causing the eyes to retract into the orbit. See–saw nystagmus (one eye goes up, the other down, with variable torsion) may be related to an imbalance in activity in structures that receive projections from the otolith organs (Kanter et al., 1987). The lesions are usually in the midbrain though see–saw nystagmus may accompany lesions in more caudal parts of the brainstem or cerebellum (Pieh and Gottlob, 2000). Humans with developmental disorders of the optic chiasm may have see–saw nystagmus (Dell'Osso et al., 1999a).

Ocular alignment: anatomic and physiologic principles

The primary pulling directions of the six extraocular muscles, when the eye is in primary position, are summarized in Table 44.1. The lateral rectus always abducts and the medial rectus always adducts the eye, but the actions of the vertical muscles depend on the starting position of the eye. The vertical recti and the oblique muscles pull the globe in both vertical and torsional directions. It is important to test the vertical recti and oblique muscles with the eye in a position that will cause the muscle in question to have its greatest vertical action. Thus, to test the vertical recti, bring the eye first into the abducted position; to test the oblique muscle, bring the eye first into the adducted position.

The fibres of the extraocular muscles show histological and histochemical differences from those of limb muscles (Spencer & Porter, 1988; Demer et al., 1995, 1997). As each muscle is traced anteriorly, two parallel layers are formed. The more central or 'global' portion of extraocular muscle contains fibre types that are specialized for developing transient, high tensions, to move the eyes quickly. This global layer of extraocular muscle contains about 60% of total muscle fibre and inserts via a tendon on the sclera of the globe. The more peripheral or 'orbital' layer of extraocular muscle is composed of fibre types that are specialized for sustaining tonic tension. An important recent discovery is that the orbital fibre layer of each muscle does not insert on the globe but, instead, attaches to a pulley of connective tissue (Demer et al., 2000). The pulley for each muscle lies contiguous with the orbital wall or its fascia, between the globe equator and the posterior pole of the eye. Thus, the functional point of origin of the extraocular muscles is not, as previously thought, at the orbital apex, but corresponds to the current position of the pulleys (Clarke et al., 2000). In this sense, all the extraocular muscles are similar to the superior oblique muscle, which has its functional origin at the trochlea (the only pulley that does not move). This scheme is consistent with older electromyographic studies of human extraocular muscles, which demonstrated a 'division of labour' between the global and orbital layers (Scott & Collins, 1973). Furthermore, the geometric rules that govern the axes of rotation of the eyes (such as Listing's law, which limits rotational axes during saccades and pursuit to an approximately frontoparallel plane, and so specifies eye torsion in eccentric gaze positions) may be imposed by the properties of the pulleys.

Extraocular muscle contains pallisade proprioceptors, which lie at the junction of the multiply-innervated extraocular muscle fibres and its tendon of insertion into the globe (Ruskell, 1999). These multiply innervated fibres receive their input from a discrete set of moto neurons, which ring the periphery of the classic borders of the oculomotor, trochlear, and abducens nuclei (Büttner-Ennever, 2000). Thus, it seems possible that the multiply-innervated fibres and pallisade proprioceptors could function similarly to muscle spindles in skeletal muscle though they may also influence dynamic properties of eye movements (Knox et al., 2000; Dell'Osso et al., 1999b). There is, however, no stretch reflex, in the classical sense, associated with the extraocular muscles (Keller & Robinson, 1971). These ocular proprioceptors also seem concerned with localization of objects for limb movements, or long-term adaptation to injury (Lewis et al., 1994, 1999; Ruskell, 1999; Weir et al., 2000).

The courses of the oculomotor nerves

The anatomy of the oculomotor, trochlear, and abducens nerves is reviewed in detail by Leigh and Zee (1999). The oculomotor nucleus sends fibres to extraocular muscles, to the levator palpebrae superioris, pupillary constrictor, and ciliary body. The oculomotor nucleus is a paired structure; its anatomy is summarized in Fig. 44.9. The classic scheme

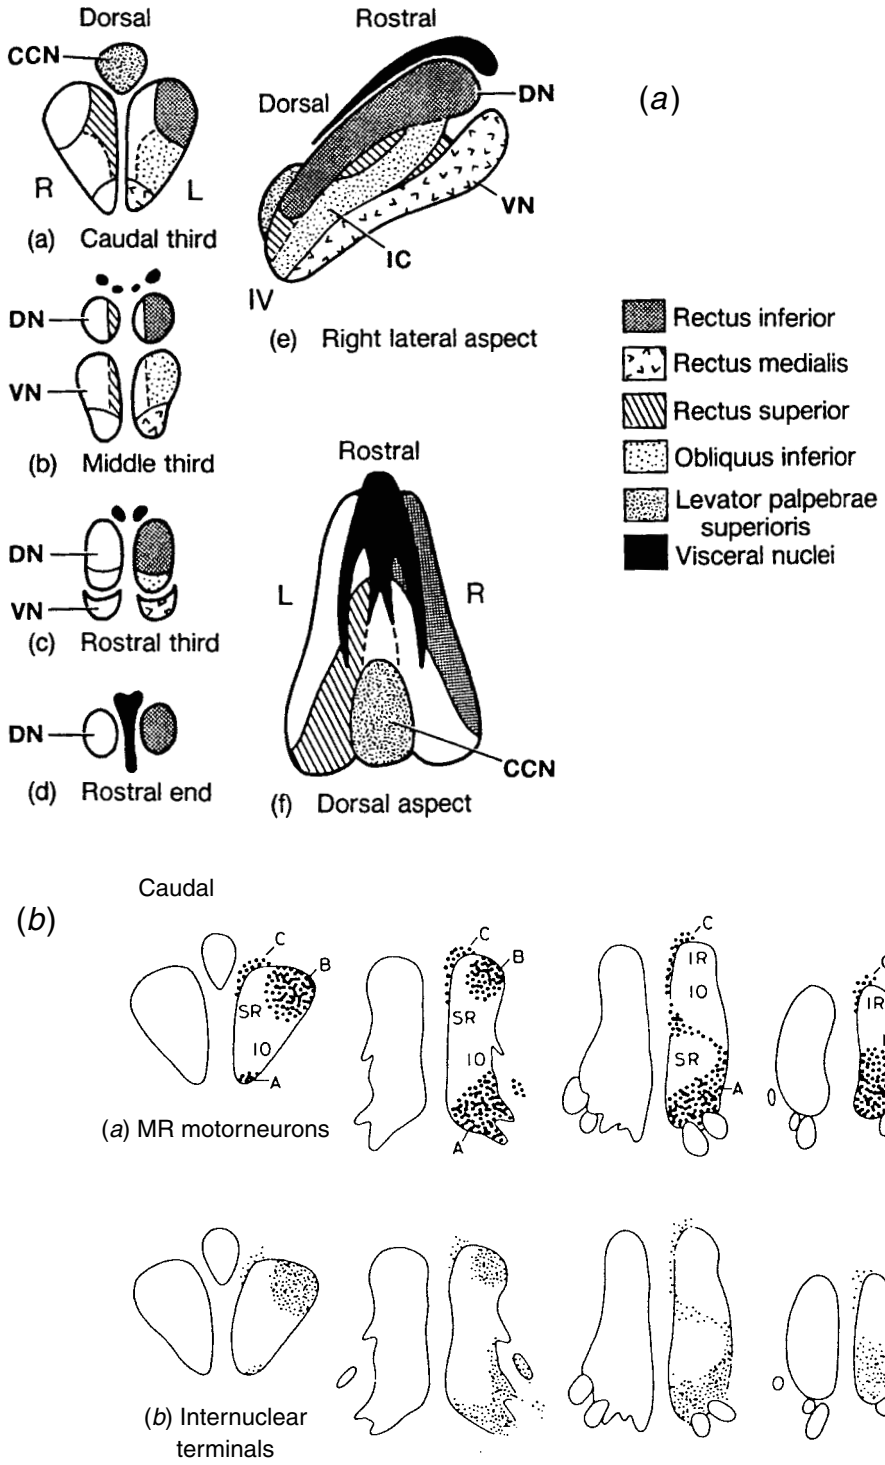

Fig. 44.9. (*a*) Warwick's scheme, based on retrograde denervation studies. CCN, caudal central nucleus; DN, dorsal nucleus; IC, intermediate nucleus; IV, trochlear nucleus; VN, ventral nucleus; R, right; L, left. (*b*) Scheme of Büttner-Ennever and Akert, based on radioactive tracer techniques. Top: The medial rectus (MR) motoneurons, identified by injecting isotope into medial rectus muscle, lie in three groups, A, B, and C. IO, inferior oblique; IR, inferior rectus; SR, superior rectus. Bottom: These same three areas also receive inputs from abducens internuclear neurons as demonstrated by injecting isotope into the contralateral sixth nerve nucleus. (From Leigh & Zee, 1999.)

of Warwick (1953), shown in Fig. 44.9(*a*), has been modified by Büttner-Ennever and Akert (1981) on the basis of studies with tracer techniques. The latter authors demonstrated that the medial rectus neurons (see Fig. 44.9(*b*), top) are distributed in three areas, A, B, and C. Neurons from area C receive pretectal inputs, and their axons mainly innervate the orbital layers of the medial rectus muscle. Neurons in all three locations receive inputs from the internuclear neurons of the contralateral abducens nucleus via the MLF (see Fig. 44.9(*b*), bottom). Projections from the oculomotor nucleus are ipsilateral except those to the superior rectus, which are totally crossed, and those to the levator palpebrae superiors, which are both crossed and uncrossed.

Clinical testing of diplopia: symptoms

Misalignment of the visual axes, strabismus, causes the two images of a seen object to fall on non-corresponding areas of the two retinas. This usually causes diplopia – the sensation of seeing an object at two different locations in space. In addition, the two foveae are simultaneously presented different images, so occasionally two different objects are perceived at the same point in space. This is called visual confusion.

If diplopia is monocular the cause is usually astigmatism or spherical refractive errors, incipient cataract, corneal irregularity, lens dislocation, or eye trauma. Such patients may report that the two images differ in brightness or that there are more than two images. Monocular diplopia caused by lens or corneal abnormality can be overcome by pinhole vision. Rarely, monocular diplopia is due to retinal detachment or to cerebral disorders.

Patients who complain of little or no visual disturbance despite an obvious ocular misalignment usually have had their strabismus from early in life. Thus, it is important to inquire about any history of strabismus, eye patching, eye surgery or abnormal head posture; old photographs may be of help.

Clinical testing of diplopia: physiologic principles

A clinical scheme for diplopia is summarized in Table 44.2. After looking for head tilts or turns, visual acuity, visual fields, pupils, and eyelids should be checked as preliminaries to testing ocular motility. Establishing the range of movement of each eye while the other is covered (ductions) and with both eyes viewing (versions) may reveal limitation of movement caused by extraocular muscle palsy. The direction of any limitation of movement can be correlated with the pulling action of a muscle (see Table 44.1). It is often useful to ask the patient to follow a penlight and to note the relative positions of the two corneal reflections with the eyes in each field of gaze. Subjective tests of diplopia depend on the patient's report of the subjective visual direction of images from one test object for each eye. If both images lie on corresponding retinal elements, for example, both foveae, the object will be reported to lie in the same visual direction. If the two images lie on non-corresponding retinal elements the object may appear to lie in two visual directions and the patient will report diplopia. Two further principles are important in this type of testing: (i) the images are maximally separated when the patient looks into the direction of action of the paretic muscle and (ii) the target seen by the paretic eye is projected more peripherally. The red glass and the Maddox rod (which takes a point source of light and makes it appear as a straight line) help the patient identify which image corresponds to the paretic eye.

Cover tests demand less cooperation by the patient than does the red glass or the Maddox rod. Cover tests depend on the principle that when one eye is required to fix on an object, it preferentially does so with the fovea. (Certain exceptions to this rule, caused by anomalous retinal correspondence, occur in congenital strabismus.) If the principal visual axis is not directed toward the object, an eye movement (saccade) will be necessary to move the image of the object, toward the fovea. The detection and estimated size of this corrective saccade ('movement of

Table 44.2. A summary scheme for diplopia testing

Preliminary examinations
Look for head tilts and turns
Check visual acuity and visual fields
Examine pupils and eyelids
Determine range of movement
First, with one eye viewing (ductions)
Second, with both eyes viewing (versions)
Use objective tests to estimate amount of diplopia in the nine cardinal positions of gaze
Red glass test
Maddox rod
Lancaster red–green test
Use the cover test to examine the tropia in the nine cardinal positions of gaze (prisms can be used to measure the deviation; For vertical deviations, use the Bielschowsky head-tilt test (Fig. 44.11).

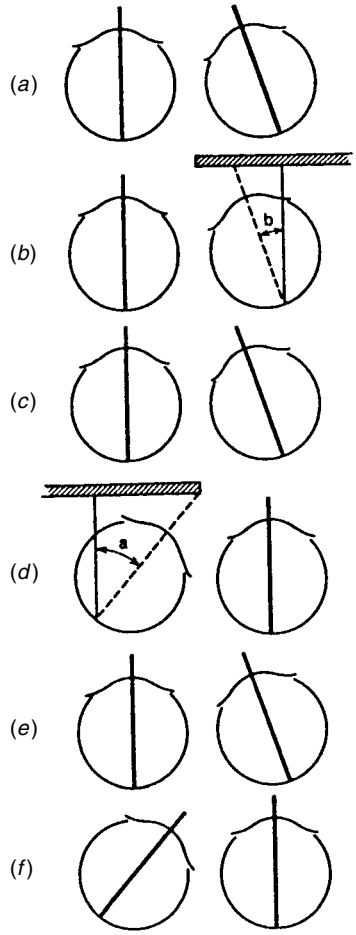

Fig. 44.10. The cover test. (*a*) Initially, with both eyes viewing, there is an esotropia (right eye turned in). (*b*) When the cover is placed before the nonfixating right eye, no movement occurs; nor does it occur when (*c*) the cover is removed. (*d*) When the left eye is covered, the right eye must fixate the target and a movement of redress occurs. Note that the deviation of the sound eye under cover (the secondary deviation-a) is greater than that of the paretic eye under cover (primary deviation-b). When the cover is removed, either (*e*) the left eye again takes up fixation, or (*f*) the paretic eye continues to fixate, if the patient is an 'alternate fixator'. (From Leigh & Zee, 1999.)

redress') provide an indication of misalignment of the visual axes.

The cover test (Fig. 44.10) reveals a tropia, a misalignment of the visual axes when both eyes are viewing. The patient is instructed to fix on a target that requires a visual discrimination (e.g. a letter) and ensures a fixed accommodative state. First, with the eyes in primary position, cover the right eye and look for a movement of the uncovered left eye (movement of redress). If no movement of the left eye is seen when the right eye is covered, remove the cover and then cover the left eye, looking for a movement of redress of the right eye. For horizontal deviations, exotropia (outward deviation) points to medial rectus weakness and esotropia (inward deviation) to lateral rectus weakness. Repeat this test with the eyes brought into the nine cardinal positions of gaze by rotating the head while the eyes fixate on the same target. In this way, the field of gaze in which the deviation is maximal can be determined.

Testing for vertical strabismus with the Bielschowsky head-tilt test

After a paralytic strabismus has been present for some months, changes in the innervation and mechanical properties of the muscles occur so that the deviation may no longer increase when the eyes look into the direction of action of the paretic muscle. This so-called spread of comitance can be particularly troublesome in the diagnosis of vertical muscle palsies. In this situation, noting any change of vertical deviation as the patient tilts the head (ear to shoulder) to the right or to the left can often be helpful (Bielschowsky, 1940). Classically, with a superior oblique palsy, the deviation is increased when the patient's head is tilted to the side of the palsy and reduced with a head tilt to the opposite side (Fig. 44.11). In a patient who has a third nerve palsy and who is unable to adduct the eye, the action of the superior oblique muscle can be best evaluated by looking for intorsion of the abducted eye on attempted downward gaze.

Topologic diagnosis of oculomotor nerve palsies

Causes of palsies of cranial nerves III, IV and VI are summarized in Tables 44.3–44.5.

Etiology of abducens nerve palsy

Disease affecting the abducens nucleus causes an ipsilateral conjugate gaze palsy. This is because the abducens nucleus contains not only abducens motor neurons (bound for the sixth nerve) but also abducens internuclear neurons that pass into the contralateral MLF and so reach the contralateral medial rectus subnucleus (see Fig. 44.3). Hereditary gaze palsies and Möbius' syndrome (horizontal gaze palsy, facial diplegia, and associated developmental anomalies) are probably due to failure of development of the abducens nucleus (Carr et al., 1997). Duane's retraction syndrome is characterized by narrowing of the palpebral fissure on

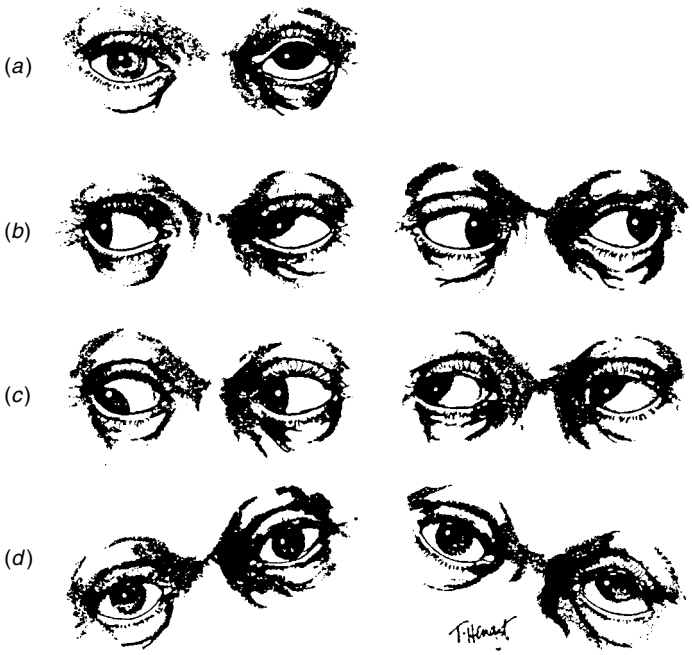

Fig. 44.11. The diagnosis of vertical ocular deviation. The steps in the diagnosis of a left superior oblique palsy are shown. (*a*) In primary position there is a left hypertropia. This could be due to weakness of elevators of the right eye or depressors of the left eye. (*b*) The deviation becomes worse on gaze to the right. This implies weakness of the right superior rectus or the left superior oblique. (*c*) With the eyes in right gaze, the deviation is more marked on looking down. This implies weakness of the left superior oblique muscle. (*d*) The Bielschowsky head-tilt test. With a rightward head tilt, there is no detectable vertical deviation of the eyes. (This would be the patient's preferred head position.) With the head tilted to the left, there is an exaggeration of the left hypertropia. (From Leigh & Zee, 1999.)

adduction (retraction) and (i) limitation of abduction but full adduction (type I), (ii) limitation of adduction but full abduction (type II) or (iii) limitation of both abduction and adduction (type III). Rare cases of Duane's syndrome are acquired, for example, through orbital injury, but in most patients the syndrome is due to abnormal development of the abducens nucleus and aberrant innervation of the lateral rectus muscle by axons from the oculomotor nucleus. Patients with Duane's syndrome seldom complain of diplopia. The syndrome occurs more frequently in females and affects the left eye more than the right.

Lesions of the fascicles of the abducens nerve usually also involve structures through which the nerve passes. For example, sixth nerve palsy may be accompanied by ipsilateral facial weakness and contralateral hemiplegia (Millard–Gubler syndrome). Within its subarachnoid

course, the sixth nerve may be involved along with other cranial nerves by infective or neoplastic meningitis, chordoma, or enlarged ectatic basilar aneurysm (Table 44.3). Both abnormally increased and decreased intracranial pressure may be associated with abducens nerve palsies (Mokri et al., 1997).

As the abducens nerve rises and passes over the petrous bone, it lies close to the fifth nerve. These adjacent nerves may be involved by infection of the petrous bone causing diplopia and facial pain, Gradenigo's syndrome; deafness commonly coexists.

Within the cavernous sinus the sixth nerve may be involved with carotid aneurysm, carotid-cavernous fistula, dural arteriovenous shunts, or tumours, and may occasionally be recurrent (Blumenthal et al., 1997). Abducens palsy may be accompanied by Horner's syndrome (caused by involvement of adjacent oculosympathetic fibres) or involvement of other cranial nerves in the cavernous sinus.

Abducens nerve palsy should always be differentiated from myasthenia gravis, divergence paresis, convergence spasm (spasm of the near triad) and diseases within the orbit (see Table 44.7).

Etiology of trochlear nerve palsy

Involvement of the trochlear nucleus is rare; when it does occur there is often an associated Horner's syndrome due to involvement of the adjacent descending sympathetic pathways. The most common site of involvement is the subarachnoid course of the nerve. Here the fourth nerves emerge together from the anterior medullary velum. Thus, bilateral fourth nerve palsy after blunt head trauma is most likely due to contrecoup forces transmitted to the emerging nerves by the free edge of the tentorium. It may be associated with cerebellar gait ataxia if the superior vermis is also damaged. The nerves may also be involved in their subarachnoid course by tumour or as a consequence of neurosurgical procedure (Table 44.4).

Within the cavernous sinus, involvement of the trochlear nerve by tumour or aneurysm is usually accompanied by involvement of adjacent cranial nerves. In many cases of trochlear nerve palsy, no cause can be found, although sometimes diabetes or hypertension is associated, and the presumed etiology is ischemic.

Superior oblique palsy should be differentiated from involvement of other vertical extraocular muscles, skew deviation, or restrictive disease of the orbit, especially due to thyroid ophthalmopathy. The Bielschowsky head-tilt test, forced duction tests, and imaging of the orbit, help in making the diagnosis.

Another syndrome peculiar to the superior oblique muscle is superior oblique myokymia. Affected patients typically complain of brief, recurrent episodes of monocular blurring of vision, or tremulous sensations in one eye (Brazis et al., 1994). Some also report vertical or torsional diplopia or oscillopsia. Attacks usually last less than 10 seconds, but they may occur many times per day. The attacks may be brought on by looking downward, by tilting the head toward the side of the affected eye, or by blinking. Most patients with superior oblique myokymia have no underlying disease, though cases have been reported following trochlear nerve palsy, head injury, possible demyelination or brainstem stroke, and with cerebellar tumour. The mechanism for superior oblique myokymia is uncertain but some degree of damage to the trochlear nerve is probably a common predisposing factor.

The eye movements of superior oblique myokymia are often difficult to appreciate on gross examination, but the spasms of torsional–vertical rotations can sometimes be

detected by looking for the movement of a conjunctival vessel as the patient announces the onset of symptoms. They are more easily detected during examination with an ophthalmoscope or slit lamp.

No treatments for superior oblique myokymia are consistently effective, but individual patients may respond to carbamazepine, baclofen, and systemically or topically administered beta blockers. In some patients, superior oblique myokymia spontaneously resolves (Brazis et al., 1994) but in others the symptoms are so troublesome that surgical treatment is considered.

Etiology of oculomotor nerve palsy

Lesions of the nucleus of the third nerve are rare. When they occur, they usually involve structures important for vertical conjugate gaze. Based on current knowledge of the anatomic organization of the oculomotor nucleus it is possible to set certain criteria for diagnosis of nuclear third nerve palsy; unilateral third nerve palsy with contralateral superior rectus paresis and bilateral partial ptosis, and bilateral third nerve palsy associated with spared levator function (internal ophthalmoplegia may be present or absent) almost invariably reflect a lesion in the oculomotor nucleus. However, it is important to recognize that in this small area of the midbrain, the nuclei and fascicles of the oculomotor nerve lie in close proximity, and both may be affected to varying degrees (Umapathi et al., 2000).

Fascicular third nerve lesions usually also involve adjacent structures. Claude's syndrome consists of third nerve palsy, contralateral cerebellar ataxia, and tremor; it is due to involvement of the red nucleus and its cerebellar connections. Weber's syndrome consists of a third nerve palsy and contralateral hemiplegia, the latter caused by involvement of one cerebral peduncle. Benedikt's syndrome combines third nerve palsy, contralateral ataxia, and contralateral hemiplegia; if vertical gaze impairment is also present, it is referred to as Nothnagel's syndrome. Fascicular lesions may lead to a pattern of weakness that mimics effects of more distal lesions.

After its exit from the brainstem, the third nerve runs in the subarachnoid space and is susceptible to meningeal processes (infection, tumour, blood). The third nerve may be compressed by aneurysm, usually from the posterior communicating artery and sometimes from the basilar artery (Table 44.5). In such cases only rarely is the pupil affected alone. A common clinical challenge is to differentiate third nerve compression due to aneurysm from nerve infarction in association with diabetes or hypertension, in which cerebral arteriography is not indicated. The presence of pupillary involvement can be relied on to identify those patients that harbour an aneurysm. Initially, however, the pupil may be spared, so pupil-sparing third nerve palsy requires careful observation for a week before a decision can be made about arteriography. After a week, third nerve palsy with complete pupillary sparing is rarely due to aneurysm. Cases of complete extraocular palsy with normal pupils due to aneurysm are rare. Partial pupillary involvement may be grounds for an arteriogram, although mild involvement of the pupil may occur with noncompressive processes. Spontaneous resolution of an oculomotor paresis does not necessarily mean that aneurysm is excluded. In patients with an acute oculomotor palsy individuals between 20 and 50 years of age are more likely to have an aneurysm (Trobe, 1998) whereas children younger than 11 years almost never do. MRI and angiography often help to differentiate nerve infarction from compressive or brainstem lesions, and gadolinium enhancement of the cisternal portion of the oculomotor nerve is a sensitive index of neoplastic or inflammatory processes, including migraine.

At least some cases of third nerve infarction, usually in association with diabetes, hypertension, or collagen-vascular disease, involve the subarachnoid portion of the nerve. Another site is within the cavernous sinus. Such 'medical third nerve palsies' usually are acute in onset, preceded by facial or orbital pains, and characterized by total or relative sparing of the pupil.

At the tentorial edge the third nerve may be compressed by the uncus of the temporal lobe during cerebral herniation. Pupillary dilatation may be the first warning of such herniation.

Within the cavernous sinus the oculomotor nerve may be compressed by aneurysm or tumour. With carotid aneurysm, about half of all patients suffer pain in the face; abducens and trochlear palsies may coexist. Sparing of the pupils is more common with cavernous sinus than with posterior communicating aneurysms. Tumours in the region of the cavernous sinus often grow slowly and pain is not a usual feature. Often multiple cranial nerves are involved. A relatively common finding with such slowly progressive processes is aberrant regeneration of the oculomotor nerve (Boghen et al., 1979). This is characterized by anomalous synkinetic movements; most commonly the lid elevates during adduction or depression of the eye. Aberrant regeneration of the third nerve also occurs after trauma, intracavernous aneurysms and congenital third nerve palsy. Tumours arising near the cavernous sinus, including meningioma, pituitary adenomas, and lymphomas, may cause third nerve palsy; usually other nerves in the cavernous sinus are also affected. Typically, the tumours grow slowly without producing any pain.

Table 44.7. Differential diagnosis of ocular motor nerve palsies

Concomitant strabismus
Disorders of vergence, especially spasm of the near triad
Brainstem disorders causing abnormal prenuclear inputs (e.g. skew deviation)
Myasthenia gravis
Restrictive ophthalmopathy (e.g. Brown's superior oblique tendon sheath syndrome)
Trauma (e.g. blow-out fracture of the orbit)
Ophthalmic Graves' disease
Orbital metastases
Orbital pseudotumour
Orbital infections (e.g. trichinosis)
Disease affecting extraocular muscle
Oculopharyngeal dystrophy
Myotubular myopathy
Myotonic dystrophy
Kearns–Sayre syndrome (mitochondrial cytopathies)

Sometimes, the diagnosis only becomes evident with serial MRI scans. Occasionally, hemorrhage occurs into a pituitary tumour, causing the syndrome of pituitary apoplexy.

As the oculomotor nerve passes through the superior orbital fissure it divides into superior and inferior branches; isolated involvement of either ramus has been reported.

Etiology of multiple oculomotor nerve palsies

The main causes of multiple oculomotor nerve palsies are trauma, basal arachnoiditis and tumour infiltrations, lesions within the cavernous sinus (where the three nerves are adjacent), and generalized neuropathies (Table 44.6).

A low-grade inflammatory disorder of the cavernous sinus produces the Tolosa–Hunt syndrome (Campbell & Okazaki, 1987). It is a disease of middle or later life, and the presenting complaints are retro-orbital pain and diplopia. The third or sixth nerve or combinations of oculomotor nerves may be involved. Sensation over the first two divisions of the trigeminal nerve may be impaired. Slight proptosis and impairment of visual acuity may occur. Diagnosis is by imaging, which demonstrates soft-tissue infiltration in the cavernous sinus, sometimes with extension into the orbit apex, but without erosion of bone (Goto et al., 1990). Corticosteroid medications usually produce a prompt improvement.

The third, fourth, and sixth cranial nerves may be involved as part of a generalized neuropathy associated with toxins or the Guillain–Barré syndrome. The Miller–Fisher variant of the latter condition consists of ophthalmoplegia, areflexia, and ataxia. The pattern of ophthalmoparesis may sometimes suggest central involvement, mimicking gaze palsies or internuclear ophthalmoplegia. Evidence suggests that anti-GQ1b antibodies play a key role in producing the disturbance of eye movements in Miller–Fisher syndrome, Guillain–Barré syndrome, and Bickerstaff's encephalitis (Newsome-Davis, 1997; Ohtsuka et al., 1998). As in Guillain–Barré syndrome, *C. jejuni* may be the responsible trigger, since anti-GQ1b antibodies bind to surface epitopes on this organism (Jacobs et al., 1995). Testing for anti-GQ1b antibodies may be positive in patients presenting with unexplained ophthalmoparesis (Yuki, 1996).

Disorders of ocular alignment not related to disease of the oculomotor nerves

Table 44.7 summarizes the various central and peripheral disorders that may mimic oculomotor palsies. Concomitant strabismus, in which the deviation is constant for all

fields of gaze, is most commonly encountered in children but may occasionally present in adulthood, for example, after one eye has been patched for ophthalmic reasons. Spasm of the near triad (convergence spasm) occurs in hysterical patients and can usually be detected by careful observation of the pupils and by demonstration of a full range of eye movements with one eye viewing or in response to rapid, passive head turns (Griffin et al., 1976). The skew deviation associated with the ocular tilt reaction (OTR) may be difficult to distinguish from peripheral muscle palsies (Donahue et al., 1999).

When diplopia is due to myasthenia gravis, characteristics findings are fatigue brought on by sustained upward or lateral gaze and involvement of extraocular muscles supplied by more than one nerve. Ptosis is common. Such patients may have characteristic 'quiver' eye movements, in which saccades begin at a high speed but fatigue in mid-flight. Intramuscular administration of neostigmine, looking for a change in saccade accuracy, may be useful in documenting a response to anticholinesterase inhibitors in ocular myasthenia gravis. Improvement in eye or lid movements following application of an ice pack or after a brief nap is also diagnostically helpful.

Restrictive ophthalmopathy includes congenital conditions such as Brown's syndrome, in which the adducted eye cannot be elevated (Wilson et al., 1989), sequelae of orbital trauma, and inflammatory conditions. Thyroid ophthalmopathy characteristically causes impaired elevation, and extortion of the eye on abduction (Dresner & Kennerdell, 1985). Thyroid function tests may be abnormal and MRI or computed scanning of the orbit, or orbital ultrasonography may demonstrate enlarged extraocular muscles. Progressive limitation of ocular motility, accompanied by ptosis, is a feature of mitochondrial disorders as well as a number of dystrophic processes. Diplopia is an uncommon complaint in these conditions.

Disorders of the auditory system

Borka Ceranic and Linda M. Luxon

Neuro-otology Department, The National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

The human auditory system possesses a remarkable ability to evaluate the acoustic environment and to provide the information necessary for normal function and survival. The process of evaluation begins at the periphery, in the ear. In the cochlea, auditory information is frequency analysed, amplified or attenuated, sharply tuned and transformed into electrical neural impulses, which are transmitted and processed in the auditory nerve. In the central auditory system, complex processing of acoustic signals, such as binaural fusion and sound localization, takes place, as well as various perceptual and cognitive processes. The efferent system plays a role in modulation of the auditory information, by balancing the processes of excitation and inhibition. Tonotopic organization, i.e. the anatomical arrangement according to sound frequencies, exists throughout the entire auditory system, and facilitates the maintenance and enhancement of frequency discrimination. The integral parts of the auditory system interact through complex, mainly feedback mechanisms, creating a highly dynamic system, in which abnormal functioning at one level may have functional consequences at other level(s). This functional plasticity in the auditory system is, for instance, reflected in the phenomenon of tonotopic reorganization in the cortex as a result of cochlear damage, and, in the opposite direction, an abnormality in the central auditory system may lead to disinhibition phenomena at the cochlear level. There is a myriad of functional disorders, resulting from pathology in the auditory system, with the loss of hearing sensitivity being the most important. From a neurological point of view, the understanding of auditory dysfunction has considerable importance, as neurological lesions may be associated with damage of auditory pathways. The identification of auditory dysfunction, its relationship to particular anatomical structure(s), and localization of the underlying pathological process, are subjects of continuing interest to both clinicians and scientists. With advances in science and technology, there has been significant progress in gaining better insight into this fascinating system.

Functional anatomy of the auditory system

Outer and middle ear

The outer ear assists in localizing a sound source and serves to reinforce the resonance of the tympanic membrane.

The middle ear (Fig. 45.1) contains the three interarticulated auditory ossicles, which form an elastic spring, the stiffness of which is controlled by the two middle ear muscles, the stapedius and the tensor tympani. Acoustic stimulation leads to contraction, mainly of the stapedius, reducing the middle ear transmission of sound. The neural network of the stapedial reflex is integrated in the lower brainstem and consists of both ipsilateral and contralateral routes, with the efferent pathway in the facial nerve.

The inner ear – cochlea

The inner ear (Fig. 45.1) consists of the organs of balance and the cochlea. The cochlea is divided longitudinally by the basilar and Reissner's membranes into three chambers: the scala vestibuli, tympani and media. The scala vestibuli and tympani contain perilymph. Via the Sylvian aqueduct, the perilymphatic system communicates with the subarachnoid space of the posterior cranial fossa. The scala media is continuous with the vestibular membranous labyrinth, which contains endolymph. The organ of Corti (Fig. 45.2) contains the auditory sensory receptor, located on the basilar membrane and includes both outer (OHC) and

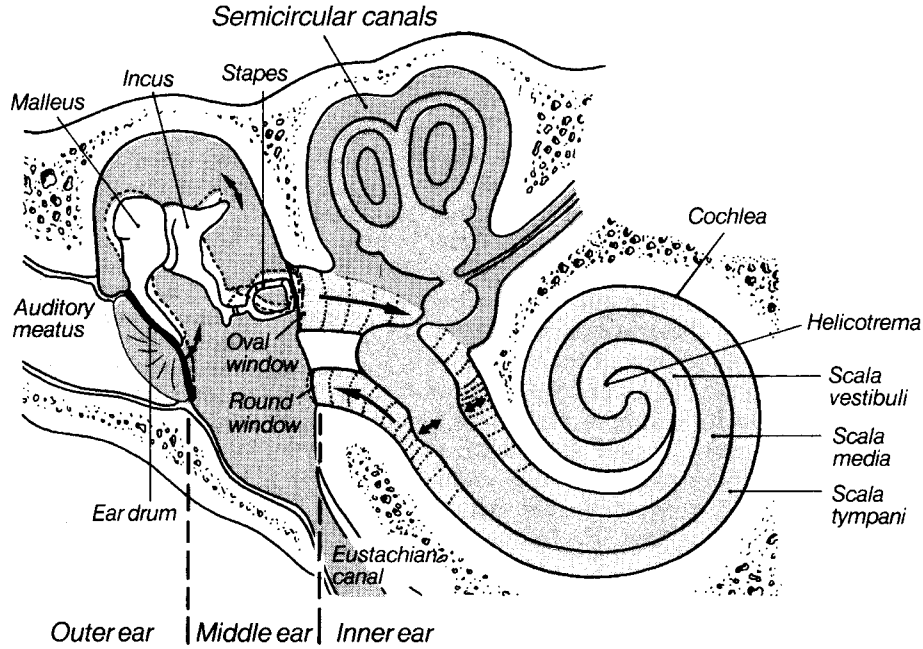

Fig. 45.1. A cross-section of the middle and inner ear. The dotted lines in the middle ear (together with arrows) indicate vibratory movements of the ossicular chain, and the perilymph of the inner ear is driven by sound pressure waves; in the inner ear, longitudinal arrows show the direction of the travelling wave propagation and transverse arrows the site of maximal displacement and vibrations of the scala media. (Adapted from Despopulous & Silbernagl, 1991.)

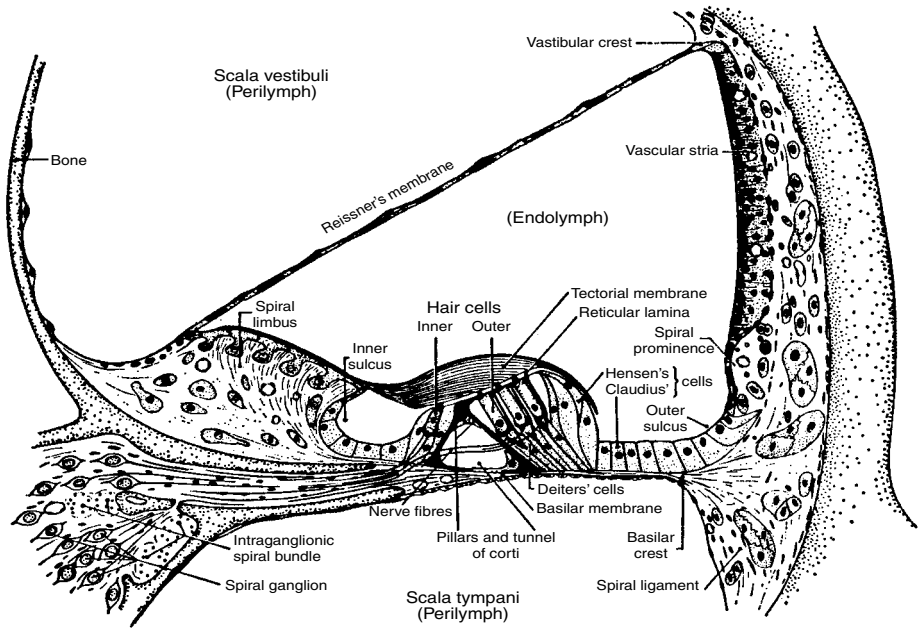

Fig. 45.2. A cross-section of the organ of Corti. (Davis and Associates, 1953.)

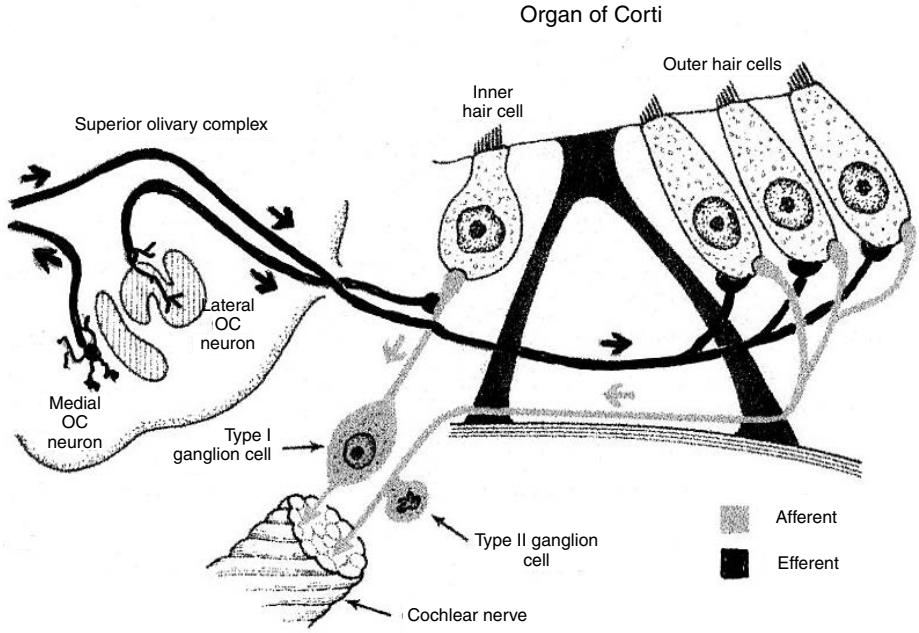

Fig. 45.3. The afferent and efferent innervation of the cochlea. (Schuknecht, 1993.)

inner hair cells (IHC). The OHCs are characterized by the presence of contractile elements, actin–myosin complexes, which are responsible for active mechanical responses in the cochlea.

The vibrations of the stapes footplate in the oval window, induced by sound pressure, cause a passive dynamic displacement of the cochlear partition in the shape of a travelling wave (von Békésy, 1960). As the walls of the endolymphatic duct (scala media) are flexible, the travelling waves are transmitted to the scala tympani, and the wave-like distortion of the endolymphatic duct causes Reissner's membrane and the basilar membrane to swing from one side to the other alternately.

However, the cochlea is not just a passive mechanical signal analyser, but plays an active role in the mechanical processing of sound. The source of active behaviour, as mentioned above, is the OHCs, with their motor capacity for fast oscillating and slow tonic contractions. The fast contractions (Brownell et al., 1985) are phase-locked to the stimulating sound and follow sound-driven passive vibrations of the cochlear partition. They stimulate the actinomyosin network of OHCs, acting to oppose viscous damping in the cochlea and to enhance the oscillations of the cochlear partition. These active oscillations of the OHCs are responsible for the generation of otoacoustic emissions (described below). The slow tonic contractions of OHCs (Zenner, 1986) can alter the stiffness of the cochlear partition in a sharply restricted area, thus modifying the envelope of the travelling wave. These slow contractions result from the activity of the efferent system.

The OHC fast (a.c.) motility, which amplifies sound (by ≈40 dB, near hearing threshold), is linearly correlated to the intensity of sound. However, with an increase in sound pressure level, the cochlea is capable of correcting undesirable (high) shifts of the basilar membrane by the slow OHC (d.c.) movements, leading to reduction of the passive displacement, and non-linear compression of cochlear dynamics (attenuation). Thus, OHCs act as controlled mechano-amplifiers, and feed mechanical oscillations to the IHCs, which are directly involved in the transformation of mechanical energy into neural activity.

Cochlear innervation

The organ of Corti has efferent and afferent innervation (Fig. 45.3). Efferent fibres (see below Efferent system) originate in the superior olivary complex. The lateral olivocochlear (OC) fibres project to afferent fibres of the IHCs, while the medial OC fibres project directly onto the OHCs. About 90–95% (Spoendlin, 1979) of the afferents originate from the IHCs, while approximately 5–10% of them originate from the OHCs. This means that the acoustic information transferred from the cochlea almost exclusively comes from the IHCs.

In contrast, about 95% of all efferent fibres have direct and wide synaptic contact with the OHC bodies, whilst an almost negligible number of the efferent neurons have

indirect postsynaptic contact with IHCs. The afferent fibres form the cochlear nerve, and efferent fibres form the olivocochlear bundle, which travels within the vestibular nerve bundle.

Glutamate is the main neurotransmitter of the afferent fibres. Beside its potent excitatory effect, glutamate also displays a highly neurotoxic effect, observed in various pathological conditions, e.g. acoustic trauma (Puel, 1995).

The efferent olivocochlear innervation to the OHCs provides control of the OHCs via predominantly cholinergic fibres (basal OHCs, for high frequencies) and γ-aminobutyric acid (GABA)-ergic fibres (apical OHCs, for low-frequencies).

The distinctly different innervation pattern of the IHCs and OHCs implies specific physiological roles of the dual sensory system in the cochlea: IHCs as the primary sensory cells that generate action potentials in the auditory nerve, and OHCs as the active mechanoreceptors, which are controlled and modulated by the central nervous system.

Retrocochlear afferent auditory system

The auditory nerve

The auditory nerve, together with the vestibular nerve, passes through the internal acoustic meatus. The high frequency fibres lie on the periphery, while mid–low frequency fibres lie more medially in the nerve. This may explain why the high frequencies are often affected initially by an acoustic neuroma. The auditory nerve enters the brainstem at the cerebellopontine angle, behind the cerebellar peduncle. It branches into three major divisions, to the cochlear nuclei (CN) (Fig. 45.4). These three divisions are located on the posterolateral surface of the pontomedullary junction, so an extra-axial expanding lesion (e.g. from the cerebellopontine angle) may affect the branches or the nuclei causing, respectively, peripheral and central auditory deficits. As the CN receive only ipsilateral input, pathology at this site produces unilateral hearing deficit. The afferents are arranged in the CN according to frequency (tonotopic organization) and various cell types in the CN analyse different aspects of sound. The CN play a fundamental role in the extraction of temporal auditory information (amplitude modulation) from auditory nerve responses and, within these nuclei, lateral inhibition enhances auditory contrast.

The fibres from the CN project ipsi- and contralaterally to the superior olivary complex (SOC), lateral lemniscus (LL) and the nuclei along the LL, and to the reticular formation. Some of the fibres from the CN bypass the SOC and the nuclei of the LL and project directly to the inferior colliculus. Bilateral projections from the CNs to the higher auditory pathways enable the comparison of intensity and travelling time of sound (lateralization).

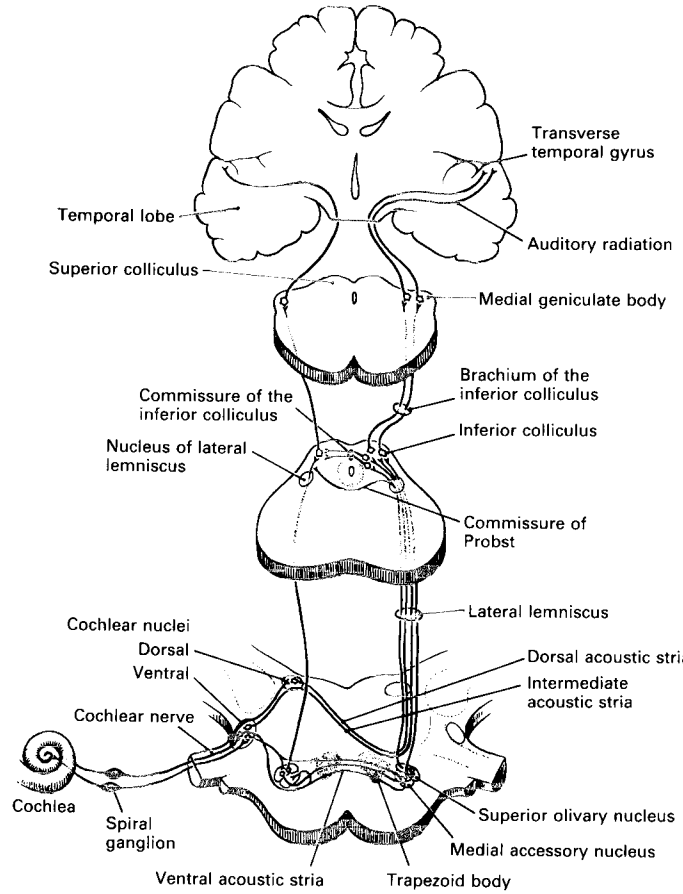

Fig. 45.4. Schematic illustration of the afferent auditory system. (Benjamin & Todd Troust, 1988.)

The superior olivary complex (SOC)

The SOC is composed of several nuclei, including the lateral (LSO) and medial (MSO) nuclei. Both of these structures receive bilateral innervation, and, therefore, provide the anatomical basis for binaural representation and integration of binaurally presented signals (interaural time, phase and intensity difference). A lesion in the SOC may lead to abnormal binaural interaction. However, unilateral disruption of auditory pathways at this level and above, would not lead to a significant hearing loss, due to the crossed, bilateral ascending auditory input.

The lateral lemniscus (LL)

The LL is a major auditory tract containing afferent and efferent fibres. The LL on both sides communicate through

the commissure of Probst, or via the pontine reticular formation.

The inferior colliculus (IC)

The IC receives the auditory fibres predominantly crossing from the opposite side. The IC is highly tonotopically organized and is characterized by extremely sharp tuning curves, suggesting a high degree of frequency resolution. Some of the neurons in the IC are time and spatially sensitive, suggesting a role in temporal and spatial resolution, and ultimately, in sound localization coding.

The medial geniculate body (MGB)

The MGB has ventral, dorsal and medial divisions, of which the ventral contains mainly acoustically responsive cells, while the other divisions are sensitive to both sensory and acoustic stimulation. The MGB is also tonotopically organized and is thought to play a role in the analysis of both binaural stimuli and inter-aural intensity differences. At this level, the processing of natural speech is thought to begin.

From the MGB, there are multiple and complex thalamocortical projections upon the tonotopically organized cortical fields. The major thalamo-cortical pathway, consisting mainly of auditory fibres, originates from the ventral MGB and projects to the primary auditory cortical area in Heschl's gyrus. Another thalamo-cortical pathway, containing in addition to auditory, somatic and, possibly, visual fibres, runs towards the external capsule, and from there to the insula.

The auditory cortical area

The auditory cortical area encompasses the posterior three-quarters of the Sylvian fissure, including the superior temporal lobe, the inferior–posterior frontal lobe and the inferior parietal lobe. Heschl's gyrus is considered the primary auditory cortical area, which receives most of the thalamocortical projections and is tonotopically organized, suggesting that most of the auditory information is processed initially in this area. The secondary auditory cortical areas include the planum temporale, which is significantly longer on the left than on the right side and is located approximately in Wernicke's area, suggesting involvement in receptive language function (left hemisphere is dominant for speech) (Musiek, 1986). Other acoustically responsive areas are the supramarginal gyrus and the insula. The inferior part of the parietal and frontal lobes and the claustrum are also responsive to acoustic stimulation.

The primary auditory area has intra- and interhemispheric connections to different parts of the brain. The auditory cortical areas also have connections to the frontal lobe, including the arcuate fasciculus, which connects Wernicke's and Broca's areas. These connections enable activation of different specialized secondary areas, depending on the complexity of the auditory signals. The secondary, association, areas for hearing are responsible for a variety of complex auditory processing, including the analysis of complex sounds (e.g. noise, music or speech decoding); short-term memory for comparison of tones; inhibition of unwanted motor responses and for intent listening. Lesions of these areas in the dominant hemisphere may lead to a specific loss of function (e.g. sensory aphasia in a lesion of the left hemisphere).

The corpus callosum (CC) contains inter-hemispheric auditory fibres, which connect the cortices of each hemisphere, predominantly homolaterally. The auditory segment of the CC is confined to the posterior half. This is supported by the findings on central auditory tests in patients with section of the posterior part of the CC (Musiek, 1986). The results of animal research indicate the presence of excitatory and inhibitory fibres, suggesting a role of the CC in modulating the activity in both hemispheres, allowing optimal integration of cortical responses. This may be of particular importance for those processes, in which one hemisphere may be dominant, e.g. left hemisphere is dominant for language and sequencing of auditory stimuli, while the right is dominant for spatial auditory perception and the perception of music.

Efferent system

The efferent system runs in parallel to the afferent system, from the cortex to the cochlea, but it is less well defined than the afferent auditory system. It is thought that there is a pathway from the cortex to the MGB and another from the cortex to the various nuclei in the brainstem. The IC receives input from both the cortex and the MGB. From the IC, there are efferent connections to the SOC system and the CN, and to the nuclei of the LL.

The best known part of the efferent system is the olivocochlear (OC) system (Fig. 45.3), arising from the SOC. Fibres from the lateral SO nucleus are arranged in the predominantly uncrossed, lateral olivo-cochlear bundle (LOCB) which projects to afferent fibres of the IHC (see above). The fibres from the medial nucleus are arranged in the mainly crossed, medial olivo-cochlear bundle (MOCB) and project directly onto the OHC. During this course, the MOCB runs in the floor of the fourth ventricle.

The medial efferent olivo-cochlear (MOC) system is considered to be inhibitory (Wiederhold, 1986) and responsible for the control of the OHC motility. It also appears to

be responsible for automatic gain control, adaptation and homeostasis of the cochlea. Anatomical and physiological studies of the IC connections with the SOC system strongly suggest that the IC plays a role in the activity of the OC system.

However, very little is known about the lateral olivocochlear system. It is believed that it modulates sensitivity of the afferent receptors and may have a protective role against excessive noise and/or excitotoxicity (Pujol, 1994; Sahly et al., 1999).

The efferent auditory system with its multisynaptic connections from the cortex to the cochlea suggests the presence of an efficient feedback mechanism, providing a balance between excitatory and inhibitory stimuli. Its assumed role is to facilitate and enhance the targeted acoustic signal and to inhibit unwanted signal, such as noise. It also mediates frequency-selective auditory attention.

Extra-auditory neural connections

The auditory pathways have connections with other parts of the central nervous system.

The reticular formation

A serotoninergic input to the lower brainstem area may provide a basis for modulation of the olivocochlear and middle ear (stapedial and tensor tympani) reflexes (Thompson & Thompson, 1995).

The somatosensory system

The medial division of the MGB (a multisensory thalamic area) probably plays the most important role in the phylogenetically 'old' connection between the auditory and somatosensory systems. Connections with the somatosensory system are also possible via the *extralemniscal system*, which branches off from the classical ascending lemniscal auditory system at the level of the IC and projects to the association cortices (prefrontal area, limbic portions, temporal, parietal and occipital areas) rather than to the primary auditory cortex (Graybiel, 1972). Neurons of the extralemniscal system respond much less specifically to sound stimulation than neurons in the lemniscal system and receive input, not only from the auditory, but also from the somatosensory system. Therefore, somatosensory stimulation, in addition to auditory stimulation, may lead to the perception of sound (e.g. electrical stimulation of the median nerve in some individuals may lead to the perception of tinnitus: Møller et al., 1992).

Another important relay in the polysensory system is the superior colliculus, which includes maps of visual and tactile receptive fields, aligned with the auditory map, and which, in part, therefore, coordinates auditory, visual and somatic information (Huffman & Henson, 1990).

The hypothalamus

The hypothalamus provides input to the auditory pathway via the IC (Adams, 1980).

The limbic system

The limbic system receives projections from the MGB and this link is hypothesized to serve in the attachment of emotional significance to acoustic stimuli (LeDoux et al., 1983).

The cerebellum

The cerebellum is linked to the auditory system probably via the cochlear nuclei (Gacek, 1973), allowing adjustment in the position of the body and the head to the location of sound. The descending acousticomotor system (Huffman & Henson, 1990) involves acousticomotor centres in the cerebellum, the superior colliculus and the medial nucleus of the MGB, which receive projections from the external nucleus (multisensory nucleus) of the inferior colliculus, allowing multisensory integration.

Functional correlates of the pathology in the auditory system

Abnormalities at different levels of the auditory system may have different functional consequences. The most important is hearing loss, which may be associated with other dysfunctions, including loudness recruitment, abnormal auditory adaptation, tinnitus and/or hyperacusis. Other auditory attributes, such as those related to frequency selectivity, temporal resolution (detection of a gap between two stimuli), pitch perception, sound localization, auditory pattern perception, speech perception, or those related to other complex processing of the auditory information are beyond the scope of this brief description.

Hearing loss

Peripheral hearing loss results from abnormalities of the external/ middle ear, cochlea and auditory nerve, up to the entry into the brainstem, beyond which, central hearing impairment occurs. Hearing loss may be divided into two types: conductive and sensorineural. Conductive hearing loss is consequent upon occlusion of the external ear canal, or secondary to pathology of the middle ear and indicates inadequate transmission of sound from the environment to the inner ear. Sensorineural hearing impairment results

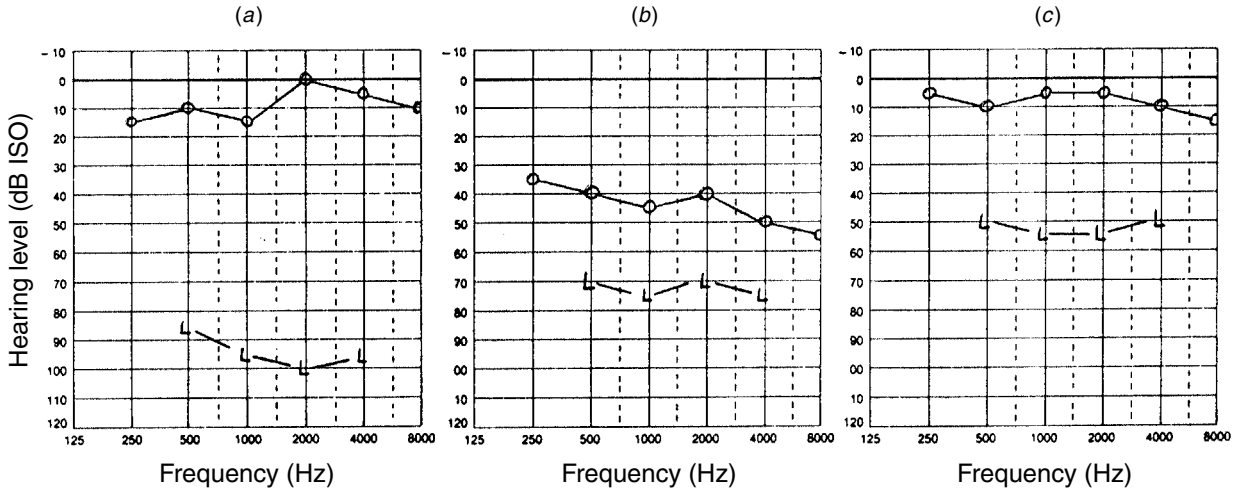

Fig. 45.5. Examples of cochlear dynamic range: in normal subjects (*a*), in cochlear lesion with loudness recruitment (*b*) and narrow dynamic range in hyperacusis (*c*).

most commonly from pathology in the cochlea, less commonly from the auditory nerve, and rarely from a central auditory abnormality.

It is of clinical importance to distinguish conductive from sensorineural hearing loss; sensorineural hearing loss of cochlear origin from that of retrocochlear origin; sensorineural hearing loss resulting from pathology of the VIIIth nerve, from that due to brainstem pathology and higher auditory pathways. The distinction may be extremely difficult if pathology involves both sensory and neural structures.

Loudness recruitment

Loudness recruitment can be defined as an abnormal growth of loudness as a function of suprathreshold sound intensity. This phenomenon is associated with cochlear lesions, in particular OHC damage, although it has been reported in patients with brainstem lesions (Dix & Hood, 1973). One of possible explanations of loudness recruitment is the loss of non-linearity in response to sound as a function of the intensity. In the cochlea, the source of non-linearity are the OHC (as explained in the section on Functional anatomy), which are responsible for the enhancement of sensitivity of signals at low intensity, while responses at high sound levels display saturation. Therefore, patients with extensive OHC lesion, have reduced hearing sensitivity at low sound levels, while with increasing sound intensity, the growth of loudness is passive and linear. An analogous explanation for the presence of loudness recruitment in brainstem lesions could be offered, which may arise due to the damage of neural fibres/nuclei, which are responsible for non-linear intensity coding.

Patients with this type of abnormality complain that loud sounds (e.g. >70 dB) are uncomfortable and even painful. Loudness discomfort levels (LDL) represent the lowest intensity of sound which the individual finds uncomfortably loud, and in normal subjects is in the range 95–115 dB hearing level (Fig. 45.5(a)). In cochlear pathology, the dynamic range is reduced (Fig, 45.5(b)).

Tone decay (or abnormal auditory adaptation)

This phenomenon refers to a very rapid decrease in neuronal responses, while the response to the onset of a sound may be normal or near normal. A reduction of the number of normally functioning auditory nerve fibres has been proposed as one explanation of this phenomenon. It manifests by the loss of sensitivity to a continuous tone (but normal sensitivity to an interrupted tone) in the affected ear, while hearing sensitivity in the unaffected ear persists as long as the stimulation.

Hyperacusis

Hyperacusis can be defined as an abnormal growth in loudness but, unlike loudness recruitment, patients complain of loud perception of ordinary environmental sounds. In the majority of cases it is associated with normal hearing. It is assumed that hyperacusis results from raised spontaneous auditory activity and is considered by some authors to be a condition preceding tinnitus. One of the hypotheses for the

underlying mechanism is disinhibition of efferent feedback auditory control, leading to an increased gain in auditory function. This hypothesis may explain hyperacusis which has been reported in facial/Bell's palsy and in the Ramsay–Hunt syndrome. In these cases, the stapedial reflex, which normally reduces acoustic input, is affected. Hyperacusis is judged clinically by measuring loudness discomfort levels (LDL) which are considerably lower in patients with hyperacusis than in normal subjects (Fig. 45.5(c)).

Tinnitus

Tinnitus is an auditory perception in the absence of external stimulation and it has been assumed that it results from an altered state of excitation and/or inhibition within the auditory system. Aberrant activity, which may be caused by different pathologies and at different levels of the auditory system, may interact with psychological factors, such as stress or depression.

Tinnitus is a subjective phenomenon and so far there has been no convincing objective evidence for tinnitus-related activity. However, the recent emergence of functional imaging techniques has provided new insight into the generation of this symptom. Single-proton emission computed tomography (SPECT), positron-emission tomogaphy (PET) and functional magnetic resonance imaging (fMRI) have demonstrated that more auditory cortical areas are activated in patients with tinnitus than in controls subjects, including the medial temporal lobe and the limbic areas (Shulman et al., 1995; Lockwood et al., 1998, 1999; Levine, 1999). The extent of the neuronal network involved is thought to influence the quality and attributes of tinnitus (e.g. a link to the limbic system may explain the emotional response to tinnitus).

Undoubtedly, functional imaging techniques have pushed forward the frontiers in research on tinnitus, supporting some of the hypotheses and providing new information on spatial aspects of tinnitus-related processing. However, temporal aspects of neural activity which may underlie tinnitus generation remain poorly understood.

Several pathophysiological mechanisms for the generation of tinnitus may be considered:

Abnormal afferent excitation at the cochlear level

- Spontaneous cochlear (OHC) activity, identified by the recording of spontaneous otoacoustic emissions, could be a cause of tinnitus in a small number ($\approx$4%) of patients (for review see Ceranic et al., 1995).
- Glutamate neuro-excito-otoxicity, e.g. in exposure to excessive noise (Pujol, 1994).
- Modulation (enhanced sensitivity) of NMDA and non-NMDA receptors by endogenous opioid peptides dynorphins, released onto the IHC synaptic region by the lateral olivocochlear fibres, as a part of the response to stress (Sahly et al., 1999).

Efferent dysfunction/reduction of GABA effect

Several studies have suggested dysfunction (a reduction in the suppressive effect) of the medial olivocochlear system, and furthermore, a global efferent dysfunction (Attias & Bresloff, 1998), as the underlying mechanisms to tinnitus.

It has also been suggested that general age-related reduction of GABA may contribute to the development of tinnitus in the elderly.

Abnormal auditory activation

- Irritative lesions (e.g. tumours, Espir et al., 1997; Milicic & Alçada, 1999)
- Activation of the auditory system through the activation of other motor/sensory systems, e.g. visual, such as that occurring in a gaze-evoked tinnitus, or tinnitus provoked by jaw clenching (Lockwood et al., 1999); tinnitus evoked by electrical stimulation of the median nerve (Møller et al., 1992). There are also patients who have developed gaze-evoked tinnitus after surgical removal of an acoustic neuroma (Cacace et al., 1994).

Alteration of spontaneous activity due to tonotopic reorganization

Peripheral lesions/dysfunctions, with sound deprivation or overstimulation, result in plastic transformations within the brain (Møller, 2000). The findings from electrophysiological studies and functional imaging (PET, fMRI) of expansion of the brain regions responsive to tones, provide strong evidence for plastic transformation of the brain in these patients. Similar observations have been made in experimental animals after damage to the cochlea (Recanzone et al., 1993). The area in the auditory cortex deprived of its characteristic frequency acquires a new characteristic frequency, which corresponds to that at the edge of the region of cochlear damage, leading to an expansion of cortical representation of a restricted frequency band adjacent to the region of cochlear loss (Robertson & Irvine, 1989). These data suggest that tinnitus may be due to altered spontaneous activity in the CNS due to aberrant neural pathways formed during plastic transformation of the brain.

Stress-related neuro-humoral activity

Circumstantial evidence exists that stress is of relevance in the generation of tinnitus, particularly in individuals with negative psychological conditions, or individuals with psychiatric disturbances. Stress may activate various

biological functions, including the sympathetic adrenal medullary system, with secretion of catecholamines, and the hypothalamic pituitary–adrenocortical system, with the secretion of glucocorticoids (e.g. Cortisol). Failure in homeostasis may lead to abnormal functioning of the auditory system, including the emergence of tinnitus.

Investigation

In addition to the assessment of auditory function, it is important to test vestibular function, in view of the common pathology which may occur at the labyrinthine (Fig. 45.1) and vestibulocochlear nerve levels. There is also the possibility of an abnormality in the acoustico-motor centres in the cerebellum, which reflects in concurrent central auditory and vestibular manifestations (Shulman & Strashun, 1999).

A detailed otoscopic examination is essential in the investigation of hearing disorder and the most relevant tests which serve to define auditory dysfunction are described.

Tuning fork tests

These are simple tests to differentiate conductive from sensorineural hearing loss: the Rinne test identifies a conductive component to hearing loss and the Weber test may detect asymmetrical sensorineural hearing loss, or lateralize a conductive loss.

Pure-tone audiometry

This is a routine clinical technique to determine hearing threshold levels for pure-tone stimuli. In conductive hearing loss the audiogram indicates an air–bone gap, as bone conduction is normal, while cochlear/retrocochlear lesions produce sensorineural hearing impairment, with similar deficits in both air and bone conduction (Fig. 45.6).

Tympanometry

Tympanometry assesses the mechanical properties of the middle ear: the ear drum compliance and the pressure in the middle ear. This test complements the identification of middle ear disorders.

Stapedial reflex

Unilateral acoustic stimulation leads to contraction of the stapedial muscle bilaterally (Fig. 45.7), thus increasing the resistance to the sound transmission through the middle ear, by up to 15 dB.

Acoustic reflex thresholds are measured in response to ipsi- and contralateral tones. They are elevated/absent in conductive and retrocochlear hearing loss. Depending on the site of a lesion and the part of the reflex arc involved, different, characteristic patterns of ipsi- and contra-lateral reflexes can be observed (Fig. 45.8).

Decay of the stapedial reflex reflects abnormal transmission of acoustic signal through the auditory nerve, by the inability to sustain the reflex over a certain period of time. Decay is, therefore, indicative of a neural (e.g. in acoustic neuroma), or a brainstem lesion.

Speech audiometry

The speech discrimination score is affected by the site of a lesion. In the case of cochlear hearing loss, the discrimination score parallels to the hearing loss and can be restored by increasing the intensity of sound. However, in the case of neural hearing loss, there is disproportionally worse speech discrimination than would be expected considering the pure-tone audiometric thresholds.

Otoacoustic emissions

Otoacoustic emissions (OAEs) are weak signals that can be recorded in the sealed ear canal and are considered to reflect cochlear, OHC activity (Kemp, 1978).

All OAEs can be divided in two classes: spontaneous and evoked. Spontaneous otoacoustic emissions are continuous narrow-band signals emitted by the cochlea in the absence of any stimulation. Evoked otoacoustic emissions are recorded following stimulation by different stimuli: transient evoked otoacoustic emissions (TEOAEs), evoked by transient impulses, or distortion product otoacoustic emissions (DPOAEs), evoked by two continuous tones at closely spaced frequencies. TEOAEs can be recorded in almost all normal subjects (Fig. 45.9). DPOAEs have similar characteristics as TEOAEs, however, they provide more frequency specific responses.

OAEs are applied in the evaluation of cochlear function and are particularly valuable in difficult-to-test subjects (e.g. children, or mentally retarded patients). They can also be used in the differential diagnosis of cochlear and retrocochlear lesions: if TEOAEs are recorded in subjects with a moderate or severe sensorineural hearing loss, this would strongly suggest a retrocochlear lesion.

It is important to note that OAE application is limited to those subjects with normal middle ear function, as a middle ear abnormality may alter the transfer of acoustic signals to the cochlea.

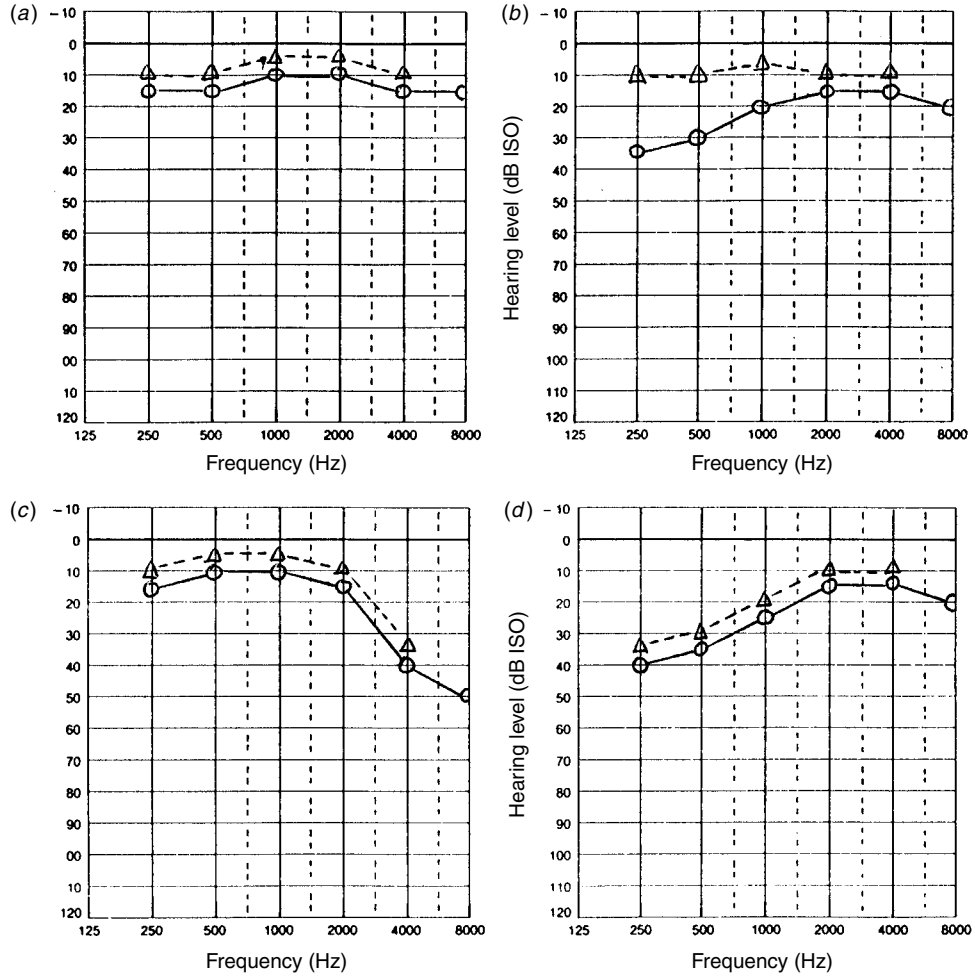

Fig. 45.6. Standard pure-tone audiogram, where the continuous line indicates air-conduction and the interrupted line indicates bone-conduction hearing threshold levels: (*a*) normal, (*b*) conductive, (*c*) sensorineural high-frequency sloping and (d) sensorineural low-frequency hearing loss.

Olivocochlear suppression test

This is an emerging technique for exploring the medial olivo-cochlear system, or so-called phenomenon of 'reciprocal cochlear interaction', in which acoustic stimulation of one ear suppresses TEOAEs in the opposite ear. The MOC suppression test provides general information on the structural integrity of the medial olivo-cochlear reflex arc, and a glimpse into the modulation of cochlear mechanics by efferent stimulation.

Electrophysiological testing

Electrocochleography (ECochG)

Three groups of ECochG potentials can be recorded: the cochlear microphonic, the summating potential, both thought to derive from mainly OHC activity, and the compound action potential, the synchronized activity of the auditory fibres, in response to stimulus onset.

ECochG is mainly used for the evaluation of cochlear function, e.g. in Menière's disease (the pathophysiological rationale is that deflection of the cochlear basilar membrane, consequent upon hydrops, creates an enlarged negative summation potential).

The auditory brainstem response (ABR)

The ABR is thought to be generated within the auditory pathway up to the inferior colliculus (Fig. 45.10). The ABR is particularly useful for the detection of acoustic neurinoma (typically prolonged wave V latency on the affected side) and is very sensitive in intra-axial brainstem lesions. The ABR is also used for objective threshold estimation,

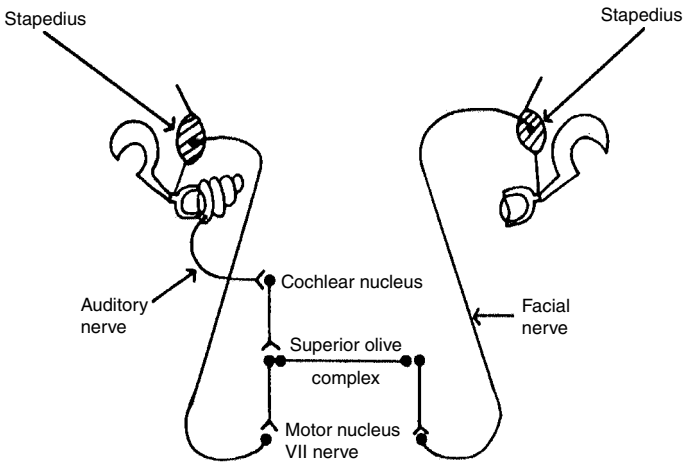

Fig. 45.7. Schematic illustration of main components of the ipsilateral and contralateral acoustic reflex. (Luxon & Cohen, 1997.)

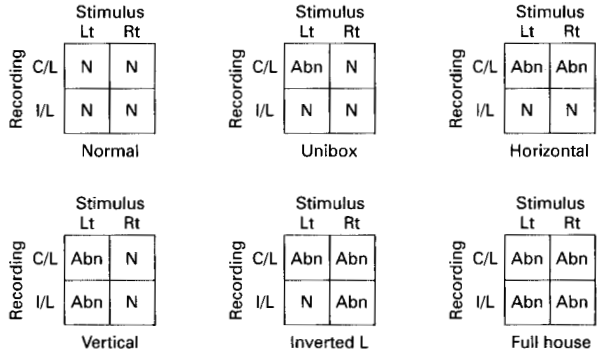

Fig. 45.8. Patterns of acoustic reflex thresholds and common interpretations (Lt-left, Rt-right, C/L-contralateral, I/L-ipsilateral): Unibox = small unilateral brain lesion medial to the cochlear nucleus; Horizontal = midline brainstem lesion; Vertical = left VIIIth nerve lesion; Inverted L = intra-axial brainstem lesion plus extension to the cochlear nucleus or VIIIth nerve on the affected side (a conductive lesion may present in this way); Full house = a midline brainstem lesion with extension to involve the cochlear nuclei and/or VIIIth nerves (N.B. bilateral conductive lesion needs exclusion); Abn = abnormal; N = normal. (Luxon & Cohen, 1997.)

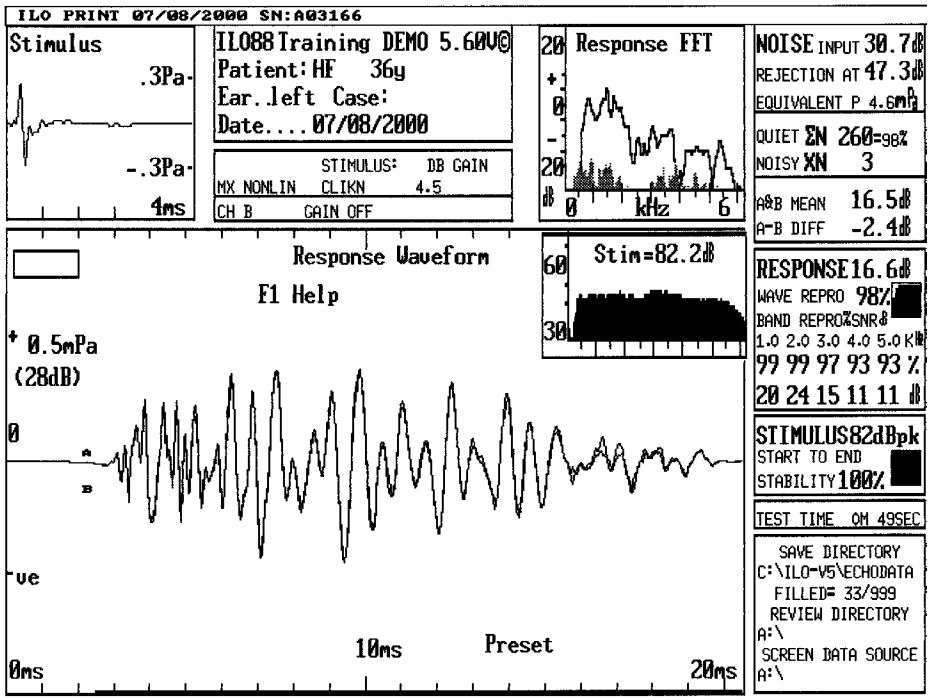

Fig. 45.9. Transient evoked otoacoustic emissions recorded following non-linear click stimulation (82.2 dBSPL) from a normal subject; in the response window (the largest box, denoted as Response Waveform), the waveforms (A and B), resulting from the signals averaged in two separate buffers, show a very high (98%) correlation (A and B almost completely overlap), suggesting a very good cochlear response; response signals are also analysed in frequency domain (Fast Fourier Transforms – FFT), shown above right; the overall response amplitude is automatically displayed, in this case 16.6 dBSPL, shown in the middle right box.

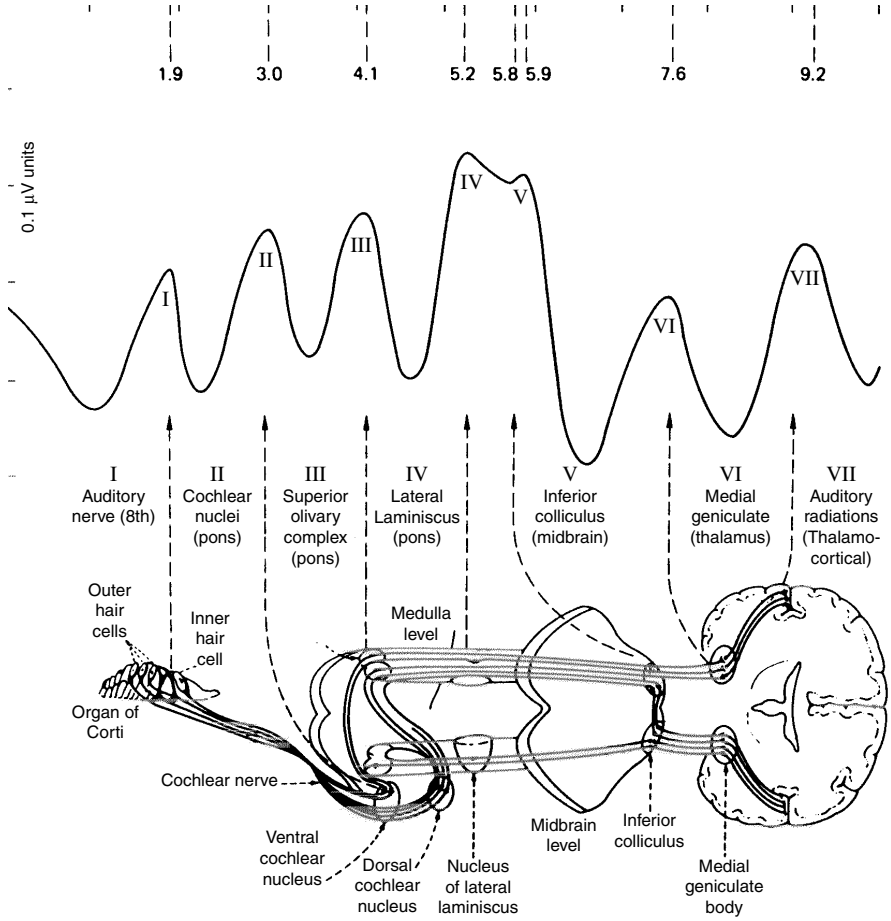

Fig. 45.10. Diagram of the anatomical correlates of the waves observed in the brainstem responses. (Duane, 1977.)

and the resistance to drug effects and general anesthesia make this technique suitable for objective evaluation of hearing thresholds in children.

Middle latency response (MLR)

The temporal lobe or thalamocortical projections are important for generation of the MLR, although it is most likely that multiple generators exist. Evaluation of the MLR is used for assessing the integrity of the central nervous system beyond the brainstem and for threshold estimation of low-frequency hearing sensitivity, as it is less dependent on neural synchrony than ABR. However, it is sensitive to the state of consciousness.

Auditory cortical responses (ACRs)

The ACRs originate mainly from the auditory cortical areas in the temporal lobe. They are generally elicited with a tone burst and, therefore, provide frequency specific responses, which are well correlated with subjective pure-tone thresholds. The ACRs are mainly used for objective threshold estimation, particularly in medico-legal cases, and are only applicable in alert subjects.

Event-related potentials (ERPs)

Unlike other auditory evoked responses, the ERPs are considered to be endogenous potentials, resulting from cognitive processing of sensory information. The temporal lobe and limbic structures, including hippocampus and amygdala, have been implicated as the major sources for the ERP.

The Mismatch negativity (MMN) is a component of the ERPs, generated by a change-discrimination process that mainly occurs in the auditory cortex. The MMN is attention-independent and can be obtained even from uncooperative individuals. In auditory pathology, the MMN might be useful in objective evaluation of cochlear implant function and for objective diagnosis of aphasic patients, dysphasic children and of children with auditory-based learning disabilities (Näätänen, 1995).

Central behavioural testing

Central behavioural tests (CBT) are applied in conjunction with electrophysiological tests and imaging techniques to define and localize an abnormality within the central auditory pathways. One of the limitations of these tests is that the assessment of central structures may be affected by peripheral abnormalities. In addition, due to the parallel organization within the central nervous system and involvement of several structures in a particular function, results may not provide information on the localization of a lesion. Another important consideration in CBT is the availability of adequate normative data.

CBT can be classified according to a common parameter, such as mode of presentation (e.g. monaural or binaural), or type of stimuli used (e.g. tones or speech), as outlined in Table 45.1 (Luxon & Cohen, 1997).

In the construction of the test battery, specific auditory tasks are used to assess specific auditory functions of a particular anatomical structure. For example, in the brainstem, binaural acoustic integration, the extraction of signals from background noise and sound localization occur, and, therefore, assessment of these functions is targeted. Cortical and hemispheric pathology produces subtle auditory dysfunctions which may not be correlated to a specific anatomical location. The classic findings of CBT are functional deficits in the ear contralateral to cortical and hemispheric pathology on dichotic testing.

Table 45.1. Behavioural tests of central auditory processing

A. Monoaural tests
- Degraded speech (filtered speech, interrupted speech, or compressed speech)
- Masked speech (speech-in-noise)
- Synthetic sentence identification with ipsilateral competing message (SSI–ICM)

B. Binaural interaction tests
- Congruent
  - Dichotic digit
  - Dichotic word
  - Dichotic sentence identification
  - Nonsense syllables
- Non-congruent
  - Binaural fusion
  - Rapid alternating speech
  - Interaural intensity difference
  - Masking level difference (MLD)
  - Interaural timing

C. Binaural separation
- Competing sentences
- Threshold of interference

D. Sequencing tasks
- Pitch pattern
- Duration pattern
- Intensity pattern
- Psychoacoustic pattern discrimination

Functional imaging techniques

Functional magnetic resonance imaging (fMRI) of auditory cortical activity

It has been observed that passive and active speech listening generate greater activation of the left than the right hemispheres and this is thought to be related to the left hemisphere specialization for processing spectral changes (Hall et al., 2000) (Fig. 45.11, see colour plate section).

Positron emission tomography (PET)

Studies on functional organization within the auditory cortex support the view of the existence of a hierarchy in functioning of the cortical areas. For example, simple auditory stimuli activate predominantly the contralateral primary cortical area 41, stimuli with interrupted pattern activate bilateral area 42, and stimuli with complex spectral, intensity and temporal structure, such as speech or music, activate more extensive association auditory areas (Mirz et al., 1999).

Etio-pathogenesis of hearing disorders

External/middle ear

The pathology at this level may sometimes affect the more proximal auditory pathway. A severe form of otitis externa (*Pseudomonas aeruginosa*), may spread through the adjacent structures and affect the auditory nerve. The middle ear disease can expand towards the apex of petrous bone (petrositis), affecting the abducens nerve and trigeminal ganglion, with the presentation of Gradenigo's syndrome: otitis media, VIth nerve palsy and trigeminal neuralgia. Involvement of the auditory nerve may lead to hearing loss on that side.

Inner ear (cochlea)

Cochlear lesions can be acquired due to various noxious factors, such as ischemia, hypoxia, trauma, excessive

Table 45.2. Causes of auditory disorders

Congenital and hereditary lesions associated with hearing loss
May be a part of many syndromes (Table 45.3)
– *Failure in normal development*
  Michel defect – complete inner ear aplasia
  Mondini defect – incomplete development of the labyrinth
  Scheibe defect – membranous cochleosaccular dyplasia
– *Secondary degeneration* – isolated auditory defect or in association with other abnormalities (e.g. Arnold–Chiari); Syndromes of inherited spinal degenerations, ataxia and neuropathies (e.g. Friedreich's ataxia)

Trauma and toxicity
– mechanical (transverse fracture of the temporal bone, concussion of the inner ear with secondary degeneration)
– barotrauma
– surgical intervention
– radiotherapy
– ototoxicity (salicylates, aminoglycosides, thalidomide, vincristine)
– acoustic trauma

Infection:
– microbial (syphilis, Lyme disease, meningitis, postchronic suppurative otitis media)
– viral (AIDS, Ramsay–Hunt syndrome)
– mycotic

Ischemia:
– vertebrobasilar ischemia
– arterial occlusion (subclavian steal syndrome)
– aneurysm (anterior inferior cerebellar artery)
– stroke
– vasculitis
– polycythemia (emboli)
– coagulopathies (hereditary coagulation disorders, sickle cells)
Risk factors: cardiovascular disease, hypertension, cardiopulmonary bypass surgery

Neoplasia:
– vestibular schwannoma (syn. acoustic neuroma)
– primary and secondary lesions

Metabolic and endocrine disorders:
– diabetes mellitus
– uremic polyneuropathy
– thyroid dysfunctions

Autoimmune disorders/vasculitis
rheumatoid arthritis, Cogan syndrome, systemic lupus erythematosus, Takayasu disease, Behçet syndrome, polyarteritis nodosa

Table 45.3. Genetic syndromes associated with hearing loss

I. Chromosomal: Down syndrome (trisomy 21), Turner syndrome (X Ch)

II. Autosomal:

Autosomal dominant	*Autosomal recessive*
– Waardenburg	– Usher progressive hearing loss
Type 1 (Ch 2q)	Type 1 (Ch 14q)
Type 2 (Ch 3q)	Type 2 (Ch 1q)
– Neurofibromatosis	Type 3 (Ch 3q)
Type 1 (Ch 17q)	– Pendred (Ch 7q)
Type 2 (Ch 22q)	– Albinism
– BOR syndrome (Ch 8q)	
– Klippel–Feil	
– Wildervanks	
– Treacher-Collins (Ch 5q)	
– Jervell Lange Neilsen syndrome (Ch 7q 11p)	
– Stickler syndrome (Ch 12q)	
– Crouzon syndrome (Ch 10q25–26)	
– Otosclerosis (multifactorial)	

III. X-linked:	*IV. Mitochondrial*
– Alport syndrome (Xq21–22)	– Kearns–Sayre
– Norrie syndrome (Xp11–3)	– Myoclonic epilepsy
– Perilymph gusher syndrome (Xq13)	– Maternally inherited diabetes
– Encephalopathy-hearing loss (Xq22)	– Maternally inherited susceptibility to aminoglycosides
– Large vestibular aqueduct syndrome	– MELAS
– X-linked non-syndromic deafness	

noise, ototoxic drugs (salicylates, aminoglycosides, thalidomide *cis*-platinum, or vincristine), due to age-related degeneration (presbyacusis), autoimmune disorders, or may result from a number congenital/ hereditary abnormalities (Tables 45.2, 45.3 and 45.4).

The molecular and biological mechanisms of ototoxic effects and other forms of cochlear damage, have been the subject of extensive scientific investigation over recent years. Formation of reactive oxygen metabolites (ROM), including free oxygen radicals and other metabolites, are thought to be central to damage of cochlear tissue, as these highly reactive compounds can oxidize a wide variety of targets, such as proteins, mitochondrial DNA (mtDNA), or lipids. Better understanding of these mechanisms has led to a series of experimental studies with coadministration of antioxidants, or ROM scavengers. For example, use of iron chelators was found to reduce gentamicin ototoxicity (Schacht, 1998), and calorie restriction, vitamin C and E

Table 45.4. Causes of hearing loss arising from dysfunctional neurological tissue

Inner ear:	Degeneration of the spiral ganglion cells (inherited – in Roussy–Levy syndrome)
	Neurinoma of the spiral ganglion
Auditory nerve:	Hereditary neuropathies Friedreich's ataxia, Charcot–Marie–Tooth and other hereditary motor-sensory neuropathies, Leber's optic neuropathy
	Auditory neuropathies associated with DIDMOAD, MELAS and other mitochondrial disorders
	Idiopathic auditory neuropathy
	Tumours: Acoustic neurinoma (incl. NF1 and NF2)
	Cerebello-pontine angle lesions
	Metastatic tumours
	Paraneoplastic syndromes
	Infections: Ramsay–Hunt syndrome
	Basal meningitis (bacterial, TB)
	Vascular: Loop, aneurysm
	Malformations: Arnold–Chiari
	Multiple sclerosis (n. root entry zone)
	Trauma (including radiation therapy)
Central nervous system:	
	Tumours: primary and metastatic
	Vascular: Infarct, hemorrhage
	Infections: Encephalitis
	Neurosyphilis
	Lyme disease
	Multiple sclerosis
	Syringo-bulbia
	Neuro-sarcoid
	Neuro-Behçet
	Trauma

supplementation, and melatonin treatment, attenuated age-related hearing loss (Seidman, 2000). These findings herald an exciting future, with potential identification of pharmacological and nutritional strategies for prevention of ototoxicity and different forms of cochlear degeneration.

Cochlear damage is reflected in degeneration and abnormal function of the proximal auditory structures. Loss of hair cells leads to degeneration of the auditory fibres, while efferent fibres remain intact. Neuronal and transneuronal degeneration of auditory axons in the brainstem of an adult mammal, resulting from cochlear damage, has been observed (Morest et al., 1997). Recordings of the spontaneous activity of the auditory nerve have shown a reduction in rate (Liberman & Kiang, 1978) and single fibre recordings have indicated that auditory sensitivity is lost and frequency resolution reduced (Pickles, 1988). However, cochlear lesions lead to an increased excitability of the cochlear nucleus, inferior colliculus (Salvi & Ahroon, 1983) and medial geniculate body (Gerken, 1979). Studies of the auditory cortical neurons have indicated changes in frequency selectivity and a sequence of changes in the relative levels of excitatory and inhibitory inputs to the primary cortical neurons. This leads to an expansion of the receptive field of the cortical neurons (Rajan et al., 1992), which in turn raises the threshold sensitivity and broadens frequency selectivity.

Menière's disease, a condition with both cochlear and vestibular manifestations, deserves special mention. It is considered that endolymphatic hydrops is the underlying pathophysiological abnormality, although it has been suspected that some other mechanisms may be involved, with endolymphatic hydrops being an epiphenomenon. In the absence of known etiology, the diagnosis of Menière's disease is based on the characteristic clinical history, with the classical triad of episodic symptoms of tinnitus, diminished hearing and vertigo, a documented sensorineural shift on pure-tone audiometry and/or reduced speech discrimination score test, as defined by the Committee on Hearing and Equilibrium, American Academy of Ophthalmology and Otolaryngology (1995). Fluctuating sensorineural hearing loss in Menière's disease, typically affects predominantly low frequencies, as in Fig. 45.6(*d*).

Auditory nerve

Different lesions of the auditory nerve, such as trauma, infection (microbial, viral and mycotic), neoplasia (acoustic neuroma, primary and metastatic tumours in the internal acoustic meatus), autoimmune, or congenital/hereditary disorders (Tables 45.2, 45.3 and 45.4), lead to unilateral neural loss. An example of mononeuritis of the eight nerve is the Ramsay–Hunt syndrome (Herpes zoster oticus), with a deep burning pain in the affected ear, followed by a vesicular eruption in the external auditory canal and concha, and subsequent hearing loss and vertigo. The auditory nerve can also be damaged due to pathological processes in the temporal bone, such as otosclerosis, Paget disease, fibrous displasia, or osteopetroses. With regard to congenital abnormalities, in addition to primary abnormalities (i.e. failure in normal development), secondary lesions may occur. Secondary degeneration of the auditory nerve has been reported in association with other defects in many syndromes (e.g. neurofibromatosis, Treacher-Collins, Wildervank, Usher, Kearns-Sayre, Waardenburg, Pendred, Alport) (Yeoh, 1997). In Arnold–Chiari malformation, it is thought that invagination of the brainstem leads to the stretching of the auditory nerve and to auditory symptoms, which could be caused by cochlear anoxia,

while associated increased intracranial pressure may be responsible for pulsatile tinnitus. Degeneration of the auditory nerve is also associated with various inherited spinal degenerations, ataxia and neuropathies (Friedreich's ataxia, hereditary sensory neuropathy) and as an isolated phenomenon (Booth, 1997).

Acoustic neuroma (AN) has been reported to represent 10% of intracranial tumours and over 95% of cerebellopontine lesions (Gonzalez-Revilla, 1948). In addition to the effect on the auditory nerve, AN may cause cochlear degeneration due to chronic partial obstruction of the blood supply by the tumour, biochemical alterations in the inner ear fluids, loss of efferent control of active mechanical tuning and degeneration due to neuronal loss (Prasher et al., 1995). Analysis of 500 patients who underwent AN resection, revealed that unilateral auditory symptoms occur in 83% of patients and that tinnitus was the initial symptom in 11% of patients (Ramsden, 1987), while in a study on 1000 patients, it was found that acoustic disturbances occur in 95% of patients (Matthies & Samii, 1997). The prevalence of tinnitus is higher in patients with a partial hearing loss than in deaf patients, however, postoperative deafness does not mean relief from tinnitus: this symptom may exist in 46% of postoperatively deaf patients (Matthies & Samii, 1997), suggesting that, although the onset of tinnitus may be due to the peripheral effect, its maintenance is mediated through the more proximal, central mechanisms.

Multiple sclerosis may occasionally affect the central auditory system, and even less commonly the auditory nerve. Auditory symptoms have been reported in less than 4% of patients, they are usually unilateral and, in most cases, are of transient character (Booth, 1997).

Auditory neuropathy is a recently recognized clinical entity (Starr et al., 1996) without apparent pathology, with normal cochlear function (normal otoacoustic emissions and cochlear microphonics), but abnormal auditory brainstem evoked responses and poor speech discrimination. Patients present typically with a mild or moderate hearing loss and are characterized by poor response to traditional hearing aids. One of the hypothetical explanations of this disorder is an altered temporal synchrony in firing of the auditory nerve, which could be an early sign of demyelination (Starr et al., 1996), but there is also a possibility of selective damage to the inner hair cells, which may reduce neural input (Salvi et al., 1999).

Central auditory pathways

With the increase in complexity of auditory pathways from the cochlea to the cortex, together with multiple representations of each ear, on each side of the brain, auditory function becomes more complex and multifaceted. Central lesions (Table 45.4) may cause varying degrees of hearing impairment and other auditory dysfunctions, such as disproportionately impaired speech discrimination (relative to hearing sensitivity), tinnitus, hyperacusis, hallucinations, and various abnormalities in sound processing, including derangements of binaural acoustic integration, sound localization, signal sequencing, or auditory pattern recognition.

Lesions of the brainstem can be caused by a variety of lesions, including neoplastic and vascular abnormalities, such as vertebrobasilar disease, mini strokes, vascular spasms, or vascular loops. Intra- and extra-axial lesions of the brainstem may affect auditory function in different ways (Musiek & Baran, 1986). An intra-axial lesion of the brainstem, especially in the pons, is likely to cause a bilateral auditory disorder, as it may disrupt the majority of crossing fibres from the cochlear nuclei and the superior olivary complex. Intra-axial lesions, for example, secondary to central pontine haemorrhage, have given rise to bilateral low-frequency hearing loss, reflecting the tonotopic organisation of the auditory pathways, with the lowest frequencies being encoded centrally (Cohen et al., 1996). An extra-axial lesion of the mid to low lateral pons may directly affect the cochlear nuclei, the only superficially located auditory structure, leading to ipsilateral deficits. An extra-axial or intra-axial lesion at the level of the inferior colliculus (midbrain) and MGB (thalamus) is more likely to cause a contralateral deficit on behavioural central tests. In general, lesions of the brainstem appear to affect dichotic integration tasks rather than dichotic separation tasks. Large space-occupying lesions in the brainstem or cerebellum may cause multiple deficits, with additional secondary effects due to compression, displacement, vascular disruption, or hydrocephalus.

Subcortical and cortical auditory pathways

The pathology of the auditory cortex (grey matter) and hemispheres (grey and white matter) results mainly from ischemic, neoplastic or demyelinating lesions. Hearing deficit at this level is very rare and is most likely to be caused by vascular disease of both temporal lobes.

Management

Hearing loss

It is important to ensure all preventive measures are undertaken to avoid permanent hearing loss, e.g. regulations regarding occupational noise exposure and serum monitoring of known ototoxic drugs, e.g. gentamicin. In the majority of cases, hearing loss is permanent, but in some

patients hearing loss can be treated surgically or pharmacologically. In those with irreversible hearing loss, the management is directed towards reduction of the effect of any auditory disability or handicap, by the application of different types of amplification devices and implants.

Surgical treatment

In a small proportion of cases, limited to those with middle ear disorders, surgical intervention may improve or restore hearing, for example, following myringotomy, with or without grommet insertion, in otitis media with effusion, stapedectomy for otosclerosis, or in osteogenesis imperfecta. Surgical procedures for acoustic neuroma, may preserve hearing, but usually lead to an increased, if not total, hearing loss. Surgical treatment is also used in Menière's disease, primarily for management of vestibular symptoms, although the evidence for conservative procedures, such as endolymphatic sac decompression, remain controversial. Destructive procedures, e.g. labyrinthectomy and vestibular nerve section, should be undertaken with great care in the light of the significant prevalence of bilateral Menière's disease.

Pharmacological treatment

This form of treatment is more orientated towards preservation, rather than towards an improvement of hearing, and is determined by the etiology of hearing loss. In hearing loss, such as Menière's disease, treatment is directed towards the assumed underlying pathophysiological mechanism (endolymphatic hydrops), and consists of diuretic treatment and/or dietary restriction of sodium intake, which has been reported to improve symptoms in 60–70% of patient (Gates, 1999). Autoimmune hearing disorders are treated with steroids (glucocorticoids), and their application in some cases of idiopathic hearing loss has also been recommended, although with questionable effect, as spontaneous remission may occur (McKee, 1997).

Rehabilitation

This is the management option for most patients with hearing loss (Stephens, 1997).

I. Instrumentational rehabilitation consists of the application of personal and environmental devices.

Personal instrumentation is the most important component of rehabilitation and includes:

1. Hearing aid systems (hearing aid and ear mould). There is a wide range of devices, from low- to high-powered, from simple linear to sophisticated programmable digital hearing aids, whose application depends on many factors, including configuration and severity of hearing loss.
2. Bone anchored hearing aids, are applied in patients with significant conductive hearing loss and consist of a surgically implanted (mastoid) titanium base to which is attached an electronic amplification system, allowing bone-transmission of sound.
3. Vibrotactile hearing aids are applied in individuals with profound hearing impairment in whom is not possible to deliver acoustic signal above the threshold. Vibrotactile information is delivered via a vibration transducer, often worn on the forearm.
4. Cochlear implants bypass the transduction mechanisms of the cochlea by electrically stimulating the auditory nerve directly, and they are used in profoundly hearing-impaired individuals.
5. Brainstem implants are applied in patients who have no remaining auditory nerve, e.g. subsequent to surgical removal of vestibular neuroma. The cochlear nucleus, as the termination site for all auditory fibres, and therefore, most peripheral of the central structures, is the target of stimulation.

II. Non-instrumental rehabilitation includes the application of environmental aids, those using sound to enhance loudness and clarity (e.g. additional speaker/receiver, or induction coil systems), or those using visual information (e.g. text telephones, subtitle TV/videos, or video telephones) and alerting and warning systems (e.g. flashing doorbell or the telephone bell, also include use of trained dogs).

Tinnitus

There are several lines in the management of this complex symptom.

Treatment of underlying disorders

Medical evaluation may indicate conditions which could be of relevance for the emergence of tinnitus (cardiovascular, renal, metabolic and autoimmune disease, or the effects of medications and drugs). Auditory assessment may identify the presence and site of a lesion, which could be treatable.

Pharmacological treatment

There have been attempts, with varying success, to base pharmacological treatment on hypothetical underlying mechanisms, as highlighted above in the section on tinnitus. Ca^{2+}-antagonists (nimodipine), $GABA_A$ and $GABA_B$ agonists (benzodiazepines and baclofen, respectively), and drugs for depression of neuronal response to excitatory stimuli and hyperpolarization of neuronal membranes (phenytoin, carbamazepine) have all been tried.

In patients with significant associated anxiety, or depression, treatment with tranquillizers and antidepressants (e.g. tricyclic nortriptyline) may be of value. More recently, selective serotonin reuptake inhibitors, as modulators of tonic inhibition of auditory pathways, were found to be effective in some patients with tinnitus, particularly in those with associated depression.

The quality of evidence for the efficacy of pharmacological treatment of tinnitus is poor. This is largely due to the difficulty in undertaking adequate studies, as tinnitus is a symptom of different pathologies and different underlying mechanisms may be involved. Therefore, it is of importance to identify any audiological, or relevant abnormality in order to provide 'tailored' treatment for each individual.

Tinnitus retraining therapy (TRT)

TRT includes counselling and sound therapy (see below Instrumentation), based on neurophysiological model of tinnitus (Jastreboff & Hazell, 1993). Directive counselling is aimed at providing the patient with clear information about the possible mechanism(s) of tinnitus and how it can be influenced adversely or beneficially; person-centred counselling deals with the stress and needs and ways of dealing with problems; cognitive counselling is aimed at identifying and dispelling patients' false beliefs, attitudes, or fears.

Instrumentation

Hearing aids are the first line in management for patients with associated hearing loss, as they reduce awareness of tinnitus by amplification of external sounds. Tinnitus maskers and low-level noise generators may mask or at least reduce the effect of tinnitus. Other devices, as a part of a masking strategy, include pillow speakers or a tape recorder, which may alleviate tinnitus at night, while walkmans can be used during the day.

Surgical treatment

In addition to evidence-based surgical treatment of specific underlying lesions, other surgical procedures, for the treatment of tinnitus *per se*, such as auditory nerve section, or cochlear destruction, have provided little evidence of effectiveness and may even make tinnitus worse.

Vertigo and vestibular disorders

Thomas Brandt

Department of Neurology, Klinikum Grosshadern, University of Munich, Germany

Vertigo is an unpleasant distortion of static gravitational orientation, or an erroneous perception of motion of either the sufferer or the environment. It is not a disease entity, but rather the outcome of many pathological or physiological processes. Vertigo is best described as a multisensory and sensorimotor syndrome with perceptual, postural, ocular motor and autonomic manifestations induced by either

– unusual and therefore unadapted (motion) stimulation of the intact sensory systems, or
– pathological (lesional) dysfunction.

Vertigo, dizziness, and disequilibrium are common complaints of patients of all ages, particularly the elderly. As presenting symptoms, they occur in 5–10% of all patients seen by general practitioners and 10–20% of all patients seen by neurologists and otolaryngologists. The clinical spectrum of vertigo is broad, extending from vestibular rotatory vertigo with nausea and vomiting to presyncope light-headedness, from drug intoxication to hypoglycemic dizziness, from visual vertigo to phobias and panic attacks, and from motion sickness to height vertigo. Appropriate preventions and treatments differ for different types of dizziness and vertigo; they include drug therapy, physical therapy, psychotherapy and surgery.

The 'vestibular' vertigo syndromes

Vertigo usually implies a mismatch between the vestibular, visual, and somatosensory systems. These three sensory systems subserve both static and dynamic spatial orientation, locomotion, and control of posture by constantly providing reafferent cues. The sensory information is partially redundant in that two or three senses may simultaneously provide similar information about the same action. Thanks to this overlapping of their functional ranges, it is possible for one sense to substitute, at least in part, for deficiencies in the others. When information from two sensory sources conflicts, the intensity of the vertigo is a function of the degree of mismatch; it is increased if information from an intact sensory system is lost, as for example in a patient with pathological vestibular vertigo who closes his eyes. The distressing sensorimotor consequences of the mismatch are frequently based on our earlier experiences with orientation, balance, and locomotion, i.e. there is a mismatch between the expected and the actually perceived pattern of multisensory input.

Vertigo may thus be induced by physiological stimulation of the intact sensorimotor systems (height vertigo; motion sickness) or by pathological dysfunction of any of the stabilizing sensory systems, especially the vestibular system (Table 46.1). The symptoms of vertigo include sensory qualities identified as arising from vestibular, visual, and somatosensory sources. As distinct from one's perception of self-motion during natural locomotion, the experience of vertigo is linked to impaired perception of a stationary environment; this perception is mediated by central nervous system processes known as 'space constancy mechanisms'. Loss of the external stationary reference system required for orientation and postural regulation contributes to the distressing mixture of self-motion and surround motion (Brandt & Daroff, 1980b).

Signs and symptoms

Physiological and clinical vertigo syndromes (Table 46.2) are commonly characterized by a combination of phenomena involving perceptual, ocular motor, postural and autonomic manifestations: vertigo, nystagmus, ataxia, and nausea (Fig. 46.1; Brandt & Daroff 1980b). These four manifestations correlate with different aspects of vestibular function and emanate from different sites within the central nervous system.

Table 46.1. Physiological or pathological vertigo

Physiological stimulation	Height vertigo
	Motion sickness
Pathological dysfunction	Labyrinthine and vestibular nerve disorders
	Central vestibular disorders

Table 46.2. Syndromal manifestations of vertigo

Syndrome	Manifestation
Perceptual	Vertigo, disorientation
Ocular motor	Nystagmus, ocular deviation
Postural	Ataxia, falls
Autonomic	Nausea, vomiting, anxiety

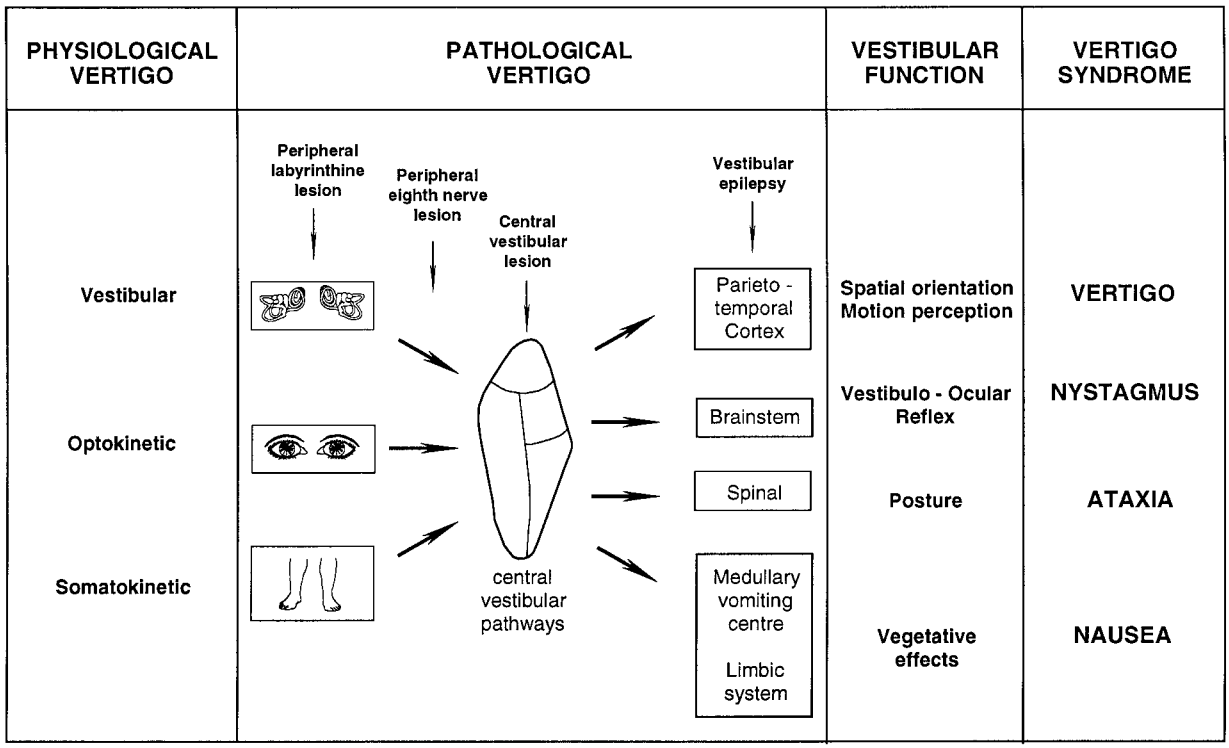

Fig. 46.1. Classification of physiological vertigo and vestibular disorders with their origin at different sites within peripheral or central vestibular structures. Vestibular disorders are not clinical entities but different sensorimotor syndromes arising from unusual stimulation or lesional dysfunction. (From Brandt & Daroff, 1980b.)

1. The vertigo itself results from a disturbance of cortical spatial orientation.
2. Nystagmus is secondary to a direction-specific imbalance in the vestibulo-ocular reflex, which activates brainstem neuronal circuitry.
3. Vestibular ataxia and postural imbalance are caused by inappropriate or abnormal activation of monosynaptic and polysynaptic vestibulospinal pathways.
4. The unpleasant autonomic responses with nausea, vomiting, and anxiety travel along ascending and descending vestibulo-autonomic pathways to activate the medullary vomiting center.

Under certain conditions, distressing symptoms and malaise may be preceded by a pleasurable autonomic sensation, which is presumably mediated through the limbic system and accounts for the popularity of amusement park rides and the like.

The mismatch concept

Physiological vertigo (motion sickness) and pathological vertigo (peripheral or central vestibular dysfunction) are thought to be generated by an acute sensorimotor conflict (mismatch) between the converging sensory inputs and

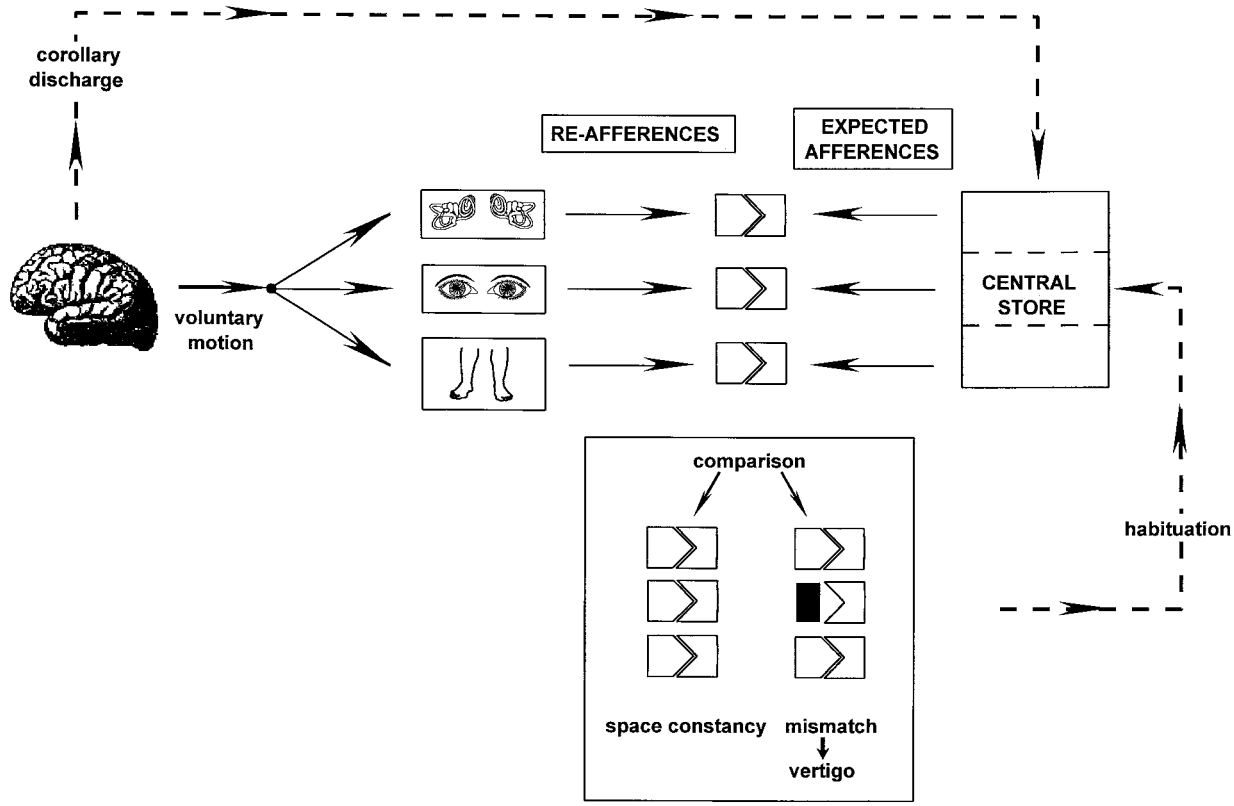

Fig. 46.2. Schematic diagram of the sensory conflict or the neural mismatch concept of vertigo and motion sickness. An active movement leads to stimulation of the sensory organs whose messages are compared with a multisensory pattern of expectation calibrated by earlier experience of motions (central store). The pattern of expectation is prepared either by the efference copy signal which is emitted parallel to and simultaneously with the motion impulse, or by vestibular excitation during passive transportation in vehicles. If concurrent sensory stimulation and the pattern of expectation are in agreement, self-motion is perceived while 'space constancy' is maintained. If, for example, there is no appropriate visual report of motion, as a result of the field of view being filled with stationary environmental contrasts (reading in the car), a sensory mismatch occurs. With repeated stimulation, motion sickness is induced through summation; the repeated stimulation leads to a rearrangement of the stored pattern of expectation, however, so that a habituation to the initially challenging stimulation is attained within a few days. An acute unilateral labyrinthine loss causes vertigo, because the self-motion sensation induced by the vestibular tone imbalance is contradicted by vision and the somatosensors.

the expected sensory patterns (Fig. 46.2) or a vestibular tone imbalance. A mismatch arises, for example, when the multisensory consequences of being a passenger in a moving vehicle or of moving actively do not match the expected patterns which have been calibrated by prior experience of active locomotion. Thus, it is the sensory mismatch (e.g. visual–vestibular or between right and left vestibular input) rather than the sensory loss which causes vertigo. The absence of one channel of the redundant sensory input, important as it is for demanding balancing tasks in sports, rarely manifests as vertigo. Inappropriate information from one or multiple sensory systems produces an illusion of body motion and causes vertigo. An acute unilateral labyrinthine dysfunction (see vestibular neuritis) causes vertigo because the sensation of self-motion induced by the vestibular tone imbalance is contradicted by vision and the somatosensors.

Approaching the patient

Dizziness is a vexing symptom, difficult to assess because of its purely subjective character and its variety of sensations. The sensation of spinning or rotatory vertigo is much more specific; if it persists, it undoubtedly indicates acute pathology of the labyrinth, the vestibular nerve, or the caudal brainstem, which contains the vestibular nuclei.

History taking allows the early differentiation of vertigo

and disequilibrium disorders into seven categories that serve as a practical guide for differential diagnosis:

(i) dizziness and light-headedness (e.g. hyperventilation, intoxication)
(ii) single or recurrent attacks of (rotatory) vertigo (e.g. Menière's disease, basilar migraine)
(iii) sustained (rotatory) vertigo (e.g. Wallenberg's syndrome)
(iv) positional/positioning vertigo (e.g. benign paroxysmal positional vertigo, central positional vertigo)
(v) oscillopsia, the apparent motion of the visual scene (e.g. bilateral vestibular failure, downbeat nystagmus)
(vi) vertigo associated with auditory dysfunction (e.g. Menière's disease, Cogan's syndrome)
(vii) dizziness or to-and-fro vertigo with postural imbalance (e.g. somatoform phobic postural vertigo, central vestibular disorders, episodic ataxia)

Management of vestibular disorders

The prevailing good prognosis of vertigo should be emphasized, because

– many forms of vertigo have a benign cause and are characterized by spontaneous recovery of vestibular function or central compensation of a peripheral vestibular tone imbalance, and
– most forms of vertigo can be effectively relieved by pharmacological treatment (Table 46.3), physical therapy (Table 46.4), surgery (Table 46.5), or psychotherapy [7].

There is, however, no common treatment, and vestibular suppressants (Table 46.6) provide only symptomatic relief of vertigo and nausea. A specific therapeutic approach thus requires recognition of the numerous particular pathomechanisms involved (Baloh & Halmagyi, 1996; Brandt, 1999; Bronstein et al., 1996). Such therapy can include causative, symptomatic, or preventive approaches.

Antivertiginous and antiemetic drugs

A variety of drugs used for symptomatic relief of vertigo and nausea (Table 46.4) have the major side effect of general sedation (Foster & Baloh, 1996). Vestibular suppressants, including anticholinergics, antihistamines, and benzodiazepines, provide symptomatic relief of distressing symptoms by down-regulating vestibular excitability. Antiemetics preferably control nausea and vomiting by acting on the medullary vomiting center, the chemoreceptor trigger zone, or the gastrointestinal tract itself. Vestibular suppressants are often acetylcholine and histamine antagonists, which act as acetylcholine antagonists by competitive inhibition at muscarinic receptors in the vestibular nuclei, their most likely site of action. Vestibular suppression by benzodiazepines is best explained by their $GABA_A$ agonistic effect, because GABA is the major neuroinhibitory transmitter for vestibular neurons. Antiemetics are effective mainly due to their dopamine (D_2) antagonist

Table 46.3. Pharmacologic therapies for vertigo

Therapy	Vertigo
Vestibular suppressants	Symptomatic relief of nausea (in acute peripheral and vestibular nuclei lesions), prevention of motion sickness
Antiepileptic drugs	Vestibular epilepsy, vestibular paroxysmia (disabling positional vertigo), paroxysmal dysarthria and ataxia in MS, other central vestibular paroxysms, superior oblique myokymia
Beta-receptor blockers	Basilar migraine (vestibular migraine; benign recurrent vertigo)
Betahistine	Menière's disease
Antibiotics	Infections of the ear and temporal bone
Ototoxic antibiotics	Menière's disease (Menière's drop attacks)
Corticosteroids	Vestibular neuritis, autoimmune inner ear disease
Baclofen	Downbeat or upbeat nystagmus or vertigo
Acetazolamide	Familial periodic ataxia or vertigo

Source: From Brandt (1999).

Table 46.4. Physical therapies for vertigo

Therapy	Vertigo
Deliberate manoeuvres	Benign paroxysmal positioning vertigo
Vestibular exercises	Vestibular rehabilitation, central compensation of acute vestibular loss, habituation for prevention of motion sickness, improvement of balance skills (e.g. in the elderly)
Physical therapy (neck collar)	Cervical vertigo (fiction or reality?)

Source: From Brandt (1999).

Table 46.5. Surgical interventions for vertigo

Surgery	Vertigo
Surgical decompression of eighth nerve	Tumour (acoustic neurinoma) or cyst
Surgical decompression of vertebral artery	Rotational vertebral artery occlusion
Ampullary nerve section or canal plugging	Benign paroxysmal positioning vertigo
Endolymphatic shunt	Menière's disease
Vestibular nerve section or labyrinthectomy	Intractable Menière's disease
Surgical patching	Perilymph fistula

Source: From Brandt (1999).

properties, but some antiemetics also have muscarinergic or antihistaminic (H_1) properties that may assist in vestibular suppression as well. Primary vestibular suppressants such as scopolamine also effectively suppress vomiting by virtue of their muscarinergic action. Antiemetics are more selective in action. They are primarily used to control nausea and vomiting; for treatment of severe vertigo with nausea, they are often combined with antivertiginous drugs (Foster & Baloh, 1996).

There are only four clear indications for the use of antivertiginous (vestibular suppressants) and antiemetic drugs to control vertigo, nausea, and vomiting (Brandt, 1999):

(i) to prevent nausea due to acute peripheral vestibulopathy (for the first 1–3 days or as long as nausea lasts),
(ii) to prevent severe vertigo and nausea due to acute brainstem or archicerebellar lesions near the vestibular nuclei,
(iii) to prevent severe vertigo attacks that frequently recur, and
(iv) to prevent motion sickness.

For conditions 1 and 2, fast-acting compounds with vestibular and general sedation should be preferably administered, e.g. diazepam or promethazine combined with dimenhydrinate if nausea and vomiting are exceptionally severe. These drugs should not be given after nausea has disappeared, because they prolong the time course of central compensation of an acute vestibular tone imbalance.

Mobility and vestibular excitability are major requirements for recovery and vestibular rehabilitation. Antivertiginous and antiemetic drugs are not indicated for patients suffering from chronic dizziness. A prophylactic treatment with vestibular suppressants, e.g. scopolamine or dimenhydrinate, is justified only in exceptional situations of rare patients who have frequent and severe vertigo attacks. In severe cases of benign paroxysmal positioning vertigo it may become necessary to control nausea and vomiting when performing physical liberatory manoeuvres. It is our own experience that severe central positioning vomiting is best controlled by benzodiazepines rather than antiemetics or typical vestibular suppressants (Arbusow et al., 1998). Scopolamine administered transdermally as Transderm Scop provides a continuous blood level over a 3-day period and effectively prevents motion sickness. The selection of vestibular suppressants and antiemetic drugs should take into account that those that reach a peak effect 7–9 hours after ingestion (Manning et al., 1992) are ineffective for treating short vertigo attacks.

Vestibular compensation

Central compensation of a unilateral peripheral vestibular loss is considered the prototype of brain plasticity. Readjustment of the vestibular reflexes, which act on eye and body muscles, requires sensory feedback from the sensory mismatch elicited by voluntary movements. Therefore, on the basis of our current knowledge of vestibular physiology, continued management should consist of vestibular exercises that promote central compensation (Strupp et al., 1998).

Postural normalization in frogs after a complete unilateral labyrinthectomy occurs within about 60 days (Flohr et al., 1981). Recovery from vestibular lesions is neither a simple nor a single process; multiple processes are involved. Analysis of the mechanisms of recovery requires a careful comparison of normalization between parallel phenomena at the behavioural level, on the one hand, and the neuronal level, on the other. Incongruences in the time course and the magnitude of the changes in behaviour and neuronal activity clearly indicate that multiple processes of compensation occur in distributed neuronal networks for vestibulo-ocular, vestibulo-spinal and perceptual disturbances at different locations and at different times (Dieringer, 1995; Curthoys & Halmagyi, 1994).

Substitution of vestibular function

Vestibular compensation is less perfect than generally believed. For instance, after acute unilateral vestibular

Table 46.6. Commonly used antivertiginous and antiemetic drugs

Drug	Dosage	Action
Anticholinergics		Muscarine antagonist
Scopolamine (Transderm Scop)	0.6 mg po q 4–6 h or Transdermal patch: 1 q 3 days	
Antihistamines		
Dimenhydrinate (Dramamine)	50 mg po q 4–6 h or im q 4–6 h or 100 mg suppository q 8–10 h	Histamine (H_1) antagonist Muscarine antagonist
Meclizine (Antivert, Bonine)	25 mg po q 4–6 h	Histamine (H_1) antagonist Muscarine antagonist
Promethazine (Phenergan)	15 or 50 mg po q 4–6 h or im q 4–6 h or suppository q 4–6 h	Histamine (H_1) antagonist Muscarine antagonist Dopamine (D_2) antagonist
Phenothiazine		
Prochlorperazine (Compazine)	5 or 10 mg po q 4–6 h or im q 6 h or 25 mg suppository q 12 h	Muscarine antagonist Dopamine (D_2) antagonist
Butyrophenone		
Droperidol (Inapsine)	2.5 or 5 mg im q 12 h	Muscarine antagonist Dopamine (D_2) antagonist
Benzodiazepines		
Diazepam (Valium)	5 or 10 mg po bid–qid im q 4–6 h or iv q 4–6 h	$GABA_A$ agonist
Clonazepam (Klonopin)	0.5 mg po tid	$GABA_A$ agonist

deafferentation, which occurs in vestibular neuritis, the process of normalization is impressive for *static* conditions in the absence of head motion: the initial rotatory vertigo, spontaneous nystagmus, and postural imbalance subside. Compensation is, however, less impressive for *dynamic* conditions, especially when the vestibular system is exposed to high-frequency head accelerations (Curthoys & Halmagyi, 1994). The dynamic disequilibrium, i.e. VOR asymmetry, causes oscillopsia, the illusory movement of the environment due to excessive slip of images upon the retina during fast head movements or walking, because after uni- and bilateral peripheral vestibular lesions the VOR cannot generate fast compensatory eye rotations during high-frequency head rotations. The dynamic vestibular tone imbalance can be detected clinically by provoking a directional head-shaking nystagmus (Hain et al., 1987) or by bedside testing of the VOR with rapid head rotation (Halmagyi & Curthoys, 1988).

Vestibular compensation is usually considered a central 'repair mechanism' for a vestibular tone imbalance secondary to a peripheral vestibular loss. However, central compensation is also possible for central vestibular tone imbalances, which is best demonstrated by the cessation of nystagmus and lateropulsion in Wallenberg's syndrome. It is still poorly understood which central vestibular syndromes can be compensated and which cannot. Upbeat and downbeat nystagmus may serve as an example. Acquired upbeat nystagmus is rarely permanent, whereas acquired downbeat nystagmus may be permanent.

Three types of vestibular dysfunction

Basically there are three types of vestibular dysfunction.

Congenital or acquired bilateral vestibular failure = vestibular loss

Key symptoms are oscillopsia associated with head movements (due to the defective vestibulo-ocular reflex) and unsteadiness of gait, particularly in the dark or on unlevel ground (when visual and somatosensory input cannot substitute for the missing vestibulo-spinal control).

These patients have no complaints when standing still without head movement.

Diagnosis is made by a bedside test for defective vestibulo-ocular reflex and the absence of nystagmic reaction to both caloric and rotatory pendular testing.

Acute unilateral lesions of the labyrinth, vestibular nerve, or central vestibular pathways = vestibular tone imbalance

Key symptoms are rotatory vertigo or perceived body tilt with spontaneous nystagmus, ocular torsion, or skew deviation associated with a direction-specific deviation of gait and body falls (due to the lesion-induced vestibular tone imbalance).

Typically a lesion-induced vestibular tone imbalance manifests as an acute syndrome with slow gradual restitution within days to weeks by either central compensation, sensory substitution, or resolution of the lesion.

Diagnosis is made by the combination of perceptual, ocular motor, and postural signs and symptoms. The direction of nystagmus or deviation of posture and gait allows one to determine the particular tone imbalance in one of the three major planes of action of the vestibular system (yaw, pitch, or roll).

Inadequate paroxysmal stimulation of the vestibular system = vestibular attacks

Key symptoms are attacks of vertigo, ocular motor dysfunction, and postural imbalance which may occur spontaneously (basilar migraine, paroxysmal vertigo of childhood, episodic ataxia type I or II, vestibular epilepsy) or may be elicited by changes in head position (benign paroxysmal positional vertigo, vestibular paroxysmia).

Diagnosis of the different etiologies for these attacks is based on careful taking of patient history, clinical examination, and testing of the vestibular function.

Table 46.7 shows the frequency of vertigo syndromes diagnosed in our Neurological Dizziness Unit and gives relevant examples that will be described in the following.

Table 46.7. Frequency of different vertigo syndromes in 3038 patients seen in a neurological dizziness unit (1989–1999)

	Frequency	
Diagnosis	*n*	%
1. Benign paroxysmal positional vertigo	533	17.6
2. Somatoform phobic postural vertigo	434	14.3
3. Central vestibular syndromes with vertigo	364	12.0
4. Peripheral vestibulopathy (vestibular neuritis)	263	8.7
5. Basilar migraine, vestibular migraine	241	7.9
6. Menière's disease	200	6.6
7. Bilateral vestibular failure	89	2.9
8. Psychogenic vertigo (without 2)	89	2.9
9. Vestibular paroxysmia (neurovascular cross-compression)	63	2.1
10. Perilymph fistula	7	0.3
Various rare vertigo syndromes	112	3.7
Unknown etiology	132	4.3
Other central vestibular syndromes (without vertigo)	396	13.0
Other disorders	115	3.8

Bilateral vestibular failure

Bilateral vestibular failure (BVF) is a disorder of the peripheral labyrinth or the eighth nerve which has various etiologies. It is either acquired or congenital, or familial or sporadic. BVF occurs simultaneously or sequentially in both ears, and takes either an abrupt or slowly progressive course. A chronic bilateral loss of vestibular function is surprisingly well tolerated. Moreover, there is no continuing distressing vertigo, spontaneous nystagmus, or postural falls, which are typical signs of a vestibular tone imbalance caused by acute unilateral lesions. The key symptoms are oscillopsia during locomotion or head movements and unsteadiness, particularly in the dark. The entity was first described by Dandy (1941) in patients who had undergone bilateral vestibular neurectomies. Generally patients with BVF are first referred not only for assessment of dizziness and dysequilibrium, but also for examination of ocular motor disorders, ataxia, or hearing loss, conditions in which BVF is often not suspected prior to investigation (Rinne et al., 1995).

The diagnosis is made with the simple bedside test for defective vestibulo-ocular reflex during rapid, passive head turns (Halmagyi & Curthoys, 1988). It is confirmed by the absence of nystagmic reaction to both caloric and rotatory pendular testing while the patient sits in a rotary chair. The most frequent etiologies include ototoxicity, autoimmune disorders, meningitis, neuropathies, sequential vestibular neuritis, cerebellar degeneration, tumours, and miscellaneous otological diseases. So-called idiopathic BVF is found in more than 20% of patients (Baloh et al., 1989; Vibert et al., 1995; Rinne et al., 1995). Subjective symptoms in the acute stage tend to improve with time by processes of somatosensory and visual 'substitution' of vestibular function. Vestibular rehabilitation is supportive of this improvement, but the efficacy of physical therapy is limited. The spontaneous recovery of patients with BVF is relatively rare and incomplete. A permanent loss of vestibular function is the more frequent result; however, the thus-afflicted patient remains largely asymptomatic until

confronted with high-frequency motion conditions or situations where proprioceptors or vision cannot replace the deficient vestibular system.

Vestibular neuritis

Acute unilateral (idiopathic) vestibular paralysis, also known as vestibular neuritis (VN), is a common cause of peripheral vestibular vertigo. It accounts for about 8% of the patients referred to a neurological dizziness unit (Table 46.7).

The chief symptom is the acute onset of prolonged severe rotatory vertigo, associated with spontaneous horizontal–rotatory nystagmus, postural imbalance, and nausea without concomitant auditory dysfunction. Caloric testing invariably shows ipsilateral hypo- or non-responsiveness (as a sign of horizontal semicircular canal paresis). Epidemic occurrence of the condition, the frequency of preceding upper respiratory tract infections, a small number of postmortem studies that found cell degeneration of one or more vestibular nerve trunks, and the demonstration of latent herpes simplex virus type I in human vestibular ganglia, all suggest that the cause may be a viral infection (or reactivation) of the vestibular nerve (Schuknecht & Kitamura, 1981; Arbusow et al., 1999), similar to those producing Bell's palsy and sudden sensorineural hearing loss.

VN is most likely a partial rather than a complete vestibular paresis, with predominant involvement of the horizontal and anterior semicircular canals (sparing the posterior semicircular canal). The condition mainly affects adults, ages 30 to 60, and has a natural history of gradual recovery within 1 to 6 weeks. Recovery is a product of combined (i) peripheral restoration of labyrinthine function (frequently incomplete); (ii) substitution for the unilateral vestibular deficit by contralateral vestibular input and the somatosensory and the visual systems; and (iii) central compensation of the vestibular tone imbalance (aided by physical exercise).

Diagnosis of VN is based on the simple assessment of an acute vestibular tone imbalance associated with a unilateral peripheral vestibular loss (bedside testing of high-frequency VOR; caloric testing) after clinical exclusion of a central neurological disorder. As this diagnostic procedure lacks selectivity, pathological processes other than VN which also cause an acute unilateral loss of peripheral labyrinthine function may be wrongly labelled. Thus, the term VN does not describe a well-defined clinical entity, but rather a syndrome in which peripheral vestibular paralysis can have a number of possible causes (usually viral or vascular). Some authors have proposed other sites for the lesion: peripheral labyrinth, vestibular nerve, or the insertion site of the root of the eighth nerve into the pontomedullary brainstem (here an MS plaque can mimic VN). Differential diagnosis includes all other causes of acute loss of peripheral labyrinthine function.

Benign paroxysmal positional vertigo

Benign paroxysmal positioning vertigo (BPPV; also known as positioning vertigo) was initially defined by Bárány in 1921. BPPV is the most common cause of vertigo, particularly in the elderly. By age 70, about 30% of all elderly subjects have experienced BPPV at least once. This condition is characterized by brief attacks of rotatory vertigo and concomitant positioning rotatory–linear nystagmus which are elicited by rapid changes in head position relative to gravity. BPPV is a mechanical disorder of the inner ear in which the precipitating positioning of the head causes an abnormal stimulation, usually of the posterior semicircular canal (p-BPPV) of the undermost ear, less frequently of the horizontal (h-BPPV) or anterior (a-BPPV) semicircular canal.

Schuknecht (1969) hypothesized that heavy debris settle on the cupula (cupulolithiasis) of the canal, transforming it from a transducer of angular acceleration into a transducer of linear acceleration. It is now generally accepted that in the typical case the debris float freely within the endolymph of the canal ('canalolithiasis') (Parnes & McClure, 1991; Epley, 1992; Brandt & Steddin, 1993). The debris, possibly particles detached from the otoliths, congeal to form a free-floating clot (plug). Since the clot is heavier than the endolymph, it will always gravitate to the most dependent part of the canal during changes in head position which alter the angle of the cupular plane relative to gravity. Analogous to a plunger, the clot induces bidirectional (push or pull) forces on the cupula, thereby triggering the BPPV attack. Canalolithiasis explains all the features of BPPV: latency, short duration, fatigability (diminution with repeated positioning), changes in direction of nystagmus with changes in head position, and the efficacy of physical therapy (Brandt & Steddin, 1993).

In 1980 Brandt and Daroff proposed the first effective physical therapy (positioning exercises) for BPPV. Based on the assumption that cupulolithiasis was the underlying mechanism, the exercises were a sequence of rapid lateral head/trunk tilts, repeated serially to promote loosening and, ultimately, dispersion of the debris toward the utricular cavity. In 1988 Semont and coworkers introduced a single liberatory manoeuvre, and Epley promoted a variation in

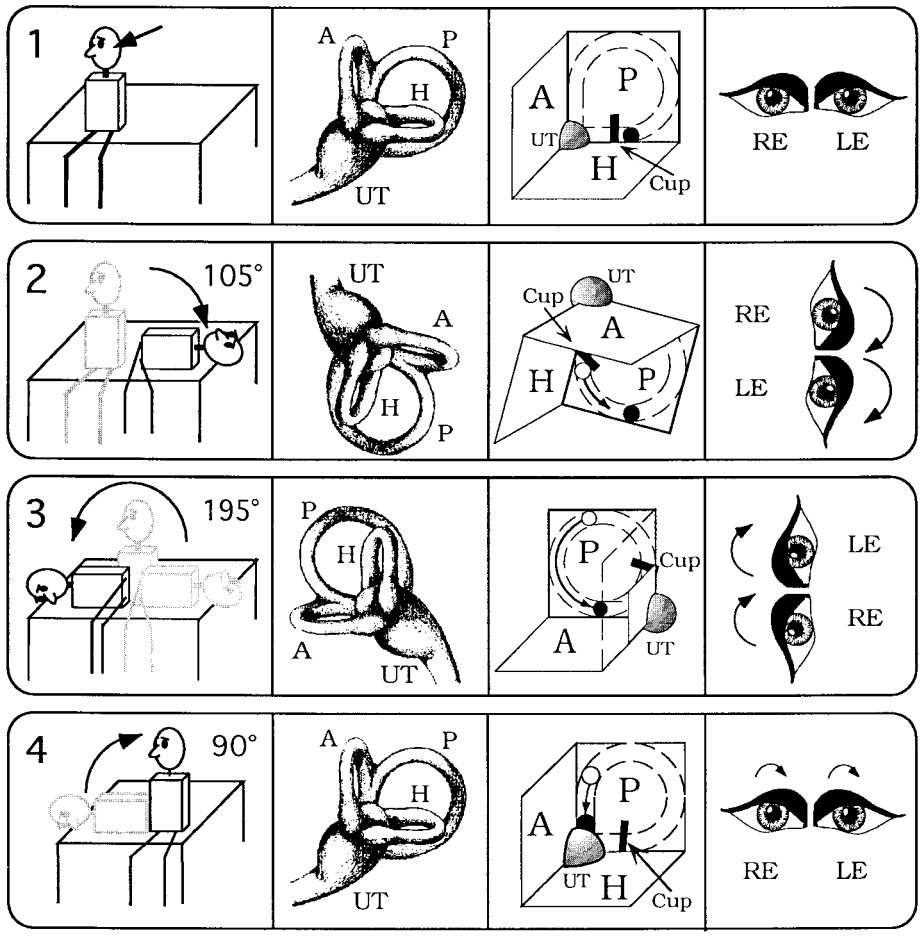

Fig. 46.3. Schematic drawing of the liberatory manoeuvre in a patient with typical BPPV of the left ear. Boxes from left to right: position of body and head, position of labyrinth in space, position and movement of the clot in the posterior canal and resulting cupula deflection, and direction of the rotatory nystagmus. The clot is depicted as an open circle within the canal; a black circle represents the final resting position of the clot. (i) In the sitting position, the head is turned horizontally 45° to the unaffected ear. The clot, which is heavier than endolymph, settles at the base of the left posterior semicircular canal. (ii) The patient is tilted approximately 105° toward the left (affected) ear. The change in head position, relative to gravity, causes the clot to gravitate to the lowermost part of the canal and the cupula to deflect downward, inducing BPPV with rotatory nystagmus beating toward the undermost ear. The patient maintains this position for 3 minutes. (iii) The patient is turned approximately 195° with the nose down, causing the clot to move toward the exit of the canal. The endolymphatic flow again deflects the cupula such that the nystagmus beats toward the left ear, now uppermost. The patient remains in this position for 3 minutes. (iv) The patient is slowly moved to the sitting position; this causes the clot to enter the utricular cavity. Abbreviations: A, P, and H = anterior, posterior, horizontal semicircular canals. Cup = cupula, UT = utricular cavity, RE = right eye, and LE = left eye. (From Brandt et al., 1994.)

1992. If performed properly, all three forms of therapy (Brandt–Daroff exercises and Semont and Epley's liberatory manoeuvre) are effective in BPPV patients (Herdman et al., 1993). The efficacy of physical therapy (Fig. 46.3) makes selective surgical destructions such as transsection of the posterior nerve (Gacek, 1984) or non-ampullary plugging of the posterior semicircular canal (Pace-Balzan & Rutka, 1991) largely unnecessary.

About 5–10% of BPPV patients suffer from horizontal canalolithiasis (h-BPPV; McClure, 1985). h-BPPV is elicited when the head of the supine patient is turned from side to side, around the longitudinal z-axis. Combinations are possible, and transitions from p-BPPV to h-BPPV occur, if the clot moves from one to the other semicircular canal. Transitions from canalolithiasis to cupulolithiasis in h-BPPV patients have been described (Steddin & Brandt,

1996). Most of the cases appear to be idiopathic (degenerative?), their incidence increasing with advancing age. Prolonged bedrest also facilitates their occurrence. Other cases arise due to trauma, vestibular neuritis, or inner ear infections.

The diagnosis of typical BPPV is simple and safe: the patient must have the usual history and exhibit positioning nystagmus toward the causative, undermost ear. Diagnosis is less easy in rare cases, for example, in patients with horizontal semicircular canal cupulolithiasis who exhibit positional nystagmus beating toward the uppermost ear for several minutes. Differential diagnosis includes different forms of central vestibular vertigo or nystagmus, vestibular paroxysmia, perilymph fistula, drug or alcohol intoxication, vertebrobasilar ischemia, Menière's disease and psychogenic vertigo.

Vestibular paroxysmia

Episodic vertigo and other vestibular syndromes can result from pathological excitation of various vestibular structures: the labyrinthine receptors, the vestibular nerve, the vestibular nuclei, and their ascending pathways to the thalamus and the cortex. There is evidence that neurovascular cross-compression of the eighth nerve is the probable cause of vestibular paroxysmia (also termed disabling positional vertigo), including both paroxysmal hyperactivity and progressive functional loss. Analogously to trigeminal neuralgia, vestibular paroxysmia is diagnosed by the occurrence of short attacks and series of rotational or to-and-fro vertigo, which are precipitated or modulated by changing head position and frequently associated with hypacusis and tinnitus (Brandt & Dieterich, 1994b).

This variable syndrome was first described by Jannetta (1975) and later labeled 'disabling positional vertigo' by the same authors (Jannetta et al., 1984; Møller et al., 1986).

Lacking a well-defined syndrome and a diagnostic test, the non-surgical clinician finds it difficult to believe in this disease. The increasing number of reports on vestibular paroxysmia prompt us to share our own preliminary experience with episodic vertigo, a treatable condition that has long escaped notice. The conservative therapeutic approach to the typical clinical syndrome of neurovascular compression of the eighth nerve is mainly based on the efficacy of treatment with carbamazepine, the recurrence of attacks following drug washout phases, and the exclusion of a central (particularly a demyelinating) disease. There is still no pathognomonic sign of the condition, and to date the current imaging techniques for identifying causative nerve-vessel contacts leave much to be desired, since vessel contacts can also be imaged (even at root entry zones) in asymptomatic patients.

According to our findings, the diagnosis can be established on the basis of six characteristic features (Brandt & Dieterich, 1994b):

(i) short attacks of rotational or to-and-fro vertigo lasting for seconds to minutes,
(ii) attacks frequently provoked by particular head positions and whose duration is modified by changing head position,
(iii) hypacusis or tinnitus permanently or during the attack,
(iv) auditory or vestibular deficits measurable by neurophysiological methods,
(v) efficacy of carbamazepine, and
(vi) a central cause excluded by clinical, neurophysiological, and imaging investigations.

As distinct from typical trigeminal neuralgia – in which there is no significant sensory loss, vestibular paroxysmia is characterized by paroxysmal hyperactivity combined with some functional deficit in the attack-free interval.

Central vestibular disorders

Topographic diagnosis in neurology is frequently based on lesions along the course of long motor or sensory pathways. This is well established for the pyramidal tract and the visual pathways. Likewise, clinical studies of the differential effects of central vestibular pathway lesions have increasingly shown vestibular syndromes to be accurate indicators for a topographic diagnosis. Vestibular pathways run from the eighth nerve and the vestibular nuclei through ascending fibres, such as the ipsilateral or contralateral medial longitudinal fasciculus, the brachium conjunctivum, or the ventral tegmental tract to the oculomotor nuclei, the supranuclear integration centres in the rostral midbrain, and the vestibular thalamic subnuclei. From there they reach several cortex areas through the thalamic projection. Another relevant ascending projection reaches the cortex from vestibular nuclei via vestibular cerebellum structures, in particular the fastigial nucleus.

In the majority of cases, central vestibular vertigo syndromes are caused by dysfunction or a deficit of sensory input induced by a lesion. In a small proportion of cases they are due to pathological excitation of various structures, extending from the peripheral vestibular organ to the vestibular cortex. Since peripheral vestibular disorders are always characterized by a combination of perceptual, ocular motor, and postural signs and symptoms, central

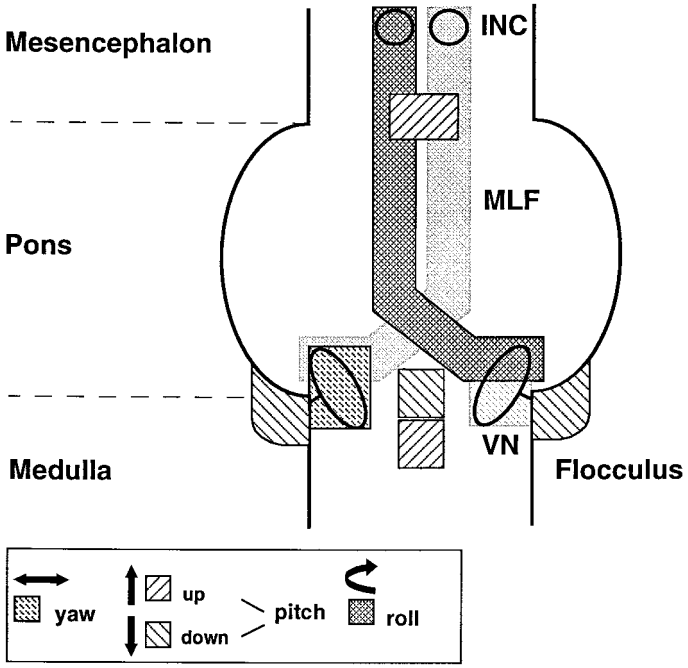

Fig. 46.4. Vestibular syndromes in roll, pitch, and yaw planes: critical areas are schematically represented based on our current knowledge of vestibular and ocular motor structures and pathways, a lesion of which causes a vestibular tone imbalance in one of the three major planes of action. The mere clinical sign of a vertical, torsional, or horizontal nystagmus, if central vestibular, allows a topographic diagnosis of the lesion, although the particular vestibular structures involved are still under discussion. Whereas a vestibular tone imbalance in the roll plane indicates unilateral brainstem lesions (a crossing in the pons), vertical nystagmus indicates bilateral lesions. Two separate causative loci are known for upbeat nystagmus: medullary or pontomesencephalic. Downbeat nystagmus indicates a bilateral paramedian lesion of the commissural fibres between the vestibular nuclei or a bilateral flocculus lesion. Horizontal nystagmus indicates unilateral pontomedullary lesions involving the vestibular nuclei. The differentiation of vestibular ocular motor signs according to the three major planes of action of the VOR and their mapping to distinct and separate areas in the brainstem are helpful for topographic diagnosis and for avoiding incorrect assignment of clinical signs to brainstem lesions identified with imaging techniques (INC = interstitial nucleus of Cajal, MLF = medial longitudinal fasciculus, VN = vestibular nucleus). (From Brandt & Dieterich, 1994.)

vestibular disorders may manifest as 'a complete syndrome' or with only single components. The ocular motor aspect, for example, predominates in the syndromes of upbeat or downbeat nystagmus. Lateral falls may occur without vertigo in vestibular thalamic lesions (thalamic astasia) or as lateropulsion in Wallenberg's syndrome.

Clinical classification (Fig. 46.4)

The 'elementary' neuronal network of the vestibular system is the di- or trisynaptic VOR. VOR properties are routinely tested in all patients who complain of dizziness (Leigh & Brandt, 1993) and are a part of the examination of the unconscious patient. There is evidence for a useful clinical classification of central vestibular syndromes according to the three major planes of action of the VOR: yaw, roll, and pitch (Brandt, 1991, Brandt & Dieterich 1994a).

Vestibular disorders in (horizontal) yaw plane

Yaw plane signs are horizontal nystagmus, past pointing, rotational and lateral body falls, deviation of perceived straight ahead.

Vestibular disorders in (frontal) roll plane

Roll plane signs are torsional nystagmus, skew deviation, ocular torsion, tilts of head, body, and perceived vertical.

Vestibular disorders in (sagittal) pitch plane

Pitch plane signs are upbeat/downbeat nystagmus, forward/backward tilts and falls, deviations of perceived horizontal.

The thus defined VOR syndromes allow for a precise topographic diagnosis of brainstem lesions as to their level and side (Brandt & Dieterich, 1994a).

- *A tone imbalance in yaw* indicates lesions of the lateral medulla including the root entry zone of the eighth nerve and/or the vestibular nuclei.
- *A tone imbalance in roll* indicates unilateral lesions (ipsiversive at pontomedullary level, contraversive at pontomesencephalic level).
- *A tone imbalance in pitch* indicates bilateral (paramedian) lesions or bilateral dysfunction of the flocculus.

It is hypothesized that signal processing of the VOR in roll and pitch is conveyed by the same rather than separate ascending pathways in the medial longitudinal fasciculus and the brachium conjunctivum. A unilateral lesion (or stimulation) of these 'graviceptive' pathways (which transduce input from vertical semicircular canals and otoliths) affects function in roll, whereas bilateral lesions (or stimulation) affects function in pitch. Thus, the vestibular system is able to change its functional plane of action from roll to pitch by switching from a unilateral to a bilateral mode of operation.

Pure syndromes in yaw are rare, since the small causative area covering the medial and superior vestibular nucleus is not only adjacent to but overlapped by the structures also subserving roll and pitch function. A lesion frequently

Table 46.8. Central vestibular syndromes

Site	Syndrome	Mechanism/Etiology
Vestibular cortex (multisensory)	Vestibular epilepsy	Vestibular seizures are auras (simple or complex partial multisensory seizures)
	Volvular epilepsy	Sensorimotor 'vestibular' rotatory seizures with walking in small circles
	Non-epileptic cortical vertigo	Rare rotatory vertigo in acute lesions of the parieto-insular vestibular cortex
	Spatial hemineglect (contraversive)	Multisensory horizontal deviation of spatial attention with (right) parietal or frontal cortex lesions
	Transient room-tilt illusions	Paroxysmal or transient mismatch of visual- and vestibular 3D spatial coordinate maps in vestibular brainstem, parietal, or frontal cortex lesions
	Tilt of perceived vertical with body lateropulsion (mostly contraversive)	Vestibular tone imbalance in roll with acute lesions of the parieto-insular vestibular cortex
Thalamus	Thalamic astasia	Dorsolateral vestibular thalamic lesions
	Tilt of perceived vertical (ipsiversive or contraversive) with body lateropulsion	Vestibular tone imbalance in roll
Mesodiencephalic brainstem	Ocular tilt reaction (contraversive; ipsiversive if paroxysmal)	Vestibular tone imbalance in roll (integrator-ocular tilt reaction with lesions of the interstitial nucleus of Cajal)
	Torsional nystagmus (ipsiversive or contraversive)	Ipsiversive in lesions of the interstitial nucleus of Cajal Contraversive in rostral lesions of the medial longitudinal fascicle
Mesencephalic brainstem	Skew torsion (contraversive)	Vestibular tone imbalance in roll with lesions of medial longitudinal fascicle
	Upbeat nystagmus	Vestibular tone imbalance in pitch in bilateral brachium conjunctivum lesions
Ponto-medullary brainstem	Tilt of perceived vertical, lateropulsion, ocular tilt reaction	Vestibular tone imbalance in roll with medial and/or superior vestibular nuclei lesions
	Pseudo 'vestibular neuritis'	Lacunar infarction or MS plaque at the root entry zone of the eighth nerve
	Downbeat nystagmus	Vestibular tone imbalance in pitch
	Transient room-tilt illusion	Acute severe vestibular tone imbalance in roll or pitch
	Paroxysmal room-tilt illusion in MS	Transversally spreading ephaptic axonal activity
	Paroxysmal dysarthria/ataxia in MS	Transversally spreading ephaptic axonal activation
	Paroxysmal vertigo evoked by lateral gaze	Vestibular nuclei lesion?
Medulla	Upbeat nystagmus	Vestibular tone imbalance in pitch? (nucleus prepositus hypoglossi)
Vestibular cerebellum	Downbeat nystagmus	Vestibular tone imbalance in pitch caused by bilateral flocculus lesions (disinhibition)
	Positional downbeat nystagmus	Disinhibited otolith–canal interaction in nodulus lesions?
	Familial episodic ataxia (EA1 with myokymia and EA2 with vertigo)	EA1 = autosomally dominant inherited potassium channelopathy EA2 = autosomally dominant inherited calcium channelopathy
	Encephalitis with predominant vertigo	Viral infection of cerebellum
	Epidemic vertigo	Viral infection of cerebellum

results in mixed (e.g. torsional and horizontal) nystagmus. The lesional sites of yaw syndromes are restricted to the pontomedullary level because of the short distance between the vestibular nuclei and the integration centre for horizontal eye movements in the paramedian pontine reticular formation. Syndromes in roll and pitch, however, may arise from brainstem lesions located in an area extending from the medulla to the mesencephalon, an area corresponding to the large distance between the vestibular nuclei and the integration centres for vertical and torsional eye movements in the rostral midbrain. Whereas vestibular tone imbalances in pitch, which involve bilateral pathways, may occur with various intoxications or metabolic disorders, this is an unusual etiology for tone imbalances in yaw or roll, which involve vestibular pathways unilaterally.

Some vestibular disorders are characterized by a simultaneously peripheral and central vestibular involvement. Examples are large acoustic neurinomas, infarctions of the anterior inferior cerebellar artery, head trauma, and syndromes induced by alcohol intoxication. Others may affect the vestibular nerve root in the brainstem (lacunar infarction, focal demyelination in MS).

Cortical vestibular syndromes include vestibular seizures (vestibular epilepsy) and lesional dysfunction with tilt of the perceived vertical, lateropulsion, rarely rotational vertigo. There is no primary vestibular cortex, but cortical vestibular function is embedded in a network of multisensory visual–vestibular–somatosensory functions and distributed over several separate and distinct areas in the temporo-parietal region.

The parieto-insular vestibular cortex (Guldin & Grüsser, 1996) seems to act as a kind of main integration centre. Dysfunction of this multisensory and sensorimotor cortex for spatial orientation and self-motion perception may be involved in spatial hemineglect and rare paroxysmal room-tilt illusions. Visual–vestibular interaction in self-motion perception is obviously based on reciprocal inhibitory interaction, a mechanism that makes perception of self-motion more robust and largely insensitive to visual–vestibular mismatches.

Most central vertigo syndromes have a specific locus (Table 46.8) but not a specific etiology.

Spinal cord injury and repair

John W. McDonald

Department of Neurology and Neurological Surgery, Center for the Study of Nervous System Injury, Washington University School of Medicine, St. Louis MO, USA

Many victims of spinal cord injury are young and will live a near-normal lifespan (Fig. 47.1). Therefore, the toll to individuals and society is high. The average lifetime cost of treating a person with traumatic spinal cord injury in the United States runs between $500 000 and $2 million, depending on factors such as the extent of injury and where the cord is injured (higher levels correspond to greater disability and greater costs). Total direct costs of caring for Americans with spinal cord injury exceed $8 billion per year (DeVivo, 1997).

Current state of acute pharmacological treatment

This enormous human and economic toll calls for effective therapies. It was not until the 1990s, however, that the first proven therapy for spinal cord injury was introduced. A multicentre clinical study (National Acute Spinal Cord Injury Study, NASCIS 2) revealed that a high dose of the steroid methylprednisolone reduced disability when administered within 8 hours of the trauma (Bracken et al., 1990). Although the effectiveness of this drug was modest, the availability of any treatment for spinal cord injury was heartening. Subsequently, the multicentre NASCIS 3 trial compared treatment with methylprednisolone for 24 h (same treatment as in NASCIS 2) vs. treatment for 48 h. All patients treated with methylprednisolone within 3 hours of injury showed essentially identical rates of motor recovery. When treatment was initiated between 3 h and 8 h of injury, patients receiving the 48-hour protocol showed significantly more improvement in motor function. Therefore, the US standard of care is administration of methylprednisolone (bolus 30 mg/kg) within the first 8 h after injury. Treatment initiated within the first 3 h is continued (5.4 mg/kg/h) for 24 h, whereas treatment initiated between 3 h and 8 h is continued for 48 h.

Despite these studies, methylprednisolone remains controversial in other countries (Short et al., 2000). Additional experimental drugs, including SYGEN (GM-1 ganglioside), naloxone, and trilizad, have been tested in multicentre clinical trials, but primary endpoints were never achieved.

More recently, cellular and molecular advances in neurobiology have provided powerful insights into the nature of spinal cord injury and opened up new horizons for neural repair and restoration of function. In this chapter we describe how this rapidly burgeoning knowledge might be harnessed to help individuals with spinal cord unjury regain lost functions.

The working cord

The spinal cord is the primary pathway of communication between the brain and the body (Fig. 47.2, see colour plate section), and excellent reviews of its anatomy and physiology are available elsewhere (Byrne et al., 2000).

Millions of axons carry impulses up and down the spinal cord. Axons from neurons in the brain's motor cortex travel up to 1 metre to reach target neurons at each segmental level of the cord; the target neurons connect to relevant muscle cells in the body. Sensations from the skin and other organs travel as electrical signals in the reverse direction, relayed to the appropriate segment of the spinal cord and then up through axons within the cord to locations in the brain and cerebellum. These ascending sensory pathways allow you to feel the soft fur of a kitten, to sense pain when stung by a bee, to locate the position of your arm in the dark, and to know when to empty your bladder. The motor and sensory pathways are organized in a well-understood somatotopic manner, with sacral fibres tending to be more peripheral and cervical fibres more central. This discrete

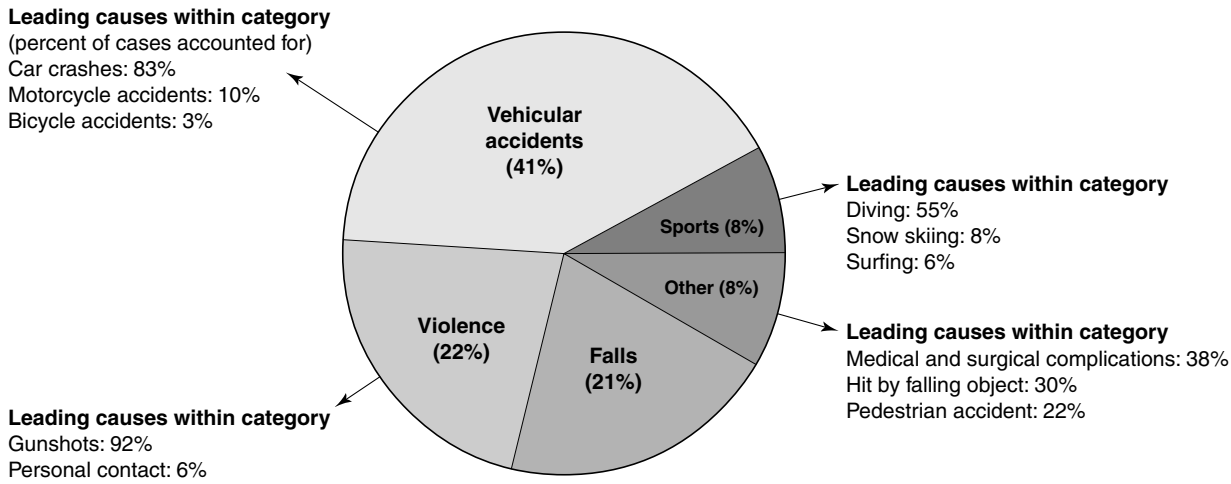

Fig. 47.1. Spinal cord injuries result from traumatic and non-traumatic causes (1994–1998), in roughly equal numbers. The following numbers and pie chart refer to traumatic cases in the United States. Incidence: 10 000 new cases per year. Prevalence: about 230 000. Men account for about 80% of cases. Most (43%) patients are injured between ages 16 and 30, whereas 28% are injured between ages 31 and 45. (Data were obtained from the National Spinal Cord Injury Statistical Center, University of Alabama, Birmingham.)

anatomical and physiological organization provides an ideal venue for research.

When injury strikes

Traumatic injury directly damages the delicate spinal cord with mechanical force, which typically is generated when broken fragments of vertebrae or soft tissue (ligament, herniated disc) impinge on the cord. Within minutes, small-blood vessels hemorrhage, and the spinal cord swells. These events obstruct the normal delivery of nutrients and oxygen to the injured part of the cord, causing many local neurons and glia to starve to death. This immediate damage is not the end of the destruction. A cascade of events triggered by the initial injury leads to secondary injury that progressively enlarges the damaged region during subsequent minutes, hours, and days (Fig. 47.3, see colour plate section). As a result of both initial and secondary injury, the cord can be left in disarray, with neuronal synaptic connections disrupted and many untraumatized axons rendered inactive by demyelination. With the exception of high velocity gunshot injuries and knife wounds, however, it is not common for trauma to completely severe the spinal cord. In postmortem studies, more than 60% of cases show some continuity of CNS tissue across the lesion (Bunge et al., 1993). Typically, a doughnut-shaped rim of white matter remains at the injury level (Bunge et al., 1993; Kakulas et al., 1998; Kakulas, 1999a,b) (Fig. 47.4). However, scarring and the formation of a fluid-filled cavity (a syrinx) can occur, providing physical barriers to axon regeneration. Unlike many of the rodent contusion spinal cord injury models that reproducibly produce a central syrinx at the lesion site, only 20% to 30% of persons surviving traumatic spinal cord injury have a syrinx (Bunge et al., 1993).

What can be done about these barriers to functional recovery? Most laboratories are trying to accomplish two main therapeutic goals: limiting tissue damage, primarily by blocking important steps in the secondary injury cascade, and enhancing recovery, primarily by promoting the regeneration and reconnection of nerve cells. Accomplishing these goals in an optimal manner will require multiple interventions, administered in an orderly sequence, and involving a delicate balance between enhancing favourable (e.g. growth-promoting) factors and neutralizing unfavourable (e.g. growth-inhibiting) ones (Fig. 47.5, see colour plate section).

Terminology, classification and evolution of clinical approaches

To establish a foundation for understanding human spinal cord injury, we will provide clinical terminology and discuss outcomes. To convey severity, medical caregivers use the simple but accurate American Spinal Injury Association (ASIA) Impairment Scale (Table 47.1), a 5-category (A to E) system (ASIA, 1996). Although this classification scale has

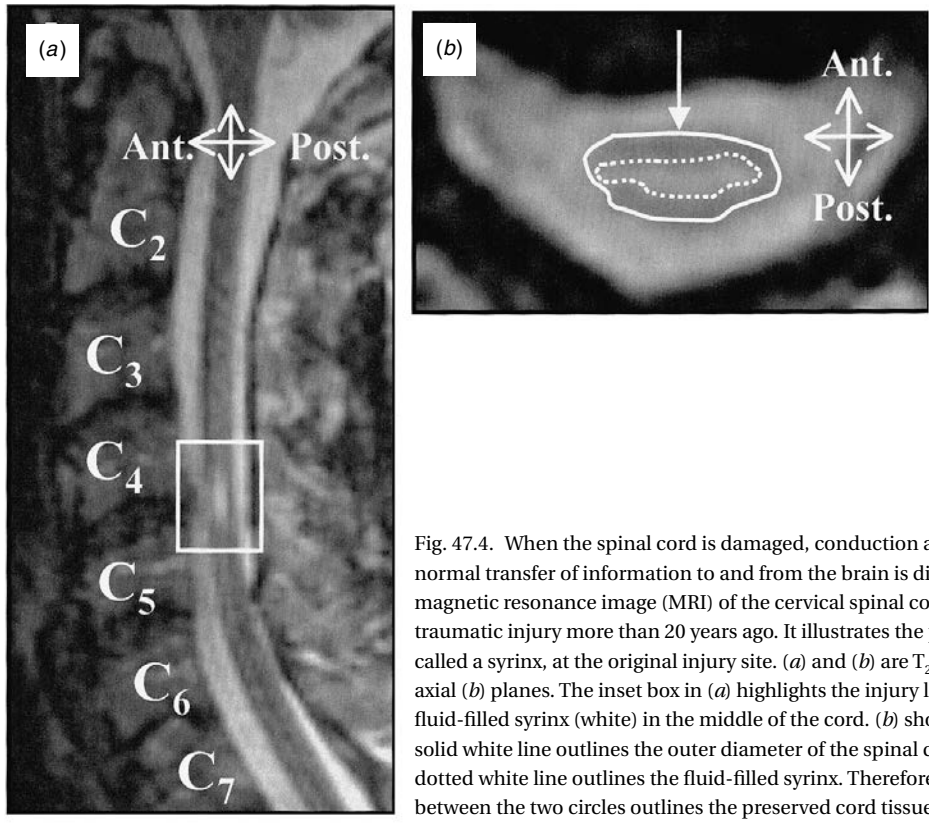

Fig. 47.4. When the spinal cord is damaged, conduction along axons is blocked, and the normal transfer of information to and from the brain is disrupted. (*a*) and (*b*) show a magnetic resonance image (MRI) of the cervical spinal cord of a patient who experienced a traumatic injury more than 20 years ago. It illustrates the presence of a fluid-filled cavity, called a syrinx, at the original injury site. (*a*) and (*b*) are T_2-weighted MRIs in sagittal (*a*) and axial (*b*) planes. The inset box in (*a*) highlights the injury level at C4/5 and demonstrates a fluid-filled syrinx (white) in the middle of the cord. (*b*) shows the syrinx more closely. The solid white line outlines the outer diameter of the spinal cord at the C4/5 level. The inner dotted white line outlines the fluid-filled syrinx. Therefore, the doughnut-shaped area between the two circles outlines the preserved cord tissue.

traditionally used the terms 'complete' and 'incomplete', there is no benefit to retaining such confusing, redundant, and outdated terminology. The terms mean little to individuals with spinal cord injury and, in most cases, are mistakenly believed to indicate the degree of anatomical connection (e.g. incomplete) or disconnection (severed cord; e.g. complete) of the spinal cord. Dimitrijevic and colleagues (Dimitrijevic, 1988; Dimitrijevic et al., 1983) introduced the term 'discomplete' to explain their finding of electrophysiological transmission of signals across a lesion in individuals with ASIA class A injuries (e.g. clinically complete, having lost all sensation and voluntary motor functions below the level of the lesion). Such a term is also not very useful because most injuries that do not physically separate the cord leave residual axonal connections across the lesion (Bunge et al., 1993; Kakulas, 1999a,b).

Our ability to accurately predict clinical outcomes based on early examination is very limited. The most important predictor of better outcomes is retention of sacral sensation (S4–5), particularly pinprick, 72 h to 1 week after injury (Waters et al., 1995; Marino et al., 1999). The most relevant generalities that can be drawn from the many years of outcome studies in the field are summarized in Table 47.2. About 10% to 15% of individuals with ASIA A-grade lesions convert to ASIA B–D; however, only about 3% regain functional strength below the lesion level (ASIA D). Approximately 54% of individuals with initial sacral sensory sparing (ASIA B grade) gain substantial functional strength below the lesion (e.g. will convert to ASIA C–D).

Eighty-six per cent of those classified as ASIA C–D at 72 h regain useful motor function. Age is also a prognostic factor: in central cord syndromes, 91% of patients under age 50 recover ambulation, whereas only 41% over age 50 recover similar capabilities. Recovery of function is the most relevant endpoint for individuals with spinal cord injury and their caregivers. Table 47.3 outlines predicted functional recovery based on injury level for the more severe (A–C) ASIA grades.

When spinal cord damage results from trauma, most initial ER examinations reveal no function below the level of injury, primarily because of spinal shock. Spinal shock is an interesting but poorly understood phenomenon (Bach-y-Rita & Illis, 1993) and this initial lack of function does not necessarily predict a poor outcome, and it should not influence medical and surgical decisions. The usefulness of tests such as motor and sensory evoked potentials,

Table 47.1. ASIA impairment scale

Scale grade	ASIA impairment scale
A	Complete: no motor or sensory function is preserved in the sacral segments S4–S5
B	Incomplete: sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4–S5
C	Incomplete: motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle strength grade <3
D	Incomplete: motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a grade of 3 or above
E	Normal: motor and sensory functions are normal.

Table 47.2. Summary of recovery in ASIA A–D patients

ASIA A

1. Most (60% to 90%) regain one motor level (Stauffer, 1984).
2. 0% to 11% will improve one or more ASIA grades (Frankel et al., 1969; Maynard et al., 1979; Wu et al., 1992; Bedbrook & Sakae, 1982; Stover & Fine, 1986; Ditunno et al., 1995).
3. 4% to 10% may undergo late conversion (after 30 days) to ASIA B or better (Waters et al., 1991, 1993). This can occur up to 2.5 yrs after injury.
4. Most motor recovery occurs during the first 6 months after injury, with the greatest rate of change during the initial 3 months. Motor strength can continue to improve during second year.
5. Muscles graded 1–3 in the zone of partial preservation (ZPP) will recover useful motor function.

ASIA B–D

6. Of ASIA B patients, sacral preservation of pinprick denotes better prognosis for recovery of functional ambulation than ability to sense light touch: 66% to 89% pinprick vs. 11% to 14% light touch (Foo et al., 1981; Folman & el Masri, 1989; Crozier et al., 1991; Waters et al., 1994; Katoh & el Masry, 1995).
7. Of ASIA C patients, 52% to 76% recover to ASIA D or E, compared with 20% to 28.3% of all ASIA B patients (Frankel et al., 1969; Ditunno et al., 1995; Bedbrook & Sakae, 1982; Stauffer, 1983).
8. Central cord syndromes (CCS): generally favourable prognosis (Merriam et al., 1986; Foo, 1986; Penrod et al., 1990; Roth et al., 1990), but age is a key determinant, with patients <50 yr having a better prognosis for ambulation than patients over 50 yr (97% vs. 41%). (Foo, 1986; Merriam et al., 1986; Penrod et al., 1990).
9. In general, Brown–Sequard syndrome (BSS) lesions recover more than central cord syndromes, which recover more than anterior cord syndromes (Stauffer, 1984).

cranial magnetic stimulation, and functional imaging is being examined, but these are still early days.

The recent rush of scientific advances in aspects of regeneration has changed the way we interact with individuals with spinal cord injury. We used to tell newly injured individuals that recovery was unlikely and that they should adapt to life in a wheelchair. This approach is no longer considered productive. Although the clinician's armamentarium for treating spinal cord injury remains limited by the lag between laboratory observations and clinical trials, we can now offer hope, because regeneration and some restoration of function are becoming achievable targets. The old view of limiting rehabilitation to ergonomics, adaptation, and strengthening is giving way to the idea that therapies that promote regeneration can restore additional function. Thus, studies of how environmental factors affect recovery from CNS injury are attracting attention (Ivanco & Greenough, 2000). The constraint-induced, forced-use studies in stroke rehabilitation (for review see Taub et al., 1999) and all the developmental data indicating the importance of patterned neural activity in preserving and (re-)generating the CNS, support the theory that modifying the environment to optimize neural activity is an important therapeutic goal.

Limiting secondary injury

As in conditions such as stroke (see 'Cellular mechanisms of neurological damage', 'Principles of neuroprotection', and 'Principles of ischemic stroke management', Chapters 5, 14, 81, this volume and Volume 2), trauma to the spinal cord appears to induce additional neural cell death through a process called excitotoxicity (for review see Schwab & Bartholdi, 1996; Lee et al., 1999; McDonald et al., 1999). Glutamate, an amino acid neurotransmitter normally released in minute amounts from nerve terminals for signalling, is discharged excessively after neuronal injury (McAdoo et al., 1997). Building up in the extracellular space, it overactivates receptors on the membranes of neighbouring neurons and glial cells. These glutamate receptors open ion channels, admitting large amounts of

Table 47.3. Expected functional outcome based on injury level

Level (ASIA)	Breathing	Mobility	Driving	Transfers	Bowel	Bladder	Eating & grooming	Dressing upper extremities	Dressing lower extremities
C1–3	D	Power chair	N/A	D	D	D	D	D	D
C4	I	Power chair	N/A	D	D	D	D	D	D
C5	I	Power chair	Modified van	D	D	D	Partially D	Partially D	D

Notes:
D = dependent.
I = independent.
O = orthosis.

calcium and sodium into the cells. The resulting sustained elevation in intracellular calcium triggers a series of destructive events: protein-destroying enzymes are switched on, and bursts of oxygen free radicals damage cell membranes and intracellular organelles. Unable to withstand these insults, nerve cells die, compounding the direct damage from the initial mechanical injury.

As well as protecting neurons from excitotoxic injury, it is vital to protect spinal cord white matter, the outer ring of tissue that carries ascending and descending axons. It is not uncommon for a lesion to be confined to the central tissue, which contains nerve cell bodies (grey matter), while the surrounding white matter is spared. Such a central cord lesion confines motor and sensory disturbances to areas innervated at that level (for example, a C6 lesion affects the upper limbs) without much affecting function below that level, such as gait, bowel or bladder function. In contrast, destruction of white matter at the same segment, even if the injury spares grey matter, renders a person tetraplegic and incontinent.

Several studies of animal models of spinal cord injury suggest that anti-excitotoxic treatments can be beneficial (Faden & Simon, 1988; Wrathall et el., 1994). However, initial work that focused on the role of NMDA-type glutamate receptors documented preferential protection of grey matter, which did not bode well for functional improvements that depend on white matter preservation (most animal models involve thoracic spinal cord injury). More recent work has focused attention on the benefits of blocking a subclass of glutamate receptors called AMPA receptors (Wrathall et al., 1994, 1996). Such treatment protects white matter and improves locomotor function, but understanding of the cellular mechanism awaits later studies.

Although excitotoxicity has traditionally been thought to kill only neurons, recent studies suggest that it may also kill oligodendrocytes, which myelinate CNS axons. Thus, excitotoxic damage to oligodendrocytes contributes to white matter injury (Matute et al., 1997; McDonald et al., 1998a, 1998b, 1999; Li et al., 1999b; Li & Stys, 2000) and to demyelination and axonal conduction block often found in the injured spinal cord (Gledhill et al., 1973; Bresnahan, 1978; Bunge et al., 1993; Waxman, 1989, 1992).

In the past 5 years, recognition that a second form of cell death, programmed cell death or apoptosis, also occurs in the injured spinal cord, has opened new doors to protective strategies (Kerr et al., 1972; Wyllie et al., 1980). Apoptosis is essential to normal CNS development, when it removes unneeded cells, and it may be triggered inappropriately later in life when certain key structures, such as DNA, sustain damage (Johnson et al., 1996; Lee et al., 1999), leading to the unfortunate loss of nerve cells. Many of the neuroprotective effects of neurotrophins observed in animal and in vitro models of CNS injury prevent such apoptotic death of neurons and glia. Thus, NT-3 and BDNF have well-described injury-limiting effects in addition to prominent regenerative actions (see below).

Recent animal (Crowe et al., 1997; Liu et al., 1997; Shuman et al., 1997; Li et al., 1999a; Springer et al., 1999) and human (Emery et al., 1998) studies have revealed that a prominent wave of oligodendrocyte apoptosis may occur days to weeks after spinal cord injury, at quite remote sites. This delayed reaction may be triggered by a combination of early excitotoxic injury and a later loss of vital surface or trophic factor interactions as truncated axons slowly degenerate (for review see Beattie et al., 2000; Zipfel et al., 2000). Furthermore, administration of drugs or creation of dominant negative mutations that inhibit apoptosis permits rats and mice subjected to traumatic spinal cord injury to regain a better level of ambulation (Liu et al., 1997; Li et al., 2000).

Ultimately, treatments aimed at reducing secondary damage in the injured spinal cord will likely encompass multiple drugs delivered at different intervals and targeted at specific mechanisms of cell death in distinct cell populations. Almost certainly, the strategy of blocking excitotoxic and apoptotic death pathways will be augmented by delivery of trophic factors capable of promoting neuronal and glial cell survival. A great deal has been learned recently about the identities of these factors, their effects, and their mechanisms of action. Factors that regulate the production of neurotrophins and their receptors in oligodendrocytes, astrocytes, and microglia also have been discovered, and these may be useful for enhancing production of selected neurotrophins in the injured spinal cord.

Once interventions can limit secondary tissue injury as much as possible, the therapeutic focus will shift to promoting nerve cell regeneration and reconnection. The reminder of this article will summarize emerging concepts and potential strategies in this area. To obtain meaningful recovery of function, we will not need to completely shield the damaged spinal cord from secondary injury or entirely rebuild it. Preserving or re-establishing a fraction of the lost connections may enhance important functions, such as control of the bladder, bowel, and respiration. Studies from as early as the 1950s have indicated that preservation of less than 10% of the normal axon complement in the cat spinal cord can support walking (Blight, 1983), though this should not be viewed as the optimal requirement for restoring function. Moreover, detailed anatomical postmortem studies of chronic human spinal cord injury reveal that small residual connections across the lesion can preserve some function (Kakulas, 1999a,b). In one individual with ASIA C spinal cord injury, only 1.17 mm^2 of white matter remained at the level of the lesion. One individual with some preserved motor function below the level of cervical injury had only 3175 corticospinal axons, less than 8% of the number (41 472) of similar axons in normal controls.

Injuries that are lower by just a single segment, at cervical level C6 instead of C5, for example (a difference of about 1.7 cm) also have fewer effects. Whereas a person with a C5 injury level has no upper extremity function other than limited motion at the shoulders, a person with a C6 injury can move shoulder and elbow joints, and surgical transfer of muscle tendons may restore partial hand function. Therefore, small anatomical gains can result in disproportionately higher functional gains Therapeutic implications of this observation are that small additive and stepwise treatments can be expected to produce large gains in function.

The critical balance

A complex constellation of signals is required for successful regeneration of spinal cord cells and for axons to reach their correct targets during development and regeneration. The fate of disconnected axons is determined by the balance between growth-promoting (chemoattractant) and growth-inhibiting (chemorepulsant) molecules in the local environment. The growth cone on the tip of a regenerating axon makes directional choices based on the multitude of guidance molecules it encounters.

Large families of guidance molecules have been discovered. They can be: (i) presented on the surface of a cell, (ii) fixed to the extracellular matrix, or (iii) secreted into extracellular fluid. Moreover, interactions can be simple or intricate. Some molecules act by altering the electrical charge of the local environment. Others work in a lock-and-key fashion, docking at specific receptors on target axons. These interactions can trigger a complex chemical cascade within the growth cone that makes the cone retreat, advance, or both, depending on the nature of the effectors. Soluble growth factors are being evaluated for their ability to stimulate regeneration after spinal cord injury, but the manipulation of substrate-bound guidance molecules lies largely in the future. Tipping the balance in favour of growth enhancement vs. growth inhibition will be the cornerstone of success.

Regrowth of nerve fibres: overcoming inhibition

Unlike developing neurons, mature peripheral nerves or certain networks in the CNS of invertebrates, fish, amphibians, and reptiles, mammals regenerate poorly after their axons are severed. This does not appear to be an intrinsic limitation of the adult neuron itself, however. In the 1980s,

Albert J. Aguayo and colleagues showed that adult rat neurons can regenerate when provided with a permissive environment. Using a piece of peripheral nerve from the leg as a graft, they constructed a bridge across the injured region of the spinal cord and redirected the cut axons across the graft. After many weeks, they observed robust axonal regeneration from the spinal cord into the graft, in some cases up to 30 to 40 mm (Richardson et al., 1980; David & Aguayo, 1981). But the credit for the first demonstration of the capacity of CNS neurons to regenerate predates these studies by 70 years (Tello, 1911); pieces of peripheral nerve were transplanted into the cortex of young rabbits, and several weeks later bundles of fibres entered the graft. These observations suggest that mammalian central neurons are reluctant to regrow after injury because of shortcomings in their immediate environment.

One promising approach to this problem is to study systems that can regenerate so factors that promote or inhibit regeneration can be identified. A particularly attractive system is the immature mammalian CNS. For example, spinal cord axons from the South American opossum, *Monodelphis domestica*, can regenerate after injury before, but not after, postnatal day 11 (for review see Nicholls & Saunders, 1996). The abrupt loss of regenerative capability appears in several cases to correlate with onset of myelination. Thus, motor axons in the hatchling chick regenerate if the spinal cord is cut before oligodendrocytes myelinate them (Steeves et al., 1994). Also, experimentally delaying myelination extends the period during which injured axons can regenerate (Keirstead et al., 1992). These studies suggest that myelin formation may be a key barrier to axon regeneration in the mature mammalian spinal cord.

More than a decade of work has focused on identifying specific nerve growth-preventing proteins in myelin (for review see Schwab et al., 1993; Schwab & Bartholdi, 1996), and the gene for one of these was recently cloned (Nogo A & B; Chen et al., 2000). Called myelin-associated neurite growth inhibitors, these proteins can prevent axonal outgrowth from cultured neurons (for review see Huber & Schwab, 2000). Applying a neutralizing antibody (termed IN–1, for inhibitor neutralizing antibody) induced axon growth from neurons cultured on the inhibitory molecules. Furthermore, infusing IN-1 into the injured rat spinal cord promoted long-distance regeneration in a small percentage of interrupted axons and improved the rats' ability to use their forepaws (Schnell & Schwab, 1990; von Meyenburg et al., 1998). In preparation for clinical trials, the active part of IN-1 has been cloned and re-engineered to be more acceptable to the human immune system. These recombinant humanized antibody fragments have recently been tested for their safety and regenerative properties in animal models of spinal cord injury (Brosamle et al., 2000).

Research has expanded the list of isolated inhibitory molecules to many families (Fitch & Silver, 1997; Kapfhammer, 1997), including the proteoglycans (for review, see Davies & Silver, 1998). In recent studies, regenerating axons from adult neurons stopped growing when confronted with a chondroitin sulfate proteoglycan-rich boundary, though they were able to cross the lesion and extend for long distances in the boundary's absence (Davies et al., 1997). Given the apparent multiplicity of molecules capable of inhibiting nerve fibre regeneration, a cocktail of drugs may be necessary to fully unmask the natural capacity of adult spinal cord neurons to regenerate after injury. As well as blocking inhibitory proteins (e.g. with antibody), it also might be possible to reduce inhibition by down-regulating production of these proteins. As the genes for key inhibitor molecules are cloned, researchers will be able to study their regulatory sites. This knowledge could be used to determine how expression of an inhibitory protein changes after injury and to devise methods for turning off the relevant gene.

Promoting outgrowth

As well as removing the inhibition of axonal regeneration, it might be possible to increase the availability of growth-promoting molecules. Major insights have come from studying axonal outgrowth during normal embryonic development. More than four decades ago, Rita Levi-Montalcini and Viktor Hamburger identified and isolated nerve growth factor (NGF), a small, soluble protein that supports the survival and development of sensory and sympathetic neurons. This pioneering work precipitated a successful search for additional neurotrophic factors, and NGF is now known to be one of a family of related neurotrophins that promote neuronal cell survival and axonal outgrowth during embryogenesis; several other families of trophic factors also have been identified (for review see Lindsay et al., 1994). However, synthesis of the messenger RNA needed to produce neurotrophic factors and their receptors can be depressed for weeks following spinal cord injury. Also, responses to neurotrophic factors can be selective for specific cell types and individual cell functions, depending on the location and expression of the receptors that are activated. For example, NT-3 selectively stimulates regrowth of injured corticospinal tract axons (Schnell et al., 1994; Grill et al., 1997; Houweling et al., 1998; von Meyenburg et al., 1998). It also can enhance cell survival and promote remyelination

(McTigue et al., 1998). In contrast, the fibroblast growth factor (FGF) family has more widespread effects, both in promoting growth and stimulating the formation of new cells from progenitors (see below). They also affect non-neural cell function. Growth-related factors such as platelet-derived growth factor (PDGF) can stimulate the replication of oligodendrocyte progenitors (for review, see Grinspan et al., 1994).

Considerable evidence suggests that endogenous production of growth factors in the injured cord falls short and that boosting the supply might improve cell survival and regeneration. This might be achieved by exogenous administration, endogenous delivery via gene transfer (see below), or modulating cellular production. Manipulating factors that regulate neurotrophin production might selectively enhance production of certain neurotrophins in the injured spinal cord and therefore promote regeneration. Promising results with many of the neurotrophic factors have been achieved in models of spinal cord injury (Schnell et al., 1994; Grill et al.;, 1997; Blesch et al., 1998; Houweling et al., 1998; von Meyenburg et al., 1998; McTigue et al., 1998; Zhang et al., 1998; Liu et al., 1999; Blits et al., 2000).

These efforts will need to be wary of unintended consequences, such as enhancing pain, already a common long-term complication of spinal cord injury (excellent reviews of this area are available: Beric, 1997; Christensen & Hulsebosch, 1997). Pain might increase because of aberrant axon sprouting within the CNS or by peripheral mechanisms such as growth factor-mediated sensitization of skin nociceptors (Mendell, 1999; Shu & Mendell, 1999). A paradoxical injury-enhancing effect of neurotrophins has also been recognized, in both culture and in vivo models of spinal cord injury (Koh et al., 1995; Gwag et al., 1995; McDonald et al., 2002).

Establishing correct functional connections

Promoting nerve outgrowth will be useful only if strategies to link regenerated axons with their suitable synaptic targets also can be developed. Powerful insights into axon guidance have come from studies of the developing nervous system, where a complex set of temporally and spatially regulated events coordinates the precise formation of intricate neural circuits. In the embryo, molecular signals that act directly on the leading tip (growth cone) of the lengthening axon choreograph outgrowth. Fortunately, the last several years have produced unprecedented advances in identifying many new families of targeting, guidance, and adhesion molecules that are expressed during development (for review see Leutwyler, 1995; Tessier-Lavigne & Goodman, 1996; Guthrie & Varela-Echavarria, 1997; Walsh & Doherty, 1997; Terman & Kolodkin, 1999; Joosten & Bar, 1999; Quinn et al., 1999; Raper, 2000 (see also Chapter 97 by Compston in Volume 2)). Some are diffusible molecules released from cells. Their concentration gradients attract the growth cone, guiding it to another neuron or developing muscle fibre. Other signals are contained in the extracellular matrix (the material outside cells). For instance, a family of factors called netrins helps guide axons in the mammalian spinal cord by calling axons in one direction and repelling them from others (Serafini et al., 1994). By displaying netrins and other guidance molecules as if they were highway signs, the extracellular matrix acts as scaffolding that tells axons precisely where to go. Like highway signs, these signals must appear in the correct sequence; otherwise, an axon would lose its way. Unfortunately, we do not yet know how to reconstitute this sequence after injury. However, our present level of understanding may permit the design of interventions aimed at modulating the presentation of some of these guidance molecules, perhaps well enough to aid regeneration. Moreover, recent experiences with grafted fetal neurons have suggested that some axons can find appropriate targets even without additional chemical signals.

Building bridges

Since the demonstration that peripheral nerves can support the regrowth of CNS axons (Richardson et al., 1980; David & Aguayo, 1981) and, in one case, lead to the formation of functional synaptic connections, many research groups have explored the value of bridging the gap created by cord damage (Fig 47.5, see colour plate section). In one study, Schwann cells (the myelinating glia of the peripheral nervous system) transplanted into the spinal cord promoted axonal regeneration after a section of the spinal cord was completely removed (Xu et al., 1995). The Schwann cell produces a variety of growth factors and extracellular matrix molecules known to promote axon regeneration. Grown in culture and packed into a plastic-like tube, they have been used to connect the two ends of transected spinal cord. In combination with growth factor or methylprednisolone treatments, these grafts have allowed neurons to grow axons (Menei et al., 1998).

Knowledge of bridges and inhibitory factors has been combined to enhance behavioural recovery in spinal cord-injured rats. Peripheral nerves were grafted between the two ends of a severed spinal cord, and glue made of fibrin kept the nerves in place and released acidic fibroblast

growth factor (aFGF) into the injured area (Cheng et al., 1996, 1997). The peripheral nerves were directed from white matter to the less inhibitory grey matter so regenerating axons would grow in that direction. Six months after this procedure, the corticospinal tract had partly regenerated. The rats also had regained some ability to walk. These studies have been difficult to replicate in other laboratories perhaps because of the complexity of the surgery.

Lessons learned from the Schwann cell have provided insights into what makes a good cellular candidate for supporting axonal regrowth (Bunge, 1993). An exciting example is the recent transplantation of olfactory ensheathing glial cells. These cells are found only in the olfactory nerve and bulb, and they reside in a unique area that permits axons to grow continually throughout adult life (for review, see Ramon-Cueto & Avila, 1998). In an early study, olfactory ensheathing glial cells were transplanted into the rat spinal cord where the corticospinal tract had been cut. After several months, there was partial regrowth of corticospinal axons and some improvement in the limb functions these nerves normally control (Li et al., 1997). In another study, transplanting ensheathing glia into cut cord stumps next to Schwann cell grafts led to long-distance axonal regeneration. It also improved growth of regenerated axons from graft into contiguous cord (Ramon-Cueto et al., 1998). Additional studies add to the intriguing concept that transplanted olfactory ensheathing glial cells might be competent escorts for regenerating axons in the damaged spinal cord (Ramon-Cueto & Nieto-Samparedo, 1994; Ramon-Cueto et al., 1994, 1998, 2000; Li et al., 1997, 1998; Perez et al., 1998; Navarro et al., 1999). Some work even suggests that these cells might be capable of myelinating single axons akin to Schwann cells (Li et al., 1997; Imaizumi et al., 1998, 2000; Barnett et al., 2000), but this finding remains controversial because these cells normally wrap groups of axons and their isolation is susceptible to contamination by Schwann cells. Understanding their regeneration-aiding properties is a next step for scientists. Armed with the why and how, researchers may be able to create or engineer cells that exhibit combinations of growth-promoting properties.

Replacing lost cells: cell transplants and genetic vectors

Cell transplants can serve three important functions (for review see Bjorklund & Lindvall, 2000). First, they can generate a local supply of key molecules, such as growth factors or guidance molecules, to promote cellular survival or regeneration. Secondly, they can provide mechanical stability and serve as a bridge (see above), supporting the regrowth of injured CNS axons. Third, they can replace lost neuronal or glial cells, restoring cellular functions such as signalling and axon myelination.

Adult neurons are unsuitable for transplantation because they neither divide nor survive isolation and relocation. Several different types of cells have been successfully transplanted into the injured spinal cord, however. They include fetal spinal cord tissue, immortalized neural cell lines, genetically engineered fibroblasts, CNS stem cells, and embryonic stem (ES) cells.

For several decades, pioneering groups have explored the transplantation of fetal CNS tissue into animal models of spinal cord injury. This tissue survives and partially integrates into the injured host cord, leading to limited segmental forms of functional recovery (Nygren et al., 1977; Buchanan & Nornes, 1986; Reier et al., 1986; Bernstein & Goldberg, 1987; Yakovleff et al., 1989; Jakeman & Reier, 1991; Bregman et al., 1993). Host fibres grow into the transplants, and transplanted neurons extend axons into host tissue. This valuable experience has emphasized the therapeutic potential of immature neuronal cells, but ethical dilemmas and the availability of suitable tissue limit the usefulness of this approach in humans. Another source of transplantable material is cell lines derived from central neurons that have been transformed by retroviral vectors. The cells are immature and capable of indefinite replication. They survive and respond to local environmental cues after transplantation; moreover, the adult CNS retains the capacity to direct their differentiation into more mature neurons (Park et al., 1999; Vescovi & Snyder, 1999; Whittemore, 1999). There is concern that such immortalized cells might undergo malignant transformation and become cancerous, however.

Other laboratories have used genetically engineered non-neuronal cells to obtain neurotrophic molecules and extracellular matrix molecules known to promote regeneration. This approach was recently applied to the injured spinal cord (Grill et al., 1997; McTigue et al., 1998). Fibroblasts were engineered to produce the neurotrophic molecule NT-3. After the cells were transplanted into the cut spinal cord, there was substantial regrowth of the corticospinal tract and improved stepping across the graft (Grill et al., 1997). Later work demonstrated enhanced myelination of regenerated axons in the graft (McTigue et el., 1998). The ability of this approach to provide effective bridges that support the regrowth of host axons is a particular strength that may well drive its incorporation into future therapies.

Another approach to cellular replacement is to take advantage of stem cells still present in the adult CNS. These retain the fetal capacity to survive isolation, replicate, and

differentiate into mature cells. For many years, it was believed that the number of neurons in the mammalian brain and spinal cord is fixed at birth and that neurons cannot be replaced, unlike cells in organs such as skin or liver. As early as the 1960s, however, pioneering studies demonstrated that some cells in the adult hippocampal dentate gyrus divide, differentiating into neurons (Altman & Das, 1965). Such progenitor cells can be isolated from the mature brain, cultured, and transplanted back into adult brain, where they can turn into neurons. Recently, this approach has been expanded to cells isolated from the mature spinal cord (Shihabuddin et al., 1997; Horner et al., 2000).

Exciting recent work has demonstrated that formation of new neurons is a more universal and dynamic process that occurs even in adult humans (Eriksson et al., 1998; Del Bigio, 1999). The process appears to be influenced by the local physical and chemical environment (Kempermann et al., 1998; Kempermann and Gage, 1999; Gould et al., 1999a,b; Nilsson et al., 1999). However, we are just beginning to understand how to regulate progenitor cell birth and survival of subsequent differentiated neural cells, and endogenous production of sufficient numbers of cells to replace those lost from spinal cord injury is not feasible at present. The potential consequences of disturbing these neurotransmitter systems with the polypharmacy typically used to treat spinal cord injury should be carefully weighed against putative benefits.

How might stem cells be used for spinal cord repair? As we begin to understand the signals that determine when stem cells divide and how they commit to a particular cell fate (oligodendrocyte, astrocyte, or neuron), we may be able to isolate adult stem cells from a biopsy of the injured spinal cord, propagate them to gain adequate numbers, induce them to form the required cell types, and transplant them back into the same person's injured cord. Moreover, stem cells can be genetically engineered as easily as fibroblasts, so they could be made to function as biological timed-release capsules, delivering growth factors or guidance molecules at key stages of regeneration. Unlike fibroblasts, stem cells are capable of migrating and integrating into host tissue. Thus stem cells delivered to a single site might repopulate remote locations.

Other researchers are beginning to examine even more primordial stem cells, called embryonic stem cells, which are pluripotent (capable of forming any cell in the body) and immortal (living and dividing forever). Such cells have been isolated from rats, fish, chickens, Rhesus monkeys, and most recently from humans (Shamblott et al., 1998; Thomson et al., 1998; Itskovitz-Eldor et al., 2000; for review, see McDonald, 2002). When embryonic stem cells that were induced by retinoic acid to become neural precursors were transplanted into the contusion injury site of rat spinal cord 9 days after injury, they migrated long distances, differentiated into neurons, astrocytes, and oligodendrocytes, and promoted some recovery of locomotion (McDonald et al., 1999). That was an important result because no previous studies had demonstrated improved walking when transplantation was delayed for more than 24 hours. Subsequently, embryonic stem cells have been successfully coaxed to produce oligodendrocyte precursors that can myelinate axons in culture and when transplanted into the immature CNS (Brustle et al., 1999) and the injured adult spinal cord (Liu et al., 2000).

Neural xenotransplantation is another approach. It has been attempted in individuals with Huntington's disease (Philpott et al., 1997; Bachoud-Levi et al., 2000), Parkinson's disease (Kordower et al., 1995, 1998; Freeman et al., 1999), stroke (http://www.laytonbio.com; http://www.diacrin.com), epilepsy (http://www.diacrin.com), and spinal cord injury (Reier et al., 1994; Thompson et al., 1998; Wirth et al., 1999; http://www.diacrin.com). Xenotransplantation is favoured for use in human studies now since the greatest safety data is available. The major disadvantage of this approach is the possibility of rejection of the foreign tissue.

As an alternative to cell transplantation, replication-deficient viral vectors could transfer genes coding for desirable growth factors, blocking antibodies, or guidance molecules directly into surviving spinal cord cells. Virus-mediated gene transfer is most easily achieved into dividing cell types, but adenoviruses and lentiviruses have been used experimentally to transfer genes into non-dividing adult neurons (Suhr & Gage, 1999; Kafri et al., 2000). Maintaining high levels of foreign gene expression over time and limiting destruction by the host's immune system remain significant technical hurdles to clinical use. The recent development of 'gutless' adenoviruses, which lack the genes for immunoreactive coat molecules, and the design of strategies to protect infected cells by selectively repelling or killing invading immune cells are producing headway.

Finally, not all CNS diseases are equally amenable to cell replacement therapy. The best chance for success may lie in applications whose clinical efficacy is determined by a single defined biological mechanism, such as myelination to restore long-tract neurotransmission in spinal cord injury. We will do well, however, not to promise too much too early and to focus on therapies that would seem likely to work, such as those that have shown benefits in animal models. At present, achievable neuronal transplantation is limited to re-establishing local, short-distance connections (such as interneurons). Long-tract connections

across a spinal cord lesion have not been seen in any animal model.

Perhaps the most success in animal models has been achieved by transplanting oligodendrocytes and their progenitors. Both the biology of the oligodendrocyte lineage and myelination are well understood, and this glial system is relatively simple compared with the neuronal system, which involves dozens of types of neurons and tens of thousands of interconnections. Therefore, the inherent risks associated with glial cells are limited compared with those associated with neurons.

Restoration of function: limited rebuilding, not cure

Fortunately, all available evidence indicates that the damaged spinal cord will not have to be completely rebuilt to obtain meaningful recovery. Animal studies suggest that less than 10% of functional long-tract connections are required to support locomotion (Blight, 1983). As previously mentioned, the preserved rim of white matter that carries long tracts between the brain and periphery of the body might be sufficient to restore meaningful function. Animal studies indicate that axons in this rim commonly remain anatomically intact but are non-functional because of focal demyelination or faulty myelination. Therefore, remyelinating intact connections seems like a reasonable approach to restoring function (Gledhill et al., 1973; Waxman, 1992; Bunge et al., 1993). Although such limited restoration may not enable people with spinal cord injury to walk, it might restore control over the bowel and bladder or improve limb mobility. Such gains facilitate independence.

Several research groups have suggested that some functional recovery may be possible without remyelination if conduction along existing dysfunctional axons can be improved. They used a potassium-channel blocker called 4-aminopyridine to enhance the flow of nerve impulses, allowing axons to transmit electrical information past demyelinated zones (Blight, 1989; Waxman, 1993). Some patients treated with 4-aminopyridine had encouraging improvement in aspects of sensory or motor function (Hansebout et al., 1993; Hayes et al., 1993, 1994).

Also, rats that sustained a lesion of the left corticospinal tract at the level of the brainstem were treated with IN-1. This antibody treatment improved movements of the forepaw (movements requiring corticospinal function) even though only a small fraction of the transected fibres regenerated. Recovery was probably attained by compensatory sprouting and reinnervation of denervated targets by unharmed fibre systems, a phenomenon not observed in untreated rats (Z'Graggen et al., 1998; Raineteau et al., 1999). Many other functions, such as gait or breathing, are partially controlled at the level of the spinal cord via central pattern generators. Recovery of limited supraspinal input is required to improve complex functions such as gait.

Rehabilitative strategies for rebuilding function

In addition to the new directions in pharmacologic, genetic, and transplantation research, there is important progress in clinical rehabilitation (for review see Sadowsky et al., 2002). For example, surgical reconstruction can provide important gains in function. Procedures include functional tendon transfers, peripheral nerve transplantation, and nerve splitting to reactive previously paralysed muscles. Functional electrical stimulation (FES) also has achieved considerable success and received FDA approval. It uses sophisticated electronics to activate intact but distant nerves, which then can regain control of muscles rendered useless by spinal cord injury. For example, FES can harness shoulder movements to move a paralysed hand (Fig. 47.6) (Freehand System; http://www.neurocontrol.com) or regain bowel and bladder control (Vocare System; http://www.neurocontrol.com; for review see Sadowsky et al., 2002). An FES system similar to the Freehand system can restore some simple functions to the legs, such as initiating standing to assist in transfers. Simpler FES systems restore diaphragmatic breathing by pacing the phrenic nerve, and they can aid coughing in patients whose respiration is impaired.

Additional research is altering the scope of rehabilitation by modifying neuronal circuitry. Several groups have shown that a distal region of the spinal cord that has been disconnected from the brain by injury is capable of learning and that early gait training may help promote walking abilities in a subset of individuals with spinal cord injury (Lovely et al., 1986; Barbeau & Rossignol, 1987; Wernig & Muller, 1992; for review see Barbeau et al., 1999). The central pattern generators can produce rhythmic, oscillating activity of limb flexor and extensor muscle groups without supraspinal or afferent input, and the molecular mechanisms that contribute to this phenomenon are being unravelled (Grillner et al., 1998; Barbeau et al., 1999). Gait patterns can be elicited by tapping into the central pattern generators via descending input and by sensory feedback. Such rehabilitative treatments may accomplish more than simple training; they may enhance regeneration. Taken together, studies of CNS development and regeneration suggest that optimal levels of patterned

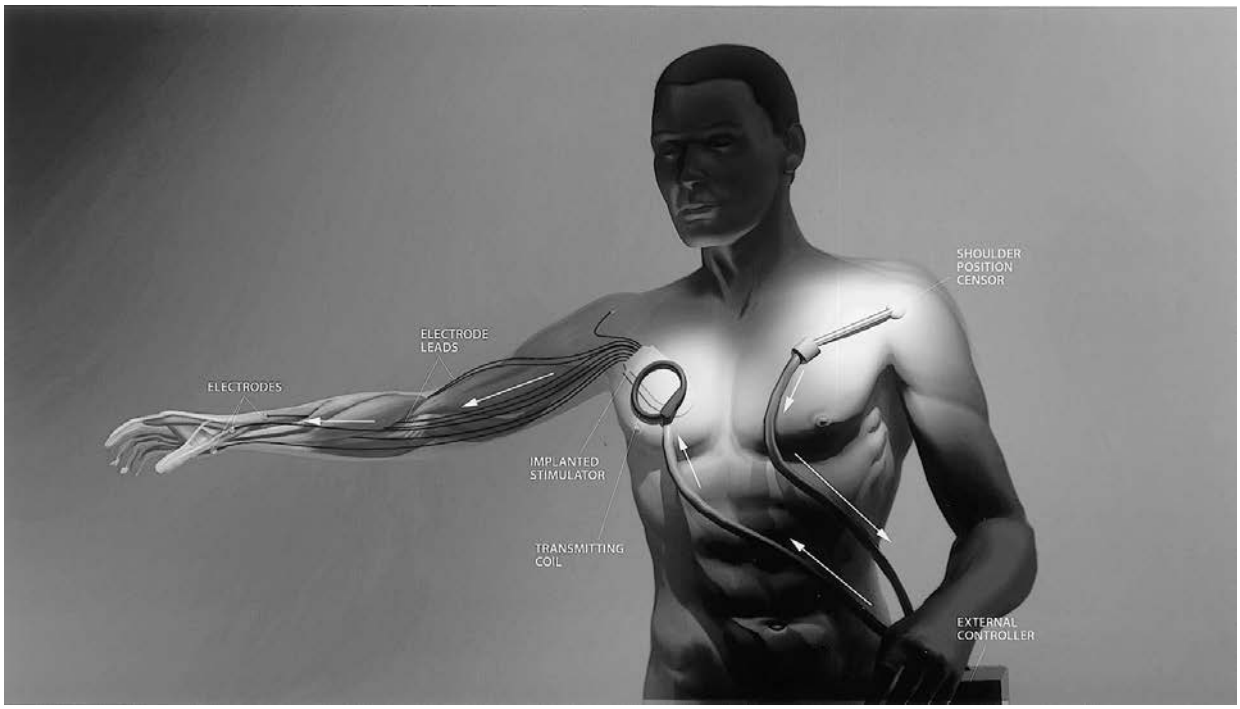

Fig. 47.6. The Freehand System is approved by the FDA for restoration of hand function in spinal cord injury. Particular movements by the opposite shoulder activate a detector that sends signals to an external control unit. That unit, in turn, relays the signals to an implanted transmitting coil connected to wires that terminate on selected arm and hand muscles. Shoulder movements then provide two types of hand function important for grasping a fork or a cup. (Reproduced with permission from *Scientific American* (McDonald et al., 1999).)

neural activity are important for many aspects of regeneration, including remyelination, new synapse formation, and the birth and survival of new progenitor cells. The enhanced functional recovery observed in the recent constraint-induced, forced-use stroke studies may represent such activity-dependent regeneration (Wolf et al., 1989; Miltner et al., 1999; van der Lee et al., 1999).

Development of systems that reduce environmental barriers to mobility and environmental control also is making major headway. For example, Johnson and Johnson recently developed a multicomputer-controlled wheelchair capable of ascending and descending stairs; it may be introduced as early as 2001. Continued progress in clinical rehabilitation will help maximize the benefits attained through advances in protective and regenerative drug therapies.

Acknowledgements

The author would like to thank Dennis Choi, MD, PhD and the members of the Christopher Reeves Paralysis Foundation Research Consortium for enlightening me to the field of spinal cord injury and for help in formulating many of the concepts that I have presented in this manuscript. I also thank Dr Cristina Sadowsky and Oksana Volshteyn for important comments on the manuscript. This work was supported by National Institute of Health grants NS01931, NS37927, NS40520, National Football Leagues, and the Keck Foundation.

An etiological classification of myelopathies yields an extensive list of diverse conditions (Table 48.1). In clinical practice, myelopathies are classified into spinal cord syndromes, based on patterns of neurological symptoms and signs, which identify the anatomical location and distribution of spinal cord pathology. The time course of symptoms is useful in distinguishing between different etiologies. Vascular lesions generally present with acute onset or rapid progression of symptoms. Inflammatory disease evolves in a subacute manner and may fluctuate over days or weeks. Compressive lesions also may present with a subacute onset and generally have a progressive course. Degenerative myelopathies are usually slowly progressive over months or years. The evolution and type of spinal cord syndrome suggest certain diagnostic possibilities and guide appropriate investigation.

Symptoms and signs of spinal cord disease

Motor symptoms and signs

The clinical presentation of an evolving myelopathy often is precipitated by limb weakness and spasticity due to corticospinal tract involvement. Arm and leg weakness suggests a cervical cord lesion. A paraparesis, with leg weakness or walking difficulty alone, suggests a lesion of the thoracic spinal cord or below. Progressive cervical cord lesions may evolve in a sequence, beginning with weakness of the arm ipsilateral to the lesion, followed by weakness of the ipsilateral then contralateral leg, and finally the contralateral arm.

Exacerbation of symptoms by exercise, or during increases in body temperature (hot weather or a hot bath) suggests demyelination, but may also occur in dural arteriovenous malformations of the spinal cord.

Motor signs of spinal cord disease reflect involvement of the long tracts of the spinal cord with increased muscle tone, brisk tendon reflexes, extensor plantar responses and weakness of hip and knee flexion and ankle dorsiflexion. Involvement of the anterior horn cells or anterior (motor) spinal nerve roots produces additional lower motor neuron signs of segmental wasting and weakness (Table 48.2).

Sensory symptoms and signs

Back pain

Back pain is often an early complaint of a myelopathy, preceding any motor symptoms. The site of pain may localize the level of a focal structural lesion such as a spinal epidural abscess, vertebral body collapse or intervertebral disc prolapse. Dull, poorly localized backache is common in intrinsic spinal lesions but is of little localizing or diagnostic value. An increase in pain when coughing and straining or exacerbation of pain with movement suggests an extramedullary (extradural) compressive lesion. Nocturnal back pain when recumbent occurs in extradural spinal lesions such as a thoracic meningioma or a benign spinal nerve root sheath tumour (schwannoma/neurofibroma). Severe thoracic or interscapular pain may be the presenting feature of inflammatory transverse myelitis.

Radicular symptoms and signs

Compression of posterior spinal roots by extrinsic spinal cord lesions or infiltration of the posterior root entry zone by intrinsic cord lesions, causes radicular pains which radiate along the affected dermatome, localizing the level of spinal pathology (Fig. 48.1). Radicular pains are typically sharp or knife-like and accompanied by cutaneous burning dysesthesia or hyperesthesia over the affected skin. Thoracic sensory root involvement can produce constricting chest or

Trauma
Vascular
Anterior spinal artery thrombosis
Spinal arteriovenous malformation
Dural arteriovenous malformation
Epidural hematoma
Hematomyelia
Arteritis (polyarteritis nodosa, systemic lupus erythematosus)
Inflammatory
Idiopathic transverse myelitis
Multiple sclerosis, Devic's disease
Postinfectious encephalomyelitis
Idiopathic necrotic myelopathy
Infectious
Neurotropic viruses
Herpes zoster, Herpes simplex, Polio
Coxsackie, echovirus, cytomegalovirus, Epstein–Barr
Retrovirus myelopathies
Human immunodeficiency virus (HIV) vacuolar myelopathy
Human T-lymphotrophic virus type I (HTLV I) tropical myelopathies
Mycoplasma myelopathy
Spinal epidural abscess
Syphilitic meningomyelitis
Tuberculosis
Osteitis (Pott's disease)
Radiculomyelitis
Schistosoma myelopathy
Granulomatous
Sarcoidosis
Neoplastic
Primary
Intramedullary – astrocytoma, ependymoma
Extramedullary – neurofibroma, meningioma
Secondary
Intramedullary metastasis (rare)
Extradural metastasis
Contiguous spread – paravertebral neuroblastoma, lymphoma
Paraneoplastic
Necrotic myelopathy
Myeloradiculoneuropathy
Degenerative
Motor neuron disease
Vertebral disease with myelopathy
Cervical spondylotic myelopathy
Intervertebral disc prolapse
Rheumatoid arthritis (atlantoaxial subluxation)
Psoriatic arthropathy
Achondroplasia
Mucopolysaccharidoses
Paget's disease
Congenital
Spinal dysraphism:
Spina bifida
Diastematomyelia
Syringomyelia
Hereditary
Hereditary spastic paraplegia
Friedreich's ataxia
Spinal muscular atrophy
Nutritional
Malabsorption syndromes with myelopathy
Vitamin B12 deficiency (subacute combined degeneration)
Vitamin E deficiency (Bassen–Kornzweig disease)
Toxins
Tropical spastic paraparesis (such as cassava)
Lathyrism (chick pea – *Lathyrus sativa*)
Miscellaneous
Caisson disease (decompression myelopathy in divers)
Myelopathy of systemic disease (liver failure)
Radiation myelopathy

Table 48.3. Segmental innervation of muscles

tract symptoms and signs early in the illness while root involvement is unusual and occurs late. In contrast to the severity of radicular pain, examination may reveal only subtle sensory loss in radicular lesions. Depression or absence of a tendon or cutaneous reflex may also be a valuable sign of a radicular sensory lesion (Table 48.3).

Sensory tract symptoms and signs

Paresthesiae (tingling, 'pins and needles') and loss of sensation are common in diseases of the long spinal sensory tracts. The distribution and extent of sensory tract symptoms depend on the site and size of the lesion. The trunk is frequently involved and is an important clinical clue to a sensory tract lesion. In progressive myelopathies, a sensory tract disturbance may evolve, ascending from the legs onto the trunk, or decending down the trunk to the legs. The pattern of spread occurs as the lesion enlarges and encroaches on adjacent laminated sensory fibres in the sensory tracts (Fig. 48.2). The combination of trunkal, upper and lower limb sensory symptoms indicates cervical cord involvement. Leg and trunk symptoms alone point towards thoracic or lumbar cord involvement.

Spinothalamic tract symptoms and signs

Cutaneous dysesthesia (burning, prickling, itching), abnormal warm or cold sensations, hyperesthesia (enhanced sensitivity to minor or trivial sensory stimuli) and hyperpathia are characteristic of a spinothalamic tract sensory disturbance. Spontaneous deep, poorly localized pain may be felt in areas of sensory loss (anaesthesia dolorosa). The patient may be unaware of the sensory deficit and sustain burns, accidental soft tissue injury or bony damage (Charcot's

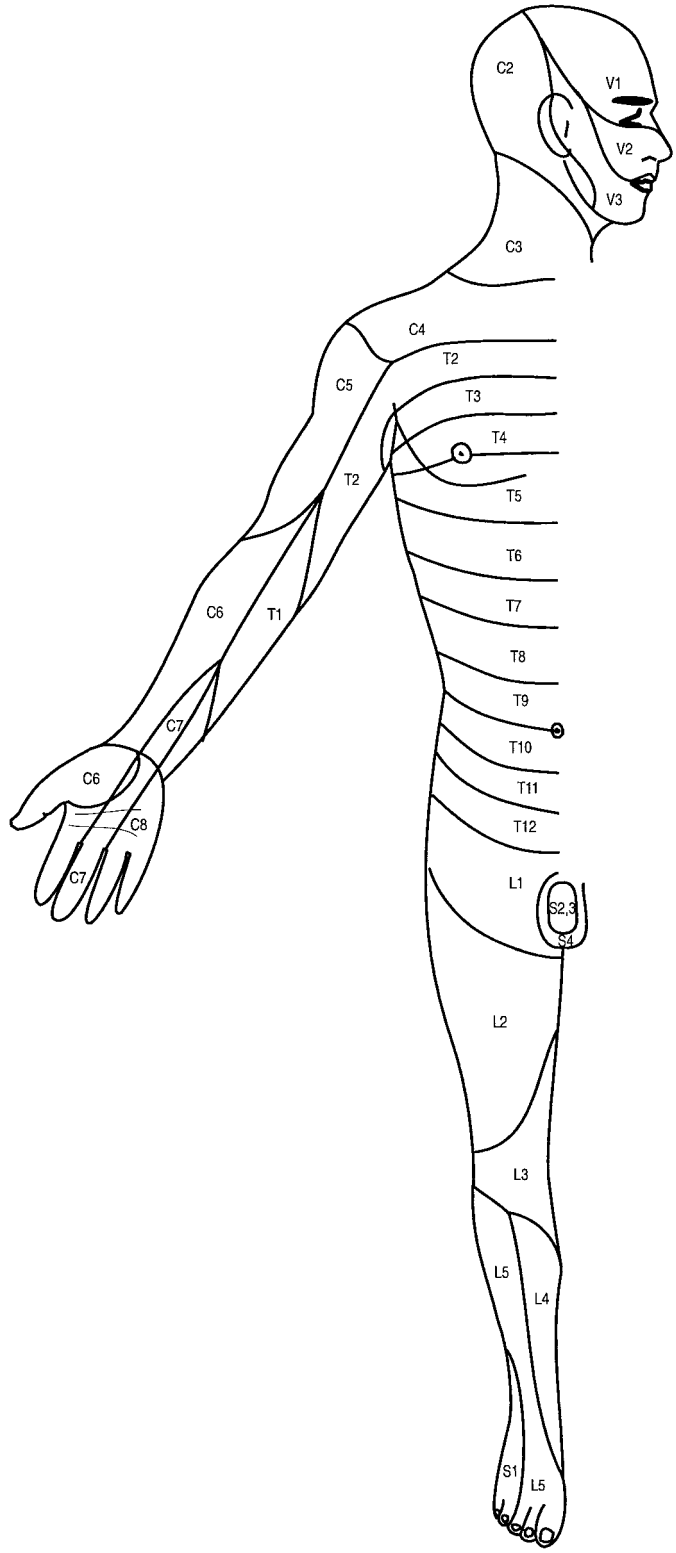

Fig. 48.1. Distribution of dermatomes on the anterior surface of the body.

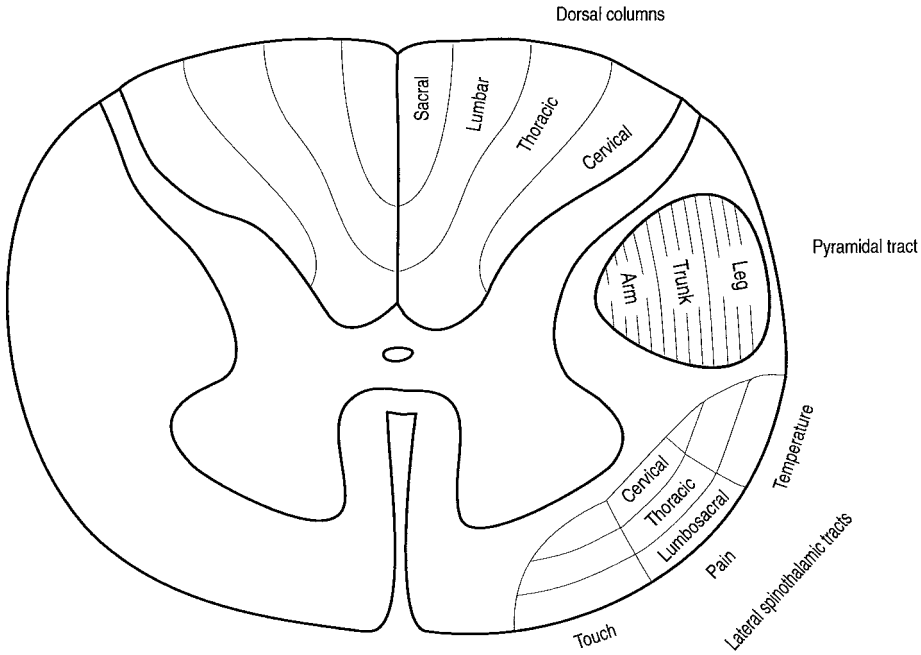

Fig. 48.2. Cross section of the cervical spinal cord demonstrating the lamination of the long sensory and motor tracts.

joints) in areas of impaired pain and temperature perception.

A lateral spinothalamic tract lesion results in contralateral pain and temperature loss (dissociated), sensory loss beginning two or three segments below the lesion. The upper limit of a spinothalamic sensory loss is often marked by a rim of hyperesthesia (Fig. 48.3). Pain and temperature fibres decussate shortly after entry into the spinal cord and ascend in the spinothalamic tract. A discrete central cord lesion may therefore only interrupt sensation from a few adjacent segments, producing a suspended, dissociated cape or breastplate sensory loss (Fig. 48.3). Lamination of the spinothalamic tract fibres leads to sparing of sacral sensation in intramedullary lesions (sacral sparing) and sensory levels that can be well below the actual lesion (Fig. 48.2). Accordingly, a spinothalamic sensory level can be misleading in assessing the site of a spinal lesion. The pattern of sensory loss also does not distinguish between intramedullary and extramedullary lesions. The precise lesion level is best obtained from magnetic resonance imaging of the whole spinal cord.

Posterior column symptoms and signs

Posterior column lesions give rise to paresthesiae and numbness often accompanied by sensations of limb swelling, constricting bands around the limbs and trunk or a sensation that a limb is 'encased in plaster'. Discrete lesions of the laminated dorsal column fibres may affect sensation in isolated body segments at the level of the lesion or several segments distal to the level of the lesion (Fig. 48.2). For example, dorsal column lesions in the cervical cord can lead to bilateral symmetrical loss of discriminatory sensation in the hands or tight bands around a leg or the trunk. Loss of proprioception (deafferentation) results in clumsiness of hand or foot movement (sensory ataxia), that may be misinterpreted as weakness. A characteristic symptom of dorsal column lesions is 'electric' paresthesiae radiating down the back, induced by neck flexion (L'hermitte's phenomenon).

Sphincters

Urinary retention and constipation may precede the onset of overt paralysis in a spinal cord syndrome, particularly when the conus medullaris or cauda equina are involved. Sphincter involvement is an early feature in intrinsic or intramedullary spinal lesions and a late feature in extrinsic compression of the spinal cord, after the appearance of motor symptoms.

Patterns of spinal cord syndromes

In lesions of the thoracic and cervical spinal cord, certain patterns of abnormality are well recognized (Fig. 48.3).

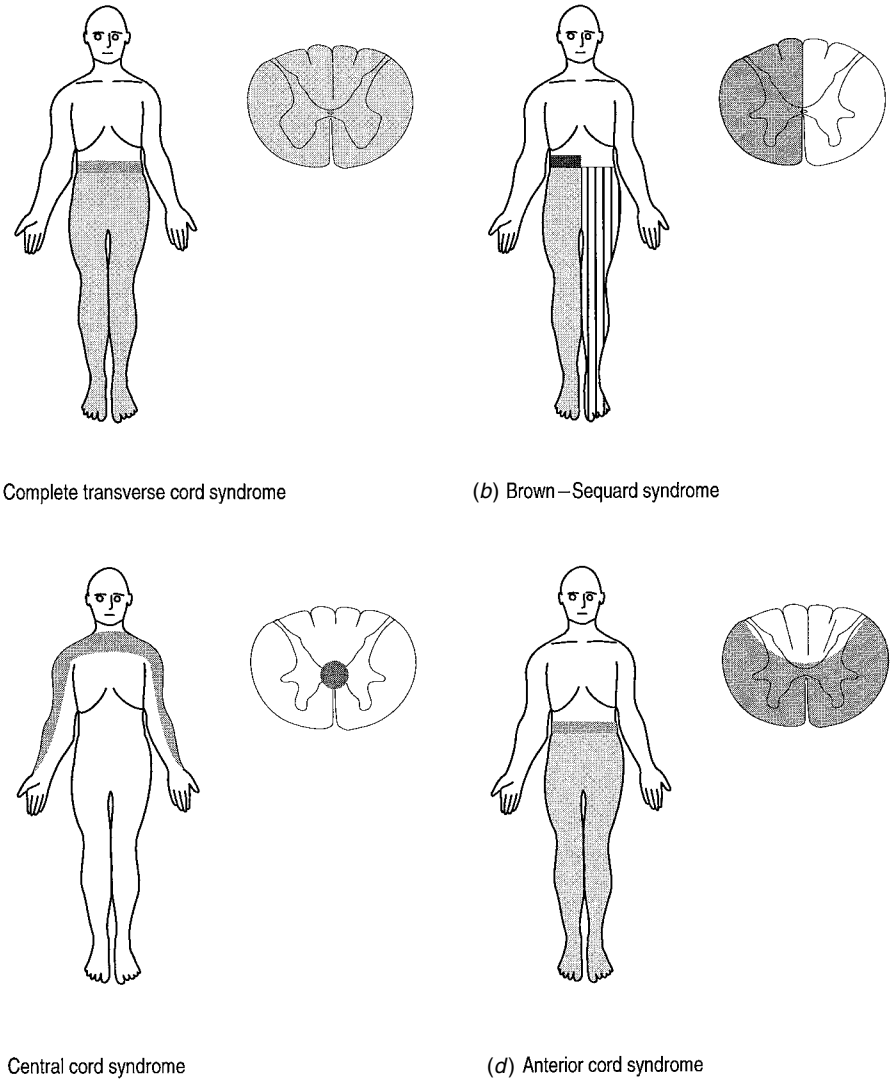

Fig. 48.3. Patterns of spinal cord disease. (*a*) Complete transection of the spinal cord produces paralysis and anesthesia below the level of the lesion. There is often a rim of hyperesthesia at the upper level of the sensory loss. (*b*) In a Brown–Sequard or hemicord syndrome, upper motor neurone signs including weakness and dorsal column signs are found below the lesion on the same side, and there is a contralateral loss of spinothalamic sensory modalities (vertical stripes). Again, there may be a rim of hyperesthesia on the side of the spinal lesion. (*c*) A central cord syndrome interrupts decussating spinothalamic fibres over a few spinal segments and produces a suspended dissociated sensory loss. In this example, C4, 5, 6 dermatomes are affected. (*d*) An anterior cord syndrome produces upper motor neurone signs below the level of the lesion with impaired spinothalamic sensation. A rim of hyperesthesia at the upper level of the spinothalamic sensory level is also shown. Dorsal column function is spared. Lower motor neuron signs may also be present if the cervical or lumbar cord is affected.

Hemicord (Brown–Séquard) syndrome

A unilateral lesion of the spinal cord results in a contralateral loss of spinothalamic sensation (pain and temperature), ipsilateral weakness with upper motor neuron signs, and ipsilateral dorsal column (proprioception) sensory loss (Brown–Séquard syndrome). Light touch is preserved. The syndrome may be partial or complete. Demyelination, knife or bullet injuries, and cord compression are common causes.

Anterior cord syndromes

The anterior cord syndrome consists of paralysis with upper and lower motor neuron signs, a bilateral spinothalamic (pain and temperature) sensory loss and sphincter paralysis. Posterior column sensory modalities are spared. Ischemia in the territory of the anterior spinal artery is the commonest cause.

Central (cervical) cord syndromes

A central cervical cord syndrome produces a combination of lower motor neuron signs of muscle wasting and weakness and depressed or absent tendon reflexes in the arms, a paraparesis and a suspended dissociated sensory loss over the arms and trunk. Acute central cervical cord lesions produce bilateral arm weakness, pain and hyperpathia. Rarely, central cord lesions may result in segmental muscle rigidity and spasms. Central cord lesions are caused by flexion–extension spinal trauma, neoplasms, watershed (hypotensive) cord ischemia and syringomyelia.

Radiculomyelopathy syndromes

Radiculomyelopathies present two broad clinical scenarios. The first comprises a sensory or motor radicular lesion at the upper level of an extrinsic compressive or intrinsic infiltrative myelopathy. Segmental amyotrophy or sensory radiculopathy are evident at the level of the lesion and upper motor neuron and sensory tract signs are found below. In the second, multiple spinal levels are involved and a combination of upper and lower motor neuron signs and sensory root and tract signs are evident. The common causes of radiculomyelopathies are listed in Table 48.4.

Spinal shock

Segmental reflex activity is abolished below the level of an acute spinal lesion (spinal shock) for 1 to 6 weeks after the injury. Areflexic quadriplegia in cervical cord lesions or paraplegia in thoracic cord lesions is accompanied by abnormal autonomic control below the lesion, with loss of vasomotor tone, profuse sweating and piloerection. Return of spinal reflex activity is marked by the appearance of upper motor neuron signs, exaggerated tendon reflexes and enhanced cutaneous flexor reflexes, which become the dominant physical signs of a chronic spinal cord lesion. Minor cutaneous stimuli may elicit flexor spasms, reflex defecation or micturition and profuse sweating.

Table 48.4. Causes of radiculomyelopathy classified according to whether one or multiple spinal levels are involved

Single level	
Acute transverse myelitis	
Vascular	Spinal cord infarction (anterior spinal artery thrombosis)
	Spinal arteriovenous malformation
Neoplastic	Primary spinal tumour
	Extradural metastatic carcinoma
	Carcinomatous meningitis
Infective	Spinal epidural abscess
Multiple levels	
Cervical and lumbar spondylosis	
Necrotic myelopathy	
Chronic meningitis (infectious or granulomatous)	
Spinal arachnoiditis	
Neoplastic	Carcinomatous or lymphomatous meningitis
Paraneoplastic	Carcinomatous neuromyopathy

Specific spinal cord syndromes

Foramen magnum lesions

A slowly evolving asymmetric quadriparesis, lower cranial nerve (accesssory and hypoglossal) palsies, neck stiffness, abnormal posturing of the neck, a Horner's syndrome and subtle sensory changes occur in foramen magnum lesions and may escape detection in the early stages. Compression of the upper cervical sensory roots and distortion of the spinal cord produce neck and occipital pain in the C2–4 dermatomes, sensory impairment in the first division of the trigeminal nerve and contralateral spinothalamic sensory loss. Downbeat nystagmus is characteristic of lesions at this site. In addition to an asymmetric quadriparesis, high cervical lesions may produce lower motor neuron signs of wasting and weakness in intrinsic hand muscles, due to venous stasis with ischemia in the distal

C8–T1 spinal segments (Stark et al., 1981). Phrenic nerve involvement may interfere with diaphragm function and ventilation. Causes include a benign nerve root sheath tumour (schwannoma/neurofibroma), anterior atlantoaxial subluxation in rheumatoid arthritis and psoriatic arthropathy, achondroplasia and the mucopolysaccharidoses.

Cervical spinal cord lesions

Lesions of the cervical spinal cord produce a myeloradiculopathy with a combination of upper and lower motor neuron signs in the arms, a spastic paraparesis, sensory loss in the arms and sensory tract signs over the trunk and lower limbs. Clinical guides to the level of the lesion include the highest motor and sensory segments affected and lower motor neuron signs (muscle wasting, weakness, and fasciculation) (Table 48.2). The pattern of muscle tone and tendon reflex change in the arms (Table 48.3) is determined by the level of the lesion. Lower motor neuron signs (muscle wasting, weakness), depression or absence of tendon reflexes and sensory loss will be evident at the level of the lesion while upper motor neurone signs (increased muscle tone, brisk tendon reflexes) will be evident below the lesion.

Sensory loss in cervical lesions may be radicular and limited to a dermatome with loss of light touch, or extend over several segments in a spinothalamic or posterior column tract distribution, with preservation of light touch.

Thoracic spinal cord lesions

The upper border of a thoracic spinothalamic sensory level lies two or three segments below the approximate level of the thoracic lesion. Radicular pain provides a more accurate thoracic level, but radicular sensory loss may be difficult to elicit. In addition to paraplegia, thoracic cord lesions may produce trunkal weakness due to either upper or lower motor neuron involvement. Signs of abdominal weakness include loss of abdominal muscle tone with paradoxical protrusion of the abdominal wall during coughing, exhalation and attempted trunkal flexion (when sitting up). Thoracic cord lesions below T10 produce differential weakness of lower abdominal muscles so that on sitting up or lifting the head when supine, contraction of the upper recti (innervated by T7–T10) will be unopposed by the paralysed lower recti (T10–T12) resulting in an upward movement of the umbilicus (Beevor's sign). Superficial abdominal reflexes are abolished below the level of the spinal lesion.

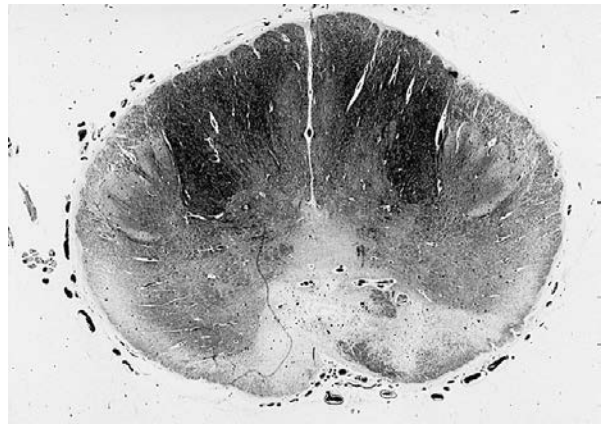

Fig. 48.4. Old cystic ischemic necrosis C4 cord in the territory of the anterior spinal artery (Weil stain for myelin ×7 magnification).

Conus medullaris and cauda equina lesions

Conus lesions result in early and prominent sphincter impairment (urinary retention and constipation), sacral sensory loss affecting lower perineal segments (S3–S5) more than leg segments (L5–S2) and impotence. Leg muscle weakness is variable in conus lesions and may be mild unless the lesion extends higher in the lumbar cord. An extensor plantar response implies the lesion affects the spinal cord above the L5 segment (innervating the extensor digitorum longus muscle). Reflex change will be determined by the level of the lesion.

An asymmetric, flaccid, areflexic paralysis with radicular sensory loss, urinary or fecal incontinence and loss of anal tone points towards predominant involvement of the cauda equina. Muscle wasting with fasciculation indicates a chronic lesion.

Causes of myelopathy

Vascular myelopathies

Spinal cord infarction

Anterior spinal artery occlusion

Infarction of the spinal cord typically involves the territory of the anterior spinal artery, which supplies the anterior two-thirds of the spinal cord and results in an anterior cord syndrome with paraplegia, a mid-thoracic spinothalamic sensory level and sphincter paralysis (Fig. 48.4). A mid-thoracic level (T4–T6) is most common, as it lies in

Fig. 48.5. Recent ischemic necrosis of central cord affecting central grey matter and surrounding white matter of T5 spinal cord secondary to prolonged hypotension. Only a peripheral rim of myelin is preserved (Weil stain for myelin ×8 magnification).

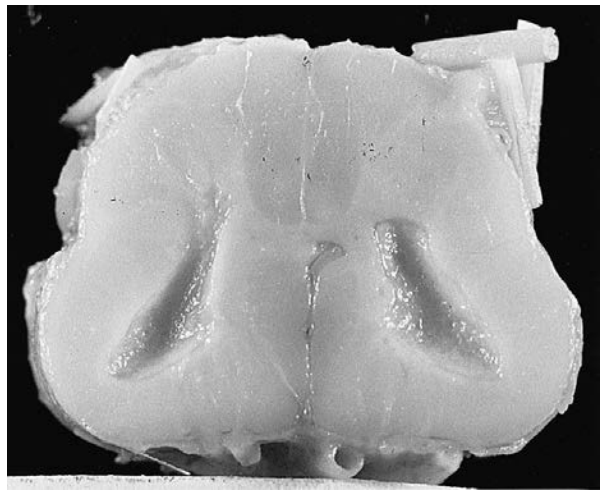

Fig. 48.6. Old central spinal cord infarction with cystic necrosis of anterior grey matter (×8 magnification).

the critical rostrocaudal watershed zone of the spinal circulation which is derived from segmental arteries between T10 and L3 (the artery of Adamkiewicz) and descending branches from the vertebral and ascending cervical arteries. The vascular pathology is usually thromboembolic occlusion of spinal segmental arteries, such as the artery of Adamkiewicz, or aortic disease (dissection, clamping in surgery, severe atheroma). Primary atheromatous occlusion of the anterior spinal artery itself is uncommon, but the vessel may be occluded by vasculitis or systemic embolism.

Segmental artery occlusion

Occlusion of cervical segmental arteries causing infarction of the cervical cord and quadriplegia is rare. Lumbosacral radicular artery thromboembolism (Anderson & Willoughby, 1987) and compression of lumbosacral radicular arteries by a prolapsed intervertebral disc (Lazorthes, 1972) may cause infarction of the conus medullaris.

Central cord infarction

Profound hypotension, aortic dissection or surgical clamping of the aorta may lead to painless watershed infarction of the central grey matter of the low thoracic and lumbosacral spinal cord (Blumbergs & Byrne, 1980) (Fig. 48.5). This selective damage produces paraparesis, patchy upper and lower motor neuron signs in the legs, dissociated sensory loss, and sphincter paralysis. Central cord ischemia may involve the interneurons in spinal grey matter (Fig. 48.6) leading to rigidity and myoclonus of

Fig. 48.7. Watershed ischemic necrosis of T3 spinal cord secondary to prolonged hypotension from a dissecting aortic aneurysm (Weil stain for myelin ×8 magnification).

spinal origin. Rarely, watershed infarction occurs at the boundary of the intrinsic anterior and posterior vascular territories of the mid thoracic spinal cord (Fig. 48.7).

Spinal vascular malformations

Intradural (especially intramedullary) spinal arteriovenous malformations present with the sudden onset of neck pain, limb weakness, radicular or tract sensory loss and sphincter disturbance due to spinal subarachnoid hemorrhage or hematomyelia. These malformations involve the cervical and thoracic spinal cord. Symptoms appear in the first and second decades (Rosenblum et al., 1987). In contrast, dural

Fig. 48.8. Magnetic resonance image of the cervical spinal cord in a 50-year-old woman who presented with an acute hematomyelia resulting in transient quadriplegia with a sensory level at C4 showing a cavernous angioma (cavernoma).

arteriovenous fistulae occur in the low thoracic and lumbar cord, most commonly in elderly men. A slowly progressive paraparesis with upper and lower motor neuron signs, sensory symptoms including pain and sphincter disturbances evolve slowly over months to years (Logue, 1979). These deficits are caused by prolonged venous hypertension (Kendall & Logue, 1977). Symptoms may be exacerbated by exercise. A spinal cavernous angioma may present with an acute cord syndrome due to hemorrhage and hematomyelia (Fig. 48.8) or a slowly progressive myelopathy secondary to the intraspinal mass lesion (Fig. 48.9) (Deutsch et al., 2000). Neurocutaneous manifestations, such as vertebral anomalies, scoliosis, cutaneous angiomata and spinal dysraphism may accompany spinal vascular malformations (Aminoff & Logue, 1974).

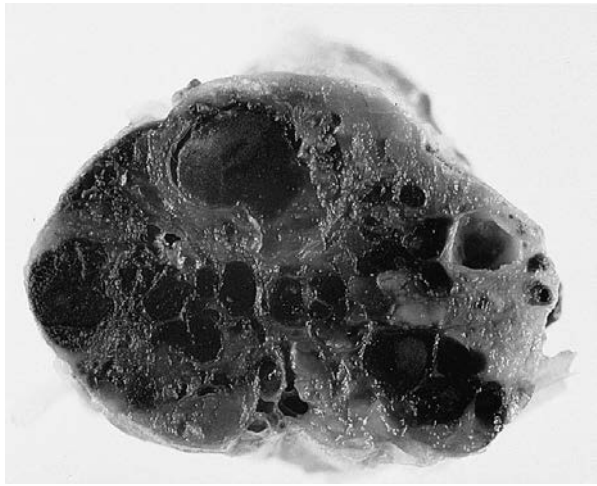

Fig. 48.9. Cavernous angioma of T5 spinal cord.

Inflammatory myelopathies – acute transverse myelitis

Acute or subacute transverse myelitis due to inflammatory demyelination may occur in multiple sclerosis or in a monophasic postinfectious encephalomyelitis. Symptoms include paresthesiae ascending from the legs onto the trunk and a thoracic sensory level (both cervical and thoracic cord can be affected), paraparesis or quadriparesis and sphincter disturbance. Ropper and Poskanzer (1978) identified three groups of acute transverse myelitis. In the first, ascending sensory symptoms evolve over 1–14 days, followed by good recovery. The second, characterized by an acute onset and rapid progression with back pain and paraplegia, had a poor outcome. A third group present with the gradual onset and stuttering progression of symptoms over weeks and have a similar outcome to the first group. This syndrome appears to represent a distinct entity. Cerebrospinal fluid may show a lymphocytic pleocytosis with raised protein but not oligoclonal bands. Magnetic resonance imaging of the spinal cord reveals extensive or confluent high signal lesions extending over several segments (Fig. 48.10). Less than 10% of cases progress to develop multiple sclerosis. This number may be even lower if cases with cerebrospinal fluid oligoclonal bands and cerebral white matter lesions on imaging, both of which favour a diagnosis of multiple sclerosis, are excluded. Acute myelopathies in multiple sclerosis tend to be of gradual evolution with partial, asymmetric spinal cord syndromes (Miller et al., 1987).

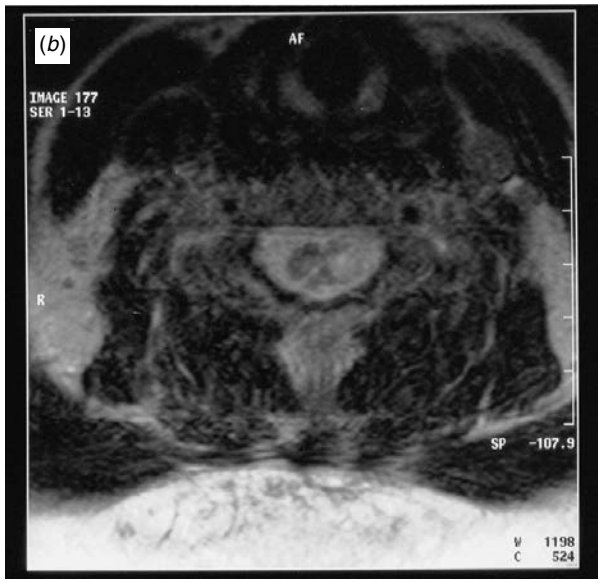

Fig. 48.10. Magnetic resonance image of the cervical spinal cord in a 53-year-old woman presenting with a left Brown–Sequard syndrome and an elongated area of high signal in the central and right side of the cervical spinal cord. The transverse view was taken at the level of C5.

Infectious myelopathies

A wide range of infections are associated with acute myelopathy, either by direct invasion, postinfectious demyelination or abscess formation. Systemic bacterial infections may be complicated by an epidural or extradural abscess. These present with back and root pain, fever and local tenderness which precedes the development of spinal cord compression by a few days. Tuberculous osteitis destroys thoracic vertebral bodies and intervertebral discs over a period of months leading to a progressive kyphosis, spinal cord compression and paraplegia (Pott's paraplegia). Schistosoma myelopathy involving the conus medullaris progresses to paraplegia over days to weeks (Scrimgeour & Gajdusek, 1985). Mycoplasma infections may be complicated by meningoencephalitis and transverse myelopathy.

Several viruses (coxsackie, echovirus, cytomegalovirus, Epstein–Barr) have also been reported to produce transverse myelitis. Neurotropic viruses (herpes zoster, poliomyelitis, herpes simplex) affect predominantly the grey matter of the spinal cord with anterior horn cell loss, resulting in segmental lower motor neuron signs of muscle fasciculation, wasting and weakness. A vacuolar myelopathy, affecting white matter tracts of the thoracic cord, particularly the posterior columns and corticospinal tract, occurs in up to 20% of patients with the acquired immune deficiency syndrome (AIDS) and HIV (human immunodeficiency virus) infection (Petito et al., 1985). Pathological changes of myelin vacuolation sparing axons is found in 50% of cases of AIDS (Shepherd et al., 1999). Asymmetric limb weakness develops over several weeks followed by sensory signs and sphincter involvement. Tropical spastic paraparesis, or myelopathy associated with human T-lymphotropic virus type I (HTLV I) infection (Johnson, 1987) (HAM), is a common cause of paraparesis in tropical regions such as the Caribbean, and also Japan. Paraparesis evolves in a slow but progressive manner with upper motor neuron signs and prominent sphincter involvement. Upper limb reflexes are brisk but arm weakness is uncommon. Loss of vibration sense, peripheral sensory

impairment and depressed or absent ankle jerks suggesting a neuropathy are common. A thoracic sensory level may be observed in some cases and sensory symptoms may herald the onset of HAM. Pathologically, the spinal lesions are characterized by degeneration of myelin and axons in the anterolateral and posterior columns and an inflammatory process presumably directed against HTLV-1 infected T-lymphocytes (Izumo et al., 2000).

Myelopathy in neoplasia

Secondary extradural metastases from lung, breast or prostate carcinoma in vertebral bodies extend into the extradural space causing focal back pain, radicular pain and subsequently spinal cord compression, evolving over weeks to months. The thoracic cord is most commonly involved. Once spinal compression begins, paraplegia evolves over days with sphincter disturbances. Neoplastic destruction of vertebral bodies may lead to vertebral collapse, dislocation and increasing angular deformity further compromising cord function. A similar progressive myelopathy may accompany intramedullary spinal metastases, which are rarer than extradural metastases and not accompanied by vertebral body destruction.

Carcinomatous meningitis due to neoplastic infiltration of the leptomeninges presents with a subacute onset of lower motor neuron signs, absent tendon reflexes, extensor plantar responses, and a peripheral sensory loss (Olson et al., 1974). Pain and multifocal involvement of the central nervous system are additional clues to the diagnosis.

Primary spinal tumours, intramedullary ependymoma and astrocytoma, or extramedullary neurofibroma and meningioma evolve slowly over months and years. Symptoms are produced by internal disruption of the long tracts of the spinal cord or the development of syringomyelia in intramedullary tumours and spinal nerve root or spinal cord compression in extramedullary tumours.

Necrotizing myelopathies

A subacute necrotic myelopathy developing over weeks occurs as a rare paraneoplastic event (Mancall & Rosales, 1964), but also may appear as an isolated myelopathy in the absence of other systemic disease (Katz & Ropper, 2000). Sensory symptoms, including pain, are prominent early and may ascend from the lower limbs or descend down the trunk. Progression may occur in a stepwise manner. Upper and lower motor neuron signs are common. Imaging studies reveal cord swelling and cavitation. Spinal cord necrosis is evident on pathological examination (Fig. 48.11).

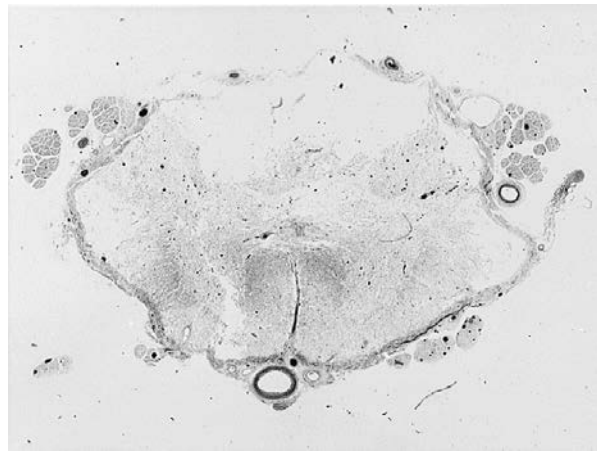

Fig. 48.11. T10 necrotic paraneoplastic myelopathy associated with renal cell carcinoma (Trichrome ×8 magnification).

Cervical spondyslosis and myelopathy

Degenerative cervical spondylosis with myelopathy is a common cause of cervical cord disease. The most frequently affected levels, in descending order of frequency are C5–C6, C6–C7, and C4–C5. The clinical picture is of a myeloradiculopathy. Wasting of intrinsic hand muscles rarely occurs in cervical spondylosis, since the levels commonly involved (C5–6, C6–7) are above the T1 spinal segment. Prominent hand wasting in association with a cervical cord syndrome suggests intrinsic spinal disease such as motor neuron disease or syringomyelia rather than cervical spondylosis. Sensory symptoms are often not prominent in cervical spondylosis and myelopathy. Pain and radicular sensory loss in the distribution of (C5, 6 or 7) dermatomes suggests a lateral cervical disc protrusion, though objective sensory loss may be subtle and less dramatic than symptoms. Reduced vibration and joint position sense in the feet reflect dorsal column involvement. Dorsal column involvement occasionally leads to loss of joint position sense and clumsy deafferented hands (Fig. 48.12). Spinothalamic involvement may manifest as a painful central cord syndrome or occasionally a distal symmetrical loss of pain and temperature mimicking a small fibre peripheral neuropathy.

Syringomyelia

The classical clinical presentation of syringomyelia is a progressive dissociated sensory loss involving pain and temperature, accompanied by loss of tendon reflexes, muscle wasting and weakness in one or both upper limbs,

Fig. 48.12. Magnetic resonance image of the cervical spinal cord in an 83-year-old woman with progressive sensory ataxia of the hands and a paraparesis showing multiple levels of spondylosis and marked canal stenosis at C3, 4, C4, 5 and C5, 6 with cord compression and distortion at these levels.

particularly the hands. Sensory loss over the limbs and trunk is 'suspended' in a cape, hemicape or breastplate distribution reflecting interruption of decussating spinothalamic fibres over a series of adjacent segments (Fig. 48.3). Deep aching neck and radicular pain are common. There may be a spastic paraparesis. Considerable variation occurs in the extent of these signs, depending on the diameter and length of the syrinx (Fig. 48.13). The advent of MRI has greatly improved the diagnosis of syringomyelia and increased recognition of variants (Fig. 48.14). Other features include soft tissue and bony damage secondary to loss of pain and temperature sensation with painless burns, thickening and discoloration of the skin, hyperhidrosis, arthropathy (Charcot's joints) and scoliosis. Occasionally, propioceptive loss is evident if the cavity encroaches on the posterior columns.

The cervical spinal cord is the commonest site for development of a syrinx. In many cases a craniocervical junction developmental defect, such as an Arnold Chiari malformation is present. A syrinx may develop in association with intraspinal tumours or follow significant spinal trauma. Post-traumatic syringomyelia may develop many years after spinal trauma, presenting with a painless deterioration in motor function and an ascending sensory level (Rossier et al., 1985).

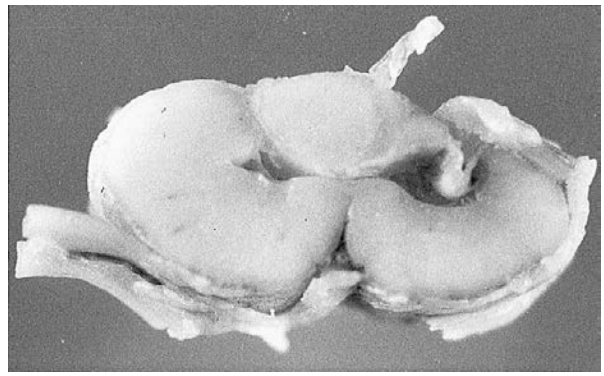

Fig. 48.13. Syringomyelia with the syrinx at C4 level involving the right lateral and dorsal white matter columns, right posterior horn of the central grey matter, base of the left dorsal white matter and adjacent left dorsal horn.

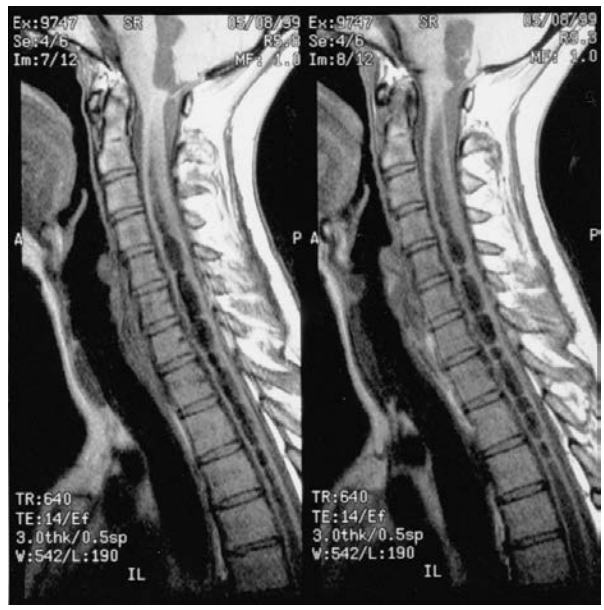

Fig. 48.14. Magnetic resonance image of the cervical spinal cord and craniocervical junction in a 32-year-old woman with loss of pain and temperature sensation and a deep burning discomfort in the C4–8 dermatomes of both arms and a mild spastic paraparesis, showing an extensive syrinx throughout the cervical spinal cord, extending into the brainstem above and the thoracic cord below.

Connective tissue disease

Myelopathy is a rare complication of connective tissue disease. Systemic lupus erythematosus may present with myelopathy. Sjogren's syndrome and mixed connective tissue disease also may be complicated by myelopathy. The presentation of myelopathy may take the form of acute transverse myelitis or evolve in a chronic progressive manner affecting predominantly the corticospinal tracts. MRI of the spinal cord may show patchy areas of increased signal or no abnormality. Pathological examination reveals microscopic perivascular inflammation, fibrinoid necrosis of arterioles and degeneration of white matter tracts. Necrotizing vasculitis affecting the anterior spinal artery and spinal subarachnoid hemorrhage have also been described.

Toxic myelopathies

Lathyrism, caused by a toxin derived from *Lathyrus sativa*, the chickling pea produces a spastic paraparesis in southern India and other tropical countries (Ludolph et al., 1987).

Nutritional deficiencies and myelopathy

Vitamin B12 deficiency and subacute combined degeneration of the cord

The myelopathy of subacute combined degeneration affects the posterior and lateral columns of the spinal cord. Neuropathy may also develop leading to a combination of upper motor neuron signs, depressed or absent ankle jerks and distal sensory impairment with prominent dorsal column sensory loss. Symptoms may begin in the upper limbs and include L'Hermitte's sign, indicating a predilection for cervical spinal cord involvement.

Increasingly recognized is the myeloneuropathy similar to subacute combined degeneration that results from prolonged exposure to nitrous oxide. Posterior and lateral columns are affected and accompanied by an axonal neuropathy and megaloblastic anemia. Nitrous oxide inhibits methionine synthetase mimicking the effect of vitamin B12 deficiency.

Radiation myelopathy

Inclusion of the spinal cord in the radiotherapy field when treatment involves radiation doses greater than 3, 500 rads predisposes to the development of radiation myelopathy. Myelopathy develops after an interval of 6 months or even years and progresses slowly over weeks to months. Initial symptoms may be sensory or a progressive quadriparesis culminating in a complete transverse cord syndrome (Fig. 48.15).

Fig. 48.15. Radiation necrosis of the C1 cord with swelling of the cord and loss of myelin (Weil stain for myelin ×5 magnification).

Decompression myelopathy

Myelopathy, presenting with predominantly sensory symptoms beginning within 6 hours of the last dive, is common in decompression sickness (Caisson disease).

Diseases of the vertebral column

Simon F. Farmer and Lucinda J. Carr

Department of Neurology, St Mary's Hospital, London, National Hospital for Neurology and Neurosurgery, London and Department of Neurology, Great Ormond Street Hospital for Children, London, UK

Abnormalities of the vertebral column

Embryology of the spine

Interpretation of congenital and acquired anomalies of the vertebral column is aided by an understanding of normal development. In early fetal life the ectodermal germ layer gives rise to the primitive neural tube. This normally closes by the end of the fourth intrauterine week; failure of this primary neurulation results in fusion defects such as anencephaly or spina bifida. By this time the primary brain vesicles are present, representing forebrain, midbrain and hindbrain. Mesoderm lies around the neural tube and by the end of the fifth intrauterine week will have completed segmentation into 42–44 recognizable somite pairs (occipital to coccygeal). Once established, the epithelioid cells of these somites rapidly transform and migrate towards the notochord where they differentiate into three distinct cell lines: sclerotomes (from which connective tissue, cartilage and bone are derived), myotomes (providing segmental muscle) and dermatomes (providing segmental skin). Chondrification of the sclerotomes leads to the development of ossification centres, with an anterior and posterior centre for each vertebral body and a pair for each arch. The process is largely complete by the end of the third month of fetal development. Disruption during these early stages accounts for many of the vertebral and craniocervical anomalies. There is increasing interest in the possible role of abnormal notochord signalling and Pax-1 gene expression in these segmentation defects (see for example, David et al., 1997). After the third month of gestation the vertebral column and dura lengthen more rapidly than the spinal cord resulting in regression of the cord tip, leaving the filum terminale below. By term the cord tip typically lies at the L2–3 interspace. Failure of normal cord ascent may lead to tethering of the spinal cord.

Idiopathic scoliosis

Scoliosis refers to a lateral deviation of the spine and is always abnormal. It may be classified on the basis of clinical examination into structural and non-structural forms. In a structural scoliosis there is a rotational component to the curve which is best seen on forward flexion when prominence of rib or loin musculature becomes apparent. This is not the case in non-structural scoliosis, where there is no rotational element. Non-structural scoliosis may be a marker of other pathology such as leg length discrepancy or muscle spasm but is rarely of clinical significance in itself. If associated with underlying neurological disease it may progress to a structural deformity.

Once a structural scoliosis is diagnosed, the severity and potential for progression must be assessed. Erect posteroanterior and lateral X-rays should be taken in a standardized manner so that serial films can be compared. The severity of the curve is given by the Cobb angle, which describes the angle created by the intersection of lines drawn across the end plates of the upper and lowermost vertebrae delineating the curve i.e those with the greatest opposing tilt as illustrated in Fig. 49.1. Angles $>20°$ in skeletally immature children demand particular vigilance; it is during periods of rapid growth that scoliosis may progress significantly, thus scoliosis presenting in younger children has a greater risk of progression. Progression in adults is less common, although underlying neuromuscular disease, pregnancy and osteoporosis pose increased risks.

The major causes of structural scoliosis are given in Table 49.1. The commonest type is idiopathic scoliosis which accounts for around 70% of all cases. The child is otherwise healthy and no underlying pathology is found. The prevalence of adolescent scoliosis, the commonest form, is approximately 4% of the population if mild cases are included (Dickens, 1997). The majority are right sided,

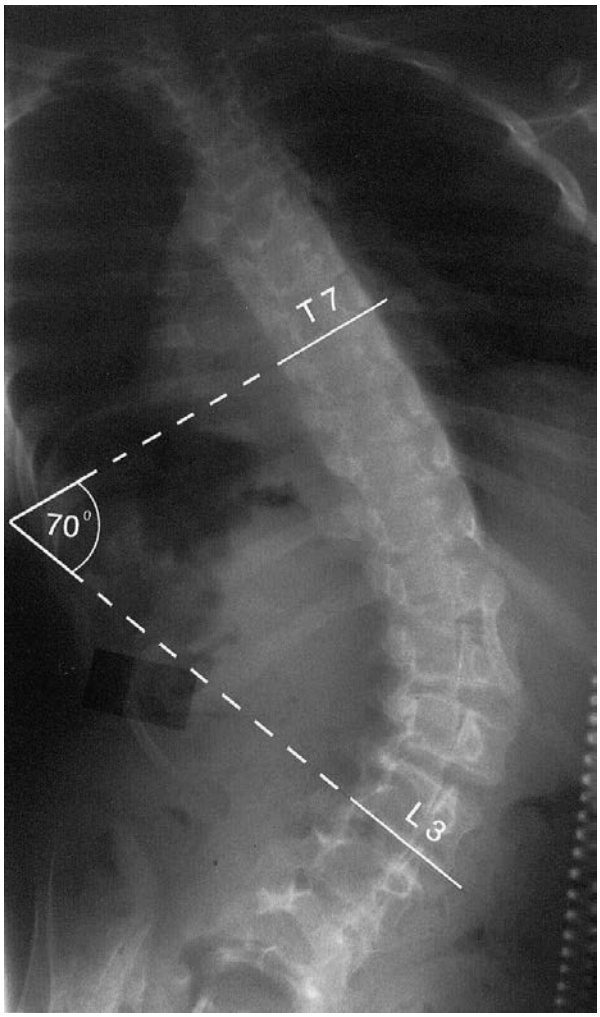

Fig. 49.1. Plain antero-posterior spine X-ray showing thoracolumbar scoliosis in an adolescent with a spino-cerebellar syndrome. The Cobb angle drawn between the apices of the curve measures 70 degrees.

Table 49.1. Causes of structural scoliosis

Idiopathic scoliosis
Infantile <3 years
Juvenile 3–10 years
Adolescent >10 years
Congenital scoliosis
Failure of vertebral segmentation and/or formation
Neuromuscular scoliosis
Neuropathic
Upper motoneuron, e.g. Cerebral palsy
Lower motoneuron, e.g. Spinomuscular atrophy, Poliomyelitis
Mixed, e.g. Myelomeningocoele and spinal dysraphism
Myopathic
Hereditary neuropathies and dysautonomias
Congential myopathies
Muscular dystrophies, e.g. Duchenne
Miscellaneous causes
Skeletal dysplasias
Marfan syndrome
Neurofibromatosis
Spinocerebellar degenerations including Freidrich's ataxia
Arthrogryposis
Rett's syndrome
Metabolic bone disease
Dystonia
Parkinson's disease and parkinsonian syndromes
Craniocervical junction anomalies especially if associated with syringomyelia
Spinal tumours/trauma/irradiation

thoracic and painless. An MRI scan is advised if features are atypical or neurological signs are present, for example a left-sided lumbar curve or absent abdominal reflexes, as these features may indicate underlying pathology such as spinal cord tumours or Chiari malformation. The infantile and juvenile forms of idiopathic scoliosis are uncommon.

The cause of idiopathic scoliosis is multifactorial and the development and progression of the scoliosis may have different mechanisms. There is often a positive family history of scoliosis, with girls eight times more likely than boys to require treatment (Dickens, 1997). The inheritance can be described by a dominant major gene diallele model (the gene is as yet unidentified) with incomplete penetrance (Axenovich et al., 1999). Progression of the curve is more common in thoracic or large curves (>35°) with skeletal maturity another important consideration. The consequences of severe idiopathic scoliosis are cosmetic deformity, cardiopulmonary compromise and back pain.

Congenital scoliosis

In congenital scoliosis the vertebrae are anomalous due either to a failure of natural segmentation, leading to asymmetric fusion, or to failure of formation, in which only part of the vertebra is formed. Often there is a combination of both pathologies. In congenital scoliosis there is a high incidence of associated anomalies. These include neuraxis anomalies in up to 40% of patients, renal and gastrointestinal tract abnormalities in around 20% and congenital heart defects in approximately 10% (McMaster & Ohtsukak, 1982). Sometimes the scoliosis is part of a syn-

dromic diagnosis such as in the Klippel–Feil and Noonan syndromes. Clinically the scoliosis may vary from a mild non-progressive deformity to a severe and rapidly progressive curve that compromises the spinal cord. There is often an associated kyphosis.

Neuromuscular scoliosis

Spinal deformity is common in many of the neuromuscular disorders. In the developed world cerebral palsy, spina bifida and Duchenne muscular dystrophy are the most common causes of neuromuscular scoliosis, although poliomyelitis is still an important cause in developing countries. Because of the underlying condition, the spinal curvature, in contrast to idiopathic scoliosis, generally presents earlier, is more extensive and is more likely to deteriorate through childhood and into adult life. Other systems are often already compromised; for example, there may be muscle imbalance, cardiopulmonary insufficiency, poor nutrition, insensate skin and osteoporosis. These problems may be further exacerbated by the physical and functional effects of the scoliosis itself. In addition, the scoliosis may adversely affect walking and seating and cause pain as the ribs abut the iliac crest. This is often compounded by coexisting pelvic obliquity, particularly in the non-ambulant patient.

Kyphosis and lordosis

The spine naturally shows some curvature in the anteroposterior plane, seen as a kyphosis in the thoracic region and lordosis at the lumbar spine. A normal lumbar lordosis shows full correction on forward flexion. Excessive lordosis may occur postlaminectomy, in the neuromuscular conditions, or when there is fixed flexion deformity at the hip.

A kyphosis $>40°$ is abnormal. It may be congenital, due to a lack of fusion of the vertebral bodies anteriorly or a lack of formation of one or more anterior bodies. Although less common than congenital scoliosis, it carries a more severe prognosis as a higher proportion of patients will develop progressive deformity and myelopathy particularly during the adolescent growth spurt (McMaster & Singh, 1999). Patients with anterior failure of vertebral body formation, who present with a sharp angle kyphosis, are at particular risk of rapid progression and spinal cord compression. Early arthrodesis is indicated in these cases. Schuermann's kyphosis is the most common form of acquired kyphosis, presenting in adolescents it is generally benign. Kyphosis only occasionally progresses once skeletal maturity is reached.

Miscellaneous causes of spinal deformity

A number of primary diseases of bone and connective tissue produce pathology of the spine and craniocervical junction. Those that present neurological problems are classified into four broad categories:

Osteopenic disorders

In these bone mineralization is reduced. These include endocrine diseases such as hyperparathyroidism, Cushing's disease, osteomalacia, primary osteoporosis and osteogenesis imperfecta.

Osteogenesis imperfecta (OI) is a heritable disorder of collagen that results in osteopenia and increased bone fragility. In the majority of patients mutations are found in the genes encoding the $\alpha 1$ and $\alpha 2$ collagen chains. These result in reduced amounts of collagen which is often structurally abnormal. To date, over 200 mutations have been described (Dalgleish, 1997); however, there is no close correlation between the molecular abnormalities and the clinical manifestations which are highly variable. Prenatal diagnosis is available for some forms of the disease. The Sillence classification delineates four major phenotypes on the basis of bone fragility, growth and the presence or absence of additional features such as blue sclerae, dentinogenesis imperfecta and presenile hearing loss (Sillence, 1981). Progressive skeletal deformity is a particular feature of OI type III and often requires orthopedic intervention. Basilar invagination is a rare but important complication of OI. This may be associated with ventral brainstem compression, hydromyelia and hydrocephalus. It generally presents in early adult life with progressive neurological symptoms and signs, the commonest being headache and lower cranial nerve dysfunction, particularly atypical trigeminal neuralgia. Other features include quadriparesis, ataxia and nystagmus (Sawin & Menezes, 1997). Trigeminal pain, if intractable, may require stereotactic surgery. The treatment of myelopathy involves ventral decompression and occipito-cervical fusion, with or without decompression of the foramen magnum (Lynch & Crockard, 1999).

Currently, there is much interest in the role of bisphosphonates in the management of OI. There is evidence that these drugs reduce bone pain, improve both bone density and vertebral height (Glorieux et al., 1998). However, long-term benefits on disease progression, function and quality of life have yet to be demonstrated.

Skeletal dysplasias

Menezes has classified these into 5 categories, the largest being the osteochondrodysplasias and the dysostoses (Menezes & Ryken, 1992). Osteochondrodysplasias are

defined as abnormalities of cartilage or bone growth and development. They generally present as short-limbed dwarfism, with achondroplasia the commonest form. Around 50% of children with achondroplasia have a thoracolumbar kyphosis in infancy and there is a risk of spinal cord stenosis. Patients characteristically have macrocephaly but a small mid face and small foramen magnum. These abnormalities place them at risk of symptomatic stenosis and hydrocephalus. Sleep apnea is seen in the majority of patients, which may have a central or respiratory cause. Cervicomedullary decompression with resection of the foramen magnum may be necessary. Atlantoaxial instability has been increasingly recognized in the skeletal dysplasias.

The dysostoses are defined as malformations of individual bones singly or in combination. These include the craniosynostoses (Crouzon and Apert syndromes) in which vertebral anomalies are commonly recognized and Klippel–Feil syndrome which is discussed later.

The metabolic storage disorders

These include the mucopolysaccharidoses, the glycoprotein storage disorders, the gangliosidoses and the mucolipidoses. These neurodegenerative diseases vary in their severity but show characteristic skeletal dysplasias, such as 'hooked' vertebrae, broad ribs and flared pelvis. Thoracolumbar kyphosis is common, with a risk of spinal cord compression. Other neurological complications include cognitive deterioration, carpal tunnel syndrome and deafness. In Morquio's syndrome (mucopolysaccharidosis IV) the os odontium is dysplastic or absent. These patients also have striking ligamentous laxity which gives a particularly high risk of atlantoaxial instablity and spinal cord compression.

Mesenchymal and connective tissue disorders

Neurofibromatosis is considered in detail in Chapter 128. Around 30% of patients will develop scoliosis, of which 40% will have associated cervical spine abnormalities. The scoliosis often manifests as an acute-angled short segment kyphoscoliosis which will inevitably progress unless fusion is performed (Winter et al., 1979). Approximately 50% of patients with Marfan's syndrome will develop significant scoliosis.

Management of spinal deformity

Patient management varies from case to case and will be influenced by the underlying diagnosis, current levels of function especially ambulatory abilities, life expectancy and concomitant medical problems.

In kyphosis bracing is advocated for skeletally immature patients with progressive curves $<60°$. Surgery is often required if the curve exceeds 60°.

In patients with idiopathic scoliosis bracing may delay or arrest scoliosis progression in the skeletally immature child. Indications for bracing are curves $>30°$ or earlier if there is radiological progression. Bracing is rarely effective once the curve exceeds 45°. It may improve pain in adults with scoliosis. A thoracolumbar spinal orthosis is generally used, with an added cervical extension (as in the Milwaukee brace) if the apex of the curve is above T8. If bracing is not appropriate, or fails to control the scoliosis, surgical stabilization is necessary, although this may be at the cost of spinal growth.

In congenital or neuromuscular scoliosis there may be a role for bracing but given the relentless progression of the scoliosis in many of these conditions, early surgery is often indicated. In non-ambulant patients the spinal fusion should involve the pelvis. Surgical risk, particularly of hemostasis and postoperative chest infection, is high in this patient group.

A solid arthrodesis is the primary goal of surgery, often requiring joint excision, decortication and bone grafts. Instrumentation is added to achieve and maintain correction as well as providing stability to the fusion mass. Surgical procedures will vary but are largely determined by the underlying pathology. The reader is referred to standard orthopedic texts (see Moe's textbook of scoliosis, 1994). Good results are dependent on meticulous patient selection at all stages, with multidisciplinary preoperative assessment, intraoperative neurophysiological spinal cord monitoring and intensive care support postoperatively. Complications include immediate perioperative problems such as hemorrhage and pneumothorax. Infection occurs in up to 2% of patients. Paraplegia occurs in $<1\%$ of patients and postoperative paraparesis warrants urgent removal of any instrumentation. Up to 5% of patients experience failure of graft implantation usually due to pseudarthrosis.

Craniovertebral junction anomalies

The pathophysiology of the craniocervical junction anomalies is complex. A useful classification is proposed by Menezes (1999), reproduced in Table 49.2, subdivides the anomalies into congenital, developmental and acquired causes.

Clinical features of craniocervical junction anomaly

Symptoms and signs may be insidious or of rapid onset. Clinical presentation is diverse as dysfunction may occur

Table 49.2. Causes of craniovertebral anomalies

1. Congenital anomalies and malformations
   A. Occipital sclerotome malformations – atlas assimilation, proatlas remnants
   B. Atlas malformations – bifid atlas, assimilation, fusion, absent arches
   C. Axis malformations – segmentation defects, odontoid dysplasias
2. Developmental and acquired anomalies
   A. Foramen magnum abnormalities
      (i) foramen stenosis, e.g. Achondroplasia
      (ii) secondary invagination, e.g. Ostoeogenesis Impefecta, Paget's

B. Atlantoaxial instability
   (i) Down's syndrome
   (ii) metabolic disorders, e.g. Morquio, Hurler syndromes
   (iii) Infections, e.g. Grisel's syndrome, Tuberculosis
   (iv) Trauma
   (v) Inflammation, e.g. rheumatoid arthritis, Reiter's syndrome
   (vi) Tumour, e.g. osteoblastoma, neurofibromatosis
   (vii) Miscellaneous, e.g. syringomyelia

Fig. 49.2. Sagittal MRI brain demonstrating basilar impression in an adolescent with severe (type III) osteogenesis imperfecta (OI).

at many levels: the lower brainstem, cranial nerves, cervical roots and upper cervical cord may be compromised by pressure from bone or soft tissue, there also may be indirect compromise of the blood supply. Congenital anomalies of the craniocervical junction are often associated with dysmorphic features and obvious skeletal anomalies. Patients most commonly complain of headache and neck pain worsened by movement and coughing. Pain characteristically originates in the suboccipital region and radiates to the vertex, in a C2 distribution. Head tilt and 'torticollis' are common. In children with craniocervical junction anomalies hearing loss is the most common cranial nerve symptom. In adults, trigeminal distribution pain and neuralgia may result from direct compression of the V nerve or compression of the V nerve nuclei in the upper cervical cord. Lesions of other cranial nerves particularly IX, X, XI and XII are also seen. Spinal cord compression produces a myelopathic picture with upper motor neuron features, often progressing to loss of bladder and bowel control. Occasionally, the myelopathy is confined to the upper limbs. Sometimes there is a predilection for the dorsal columns, producing marked joint position sense loss. Brainstem involvement may produce dysphagia, dysarthria, internuclear ophthalmoplegia and nystagmus (most commonly horizontal but more classically down beating). Central apnea, drop attacks and syncope are important additional features. The intimate relationship of the vertebral arteries to the upper cervical spine and foramen magnum may increase the risk of basilar migraine and vertebro-basilar ischemia.

There are three principal mechanisms by which the craniocervical junction anomalies lead to neurological signs. Frequently, more than one mechanism coexists.

Direct compression

This may result from developmental abnormalities of the odontoid process. Of particular importance is the condition os odontoidium where the odontoid and the body of the axis are not fused. Atlas assimilation, where there is failure of segmentation between the fourth occipital and first spinal sclerotomes, is relatively common and is particularly associated with the Chiari malformations. Direct compression may also result from abnormal articulation around cervical vertebral blocks as is seen in the Klippel–Feil syndrome.

Structural

Basilar invagination describes deformity of the osseous structures of the skull base which leads to upward displacement of the edge of the foramen magnum (see Fig. 49.2). In its primary congenital form it is often associated with platybasia where the clivus and anterior skull base are abnormally flattened. It may be associated with more subtle developmental bony anomalies and associated neurodysgeneses such as hindbrain herniation (particularly Chiari malformations) and syringohydromyelia. The

foramen magnum itself may be narrow, usually as a feature of underlying skeletal dysplasia, as in achondroplasia. Acquired forms of basilar invagination are more common and result from any bone softening condition. The most important causes are osteogenesis imperfecta (see Fig. 49.2) and Paget's disease. Diagnosis of basilar invagination on cervical spine X-ray involves measuring the position of the odontoid tip with respect to either the foramen magnum itself (McRae's line) or from lines drawn between the roof of the hard palate and either the posterior lip of the foramen magnum (Chamberlain's line) or the caudal part of the occipital bone (McGregor's line).

Atlantoaxial instability

Atlantoaxial dislocation results from incompetence of the transverse ligaments or abnormalities of the dens itself (Stevens et al., 1994). Instability is defined by an atlanto-dens interval >5 mm, and is demonstrated by flexion/extension X-rays of cervical spine or 3D CT reconstruction, the latter also allows assessment of any rotational component. Instability may occur spontaneously or develop secondarily due to inflammation or trauma. It is a recognized feature of the complex developmental craniofacial and cranio-vertebral anomalies, particularly if there is atlas assimilation and segmentation failure as in the Klippel–Feil syndrome. Syndromes which are also associated with ligamentous laxity carry a particular risk of dislocation; such as the mucopolysaccharidoses and Down's syndrome (Fig. 49.3).

The surgical treatment of craniocervical junction anomaly is complex and beyond the scope of this chapter (see Robertson & Coakham, 1999). If neurological symptoms and signs of brain stem compression occur surgery is usually indicated. Treatment of basilar invagination, for example, due to osteogenesis imperfecta involves ventral decompression and dorsal occipitocervical fusion.

Down's syndrome

Trisomy 21 occurs in around one in 650 live births and is the single most common cause of severe learning difficulties. It initially presents with characteristic dysmorphic features and hypotonia, often with associated cardiac and gastrointestinal anomalies. It is estimated that up to 25% of patients with Down's syndrome have asymptomatic atlantoaxial instability. Only around 1% are symptomatic (Pueschal & Scola, 1987). Recognized presentations include mild pyramidal tract signs with gait disturbance or the precipitous onset of cord compression. In the absence of signs or symptoms, screening of the atlanto-dens interval is no longer routine, however sports such as trampolining and somersaults should be avoided. Once symptoms are present, surgical stabilization is recommended.

Fig. 49.3. Three dimensional CT reconstruction showing atlanto-axial subluxation in an 8-year-old child with Down's syndrome.

Chiari malformations

Chiari described four types of hindbrain malformation. The Chiari I malformation is demonstrated on neuroimaging by the dorsal extension of the cerebellar tonsils below the level of the foramen magnum (Fig. 49.4). Some studies report the prevalence of tonsillar descent (3–5 mm below the foramen magnum) on sagittal MRI in asymptomatic individuals to be as high as 20%. However, more definitive volumetric reconstruction of coronal MRI demonstrates that the complex shape of the rostral cerebellum may lead to sagittal MRI overestimating tonsillar descent (Savy et al., 1994). The true prevalence of Chiari I in asymptomatic individuals is probably less than 1%, although it rises if tonsillar descent on sagittal MRI is associated with appropriate symptoms or other hind brain anomalies and in around 50% of cases of true cerebellar ectopia there is elongation of the medulla. Approximately 50% of Chiari I malformations are associated with craniocervical anomalies and

Fig. 49.4. Sagittal MRI brain showing Chiari I malformation.

syringomyelia (Milhorat et al., 1999). The development of Chiari I is likely to be multifactorial. It has been postulated on the basis of familial aggregation that Chiari I is a disorder of para-axial mesoderm (Milhorat et al., 1999). However, unlike Chiari II–IV there are clear examples of acquired Chiari I in which serial MRI has demonstrated postnatal development of the anomaly (Huang & Constantine, 1994). Furthermore, lowering of CSF pressure following lumbar puncture or lumbar peritoneal shunting may be a risk factor for cerebellar tonsil descent (Chumas et al., 1993; Payner et al., 1994). There are well-documented examples of 'Chiari' or 'pseudo-Chiari' malformations improving following treatment of abnormally low CSF pressure due to CSF leakage (Samii et al., 1999).

The symptoms and signs resulting from Chiari I overlap with those associated with other craniocervical anomalies (see above). These include headache especially cough headache, nystagmus and quadriplegia. Additional symptoms and signs may result from associated hydrocephalus or syringomyelia. The condition is rarely symptomatic in childhood. Unusual presentations of Chiari I have been described. These include sudden death, syncope, ventricular fibrillation due to head movement, lingual myoclonus, pulsatile tinnitus, Menière's-type symptoms, acquired esotropia, central apnea and paroxysmal rage. Surgical treatment involves decompression of the foramen magnum and should be offered on the basis of significant and relevant symptoms, e.g. severe cough headache, or the presence of physical signs indicating neurological compromise.

Chiari II malformation is a congenital anomaly which is associated with myelomeningocele and hydrocephalus in >90% of cases and generally manifests in the neonatal period. It consists of caudal displacement of the medulla and cerebellum (particularly vermis) into the cervical canal overriding the spinal cord often accompanied by partial herniation of the fourth ventricle and distortion of midbrain tectum. Associated abnormalities of supratentorial and midbrain structures are common. Chiari III is analogous to type II but describes downward displacement of the cerebellum into a posterior encephalocele, again with elongation and herniation of the fourth ventricle. Clinical features are severe and often life threatening, particularly where there is cranial nerve dysfunction.

The Chiari IV malformation describes cerebellar hypoplasia and on current understanding is not part of the Chiari spectrum.

Spinal dysraphism

Spinal dysraphic states are caused by localized failure of neural tube closure during fetal development. Myelomeningocele is the most common form, with an incidence of 0.8/1000 live births. There are marked regional variations in its incidence and the condition is heterogeneous. There are strong genetic components and recurrence risks rise from 1–2% after one affected child to 10% with two affected children (Todorov, 1982). The process of neuralation may be disrupted by teratogenic agents and in particular by maternal and/or fetal folate deficiency. Early folic acid supplementation reduces the incidence of neural tube defects, so that all women are recommended to take supplemental folate prior to conception and during the first trimester. This advice is especially important for women with a previously affected pregnancy or those taking anticonvulsants in whom the incidence of neural tube defects is around 1% of pregnancies, larger amounts of folic acid are recommended for these women. Routine antenatal screening provides a prenatal diagnosis in many cases; raised maternal serum α fetoprotein is associated with open neural tube defects and fetal ultrasonography allows cranial and vertebral structures to be visualized directly. Prenatal counselling and termination can then be offered.

Myelomeningocele and myeloscisis comprise 95% of cases of spinal dysraphism, with exposed neural tissue a common feature (Fig. 49.5). In a meningocele and in spina bifida occulta neural elements are covered by skin. The clinical features are determined by the extent of the myelocele and the presence of associated abnormalities, which may include both neural and extraneural anomalies.

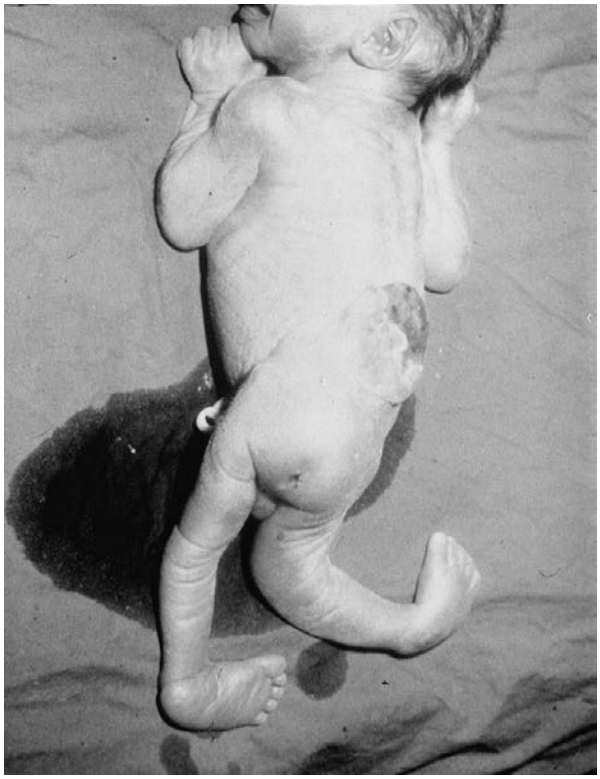

Fig. 49.5. A new born infant with thoroco-lumbar myelomeningocele. He has a neuropathic bladder, patulous anus and flaccid lower limbs with bilateral talipes.

Fig. 49.6. Sagittal MRI of lumbar–sacral spine showing a lipomyelomeningocele.

Progressive hydrocephalus requiring surgical treatment is present in 90% of cases and around 70% have a Chiari II malformation. Learning difficulties are common, one-third have an IQ < 80. Syringomyelia is present in up to 75% of cases and is often associated with severe scoliosis. Approximately a third of patients have diastematomyelia.

Approximately 80% of open spina bifida defects are located in the lumbosacral area. The sensory level indicates the upper level of the lesion. Lesions above L3 result in complete paraplegia, but motor deficits may otherwise be patchy with a mixed pattern of upper and lower motoneuron signs. Sphincter and detrusor function is always compromised and careful urological assessment is required. Surgical closure is undertaken within 48–72 hours of delivery to reduce the risk of ascending infection and protect viable neural tissue within the placode. Following closure delayed hydrocephalus is likely. Patients generally require ongoing medical care by a multidisciplinary team.

Spina bifida occulta describes occult dysraphism, where neural structures have not herniated through the mesenchymal defect. It includes diastematomyelia, terminal myelocystocele and tight filum terminale. Lipomyelomeningocele and dermal sinuses are often included in this classification as they also result from abnormal neurulation. Spina bifida occulta is often neurologically asymptomatic. The majority of patients have associated cutaneous abnormalities such as a tuft of hair or a dimple over the region, and plain X-rays show underlying vertebral anomalies. MRI scan then confirms the diagnosis (Fig. 49.6). Two neurological presentations are recognized. First, a congenital asymmetric weakness and atrophy of the lower limbs and second the 'tethered cord syndrome' with progressive and sometimes precipitous onset of weakness and spasticity. The latter often presents in childhood or during the adolescent growth spurt and is an important cause of toe walking in childhood. Both presentations may be associated with sphincter disturbance. Treatment is primarily neurosurgical, with release of the spinal cord from the tethering lesion, with full preoperative neurological and urological assessment. Orthopedic, orthotic and physiotherapy management of lower limb deformity is also important.

Klippel–Feil syndrome

Described in 1912, the disorder is characterized by a short neck, impaired neck mobility and a low hairline (Klippel & Feil, 1912). The incidence is approximately 1: 40 000 births. The skeletal abnormalities include fusion of two or more

Fig. 49.7. Axial CT myelogram with sagittal reconstruction showing split cervical spinal cord in a patient with Klippel–Feil syndrome.

cervical or cervicothoracic vertebrae. The syndrome is heterogeneous; differing numbers and positions of fused vertebrae are described and the associated anomalies are highly variable (Clarke et al., 1998). The condition may be familial: dominant, recessive and X-linked inheritance patterns have been proposed. A dominant form in which there is chromosome 8 inversion is described (Clarke et al., 1995). Despite the sometimes dramatic spinal abnormalities, a follow-up study over a 10-year period has indicated that only 20% of patients experienced significant cervical spine symptoms and only 6% required surgical intervention (Theiss et al., 1997).

Extravertebral anomalies associated with Klippel–Feil syndrome affect multiple systems. Skeletal and systemic abnormalities include: scoliosis, scapula elevation, rib anomalies, cranio-facial dysmorphology, pulmonary, cardiac, gastrointestinal and urogenital anomalies. Neurological problems include syringomyelia, cranial nerve abnormalities, Duane's retraction syndrome, deafness, acquired myelopathy due to the spinal abnormality, thin corpus callosum, split cervical spinal cord (see Fig. 49.7) and failure of pyramidal tract decussation (Gunderson & Solitaire, 1968; Schott & Wyke, 1981; David et al., 1996). The latter anomaly is particularly interesting as it may underlie the intense congenital mirror movements which affect a number of these patients.

Congenital mirror movements

These are intense involuntary movements, primarily of distal upper limb muscles, which mirror the voluntary unilateral movement. They cannot be suppressed and typically do not occur during passive movement. Mirror movements occur normally during a child's motor development, however, they are rarely intense and disappear by the age of 6 years. Pathological mirror movements are rarely disabling and patients learn adaptive proximal movements so as to avoid inappropriate finger movements, for example wrong key strikes whilst typing. Neurophysiological study of mirror movements has provided new insights into central motor control and plasticity.

A single subject with Klippel–Feil syndrome and mirror movements has been studied in detail (Farmer et al., 1990). Similar neurophysiological findings have been reported in patients with congenital mirror movements and mirror movements in association with X-linked Kallman syndrome (Cohen et al., 1991; Mayston et al., 1997). Unilateral focal electrical or magnetic brain stimulation of either left or right primary motor cortex at threshold in non-mirroring subjects evokes contralateral short latency EMG responses due to rapid conduction through pyramidal tract pathways (see Fig. 49.8). In contrast, mirroring individuals show simultaneous bilateral short latency EMG responses following unilateral motor cortex stimulation. Abnormal bilateral EMG responses indicate that in subjects with mirror movements the corticospinal tract is aberrant and bilaterally represented. In mirroring subjects the short latency (N20) component of the somatosensory evoked potential is confined to the contralateral sensory cortex. Spinal (short) latency cutaneomuscular (CMR) and stretch reflexes are confined, as in normal subjects, to the stimulated side. However, in mirroring subjects the long-latency components of the CMR and stretch reflexes are simultaneously present in both the stimulated and non-stimulated limbs (Farmer et al., 1990; Matthews et al., 1990; Capaday et al., 1991). This abnormal crossing of the long-latency CMR and stretch reflexes in mirroring subjects has provided strong evidence in support of the view that in human hand muscles long-latency reflexes are transmitted via a transcortical loop (see Fig. 49.8). Cross-correlation analysis of EMG activity recorded simultaneously from homologous muscles of left and right hands, reveals, in contrast to healthy subjects, the presence of a short duration peak at time zero, indicating that during normal muscle contraction both hands receive abnormal common presynaptic drive (see Fig. 49.8). This abnormal drive can be shown to be highly muscle specific, indicating that abnormal bilateral corticospinal axons innervate the

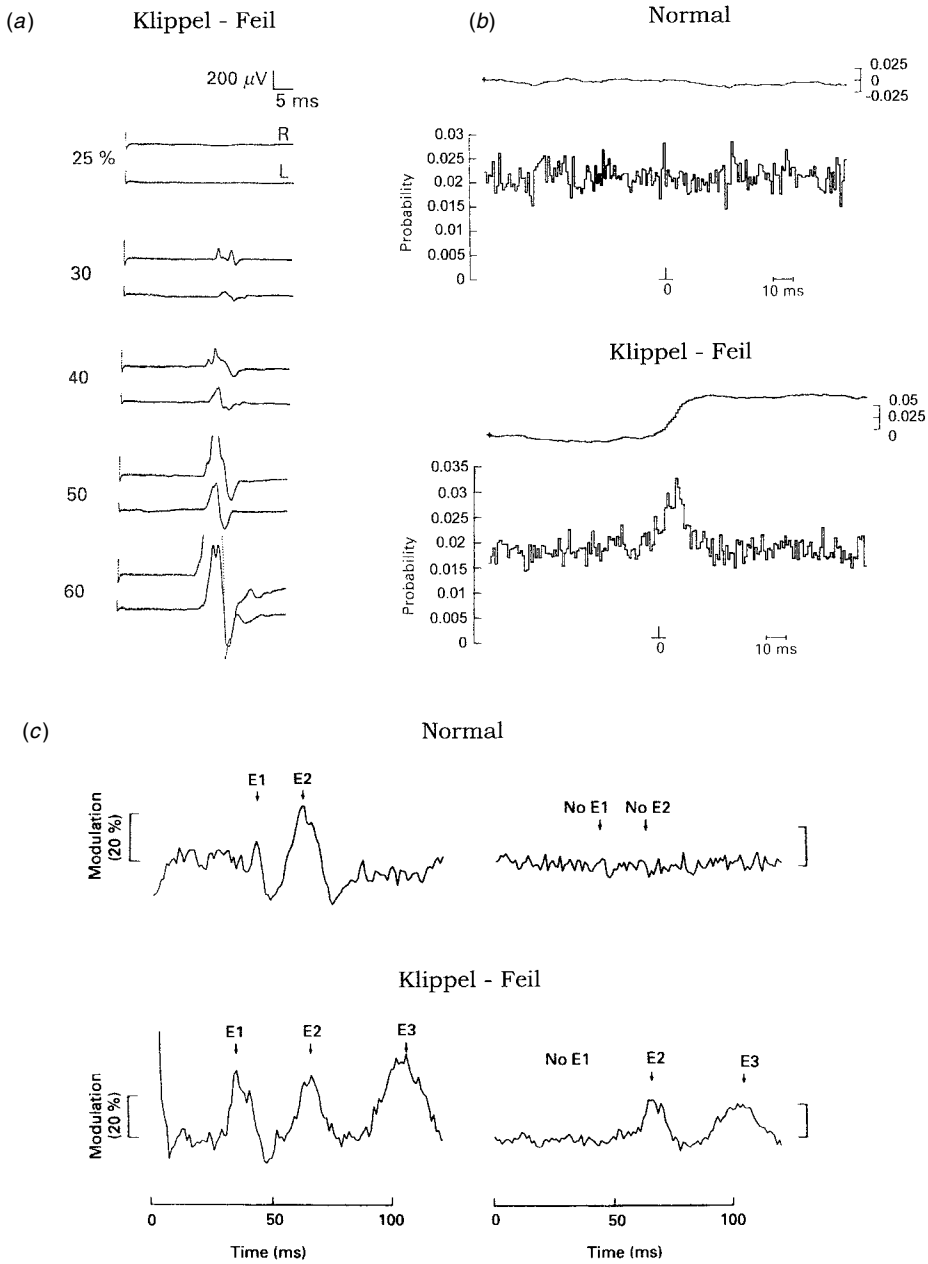

Fig. 49.8. Neurophysiological data from a normal subject and a subject with Klippel–Feil syndrome and mirror movements. (*a*) Abnormal bilateral short-latency muscle responses to focal transcutaneous electrical stimulation of the left motor cortex in the Klippel–Feil subject. (*b*) Cross-correlation histograms and CUSUM constructed between simultaneous left and right hand muscle EMGs in the normal subject and the Klippel–Feil subject. The abnormal peak in the Klippel–Feil subject data reflects abnormal common presynaptic drive to left and right spinal motoneurons. (*c*) Cutaneomuscular reflexes in the normal subject and Klippel–Feil subject. In contrast to normal subjects, those with mirror movements show crossing of long-latency reflex activity (E2 and E3 components), similar results are found for the long-latency stretch reflex, indicating that late reflex components are generated by a transcortical loop.

equivalent motoneuron pools, e.g. those of first dorsal interosseous muscle on left and right sides of the spinal cord. These findings indicate that voluntary and long-loop reflex activity in abnormal central motor pathways produces the mirror movements of Klippel–Feil syndrome.

Mirror movements in childhood hemiplegia

Neurophysiological studies of mirror movements have been extended to include childhood hemiplegia. Intense mirror movements are a recognized feature of childhood hemiplegia and have been proposed to represent a physical sign of corticospinal tract re-wiring following early brain damage (Woods & Teuber, 1978). Children with hemiplegia and mirror movements have been studied using the approach outlined above for Klippel–Feil syndrome. The findings are similar except that the corticospinal axons reach both sides of the spinal cord from the undamaged motor cortex (Farmer et al., 1991; Carr et al., 1993). The presence of mirror movements with characteristic neurophysiological findings is associated with MRI scans in which there is no gliosis in response to the cerebral injury, suggesting that antenatal insults before gestational age 28 weeks causing hemiplegia are associated with pyramidal tract plasticity and mirror movements. This remarkable central nervous reorganization may help to sustain function of the child's hemiplegic hand albeit at the expense of mirror movements (Carr et al., 1993).

Paget's disease

The disorder is rare before the age of 40 but becomes increasingly common with time, affecting 10% of 90-year-olds. The clinical features are those of bone pain, local deformity, bone enlargement, pathological fracture and a predisposition to sarcomatous change. The disorder often affects the skull and spine and as a result neurological involvement is common. Diagnosis is made by typical radiological appearances and the finding of an elevated serum alkaline phosphatase. The disease is one of excessive bone resorption with excessive osteoblastic and osteolytic activity. A genetic predisposition is described and some familial cases have been linked to chromosome 18q (Cody et al., 1997). Pagetic osteoclasts contain nuclear inclusions and osteoclastic infection with paramyxoviruses is one postulated cause of the disease (Singer, 1999).

There are a numerous potential neurological sequelae of Paget's disease. Direct compression by Pagetic bone may lead to the following: headache, dementia, brainstem and cerebellar dysfunction, cranial neuropathies, myelopathy, cauda equina syndrome, and radiculopathies. The most common cranial neuropathy is sensorineural deafness; optic atrophy, trigeminal neuralgia and hemifacial spasm are also described. Pagetic softening of the skull may lead to basilar invagination resulting in brain stem and high cervical compression syndromes and occasionally hydrocephalus. The brain and spinal cord can become acutely compressed due to epidural hematoma. The vascularity of Pagetic bone may lead to cerebral ischemia as part of a steal syndrome (compared to normal bone, blood flow in Pagetic bone is increased threefold). Neurological syndromes may also develop due to compression of blood vessels.

Paget's disease generally responds to treatment with bisphosphonates although a relative resistance to these drugs is described (Gutteridge et al., 1999). First-line treatment is with potent oral bisphosphonates. Second-line treatment regimes include calcitonin, etidronate and intravenous bisphonsphonates (Poncelet, 1999). Bone pain in particular can resolve within 1–2 weeks of commencement of treatment, treatment efficacy may be monitored by serum alkaline phosphatase levels and a therapeutic response may be expected in approximately 80% of patients treated. Neurological syndromes often improve with medical treatment. Rapidly progressive neurological syndromes require high dose intravenous bisphosphonate therapy and/or treatment with calcitonin. However, hydrocephalus generally requires shunting. Surgical decompression for basilar invagination, cranial nerve lesions, spinal cord and root compression is indicated if neurological symptoms and signs progress rapidly or despite best medical treatment (Poncelet, 1999). Medical treatment prior to surgical intervention may reduce bone vascularity and thus the risk of perioperative hemorrhage.

Rheumatoid arthritis

Rheumatoid arthritis is a chronic, inflammatory, immune-mediated symmetrical polyarthritis with a predilication for the distal joints. Females are affected twice a commonly as males and the prevalance ranges from 0.2–2 % of the population. The inflamed synovium is termed the pannus; it is characterized by T and B cell activation, cytokine release, immune complex deposition, angiogenesis, and cellular proliferation. This inflammatory process leads to damage and destruction of bone, cartilage and ligaments. Aggressive immunosuppressive therapy with disease modifying drugs (in particular sulfasalazine and methotrexate) improves the prognosis of rheumatoid arthritis (Madhok et al., 2000), it is not yet known whether this approach

reduces the incidence of neurological complications of the disease.

Neurological manifestations of rheumatoid arthritis include entrapment neuropathy, vasculitic neuropathy, myopathy and ischemic syndromes due to vasculitis, these are discussed further in Chapter 94 on the vasculitides. The spinal cord manifestations result from ligamentous disruption, bone destruction and secondary osteoporosis. A rare syndrome of diffuse dural infiltration with inflammatory cells producing a pachymeningitis has been described.

Patients with rheumatoid arthritis of the cervical spine frequently experience headache and neck pain. The most feared neurological complication of rheumatoid arthritis is upper cervical cord and brainstem compression. Involvement of the atlanto-axial ligament often combined with local pannus formation and bone destruction produces subluxation. Atlanto-axial subluxation affects 25% of rheumatoid patients of whom 25% have neurological signs. Atlanto-axial subluxation may occur in lateral, rotational, anterior, posterior and vertical directions; the latter three directions being the most neurologically significant. Rheumatoid arthritis may affect the spinal cord caudal to the C1/C2 level independently or in association with a high cord lesion. Postmortem studies of myelopathy show necrosis, gliosis and Wallerian degeneration within ascending and descending white matter (Fujiwara et al., 1999). The degree of atlanto-axial subluxation is well characterized by plain flexion–extension radiography; however, because a large part of the compression is due to inflammatory soft tissue proper assessment requires magnetic resonance imaging (Rogers et al., 1994).

In a series of 235 rheumatoid patients referred for neurosurgical assessment of craniocervical junction instability 60% had myelopathy, the majority of these either had motor or mixed motor and sensory long-tract signs; in approximately 10% the predominant deficits were loss of joint position and Rombergism, indicating a mainly posterior compression. Cranial nerve signs and nystagmus were rare and in this series were associated with other pathologies especially Chiari malformation (Rogers et al., 1994). The combination of mild neurological impairment and rheumatological/orthopedic problems puts rheumatoid patients at increased risk of falls and even minor cervical injury can produce catastrophic neurological deterioration. Atlanto-axial subluxation increases the anesthetic risk due to neck extension during artificial ventilation. Surgical treatment of these patients requires posterior stablization. However, in patients with irreducible subluxation and anterior neuroaxis compression, transoral decompression is undertaken first.

Fig. 49.9. Sagittal MRI of a patient with rheumatoid arthritis showing hind-brain compression from atlanto-axial involvement and multilevel degenerative disease of the cervical spine.

Selection of appropriate patients for surgical intervention presents a major clinical problem. The policy of waiting until rheumatoid patients with atlanto-axial subluxation develop signs of serious myelopathy has been strongly challenged on the basis that once spinal cord damage has been sustained it is rarely reversible (Fig. 49.9). In a prospective trial it has been shown that, following surgical stabilization with or without transoral anterior decompression, approximately 60% of ambulant patients will show stabilization or improvement of their functional status, in contrast only 20% of non-ambulant patients will show any recovery (Casey et al., 1996). Furthermore, surgical morbidity and mortality were found to be significantly higher in the non-ambulant (12.7%) compared to the ambulant group (8.9%).

Spondyloarthropathies

The inflammatory spondyloarthropathies include ankylosing spondylitis, psoriatic arthritis, arthritis associated with inflammatory bowel disease and reactive arthritis, e.g. Reiter's disease. Low back pain is common to all conditions. The primary neurological manifestations are best

represented through consideration of ankylosing spondylitis, although they may also occur in association with the other spondyloarthritides.

Ankylosing spondylitis usually presents with gradual onset low back pain and stiffness of the large joints. The condition can affect other organ systems. Men are affected more than women. Disease onset is typically before age 40. HLA B27 is strongly associated with in excess of 90% of patients expressing the antigen. The pathological hallmark is the development of enthesopathy, that is inflammation around sites of tendonous insertion. In the spine syndesmophytes form at the point where spinal ligaments attach to the vertebral bodies.

The neurological manifestations of ankylosing spondylitis are usually a late stage complication. Loss of spinal movement is associated with vertebral body squaring and extensive loss of ligamentous laxity due to syndesmophyte formation. This process produces a rigid spine with kyphosis. Spinal involvement may produce atlanto-axial subluxation, pathological vertebral fracture, discovertebral destruction, spinal canal especially lumbar canal stenosis and a cauda equina syndrome. Atlanto-axial subluxation is rarer than in rheumatoid arthritis; the management issues, however, are similar. Spinal rigidity and disco-vertebral problems predispose to cord compression. Acute spinal cord compression due to epidural hematoma is a recognized problem.

Cauda equina syndrome is a rare late stage complication of ankylosing spondylitis. It presents gradually with leg pain, leg weakness, sensory disturbance and sphinteric dysfunction. On imaging studies posterior lumbar–sacral diverticulae are present. An arachnoiditis may also contribute to the development of the cauda equina syndrome, the presence of the diverticulae, however, indicates that ankylosing spondylitis is the likely cause rather than some other form of arachnoiditis. It is important to remember that spinal irradiation was used to treat ankylosing spondylitis and late radiation neurological damage and bone sarcoma may result.

Superficial siderosis

This is a condition in which there is abnormal subarachnoid hemosiderin deposition. The condition affects many neurological systems and when taken together the symptoms and signs form a coherent and recognizable clinical picture. A recent literature review of 87 cases (Fearnley et al., 1995) revealed the following clinical features: sensorineural deafness (95%), cerebellar ataxia (88%), pyramidal signs (76%), dementia (24%), bladder disturbance (24%), anosmia (at least 17%), aniscoria (at least 10%) and sensory signs (13%). Less frequent features included extraocular motor palsies, and lower motor neuron signs (5–10% each). Neck pain, low back pains and sciatic type pain were well-recognized clinical features. T2-weighted MRI studies of these patients reveal a dark rim, representing the paramagnetic affects of iron deposition, particularly around posterior fossa structures, the spinal cord and occasionally the cerebral hemispheres (Fig. 49.10).

Fig. 49.10. Axial MRI of the brain in a patient with superficial siderosis showing a dark rim around dorsal and ventral mid-brain structures due to iron deposition.

Previous spinal surgery is a recognized cause of superficial siderosis with chronic subarachnoid bleeding due to small blood vessel anomaly. Local spinal pathology affecting the dura such as a root lesion or vascular anomaly is a recognized cause of the condition. The remainder of cases in which a cause may be identified result from subarachnoid hemorrhage or the consequences of hemispherectomy. The serious long-term prognosis of the disorder means an exhaustive search for a bleeding source should be undertaken. This may involve exploratory surgery of a region from which chronic bleeding may occur, for example the site of previous surgery. Successful surgical

ablation of a bleeding source has, in anecdotal accounts, produced arrest of the condition. The role of medical treatment with chelation therapy (trientene) is not established although again anecdotal accounts suggest such treatment may have a role in slowing disease progression.

In conclusion, diseases of the vertebral column are relatively common. However, the neurologist or neurosurgeon will tend to see only those cases at the severe end of the spectrum. A good understanding of these conditions is necessary for diagnosis both of the condition, its neurological sequelae and optimal medical and surgical management.

Acknowledgments

We thank Dr J. Stevens and Mr D. Thompson who provided many of the figures and valuable advice during preparation of this chapter.

Cervical pain

Nikolai Bogduk

Newcastle Bone and Joint Institute, University of Newcastle, Royal Newcastle Hospital, New South Wales, Australia

Several terms apply to pain of cervical origin. These include radiculopathy, radicular pain or brachialgia, neck pain, and somatic referred pain. In the past and to some extent still, these terms have been confused, and sometimes used wrongly as equivalent and referring to the same phenomenon. The conditions or symptoms to which these terms refer differ in mechanism and cause; they differ with respect to the investigations required and the treatment that is appropriate. It is important, therefore, not just for taxonomic purposes (Merskey & Bogduk, 1994) but also for clinical purposes, to define how the terms should correctly be used.

Radiculopathy is a condition in which conduction along peripheral nerves is blocked at the level of the spinal nerve or its roots (Merskey & Bogduk, 1994). It is manifest clinically as numbness and/or weakness in a segmental distribution. Reflexes may be impaired according to whether conduction is blocked in Ia afferents or motor efferents or both. Paresthesiae may be another feature, and are indicative of the spinal nerve or its roots becoming ischemic. In essence, radiculopathy is a classical neurological disorder, manifest by objective neurological signs in a segmental distribution. Although pain may be an accompanying feature, it is not a necessary criterion. The diagnosis of radiculopathy is based on the objective neurological signs.

Radicular pain is pain arising from a disorder of a spinal nerve or nerve root (Merskey & Bogduk, 1994). It is perceived in the distribution of that nerve. Accordingly, cervical radicular pain is perceived in the upper limb. For that reason cervical radicular pain is not neck pain. Although neck pain may be a small component of radicular pain, radicular pain is never perceived exclusively in the neck. Its cardinal distribution is in the arm and forearm. Radicular pain may occur in association with radiculopathy, and for that reason it has been customary to group the two into one entity. Doing so, however, creates misconceptions, for not all pain that is associated with radiculopathy is necessarily radicular pain; radicular pain can occur without features of radiculopathy; and radiculopathy can occur without pain.

Neck pain is pain perceived in the cervical region of the spine, i.e. anywhere in the region bounded superiorly by the superior nuchal line, inferiorly by an imaginary transverse line through the T1 spinous process, and laterally by the margins of the posterior cervical muscles (Merskey & Bogduk, 1994). In this regard, it is clearly distinguished from radicular pain for, by definition, it is not perceived in the upper limb. Moreover, neck pain and radicular pain differ in mechanism. Neck pain is nociceptive, i.e. it arises as a result of stimulation of nerve endings in the structure that is the source of pain. In contrast, radicular pain is produced by the generation of ectopic impulses in the affected nerve.

Somatic referred pain is pain perceived in a region innervated by nerves, or branches of nerves, other than those that innervate the actual source of pain (Merskey & Bogduk, 1994). It does not involve the stimulation of nerve roots. Its mechanism involves convergence within the central nervous system between afferents from the two disparate sites. In that regard it is an extension of nociceptive pain. Its causes are the same as those of neck pain.

From the cervical spine, somatic pain can be referred to the head, to the anterior chest wall, to the upper limb girdle, and into the upper limb itself. In this latter distribution it can be confused with, and may be difficult to distinguish from, cervical radicular pain. It is that confusion, in the past, that has perhaps caused disappointment to physicians and their patients. Failure to recognize the difference between somatic referred pain and cervical radicular pain can result in investigations being pursued and treatments being applied for radicular pain when the patient has somatic referred pain; the result being either negative results, or false positive results and failed treatment.

Table 50.1. Less common causes of cervical radiculopathy, listed by structure and pathology

Structure	Pathology
Zygapophysial joint	Ganglion
	Tumour
	Inflammation
	Rheumatoid arthritis
	Gout
	Ankylosing spondylitis
	Fracture
Vertebral body	Primary tumour
	Secondary tumour
	Paget's disease
	Fracture
	Osteomyelitis
	Hydatid
	Hyperparathyroidism
Meninges	Cysts
	Meningioma
	Dermoid cyst
	Epidermoid cyst
Blood vessels	Angioma
	Arteritis
Nerve sheath	Neurofibroma
	Schwannoma
Nerve	Neuroblastoma
	Ganglioneuroma

Radiculopathy

Pathology

There is a large number of possible causes of cervical radiculopathy. In essence, any space-occupying lesion that compromises a cervical spinal nerve or its roots can cause radiculopathy (Bogduk, 1999), (Table 50.1). Rare causes of cervical radiculopathy include conditions that affect the nerve intrinsically or do not involve the anatomic relations of the nerve. These include: giant-cell arteritis (Sanchez et al., 1983), sarcoidosis (Atkinson et al., 1982), Pancoast tumour (Vargo & Flood, 1990), and even intracranial tumour (Clar & Cianca, 1998). However, by far the most common causes of cervical radiculopathy are disc protrusions and cervical spondylosis.

Disc protrusions are described as 'soft' or 'hard'. Soft protrusions consist of nuclear material that is extruded into the vertebral canal in a fairly focal manner. Hard protrusions are masses of disc material, usually in the form of a transverse bar or ridge, and which consist of fibrocartilage or are otherwise rendered hard by being ossified or encased by osteophytes from the vertebral margins.

Disc protrusions are also classified as medial or lateral, according to their principal location and the structures that they affect. Medial protrusions narrow the vertebral canal and affect the spinal cord. They typically cause myelopathy and so, are manifest by long tract signs. Lateral protrusions narrow the intervertebral foramen, and cause radiculopathy. They occur most commonly at the C5–6 and C6–7 levels, less commonly at C4–5, and all but rarely at C3–4 and C7–T1 (Odom et al., 1958; Yamano, 1985; Yoss et al, 1957; Henderson et al., 1983).

Cervical spondylosis is characterized by hard disc protrusions and osteophytes from the uncovertebral region or the zygapophysial joints. These can cause radiculopathy if and when they compromise the spinal nerve in the intervertebral foramen.

Mechanism

There are no experimental data that explicitly reveal the mechanism of radiculopathy. The prevailing view is that conduction block in the affected nerve is produced by compression of the nerve. Either the axons are compressed directly or their blood supply is compromised by the compression. Post-inflammatory scarring is another possibility, but its incidence has not been explicitly determined.

It is probably important not to extrapolate to the cervical spine data from experimental and clinical studies in the lumbar spine. In the lumbar spine, the evidence points to inflammatory processes being cardinal amongst the mechanisms of lumbar radiculopathy (Bogduk & Govind, 1999), but this may not pertain to the cervical spine. Lumbar disc prolapse is an acute event that involves an inflammatory response to the prolapsed material. Whereas this may be analogous to soft protrusions in the neck, it is not analogous to hard protrusions or spinal nerve compression by osteophytes, for which there is no evidence of an inflammatory process.

Clinical features

The characteristic features of cervical radiculopathy are numbness, weakness, paresthesiae, and hyporeflexia, in some combination. Different studies attest to a different relative incidence of these features in patients with surgically proven radiculopathy (Table 50.2), but this may reflect differences in the criteria used by surgeons to justify operation, rather than real differences in incidence.

Table 50.2. Proportion of patients with radiculopathy presenting with the neurological features listed

Ref	N	Numbness	Weakness	Paresthesiae	Hyporeflexia
Gregorius et al., 1976	41	0.60	0.70	–	–
Lunsford et al., 1980	295	0.50	0.35	0.26	0.55
Yoss et al., 1957	100	0.24	0.10	0.65	0.65
Honet and Puri, 1976	82	0.59	0.51	–	0.52
Henderson et al., 1983	841	0.85	0.68	0.99	0.71

Clinical diagnosis

The presence of numbness, weakness, or paresthesiae allows the diagnosis of radiculopathy to be made clinically. Testing for numbness is a reasonably reliable procedure, carrying a kappa score of between 0.45 and 0.64 (Viikari-Juntura, 1987). The validity of clinical examination is also reasonable, but differs according to the criterion standard used (Bogduk, 1999). If the criterion standard is evidence of nerve root compression on CT myelography, neurological signs have high sensitivity, but only moderate to good specificity (Viikari-Juntura et al., 1989), resulting in positive likelihood ratios of only between 2 and 4 (Bogduk, 1999). Better figures arise when surgical findings are used as the criterion standard, and in the context of determining the segmental level.

For correctly detecting a C6 radiculopathy, the likelihood ratio of numbness in the C6 dermatome is 2.7, and that of biceps weakness is 3.4. For a decreased biceps jerk the likelihood ratio is 4.8, and that of paresthesiae in the C6 dermatome is 3.2 (Bogduk, 1999). For correctly detecting C7 radiculopathy, the likelihood ratio of C7 numbness is 4.4; that of triceps weakness is only 2.0; but that of a decreased triceps reflex is 3.8 (Bogduk, 1999). Paresthesiae in the C7 dermatome has a likelihood ratio of 7.7, and is therefore the strongest indicator of C7 radiculopathy (Bogduk, 1999).

The axial compression test (An, 1996; Spurling & Scoville, 1944) has good reliability (Viikari-Juntura, 1987). Adding the compression test to the neurological examination increases diagnostic confidence considerably, by increasing specificity (Viikari-Juntura et al., 1989), and raising the likelihood ratio to more than 8.0 (Bogduk, 1999). Other tests, such as the arm abduction test (Beatty et al., 1987; Davidson et al., 1981; Fast et al., 1989), and manual traction on the neck (Viikari-Juntura et al., 1989) are highly specific but poorly sensitive (Viikari-Juntura et al., 1989); and when added to the examination do not improve diagnostic confidence (Bogduk, 1999).

In essence, radiculopathy can be strongly suspected when the patient presents with some combination of numbness, weakness, paresthesiae, and hyporeflexia, in a segmental distribution. Diagnostic confidence is increased if a compression test is added, but other clinical tests are not contributory and are superfluous. The affected segment can be determined quite well from a good clinical examination alone.

Investigations

Nerve conduction tests do not aid in establishing the diagnosis of cervical radiculopathy (Bogduk, 1999). Clinical examination provides sufficient diagnostic confidence to make 'confirmation' by nerve conduction tests superfluous. Nor does electromyography help in pinpointing the affected segment (Bogduk, 1999). Nerve conduction tests are required only when the clinical picture is not distinctly one of radiculopathy, and the possibility arises of a peripheral neuropathy being the cause of the symptoms and signs.

Nor is medical imaging required to make the diagnosis of radiculopathy, in the first instance. Its role, rather, is to identify the actual cause of the radiculopathy. For this purpose, MRI has a greater sensitivity and specificity than CT or CT myelography, for it can better resolve soft-tissue lesions, and detect them sooner (Bogduk, 1999). Any deficiency of MRI in resolving small bony lesions can be overcome by supplementing MRI with a plain film (Kaiser & Holland, 1998).

Treatment

In considering treatment, it is important to distinguish radiculopathy from radicular pain. If radiculopathy is due to compression of nerve roots, there is no reason, *a priori*, to believe or to expect that physical therapy, drug therapy, or exercise will somehow relieve that compression. Indeed, there are no data from descriptive studies, let alone from controlled trials, to indicate that any form of conservative therapy is of benefit expressly for cervical radiculopathy. Surgical decompression is the only definitive form of management.

Radicular pain

Causes

No literature explicitly lists the causes of cervical radicular pain. Instead, because radicular pain has usually been considered in conjunction with radiculopathy, radicular pain has conventionally been attributed to the same conditions as cause radiculopathy. Accordingly, the most common causes of cervical radicular pain are cervical disc protrusions and cervical spondylosis.

Mechanisms

There are also no data on the mechanisms explicitly of cervical radicular pain. Such experiments as have been conducted, both in animals (Howe, 1979; Howe et al., 1977) and in human subjects (MacNab, 1972; Smyth & Wright, 1959), pertain to lumbar radicular pain. Those experiments show that compression or traction of normal nerve roots evokes paresthesiae or numbness, but does not cause pain. For a nerve root to produce pain it has to be inflamed. However, compression of a dorsal root ganglion does evoke activity in nociceptive afferents. Therefore, it would seem that for compression to be a mechanism of cervical radicular pain, the dorsal root ganglion of the affected nerve has to be compressed. The specific pathophysiological mechanism would appear to be the generation of ectopic impulses from the ganglion, although this has yet to be explicitly demonstrated experimentally.

Clinical features

Rules that maintain that radicular pain follows a dermatomal pattern (Ahlgren & Garfin, 1996) are wrong. Experimental studies, in which cervical nerves have been stimulated mechanically with a needle, show that radicular pain is perceived widely over areas not encompassed by any single dermatome (Slipman et al., 1998). Moreover, regardless of the segment involved, cervical radicular pain is perceived proximally over the scapular region and shoulder girdle, where the corresponding dermatome is not represented. Furthermore, it is perceived deeply and, indeed, more so than in areas of skin.

This should not be surprising, even though it may seem contrary to popular wisdom. If a dorsal root ganglion is compressed and causes pain, all afferents subtended by that ganglion are likely to be affected, not just those from the corresponding dermatome. That includes afferents from deep tissues such as muscles, ligaments and joints. This would seem to be the basis of the deep, gnawing pain that accompanies stimulation of a cervical spinal nerve.

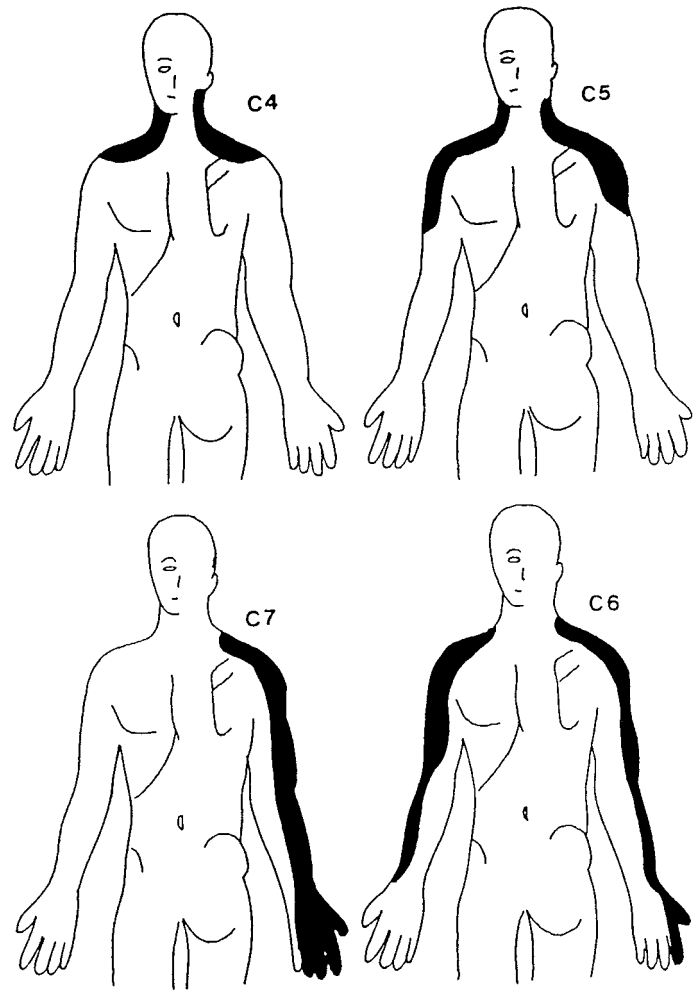

Fig. 50.1. Maps of the most common and consistent distributions of pain evoked by mechanical stimulation of the C4, C5, C6, and C7 spinal nerves. (Based on Slipman et al., 1998. Reproduced, with permission, from Bogduk, 1999.)

Although cervical radicular pain is not dermatomal, it can be portrayed as following a nevertheless segmental pattern, referred to as dynatomal (Slipman et al., 1998). Although the pain may extend to other areas, and although particular dynatomes differ from individual to individual, the areas in which radicular pain is most often and most consistently perceived are illustrated in Fig. 50.1. Quite clearly, the areas are not dermatomes, even though some do overlap the corresponding dermatome, although only in part. Conspicuously, the dynatomes for C6 and for C7 radiate from over the shoulder into the distal upper limb. They are not restricted to the forearm

and hand. The dynatomes for C4 and C5 are not distinguishable from one another clinically; but those of C6 and C7 are distinguished from C5 by their distal extent. However, although the C7 dynatome extends somewhat more posteriorly over the forearm than does the C6 dynatome, C7 radicular pain cannot be reliably distinguished from C6 pain.

Diagnosis

An important realization is that not all pain in the upper limb is necessarily radicular pain. Radicular pain needs to be distinguished from somatic referred pain (q.v.). This becomes particularly pertinent when pain is the only clinical feature, i.e. neurological signs are absent.

If features of radiculopathy are present, any accompanying pain in the upper limb is likely to be radicular in origin, particularly if it extends distally into the forearm. In that event, however, the pain and its distribution do not bear on the diagnosis. The diagnosis rests on the features of the radiculopathy. It is the segmental distribution of numbness, weakness, paresthesiae, and hyporeflexia that implicate a radiculopathy and its segmental level. It is only the association with radiculopathy that permits the assumption that the pain is radicular.

Investigations

No investigations confirm or help in the diagnosis of cervical radicular pain. Nerve conduction tests and medical imaging may be applied in the pursuit of radiculopathy, but they demonstrate nothing about pain. If medical imaging demonstrates nerve root compression, it explains the radiculopathy. Any relationship with pain is only inferential. Medical imaging does not show pain. Indeed, cervical radicular pain bears only a weak relationship with radiological signs of nerve root compression (Viikari-Juntura et al., 1989). Neither is dependably predictive of the other. Therefore, whereas it may be appropriate to undertake medical imaging for radiculopathy, it is not appropriate for the investigation of pain.

Natural history

There are few data on the natural history of cervical radicular pain. On the basis of anecdotal reports, cervical radicular pain seems to have a favourable natural history (Dillin et al., 1986; Persson et al., 1997). In studies of conservative therapy, some 70% of patients treated with placebo improve, and 20% lose all symptoms (British Association of Physical Medicine, 1966). In one survey of 561 patients, 90% were considered normal or only mildly incapacitated at 5 years (Radhakrishan et al., 1994).

Treatment

It has been traditional to treat cervical radicular pain conservatively. However, the literature is quite vague about what constitutes conservative therapy. By default, it is any therapy that occurs before surgery. The literature that provides information embraces various combinations of drug therapy, physical therapy, traction, collars, bed rest, exercise and transcutaneous electrical nerve stimulation (Bogduk, 1999).

The few controlled trials available paint a sobering picture of the efficacy of conservative therapy for cervical radicular pain. One study found no difference in outcome for patients treated with traction, sham traction, collar, heat, or placebo (British Association of Physical Medicine, 1966). Another study compared neck exercises, traction, and no treatment (Goldie & Landquist, 1970). According to the patients, a greater proportion of those receiving no treatment failed to improve. According to the physician's assessment, there was no difference between the three groups. In a rigorous study of patients with chronic radicular pain due to cervical spondylosis, weighted traction proved no better than placebo traction, in terms of pain scores, sleep disturbance, social dysfunction, and activities of daily living (Klaber-Moffett et al., 1990).

Some studies in the pain literature promote the use of epidural injections of steroids for cervical radicular pain. No controlled studies validate this therapy, and the descriptive studies are far from compelling. Collectively, they attest to between 0% and 30% of patients obtaining complete relief, and a similar proportion of patients obtaining 75% relief (Bogduk, 1999). One descriptive study has promoted fluroscopically-guided, transforaminal injection of steroids, but provides incomplete data on efficacy (Bush & Hillier, 1996).

Surgery is ultimately the mainstay of treatment for cervical radicular pain. According to descriptive studies it offers a high yield of successful results, irrespective of the technique used (Bogduk, 1999). There has been only one controlled study of surgery for cervical radicular pain (Persson et al., 1997). Patients were randomly allocated to treatment by physiotherapy, a collar, or surgery. At 4 months follow-up, all groups had improved, and the surgery group had less pain; but this difference was extinguished by 12 months. However, fewer than 10% of patients in each group were free of pain at 12 months. This low success rate is inconsistent with the reputed efficacy of surgery for cervical radicular pain.

Somatic referred pain

The early clinical experiments on somatic referred pain determined the distribution of pain when noxious stimuli were administered to interspinous muscles in normal volunteers (Kellgren, 1939; Feinstein et al., 1954). The patterns of distribution observed were segmental, but did not correspond to dermatomes (Fig. 50.2). The significance of these studies was that they showed that pain referred into the upper limb could be produced by means other than the stimulation of spinal nerves or nerve roots. For clinical purposes, these studies established that not all pain referred to the upper limb was necessarily radicular.

More recent studies have examined the patterns of distribution of pain in normal volunteers from particular structures in the cervical spine other than the interspinous muscles. These include the atlanto-axial and atlanto-occipital joints (Dreyfuss et al., 1994), and the cervical zygohypophyseal joints (Dwyer et al., 1990). The patterns observed are quasi-segmental but unrelated to dermatomes (Fig. 50.3). Similar patterns of pain have been noted in patients with neck pain undergoing cervical disc stimulation (Grubb & Kelly, 2000). This similarity indicates that patterns of referred pain do not reflect the structure that is the source of pain, but they do relate to its innervation. Structures with the same segmental innervation will produce referred pain in similar areas.

Somatic referred pain is not a separate diagnostic entity. It is just a physiological phenomenon. Since it can arise from virtually any structure in the neck its sources and causes are the same as those of neck pain.

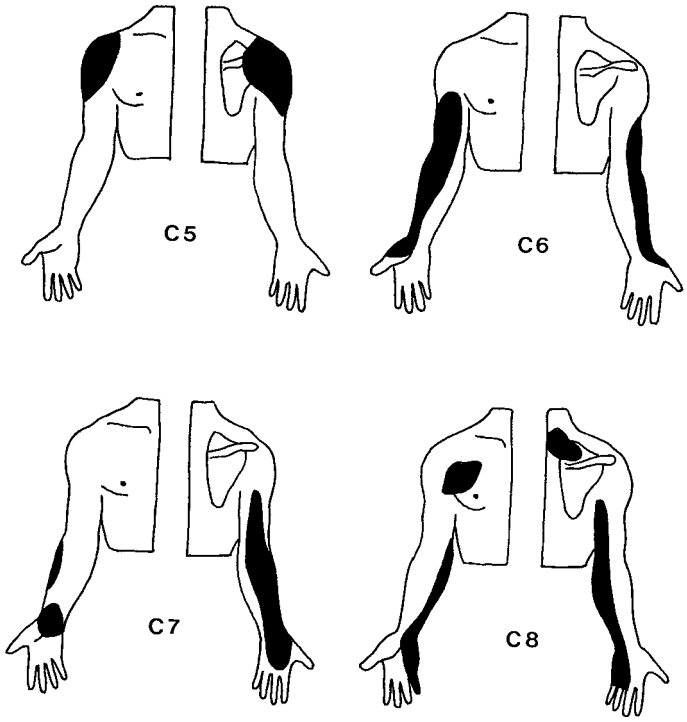

Fig. 50.2. Maps of the distribution of somatic referred pain elicited in normal volunteers by noxious stimulation of the interspinous ligaments. (Based on Kellgren, 1939.)

Neck pain

Epidemiology

Neck pain is common. Acute neck pain affects some 10% of the community, and the prevalence of chronic neck pain is about 14% (Bovim et al., 1994; Makela et al., 1991; van der Donk et al., 1991; Lawrence, 1969). It is more common among manual workers, office workers, secretaries and sewing machine operators (Vasseljen & Westgaard, 1995; Kamwendo et al., 1991; Westgaard & Jansen, 1992).

Etiology

The possible causes of neck pain can be classified as serious or non-threatening conditions, and as common or uncommon conditions (Table 50.3). Known causes involving demonstrable pathology are uncommon.

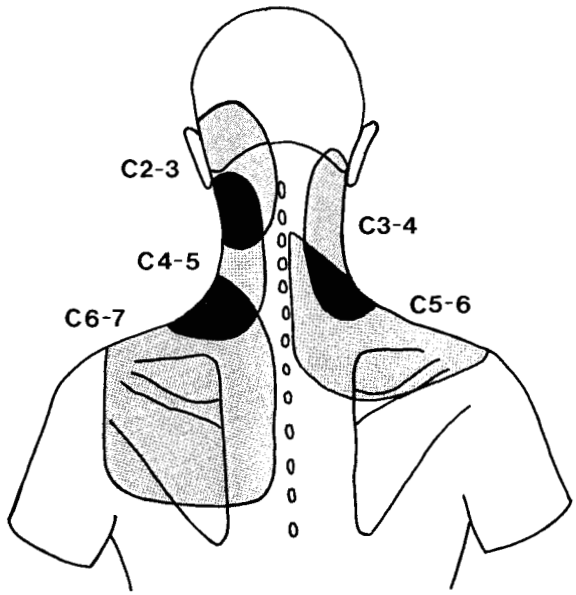

Fig. 50.3. Maps of the distribution of referred pain elicited in normal volunteers by noxious distension of the cervical zygapophysical joints. (Based on Dwyer et al., 1990.)

Table 50.3. The causes of neck pain grouped according to whether they are common and serious

	Non-threatening	Serious
Uncommon	Rheumatoid arthritis Ankylosing spondylitis Reiter's syndrome Psoriatic arthritis Crystal arthropathies	Fractures Tumours Spinal infections Dissecting aneurysms Spinal hematomas Metabolic disorders
Common	Cervical spinal pain of unknown origin Acceleration-deceleration Injuries of the neck Zygapophysial joint pain Discogenic pain	

Neck pain can occur in patients with rheumatoid arthritis, but it is unlikely to be the sole presenting feature. Fewer than 2% of patients with rheumatoid arthritis have neck pain as their only feature (Sharp et al., 1958). Rheumatoid arthritis becomes potentially serious if it affects the C1–2 joints, but even then the prognosis is favourable (Isdale & Conlon, 1971). Some 10% of patients with ankylosing spondylitis may present with neck pain (Hochberg et al., 1978), but the rarity of ankylosing spondylitis renders it an uncommon cause of neck pain.

Tumours, infections and metabolic disorders are very uncommon causes of neck pain. Although their prevalence has not been explicitly established, the failure of large radiological surveys to detect such conditions (Heller et al., 1983; Johnson & Lucas, 1997) implies that their prevalence is less than 0.4% in primary care.

Headache is the most common presenting feature of internal carotid artery dissection, but neck pain has been the sole presenting feature in some 6% of cases (Silbert et al., 1995; Biousse et al., 1994). In 17% of patients headache may occur in combination with neck pain (Biousse et al., 1994). Neck pain has been the initial presenting feature in 50% to 90% of patients with vertebral artery dissection, but is usually also accompanied by headache, typically in the occipital region although not exclusively so (Silbert et al., 1995; Sturzenegger, 1994). Although the typical features of dissecting aneurysms of the aorta are chest pain and cardiovascular distress, neck pain has been reported as the presenting feature in some 6% of cases (Garrard & Barnes, 1996; Hirst et al., 1958).

Although considered common, and feared as a cause of neck pain (for medicolegal reasons), fractures of the neck are actually not common. In accident and emergency settings, only about 3% of patients suspected of having a fracture prove to have fractures upon cervical radiography (MacNamara, 1988; Bachuklis et al., 1987; Roberge et al., 1988; Kreipke et al., 1989; Hoffman et al., 1992; Gerrelts et al., 1991).

Missing from Table 50.3 are cervical spondylosis and cervical osteoarthrosis. Although hallowed by tradition, these entities defy legitimate diagnosis. Clinically, they are indistinguishable from any other cause of neck pain. The only available diagnostic criterion are the radiological features of these conditions, but these features are only age-changes. They correlate poorly with neck pain (Heller et al., 1983). Indeed, cervical osteoarthrosis is more common in patients with no neck pain (Fridenberg & Miller, 1963).

For patients with neck pain whose cause is not apparent, the International Association for the Study of Pain recommends the rubric: cervical spinal pain of unknown origin, as an honest diagnosis (Merskey & Bogduk, 1994). Acceleration– deceleration injury, or whiplash, is perhaps the most common traumatic basis for neck pain. However, it does not constitute a diagnosis in a patho-anatomic sense. It is a label that simply recognizes the reported circumstances of onset of neck pain. Zygapophysial joint pain and discogenic pain are specific subsets of what otherwise might be known as 'mechanical' neck pain but their diagnosis requires invasive procedures such as zygapophysial joint blocks and disc stimulation (q.v.).

Although favoured by many, there is no evidence that trigger points are a cause of neck pain. Even in the hands of experts, the diagnosis is unreliable (Wolfe et al., 1992); and the absence of a criterion standard means that its validity cannot be tested. Furthermore, trigger points in the neck do not satisfy the prescribed criteria for a trigger point. They are characterized solely by tenderness and reproduction of pain, in which regard they cannot be distinguished from tenderness of underlying zygapophysial joints (Bogduk & Simons, 1993).

Whiplash

Neck pain due to whiplash is distinguished by an onset attributed to a motor vehicle accident. In western societies the incidence of reported whiplash accidents is about 1 per 1000 population per year (Barnsley et al., 1994a, 1998). However, that is not to say that all cases develop neck pain. The natural history of neck pain attributed to whiplash is quite benign. Within 12 months some 75% of victims are asymptomatic, with the figure rising to 82% by 2 years. This leaves some 20% of patients still with symptoms, but only 4% are severely disabled (Radanov et al., 1995). The prevalence, in the general community, of chronic neck pain due

to whiplash has been calculated as about 1% or less, making it only a fraction of the causes of chronic neck pain (Barnsley et al., 1994a, 1998).

Given the natural history of neck pain after whiplash, the majority of patients must sustain no substantive injury to their neck. Perhaps they suffer a minor muscle sprain, or simply jarring of their neck. However, a minority of patients suffer definite injuries.

Rare injuries include disruption of the alar ligaments, prevertebral hematoma, perforation of the oesophagus, tears of the sympathetic trunk, damage to the recurrent laryngeal nerve, spinal cord injury, periplymph fistula, thrombosis or traumatic aneurysms of the vertebral or internal carotid arteries, retinal angiopathy, and anterior spinal artery syndrome (Barnsley et al., 1994a, 1998). Fractures after whiplash are so uncommon as to be rare. Such fractures as have been attributed to whiplash have been reported only in case studies or small, descriptive series. These fractures may be difficult to detect on conventional investigations, and special attention needs to be paid to their possibility if they are to be detected. The majority involve the upper cervical spine, and include fractures of the odontoid process (Seletz, 1958; Signoret et al., 1986), the laminae and articular processes of C2 (Seletz, 1958; Signoret et al., 1986; Craig & Hodgson, 1991), and the occipital condyles (Stroobants et al., 1994). In one study of 283 patients with acute neck pain after whiplash, however, no fractures were found on plain radiography (Hoffman et al., 1992). This result implies a prevalence of less than 1.3%.

The most likely lesions that underlie chronic neck pain after whiplash are injuries to the intervertebral discs and zygapophysial joints. Cineradiography studies in normal volunteers undergoing simulated whiplash collisions reveal that at some 100 msec after impact, the cervical spine undergoes a sigmoid deformation, during which the lower cervical vertebrae undergo extension about an abnormal axis of rotation (Kaneoka et al., 1999). The movement is such that the anterior edges of the vertebral bodies separate and the zygapophysial joints impact. These movements indicate that the anterior anulus fibrosus can be sprained while the zygapophysial joints can suffer impaction fractures or contusions to their meniscoids (Kaneoka et al., 1999). These are the very lesions that have been demonstrated in postmortem studies of victims of motor vehicle accidents (Jonsson et al., 1994; Taylor & Twomey, 1993; Taylor & Taylor, 1996).

Clinical diagnosis

Critical to the clinical assessment of neck pain is a thorough and careful history. A history of substantial trauma warns of the possibility of fracture, or of vascular injury. Past medical history, current general health, and associated features provide clues to possible serious causes of neck pain. A past history of cancer, weight loss, and ill health, warn of tumour. Transient ischemic episodes warn of vertebral or carotid aneurysms. Arthropathy elsewhere in the body warns of inflammatory joint disease. Neck pain in the elderly warrants consideration of myeloma and Paget's disease. Hyperparathyroidism is a possible cause of spinal pain that is easily overlooked because of its rarity. Neurological symptoms, however, convert the presentation from one of neck pain to one of a neurological disorder. In most cases, however, history reveals no medical disorder; the presentation is simply one of neck pain.

Physical examination offers little towards the diagnosis of neck pain. Typically, the patient will be tender in the cervical spine, and will exhibit restriction of neck movements because of pain. Neither of these features, however, is a valid indicator of any particular source or cause of pain.

In this context, neurological examination is immaterial in the assessment of neck pain, for it is not a neurological disorder. Neurological examination is pertinent if the patient has neurological symptoms, but not if pain is the only presenting feature. In that event, a screening neurological examination, looking for weakness or numbness, is all that is warranted.

Special techniques of examination, such the detection of cervical intersegmental motion, have either not been shown to be valid, or have been found to lack reliability, validity or both. For the detection of tenderness over the zygapophysial joints, inter-observer agreement is good, with a kappa score of 0.68 (Hubka & Phelan, 1994). For other signs, particularly those espoused by chiropractors, observer agreement is poor (Gross et al., 1996; Levoska et al., 1991; Sandmark & Nisell, 1995; De Boer et al., 1985; Nansel et al., 1989; Mior et al., 1985; Smedmark et al., 2000).

Plain radiography

Plain radiography for neck pain is indicated only if the physician has grounds to suspect a fracture or some other serious condition. In the absence of such clinical indicators, different guidelines apply. In two large studies, each involving over 1000 patients with neck pain, no instances of unexpected malignancy or infection were found (Heller et al., 1983; Johnson & Lucas, 1997). The British study concluded that 'the request for X-ray films of the cervical spine "just in case" such a finding is present is probably unjustified.' (Heller et al., 1983). The US study found that upon 5-year follow-up 'no medically dangerous diagnoses would

have been missed if the cervical spine series had not been done'. (Johnson & Lucas, 1997).

What plain radiography is likely to reveal in a patient with neck pain is either a normal cervical spine or cervical spondylosis. The features of cervical spondylosis, however, are simply age-related changes. In some studies cervical spondylosis occurs somewhat more commonly in symptomatic individuals than in asymptomatic individuals (van der Donk et al., 1991; Heller et al., 1983), but the odds ratios for disc degeneration or osteoarthritis as predictors of neck pain are only 1.1 and 0.97, respectively, for women, and 1.7 and 1.8 for men (van der Donk et al., 1991). In other studies, the prevalence of disc degeneration, at individual segments of the neck, is not significantly different between symptomatic patients and asymptomatic controls (Fridenberg & Miller, 1963). Non-covertebral osteophytes and osteoarthrosis are less prevalent in symptomatic individuals (Fridenburg & Miller, 1963).

Loss of lordosis is a feature sometimes reported in cervical spine films, but this phenomenon is a normal variant, and carries no diagnostic implication. It is equally prevalent amongst patients with acute neck pain, chronic neck pain and no neck pain (Helliwell et al., 1994). It is independent of age and symptoms but is more common in females (Helliwell et al., 1994).

CT scanning

No data, and no studies, justify the use of CT as a screening test for undiagnosed neck pain. CT may be of use in better defining known or suspected pathology, such as fractures or tumours; it may be of value in defining the cause of radicular pain; but it offers no value in the pursuit of uncomplicated neck pain. Nothing that might be evident on CT has been shown to correlate with any known cause of neck pain.

MRI

In the context of neck pain, magnetic resonance imaging offers little prospect of a positive diagnosis. Nevertheless, because of its high sensitivity for unusual disorders it is the premier screening tool for chronic, undiagnosed neck pain. In that context, however, its utility lies in ruling out undetected disorders rather than in pinpointing the cause of pain. For finding the cause of pain, MRI is as useless as CT. Moreover, it is confounded by the high incidence of so-called abnormalities in totally asymptomatic individuals.

Disc degeneration, disc bulges, spinal stenosis, and even spinal cord impingement occur in asymptomatic individuals, and with increasing frequency with age (Boden et al., 1990; Teresi et al., 1987). Finding such abnormalities does not provide a diagnosis. In the context of whiplash, multiple studies have failed to detect any diagnostic abnormality in patients with uncomplicated neck pain (Ellertsson et al., 1978; Pettersson et al., 1994; Fagerlund et al., 1995; Borchgrevink et al., 1995; Ronnen et al., 1996; Voyvodic et al., 1997).

SPECT scanning

A small study has provided encouraging news concerning the possible utility of single-positron emission tomography (Seitz et al., 1995). It found that, in patients with acute neck pain after whiplash, SPECT could reveal small fractures undetected by plain radiography or obscured by osteoarthrosis of the joint affected. The fractures consisted of small articular fractures and avulsions of the vertebral rims. The optimum time for using SPECT would seem to be at about four to six weeks after injury. However, the utility of SPECT needs to be determined by larger studies before its wholesale application can be justified.

In the context of chronic neck pain, the one study published on SPECT scanning reported no correlation between whether a zygapophysial joint appeared active or not and whether or not it was painful (Barnsley et al., 1992). Thus, there is no proven utility of SPECT in chronic neck pain.

Invasive techniques

It is not surprising that medical imaging lacks utility for the vast majority of patients with neck pain. Pain is a symptom. It cannot be seen on morphological tests. It requires physiological tests. In this regard, two such tests have been advocated.

Disc stimulation

Disc stimulation is a test designed to determine if an intervertebral disc is painful or not. It involves introducing a needle into the centre of the suspected disc, through which contrast medium is injected in order to stress the disc by distending it from within (Bogduk et al., 1995). The recommended criteria for a diagnosis of discogenic pain are that stressing a particular disc reproduces the patient's pain but provided that stressing adjacent discs does not (Merskey & Bogduk, 1994; Bogduk et al., 1995).

Although championed in some quarters, cervical disc stimulation is fraught with persisting problems. Cervical discs are painful even in asymptomatic individuals.

However, they are not particularly painful. Therefore, it is recommended that the criteria for discogenic pain include reproduction of pain to a level of at least 7 on a 10-point visual analogue scale (Schellhas et al., 1996).

Even so, cervical disc stimulation is compromised by false-positive responses. Disc stimulation can be positive in patients in whom the zygapophysial joints of the same segment are actually the source of pain (Bogduk & Aprill, 1993). Consequently, discogenic pain cannot be diagnosed unless it is shown that other joints in the same segment are not painful.

Furthermore, a recent study has shown that cervical discs are infrequently symptomatic at single levels (Grubb & Kelly, 2000). Positive responses are commonly encountered at two, three, and even four levels or more. The assessment of the patient is, therefore, not complete unless and until all levels are studied; which makes cervical disc stimulation a demanding procedure. If disc stimulation is undertaken at only one, two, or three, preferred or habitual levels, the likelihood of a false-positive result is high.

The one virtue of cervical disc stimulation is that, if multiple discs are found to be symptomatic, surgery is not indicated. Disc stimulation, therefore, plays an important role in reducing unnecessary and futile cervical surgery (Grubb & Kelly, 2000).

Zygohypophyseal joint blocks

Zygohypophyseal (Z joint) blocks can be used to test if a zygohypophyseal joint is the source of a patient's neck pain. They involve anesthetizing, under fluoroscopic control, the small nerves that innervate the target joint, each with not more than 0.3 ml of local anesthetic (Bogduk & Lord, 1998). Z joint blocks have face-validity, in that they selectively anesthetize the target nerves, and do not anesthetize any nearby structures that realistically might be the source of pain (Barnsley & Bogduk, 1993). Single diagnostic blocks, however, are not valid. They carry a false-positive rate of some 27% (Barnsley et al., 1993a). Controls are, therefore, required in each and every patient. When performed under controlled conditions, Z joint blocks have proven construct validity (Barnsley et al., 1993b).

Depending on the circumstances, either placebo controls or comparative diagnostic blocks can be used (Bogduk & Lord, 1998). Comparative blocks involve the administration, on separate occasions, of local anesthetic agents with differing durations of action (Barnsley et al., 1993a). A valid response is one in which the patient obtains a duration of relief concordant with the expected duration of action of the agent administered, i.e. long-lasting relief when a long-acting agent is used, and short-lasting relief when a short-acting agent is used. Controlled studies have shown that diagnostic decisions based on this paradigm are robust (Lord et al., 1995).

Epidemiological studies, using double-blind, controlled, diagnostic blocks, have shown that zygapophysial joint pain is the single most common basis of chronic neck pain after whiplash. On worst-case figures, it accounts for at least 49% of patients (Barnsley et al., 1995; Lord et al., 1996a). In patients with neck pain after severe motor vehicle accidents, the prevalence of Z joint pain is as high as 80% (Gibson et al., 2000). The joints most commonly involved are C5–6 and C6–7 in patients with neck pain and somatic referred pain to the shoulder girdle, and C2–3 in patients with neck pains and headache (Lord & Bogduk, 1996). In patients in whom headache is the dominant symptom, the source of pain can be traced to the C2–3 joint in some 53% of cases (Lord et al., 1994).

Of all the possible diagnostic tests that might be applied to a patient with neck pain, Z joint blocks are the only validated test. Of all the possible causes of chronic neck pain, Z joint pain is the only proven entity, and is the most common cause after whiplash.

Conservative therapy

Many treatments have been used and recommended for neck pain (Bisbee & Hartsell, 1993; Greenman, 1993; Tessell et al., 1993). These include, rest, collars, exercises, posture control, physical therapy, traction, manual therapy, analgesics, trigger point injection, epidural steroids, craniosacral manipulation, and manipulation under general anesthesia. Compelling evidence of efficacy is lacking for most of these interventions. For others the evidence indicates lack of efficacy.

A systematic review of physical and manual therapies (Aker et al., 1996) detailed the positive and negative studies and, where possible, calculated effect sizes of various therapies. Some therapies were reported as having no effect above comparison therapies; others were found to have a positive effect. However, the review did not address the duration of positive effects or their clinical significance; nor did it address outcome measures such as the proportion of patients obtaining complete relief. The only outcome measure used to identify positive effects was improvement of pain, in terms of the mean or median scores on a visual analogue scale. The review was satisfied with statistically significant improvement beyond control as the cardinal, if not only, measure of successful therapy.

Despite its graciousness in this regard, the review nonetheless concluded that:

> there is early evidence to support the use of manual treatments in combination with other treatments for short term pain relief, but in general, conservative interventions have not been studied in enough detail to assess efficacy or effectiveness adequately (Aker et al., 1996).

A less gracious appraisal of the literature (Bogduk, 1998) provides a more alarming view. For acute neck pain not due to whiplash, spray and stretch therapy (Snow et al., 1992) and laser acupuncture (Thorsen et al., 1992) are no more effective than placebo. Traction is not discernibly more effective than isometric exercises (Goldie & Landquist, 1970), and when combined with other interventions, traction offers no advantage over traction alone (Caldwell & Krusen, 1962). Neck school is no better than no treatment (Kamwendo & Linton, 1991). One study reported that, immediately after treatment, manipulation combined with azopropazone afforded greater relief of pain than treatment with azopropazone alone, but the difference was extinguished one and three weeks later (Howe et al., 1983). In another study, there was no significant difference at 3 weeks between patients receiving one to three manipulations and those treated with a muscle relaxant (Sloop et al., 1982).

For chronic neck pain not due to whiplash, there are no studies of the efficacy of exercise, collars, TENS, neck school, spray and stretch, or traction. Wearing magnetic necklaces is no more efficacious than placebo (Hong et al., 1982). Laser acupuncture is no more effective than sham transcutaneous electrical nerve stimulation (TENS) (Lewith & Machin, 1981); and needle acupuncture is no more effective than sham acupuncture or an injection of diazepam (Thomas et al., 1991), or sham TENS (Petrie & Langley, 1983; Petrie & Hazelman, 1986). Compared to no treatment, a programme of gymnastics was found to offer no therapeutic benefit (Takala et al., 1994).

In a study that focused on manipulation for back pain, 64 patients with neck pain were treated (Koes et al., 1992). Separate data on these patients were not reported in the original publication, but subsequent analysis found no statistically significant differences in response between those patients receiving manual therapy and those receiving physiotherapy and general practice care (Hurwitz et al., 1996). Another study compared manipulation, physiotherapy, and being treated with salicylate (Brodin, 1984, 1985). It reported a statistically significant benefit from manipulation. Analysis of the data, however, reveals that the difference arose because of poorer outcomes in the patients treated with physiotherapy. Between the outcomes of patients treated with manipulation and those treated with salicylate, there was no statistically significant difference.

In a methodologically strong study (Foley-Nolan et al., 1990) pulsed electromagnetic therapy delivered through a collar was found to have a significantly greater effect on pain than a collar alone. The difference arose, however, because of a greater proportion of patients in the active treatment group reporting 'moderately better' as opposed to 'no change' in the control group. The number of patients 'completely well' or 'much better' was not significantly different in the two groups. The study did not report the duration of effect for any period after cessation of treatment.

For acute neck pain after whiplash, the Quebec Task Force on Whiplash Associated Disorders attempted a major synthesis of the literature available up to September 1993, but was unable to compose a systematic review or meta-analysis (Spitzer et al., 1995). Out of 10382 potentially relevant articles, only 62 were accepted as both relevant and scientifically meritorious. The Task Force concluded that: 'the evidence was found to be sparse and generally of unacceptable quality' (Spitzer et al., 1995).

Rest and analgesia (McKinney et al., 1989), combinations of TENS, ultrasound and pulsed electromagnetic therapy (Provinciali et al., 1996), and soft collars (McKinney et al., 1989; Foley-Nolan et al., 1992; Mealy et al., 1986), have each been used in controlled studies as reference treatments, and each has been found to be inferior to other interventions. Traction offers no additional benefit when added to instruction, moist heat and exercise (Zylbergold & Piper, 1985), and is no better than rest in a collar (Pennie & Agambar, 1990). Receiving pulsed electromagnetic therapy delivered from a device implanted in a collar affords greater improvement in pain than wearing the same collar with a dummy device (Foley-Nolan et al., 1992); but the difference is apparent only for the first four weeks of treatment; by 12 weeks electromagnetic therapy affords no advantage.

The application of ice for the first 24 hours after injury, followed by mobilization, local heat, exercises and analgesia is superior to rest, analgesia and a soft collar (Mealy et al., 1986), at 4 weeks and 8 weeks after treatment, but no long-term data are available. Active out-patient physiotherapy (consisting of a tailored programme of hot and cold applications, short-wave diathermy, hydrotherapy, traction, and mobilization), and a home-exercise programme both achieve greater improvements than rest and analgesia, at one month and two months after treatment, but active physiotherapy is not superior to home exercises alone (Provinciali et al., 1996). In a long-term follow-up,

however, home exercises achieved a greater proportion of patients free of pain (McKinney, 1989).

So-called 'multimodal therapy', consisting of relaxation training, reduction of cervical lordosis, psychological support, eye fixation exercises, and massage and mobilization, is superior to applications of TENS, pulsed electromagnetic therapy, ultrasound, and calcic iontophoresis, at 2 weeks and 4 weeks after therapy (Provinciali et al., 1996); but in the long term, results are no better than those achieved by other and simpler means, including rest and analgesia and wearing a collar.

In essence, the combined data on physical and manual therapy, do show that intervention is superior to rest and analgesia, but the impact pertains to a decrease in average pain score, and is evident only at 4 to 8 weeks after onset of pain. Thereafter, either there are no data or the suggestion that patients not treated actively eventually achieve the same degree of recovery. The impact of physical and manual therapy is to achieve not resolution in a greater proportion of patients but a more rapid resolution in the early weeks after onset of pain. The only long-term data indicate that a greater proportion of patients achieve complete recovery when treated with home exercise.

A challenging observation has been a study in which an index treatment was compared with rest, analgesia and a collar. At 6 months and at 1 year after treatment, there were few differences, but the results favoured the index treatment. That treatment was reassurance, a direction to resume normal activities, and denial of sick-leave (Borchgrevink et al., 1998).

For chronic neck pain after whiplash, there is no evidence of the efficacy of any conservative therapy. Even the Quebec Task Force (Spitzer et al., 1995), in its consensus approach, recommended no specific therapy. For patients still unresolved by 12 weeks, it recommended only evaluation by a multidisciplinary team, without venturing what sort of management this might result in, and without offering any evidence of the efficacy of multidisciplinary pain management.

Medical therapy

There are no data explicitly demonstrating the efficacy of analgesics, non-steroidal anti-inflammatory agents, or other drugs, for neck pain of any nature (Spitzer et al., 1995). If such agents are used, it is on the basis of presumed efficacy, but should be in the full knowledge that, for neck pain, they may be no more effective than placebo.

No studies have demonstrated the efficacy for neck pain of any form of injection into the neck, be that using local anesthetic, sclerosing agents, or corticosteroids. For chronic neck pain stemming from the zygapophysial joints, intra-articular injections of corticosteroids are no more effective than injections of local anesthetic, and both treatments fail to achieve sustained relief in more than a minority of patients (Barnsley et al., 1994b).

Surgical therapy

There is no compelling evidence of the efficacy of cervical fusion for neck pain. Such studies as have reported on this therapy claim success (Kikuchi et al., 1981; Whitecloud & Seago, 1987) but outcome measures are few and lacking in rigour. Some studies report disheartening results (De Palma et al., 1972), particularly for surgical therapy of neck pain after whiplash (Algers et al., 1993).

The one surgical procedure that has withstood scientific scrutiny is percutaneous, radiofrequency, medial branch neurotomy. In this procedure, the nerves that innervate the cervical zygapophysial joints are coagulated in an effort to relieve pain stemming from these joints (Lord et al., 1998). Under double-blind, controlled conditions, the procedure has proven not to be a placebo (Lord et al., 1996b). Moreover, it is the only treatment for neck pain that has been shown to achieve complete relief of pain, and restoration of activities of daily living (Lord et al., 1996b; 1998). Furthermore, relief of pain is attended by complete resolution of psychological distress (Wallis et al., 1997). A limitation of the procedure, however, is that pain recurs as the nerves regenerate. However, in that event, the procedure can be repeated and the pain once again completely relieved. Long-term studies have shown that continued, repeated relief can be sustained for up to 2000 days (McDonald et al., 1999).

Recommendations

In the light of the available evidence, the best recommendations that might be offered are:

For acute neck pain,

- Simple analgesics or non-steroidal anti-inflammatory agents might be used to provide analgesia while patients undergo natural recovery, but in the knowledge that the efficacy of these agents may be no greater than placebo.
- There is no evidence to justify the use of major tranquillizers or tricyclic antidepressants.

For neck pain after whiplash, during the first 8 weeks after injury,

- Patients could be treated with rest and analgesia, but
- A more rapid resolution of pain might be achieved by the use of ice, and passive mobilization, although
- A home-exercise programme offers just as much chance

of rapid resolution and a greater chance of being pain-free at 2 years; however,
- Firm reassurance, and insistence to resume normal activities, may be as effective as any other measure.

In the face of refuting data, and given the availability of a proven alternative,
- Traction, electromagnetic therapy, collars, TENS, ultrasound, neck school, spray and stretch, laser therapy, or traction, should not be used in the treatment of acute neck pain.

For chronic neck pain,
- No physical therapy is justified on the basis of available evidence.
- The use of analgesics might be justified on humanitarian grounds but not on the basis of evidence of efficacy.
- If NSAIDs are used their efficacy should be determined, and patients carefully monitored for side effects.
- Intra-articular injections of corticosteroids into the cervical zygapophysial joints should not be used unless it can be shown that the patient can achieve lasting and worthwhile relief that is cost-effective.
- Disc excision and fusion for neck pain without neurological signs might be entertained on the basis of uncontrolled clinical trials of this procedure, but this form of therapy would best be reserved for the context of clinical trials approved by an ethics committee or an institutional review board, and designed to determine its efficacy and safety.
- Radiofrequency neurotomy can be used to provide complete relief of pain in patients diagnosed rigorously as suffering from cervical zygapophysial joint pain, but the use of this procedure should be restricted to trained and accredited providers.

Resolving a dilemma

Quite clearly, neck pain is not radicular pain. Neck pain is perceived in the cervical region, not in the upper limb. Neck pain, however, can be associated with referred pain; and it is this somatic referred pain that can be difficult to distinguish from radicular pain.

The patterns observed for referred pain from cervical joints in normal volunteers (Fig. 50.3) were more restricted than those reported for interspinous ligaments (Fig. 50.2). The pain was restricted to the immediate vicinity of the neck and shoulder girdle, and did not extend distally into the upper limb. One reason for this difference is perhaps that the stimuli used were more restrained and less intense. Whereas the interspinous ligaments were stimulated with injections of hypertonic saline, the cervical joints were stimulated with injections of contrast medium to distend the joint. In order not to disrupt the joint, injections were terminated immediately once pain was elicited. In essence, the stimulus was minimal. It may be, therefore, wider areas of referral could occur from cervical joints or discs if stronger noxious stimuli were applied to these structures. However, this has not been tested experimentally; nor has it been borne out clinically.

No clinical studies have reported relief of somatic referred pain in the distal upper limb. Patients in whom somatic referred pain has been relieved by injections of local anesthetic into the neck have had referred pain no further than the shoulder girdle (Barnsley et al., 1995; Lord et al., 1996a). It seems, therefore, in practice, that somatic referred pain from the neck does not commonly extend beyond the region of the shoulder girdle. This empirical fact bears on the distinction between somatic referred pain and cervical radicular pain.

Since somatic referred pain from C6 or C7 does not commonly extend into the forearm, yet C6 and C7 radicular pain does, it is reasonable to deduce that referred pain that extends into the forearm is more likely to be radicular in origin than to be somatic referred pain. In contrast, C5 radicular pain typically extends only over the shoulder girdle (Fig. 50.1), and in that regard cannot be distinguished from somatic referred pain stemming from C5,6 structures (Fig. 50.3). However, epidemiologically, C5 radicular pain is not common (Merskey & Bogduk, 1994) but C5,6 somatic referred pain is (Barnsley et al., 1995; Lord et al., 1996a; Lord & Bogduk, 1996). Therefore, the pre-test probability of pain over the shoulder girdle favours somatic referred pain. Consequently, physicians should be guarded in diagnosing pain over the shoulder girdle as radicular pain.

The cardinal distinction between cervical radicular pain and somatic referred pain is that somatic referred pain is not associated with neurological signs; yet radicular pain usually is. Therefore, the presence of neurological signs favours a diagnosis of radicular pain, and in the case of pain extending into the forearm, neurological signs all but confirm the diagnosis of radicular pain.

These guidelines, however, are not absolute. Physicians need to heed that a patient's pain may not necessarily be entirely radicular; they may have components both of radicular pain and of somatic referred pain. It may be that a patient suffers a condition that by different, and parallel, mechanisms produces different clinical features. The condition may produce nociceptive pain, which if severe may radiate as somatic referred pain. Meanwhile, the same condition may also mechanically compromise a spinal nerve and produce both radicular pain and radiculopathy. For example, an arthritic C6–7 zygapophysial joint may be

locally painful and produce neck pain; it may produce somatic referred pain to the shoulder region; but its osteophytes may also compress the C6 spinal nerve to produce C6 radicular pain and C6 radiculopathy. In that event, the neurological signs and the forearm pain can be attributed to the radicular component of the diathesis; the neck pain stems from the joint itself, and not from nerve root irritation; but the pain across the shoulder is a mixture of somatic referred pain and the proximal component of the radicular pain.

Such combinations may underlie treatment failures. If all of the patient's symptoms are summarily attributed to radiculopathy and are treated as such, the radicular components may well be relieved; but the somatic components may not; and the patient will be left with neck pain and somatic referred pain. It is for such reasons that each of the patient's symptoms and signs should be analysed separately, and if necessary investigated and treated separately.

Diagnosis and management of low back pain

Donlin M. Long and Mohammed BenDebba

Department of Neurosurgery, Johns Hopkins School of Medicine, Baltimore, Maryland, USA

Low back pain (with or without sciatica) is one of the most common complaints of patients in all developed countries (Ackerman et al., 1997a; BenDebba et al., 1997; Deyo & Tsui-Wu, 1987; Fredrickson et al., 1984; Long, 1989; Long et al., 1979). In the USA, it is the second most common reason to see a physician (Carey et al., 1995), and the most common reason for Workmen's Compensation claims (Long et al., 1996). Surgery on the spine now ranks third among procedures in the Medicare population (Zeidman & Long, 1996).

Thus, it is surprising to discover that there is no complete classification system for low back pain with or without sciatica, and standards for diagnosis, treatment, and assessment of outcomes of therapy have not been established (BenDebba et al., 1997; Merskey & Bogduk, 1994).

One of the principal reasons why this situation exists is that for most patients, the causes of low back pain remain unknown, and the value of therapy is uncertain (Bigos et al., 1994; Waddell et al., 1984). The magnitude of the problem and the huge expenditures required for low back pain make it particularly important to understand what is currently known and not known about back pain, so that treatment is rational and based upon the most up-to-date information and guidelines.

Classification of low back pain

Classifications may be etiologic, based upon anatomical descriptions, or may use surrogate descriptors when anatomical and pathological details are not well understood. The most common classification system for low back pain is temporal and relates to descriptions of patients, rather than to pathological processes (BenDebba, 1997; Bigos et al., 1994; Long et al., 1996). This practical system is of real value in managing patients, although it does not provide the desired etiologic accuracy that is available with anatomical and pathological classifications (Bogduk, 1997; Main et al., 1992).

Transient low back pain

Transient low back pain is that which occurs so briefly that the patient does not seek medical attention. The etiologies of these brief periods of low back pain remain unknown, but will be discussed in greater detail later in the chapter.

Acute low back pain

Acute low back pain lasts for a longer period of time, usually a few days, and often brings the patient to medical attention. These patients have been addressed in guidelines promulgated by the consensus method from the National Institute for Health Policy Research (Bigos et al., 1994). Such patients require a careful history with the intent to determine if there are danger signals suggesting that this episode of back pain is a symptom of a serious underlying disease or the result of major trauma. It is unlikely that the history will be important otherwise, but in the acute phase, the primary concern is that an important intercurrent disease such as trauma with resultant fracture or instability, infection, or neoplasm may be missed. The physician needs to ensure that the back pain is not referred from gastrointestinal or renal disease and is not a symptom of vascular disease such as aortic aneurysm. Back pain as a part of an arthritic syndrome, such as ankylosing spondylitis or rheumatoid arthritis is possible, but generally such a diagnosis is less critical in the acute phase.

The physical examination requires inspection of the back, palpation for assessment of muscle spasm and local tenderness, assessment of range of motion, and/or a neurological evaluation that examines reflexes, strength,

and sensation in the lower extremities. Any acute neurological loss is important, but only severe deficits are likely to precipitate immediate therapy. Patients usually know about bowel or bladder dysfunction, but it is important to ask even though definitive testing is not required in the absence of complaints. A key issue in the neurological examination is the differential diagnosis, which should separate lumbar radicular abnormalities from other neurological deficits (Deyo et al., 1992; Dreyfuss et al., 1996; Mooney, 1987).

Management of acute low back pain

If there are no indications of intercurrent disease and no evidence of significant neurological loss, consensus guidelines indicate that no further evaluation is required (Bigos et al., 1994). Specifically, imaging studies need not be done. Indications for imaging of any kind are: a history of significant trauma, the presence of known or suspected intercurrent disease, and the presence of a significant neurological deficit. Without them, treatment is expectant. Patients should be prescribed rest or limited activity for a few days until improvement begins. Adequate analgesia is important (Long et al., 1979; Solomon et al., 1980). No other treatment is required because spontaneous recovery will occur in most patients within a few days. In fact, patients should be returned to full function as soon as possible (Turner, 1996). There is good evidence that recovery is hastened by increased activity as tolerated (van den Hoogen et al., 1998). Most patients will recover substantially within the first month. If they do not, or if any new important neurological or other symptomatic changes occur, imaging is then reasonable (Bigos et al., 1994; Liang & Komaroff, 1982). Plain films with flexion/extension and MRI give the most information. CT is a reasonable substitute, but will provide less information about soft tissue changes than MRI. The purpose of imaging is not necessarily to make a diagnosis, but rather to determine if a surgically remediable abnormality or otherwise treatable disease is present (Ackerman et al., 1997b,c; Lindstrom et al., 1992). There is little evidence to support the use of physical therapy, manipulation therapy, or any alternative medicine treatments at any time in the management of acute low back pain. The cost is substantial and the benefit marginal even in the most favourable studies (American Academy of Orthopedic Surgeons and North American Spine Society, 1996; Anderson et al., 1999; Bigos et al., 1994; Cherkin et al., 1996b, 1998; Koes et al., 1991a,b, 1994; Koes & van den Hoogen, 1994; Linton & Kamwendo, 1987).

Many experienced practitioners use a short course of oral steroids when an acute radicular syndrome is present without neurological deficit (Sonne et al., 1985). There is no definitive study supporting this practice, but many practitioners find that a short course of oral steroids will rapidly relieve radicular pain. Some clinicians use epidural steroids for the same purpose. It has always been our contention that the evidence for substantial improvement is meagre and that the procedure is not without risk. We use oral steroids for acute radicular syndromes, but have discouraged the use of epidural steroids because we believe that their limited benefits do not clearly justify the cost and risks associated with them. Since most patients recover spontaneously, the least intervention possible in acute syndromes is best (American Academy of Orthopedic Surgeons and North American Spine Society, 1996; Bigos et al., 1994; Carey et al., 1995; Indahl, 1995; Long & Watts, 1996; Long & Zeidman, 1994; van Tulder et al., 1997).

The persistent low back pain syndrome

Not all patients recover spontaneously (Lindstrom et al., 1995). Recently, we identified a subgroup in which symptoms persist after 3 months and apparently become permanent (Ackerman et al., 1997c; Long et al., 1996; Long & Watts, 1996; Long & Zeidman, 1994). For these patients who still complain of substantial pain and disability after 3 months, it is appropriate to carry out an immediate investigation to identify the cause of the pain. Although there are specific constellations of signs that denote specific root involvement, they occur rarely and the neurological examination is seldom diagnostic. The most important sign is the positive straight leg-raising test. When present, this strongly suggests root compression, but does not suggest the cause (Long et al., 1996).

The imaging evaluation begins with flexion and extension plain films and MRI (Ackerman et al., 1997c; American Academy of Orthopedic Surgeons, 1995). CT of the lumbar spine is indicated when the disease is thought to have a significant bony involvement. CT myelogram, which was the major diagnostic test until fairly recently, is now rarely indicated. It is used principally when intradural pathology is suspected or when a patient cannot tolerate MRI and plain CT does not provide adequate information (Fullenlove & Williams, 1957; Loisel et al., 1997; Scavone et al., 1981).

Of interest is that in an extensive prospective review of nearly 4,000 patients, we found no clinically significant psychological dysfunction in patients with persistent low back pain complaints (BenDebba et al., 1997; Long et al., 1996).

The chronic pain syndrome

The group described above is quite different from a group of patients identified well over 30 years ago in whom pain

complaints with clinically significant psychological dysfunction produce a completely disabling syndrome (Morley et al., 1999; Waddell et al., 1984). These patients, who have high levels of psychological distress and are disabled by pain without evidence of physical impairment, differ from patients with the persistent pain syndrome (Bigos et al., 1991; Main et al., 1992). Their evaluation and treatment has been studied intensively in multidisciplinary pain treatment centres (Long et al., 1981, 1988; Long, 1992). At Johns Hopkins, we evaluate this group by using a medical model that comprises an exhaustive investigation of possible causes of the pain, assessment of physical impairment, and careful assessment of psychological dysfunction. Treatment consists of a multidisciplinary approach that involves eliminating the cause of the pain, improving physical functioning, and attending to psychological needs (Loisel et al., 1997; Long 1991a,b; Phillips & Grant, 1991a; Zeidman & Long, 1996).

Etiologies of low back pain

The major problem in classifying low back pain is that it is a symptom of many diseases for which correlations are excellent, but the underlying causative factors are not understood (Bogduk & Long, 1979). Obviously, the pain is generated through the activation of nociceptors serving the abnormal areas (Ackerman et al., 1997c; Long, 1989; Merskey & Bogduk, 1994). What activates these nociceptors, however, is unclear (Mooney, 1987). Most experts agree that compression of individual lumbar nerve roots will produce pain, both localized in the spine and with a radicular character (Smyth & Wright, 1959). Relief of the compression usually improves the pain. Severe degrees of dislocation with movement also produce pain (Fredrickson et al., 1984). Nevertheless, there is no consensus about what minimal degree of subluxation is required to be either pathological or painful. Some believe that small movements that are not discernible on imaging studies may be sufficient to cause chronic pain (Mooney & Robertson, 1976; Morley et al., 1999); others suggest that the mediators are the chemical components of the inflammatory cascade that may occur acutely or may be a part of the spondylotic process (Mooney, 1987). Definitive data do not exist to prove or disprove these hypotheses. Although, there is a strong association of back pain with spondylotic disease in the majority of sufferers, this correlation is clearly not absolute. Moreover, several authors have demonstrated that patients with significant spondylotic disease may be asymptomatic (Ackerman et al., 1997b; Fullenlove & Williams, 1957; Splinthoff, 1953).

In the absence of definitive data, it is necessary to define clinical hypotheses for the origins of back pain and direct treatments empirically. The fundamental hypothesis that leads to surgery is that some patients have back and leg pain associated with nerve root compression, instability of the spine, or both, and that these are the only conditions currently known that surgery can ameliorate (Long, 1978, 1985, 1987; Long et al., 1988). Only a small minority of patients with back pain have either of these conditions demonstrated. So, for the majority of patients, the cause of their complaint remains unknown and assumptions about primary or secondary painful phenomena remain descriptive (Bogduk & Long, 1979; Dreyfuss et al., 1996; Hirschberg et al., 1979; Ingpen & Burry, 1970; Johnson, 1989).

Specific conditions associated with back pain

Back pain as a consequence of systemic disease

Back pain may occur as a consequence of a number of organ-specific diseases that manifest themselves in or near the lumbar spine, particularly in the retroperitoneal space. These include aortic aneurysm, metastatic or locally invasive neoplasm, inflammatory disease of the bowel, kidney diseases of many kinds, pelvic neoplasia and inflammatory disease, and endometriosis. Hip disease, lower extremity occlusive vascular disease, and sensory motor neuropathies can mimic lumbar radiculopathy. In a study of nearly 4000 patients, however, only 3% had back pain as a symptom of intercurrent disease and almost all of these were previously undetected metastatic cancer (Long et al., 1996; Magora & Schwartz, 1976). Intradural spinal cord tumours are occasionally present with back pain. In all these instances, the history usually reveals that this pain differs from the usual back pain of unknown etiology (Ackerman et al., 1997c; Deyo et al., 1992; Deyo & Tsui-Wu, 1987; Phillips & Grant, 1991b; van den Hoogen et al., 1998; von Korff, 1994).

Infections

Lumbar diskitis, with or without paravertebral abscess, is an unusual and extremely serious cause of back pain (Waldvogel & Vasey, 1980; Zeidman & Long, 1996). The most common infective agents are tuberculosis and infections spread from other sources, such as dental or kidney infections. Most patients have a history suggestive of infection, including malaise, chills, and fever, but sometimes pain is the only or predominant symptom and fever does not occur. Imaging studies based upon symptoms indicative of infection will invariably make the diagnosis, except in the most acute cases.

Arthritis and spondylitis

Severe back pain is the defining symptom in a number of spondylitic and arthritic diseases, the most common of which is rheumatoid arthritis. Ankylosing spondylitis in males is another well-known disease. Arthropathy of zygapophyseal joints occurs in psoriasis, and in both gout and pseudo-gout. Inadequately treated acromegaly is often complicated by intractable back pain. Most of the less frequently encountered arthritides can also present with back pain. Back pain and spinal stenosis are common early midlife complications in achondroplasia. Imaging studies and an appropriate diagnosis of the underlying arthritic condition usually establish the cause of the pain (Long, 1978, 1991a).

Back strain and fibromyalgia

The most common cause of acute back pain is generally assumed to be muscular strain and/or muscular-ligamentous inflammation (Ingpen & Burry, 1970; Johnson, 1989). The assumption is made because of the presence of focal tender points and spasm in muscles. Since no clearly defined structural abnormalities are found, back strain, myositis, fibromyalgia, or any of several other descriptive diagnoses are commonly made (Johnson, 1989). There is no definitive evidence that these are real entities; they are inferred because of local nonspecific findings. Clearly, all of these local changes exist in patients, but whether they are primary causes of the problem or simply secondary to the, as yet, undefined abnormalities of the lumbar spine is not known. Still, patients improve with treatment of these local abnormalities, whether they are primary or epiphenomena (Anderson et al., 1999; Cherkin et al., 1998; Fordyce et al., 1986; Indahl et al., 1995). Treatment consists of analgesic and anti-inflammatory agents, and passive measures such as heat, massage, ultrasound, electrical stimulation, and local analgesic and/or steroid injection. Bed rest is often helpful for a few days, as well as some restriction of activities that aggravate the pain (Bigos et al., 1994; Deyo, 1996; Long, 1989).

The argument over the reality of a primary diagnosis of fibromyalgia persists. Those who believe in a unifying diagnosis have not yet demonstrated diagnostic features that reliably define a disease process. In practical terms, it makes little difference, because the treatments are all symptomatic (Wheeler & Hanley, 1995).

Surgery is indicated for very specific diagnoses and all other treatments for spinal problems are either expectant, awaiting spontaneous resolution, or symptomatic (American Academy of Orthopedic Surgeons, 1995). For this reason, the most important issues for patients with persistent or chronic low back pain are to be certain that there is no treatable underlying pathology, that there is no evidence of serious intercurrent disease, and to determine if surgical therapy can change the structural abnormalities found in the spine. When all three issues are addressed and nothing treatable is found, use of symptomatic therapies is routine. The evidence that these symptomatic therapies are valuable is marginal. The best published data suggest that weight loss, general conditioning, and a specific exercise program aimed at strengthening lumbar and abdominal muscles will be beneficial (Forssell, 1981; Indahl et al., 1998; Jackson & Brown, 1983; Lindstrom et al., 1992; Moffett et al., 1999). Our data strongly suggest that most of the currently used symptomatic therapies will not result in significant improvement (Cherkin et al., 1996a; Frymoyer & Cats-Baril, 1987; Koes et al., 1991a,b, 1994).

Degenerative disc disease and spondylosis

The majority of patients with persistent low back pain have general spondylotic changes that are characterized by loss of disc hydration, inflammatory and hypertrophic changes in bones and ligaments, fissures and tears in the annulus, fibrosis, loss of disc height, facet arthropathy including synovial cyst formation, and changes in spinal alignment including spondylolisthesis, retrolisthesis, and many variations of scoliosis. The simplest expression is lumbar disc herniation.

The herniated lumbar disc

Disc herniations are usually heralded by back pain and radicular pain in the distribution of the nerves affected, with or without neurological changes related to those same nerves. Herniation may be traumatic or spontaneous. It may be preceded by a long history of lesser back problems or may occur as a first-time event. Herniation occurs most commonly at L4–L5 and L5–S1 with higher levels being involved only about 15% of the time. Typical herniations are midline, lateral within the spinal canal, or far lateral in the foramen or beyond. The most important feature is the history of radicular pain. Massive disc herniations may also compromise bowel, bladder, and sexual functions, but the typical disc affects one or two nerve roots only.

Herniations at L5–S1 may affect either nerve root or both. Involvement of the S1 nerve root produces sciatica with pain reaching the lateral side of the foot and sole. The ankle reflex is diminished or absent. Sensory loss occurs in the lateral two toes, lateral foot, and sole. Motor loss produces weakness of extension of the foot. Involvement of the L5 nerve root produces sciatica that reaches the top of

the foot, the medial foot, and first three toes, in particular the great toe. There is no associated reflex change. Sensory loss occurs in the top of the foot and specifically in the web space between the first and second toes. Weakness is manifested by impaired ability to flex foot and toes. Straight leg-raising is a strong confirmatory sign. With a patient lying flat, the painful leg is raised slowly while extended. Sciatic pain must be reproduced for the test to be positive. When the non-painful leg is raised and contralateral pain occurs, this is called positive crossed straight leg-raising and is a very reliable sign of nerve root compression. In all patients with disc herniation, there may be associated non-specific findings of muscle spasm, paravertebral muscle tenderness, sciatic notch and sciatic nerve tenderness, but these do not aid in the diagnosis.

Involvement of the L4 nerve root causes absence or diminution of the knee reflex, sensory loss in the anterior thigh and lateral leg, and weakness of leg extension. Sciatic stretch by straight leg-raising may be positive. The femoral stretch, which is assessed by passively moving the leg posteriorly, may also be positive.

Higher disc herniations affecting the upper lumbar roots have no associated reflex changes. Sensory and motor changes are those appropriate for the roots involved. Femoral stretch will be positive, but straight leg-raising will be negative.

Far lateral disc herniations may have a special characteristic. Because the dorsal root ganglion is affected, the pain is perceived as burning and particularly unpleasant. Such a sign is suggestive only.

Most acute disc herniations relent with time and do not require surgery. Indications for urgent operation are intractable pain that cannot be relieved with reasonable analgesics; a lower extremity neurological loss that would be undesirable if permanent; and significant change in bowel, bladder or sexual function. Otherwise, most patients can be treated expectantly with adequate analgesia, bed rest, and then restriction of activities until recovery occurs. Most patients begin to improve within a few days and many show signs of recovery within the first week. Substantial improvement is probable within the first month. Most patients recover completely within 3 months. In the acute situation, imaging studies are not required immediately unless pain or neurological deficits are severe. If a patient fails to follow the expected course of spontaneous improvement, MRI is the imaging study of choice. Surgical therapy should proceed when it is clear the patient's symptoms warrant intervention and spontaneous recovery is not likely to occur. There is no evidence that interposing physical therapy, manipulation, or any form of alternative medicine will alter the natural history of the disc herniation. For many years, the standard practice has been to interpose physical therapy as a requirement for surgery. The evidence that this is beneficial is marginal (Long, 1987; Long et al., 1996).

New treatments for the herniated lumbar disc are introduced continually (Solomon et al., 1980; van Tulder et al., 1997). Intradiscal therapies have included the injection of steroids, agents that dissolve the nucleus pulposus, and sclerosing agents to strengthen ligaments. Percutaneous removal of disc material has been attempted with lasers, nucleotones, and more typical surgical instruments controlled by endoscopes. A recent addition to this percutaneous armamentarium has been the concept of intradiscal heat coagulation, which is thought to strengthen the internal structure of the disc and which some postulate may destroy sensory nociceptors. Most of these techniques come and go without being subjected to rigorous clinical trials. Because the natural history of acute back pain and sciatica is one of spontaneous improvement, it is easy for practitioners and patients to believe that the prescribed treatments have produced the observed improvement (Wheeler & Hanley, 1995).

Spinal stenosis

Another common spondylitic syndrome is spinal stenosis. The disease usually appears in patients who begin with congenitally short pedicles and then have further compromise of the central spinal canal and neural foramina by age-related spondylotic changes. The typical syndrome combines back pain with a leg pain complex known as claudication. With activity, leg pain generally worsens and a transient neurological deficit may occur. The syndrome is very similar to vascular claudication, but examination of the vascular system usually reveals no significant abnormality. Neurological findings are variable and the history is more important because the neurological abnormalities are often transient and related to exercise or position. In severe cases simply standing is enough to precipitate symptoms. Diagnosis is obvious on MRI. In severely incapacitated patients, surgical decompression with restoration of an adequate canal and/or foraminal capacity is, typically, highly efficacious (Long & Watts, 1996).

Spinal instability

There is much debate about what constitutes spinal instability. Pain associated with obvious subluxation of spinal elements with movement is well-documented (Schneiderman et al., 1995), but how to define the degree of movement required to diagnose instability is uncertain (Bogduk, 1997; Bogduk & Long, 1979, 1980). So-called glacial instability that changes perceptibly over months or

years is also generally thought to be painful, but definitive supportive clinical data are lacking (Phillips & Grant, 1991b). All spinal fusions are based upon the elimination of instability or correction of biomechanical deformity (Indahl et al., 1998). Correction of significant and/or progressive scoliosis in all its forms and stabilization of obvious subluxation are well accepted. The value of fusion procedures in less obvious instability situations is less well demonstrated (Moreton, 1966).

Degenerative disc and spondylotic abnormalities without instability or root compression

Degenerative changes have been observed on imaging studies in many people. Loss of disc hydration begins in late youth to early middle age in a large percentage of the population. This so-called degenerative disc disease continues to progress to late middle age and then usually stabilizes. In some people progressive changes continue to occur. Nevertheless, many people with substantial degenerative changes have no symptoms, and many people with significant symptoms have few, if any, degenerative changes. It is generally accepted that these degenerative disc changes are causally related to pain, but the cause of the pain is unknown. Because of the poor correlation between clinical syndrome and imaging findings, a large variety of treatment modalities have been used without strong evidence of their efficacy. Therapy is usually symptomatic, of limited value, so it is not surprising that there are many treatment schemes touted to be the answer for low back pain (Moffett et al., 1999). The appearance of new explanations and new treatments has been a cyclical event.

The national low back pain study (NLBPS)

Our concepts of treatment are based on the results of an eight-centre nationwide study of patients with significant persisting back and/or leg pain, known as the NLBPS. The study began more than 10 years ago and is still ongoing. Our goal was to study those patients who were seriously incapacitated by low back pain uncomplicated by multiple interventional treatments or previous surgery. As already stated, most acute back and leg pain is self-limited and does not require significant treatment. Therefore, we identified a group of patients with pain persisting for 3 months or longer, who were referred to orthopedic or neurological surgeons for evaluation and possible surgical treatment. Complete history and a thorough physical examination, as well as imaging studies, were used to establish the diagnosis thought most likely to account for each patient's pain and functional impairment. The outcome of therapy was monitored over a 2-year period with a battery of tests that assess all the characteristics of the complaint: pain severity, function disability, psychological status, symptoms other than pain, and healthcare utilization. This was an effectiveness study that examined the value of all therapies employed, but did not allow comparisons between therapies.

The demographic make-up of the patient population proved to mimic that of the general population. Of the more than 2300 patients enrolled in the study, 1441 were prescribed conservative care, 332 were prescribed no treatment, and 331 were prescribed immediate surgical care. Another 254 patients went to surgery after failure of conservative care.

All the patients in the study were significantly disabled by their problem, such that they had been referred to an orthopedic or neurological surgeon for possible surgery. Over 80% had a final diagnosis implicating spondylotic disease as the cause of their symptoms, and 60% had a diagnosis of nerve root compression syndrome. Nevertheless, only 25% of the entire study population were selected for surgery.

Instability was infrequently diagnosed, occurring in only 10% of the patients. It was surprising to discover that the physical examination was irrelevant to the diagnosis. The history was the most important diagnostic determinant, and as expected, sciatica was the predominant symptom leading to surgery. The only physical finding consistently predictive of nerve root compression was a positive straight leg-raising test. Most patients had no neurological abnormalities. Reflex, motor, or sensory changes occurred in about one third of the patients, and the classic triad taught to be diagnostic of lumbar disc disease was observed in less than 1% of patients. Whereas significant neurological deficits are certainly indications for surgery, we found such cases to be rare even in patients with significant disc protrusion (Long et al., 1996).

The patients' psychological profile was consistent with that of a typical ill patient population. There was no evidence for psychopathology in the genesis of the complaint of low back pain (BenDebba et al., 1997; Phillips Grant, 1991a).

The first important finding from the follow-up studies was that there was no significant spontaneous improvement with time. The entire cohort was followed for 2 years and a subset was followed for 5 years. Spontaneous improvement was observed in neither. Thus, we believe we have identified a group of patients who comprise a consistent syndrome. These are patients who do not improve spontaneously; but usually have episodic pain for years. We have referred to them as persistent back pain patients

to differentiate them from acute and chronic low back pain patients. No conservative care modality, whether recommended by the study physicians, other physicians, or chosen independently by patients, had any significant effect on the complaint of back pain and sciatica. Since none were of significant value, there is little evidence to suggest that using any of the so-called conservative care measures could prevent surgery (Long et al., 1996).

It is important not to misunderstand these statements. They apply only to persistent back pain patients. Most patients with acute low back pain and sciatica, even with demonstrated disc herniation, will improve spontaneously with no more than symptomatic treatment (Bigos et al., 1994). Surgery is rarely required, unless pain is intolerable or a significant neurological deficit is present. Our data indicate that when spontaneous recovery does not occur, it is unlikely that any of the conservative care measures will change the natural history of the disease, or give the patient symptomatic relief. This is a radical departure from the usual treatment approach and will require long-term validation.

The outcome of surgery was quite different and very satisfactory. However, the experts in spinal surgery involved in our study chose only a small number of the referred patients for surgical treatment. The most common indication for surgery was unrelieved radicular pain (BenDebba et al., 2000). For most patients, the severity of pain led to the surgical decision, and most of the surgeries were complex procedures. The goal was to relieve nerve root compression, and/or eliminate instability. Twenty per cent of the surgically treated patients has a fusion.

Outcomes for the surgically treated patients were excellent, with over 90% of patients being satisfactorily relieved of pain without mortality and without significant morbidity. Only 2% of patients were unchanged or worse, and only 5% required reoperation. These outcomes persisted throughout the follow-up period. Thus, it appears that patients with sciatica secondary to disc herniation, spinal stenosis, or spondylolisthesis, whose pain is severe enough to warrant surgery, can be predictably relieved with little or no risk. Nevertheless, these patients constitute a small minority, even among those who are referred to orthopedic and neurological surgeons who are knowledgeable about spinal problems (Long et al., 1996).

Diagnostic blocks in decision-making in low back pain

Diagnostic blockade is widely used in patients with low back and leg pain as an adjunct in the decision-making process (Bogduk & Long, 1979, 1980). The rationale is sound, but clinical correlations are as tenuous as those between radiological findings and clinical syndromes. The concept is that if a specific structure in the spine is anesthetized with a local anesthetic, the pain originating in or mediated by that structure should be relieved. In an effort to make the blocks more helpful, a second parameter, the provocation of the patient's own pain syndrome, has been added to the interpretation. Thus, with provocative diagnostic blockade, the patient is queried about the reproduction of their usual pain syndrome during needle placement and during injection. Relief of pain is assessed after injection. The most significant block is the one that both provokes and relieves pain. Blocks in common usage include lumbar zygapophyseal joints, individual nerve roots, and intradiscal blocks. Although these applications are rational and intuitively correct, there are two problems with their utilization: first, selectivity and specificity are weak; second, clinical correlations between the results of blocks and treatment outcomes are lacking. Bogduk has studied specificity and selectivity of cervical blocks in great detail. The most reliable blocks include placebo controls. Uncontrolled blocks, and blocks of adjacent nerves or major nerve trunks made up of overlapping root origins are less specific. Currently, in our clinic, provocative blocks are used as adjuncts to strengthen clinical decisions already made on other grounds. They are never used alone to guide surgery. Much more data will be required before these provocative blocks can be considered more than adjunctive in the diagnostic and decision-making process.

Impairment, disability, litigation, and the compensation process

The problem of low back pain in the United States and in most developed nations is complicated by its intimate relationship with disability and litigation (Bigos et al., 1991; Frank et al., 1998; Mayer et al., 1987; Scheer et al., 1995). The impairment guides of The American Medical Association are used 94% of the time for the spine. It is clear to most experts that patients involved in litigation and disability claims do not recover as well as those without such claims. In our own national low back pain study, all patients employed at the time of surgery returned to work at the same job without restrictions; virtually none of the patients involved in disability returned to work. Those involved in litigation complained much more, used more medical resources, and were much less likely to return to work when compared with similar patients without litigation, although no significant differences between the two

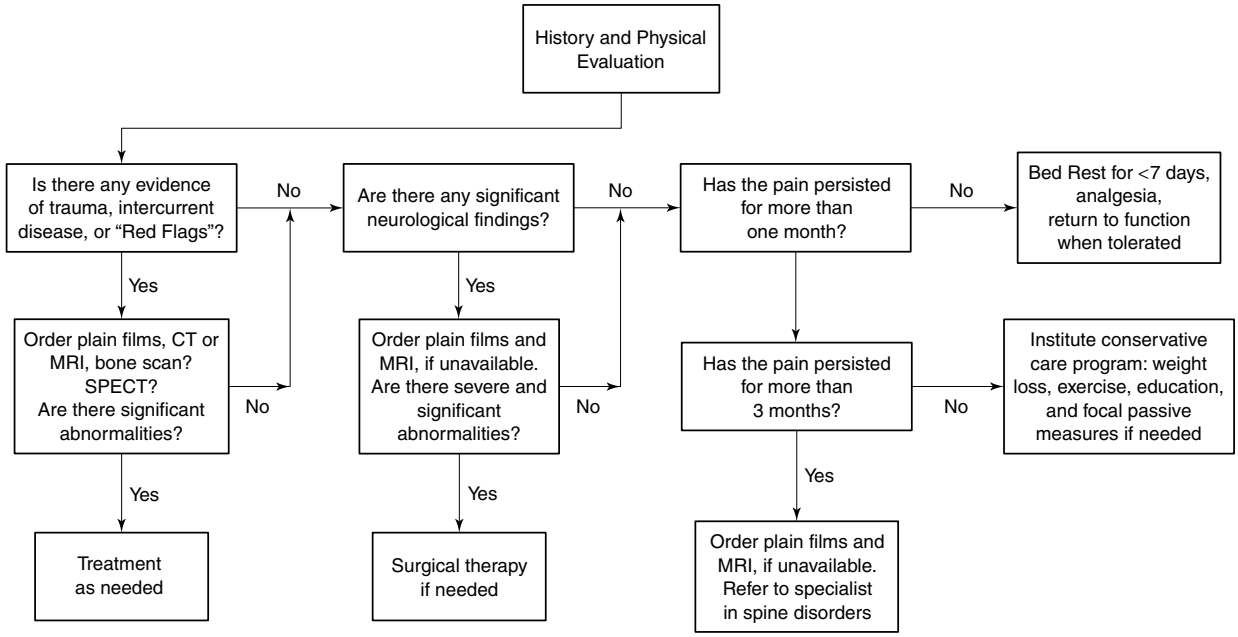

Fig. 51.1. A paradigm for the management of low back pain complaints.

groups in terms of diagnoses or therapies could be discerned. Nevertheless, physicians complicate the social issues through diagnoses and choice of treatments. The social and political issues surrounding the disability question are complex and well beyond the scope of this chapter. There is no doubt, however, that the presence of claimed disability increases complaints, leads to greater medical utilization, and greatly reduces the vocational capabilities of patients after apparently successful surgery. Patients with disability claims should not be deprived of surgical treatments for diseases known to respond well to surgery, nor should the indications for surgery be expanded for them.

A management paradigm for low back pain

Our current paradigm, illustrated in Fig. 51.1, follows the rules for management of acute low back pain with or without leg pain promulgated by the Agency for Health Policy and Research. This means no evaluation for the majority of patients acutely, but adequate symptomatic relief. Rapid return to function is important. Patients are restricted from aggressive practitioners who use any form of surgical or conservative care, and spontaneous healing is allowed to occur. When patients do not improve spontaneously within 1 month, or if symptoms remain incapacitating for more than a short period of time, evaluation proceeds. Surgery is performed immediately for those with sufficient symptoms and clear-cut root compression or instability. There is no reason to implement any conservative care program since none will be of value. When surgery is contemplated it should proceed only after 3 months of waiting, unless symptoms preclude such a wait. The majority of patients will not be candidates for surgery. The best evidence suggests that most patients do not respond to conventional conservative programs, but can benefit by an intensive program that includes weight control, local measures for relief of muscular and ligamentous pain, and a vigorous functional exercise program that restores them to their maximum capabilities.

Part VI

Disorders of body functions

52

Autonomic function and dysfunction

Christopher J. Mathias

Neurovascular Medicine Unit, Division of Neuroscience and Psychological Medicine
Imperial College of Science, Technology & Medicine at St Mary's, and Autonomic Unit, National Hospital for Neurology and Neurosurgery, Queen Square/
University Department of Clinical Neurology, Institute of Neurology, University College London, London, UK

The autonomic nervous system is a dynamic system intimately involved with the function of every organ in the body. In addition, it plays a key role in integrative function, such as control of the circulation and regulation of body temperature. Its motor (efferent) components, consist of the parasympathetic nervous system with a cranial and sacral spinal outflow, and the sympathetic nervous system with a thoraco-lumbar spinal outflow (Fig. 52.1). However, there is interaction at various levels of the neural axis. Thus, virtually every afferent in the body, through relays at a cerebral or spinal level, influences function of the autonomic nervous system. Centres in the brain can activate autonomic pathways directly or by stimulating spinal autonomic centres. There are multiple neurotransmitters at different synapses and ganglia that are better defined in the periphery than centrally (Fig. 52.2). Complex processes at parasympathetic and sympathetic nerve terminals influence the synthesis, release and re-uptake of various transmitters (Figs 52.3 and 52.4). The autonomic supply to the gut and pelvic viscera (enteric nervous system) additionally is richly endowed with peptides, amines and purines involved in neurotransmission and neuromodulation; they also have direct effects, especially upon the gastrointestinal tract and splanchnic circulation.

Classification of autonomic disorders

An outline classification is provided (Table 52.1). There are primary disorders where the etiology is not known; examples are pure autonomic failure (PAF) and multiple system atrophy (MSA). A large number of secondary autonomic disorders may be hereditary, associated with disease (such as diabetes mellitus), due to a specific deficit (dopamine beta-hydroxylase deficiency) or the result of trauma. A variety of drugs, poisons and toxins cause autonomic dysfunction by directly influencing sympathetic or parasympathetic activity, or by causing an autonomic neuropathy. In neurally mediated syncope, autonomic function is intermittently abnormal with either overactivity (such as increased vagal tone causing bradycardia) or underactivity (sympathetic withdrawal causing hypotension); the most common is vasovagal syncope. A recently described disorder is postural tachycardia syndrome (PoTS).

In many of these autonomic disorders there is involvement of different organs or systems. Some are localized, predominantly affecting one organ, area or system, such as the pupil in the Holmes–Adie syndrome, the face in Horner's syndrome and sweat glands in essential hyperhidrosis.

Clinical manifestations

Characteristic features follow dysfunction affecting the sympathetic and parasympathetic nervous systems. Sympathetic adrenergic failure results in orthostatic (postural) hypotension and ejaculatory failure, while sympathetic cholinergic failure causes anhidrosis. The reverse, sympathetic overactivity, may result in hypertension, tachycardia and hyperhidrosis. Parasympathetic failure causes a fixed heart rate, an atonic urinary bladder, a sluggish large bowel and erectile failure; overactivity can result in bradycardia and even cardiac arrest. Thus, a wide spectrum of manifestations can occur in autonomic dysfunction (Table 52.2), with various combinations depending upon the extent of the lesion, the associated disorder and the ensuing functional deficit. In disorders such as multiple system atrophy, there may be difficulties in diagnosis, as non-automic disorders may result in similar symptoms.

In the Riley–Day syndrome (familial dysautonomia), there usually is a history of consanguinity and an Ashkenazi

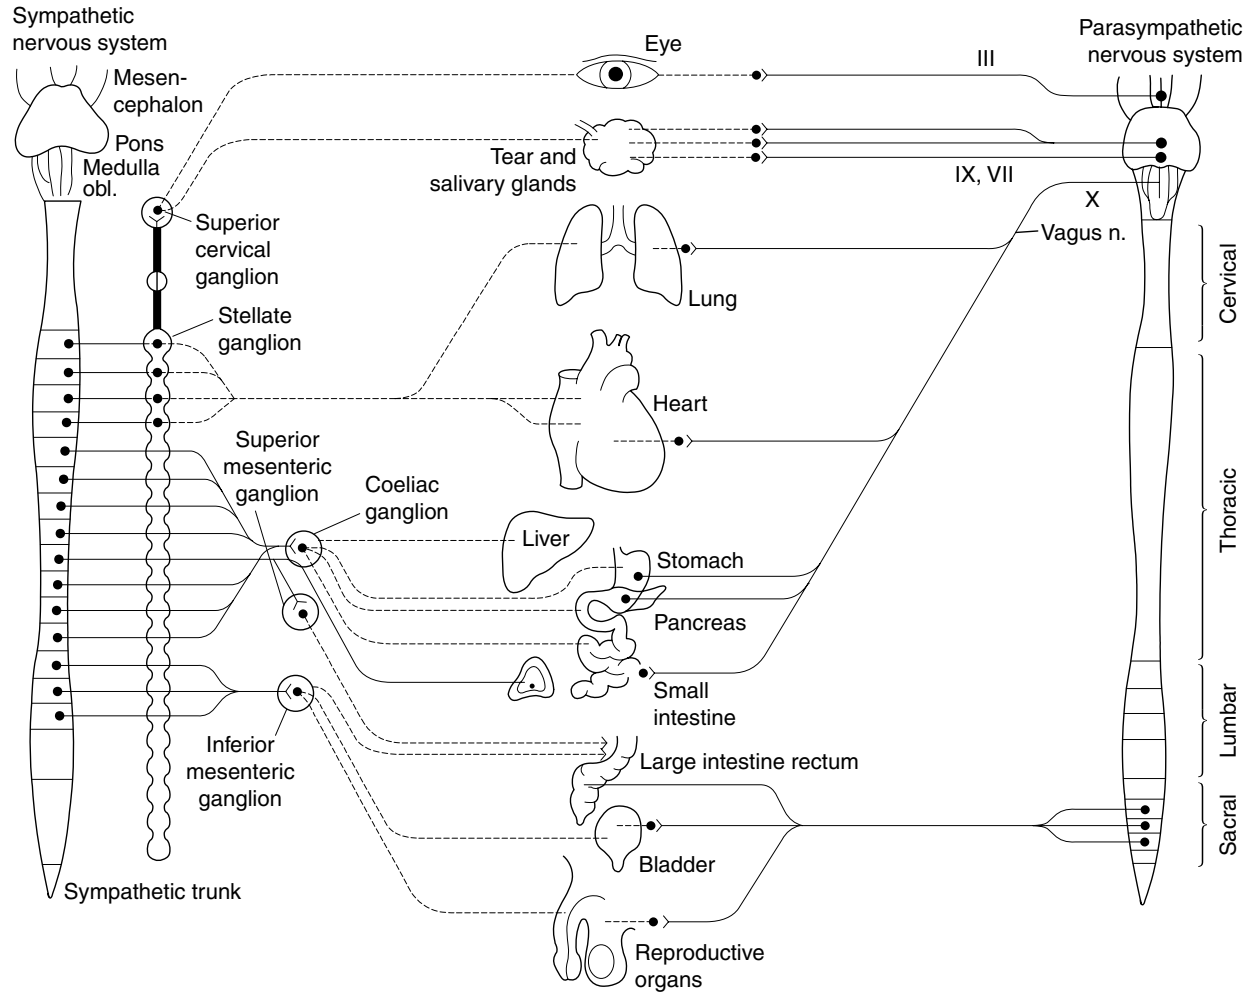

Fig. 52.1. Parasympathetic and sympathetic innervation of major organs. (From Janig, 1987.)

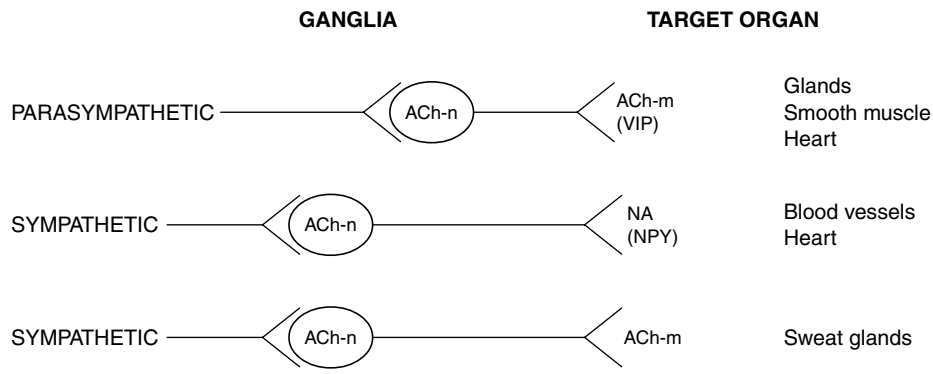

Fig. 52.2. Outline of the major transmitters at autonomic ganglia and postganglionic sites on target organs supplied by the sympathetic and parasympathetic efferent pathways. The acetylcholine receptor at all ganglia is of the nicotinic subtype (ACh-n). Ganglionic blockers such as hexamethonium thus prevent both parasympathetic and sympathetic activation. Atropine, however, acts only on the muscarinic (ACH-m) receptor at postganglionic parasympathetic and sympathetic cholinergic sites. The cotransmitters along with the primary transmitters are also indicated (NA = noradrenaline; VIP = vasoactive intestinal polypeptide; NPY = neuropeptide Y). (From Mathias, 2000a.)

Table 52.1. Outline classification of autonomic disorders

Primary
- Acute/subacute autonomic neuropathy
- Chronic autonomic failure
  - – pure autonomic failure
  - – multiple system atrophy

Secondary
- Hereditary
  - – Riley–Day syndrome
  - – familial amyloid polyneuropathy
- Metabolic
  - – diabetes mellitus
- Enzyme deficiency
  - – dopamine beta-hydroxylase deficiency
- Inflammatory
  - – Guillain–Barré syndrome
- Infectious
  - – Chagas disease
- Trauma
  - – spinal cord transection

Drugs, poisons and toxins
- Direct effects
- Autonomic neuropathy
  - – alcohol

Neurally-mediated syncope
- Vasovagal syncope
- Carotid sinus hypersensitivity
- Miscellaneous causes
  - – micturition syncope

Postural tachycardia syndrome

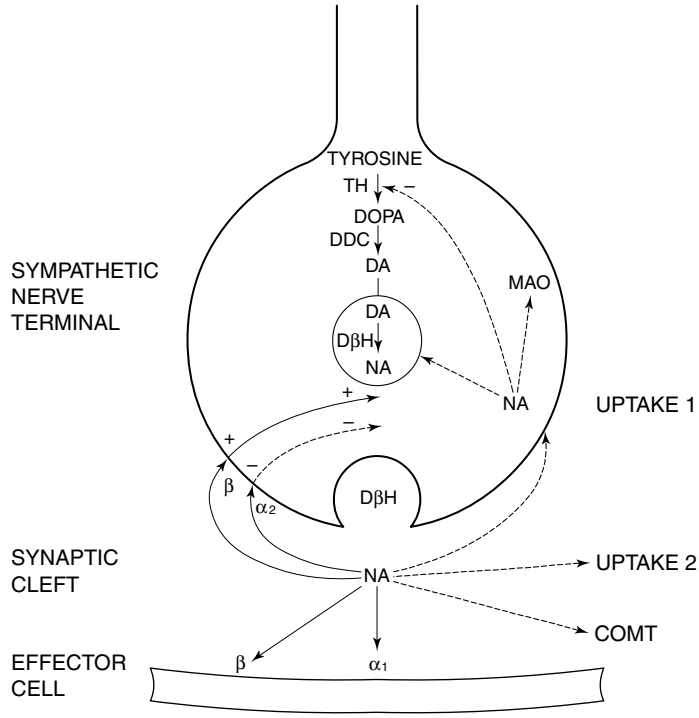

Fig. 52.3. Schema of some pathways in the formation, release and metabolism of noradrenaline from sympathetic nerve terminals. Tyrosine is converted into dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH). DOPA is converted into dopamine (DA) by dopadecarboxylase. In the vesicles DA is converted into noradrenaline (NA) by dopamine beta-hydroxylase (DβH). Nerve impulses release both DβH and NA into the synaptic cleft by exocytosis. NA acts predominantly on alpha$_1$-adrenoceptors but has actions on beta-adrenoceptors on the effector cell of target organs. It also has presynaptic adrenoceptor effects. Those acting on alpha$_2$ adrenoceptors inhibit NA release; those on beta-adrenoceptors stimulate NA release. NA may be taken up by a neuronal (uptake 1) process into the cytosol, where it may inhibit further formation of DOPA through the rate-limiting enzyme TH. NA may be taken into vesicles or metabolized by monoamine oxidase (MAO) in the mitochondria. NA may be taken up by a higher capacity but lower affinity extraneuronal process (uptake 2) in peripheral tissues, such as vascular and cardiac muscle and certain glands. NA is also metabolized by catechol-o-methyl transferase (COMT). NA measured in plasma is the overspill not affected by these numerous processes. (From Mathias, 2000a.)

Jewish origin; the disorder often is recognized at birth. Vasovagal syncope presents commonly in the teenage years, while familial amyloid polyneuropathy begins in early adulthood and middle age. Neurodegenerative disorders such as multiple system atrophy present in the mid- to late 50s. There may be a gender preponderance; vasovagal syncope is more common in females. A detailed history is essential and must include drug medication intake and previous exposure to chemical substances.

In secondary autonomic disorders and those caused by drugs, the features of the underlying or associated disorder need consideration as these may exacerbate autonomic manifestations. Individual assessments are necessary, especially of psyche, in conditions such as vasovagal syncope, also know as emotional syncope.

The clinical findings may be confined to an area, organ or involve a system. In essential hyperhidrosis only the palms and soles may be affected, while in the Holmer – Adie pupil there is impairment of parasympathetic function of the iris musculature. In generalized disorders a cardinal feature is orthostatic (postural) hypotension (Fig. 52.5). This is defined as a decrease in systolic blood pressure of more than 20 mm Hg, or a fall in diastolic blood pressure of more than 10 mm Hg, while either standing or during head-up tilt to 60° for at least 3 minutes (Schatz et al., 1996). A variety of

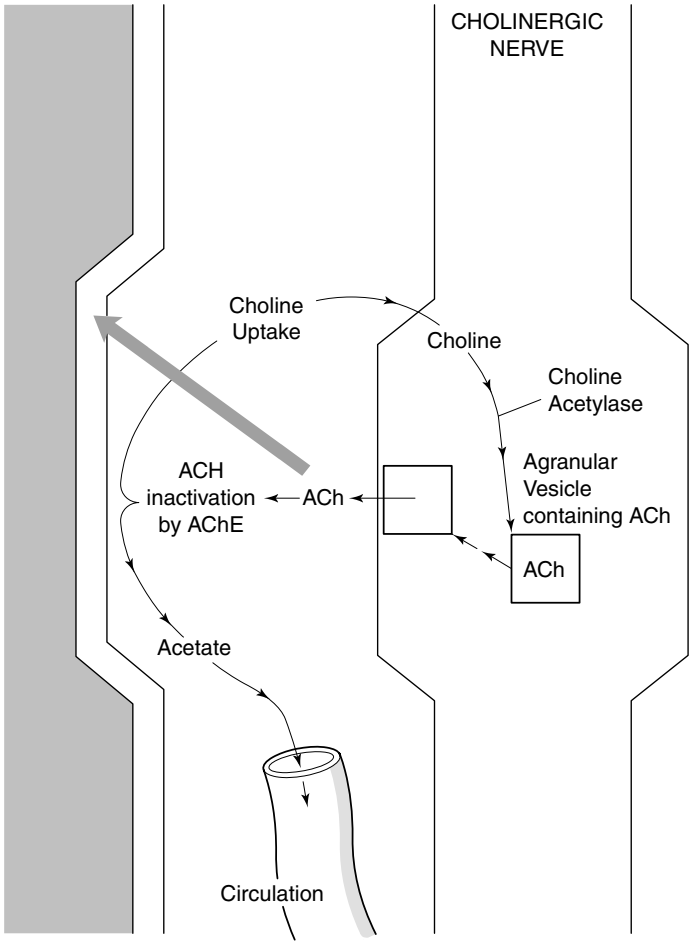

Fig. 52.4. Schema of pathway in the formation of acetylcholine (AChL) from choline and its inactivation by acetylcholine esterases (from Appenzeller & Oribe, 1997).

Table 52.2. Some clinical manifestations of autonomic dysfunction

Cardiovascular	
Postural hypotension	Supine hypertension
Lability of blood pressure	Paroxysmal hypertension
Tachycardia	Bradycardia
Sudomotor	
Hypohidrosis or anhidrosis	Hyperhidrosis
Gustatory sweating	
Hyperpyrexia	Heat intolerance
Alimentary	
Xerostomia	Dysphagia
Gastroparesis	Dumping syndrome
Constipation	Diarrhea
Urinary	
Nocturia	Frequency
Urgency	
Retention	Incontinence
Sexual	
Erectile failure	Ejaculatory failure
Retrograde ejaculation	
Eye	
Pupillary abnormalities	Partial ptosis
Alacrima	Lachrymation with food ingestion

symptoms accompany the fall in blood pressure (Mathias et al., 1999) (Table 52.3). These depend upon the rapidity and degree of fall in blood pressure, the extent to which compensatory factors come into play and the underlying disorder; additionally many factors influence orthostatic hypotension (Table 52.4). These range from stimuli in daily life such as food ingestion and mild exercise (Figs. 52.6 and 52.7) that can accentuate or exaggerate orthostatic hypotension. Determination of the mechanisms contributing to orthostatic hypotension is of importance in management.

Investigation of autonomic function and dysfunction

Activity may be measured directly or indirectly; sympathetic neural activity is measured electrophysiologically (using microneurography) or biochemically (by measuring plasma levels of noradrenaline and adrenaline or using spillover techniques) (Wallin et al., 1996). Each has its limitations, especially as measurements in a particular territory may not reflect activity either in the whole body or in other regions. In clinical practice, functional effects are measured with investigation directed to systems and organs (Mathias & Bannister, 1999a, b) (Table 52.5). Screening tests have been developed for evaluating cardiovascular autonomic function. They utilize safe and mainly non-invasive techniques and in combination with the clinical history and examination determine if further or detailed investigation is needed. The main objectives of investigation are:

(i) to assess if autonomic function is normal or abnormal;
(ii) if the latter, to ascertain the degree of autonomic dysfunction with an emphasis on the site of lesion and functional deficit;
(iii) to determine the underlying or associated disease as this will need concurrent treatment with management of autonomic dysfunction.

Non-autonomic tests may be needed to diagnose or delineate the underlying disorder. These include MRI scans of

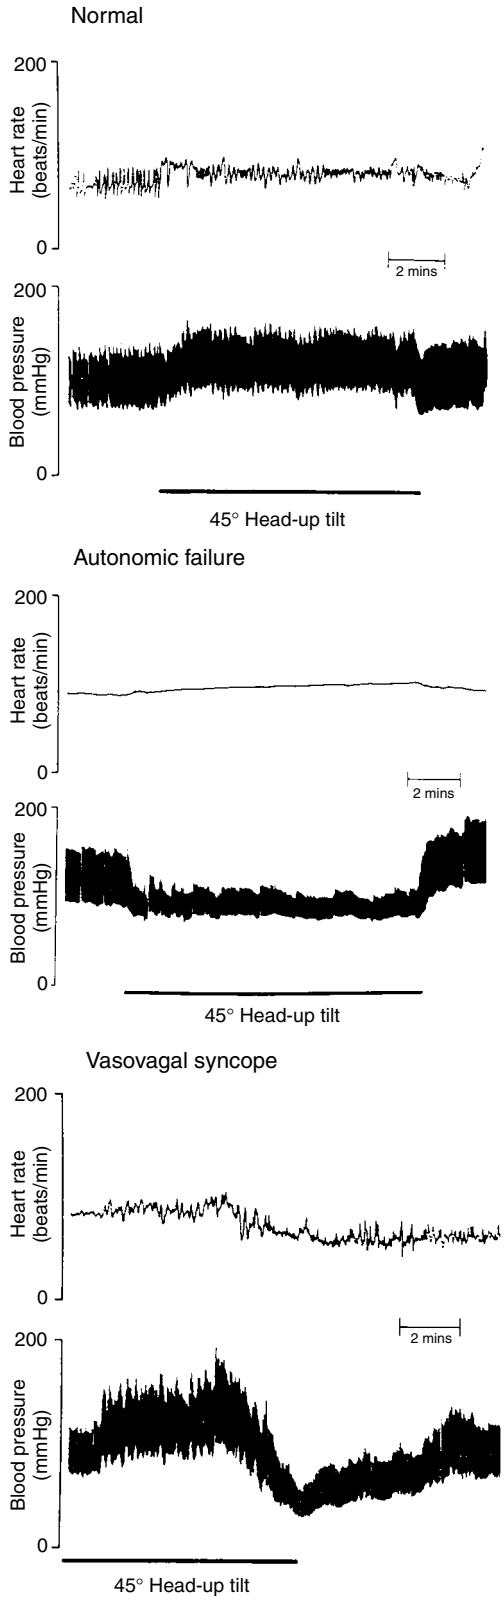

Table 52.3. Some of the various symptoms resulting from orthostatic hypotension and impaired perfusion of various organs

Cerebral hypoperfusion
- Dizziness
- Visual disturbances
  - Blurred
  - Tunnel
  - Scotoma
  - Greying out
  - Blacking out
  - Colour defects
- Loss of consciousness
- Impaired cognition

Muscle hypoperfusion
- Paracervical and suboccipital ('coathanger') ache
- Lower back/buttock ache
- Calf claudication

Cardiac hypoperfusion
- Angina pectoris

Spinal cord hypoperfusion

Renal hypoperfusion
- Oliguria

Non-specific
- Weakness, lethargy, fatigue
- Falls

Source: Adapted from Mathias (2000a).

Fig. 52.5. Blood pressure and heart rate before, during and after head-up tilt in a normal subject (uppermost panel), a patient with pure autonomic failure (middle panel), and a patient with vazovagal syncope (lowermost panel). In the normal subject there is no fall in blood pressure during head-up tilt, unlike the patient with autonomic failure in whom blood pressure falls promptly and remains low with a blood pressure overshoot on return to the horizontal. In the patient with autonomic failure there is only a minimal change in heart rate despite the marked blood pressure fall. In the patient with vazovagal syncope there was initially no fall in blood pressure during head-up tilt; in the latter part of tilt, as indicated inthe record, blood pressure initially rose and then markedly fell, to extremely low levels, so that the patient had to be returned to the horizontal. Heart rate also fell. In each case continuous blood pressure and heart rate were recorded with the Portapress II. (From Mathias & Bannister, 1999a).

Table 52.4. Factors influencing postural (orthostatic) hypotension

Speed of positional change
Time of day (worse in the morning)
Prolonged recumbency
Warm environment (hot weather, central heating, hot bath)
Raising intrathoracic pressure – micturition, defecation or coughing
Food and alcohol ingestion
Water ingestion[a]
Physical exertion
Manoeuvres and positions[b] (bending forward, abdominal compression, leg crossing, squatting, activating calf muscle pump)
Drugs with vasoactive properties (including dopaminergic agents)

Notes:
[a] May raise blood pressure, unlike food and alcohol.
[b] Usually reduce the postural fall in blood pressure.
Source: Adapted from Mathias and Bannister (1999).

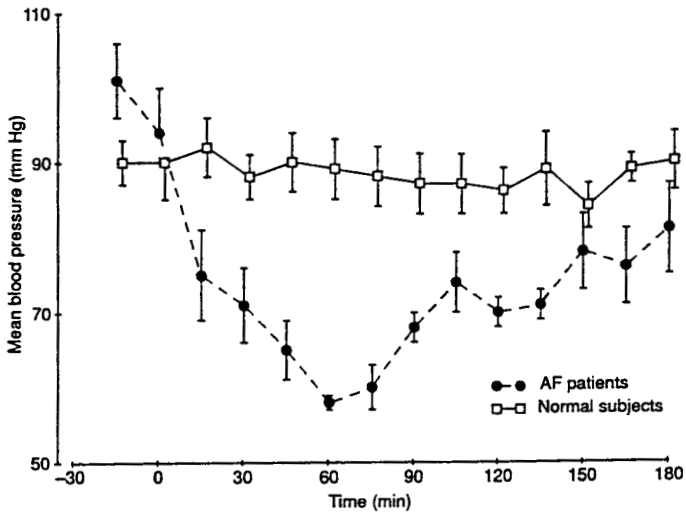

Fig. 52.6. Percentage change in mean blood pressure in a group of patients with chronic autonomic failure (dashed line, filled circles) and normal subjects (continuous line, open square) before and after food ingestion at time 0. The indicate mean ± SEM. (From Mathias et al., 1989.)

Table 52.5. Outline of investigations in autonomic failure

Cardiovascular	
Physiological	Head-up tilt (45°)[a]; standing[a]; Valsalva[a] manoeuvre[a]
	Pressor stimuli – isometric exercise[a], cold pressor[a], mental arithmetic[a]
	Heart rate responses – deep breathing[a], hyperventilation[a], standing[a], head-up tilt[a], 30: 15 ratio
	Liquid meal challenge
	Exercise testing
	Carotid sinus massage
Biochemical	Plasma noradrenaline – supine and head-up tilt or standing; urinary catecholamines; plasma renin activity and aldosterone
Pharmacological	Noradrenaline – α-adrenoceptors – vascular
	Isoprenaline – β-adrenoceptors – vascular and cardiac
	Tyramine – pressor and noradrenaline response
	Edrophonium – noradrenaline response
	Atropine – parasympathetic cardiac blockade
Sudomotor	Central regulation – thermoregulatory sweat test
	Sweat gland response – intradermal acetylcholine, quantitative sudomotor axon reflex test (Q-SART), localized sweat test
	Sympathetic skin response
Gastrointestinal	Barium studies, video-cine-fluoroscopy, endoscopy, gastric emptying studies
Renal function and urinary tract	Day and night urine volumes and sodium/potassium excretion
	Urodynamic studies, intravenous urography, ultrasound examination, sphincter electromyography
Sexual function	Penile plethysmography
	Intracavernosal papaverine
Respiratory	Laryngoscopy
	Sleep studies to assess apnea/oxygen desaturation
Eye	Lachrymal function – Schirmer's test
	Pupil function – pharmacological and physiological

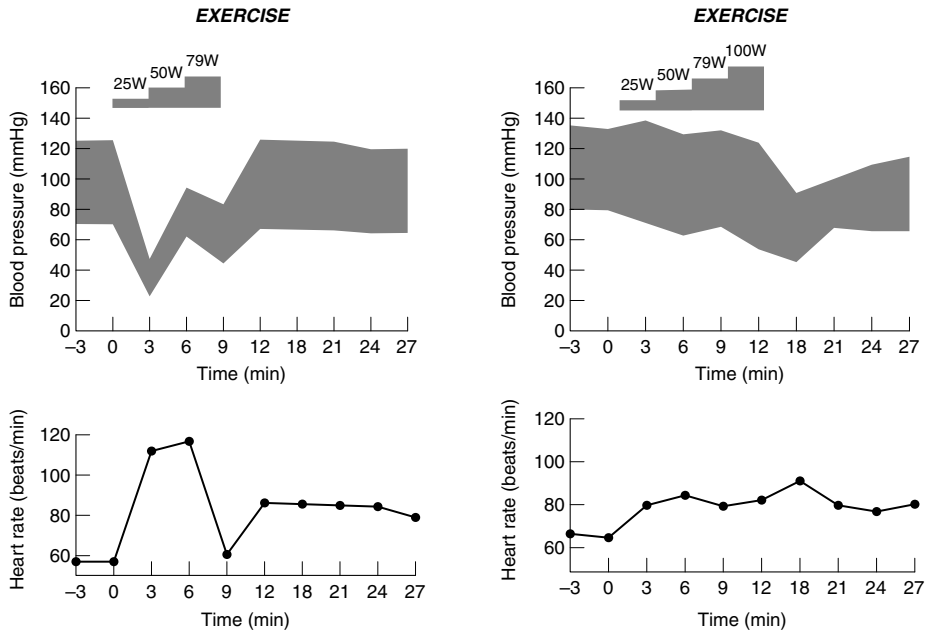

Fig. 52.7. Systolic and diastolic blood pressure (top) and heart rate (bottom) in two patients with autonomic failure before, during and after bicycle exercise performed with the patients in the supine position at different workloads, ranging from 25 to 100 watts. In the patient on the left there is a marked fall in blood pressure on initiating exercise; she had to crawl upstairs because of severe exercise induced hypotension. In the patient on the right, there are minor changes in blood pressure during exercise, but a marked decrease soon after stopping exercise. This patient was usually asymptomatic while walking, but developed postural symptoms when he stopped walking and stood still. It is likely that the decrease in blood pressure postexercise was due to vasodilatation in exercising skeletal muscle, not opposed by the calf muscle pump. (From Mathias & Williams, 1994.)

the brain in neurodegenerative disorders, sural nerve or cutaneous nerve biopsy in peripheral nerve disorders, genetic testing in familial amyloid polyneuropathies, and a range of non-neurological investigations, from HIV testing to defining the site of the primary in paraneoplastic autonomic neuropathy.

Management of autonomic disorders

A comprehensive approach is needed, especially in autonomic disorders that involve multiple systems and organs. The principles outlined for the management of orthostatic hypotension involve a combination of non-pharmacological and pharmacological measures (Table 52.6), that are based on pathophysiological mechanisms (Mathias & Kimber, 1999). In neurogenic orthostatic hypotension cure usually is not possible, and management in the individual patient should be directed to reducing disability, enabling independence and ensuring a reasonable quality of life whilst providing advice that is practical, and drugs that are safe. A similar approach should be used for impairment of sudomotor, gastrointestinal, urinary bladder and sexual function (Table 52.7) and modified accordingly.

Surgical intervention may be needed, such as tracheostomy in MSA with laryngeal abductor paresis or insertion of a percutaneous enterogastrotomy tube for severe dysphagia. Complex procedures, such as hepatic transplantation reduce levels of variant transthyretin in familial amyloid polyneuropathy and halt deposition of amyloid in nerves, while pancreatic (usually in combination with renal) transplantation improves certain features in diabetic autonomic neuropathy. In essential hyperhidrosis there is a role for percutaneous endoscopic sympathectomy; botulism toxin has been proved useful (Naumann et al., 1997).

In addition to autonomic deficits, attention should be paid to associated features, such as depression in the parkinsonian syndromes, or anxiety and phobia in vasovagal syncope. Education of the patient is of importance as increased knowledge of the disorder and its mechanisms improves patient compliance and management. In disorders such as MSA, education of the spouse, carers and medical therapists is important.

Table 52.6. Management of orthostatic hypotension

Non-pharmacological measures
To be avoided
– Sudden head-up postural change (especially on waking)
– Prolonged recumbency
– Straining during micturition and defecation
– High environmental temperature (including hot baths)
– 'Severe' exertion
– Large meals (especially with refined carbohydrate)
– Alcohol
– Drugs with vasodepressor properties
To be introduced
– Head-up tilt during sleep
– Small, frequent meals
– High salt intake
– Judicious exercise (including swimming)
– Body positions and manoeuvres
To be considered
– Elastic stockings
– Abdominal binders
– Water ingestion
Pharmacological measures
Starter drug:
– fludrocortisone
Sympathomimetics
– ephedrine, midodrine, l-dihydroxyphenylserine
Specific Targeting
– desmopressin for nocturnal polyuria
– octreotide for postprandial hypotension
– erythopoietin for anemia

Sources: Adapted from Mathias and Kimber (1999).

Primary autonomic failure syndromes

These include the acute/sub-acute dysautonomias and chronic autonomic failure syndromes (Table 52.8).

Acute/subacute dysautonomia

These are relatively rare disorders. In pure pandysautonomia, there are features of both sympathetic and parasympathetic failure. Orthostatic hypotension often is a major problem. The peripheral nerves may be affected in pure dysautonomia with other neurological features. The prognosis in pandysautonomia is variable, with complete recovery in some. The response to immunoglobulin therapy (Heafield et al., 1996; Smit et al., 1997) suggests an immunological etiology.

Table 52.7. Outline of management strategies in autonomic failure when different systems are involved, as in MSA

Specific	for orthostatic hypotension and bladder, bowel and sexual dysfunction: non-pharmacological and pharmacological therapy
	for respiratory abnormalities: to consider tracheotomy
	for oropharyngeal dysphagia: to consider percutaneous endoscopic gastrotomy
General	for depression etc.
Education	of patient, partners, relatives, carers, practitioners (medical and supportive therapists, to include physiotherapists, occupational therapists, speech therapists, dietitians)
Patient support groups	
	to disseminate information and increase awareness. They include:
	Shy–Drager Association in USA
	Autonomic disorders Association Sarah Matheson Trust in UK
Integrative approaches	
	Autonomic nurse specialist or autonomic liaison nurse to co-ordinate and promote seamless management

Pure cholinergic dysautonomia is an even rarer condition mainly affecting children and young adults. There are symptoms of parasympathetic failure (blurred vision, dry eyes, xerostomia, dysphagia involving mainly the lower esophagus, constipation and urinary retention), and sympathetic cholinergic failure (anhidrosis and a tendency to hyperthermia). The signs include dilated pupils, raised heart rate, dry and hot skin, a distended abdomen and a palpable urinary bladder. Orthostatic hypotension is absent as sympathetic vasoconstrictor function is not impaired. Recovery from the defect is unlikely. Therapy should include maintenance of fluid balance and body temperature. A barium meal examination must be avoided as it will be retained in the colon. The differential diagnosis includes anticholinergic drugs that may cause similar features, but with recovery in a few days. A variant of botulinum (botulism B) affects cholinergic pathways alone with sparing of the motor pathways; substantial recovery often occurs within a few months.

Chronic autonomic failure syndromes

The main disorders, along with diseases with overlapping features, are schematically outlined in Fig. 52.8.

Table 52.8. Primary autonomic failure syndromes

Acute/subacute autonomic neuropathy
– Pure pandysautonomia
– Pandysautonomia with additional neurological features
– Pure cholinergic dysautonomia
Chronic autonomic failure
– Pure autonomic failure
– Multiple system atrophy
– Parkinson's disease with autonomic failure
– Diffuse Lewy Body Disease

Table 52.9. Clinical manifestations and possible presenting features of syndromes of primary chronic autonomic failure

System affected	Clinical features
Cardiovascular	Orthostatic hypotension
Sudomotor	Anhidrosis, heat intolerance
Gastrointestinal[a]	Constipation, occasionally diarrhea, dysphagia
Renal and urinary bladder	Nocturia, frequency, urgency, incontinence, retention of urine
Reproductive	Erectile and ejaculatory failure
Ocular	Anisocoria, Horner's syndrome
Respiratory[a]	Stridor, inspiratory gasps, apneic episodes
Neurologic	Parkinsonian, cerebellar and pyramidal

Notes:

[a] Certain features, such as oropharyngeal dysphagia and respiratory abnormalities (including those resulting from laryngeal-abductor paresis), occur in multiple system atrophy rather than in pure autonomic failure.

Source: From Mathias (1997).

Pure autonomic failure

These patients often are over the age of 50 at presentation. In the majority the diagnosis usually is considered when orthostatic hypotension is detected. The onset may be insidious as a number of compensatory mechanisms, often unwittingly used, help reduce the symptoms of orthostatic hypotension. Alternative diagnoses, ranging from epilepsy to a psychiatric disorder, may be considered erroneously. In males, impotence is common. Nocturia (rather than the urinary symptoms listed in Table 52.6) is frequent, along with constipation. Impairment of sweating may not be recognized in temperate climates. Heat intolerance and collapse may occur in tropical areas. The clinical and laboratory features include widespread sympathetic failure, usually with parasympathetic deficits. The physiological and biochemical tests indicate a peripheral autonomic lesion which is consistent with the neuropathological data available (Matthews, 1999). Lewy bodies have been reported in autonomic ganglia.

In PAF, management of orthostatic hypotension is of importance as it contributes to morbidity and may result in injury. Control of bowel and bladder function, and in males sexual function, may need to be addressed. The overall prognosis in PAF is good, with a life expectancy not dissimilar to healthy individuals of an equivalent age.

Multiple system atrophy

This probably is the most common neurodegenerative condition affecting the autonomic nervous system in humans. It is synonymous with the Shy–Drager syndrome and is a sporadic non-familial disorder with autonomic, parkinsonian, cerebellar and pyramidal features that occur in any combination over a varying time scale (Mathias & Williams, 1994; Wenning et al., 1994; Gilman et al., 1998) (Table 52.9). It is a progressive disorder but with an unpredictable rate of progression; this adds to difficulties in diagnosis. The majority with MSA have parkinsonian features at some stage of the disease. When parkinsonism is a presenting feature there are difficulties in distinguishing MSA from Parkinson's disease (PD). This accounts for why up to 25% of patients diagnosed in vivo as IPD were found at postmortem to have the characteristic neuropathological features of MSA. In the early stages, depending on the presentation, patients may consult a range of specialists, from neurologists and cardiologists to urologists and psychiatrists.

There are three major subgroups in MSA based on their neurological features; the parkinsonian form (MSA-P; where the neuropathological findings include striatonigral degeneration), the cerebellar form (MSA-C; with olivopontocerebellar degeneration) and the mixed form, with a combination of neurological features (MSA-M); with striatonigral and olivopontocerebellar degeneration (Daniel, 1999). A key neuropathological feature is the presence of intracytoplasmic argyrophyllic inclusions in oligodendrocytes, within defined areas of the brain and spinal cord. Programmed cell death (apoptosis) appears to be specific for oligodendrocytes in MSA (Probst-Cousin et al., 1998). Cell loss in various brainstem nuclei (including the vagus), the intermediolateral cell mass in the thoracic and lumbar spinal cord, and Onuf's nucleus in the sacral spinal cord account for various abnormalities. The paravertebral ganglia and visceral (enteric) plexuses are not affected.

In MSA, the additional neurological features do not necessarily help distinction from overlapping syndromes. In

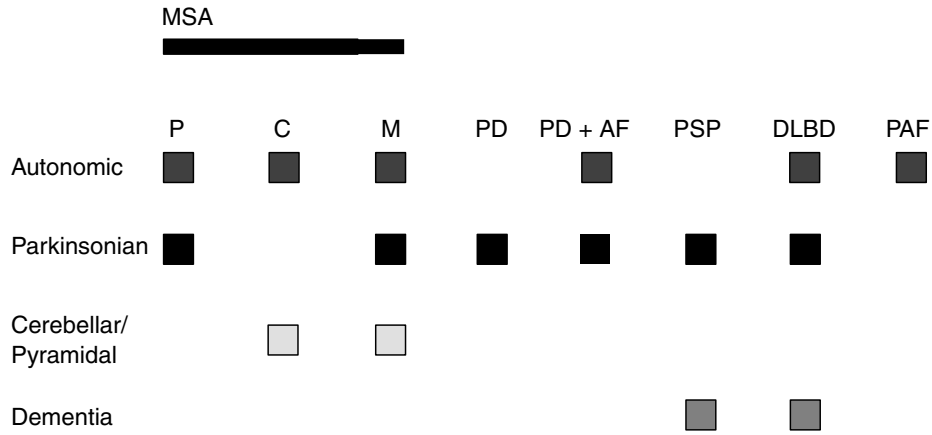

Fig. 52.8. The major clinical features in parkinsonian syndromes and allied disorders with autonomic failure. These include the three major neurologic forms of multiple system atrophy – the parkinsonian form (MSA-P, also called striatonigral degeneration), the cerebellar form (MSA-C, also olivoponocerebellar atrophy) and the multiple or mixed form (MSA-M, which has features of both other forms); idiopathic Parkinson's disease (PD), Parkinson's disease + autonomic failure (PD + AF); progressive supranuclear palsy (PSP), diffuse Lewy body disease (DLBD) and pure autonomic failure (PAF). (Adapted from Mathias, 1997.)

the parkinsonian forms, the onset of bradkinesia and rigidity is often bilateral, with minimal or no tremor, unlike PD. Lack of a motor response to dopaminergic drugs alone is not helpful, as two-thirds of MSA patients respond favourably initially, although side effects and refractoriness to the motor benefits with time lowers this to a third or less. The presence of autonomic failure (especially cardiovascular and genitourinary) in a patient with parkinsonism should alert one to the possibility of MSA. Respiratory abnormalities and oropharyngeal dysphagia favour MSA, and often occur as the disease advances.

Investigation aids diagnosis and management (Table 52.10). Neuroimaging (especially positron emission tomography, MR scanning of the brain and proton magnetic resonance spectroscopy of the basal ganglia), may help distinguish MSA from other parkinsonian syndromes. The presence of orthostatic hypotension does not necessarily indicate autonomic failure (Table 52.11), although its recording is of importance for management. Cardiac sympathetic denervation is not observed in MSA, and this is consistent with a central, preganglionic lesion. The sympathetic skin response often is abnormal in the mixed form, but up to a third of either MSA-P or MSA-C have a preserved SSR, excluding it as a diagnostic test in the early stages. The combined neuropharmacological–neuroendocrine approach using clonidine-growth hormone (GH) testing separates central from peripheral autonomic failure (Thomaides et al., 1992). The centrally acting alpha-2 adrenoceptor agonist clonidine stimulates hypothalamic GH releasing hormone that acts on the anterior pituitary to release GH (Fig. 52.9(a),(b)). After clonidine, levels of GH rise in PAF, where there is no central autonomic abnormality. In the different forms of MSA there is no GH response to clonidine. However, another GH secretagogue, L-dopa, raises GHRH and GH levels in MSA (Kimber et al., 1999) while apomorphine raises GH in MSA with a greater response in PD (Friess et al., 2001), indicating that the abnormal response is not the result of widespread and hypothalamic neuronal fall-out, and probably indicates a specific alpha-2 adrenoceptor-hypothalamic deficit. Early reports indicate preservation of the clonidine-GH response in non-drug treated PD (Kimber et al., 1997a); this may not apply to drug-treated PD. Whether the clonidine-GH test will distinguish MSA from other parkinsonian and peripheral autonomic syndromes at an early stage remains to be determined. In MSA, the urethral or anal sphincter electromyograph is usually abnormal, characteristically indicating denervation and reinnervation (Palace et al., 1997). False positives include prostatic surgery in the male and multiparous females; it also may be abnormal in progressive supranuclear palsy (PSP). The combination of orthostatic hypotension and an abnormal urethral/anal sphincter electromyograph, in conjunction with the characteristic clinical features, are virtually confirmatory of MSA.

The prognosis in MSA is poor compared with PD and PAF, as the motor and autonomic deficits progressively worsen. There is a refractoriness to anti-parkinsonian agents; orthostatic hypotension may further impair mobility. Communication becomes increasingly difficult. In the cerebellar form, worsening truncal ataxia may cause falls

Table 52.10. Some of the investigations used in parkinsonism to evaluate autonomic function and separate MSA from IPD

Neuroimaging studies
- Magnetic resonance imaging
- Magnetic resonance spectroscopy
- Positron emission tomography – with various ligands

Autonomic screening tests
- to determine if orthostatic hypotension is present
- to assess sympathetic vasoconstrictor responses
- to evaluate parasympathetic cardiac responses

Additional autonomic tests
- food and exercise challenge
- 24-hour ambulatory blood pressure and heart rate profile

Cardiac sympathetic evaluation
- meta-iodo-benzyl-guanidine and gamma scintiscanning
- 6-Fluorodopamine and positron emission tomography scanning

Sympathetic skin response

Clonidine-growth hormone stimulation test

Urethral or anal sphincter electromyography

Table 52.11. Some of the possible causes of orthostatic hypotension in a patient with parkinsonian features

Side effects of anti-parkinsonian therapy
L-DOPA, bromocriptine, pergolide
the combination of L-DOPA and COMT inhibitors (tolcapone)
the MAO 'b' inhibitor, selegiline

Coincidental disease causing autonomic dysfunction
e.g. diabetes mellitus

Coincidental administration of drugs for an allied condition
Antihypertensives
α-adrenoceptor blockers (for benign prostatic hypertrophy)
Vasodilators (for ischemic heart disease)
Diuretics (for cardiac failure)

Multiple system atrophy (Shy–Drager syndrome)

Parkinson's disease with autonomic failure

Diffuse Lewy body disease

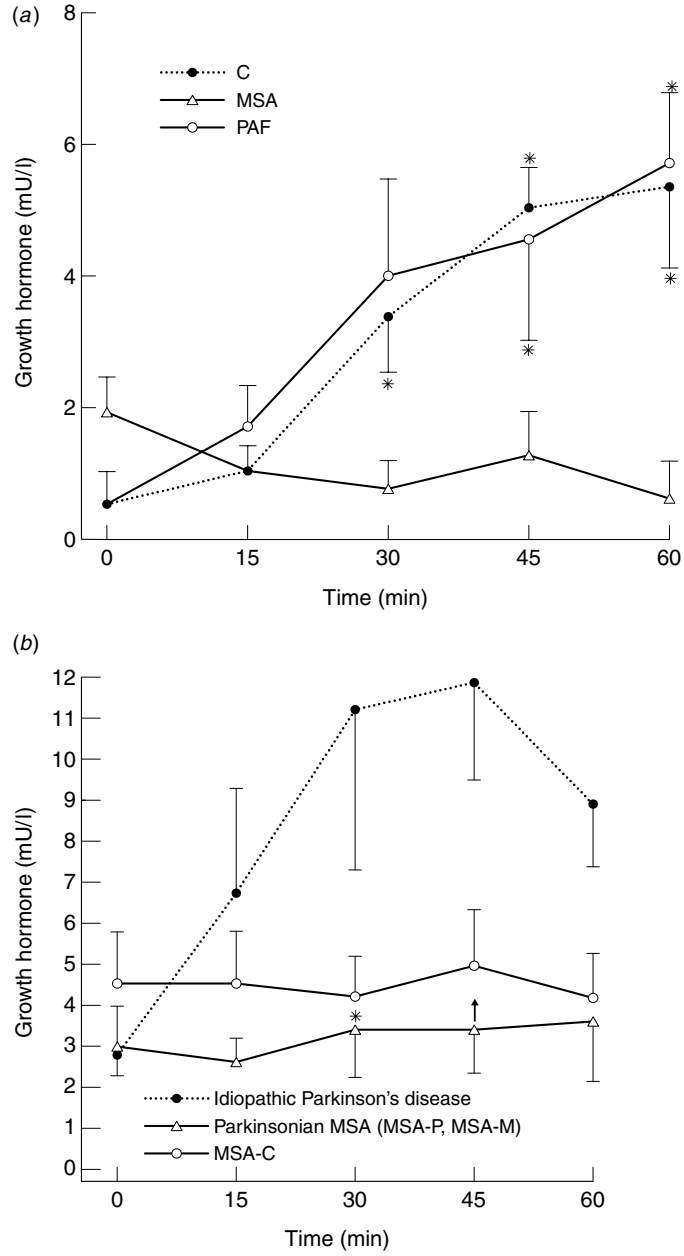

Fig. 52.9. (*a*) Serum growth hormone (GH) concentrations before (0) and at 15 min intervals for 60 min after clonidine (2 μg/kg/min) in normal subjects (C, controls) and in patients who have multiple system atrophy (MSA) and pure autonomic failure (PAF). GH concentrations rise in controls and in patients who have PAF with a peripheral lesion; there is no rise in patients with MSA with a central lesion. (From Thomaides et al., 1992.)

(*b*) Lack of serum GH response to clonidine in the two forms of MSA (the cerebellar form, MSA-C and the parkinsonian forms, MSA-P and MSA-M) in contrast to patients with idiopathic Parkinson's disease with no autonomic deficit, in whom there is a significant rise in GH levels. (From Kimber et al., 1997a.)

and an inability to stand upright; incoordination in the upper limbs, speech deficits and nystagmus add to the disability. Oropharyngeal dysphagia enhances the risk of aspiration, especially as many have vocal cord abnormalities; a percutaneous feeding gastrostomy may be needed. Respiratory abnormalities that include obstructive (due to laryngeal abductor cord paresis) and central apnea, may necessitate a tracheostomy.

In MSA there currently is no means of reversing the neurological decline. Supportive therapy is an essential component in management and should incorporate the family, therapists and community. Many autonomic features can be helped, and this includes orthostatic hypotension, bowel, bladder and sexual dysfunction.

Idiopathic Parkinson's disease and other parkinsonian disorders

In PD, autonomic features usually are not prominent, especially in the early stages. Orthostatic hypotension if present, may be related to increased duration of disease, age and multiple drug therapy. A varying prevalence has been described, from rare to high (58% with 38.5% symptomatic) (Mathias, 1998a,b). Meta-iodo-benzylguanidine with gamma scintiscanning, and fluorodopamine with positron emission tomographic scanning, of the heart indicate that cardiac sympathetic denervation may occur early in the disorder, often without other detectable autonomic features (Goldstein et al., 1997, Orima et al., 1999). The implications of this observation are unclear and have relevance to cardiac arrhythmias and drug therapy in PD. Whether the urinary and gastrointestinal features are due to autonomic or other mechanisms is unclear. In PD Lewy bodies are present in the esophageal and colonic myenteric plexuses with reduction of dopaminergic neurons in the latter.

There is a smaller group, often of older patients with apparently classic PD, who have been successfully treated with l-dopa for many years and then develop features of autonomic failure, usually with severe postural hypotension. They thus differ from the majority of patients with PD in whom autonomic deficits, if present, are relatively mild. Cardiac scanning techniques indicate sympathetic denervation, favouring a peripheral lesion similar to PAF (Goldstein et al., 1997). These patients also have low basal plasma noradrenaline levels and their orthostatic hypotension does not respond to yohimbine (whose actions are dependent on intact sympathetic nerves). The etiology of PD with AF is unknown. It may be a coincidental association of a common condition with an uncommon disorder (PAF), or an indication of vulnerability to autonomic degeneration in a sub-group of PD, that may be linked to increasing age, chronic anti-parkinsonian drug therapy, an inherent metabolic susceptibility, or to a combination of these factors. These patients do not appear to suffer from the many complications of MSA and clinically appear to differ from them.

Dizziness and orthostatic hypotension is more common in diffuse Lewy body disease(DLBD), than previously recognized. Some patients may be mistakenly diagnosed as PAF or MSA. In PAF, Lewy bodies are also present in the peripheral autonomic nervous system, raising the possibility that it may be a forme fruste, or an early stage, of DLBD. In PSP, unlike previous reports, more recent studies indicate lack of orthostatic hypotension and cardiovascular autonomic features, which has now been proposed as an exclusionary feature in the diagnosis of this disorder (Kimber et al., 2000). Urinary abnormalities and an abnormal sphincter electromyograph may be present; there is evidence of degeneration of Onuf's nucleus in the sacral cord. In Huntingdon's disease, defects in vasoregulation have been described and attributed to involvement of suprabulbar structures including caudate nuclei, but there is no significant cardiovascular abnormality; however, hyperhidrosis, diarrhea and sphincter disturbances may occur. In Guamanian parkinsonism and parkinsonian–dementia complex, there are autonomic abnormalities affecting the cardiovascular system that are greater than usually observed in PD and less than MSA but may be confounded by diabetes and antihypertensive drug therapy. Whether there are autonomic abnormalities of significance in other parkinsonian syndromes remains to be determined.

Secondary autonomic failure

There is a wide range of secondary disorders (Table 52.12). Some are described briefly below.

Hereditary

Riley–Day syndrome; familial dysautonomia

This occurs in children of Ashkenazi–Jewish extraction (Axelrod, 1999). They have absent fungiform papillae, lack of corneal reflexes, decreased deep tendon reflexes and a diminished response to pain. This is often observed at birth. An abnormal intradermal histamine skin test (with an absent flare response) and pupillary hypersensitivity to cholinomimetics, confirms the diagnosis. The defective gene has been mapped to the long arm of chromosome 9 (q31).

Table 52.12. Secondary autonomic failure

Congenital
- Nerve growth factor deficiency

Hereditary

Autosomal dominant
- Familial amyloid neuropathy
- Porphyria

Autosomal recessive
- Familial dysautonomia (Riley–Day syndrome)
- Dopamine beta-hydroxylase deficiency
- Aromatic L-amino acid decarboxylase deficiency

X-linked recessive
- Fabry's disease

Metabolic diseases
- Diabetes mellitus
- Chronic renal failure
- Chronic liver disease
- Vitamin B_{12} deficiency
- Alcohol-induced

Inflammatory
- Guillain–Barré syndrome
- Transverse myelitis

Infections
- Bacterial – tetanus, leprosy
- Viral – human immuno-deficiency virus infection
- Parasitic – Chagas' disease
- Prion – fatal familial insomnia

Neoplasia
- Brain tumours – especially of third ventricle or posterior fossa
- Paraneoplastic, to include adenocarcinomas – lung, pancreas and Lambert–Eaton syndrome

Connective tissue disorders
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Mixed connective tissue disease

Surgery
- Regional sympathectomy – upper limb, splanchnic
- Vagotomy and drainage procedures – 'dumping syndrome'
- Organ transplantation – heart, kidney

Trauma
- Spinal cord transection

A variety of symptoms, resulting from both autonomic underactivity and overactivity may occur. These include a labile blood pressure (with hypertension and postural hypotension), parasympathetic abnormalities (with periodic vomiting, dysphagia, constipation and diarrhea) and urinary bladder disturbances. Neurological abnormalities, associated skeletal problems (scoliosis) and renal failure previously contributed to a poor prognosis. The ability to anticipate complications and provide adequate support and therapy has resulted in a number of children now reaching adulthood.

Amyloid polyneuropathy

Both light chain (AL) and familial amyloid polyneuropathy (FAP) result in autonomic dysfunction (Reilly & Thomas, 1999). In the AL form, amyloid is derived from monoclonal light chains, secondary to multiple myeloma, malignant lymphoma or Waldenstrom's macroglobulinemia. The features vary with an overall poor prognosis. In FAP, symptoms usually occur in adulthood. Sensory, motor and autonomic abnormalities result from deposition in peripheral nerves of mutated amyloid protein, mainly produced in the liver. Motor and sensory neuropathy often begins in the lower limbs. Classification of FAP is now based on the chemical and molecular nature of the constituent proteins and not on clinical presentation. There are various forms; transthyretin (TTR) FAP; FAP Ala 60 (Irish/ Appalachian) and FAP Ser 84 and His 58. The cardiovascular system, gut and urinary bladder can be affected at any stage. The disease relentlessly progresses but at a variable rate. There may be dissociation of autonomic symptoms from functional deficits; this is of importance, as evaluation and treatment of cardiovascular autonomic abnormalities is essential in reducing morbidity and mortality especially during hepatic transplantation. Currently, this is the only way to reduce levels of variant transthyretin and its deposition in nerves; it prevents progression of, and may reverse some, neuropathic features. It may be of greater value if performed before nerve damage occurs.

Dopamine beta-hydroxylase deficiency

This rare disorder, recognized in the mid-1980s, has been described in seven patients, two of whom are siblings (Mathias & Bannister, 1999c). Symptoms began in childhood, although an autonomic disorder was not considered until they became teenagers, when orthostatic hypotension was first recognised. Whether the symptoms become more prominent, or are easier to detect at this time, is unclear. The clinical features indicate sympathetic adrenergic failure with sparing of sympathetic cholinergic and parasympathetic function. Sweating is preserved and

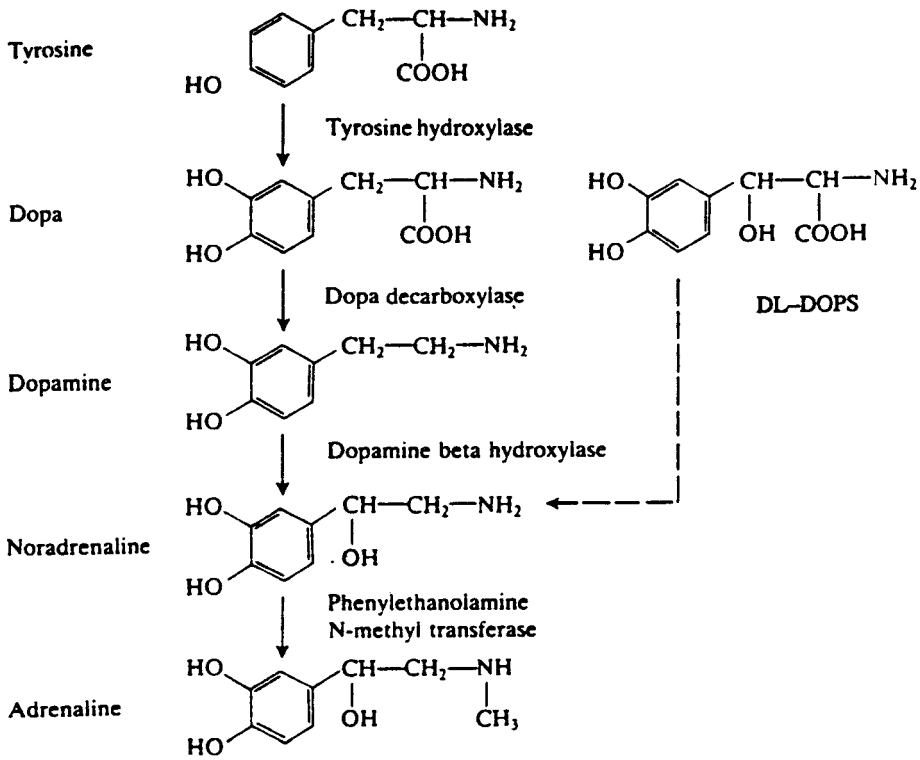

Fig. 52.10. Biosynthetic pathway in the formation of noradrenaline and adrenaline. The structure of DL-DOPS is indicated on the right. It is converted directly to noradrenaline by dopa decarboxylase, thus bypassing dopamine β-hydroxylase.

urinary bladder and bowel function is normal; in one of the males erection was possible but ejaculation was difficult to achieve. The diagnosis may be made from basal levels of plasma catecholamines, as noradrenaline and adrenaline levels are undetectable while dopamine levels are elevated. The enzymatic defect is highly specific, with the sympathetic nerve pathways and terminals otherwise intact, as has been demonstrated by both electron microscopy and preservation of muscle sympathetic nerve activity using microneurography. These subjects, therefore, are a unique model of superselective sympathetic adrenergic failure. Treatment is with the pro-drug L-dihydroxyphenylserine (Fig. 52.10), which has a structure similar to noradrenaline except for a carboxyl group that is acted upon by the enzyme dopadecarboxylase (abundantly present in extraneuronal tissues such as the liver and kidneys), thus transforming it into noradrenaline. This reduces orthostatic hypotension and has resulted in remarkable improvements in their ability to lead active lives.

Diabetes mellitus

There is a high incidence of both peripheral and autonomic neuropathy, especially in older, long-standing diabetics on insulin therapy (Watkins, 1998). Their morbidity and mortality is considerably higher than in those without a neuropathy. It initially often involves the vagus, with characteristic features of cardiac vagal denervation. This may occur in conjunction with partial preservation of the cardiac sympathetic and may predispose diabetics, many of whom have ischemic heart disease, to sudden death from cardiac dysrhythmias. In some, sympathetic failure may cause orthostatic hypotension, that may be enhanced by insulin (Fig. 52.11). Awareness of hypoglycemia, that depends on autonomic activation, is diminished. There may be involvement of the gastro-intestinal tract (gastroparesis diabeticorum and diabetic diarrhea), the urinary bladder (diabetic cystopathy) and in the male, impotence. Sudomotor abnormalities include gustatory sweating. Damage to other organs may occur through non-neuropathic factors and compounds the problems caused by the neuropathy. Diabetic foot problems may result from a combination of neuropathy and ischemia. Other than maintaining normoglycemia, there is no known means to prevent and reverse the neuropathy except possibly by pancreatic transplantation.

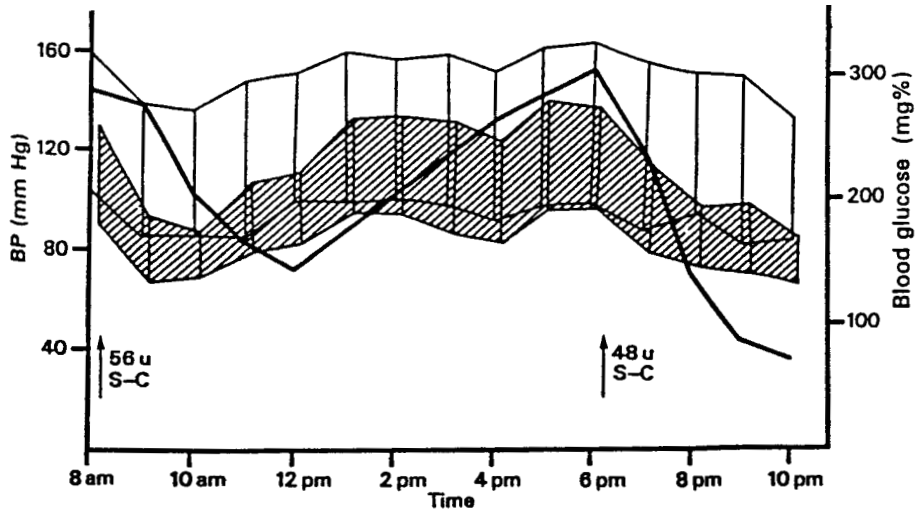

Fig. 52.11. Diurnal variation of lying and standing blood pressure in a 48-year-old man with severe diabetic autonomic neuropathy. Insulin was given subcutaneously (S-C) at times shown by the vertical arrows. The unhatched area shows supine blood pressure, the hatched area the standing blood pressure, and the continuous line the blood glucose. (From Watkins & Edmonds, 1999.)

Spinal cord diseases

Autonomic dysfunction affecting various systems occurs in spinal cord disease, as the entire sympathetic and the sacral sympathetic outflow is from the spinal cord (Mathias & Frankel, 1999). The level of completeness of lesion determines the degree of dysfunction.

Cardiovascular autonomic dysfunction can contribute to morbidity and mortality, especially in cervical and high thoracic spinal cord lesions. Orthostatic hypotension results from the inability of the brain to activate efferent sympathetic pathways, despite preservation of baroreceptor afferent and central connections. In these subjects the reverse, paroxysmal hypertension, may occur following large bowel and urinary bladder contraction as part of the mass reflex, in the syndrome of autonomic dysreflexia (Fig. 52.12). This is due to isolated spinal cord reflex activity (without the restraint of cerebral control) and can be induced by a variety of stimuli, from cutaneous, skeletal muscle or visceral sources, below the level of the lesion. In the acute phase after injury, such patients may have a different set of clinical problems, because of 'spinal shock' and the absence of even isolated spinal sympathetic activity; some of these result also from excessive cardiac vagal activity causing bradycardia or even cardiac arrest.

A combination of autonomic underactivity and overactivity may occur in non-spinal disorders. In the Guillain–Barré syndrome both autonomic hyperactivity and underactivity may occur (Asahina et at., 2001); tachycardia and hypotension may alternate with bradycardia and hypertension. The precise mechanisms are unclear and the possibilities should be anticipated as appropriate drugs may be needed. Cardiovascular disturbances of a similar nature may occur in tetanus, especially in those who suffer muscle paralysis and are on assisted respiration.

Drugs, chemicals, toxins

Drugs may cause autonomic dysfunction through their recognized pharmacological effects, such as sympatholytic agents (Table 52.13). A side effect of a drug may cause clinical problems when used in high dosage or over a prolonged period (such as the anticholinergic effects of antidepressants), or when autonomic deficits are unmasked or induced in susceptible individuals. Examples of the latter include L-dopa worsening orthostatic hypotension in MSA (Fig. 52.13), the ability of pressor agents to cause severe hypertension in autonomic failure because of denervation supersensitivity (Fig. 52.6), and the antiarrhythmic disopyramide inducing urinary retention in subjects with benign prostatic hypertrophy. Drugs such as perhexeline maleate, vincristine and alcohol may induce autonomic dysfunction independently of their pharmacological properties, by causing an autonomic neuropathy.

Neurally mediated syncope

These disorders are characterized by an intermittent cardiovascular autonomic abnormality resulting in syncope (loss of consciousness synonymous with fainting, blackouts) (Kapoor, 2000; Mathias et al., 2001) (Table 52.14). An

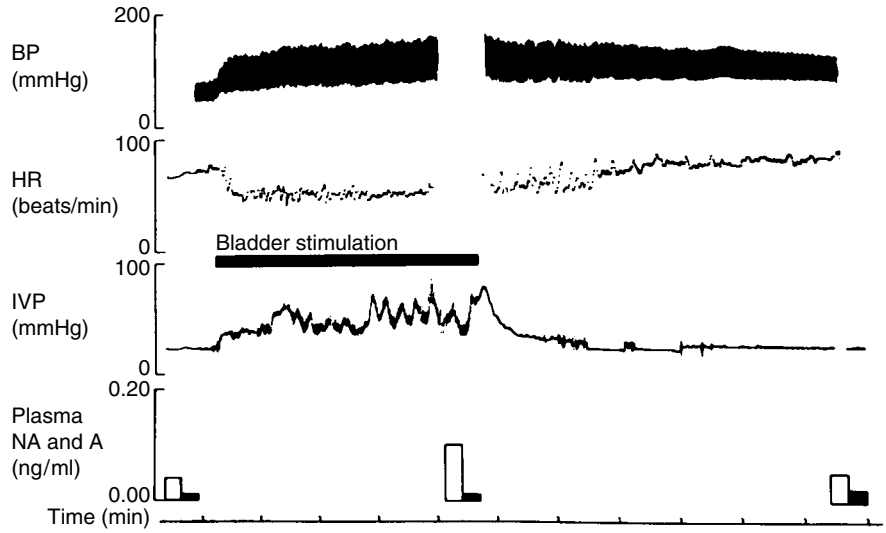

Fig. 52.12. Blood pressure (BP), heart rate (HR), intravesical pressure (IVP), and plasma noradrenaline (NA; open histogram) and adrenaline (A; filled histogram) levels in a tetraplegic patient before, during and after bladder stimulation induced by suprapubic percussion of the anterior abdominal wall. The rist in BP is accompanied by a fall in heart rate as a result of increased vagal activity in response to the rise in blood pressure. Levels of plasma NA, but not A rise, suggesting an increase in sympathetic neural activity independently of adrenomedullary activation. (From Mathias & Frankel, 1999.)

increase in cardiac parasympathetic activity causes severe bradycardia or cardiac arrest (cardio-inhibitory form) and withdrawal of sympathetic nerve activity results in hypotension (vasodepressor form). The two may occur separately, or together as the mixed form (Fig. 52.14). Between episodes there may be no abnormalities detected on routine autonomic testing.

In the young, the more common condition is vasovagal syncope. There is often a family history of a similar disorder (Mathias et al., 1998). It is more common in women. It may be induced by various stimuli, from fear and the sight of blood, to venepuncture and at times even discussion of venepuncture. Standing still, a warm environmental temperature and other factors that promote vasodilation, including gravitational pooling, can induce syncope. Modified testing, which includes prolonged tilt-table testing and, in some, application of a provocative stimulus (including venepuncture or pseudo-venepuncture), may induce an episode. Cardiac conduction disorders and other causes of syncope need to be excluded. Some advocate supraphysiological (head-up tilt and lower body negative pressure) and pharmacological (head-up tilt and isoprenaline infusion) testing; these stimuli however, may provoke an attack in subjects who have never fainted (El-Bedawi & Hainsworth, 1994; Morillo et al., 1995). Management includes reducing or preventing exposure to precipitating causes although these may be unclear; in some behavioural therapy (especially in those with phobias), is needed. A high salt diet, exercise and various drugs such as fludrocortisone, vasopressor agents, and antidepressants (including the serotonin-uptake release inhibitors), have been used with varying success. In some with the cardio-inhibitory form, a cardiac demand pacemaker is of value. The long-term prognosis is favourable and in many, attacks do not occur after the third decade.

In the elderly, carotid sinus hypersensitivity may be more common than previously thought; it may be a major cause of unexplained falls (McIntosh et al., 1993). There may be a classical history of syncope induced by head movements or collar tightening; in many the precipitating factors are unclear. Investigation should include carotid sinus massage performed with requisite precautions in the laboratory with adequate resuscitation facilities, ideally using beat-by-beat blood pressure and heart rate recording. Carotid massage also should be performed with the subject tilted head-up, as hypotension is more likely to occur in situations when sympathetic nerve activity is needed. In the cardio-inhibitory form a cardiac demand pacemaker is used. The vasodepressor forms are more difficult to manage and pressor agents have been used. Denervation of the carotid sinus may be used especially in unilateral hypersensitivity.

Table 52.13. Drugs/chemicals/poisons/toxins

DECREASING SYMPATHETIC ACTIVITY

Centrally acting

- Clonidine
- Methyldopa
- Reserpine
- Barbiturates
- Anesthetics

Peripherally acting

- Sympathetic nerve ending (guanethidine, bethanadine)
- Alpha-adrenoceptor blockade (phenoxybenzamine)
- Beta-adrenoceptor blockade (propranolol)

INCREASING SYMPATHETIC ACTIVITY

- Amphetamines
- Releasing noradrenaline (tyramine)
- Uptake blockers (imipramine)
- Monoamine oxidase inhibitors (tranylcypromine)
- Beta-adrenoceptor stimulants (isoprenaline)
- Following drug withdrawal (clonidine, alcohol, opiates)

DECREASING PARASYMPATHETIC ACTIVITY

- Antidepressants (imipramine)
- Tranquillizers (phenothiazines)
- Antidysrhythmics (disopyramide)
- Anticholinergics (atropine, probanthine, benztropine)
- Toxins (botulinum)

INCREASING PARASYMPATHETIC ACTIVITY

- Cholinomimetics (carbachol, bethanechol, pilocarpine, mushroom poisoning)
- Anticholinesterases
- Reversible carbamate inhibitors (pyridostigmine, neostigmine)
- Organophosphorus inhibitors (parathion)

Miscellaneous

- Alcohol, thiamine (vitamin B_1 deficiency)
- Vincristine, perhexiline maleate
- Thallium and arsenic
- Mercury poisoning (Pink disease)
- Cyclosporin
- CNS serotonergic syndrome
- Ciguatera (reef fish) toxicity
- Jelly fish and marine animal venoms

Table 52.14. Neurally mediated syncope

Vasovagal syncope

Carotid sinus hypersensitivity

Variants of reflexly induced syncope

- Tracheal stimulation in spinal shock
- Swallow syncope
- Glossopharyngeal vagal irritation
- Pelvic examination/instrumentation
- Defecation syncope
- Micturition syncope
- Cough syncope
- Laughter-induced syncope
- Fainting lark (Mess trick)

Associations with

- Children (vagotonia)
- Athletes (postexercise)
- Weight lifters
- Oarsmen

Drug-induced (Bezold–Jarisch reflex)

- First dose effect of angiotensin-1 converting enzyme inhibitors and prazosin

A variety of stimuli and circumstances may induce neurally mediated syncope. In some, reflexly induced exaggeration of vagal activity is responsible, as in cardiac arrest caused by tracheal stimulation in tetraplegics on artificial respiration, where increased vagal tone is not opposed by sympathetic activity or the pulmonary inflation reflex (Fig. 52.15). Syncope induced by swallowing (in some in association glossopharyngeal neuralgia) (Deguchi & Mathias, 1999) and, caused by pelvic and rectal examinations or instrumentation, are other examples. Malignancies in the pharynx and thorax may increase the tendency to reflexly induced syncope. In micturition and defecation syncope changes in intrathoracic pressure may contribute as in cough and laughter-induced, trumpet blowing and voluntary syncope ('fainting lark'). In extremely fit subjects, such as sportsmen, increased vagal tone, as occurs in children, also may contribute to syncope. The first-dose hypotensive effect of certain drugs may be neurally mediated, via the Bezold–Jarisch reflex.

Postural tachycardia syndrome (PoTS)

The postural tachycardia syndrome (PoTS) is a disorder mainly affecting women between the ages of 20 and 50, with symptoms of orthostatic intolerance (light headedness and other manifestations of cerebral hypoperfusion), often with palpitations (Low et al., 1995). The symptoms disappear on sitting or lying down. Investigations exclude orthostatic hypotension and autonomic failure. During postural challenge heart rate increases by 30 beats per minute or over. There are similarities with the syndromes initially described by Da Costa & Lewis (also known as

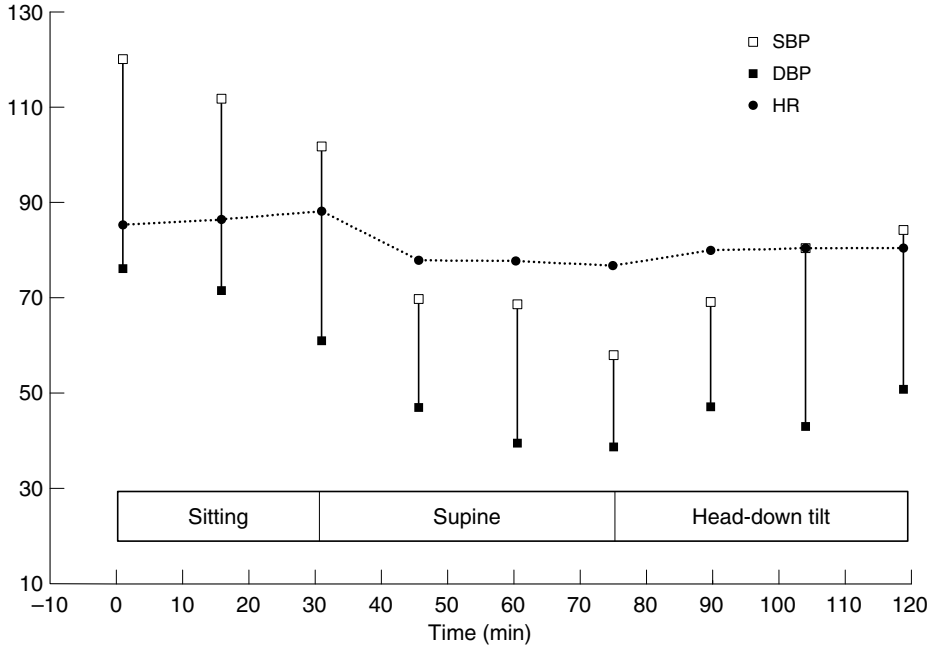

Fig. 52.13. The effect of a single standard oral dose of L-dopa (250 mg) and a dopa-decarboxylase inhibitor carbidopa (25 mg) given at time zero, on the blood pressure of a patient with parkinsonian features. There was a marked fall in blood pressure after 30 mins, resulting in the patient first being placed supine and then head-down. On investigation the patient had autonomic failure, with orthostatic hypotension unmasked by L-dopa; the final diagnosis was the parkinsonian form of multiple system atrophy. SBP, systolic blood pressure; DBP, diastolic blood pressure; HR, heart rate. (From Mathias, 2000b.)

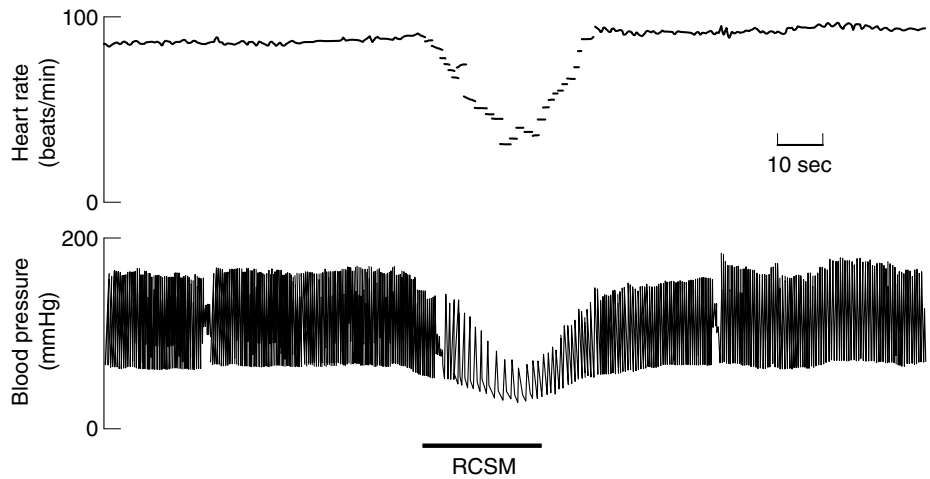

Fig. 52.14. Heart rate and blood pressure before, during and after right carotid sinus massage (RCSM) in a patient with syncopal episodes. There is a fall in both heart rate and blood pressure during carotid sinus massage, typical of the mixed (cardioinhibitory and vasodepressor) form of this disorder. The breaks in the record indicate calibration at intervals by the Finapres machine. (From Mathias, 2000a.)

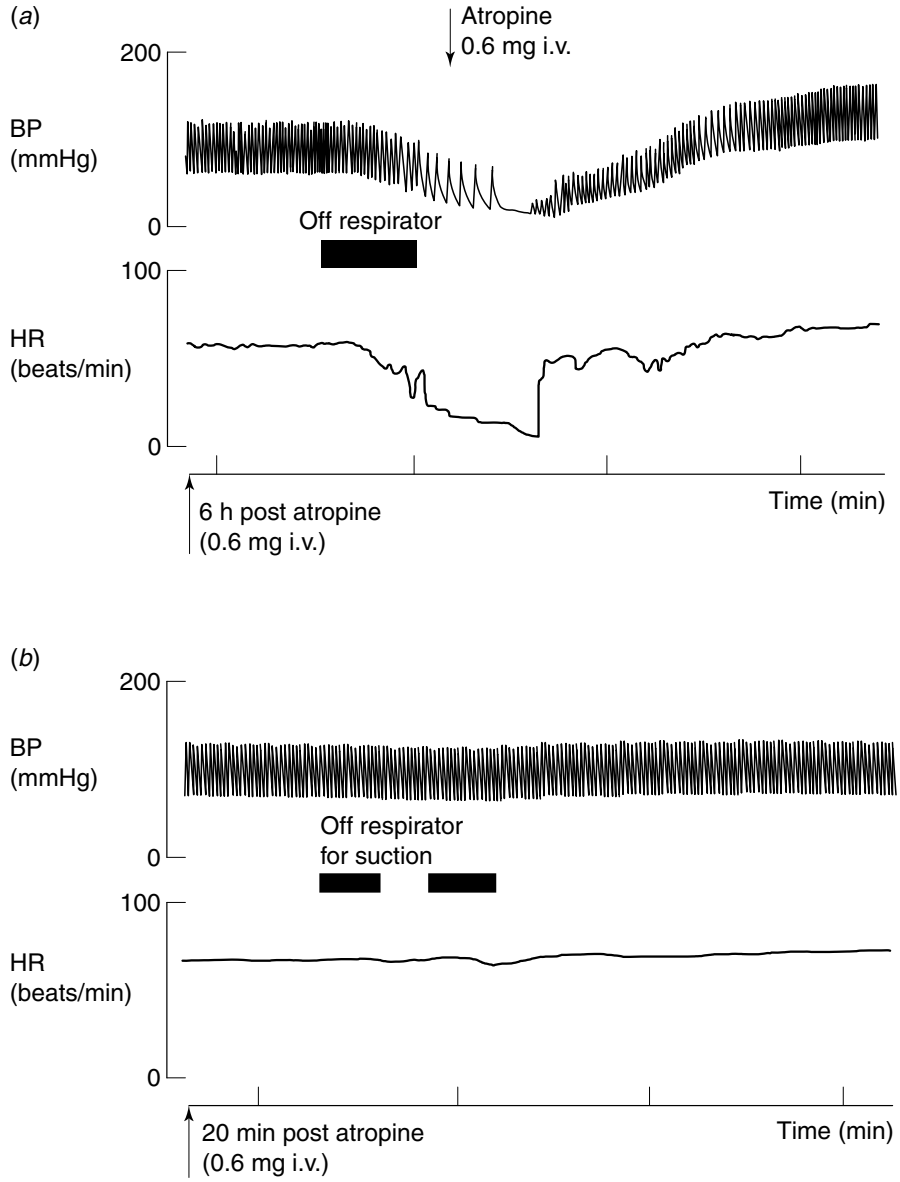

Fig. 52.15. (*a*) The effect of disconnecting the respirator (as required for aspirating the airways) on the blood pressure (BP) and heart rate (HR) of a recently injured tetraplegic patient (C4/5 lesion) in spinal shock, 6 hours after the last dose of intravenous atropine. Sinus bradycardia and cardiac arrest (also observed on the electrocardiograph) were reversed by reconnection, intravenous atropine and external cardiac massage. (From Frankel et al., 1975.)

(*b*) The effect of tracheal suction, 20 minutes after atropine. Disconnection from the respirator and tracheal suction did not lower either heart rate or blood pressure. (From Mathias, 1976.)

soldier's heart syndrome or neurocirculatory esthenia), mitral valve prolapse syndrome, chronic fatigue syndrome (Schondorf & Freeman, 1999) and deconditioning following prolonged bed rest and microgravity during spaceflight. The condition appears heterogenous (Khurana, 1995). In some the disorder appears to follow a viral infection. There may be features of a partial autonomic neuropathy, with lower limb denervation (Schondorf & Low, 1993; Jacob et al., 2000). In a family with affected twins, a genetic basis, with a defect in the noradrenaline transporter system, has been described which accounted for the raised basal noradrenaline levels. A mutation of the gene encoding the noradrenaline transporter was thought responsible for the hyperadrenergic state (Shannon et al., 2000). Hypovolemia may contribute.

The prognosis is variable, and some patients may recover with time. A variety of drugs, including beta blockers and drugs used in the treatment of orthostatic hypotension need to be considered; methods to increase volume expansion appear beneficial.

Localized autonomic disorders

Examples of these are listed in Table 52.15 with a brief description of a few.

The Holmes–Adie pupil is characteristically dilated and sluggishly responsive to light but responds to near vision, hence the descriptive term 'near-light dissociation'. It results from parasympathetic denervation, probably of the ciliary ganglia, with supersensitivity of the iris musculature to locally applied cholinomimetics. The term Holmes–Adie syndrome is used when associated with absent tendon reflexes; this probably is due to involvement of dorsal root ganglia, accounting for the absent H reflex on electrophysiological testing. Some patients have areas of anhidrosis, although they often complain of hyperhidrosis that is likely to be compensatory in nature (Ross syndrome). Others may have cardiovascular autonomic deficits, a chronic dry cough and diarrhea (Kimber et al., 1998). Although considered benign, in some the disorder may be progressive, with baroreceptor reflex dysfunction causing labile hypertension and also orthostatic hypotension.

In Horner's syndrome, there is partial ptosis and a small pupil as the sympathetic fibres to the face are affected. It may result from a lesion along the course of the facial sympathetic supply, in the brain, spinal cord, the upper thoracic ganglia or post-ganglionic efferents that follow the vasculature. Although it causes few, if any, symptoms it may be a harbinger of a serious underlying disorder.

Table 52.15. Examples of localized autonomic disorders

Holmes – Adie pupil
Horner's syndrome
Crocodile tears (Bogorad's syndrome)
Gustatory sweating (Frey's syndrome)
Essential (primary) hyperhidrosis
Reflex sympathetic dystrophy
Hirchsprung's disease (congenital megacolon)
Chagas' disease (*Trypanosomiasis cruzii*)
Surgical procedures[a]
– Sympathectomy – regional
– Vagotomy and gastric drainage procedures in 'dumping syndrome'
– Organ transplantation – heart, lungs

Notes:

[a] Surgery may cause some of the disorders listed above (such as Frey's syndrome following parotid surgery).

The lachrymal glands have a rich autonomic innervation. Alachryma may occur as part of a generalized autonomic disorder. 'Crocodile' tears may result from aberrant reinnervation of the lachrymal gland with fibres from the salivary glands. The mechanisms are similar to gustatory sweating, due to aberrant reinnervation between salivary and facial sweat glands; in both acetylcholine is the neurotransmitter. In essential (primary) hyperhidrosis there is no peripheral neural abnormality; whether hypothalamic dysfunction or altered behavioural responses are the trigger to hyperhidrosis is unclear. The treatment of hyperhidrosis, especially of the palms and face includes percutaneous endoscopic transthoracic sympathectomy, with bilateral ablation of ganglia between T2 and T4; compensatory hyperhidrosis affecting the trunk and lower limbs may occur postsurgery and in some may be worse than the original complaint. Injection of botulinum toxin especially into small areas such as the palm, face and axillae has been successfully used, but needs to be repeated and long-term benefits are unknown (Naumann et al., 1997). In reflex sympathetic dystrophy (chronic regional pain syndrome; CRPS type 2), there is debate about whether features such as sweating and vascular changes have an autonomic basis (Kimber et al., 1997b; in some these abnormalities are relieved by sympatholytic (guanethidine) blockade.

Localized disorders of the gut include Hirschsprung's disease. In Chagas' disease (after infection with *Trypanosoma cruzii*) the intrinsic autonomic ganglia in the esophagus, colon and heart are specifically targeted, probably by an immunological process. Various surgical procedures may be complicated by autonomic dysfunction, an

example being the dumping syndrome complicating vagotomy and gastric drainage procedures. Denervation of transplanted organs such as heart or kidneys also may result in dysfunction; reinnervation may occur in due course.

Human brain–gut interactions: mechanisms of swallowing, visceral perception, and anal continence in health and disease

Shaheen Hamdy

Department of GI Science, Hope Hospital, Salford, Manchester, UK

It is now increasingly recognized that the brain plays an important role in modulating gut function. For example, alterations in emotional state can lead to disturbed gastrointestinal symptoms such as diarrhea, dyspepsia and even abdominal pain. Furthermore, alterations in gastrointestinal motility have been described after lesions to the central nervous system, for instance symptoms such as dysphagia after stroke, anal incontinence in cerebrovascular disease and multiple sclerosis and even alterations in small bowel motility following brainstem damage.

In this chapter I will describe current knowledge of human brain–gut interactions both in health and disease in relation to three specific areas: mechanisms of swallowing, mechanisms of anal continence and mechanisms of visceral perception. Particularly, I aim to bring the reader up to date with some newer concepts in relation to the neurophysiology of human cortical swallowing and anal motor function as well as touching on the newer areas of visceral sensitivity and functional bowel disorders. Finally, I will look at future directions specifically looking at potential therapies which may help in disease states that disrupt the human brain–gut axis.

Basic anatomy and physiology of the brain–gut axis

The enteric nervous system

The human brain–gut axis is a complex sensory motor system which has both extrinsic and intrinsic neural elements. At the intrinsic level the enteric nervous system represents an integrative system of neurons and interneurons with structural complexity and functional heterogenicity similar to that of the brain and spinal cord (Gershon, 1981). The principal role of the enteric nervous system (ENS) is to control and coordinate gut functions, including motility, secretion, mucosal transport and blood flow as necessary for normal digestive processes. These functions are mediated by the ENS via motor neurons located within enteric ganglia which form the final common pathway to the effector cells of the GI tract. The ENS houses a matrix of differing cell populations, which each play a role in maintaining intrinsic gastrointestinal sensory motor activity and include mast cells, smooth muscle cells, interstitial cells of Cajal, enteric enteroenteric cells and motor neurons. These also are subject to the release of various neurotransmitters, growth factors and cytokines which result in an enteric micro-environment that controls GI motility in an autonomous manner.

Vagal and spinal innervation

Whilst the enteric nervous system is almost autonomous it does receive input from extrinsic pathways via the central nervous system (CNS) via both vagal and spinal pathways linking it with the brain and spinal cord (Fig. 53.1). As a result this has led to the concept of the brain–gut axis revolving around both the 'big brain' and the 'little brain' representing the CNS and the ENS, respectively (Aziz & Thompson, 1998). The connecting pathways intervening can be conveniently divided into vagal (para-sympathetic) pathways and spinal (sympathetic) pathways.

Vagal pathways

The vagus nerve conveys a large amount of information between viscera and the brainstem, and contains both afferent and efferent fibres which in man innervate the entire gut as far as the distal third of the colon (Roman & Gonella, 1987). Approximately 90% of fibres within the vagal trunks are unmyelinated afferent neurons with cell bodies located in the nodose ganglion which lies just below

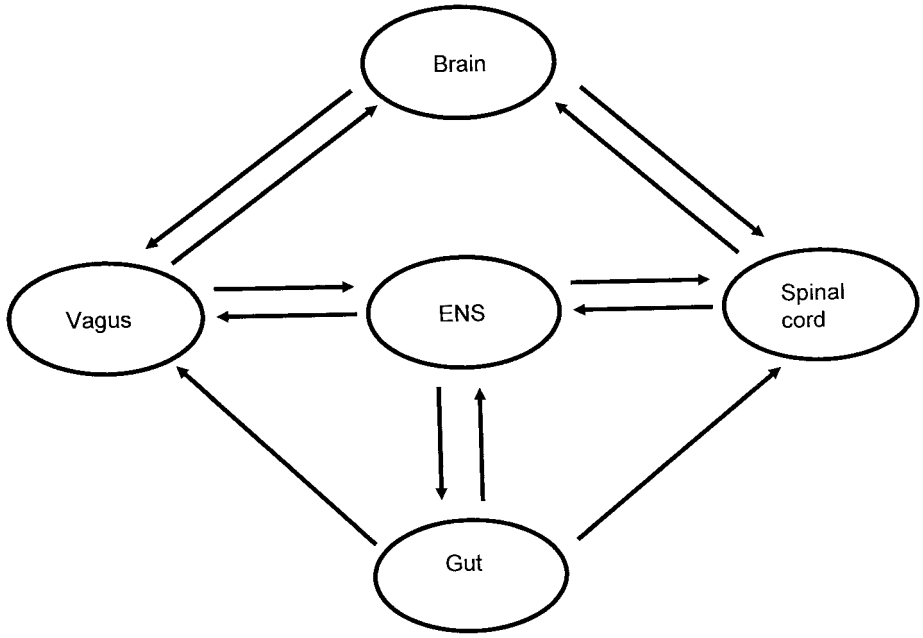

Fig. 53.1. Schematic representation of the intrinsic and extrinsic innervation of the gut.

the jugular foramen. There resides within the nodose ganglia a crude viscerotopic organization corresponding to sensory neurons projecting to soft palate and pharynx located superiorly and those projecting to the stomach, small bowel and lower GI tract which are located more caudally (Altschuler et al., 1989). Afferent fibres from the nodose ganglia then terminate in the brainstem within the medial division of the nucleus tractus solitarius (NTS), where a further viscerotopic organization within distinct subnuclei is displayed. Vagal afferents are believed to mediate non-noxious physiological sensation, such as anxiety and nausea and have a relatively low threshold of response to mechanical and electrical stimulation. There is also increasing evidence that vagal afferents may play a role in the modulation, at least, of nociceptive input from the bowel (Randich & Gebhart, 1992).

The other 10% of the vagal fibres are efferents that project from both the nucleus ambiguous and the dorsal motor nucleus representing the vagal motor nuclei complex. The nucleus ambiguous (NA) is located in the ventrolateral medulla and tends to innervate the striated musculature of the upper GI tract including the pharynx, larynx and upper esophagus and thus plays an important role in the complex motor act of swallowing. By comparison, the dorsal motor nucleus (DMN) of the vagus provides efferents to smooth muscle regions of the gut in association with myenteric plexus neurons. DMN motor neurons display extensive dendritic arborizations allowing some degree of coordination of efferent activity. These dendrites not only innervate specific viscera but also have linkages with NTS resulting in organ specific monosynaptic interactions between the NTS and the DMN and functionally provide the circuitry for 'the vasovagal' reflexes, such as the gastro-gastric reflex, the enterogastric reflex, the hepatopancreatic reflex and the gastrocolic reflex (Gillis et al., 1989). In both the DMN and NA there is some topographic subnuclei organization both in terms of the striated muscle of the gut in the nucleus ambiguous and in abdominal viscera in the dorsal motor nucleus.

In addition to the vagus there is a second 'parasympathetic' innervation of the GI tract which will be further described in this chapter as sacral pathways. These are projections from pre-ganglionic neurons located in the intermediate grey matter of the sacral cord segments (S1 to S5) and innervate the distal colon, rectum and internal anal sphincter via pelvic ganglia from where postganglionic pelvic nerve fibres innervate the enteric ganglia. As with the vagus, there are both afferent and efferent pathways with the afferent fibres from the colon going via the pelvic nerve afferents to the dorsal root ganglia of the sacral segments. Some of these fibres then send projections to preganglionic neurons to the ENS of the lower colon and result in spinal reflexes that regulate colonic motility and defecation. A somatic component of this innervation is the pudendal nerve which has motor neurons located in the ventral horn of S1 and S2 segments and innervates the

external anal sphincter while pudendal afferents relay sensory information from the anal sphincter margin and canal back to the spinal cord.

Spinal pathways

In addition to the vagal pathways innervating the gastrointestinal tract, there are also spinal visceral afferents which have been wrongly termed 'sympathetic' pathways as they pass via prevertebral and paravertebral ganglia of the sympathetic system to the spinal cord but importantly have their cell bodies in the dorsal root ganglia of the cervical, thoracic, and upper lumbar spinal segments. These spinal afferents are predominately unmyelinated C and A-delta fibres and relay predominantly mechanoreceptive and chemical stimuli to a noxious level (Sengupta & Gebhart, 1994). It is important to recognize that considerable segmental overlap exists in the spinal cord in relation to the spinal afferents which partially explains the poor viscerotopic localization of sensation from the GI tract. Furthermore, because there is convergence of such spinal afferents with somatic afferents, the result is some degree of referred pain from a particular organ to a corresponding cutaneous area on the body surface. As with other spinal afferents, visceral spinal afferents are then transmitted proximally within the spinal cord via a number of tracts of which the spinothalamic and the dorsal column pathways are most important. Thus the role of visceral spinal afferents is one predominantly of transmission of nociceptive information; however, it is likely that these afferents have stimulus response functions that cover both physiological and nociceptive ranges of stimulation so that they play the major role in visceral perception and sensitivity.

In addition to spinal afferents there are also associated sympathetic efferent pathways from the cervical, thoracic and lumbar segments of the spinal cord. These have preganglionic and postganglionic synaptic connections the latter of which most prominently represent the celiac and superior mesenteric ganglia and the inferior mesenteric ganglion which innervate the proximal bowel and the distal bowel respectively. It is likely that these sympathetic efferent connections result in an inhibition of GI function and consequently a reduction in motility via the release of acetylcholine.

Supra spinal and higher centre influences on intrinsic and extrinsic neural pathways to the gut

Both the vagal and spinal pathways and consequently the enteric nervous system are under the influence of higher centre regulatory processing. The vagus nerve carries afferent projections via the NTS to higher brain regions via a relay in the pons and medulla, from where there appear to be at least four levels of input. The first are direct projections to autonomic motor nuclei involving both parasympathetic and sympathetic preganglionic neurons in the dorsal motor nucleus and the nucleus ambiguous of the vagus as well as the intermediolateral cell column of the spinal cord. These projections provide the anatomical substrate for short autonomic reflex loops. Secondly, the NTS sends relays to the motor components for ingestion found in the trigeminal, facial, and hypoglossal nuclei and also in the nucleus ambiguous. Thirdly, visceral information is relayed to more rostral regions of the brainstem such as the parabrachial nuclei, which are in turn connected to higher centres. Fourthly, long projections terminate in the thalamus, hypothalamus and limbic and insular cortical regions that mediate autonomic neuroendocrine and behavioural functions. These regions all have reciprocal connections with other brain regions such as the area prostrema, the parabrachial nucleus, hypothalamus, amygdala and the orbitofrontal, insular and inferior limbic and cingulate cortex (Sawchenko, 1983). These connections integrate sensory input arriving from the nucleus of the tractus solitarius with descending influences from higher brain centres and provide the circuitry for visceral reflex loops. This integration presumably results in the orchestration of autonomic reflexes involving GI, cardiovascular and respiratory activities such as that which occur in vomiting. Visceral spinal afferents also project to higher centres via relays in the brainstem and thalamus. From the thalamus, sensory information passes to the insular cortex, the primary somatosensory cortex and the prelimbic, limbic and infra-limbic areas of the medial pre-frontal cortex. It is likely that these pathways are responsible for the integration of somatic and visceral input from wide areas of the body.

Vagal motor pathways also receive direct connections from anterolateral motor strip, premotor cortex, insula and probably a number of other areas including the supplementary motor cortex, all of which have been associated with the motor control of swallowing and other GI functions. In a similar manner, sacral motor pathways appear to have direct connections via cortical spinal tracts from more medial aspects of the motor strip as well as areas similar to that which have already been mentioned to the vagus nerve. Finally, sympathetic efferents are recognized to have connections via projections from the hypothalamus, medial forebrain, anterior sigmoid and orbital and cingulate gyri of the cerebral cortex, which when stimulated can result in inhibition of colonic motility (Rostad, 1973).

Mechanisms of swallowing

The process of swallowing is a complex neuromuscular activity which allows the safe transport of material from the mouth to the stomach for digestion without compromising the airway. This is a fairly simplistic description as the act of swallowing requires a sophisticated integration of both central control and anatomical structures to produce the sensory motor output that we call the swallow. In addition to transporting food, swallowing is also concerned with the protection of the airway, ejection of noxious ingested substances and the preparation of food material. Therefore, when considering swallowing it is important to consider both the anatomy, physiology and the neurophysiology behind this exquisitely complex function.

Anatomy of the swallowing tract

The anatomy of the swallowing tract encompasses the oral cavity, the pharynx which is functionally linked with the larynx and the esophagus. In total, there are at least 32 pairs of muscles which act synergistically to produce the swallow, thereby making it one of the most superior 'reflexes' in the human body. The oral cavity is surrounded by supportive structures including the mandible, maxilla, hard palate and alveolar ridges which house dentition. The mouth itself is enclosed by various muscles including those of mastication and facial expression as well as the intrinsic and extrinsic muscles of the tongue and soft palate. The pharynx supported by pharyngo-basilar fascia comprises three sequentially placed constrictor muscles with the cricopharyngeus distally and stylopharyngeus proximally. Anterior to this, on the anterior wall of the hypopharynx is a cartilaginous box known as the larynx which is surrounded and connected to the hyoid bone and thyroid fascia by the strap muscles of the neck. Intrinsically, the larynx contains eight pairs of muscles of which only two pairs (the aryepiglottic muscles or 'false vocal cords' and the lateral cricoarytenoid muscles or 'true vocal cords') are responsible predominantly for airway protection during swallowing. Extending posteriorly and rostrally is the epiglottis, which forms the base of the tongue and is at its apex connected with the larynx. Beyond the pharynx and the high pressure zone of the upper esophageal sphincter is a 20 cm long muscular tube known as the esophagus. The esophagus consists of predominately striated muscle fibres in its proximal one-third, mixed smooth muscle and striated muscle fibres in its middle third, and predominantly smooth muscle fibres in its distal third which merge with the cardia of the stomach at the level of the lower esophageal sphincter.

The physiological events of swallowing

Swallowing is commonly described as having three distinct phases or stages which comprise the oral phase, the pharyngeal phase and the esophageal phase (Kennedy & Kent, 1988). It was generally thought that the oral phase is voluntary, whereas the pharyngeal and esophageal phases are involuntary; however, it is now accepted that higher inputs can influence both these latter two phases, probably more in a modulatory capacity. Humans swallow on average once every minute which is supplemented by the production of saliva which when absent or reduced inhibits the ability to swallow. Swallowing almost completely tails off during deep (stage 4) sleep but does occur during REM sleep, indicating that a level of arousal is necessary for swallowing to take place (Lichter & Muir, 1975). The oral phase is sometimes described as being preceded by the preparatory phase, particularly when solid or semisolid foods are ingested. Mastication and mixing with saliva occurs at this point and the bolus is then cupped in the anterior portion of the tongue before being propelled by an upward and compressing force initiated by the tongue against the hard palate to 'squeeze' the bolus into the pharynx. During this phase, the soft palate rises to seal off the naso-pharynx and thus completes the oral phase which lasts 0.6 to 1.2 seconds.

The pharyngeal phase typically begins as the bolus reaches the faucial pillars of the hypopharynx. Simultaneously, the larynx and hyoid bone are lifted upwards and forwards by contraction of the strap muscles of the neck and in so doing enlarges the space available for the pharynx to receive the incoming bolus. The bolus is then propelled aborally by sequential contractions of the constrictor muscles of the pharynx and this is associated with a reflex relaxation of the normally high toned upper esophageal sphincter to allow passage of the bolus into the esophagus. During transport through the pharynx, respiration is momentarily halted, the swallow usually occurring whilst in expiration. Concurrently, a protective mechanism of aryepiglottic fold closure and approximation of the arytenoid and epiglottic cartilage by contraction of the intrinsic muscles of the larynx then occurs. The whole pharyngeal phase usually takes less than 0.6 seconds.

Thus commences the esophageal phase of swallowing which comprises a propagated peristaltic wave which propels the bolus at approximately 2 to 4 cm per second. As the bolus passes through the esophageal body, the lower esophageal sphincter relaxes and the bolus enters the stomach, the esophageal phase lasts between 6 and 10 seconds, and the whole process of swallowing usually 12 seconds in total.

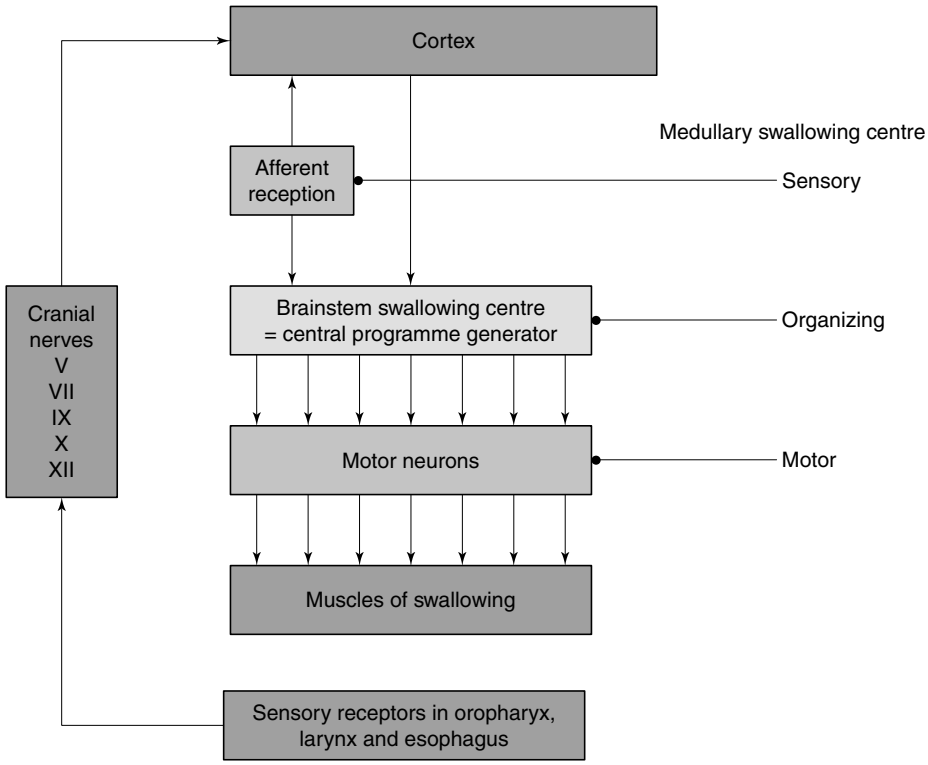

Fig. 53.2. The hierarchical organization of the central regulation of swallowing. Input from the periphery and higher centres converge onto interneurons in the brainstem swallowing centre, which generates the sequenced pattern of swallowing via the bulbar motor nuclei.

The neurophysiology of swallowing

The central neural control of swallowing can be divided into essentially three basic components: an afferent system, a central processor and regulating system and an efferent system (Fig. 53.2). At this point it is important to emphasize that the central processing system has at least three levels including the brainstem swallowing centre, subcortical structures and the cortex itself.

The afferent system

Afferent input comes from three cranial nerves innervating the muscles of the swallowing tract and includes the trigeminal nerve, the glossopharyngeal nerve and the vagus nerve, of which its superior laryngeal branch appears to have most importance. Stimulation of any of these nerves can initiate or modulate a swallow (Miller, 1982). These afferent fibres terminate centrally at the level of the brainstem in the tractus solitarius and in the nucleus of the spinal trigeminal system before converging in the NTS. There is however, a second projection which ascends via a pontine relay to the level of the cortex without transgressing the NTS (Car et al., 1975). The most potent trigger for swallowing is the superior laryngeal nerve which is only matched by direct stimulation of the nucleus of the tractus solitarius, suggesting that the solitary system is a major contributor of swallowing afferent input (Jean, 1984). Importantly, anesthesia of areas innervated by these cranial nerve afferents will disrupt but will not necessarily completely abolish the ability to swallow (Mansson & Sandberg, 1974). Sensation from the oral, pharyngeal and laryngeal regions includes a broad range of modalities including two point discrimination, vibrotactile detection, somesthetic sensitivity, proprioception, nociception, chemical sensitivity and thermal sensitivity (Miller, 1999). The oral, pharyngeal and laryngeal mucosae possess an epithelium innervated by both free nerve endings and within deeper layers more organised sensory receptors. Of interest there appear to be chemosensitive receptors that are specifically water responsive which will not trigger at isotonic levels. There also appear to be different groups of cold responsive sensory fibres which discharge at around 25 to 30 °C. Mechanical stimuli appear to be the most effective stimuli for exciting NTS neurons within receptive fields

of the oral cavity and epiglottis, a moving mechanical stimulus excites more neurons than a static stimulus. When comparing the receptive field responsiveness within the oral cavity, it appears that mechanical stimulation is more potent than chemical stimulation which in turn is greater than thermal stimulation (Miller, 1999).

The efferent system

The efferent system comprises motor neuron pools, consisting of the facial motor nucleus, the hypoglossal motor nucleus, the trigeminal motor nucleus, and the vagal motor nuclei. Inputs from the brainstem central pattern generator and from supra-bulbar regions impinge on these motor nuclei in a manner which synergistically produces the swallow. The cranial motor nuclei mentioned above have subdivisions based on the motor neurons innervating specific muscles. The facial motor nucleus is involved with the labial muscles for which there are several functions both in swallowing and speech as well as chewing. The hypoglossal nucleus contains the motor neurons innervating the intrinsic and extrinsic muscles of the tongue, which are involved in numerous motor functions including speech, respiration, licking, mastication as well as swallowing. The trigeminal motor nucleus contains the motor neuron pools that innervate the mandibular muscles and can be divided into four nuclei which appear to develop at different times during development in the fetus (Miller, 1999). The nucleus ambiguous is also subdivided into at least four layers including the compact layer, semi-compact layer, the loose layer and the external formation. These motor neurons innervate the palatal, pharyngeal, laryngeal and esophageal muscles. Finally the dorsal motor nucleus of the vagus contains neurons that innervate the esophagus and portions of the proximal gastrointestinal tract. It appears that the earliest motor neuron to develop during swallowing in the fetus is probably the hypoglossal nerve (Miller, 1999) as tongue activities are present in the fetus at about the same time as the jaw opening reflex. Indeed by the eleventh week of development of the human fetus, the first pharyngeal motor responses can also be detected.

Whilst lesions to the facial motor nucleus do not implicitly result in dysphagia, lesions to the nucleus ambiguous and to a lesser extent the hypoglossal and trigeminal motor nuclei result in more significant dysphagic symptoms (Miller, 1999). Thus, as a result of input from the NTS and higher centres to the dorsal region of the medulla and the brainstem swallowing centre, motoneurons in this region will provide the patterned sequential discharge activating the oral pharyngeal and esophageal phases of swallowing.

Central and supra-bulbar regulatory systems

Brainstem swallowing centre

Much of the research pertaining to the central regulation of human swallowing has focused on the issue of the brainstem swallowing centre. This important swallowing region is central to the regulation of human swallowing and is distributed within the reticular formation just dorsal to the inferior olive either side of the midline in the medulla (Jean, 1990). It is believed that this network of neurons and interneurons integrates incoming information from other levels, both central and peripheral, before activating a preprogrammed sequence of responses which then dictate the pattern of swallowing. The concept of a central pattern generator within the brainstem is supported by the fact that even after disruption of both afferent and efferent fibres to this region, the pattern of swallowing remains essentially unchanged when studied in animals (Jean, 1990).

It appears that the circuitry of the central pattern generator has different populations of interneurons responsible for the different temporal stages of swallowing and termed 'early' 'late' and 'very late' neurons which closely correspond to their muscular counterparts within the oropharynx, lower pharynx and striated muscle portion of the esophagus, and the smooth muscle esophagus respectively (Jean, 1984). Functionally, it appears that the brainstem swallowing centre can be divided into two, the dorsal medullary region and the ventral medullary region. The dorsal medullary region provides the neurons that initiate the sequential activity of swallowing and can be defined as generating neurons. The ventral medullary region which includes an area around the nucleus ambiguous appears to play a switching role in modifying and activating the motor neuron pools controlling swallowing output. In between these two regions there is a short interneuronal network that has both excitatory and inhibitory components and which relays information from the dorsal region to the ventral region.

Within both regions of the medulla there are a number of neurotransmitter substances which appear to have relevant roles (Bieger, 1993); for example, the injection of glutamate into the dorsal region of the brainstem evokes pharyngeal swallowing suggesting that it is excitatory. By comparison, injection of dopamine or noradrenalin appears to inhibit the elicitation of pharyngeal swallowing. It also appears likely that gamma-aminobutyric acid, acetylcholine, n-methyl D-aspartate and nitric oxide probably play an important role in the inhibitory and excitatory regulation of swallowing.

In addition to the medullary brainstem swallowing centre, there appears to be a separate area within the

pontine reticular formation which will also when stimulated evoke swallowing. This region, when stimulated at low intensity will evoke both swallowing and rhythmic jaw movements but at high intensity results in more inhibitory effects. It is likely that pathways from the afferent innervation of swallowing project to this region as well as the medullary area on their way to the antero-lateral cortex. Activation of the pontine region may in fact result in a transcortical reflex to evoke the swallow rather than the pontine area being directly involved in the initiation of swallowing.

Supra-bulbar regions influencing swallowing

There is extensive experimental evidence to support the role of subcortical structures in the control and modulation of swallowing (Bieger & Hochman, 1976). These regions can be anatomically divided into the hindbrain, comprising the cerebellum, the midbrain, comprising the substantia nigra and the ventral tegmentum and basal forebrain, comprising the hypothalamus, amygdala and basal ganglia. In animals, activation of all these sites has been shown to facilitate the swallow response when combined with either superior laryngeal nerve stimulation or cortical stimulation. Evidence from human studies also suggests an important contribution from subcortical areas, such as the basal ganglia, where dysphagia is a common consequence of Parkinson's disease (Bernheimer et al., 1973). In a recent functional imaging study of human swallowing it was demonstrated that areas including the left amygdala and the left cerebellum as well as the dorsal brainstem show increased regional cerebral blood flow during volitional swallowing (Hamdy et al., 1999). The lateralized nature of these activations was of interest and supported the possibility that swallowing displays significant interhemispheric asymmetry in its motor control.

The cerebral cortex has been strongly implicated in the control of swallowing where numerous investigators have observed a stimulation of the cerebral cortex both in animals and humans can elicit the full swallow sequence (Martin & Sessle, 1993; Penfield & Boldery, 1937). The areas implicated in these studies seem to be the dorsolateral and antero-lateral frontal cortex as well as the premotor cortex, the frontal operculum and also the insula. Much of the information regarding the cerebral localization of human swallowing has relied on inference from studies of swallowing abnormalities following cerebral injury (Veis & Logemann, 1985; Gordon et al., 1987; Horner & Massey, 1988). From these reports a rather diffuse picture has emerged of those areas of the brain considered important, for example, lesions located in the thalamus, pyramidal tracts, frontal operculum and the insula have all been associated with dysphagia. More recently, functional imaging has also established a clear role for the lateral sensorimotor cortex and, in particular, the right insula during the process of swallowing (Hamdy et al., 1999). More information has come from the studies of transcranial magnetic stimulation of the human precentral gyrus in understanding the cortical control of swallowing (Hamdy et al., 1996, 1997b, 1998a). Transcranial magnetic stimulation uses a very short rapidly changing magnetic field to induce electric current in the brain beneath the stimulator. These studies usually employ single shocks given several seconds apart and, following stimulation, the cortical evoked motor response can be recorded as electromyographic activity from electrodes housed within an intraluminal catheter inserted into pharynx and esophagus. Following cortical stimulation, the type of response observed is usually a simple EMG potential which has a latency of about 8 to 10 milliseconds, compatible with a fairly direct and rapidly conducting pathway from cortex to the muscle (Fig. 53.3). During these magnetic stimulation mapping studies the projections to the various swallowing muscles were demonstrated to be somatotopically arranged in the motor strip with the oral muscles most lateral and the pharynx and esophagus more medial. A more interesting finding from a large group of healthy subjects studied was that in the majority of individuals, the projection from one hemisphere tended to be larger than the other suggesting an asymmetric representation for swallowing between the two hemispheres, independent of handedness. These findings have also been validated with functional imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) where cerebral lateralization has been also observed (Hamdy et al., 1996, 1999). These functional imaging studies have, however, identified a number of other cortical areas associated with swallowing including anterior cingulate cortex, premotor cortex (including the supplementary motor cortex), the insular cortex, frontal opercular cortex and the temporal cortex. Taken together these observations suggest that swallow-related cortical activity is multidimensional, recruiting brain areas implicated in the processing of motor, sensory and presumably attention/affective aspects of the task.

Swallowing dysfunction after injury to the central nervous system

Difficulty in swallowing can occur as a consequence of disease to either the anatomical structures involved in swallowing or more commonly to the central nervous system controlling swallowing (neurogenic dysphagia).

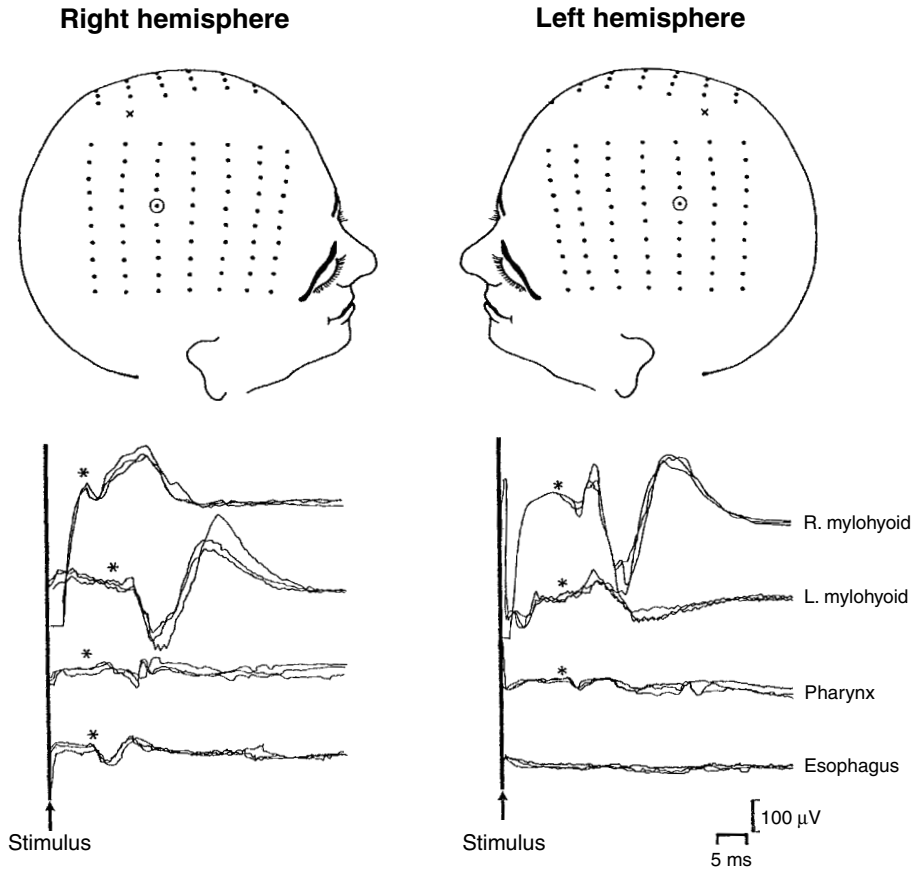

Fig. 53.3. Schematic representations of the sites of stimulation on a scalp grid in relation to the head surface are shown above. The cranial vertex is marked by X. The cortically evoked EMG responses recorded in one normal subject from: right mylohyoid muscle, left mylohyoid muscle, pharynx, and esophagus, following transcranial magnetic stimulation of the right and left hemispheres are shown below. The sites of stimulation on the grid from which these responses were obtained are indicated by the open circle. Responses to three stimuli have been superimposed to show reproducibility. It is evident, however, that the pharyngeal and esophageal responses obtained from the right hemisphere are larger than those from the left hemisphere. (* indicates onset of EMG response.)

The anatomical problems which disrupt swallowing are myriad and include almost any gastrointestinal disease process which affects the oral cavity through to the duodenum. It is therefore important to exclude any intrinsic disease to the gut before making a diagnosis of neurogenic dysphagia in someone presenting with symptoms of swallowing difficulty.

There are many neurological conditions that can disrupt swallowing including diseases of the muscle or neuro muscular junction, e.g. polymyositis, myasthenia gravis and the muscular dystrophies; diseases of the peripheral nerves, e.g. Guillain–Barré syndrome, polio and diptheria; and disease affecting the central swallowing centres, e.g. stroke, head injuries, motor neuron disease, Parkinson's disease, multiple sclerosis and other neurologic diseases. In addition, it is important to recognise that any pharmacological agent which alters neuromuscular function can produce dysphagia. It is beyond the scope of this chapter to go into detail of the many neurological conditions which can affect swallowing and for the rest of this section I will discuss the clinical consequences and underlining mechanisms related to dysphagia following cerebrovascular disease, specifically stroke.

Injury to swallowing areas of motor cortex and/or their connections to the brainstem will usually result in problems with swallowing (dysphagia). The commonest reason for dysphagia is now stroke. Traditionally, it had been assumed that only strokes producing brainstem or bilateral cortical damage are associated with dysphagia; however, since the 1970s it has been increasingly recognized that unilateral cerebral lesions can also cause dysphagia (Barer, 1989; Meadows, 1973; Daniels & Foundas,

1997). Up to half of all stroke patients experience dysphagia, which is associated with the life-threatening complications of pulmonary aspiration and malnutrition. Dysphagia leads to increased lengths of stay in hospital and greater demands on health service resources.

Diagnosing dysphagia following cerebral injury can be difficult and therefore requires a high level of clinical suspicion. The pattern of disordered swallowing after stroke is usually a combination of oral and pharyngeal abnormalities, typically delayed swallow reflex with pooling or stasis of residue in the hypopharynx associated with reduced pharyngeal peristalsis and weak tongue control but occasionally esophageal abnormalities may be apparent. Clinical suspicion of swallowing difficulty should be followed up by thorough bedside swallowing assessment and where appropriate imaging of the swallowing process such as videofluoroscopy. The bedside examination incorporates a number of clinical measures including assessment of the patient's feeding status, posture, breathing and cooperation levels before examining the patients oral musculature, oral reflexes, pharyngeal swallow and usually a trial feed with 5 to 10 ml of water given either by spoon or in a beaker. The bedside assessment is cheap and relatively easy to perform and has the advantage of involving no radiation exposure. However, it lacks sensitivity and does not give detailed information of the pharyngeal stage of swallowing making it prone to missing significant aspiration, especially silent aspiration. When the diagnosis is in doubt, videofluoroscopy can give a detailed anatomical assessment of the pharyngeal swallow and has the advantage of detecting silent aspiration and other abnormalities of the swallow anatomy. However it is expensive, involves radiation and uses a non-physiological medium i.e. barium, which may not give a true picture of the patients swallowing performance. A recent advance is the introduction of flexible endoscopic evaluation of swallowing (FEES). FEES involves the passing of a nasoendoscope into the oropharynx while a small volume of a coloured physiological meal or liquid is ingested. This allows the anatomy of the pharyngeal swallow to be directly visualized and the swallowing mechanism assessed.

The management of dysphagia after stroke is therefore critical. With severe dysphagia the risk of aspiration is high and the patient is therefore kept nil by mouth with early commencement of parenteral fluids. With less severe dysphagia, based upon videofluoroscopic and bedside swallowing assessment outcomes, there are a number of therapeutic interventions which can be tried. These interventions include changing diet, posture and food placement adjustment as well as methods for sensitizing or de-sensitizing the oropharynx to alter the swallow reflex. Unfortunately, the efficacy of these therapeutic manoeuvres is a matter of some controversy: at present there are no randomized controlled trials of these interventions to show proven efficacy in improving the swallow after stroke. Consequently, patients often require nasogastric tube or gastrostomy feeding until swallowing improves spontaneously.

Mechanism for dysphagia following stroke

Whilst it is relatively easy to appreciate the mechanisms behind dysphagia following bilateral cortical stroke or brainstem disease the mechanism underlying dysphagia after unilateral cerebral injury particularly after hemispheric injury has remained unclear. Speculated suggestions include occult disease in the unaffected hemisphere, cerebral edema leading to pressure on the adjacent hemisphere or brainstem, and the possibility that swallowing, like speech, may show significant cerebral lateralization. Indeed, in a transcranial magnetic stimulation study of the projections from both hemispheres to the swallowing musculature in a large series of pure unilateral hemispheric stroke patients, of which half had dysphagia, it was observed that whilst stimulation of the damaged hemisphere produced little or no response in either dysphagic or non-dysphagic patients, stimulation of the undamaged hemisphere evoked much larger responses in the non-dysphagic than in the dysphagic subjects (Hamdy et al., 1997a). The conclusion from this study was that the size of the hemispheric projection of the undamaged side to swallowing muscles determined the presence or absence of dysphagia with the implication that dysphagia would occur if damage had affected the side of the brain with the largest or dominant projection. This observation supported the concept that swallowing is lateralized within the cerebral cortex.

Mechanisms of recovery of swallowing after cerebral injury

Given sufficient time, a large proportion of dysphagic stroke patients eventually recover the ability to swallow again (Barer, 1989). The mechanism for this recovery, seen in as many as 90% of the initially dysphagic stroke patients has, however, remained controversial. In a recent study of stroke using transcranial magnetic stimulation both dysphagic and non-dysphagic patients were serially mapped over several months while swallowing recovered (Hamdy et al., 1998a). The findings of this study showed that the area of pharyngeal representation in the undamaged hemisphere increased markedly in patients who recovered

whilst there was no change in patients who had persistent dysphagia or in patients who were non-dysphagic. Furthermore no changes were seen in the damaged hemisphere in any of the groups of patients. These observations imply that over a period of weeks, the recovery of swallowing after stroke depends on compensatory reorganization in the undamaged hemisphere. The situation appears to differ from that in the limb muscles where some magnetic stimulation studies have indicated that limb recovery after hemiparesis is more likely to result from an increase in the activity of the remaining viable cortex in the damaged hemisphere (Turton et al., 1996). In such cases, scope for expansion of a normal connection from the undamaged part of the brain may be a limiting factor in recovery.

Mechanisms of anal continence

The anal sphincter is a midline muscular structure at the terminus of the gastrointestinal tract that functions to maintain fecal continence. It has two components, the internal sphincter and the external sphincter. Whereas the internal anal sphincter consists of circular smooth muscle and is innervated predominately by autonomic fibres from the pelvic plexus and sacral spinal cord, the external sphincter is of striated muscle and is innervated by the somatic fibres of the second, third and fourth sacral segments via the pudendal nerve. The neural control of anal continence therefore has sensorimotor contributions from both intrinsic and extrinsic reflexes, the former predominately via myenteric interaction within the internal anal sphincter, and the latter via strong descending volitional interactions with the motor neurons innervating the external anal sphincter (Christensen, 1983).

The neurophysiology of anal continence

Anal continence represents an important physiological and socially essential gastrointestinal function which is regulated by sensorimotor interactions within the anal sphincter and pelvic floor. In particular, contraction of the external anal sphincter serves to increase anal canal pressure both voluntarily, when the urge to defecate becomes strong and via more involuntary reflexes, for instance during coughing when intra abdominal pressure suddenly rises. In either case, the cerebral cortex is able to modulate this activity via powerful descending inputs to the pelvic plexus and sacral nerves so defecation can be resisted until a socially convenient opportunity arises. The importance of cortical influences in the control of the external anal sphincter is well recognized, direct stimulation of the most medial motor cortex adjacent to the interhemispheric fissure will induce anal sphincter contractions (Leyton & Sherrington, 1917). More recent experiments in humans have shown that the corticofugal pathways to the external anal sphincter can be studied non-invasively by recording the electro-myographic and manometric responses evoked by transcranial electric and magnetic stimulation of the motor cortex (Merton et al., 1982; Turnbull et al., 1999). These studies have suggested that the motor cortical representation of anal sphincter function is bilateral and may display, as with swallowing, an interhemispheric asymmetry.

The peripheral innervation of the external anal sphincter comes from the pudendal nerve. Anatomical and electrical physiological studies of the innervation of the external anal sphincter in animals has shown that most of the pudendal projections to and from the external anal sphincter are centrally organized to spinal segments L6 to S3 with the majority with the S1, S2 segments (Thor et al., 1989). Furthermore the motor neurons innervating the external anal sphincter, are particularly located in the dorsomedial and ventromedial divisions of Onuf's nucleus in the ventral horn of the spinal cord while the afferent axonal projections appear to cluster within the marginal zone, intermediate grey and dorsal grey surrounding the nucleus gracile of the dorsal column and laminal 1, around the dorsal horn of the spinal cord. Of interest is the observation that, while there is clear unilateral spinal predominance of these projections during retrograde tracing studies of a single nerve, in both the efferent and afferent pathways, there is contralateral axonal connectivity across the midline, suggesting degrees of bilateral convergence. In a recent study of pudendal nerve function it was found in a number of healthy volunteers that the evoked muscle potential to pudendal nerve stimulation can be quite asymmetric between the two sides (Hamdy et al., 1999). Furthermore, when pudendal or even lumbar sacral stimulation was used to condition the peripheral pathway, cortical stimulation of the anal region of the motor strip induced much greater responses in the anal sphincter compared to no conditioning (Hamdy et al., 1998b). Importantly, stimulation of the pudendal nerve with the larger response induced significantly more facilitation of the cortico-anal pathway than stimulation of the pudendal with the smaller response. This suggested that there may indeed be some functional asymmetry in the pudendal pathways to the anal sphincter possibly in conjunction with asymmetry at higher levels.

Anal incontinence

Anal incontinence represents a distressing complication of disease to the central nervous system, for example injury to

the pelvic nerves, as in instrumental deliveries at child birth, will result in significant anal sphincter dysfunction, as well as disruption of the brain–gut axis from cortex to sphincter seen in conditions such as stroke, multiple sclerosis and spinal injury. In the case of the former, anal incontinence has been attributed to pudendal nerve damage where a number of studies have shown clear abnormalities in pudendal nerve function (as determined by prolonged nerve conduction terminal latency) in incontinent female patients following vaginal delivery both with and without instrumental intervention (Snooks et al., 1984). It is important to mention at this stage that more detailed evaluation of these patients, however, often reveals underlying anatomical defects of the anal sphincter as a consequence of the delivery and which also explains the incontinence in many cases (Sultan et al., 1993). Nonetheless electrophysiologic assessment of pudendal nerve function remains of some importance as this parameter may be clinically relevant in differentiating patients with fecal leakage from solid stool incontinence and there exist patients without external anal sphincter defects who have significant continence problems and whose only demonstrable abnormality is that of pudendal neuropathy.

Fecal incontinence can present in the setting of central nervous system damage such as in patients with stroke or frontal lobe damage, for example it has been demonstrated that the fecal incontinence is strongly associated with larger strokes and particularly when the cerebral cortex is involved (Nakayama et al., 1997). Fecal incontinence is also frequently encountered in patients with multiple sclerosis and one survey of anorectal function in subjects with multiple sclerosis has suggested that there may be central motor mechanisms involved (Jameson et al., 1994).

Functional bowel disorders

An increasingly common condition seen by both general practitioners and hospital doctors is that of functional bowel disorder, of which the most important is irritable bowel syndrome. This and its associated conditions including non-ulcer dyspepsia, non-cardiac chest pain and proctalgia are likely to have some degree of commonality in both their physiological mechanisms and treatment approaches. Irritable bowel syndrome (IBS) has often been characterized into a syndrome consisting of abdominal pain or discomfort for at least 12 weeks in the preceding 12 months and two of the following: pain relief with defecation; onset associated with change in frequency of stool; onset associated with change in form (appearance of) stool. As many as 15% of all people experience a mild version of irritable bowel syndrome although only a small minority seek medical care. The speculated underlying mechanisms behind irritable bowel include a disturbance of colonic motility, visceral hyper-algesia and an abnormality of processing sensory information from the gut within the cerebral cortex (Mayer & Raybould, 1990). Whilst the pathophysiology of IBS remains a matter of controversy it is likely that the condition is multifactorial involving all three potential mechanisms as well as other factors including genetics, environment, psychological factors including life stress, psychological state, coping mechanisms and social support. Therefore, the treatment of functional bowel disorders such as IBS revolves around both psychologic and pharmacological treatments. These include education and reassurance, potential lifestyle and dietary modifications and then pharmacological agents, which may act on gut motility and sensation, such as either laxatives or antidiarrheal agents and for more severe cases, psychological treatment including antidepressants.

Future directions in human brain–gut interactions

With the advent of functional non-invasive brain imaging techniques it is likely that future understanding of the mechanisms underlying visceral sensitivity, functional bowel disorders and indeed understanding mechanisms behind dysphagia after cerebral injury and incontinence after central nervous system injury will be further elucidated. For example, it has been recently demonstrated that sensory stimulation of the pharynx can induce reorganizational changes in swallowing areas of the motor cortex which outlast the period of stimulation by several minutes (Hamdy et al., 1998a,b,c). The changes recorded to pharyngeal stimulation appear reminiscent of the spontaneous changes associated with swallowing recovery after stroke. It is possible therefore that sensory stimulation techniques may hold an attractive therapeutic approach for treating dysphagia after stroke. Furthermore, lumbo-sacral stimulation which normally induces sphincter contraction in the external anal sphincter, may in future play a role in conditioning anal sphincter muscles in a way which aids anal function in patients with fecal incontinence. Finally functional imaging techniques such as fMRI and PET as well as magnetoencephalography may also allow the dissection of mechanisms underlying functional bowel disorders including influences such as emotion, attention and other psychological constructs. The ability of PET studies to provide ligand information on the neuropharmacology of the brain processing of visceral sensation as well as the

motor control of swallowing and anal continence may well allow future drug treatment to be developed which may be able to target abnormal processing of visceral areas with a view to either enhancing function or blocking aberrant function within the human brain–gut axis.

Eating disorders: neurobiology and symptomatology

David C. Jimerson and Barbara E. Wolfe

Department of Psychiatry, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA

The 1990s have witnessed a remarkable upsurge in research on neurochemical pathways in the central nervous system (CNS) that contribute to the regulation of food intake and body weight homeostasis. These investigations have been driven in part by increasing recognition that obesity, anorexia nervosa and bulimia nervosa represent major public health concerns. Moreover, advances in molecular neurobiology have accelerated the identification of new peptides, proteins and their receptors in the hypothalamus and other brain regions critical to the regulation of ingestive behaviour. This chapter begins with a clinical overview of anorexia nervosa and bulimia nervosa, including brief summaries of diagnostic criteria and therapeutic considerations. Subsequent sections highlight promising areas of research on the clinical neurobiology of these disorders. Findings to date suggest that alterations in regulatory systems involving serotonin, cholecystokinin (CCK) and leptin may contribute to the initial onset or perpetuation of eating disorder symptoms.

Anorexia nervosa

Symptom patterns and diagnostic criteria

Descriptions of anorexia nervosa as a disorder of unexplained weight loss first appeared in the medical literature more than a century ago. The central psychological symptom of the disorder is 'refusal to maintain body weight at or above a minimally normal weight for age and height' (Table 54.1) (American Psychiatric Association, 2000). Patients demonstrate a persistent preoccupation with body shape and weight, with an underlying pervasive fear of becoming fat. Clinical observations and laboratory studies have shown that patients with anorexia nervosa do not suffer from loss of appetite, however (Sunday & Halmi, 1996). The characteristic amenorrhea appearing in postmenarcheal women is generally thought to be a consequence of malnutrition, although in some cases the loss of menstrual cycles can precede the onset of significant weight loss.

In most survey data, the prevalence of anorexia nervosa is approximately 0.5% among adolescent girls and young women. The typical age of onset is 18 years, and the prevalence in boys and young men is estimated to be 10% of that in females (Lucas et al., 1991; Whitaker et al., 1990). Episodes of recurrent dieting typically precede the onset of an eating disorder, and psychological and cultural factors contributing to increased preoccupation with body weight and appearance are thought to play a role in the etiology of anorexia nervosa. Behavioural risk factors include perfectionism and negative self-esteem (Fairburn et al., 1999). Based on family and twin studies, heritability estimates for the disorder are approximately 60% (Wade et al., 2000).

Anorexia nervosa is often a chronic illness, with multiple episodes of weight recovery and relapse. Studies of the natural course of the disorder have shown that 50% or more of patients recover after 10 years. Up to 20% or more of patients are likely to have a poor outcome (Eckert et al., 1995; Hsu, 1996; Strober et al., 1997b), with an aggregate mortality rate of approximately 6% per decade (Sullivan, 1995). There are few predictors of clinical outcome, although very early onset and very low weight at initial assessment may be associated with less favourable outcomes.

Clinical assessment and therapeutic approaches

In the clinical evaluation of patients with an eating disorder, it is useful to obtain detailed information about the individual's daily eating patterns, quantity of foods consumed, eating-related rituals and perceptions, and associated feelings of anxiety. Although the prototypical

Table 54.1. Diagnostic criteria for anorexia nervosa[a]

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g. weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or denial of the seriousness of current low body weight.
D. In postmenarcheal females, amenorrhea, i.e. the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g. estrogen, administration.)

Specify type:

Restricting type: during the episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behaviour (i.e. self-induced vomiting or the misuse of laxatives, diuretics or enemas)

Binge-eating/Purging type: during the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behaviour (i.e. self-induced vomiting or the misuse of laxatives, diuretics or enemas)

Notes:

[a] Diagnostic criteria in Tables 54.1 and 54.2 are reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, 4th edn, Text Revision. © 2000 American Psychiatric Association.

Table 54.2. Diagnostic criteria for bulimia nervosa[a]

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
(1) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
(2) a sense of lack of control over eating during the episode (e.g. a feeling that one cannot stop eating or control what or how much one is eating)
B. Recurrent inappropriate compensatory behaviour in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas or other medications; fasting; or excessive exercise.
C. The binge eating and inappropriate compensatory behaviours both occur, on average, at least twice a week for 3 months.
D. Self-evaluation is unduly influenced by body shape and weight.
E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify type:

Purging type: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics or enemas.

Non-purging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviours, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics or enemas

patient is often described as food avoidant, approximately half of women with anorexia nervosa develop recurrent binge eating episodes, often after about a year of the disorder. To facilitate increased understanding of clinical and biological correlates of these patterns, diagnostic criteria include designations for patients with 'restricting' and 'binge-eating/purging' types (Table 54.1).

A detailed psychiatric history is important for evaluation of comorbid major psychiatric disorders. Major depression occurs in more than half of patients with anorexia nervosa, although depressed mood can also be a consequence of weight loss *per se* and may resolve spontaneously with weight gain. Attention should be given to the evaluation of suicidality, anxiety disorders (including obsessive–compulsive disorder) and substance use disorders. The clinician also needs to be alert to the possibility of other neuropsychiatric syndromes (e.g. psychotic disorders) which can in rare instances present with unexplained weight loss. Assessment of psychosocial stressors, family history and, for younger patients, family relationships can be important in planning therapeutic interventions.

The initial assessment of a patient with anorexia nervosa includes a careful medical history and physical examination, with particular attention to possible medical or neurological causes for altered eating patterns and malnutrition. Physical examination commonly reveals signs of cachexia, e.g. bradycardia and hypotension. Basic laboratory tests include complete blood count, urinalysis, evaluation of serum electrolyte, blood urea nitrogen, and creatinine levels, and thyroid function tests (American Psychiatric Association Workgroup on Eating Disorders, 2000). An electrocardiogram is often part of the initial evaluation. Inclusion of additional laboratory tests, as well as evaluation for osteopenia and osteoporosis, is related to the extent and duration of malnutrition. Endocrine abnormalities are commonly present, including elevated serum cortisol, decreased thyroid hormone levels, and decreases in gonadal hormone levels (Stoving et al., 1999). Neurological

complications include myopathy (McLoughlin et al., 1998), or central pontine myelinolysis (Copeland, 1989).

Neuroimaging studies may be included in the clinical assessment for the evaluation of neurological or atypical behavioural symptoms (American Psychiatric Association Workgroup on Eating Disorders, 2000). Brain imaging studies have shown that low weight anorexic patients have decreased cortical size reflected in enlargement of cerebral ventricles and cortical sulci (Jimerson et al., 1998). These patterns usually normalize with weight restoration, although there is some evidence for persistent changes (Lambe et al., 1997). Studies of cerebral blood flow with single-photon emission computed tomography (SPECT) and cerebral metabolic rate with positron emission tomography (PET) have reported unilateral decreases in temporal lobe blood flow (Gordon et al., 1997), and trends toward alterations in frontal and parietal cortical metabolic rates that persist following weight restoration (Delvenne et al., 1996).

Treatment planning for anorexia nervosa generally includes the collaborative efforts of a primary care physician and a mental health professional. Interventions commonly involve individual psychotherapy, family therapy (particularly for the younger patient) and nutritional consultation. Hospitalization may be necessitated for medical stabilization or for monitoring of severe psychiatric symptomatology such as suicidal ideation. Although the recent trend has been toward relatively brief inpatient stays, specialized inpatient programmes based on behavioural and cognitive–behavioural interventions can be of significant benefit to the severely underweight patient. Participation in a day treatment programme can facilitate the transition from hospitalization to outpatient treatment.

In controlled trials, pharmacological treatments including antidepressants and neuroleptic medications have generally demonstrated very limited benefit as an adjunct to inpatient-based weight restoration programmes (Jimerson et al., 1996). Similarly, recent studies have failed to demonstrate a significant benefit for selective serotonin reuptake inhibitor (SSRI) antidepressant medications in weight restoration programmes (Attia et al., 1998; Ferguson et al., 1999; Strober et al., 1999). Preliminary studies have provided mixed evidence regarding the possible efficacy of an SSRI in the prevention of relapse following weight restoration (Kaye et al., 1998a; Strober et al., 1997a).

Bulimia nervosa

Symptom patterns and diagnostic criteria

In the 1970s, clinicians recognized a syndrome in normal weight individuals characterized by recurrent episodes of binge eating accompanied by compensatory weight-control measures. Initially conceptualized as a variant of anorexia nervosa, bulimia was included in the psychiatric diagnostic criteria in 1980. Current diagnostic criteria specify that binge eating episodes occur on average twice per week, and that abnormal eating patterns are accompanied by psychological symptoms involving preoccupation with body shape and weight (Table 54.2) (American Psychiatric Association, 2000). Survey studies have suggested that important clinical characteristics of bulimia nervosa may be manifested by individuals with subclinical forms of the disorder (e.g. individuals who meet all criteria except that their average frequency of binge eating is only once per week).

Bulimia nervosa has a prevalence of approximately 2–3% among adolescent girls and young women (Kendler et al., 1991), and resembles anorexia nervosa in the average age of onset (approximately 18 years) and in the ten-fold increased prevalence in girls and young women in comparison to boys and young men. Psychological and cultural factors resulting in increased preoccupation with slimness, as well as a history of obesity, are thought to play a role in the onset of bulimia nervosa (Fairburn et al., 1997). There is an increased risk of eating disorders in family members of bulimic patients (Kassett et al., 1989), and twin studies have shown heritability of approximately 55% (Kendler et al., 1991). Naturalistic follow-up studies indicate that approximately three-quarters of patients have recovered by seven years following initial assessment (Herzog et al., 1999).

Provisional criteria for 'binge eating disorder' have been included in an appendix listing in DSM-IV-TR (American Psychiatric Association, 2000). As recently reviewed, this disorder is characterized by recurrent binge eating in the absence of compensatory weight control behaviours, resulting in patients who tend to be overweight (Devlin, 1996).

Clinical assessment and therapeutic approaches

During the initial clinical assessment, it is valuable for the clinician to inquire specifically regarding eating patterns, frequency and type of purging behaviours, and body weight fluctuations. Clinical observations and laboratory studies have demonstrated that patients with bulimia nervosa have impaired postingestive satiety, possibly contributing to the large size of binge meals (Kissileff et al., 1996). Although 'objectively' large binge eating episodes are required by the diagnostic criteria (Table 54.2), some patients may describe 'subjective' binge episodes which have similar psychological characteristics but are smaller in size. A detailed psychiatric history is important to identify comorbid major psychiatric disorders, including major depression, which occurs in more than half of patients with bulimia nervosa, suicidal ideation, substance use disorders and anxiety disorders. As with ano-

rexia nervosa, review of family history and psychosocial stressors is important in planning therapeutic interventions.

The scope of the medical assessment is based on the patient's symptoms and the clinical setting. In reviewing the clinical history, the clinician should be alert to atypical symptoms suggestive of an underlying medical or neurological disorder (e.g. Kleine–Levin syndrome). The physical examination may reveal findings such as bradycardia and hypotension associated with nutritional abnormalities, or erosion of the dental enamel or parotid gland swelling associated with binge eating and purging behaviours. Based on symptom patterns, initial laboratory tests may include serum electrolytes, blood urea nitrogen levels, creatinine levels, thyroid function tests, complete blood count, urinalysis, and electrocardiogram (American Psychiatric Association Workgroup on Eating Disorders, 2000). Although abnormal results are less common than for anorexia nervosa, bulimia nervosa is associated with hypokalemia (Wolfe et al., 2001), which could contribute to life-threatening cardiac arrhythmias. Atypical behavioural symptoms or abnormal findings on neurological examination may necessitate neuroimaging studies.

Since 1990 there have been extensive studies of psychotherapeutic and psychopharmacological interventions for bulimia nervosa (Jimerson et al., 1996; Mitchell et al., 1997). For many patients, the initial intervention is a trial of short-term psychotherapy, with recent studies of cognitive–behavioural therapy or interpersonal therapy showing an approximately two-thirds decrease in frequency of binge eating. Efficacy of antidepressant medications has also been demonstrated in double-blind, controlled trials, the largest of which showed significant therapeutic response to an SSRI medication (fluoxetine). Relatively early intervention with antidepressant medications is often considered for patients who do not respond during the initial phases of psychotherapy (Agras et al., 2000), and for patients who have comorbid psychiatric disorders such as major depression. In spite of the effectiveness of current treatment approaches, only a minority of patients achieve full abstinence from binge eating and purging during short-term treatments. In planning medication treatment for an individual patient, consultation with a specialist may assist in considering choice and dose of medication, and special side effects issues in this patient group.

Neurobiology of the eating disorders

Serotonin

Hypotheses linking abnormal regulation of CNS serotonin with the eating disorders resulted from preclinical observations showing that this neurotransmitter, as well as the catecholamines, play an important role in the regulation of ingestive behaviour (Blundell, 1986; Samanin & Garattini, 1996). Activation of serotonergic pathways in the medial basal hypothalamus was shown to limit meal size by enhancing postingestive satiety (Leibowitz & Alexander, 1998). Conversely, activation of inhibitory serotonin-1A somato-dendritic autoreceptors on cell bodies in the raphe nuclei decreases hypothalamic serotonin release and enhances food intake. Serotonin-2C receptors are thought to play an important role in the satiety response, given that mutant mice deficient in serotonin-2C receptors have significantly increased food intake, with resulting obesity (Tecott et al., 1995). Studies in healthy volunteers have shown that serotonin receptor agonist drugs such as *m*-chlorophenylpiperazine (*m*CPP) decrease food intake (Brewerton et al., 1994). The indirect serotonin agonist dexfenfluramine, which was used in the treatment of obesity prior to its withdrawal from the market because of cardiac side effects, was thought to decrease food intake through facilitation of CNS serotonergic transmission.

Based on these observations, clinical investigators hypothesized that increased serotonin function could contribute to small meal size and weight loss in anorexia nervosa (Jimerson et al., 1990). Cerebrospinal fluid (CSF) concentrations of the major serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) were abnormally low in anorexia nervosa, however (Kaye et al., 1984). Responsiveness of CNS serotonin pathways, assessed by measuring the release of prolactin and cortisol following the administration of serotonin agonist drugs, was also diminished in low weight anorexic patients. As patients gained weight, CSF metabolite and neuroendocrine response measures returned towards normal, suggesting that abnormalities in the low weight patients could be a result of malnutrition (Brewerton & Jimerson, 1996; Hadigan et al., 1995; Monteleone et al., 1998; O'Dwyer et al., 1996). Studies showing elevated CSF 5-HIAA levels and abnormal test meal responses in patients who have achieved stable weight restoration suggest that anorexia nervosa may be associated with abnormalities of serotonin regulation independent of nutritional status (Kaye et al., 1991; Ward et al., 1998). There has also been considerable interest in genetic linkage studies in anorexia nervosa (Gorwood et al., 1998), with preliminary findings suggesting a possible association with an altered serotonin-2A receptor gene promoter polymorphism (Collier et al., 1997).

Diminished serotonergic responsiveness in bulimia nervosa is thought to contribute to impaired satiety and binge eating, and to the efficacy of antidepressant medications. Thus, patients with severe symptoms of bulimia

nervosa have low CSF 5-HIAA concentrations (Jimerson et al., 1992), and diminished neuroendocrine responses following single dose administration of serotonin agonist drugs (Brewerton et al., 1992; Jimerson et al., 1997; Levitan et al., 1997; Monteleone et al., 1998). Differences were observed following careful matching of controls for such clinical parameters as height-adjusted body weight, age, and menstrual cycle phase. Patients who have recovered from bulimia nervosa also demonstrate abnormal serotonin-related behavioural responses, although neuroendocrine hormone release appears to be normal (Kaye et al., 1998b; Smith et al., 1999; Wolfe et al., 2000). Recent studies have begun to explore whether recurrent dieting episodes may promote the onset of bulimia nervosa by decreasing CNS serotonin synthesis (Cowen et al., 1996).

Cholecystokinin

Normal regulation of body weight is dependent on a homeostatic balance between energy expenditure and food intake. While initial investigations of the CNS control of eating behaviour focused on the role of the monoamine neurotransmitters, studies of peripheral influences on eating behaviour revealed that the gut-related peptide CCK is involved in limiting meal size (Gibbs et al., 1973). In humans, exogenous CCK administration decreased meal size through augmentation of postingestive satiety (Kissileff et al., 1981). These effects are thought to be mediated in part through inhibition of gastric emptying, with resultant satiety-related signalling relayed to the CNS via vagal afferent pathways. Additionally, CCK released into the circulation may act at selective receptors in brain regions where the blood–brain barrier is relatively permeable to peptides (Moran et al., 1986).

It has been postulated than an increase in postingestive CCK release might contribute to small meal size in anorexia nervosa. However, CCK response to a test meal does not appear to be abnormal in patients with anorexia nervosa (Geracioti, Jr. et al., 1992; Pirke et al., 1994). Variability in responses across studies has been noted, possibly a result of differences in patient characteristics and peptide assay methodology. Other related studies in anorexia nervosa have shown normal CCK-like immunoreactivity in CSF (Gerner & Yamada, 1982), and low T-lymphocyte concentrations of cholecystokinin octapeptide (Brambilla et al., 1996).

Studies in bulimia nervosa indicate that diminished CCK responsiveness may contribute to attenuated postingestive satiety. Thus, in comparison to healthy controls, patients with bulimia nervosa have shown significantly attenuated responses in plasma CCK concentrations and in satiety ratings (Geracioti, Jr. & Liddle, 1988; Pirke et al., 1994; Devlin et al., 1997). Further studies are needed to evaluate the extent to which these changes may be a consequence of abnormal eating patterns and related changes in gastric physiology (Geliebter et al., 1992). Other findings in bulimia nervosa include decreased concentrations of CCK octapeptide in CSF (Lydiard et al., 1993) and in T-lymphocytes (Brambilla et al., 1996). Thus, current studies indicate that changes in CCK function may help to perpetuate recurrent binge eating in bulimia nervosa.

Leptin

An important new chapter in research on the regulation of food intake and body weight opened with the discovery of the adipose tissue hormone leptin (Zhang et al., 1994). Leptin acts in the CNS to decrease food intake, and in the periphery to increase energy metabolism (Friedman & Halaas, 1998; Schwartz et al., 1999; Tang-Christensen et al., 1999). Leptin administration decreases meal size in rodents (Kahler et al., 1998; Flynn et al., 1998), suggesting a role in mechanisms related to satiety. Leptin may be particularly involved in the longer-term regulation of body weight, acting as a feedback signal to the CNS conveying information related to adipose stores (Woods et al., 2000).

The effects of leptin on eating behaviour are likely to be mediated in the medial hypothalamus, where there are relatively high concentrations of the signalling, long-form of the leptin receptor. Activation of leptin receptors in the arcuate nucleus is thought to inhibit the release of the orexigenic peptide NPY in the paraventricular nucleus of the hypothalamus (Schwartz et al., 1996). On-going studies have delineated complex interactions between a number of other CNS neuropeptides, such as the melanocortins and their antagonists, in the regulation of feeding (Elmquist et al., 1999). There is also recent evidence that hypothalamic regulation of food intake may be influenced by alterations in fatty acid synthesis. Thus, inhibition of fatty acid synthase in mice through peripheral administration of C75, a synthetic derivative of cerulenin, resulted in marked weight loss which was not dependent on leptin (Loftus et al., 2000). This observation may reflect a novel mechanism for body weight homeostatis, and a possible future direction for therapeutic intervention research in obesity.

While a role for leptin deficiency has been demonstrated in animal models of obesity, the role of abnormal leptin regulation in human obesity is uncertain. In healthy volunteers and overweight individuals, there is a high correlation of leptin with body mass index or percentage body fat (Considine et al., 1996). In general, obese patients do not have decreased leptin levels, so it has been proposed that obesity may involve postreceptor forms of leptin resis-

tance. Preliminary clinical trials in obese patients have shown a modest effect of leptin in decreasing body weight (Heymsfield et al., 1999).

In anorexia nervosa, leptin levels are markedly reduced and increase to normal levels following weight restoration (Hebebrand et al., 1995; Grinspoon et al., 1996; Mantzoros et al., 1997; Eckert et al., 1998). A disproportionate rise in leptin levels during treatment could contribute to the commonly observed resistance to weight restoration (Mantzoros et al., 1997). Leptin may play a role in some of the neuroendocrine alterations (e.g. decreased gonadal hormones and decreased thyroid hormone levels) observed in low weight anorexic patients (Flier, 1998).

In comparison to controls matched for age, gender and body weight, patients with bulimia nervosa have significantly decreased leptin levels (Brewerton et al., 2000; Jimerson et al., 2000; Monteleone et al., 2000). Moreover, there appears to be a persistent decrease in leptin levels in patients who have achieved stable remission from bulimia nervosa, suggesting a trait-related characteristic (Jimerson et al., 2000). Follow-up studies are needed to assess whether diminished leptin function contributes to impaired satiety, decreased thyroid hormone levels, and decreased resting metabolic rate in this disorder (Obarzanek et al., 1991), possibly reflecting a biological risk factor for the onset of bulimia nervosa.

Sleep and its disorders

Robert Y. Moore, and Eric A. Nofzinger

Departments of Neurology, Psychiatry and Neuroscience, University of Pittsburgh, PA 15213, USA

Sleep is a necessary behaviour

Our lives are dominated by daily cycles of sleep and wake. The origin of these cycles begins with the earliest life on this planet. Life requires energy and the only available source of energy for the earliest life was the sun. Because of the cyclic availability of solar energy, prokaryotes evolved adaptations to use energy during the solar day, and to carry out other functions at night. With the evolution of nervous systems in primitive animals, this pattern of adaptation was maintained as rest–activity cycles. Recent studies indicate that, even in an invertebrate such as the fruit fly, *Drosophila*, the rest–activity cycles bear a striking resemblance to sleep–wake cycles in mammals. Sleep has long been recognized to have a restorative function and sleep is required to maintain life. Total deprivation of sleep results in death and even relatively brief periods of sleep deprivation, when repeated over several days, produce profound decrements in vigilance, psychomotor performance and mood. One of the commonest, transient forms of sleep disruption, that occurring with jet lag, can produce cognitive impairment and structural brain changes when it is chronic. Thus, sleep is necessary for life and successful adaptive, waking behaviour.

Sleep disorders are common and important

Loss of sleep is a major problem in our industrialized society, with an immense impact on health and productivity. This occurs as a conseqeunce of economic pressures and the pace of modern life but also results from environmental constraints that alter the normal pattern of the rest–activity cycle; shift work is an important example. Further, common medical and psychiatric illnesses impair sleep resulting in insomnia and chronic sleep deprivation. Finally, we now recognize that there are many primary sleep disorders that have a significant impact on health and normal function. In this chapter, we will review the neurobiology of sleep and important sleep disorders.

Neurobiology of sleep

Behaviour is divided into three states, waking, REM sleep and non-REM (NREM) sleep

With the development of electroencephalography (EEG) in the first half of the twentieth centry, it became possible to record brain activity continuously and to correlate the activity obtained from surface scalp electrodes with behavioural state. With this it was quickly recognized that the waking state is associated with desynchronized, low voltage EEG dominated by high frequency activity, predominantly in the 8–12 Hz range. As sleep supervenes, the EEG activity increases in voltage but decreases in frequency progressively over time with increasing synchrony until, with deep sleep, the very high voltage, slow activity of non-REM (NREM), or slow wave, sleep is evident. In a normal, young individual, sleep is initiated with a gradual slowing of EEG activity accompanied by a loss of responsiveness. Sleep is initiated with NREM sleep which is typically described to have four stages, designated stages 1–4, which are characterized by increasing unresponsiveness and slowing of the EEG. After 60–75 minutes of NREM sleep, REM sleep, a state characterized by an activated EEG, irregular, rapid eye movements (REM), muscular atonia, and unresponsiveness to sensory stimuli replaces it (Fig. 55.1). Work by several investigators, particularly Nathaniel Kleitman and his associates, demonstrated that the activated EEG of REM sleep is essentially equivalent to that of waking and that dreaming is the behavioural concomitant of the activated cortex of REM sleep.

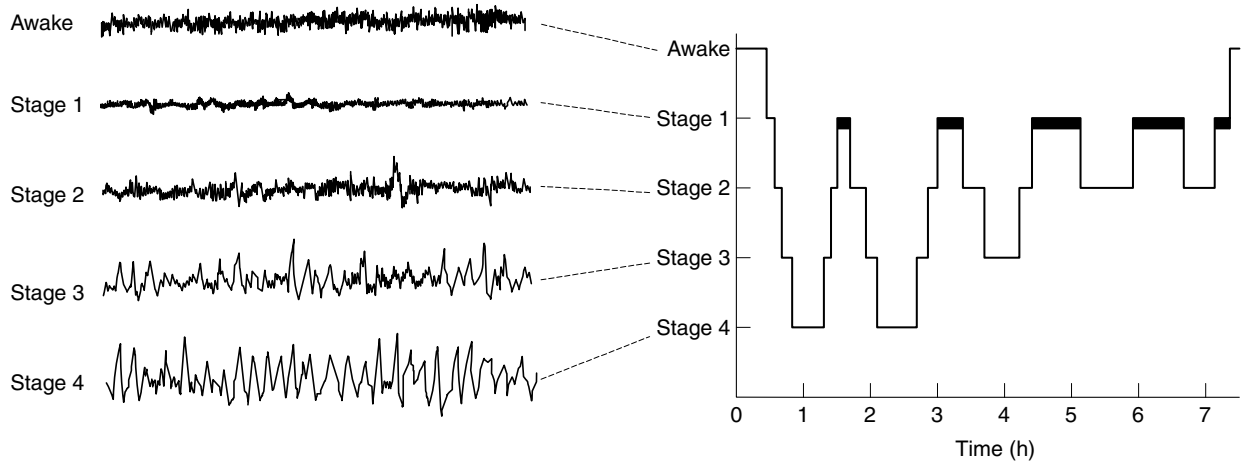

Fig. 55.1. NREM sleep stages and distribution of NREM and REM sleep through a single night. The EEG patterns of the stages (stages 1–4) of NREM sleep are shown on the left. On the right is the transition from NREM to REM sleep over the course of the sleep period. REM sleep epochs are designated by the dark bars above NREM stage 1 (▬).

Waking is an active state with behavioural adaptation

The waking state is associated with a conscious perception of environmental events and ongoing integrative activities of learning, problem solving, cognition and emotion and a motor output which includes speech, writing and a panoply of simple and complex motor acts. The essential feature of human adaptive waking behaviour is its complexity. It was assumed early in the twentieth century that waking was maintained by sensory information transmitted through the well-known lemniscal sensory pathways. This view was revised in the late 1940s when Giuseppi Moruzzi and Horace Magoun showed that the rostral brainstem reticular formation is critical to maintaining the waking state. Animals with lesions destroying the midbrain reticular formation, but preserving lemniscal sensory pathways, particularly visual and olfactory input, remained in a constant, unresponsive state with a high voltage, low frequency EEG. The same state is observed in humans with similar lesions. These observations led to the concept of an 'ascending reticular activating system', which has been extended and amplified over the last 50 years. The components of this system and the pathways through which it activates the cerebral cortex are shown in Fig. 55.2. Activity in the reticular activating system is driven, at least in part, by sensory input from all primary modalities. The reticular activating system provides input to activating-arousal systems in brainstem (locus ceruleus, midbrain raphe nuclei, pontine cholinergic nuclei), hypothalamus (posterior and lateral hypothalamus), thalamus and basal forebrain. These systems provide input to the cerebral cortex to maintain it in an activated state which permits the elaboration of the varieties of adaptive, and sometimes maladaptive, behaviours that characterize the waking state. The contribution of each of these systems to arousal and the waking state is different, and not yet thoroughly understood. Recent work, which will be described in greater detail in a discussion of narcolepsy, has emphasized the role of the hypothalamus. This was first appreciated by Constantine von Economo in the pathology of encephalitis lethargica and demonstrated experimentally by Walle Nauta who showed prolonged and profound deficits in arousal in animals with posterior hypothalamic lesions. The important role of the hypothalamus in sleep–wake regulation was neglected for many years but is now more fully appreciated. The hypothalamus contains both arousal/wake-promoting areas and sleep-promoting areas (for review, see Jones, 2000). Lesions involving the anterior hypothalamus result in diminished arousal. Recent work has shown a small group of ventrolateral preoptic neurons that are activated during NREM sleep and, as we will see in sections to follow, the posterior hypothalamus contains several areas which appear to function in waking and arousal.

In the 1960s, the noradrenaline neurons of the locus ceruleus and the serotonin neurons of the midbrain raphe were shown to project widely over the forebrain, including to the entire cerebral cortex, a pattern of projection that indicates a role in behavioural state regulation. Neurons of the locus ceruleus fire continuously during waking. They respond particulary to stimuli that produce behavioural vigilance and may have a special function in producing the heightened capacity for adaptive behaviour that accompanies

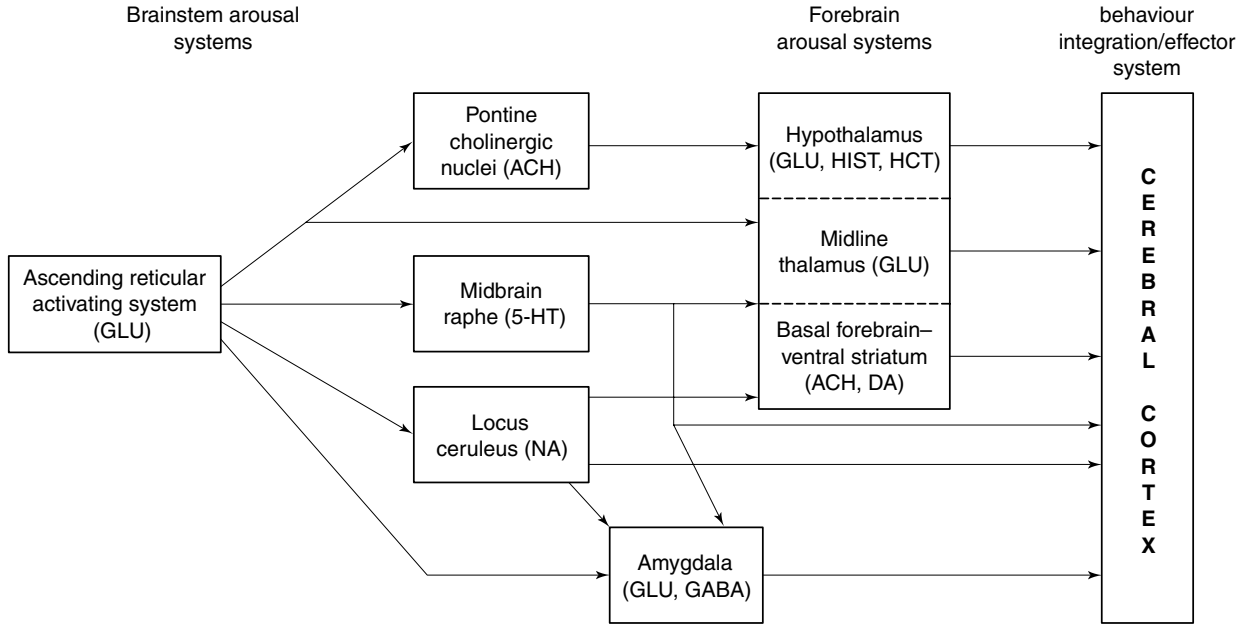

Fig. 55.2. Arousal systems in the human brain (see text for description). The transmitters associated with each system are abbreviated: ACH, acetylcholine; DA, dopamine; GABA, gamma aminobutyric acid; GLU, glutamate; HIST, histamine; HYP, hypocretin; NA, noradrenaline; 5HT, serotonin.

vigilance. During NREM sleep, the firing of locus ceruleus neurons diminishes compared to waking and they cease firing in REM sleep. The firing of midbrain raphe neurons projecting to forebrain has a similar pattern except that they typically do not respond to sensory input. Both of these systems, the noradrenaline neurons of the locus ceruleus and the serotonin neurons of the midbrain raphe nuclei, have widespread projections to diencephalon, basal forebrain and cerebral cortex. The action of norepinephrine and serotonin at synapses is predominantly modulatory and its seems likely that the action of these systems is to alter the responsiveness of forebrain neurons to other inputs and to contribute to induction of arousal and the maintenance of the waking state in this manner. In contrast, the cholinergic input from basal forebrain and the glutamatergic inputs from thalamus and hypothalamus play a more direct role in arousal and maintaining the waking state.

Sleep–wake regulation requires circadian and homeostatic factors

Circadian timing is crucial to sleep–wake regulation

The solar cycle of light and dark is the most pervasive, cyclic stimulus in the environment. Animals have evolved rest–activity cycles, sleep–wake cycles in higher vertebrates, to maximize adaptation to their environment. These cycles have two predominant features: (i) in a normal solar cycle, they are exactly 24 hours in length and exhibit a precise phase relationship to the solar cycle, a phenomenon termed 'entrainment'; (ii) in the absence of a light–dark cycle, they are maintained by endogenous timing mechanisms, or clocks. These features predict the fundamental organization of a circadian timing system, a set of related neural structures which functions to provide a precise temporal organization of physiological processes and behaviour. The circadian timing system has three components: (i) photoreceptors that transduce photic information into neural information that is conveyed to circadian pacemakers by entrainment pathways; (ii) pacemakers which receive entrainment information and contain genetically determined molecular timing mechanisms that generate a cellular circadian output; (iii) efferent pathways from the pacemakers to effector systems that are under circadian control. The components of the circadian timing system are shown in Fig. 55.3. Photic information appears to be transduced by a unique set of photoreceptors which appear to be neither rods nor cones. These photoreceptors are connected by as yet unknown retinal elements to a subset of retinal ganglion cells distributed over the entire retina that project only to the circadian timing system through the retinohypotha-

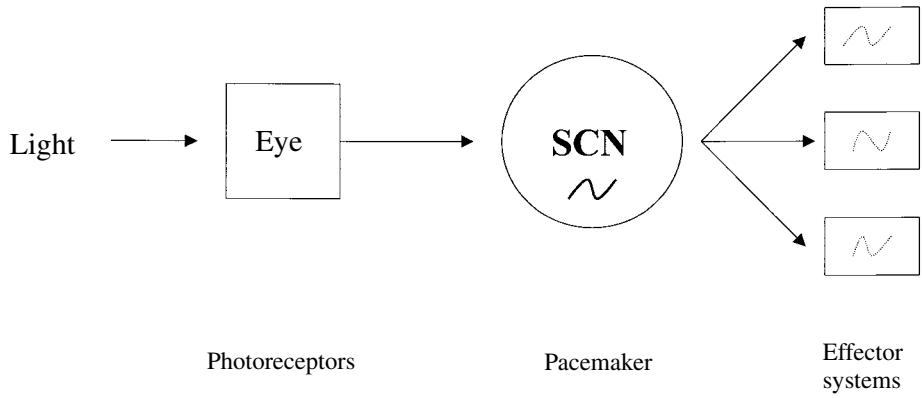

Fig. 55.3. Components of the circadian timing system. See text for description.

lamic tract. Destruction of the retinohypothalamic tract eliminates circadian rhythm entrainment without affecting other aspects of visual function, providing the basis for a disorder of entrainment as a specific sleep disorder (see below).

The circadian pacemaker in mammals that controls most circadian rhythms, particularly the sleep–wake rhythm, is the suprachiasmatic nucleus (SCN) of the hypothalamus. Lesions of the SCN eliminate most circadian rhythms, including the rhythm in sleep–wake behaviour. Neurons of the SCN exhibit a circadian rhythm in firing rate, both in vivo and in vitro and transplantation of fetal SCN into the brains of animals rendered arrhythmic by SCN lesions restores circadian control of sleep–wake behaviour. The output of the SCN is predominantly to hypothalamus and different pathways provide circadian control of separate functions. For example, SCN projections to paraventricular hypothalamic nucleus neurons which, in turn, project to the upper thoracic intermediolateral cell column provide circadian control of melatonin secretion through superior cervical ganglion sympathetic innervation of the pineal gland. Similarly, a separate set of SCN projections to parvocellular corticotropin releasing hormone (CRH) neurons of the paraventricular hypothalamic nucleus controls the production and secretion of CRH at the median eminence with downstream control of pituitary corticotropins and cortisol producing cells of the adrenal cortex. Until recently, the pathways involved in sleep–wake regulation were not well understood. It now seems clear that SCN projections to neuron groups in the posterior and lateral hypothalamus promoting arousal and wakefulness (Fig. 55.2) mediate this function. The function of the SCN in controlling the sleep–wake cycle is one of maintaining arousal against homeostatic drive for sleep. Thus, the circadian system, particularly the SCN, could be viewed as the component of the hypothalamic arousal/waking system depicted in Fig. 55.2.

Homeostatic drive for sleep interacts with circadian control of waking

It is apparent to all humans that a need for sleep, termed homeostatic drive, increases as a function of the waking time since the last period of sleep. Early in the study of sleep control, it was assumed that this was the principal mechanism controlling sleep onset and duration. The role of the circadian system was first recognized to interact with homeostatic mechanisms in a systematic way by Alexander Borbély and Sergei Daan and their associates (Borbély et al., 1989). The homeostatic mechanisms can be conceptualized as a simple, time-dependent accumulation of a sleep-promoting substance, S, which continues to accumulate until it is dissipated by sleep. The extent to which S is lost is a function of the duration of the sleep period.

The nature of S, of whether it is a simple mechanism or multiple factors, is not known. For many years, there have been proposals that the homeostatic propensity for sleep reflects the build-up of sleep-promoting substances in brain. A number of studies have implicated a variety of neuroactive peptides and cytokines as sleep promoting. Perhaps the most intriguing molecule is adenosine. The effects of caffeine and related adenosine-receptor blockers are well known. Adenosine has been shown to accumulate in brain with sleep deprivation, including in areas important for the maintenance of arousal, further supporting this compound as a sleep-promoting substance.

NREM sleep facilitates adaptive, waking behaviour

NREM, or slow wave, sleep is a behavioural state characterized by a lack of response to environmental stimuli, minimal movements and a reduction of brain activity. The

majority of total sleep time, which averages 7.5–8.5 hours a day in normal young adults, is spent in NREM sleep. Sleep is typically consolidated with approximately 95% of the night spent asleep in normal young individuals. NREM sleep occupies 75 to 80% and REM 20 to 25% of the total sleep period. NREM and REM sleep alternate in approximately 90-minute epochs with NREM periods becoming shorter and REM periods longer over the night. The proportion of total sleep time in NREM sleep gradually increases over the lifespan as REM sleep diminishes and aging is typically associated with less stage 3 and 4 NREM sleep and more sleep interruptions. Although dreaming is associated primarily with REM sleep, it is well established that dreams can occur in NREM sleep. In general, dreams in NREM sleep are much less frequent, briefer and less complex than those occurring with REM sleep. Although there continues to be speculation about the function of REM sleep (see below), it is generally accepted that NREM sleep has a restorative function that promotes successful adaptive waking behaviour. This includes both a permissive role in restoring a variety of somatic functions and one in restoring brain function. There is substantial support for a hypothesis that NREM sleep works to restore effective brain energy metabolism. Recent data indicate that memory consolidation is an important concomitant of NREM sleep.

Brain activity is reduced in NREM sleep

Consonant with the view that NREM sleep is restorative, the onset of NREM sleep is heralded by increased voltage, slow activity that reflects a synchronous discharge of populations of thalamocortical neurons. And, with positron emission tomography (PET), global cerebral blood flow (CBF) and glucose utilization are shown to be reduced indicating a decrease in information processing as that is reflected in the energy requirements of synaptic activity. CBF decreases by approximately 25% in stages 3–4 NREM sleep in comparison to waking. With analysis of regional blood flow (rCBF), decreases are found in cerebellum, brainstem, thalamus, basal ganglia, basal forebrain and over much of the cortex with only primary sensory areas maintaining waking levels of rCBF (Braun et al., 1997). Extensive electrophysiological analysis since 1985, particularly by Mircea Steriade and David McCormick and their collaborators (for review, see McCormick & Bal, 1997), has shown that NREM sleep represents an interaction between the neurons of thalamic relay nuclei which each project to cerebral cortex with collaterals to thalamic reticular nucleus, cortical neurons projecting to thalamic reticular nucleus and thalamic relay nuclei and the inhibitory projections of thalamic reticular nucleus to relay nuclei. With the sleep-promoting effects of the sleep homeostatic control mechanisms, there is a gradual hyperpolarization of the components of the thalamocortical system that results in synchronous firing with consequent EEG changes of sleep spindle formation and slow waves which result in the NREM state.

REM sleep reflects an activated forebrain

The typical pattern of sleep is onset with NREM sleep followed by REM sleep in epochs of 90–100 minutes. Through the night the NREM component decreases while the REM component increases and awakening typically occurs from REM sleep. In REM sleep, individuals are unresponsive but the EEG is essentially indistinguishable from waking with low voltage, desynchronized activity. REM sleep is also associated with muscular hypotonia and with saccadic eye movements, the 'REM' of REM sleep. The behaviour of REM sleep is dreaming. When individuals are awakened from REM sleep, approximately 80% report having a dream. There is an extensive literature, beginning particularly with the Freudian psychoanalytic era in psychiatry, reporting analysis of the content of dreams. More recently, attempts have been made to provide a formal, scientific analysis of dream content (for review see Hobson et al., 1998). The content of dreams typically includes visual and motor material which, since sensory input and motor output are inhibited in REM, represent hallucinations. Dream imagery is often bizarre and it is typical to have abrupt transitions in content. There is increased and intensified emotion associated with dream content, particularly fear–anxiety. Dream content proceeds without volitional control. This changing, vivid material of dreams is consonant with an activated cerebral cortex, as is indicated by the nature of REM sleep EEG activity and the fact that glucose utilization in the cortex in REM sleep is equivalent to that in waking. It seems likely that dream content reflects an activated state, and the fact that the cortex is isolated from sensory input and motor output. The other constant feature of dreams is that they are forgotten, lost to conscious recall, unless the individual awakens from a dream and immediately recounts the dream content in the waking state. Since dreams appear to represent a process of cortical activation superimposed on the relatively quiescent state of NREM sleep, the content of the dream can only reflect an ensemble activity of cortical neuronal populations. The mental content of that activity, in turn, must be founded in the experience of that individual and the specific patterns of brain activation occurring in the REM state.

Recent PET studies have provided new insight into the neurobiology of REM sleep. Although there are some small differences among the studies, all show that REM sleep, in comparison to waking, is associated with increased activity in the pons and midbrain, the basal ganglia, hypothalamus and a set of limbic–paralimbic structures including the anterior cingulate and subgenual cortex, orbitofrontal cortex, parahippocampal cortex, and amygdala either as increased cerebral blood flow or as increased glucose utilization. This pattern of increased regional activity in REM is strikingly different from the regional pattern in waking, and that in NREM sleep.

The mechanisms that initiate the onset of REM sleep are unknown, but also probably reflect a combination of homeostatic and circadian factors. The onset of REM sleep occurs with the coincidence of two sets of events, firing from a group of cholinergic REM-on neurons in the pontine reticular formation and diminished firing of the aminergic neurons of the locus ceruleus and raphe nuclei. The firing of the pontine cholinergic neurons generates the forebrain activation of REM sleep and this appears to occur as a consequence of the removal of a tonic inhibition of these neurons by the locus and raphe.

Sleep disorders

Disturbances of sleep are among the most frequent complaints brought to physicians. Sleep disorders are both common and have an extensive morbidity, interfering with performance on the job and in social and family interactions and leading to accidents at work and while driving. And sleep disorders exacerbate medical and psychiatric illnesses. Patients with sleep disorders typically complain of one or more of three types of problems, insomnia, excessive daytime sleepiness or abnormal movements, sensations and behaviours during sleep or at nocturnal awakenings. The approach to these complaints requires a detailed history, physical and neurological examination including an assessment of mental status and the appropriate laboratory tests. Sleep disorders medicine has evolved into a subspeciality with a board examination. There is an International Classification of Sleep Disorders: Diagnostic and Coding Manual (1997) which has four categories of disorders: (i) dyssomnias, disorders of initiating and maintaining sleep and disorders of excessive daytime sleepiness; (ii) parasomnias, disorders which do not present with insomnia or excessive daytime sleepiness; (iii) disorders associated with medical or psychiatric illnesses; (iv) proposed sleep disorders, ones for which there is insufficient current evidence to definitively establish them as sleep disorders. Major examples of the first three categories will be presented below.

Dyssomnias

Sleep apnea syndrome

Sleep apnea syndrome refers to episodes of transient cessation of breathing during sleep ($\geqslant$10 seconds) that disrupt sleep and thereby lead to excessive daytime sleepiness. In most cases, this is related to occlusion of the pharyngeal airway and is referred to as an obstructive sleep apnea syndrome. In other cases, there is reduced ventilatory effort during sleep in the absence of any discrete airway obstruction, and this is referred to as a central sleep apnea syndrome. A third condition, the upper airway resistance syndrome (UARS), consists of increased respiratory effort in the absence of discrete apneic events. This increased effort leads to non-restorative sleep which, in turn, produces daytime sleepiness.

These syndromes occur most commonly in obese, aging men but are not restricted to these Pickwickian types. Epidemiological studies suggest that roughly 4% of men and 2% of women ages 30 to 60 will meet minimal diagnostic criteria for obstructive sleep apnea syndrome. The most common clinical symptoms reported are daytime sleepiness in the presence of sleep-related snoring with occasional pauses in breathing or 'gasping' for breath during sleep. Other daytime symptoms include fatigue, morning headaches, and cognitive changes such as reduced concentration and attention. The sleepiness of sleep apnea is differentiated from the sleepiness of narcolepsy by the constant, unrelenting nature of the sleepiness, whereas, in narcolepsy, the sleepiness is qualitatively more sudden in onset and offset. The constant sleepiness and fatigue need to be differentiated from similar sleep symptoms in psychiatric patients by the concurrent changes in mood or personality found in psychiatric disorders that are not found in the isolated apneic patient.

The pathophysiology of obstructive sleep apnea syndrome is related to the anatomic factors that maintain airway patency during sleep. The site of airway obstruction in obstructive sleep apnea syndrome is in the pharynx. Whether this airway will close during sleep reflects the balance between forces that narrow the airway, such as intrapharyngeal suction during inspiration, and forces that dilate the airway, such as the tone of pharyngeal airway muscles. Anatomical abnormalities found in apneic patients in this area include the manifestations of obesity, enlarged tonsils, and facial bony abnormalities. Additionally, sleep itself is associated with a loss of tone in

pharyngeal muscles that maintain the outward pressure necessary for airway patency. Alcohol may contribute to symptoms by acting as an extrinsic suppressant of pharyngeal muscle tone that exacerbates apnea by reducing the outward pressure on the pharyngeal airway.

Central sleep apnea syndrome refers to the periodic loss of ventilatory effort with associated cessation of breathing during sleep. This is differentiated from obstructive type apneas in which there is a loss of breathing despite persistent attempts at ventilation. These patients constitute less than 10% of apneic patients. The pathogenesis of central sleep apnea is likely to be diverse, given the broad conditions that produce this type of breathing during sleep such as central alveolar hypoventilation, congestive heart failure, nasal obstruction and dysautonomias. In general, a final common pathway appears to be some disturbance in the respiratory control system that includes sensors for hypoxia and hypercapnia and brainstem and forebrain centres that influence respiratory function in response to metabolic and behavioural demands. Clinically, patients with alveolar hypoventilation present with signs of respiratory failure, whereas non-hypercapnic patients may present with insomnia, normal body habitus and awakenings with gasping for breath. Diagnosis is definitively made in the research setting by the use of an esophageal balloon. Treatment for the hypercapnic patient with hypoventilation during waking requires ventilation at night using a nasal mask and a pressure-cycled ventilator. For the non-hypercapnic patient, treatment consists of correcting the underlying problem (e.g. nasal obstruction, congestive heart failure) or watchful waiting as approximately 20% may resolve spontaneously. Nasal CPAP can be tried if the patient is obese, snores and has heart failure. Oxygen administration may be helpful if the apneic events are associated with hypoxemia. If symptoms are persistent, a carbonic anhydrase inhibitor can be useful.

Primary insomnia

Insomnia is the experience of inadequate or poor quality of sleep and is characterized by one or more of the following: difficulty falling asleep, difficulty maintaining sleep and/or awakening earlier than one would prefer. Additionally, patients have daytime dysfunction that may include fatigue, altered mood and difficulty with cognitive functions that require attention and concentration. Roughly 10% of the adult population suffers from chronic insomnia and 30 to 50% will experience transient insomnia at some point in their life. Females appear to be more affected across the lifespan and the elderly are particularly vulnerable. Consequences of insomnia may include poor daytime performance, an increased likelihood of subsequent development of a mental disorder such as depression or anxiety, and increased medical morbidity and mortality. Insomnias may be classified as either short term (transient) or long term (chronic) and as either primary or secondary to another general medical or mental disorder.

Transient insomnias occur in otherwise healthy individuals and are usually related to sleeping in an unfamiliar environment, an environment that is temporarily disrupted by noises, sounds or temperature changes, a recent life stressor, a change in the timing of bedtime related to travel across time zones or shift work, or to acute administration or withdrawal of a medication that affects the sleep/wake cycle. In each case, identification of the etiology is important. Short-term (1 to 4 weeks) sedative hypnotic use may be indicated. Care should be taken to taper and discontinue this medication following resolution of the acute event to avoid the development of psychological or physiological dependence on the hypnotic.

Chronic primary insomnias are by definition primary and not secondary to other medical or mental disorders. Other terms that have been used to define this population include pyschophysiological insomnia, sleep state misperception and idiopathic insomnia. The term psychophysiological insomnia stems from a literature which suggests that insomnia patients suffer from psychophysiological 'hyperarousal'. A vicious cycle of precipitating event, increased arousal, difficulty sleeping, preoccupation with inability to sleep leading to even more arousal and inability to sleep defines the pathophysiology of these patients. The neurobiology of the concept of 'hyperarousal' however, remains poorly defined. In part, the presence of an excessive amount of high frequency EEG activity within the sleep period is used in support of the concept of hyperarousal. Sleep state misperception refers to the subjective perception of being awake throughout the night, despite the presence of polysomnographically determined sleep. In general, primary insomnia patients tend to underestimate the actual amount of sleep they are getting in a night. These observations raise the likelihood that the sleep that insomniac patients experience may not represent the restorative sleep that non-insomniac patients receive each night. The presence of high frequency EEG activity within polysomnographically determined sleep may represent a less differentiated behavioural state that includes components of both sleep and wakefulness in the same individual. Treatment of insomnia is multifaceted and includes behavioural and pharmacological approaches. Historically, there should be no evidence that the insomnia is secondary, and if so, the underlying disorder should be evaluated and treated. Several behavioural strategies are available. Relaxation techniques include progressive

muscle relaxation, EMG biofeedback, meditation, and guided imagery. Stimulus control therapy follows from a learning model of insomnia. In this model, insomniacs develop negative associations to the bedroom, and the sleeping environment that when exposed to, produce increased arousal and subsequent insomnia. Stimulus control instructions include: 'lie down only when you feel sleepy', 'use the bed and bedroom for sleep and sex only', and 'get out of bed and go to another room if you are not sleeping'. Along with these instructions include prescriptions to maintain the same clock times for going to bed and getting out of bed the next day as well as to avoid daytime napping, irrespective of how much sleep had been obtained on the preceding night. Sleep restriction therapy refers to restricting the amount of time in bed to the time that a person believes he/she is actually sleeping. For example, a schedule for someone who believes he/she is sleeping for 6 hours might be set for midnight to 6 am; for 4 hours from 1 am to 5 am; or for 8 hours from 10 pm to 6 am. These individuals should also be instructed to avoid daytime napping. This counters the natural tendency of insomniac patients to nap or prolong their times in bed in an effort to obtain more sleep. This is often counterproductive as it lightens the sleep that they do get, increasing the likelihood of middle of the night and early morning awakenings. Cognitive therapy for insomnia includes questioning erroneous beliefs that an insomniac patient may have regarding the catastrophic consequences of insomnia and beliefs regarding the inadequacy of sleep that they are having.

Narcolepsy

Narcolepsy is a sleep disorder, recognized as a distinct entity for more than a century, characterized by excessive daytime sleepiness and the intrusion of REM sleep phenomena, particularly cataplexy (muscle atonia induced by emotion-provoking stimuli), into waking. Individuals with narcolepsy may fall asleep at any time during the day, often very abruptly. These uncontrollable episodes of daytime sleeping are the necessary and predominant manifestation of narcolepsy in most affected individuals and this symptom, particularly when associated with cataplexy, produces severe impairment of function in social interactions and work performance and a very diminished quality of life. Despite the occurrence of daytime sleep episodes, total daily sleep time is unaltered because night sleep is reduced proportionately to that occurring during the day. The diagnosis of narcolepsy is often difficult because there are many causes of excessive daytime sleepiness, and this problem is accentuated because a lack of understanding of the pathophysiology of the disease has prevented development of a simple and reliable diagnostic test. It appears, however, that this situation will change in the near future. A series of recent studies indicates that narcolepsy will be a model for the application of molecular genetics and molecular biology to the understanding of disease.

Unfolding the basis for narcolepsy began in 1998 with the discovery of a new gene, expressed in the hypothalamus, that codes for new peptides termed hypocretins, or orexins. The term 'orexin' appears inappropriate as it was applied with the view that the peptides function primarily in the control of feeding and this clearly is not the case. 'Hypocretin' was applied to signify that the gene is expressed in the hypothalamus and that the peptide product belongs to the secretin family of peptides. Following discovery of the hypocretin gene, and characterization of the peptide, immunohistochemical studies showed that hypocretin neurons are located exclusively in the posterior and lateral hypothalamus with axonal projections distributed widely over the neuraxis, particularly to areas involved in arousal and to the entire neocortex in rodents and the human. Transgenic mice with deletion of the hypocretin gene exhibit a behavioural phenotype consistent with narcolepsy, and a well-characterized canine model of narcolepsy was found to carry a mutation in the gene for a hypocretin receptor. Analysis of CSF from narcoleptic patients demonstrated a marked reduction in hypocretin content in comparison to controls. Finally, immunohistochemical analysis of narcoleptic brains shows a striking loss of hypocretin neurons and their axonal plexuses in the hypothalamus. Thus, in less than 2 years we progressed from almost no understanding of the pathophysiology of narcolepsy to a detailed account of a very selective neuropathology. The principal issues remaining are to determine the basis for the hypocretin neuron pathology and how this results in the manifestations of the disease. Although there are instances of familial cases, narcolepsy is predominantly a sporadic disease. Until the recent work on the hypocretin neuron pathology, the only known biological association was the finding that over 90% of narcoleptics have the histocompatibility marker HLA-DQB1 0602. This suggests that the hypocretin neuron pathology may occur on an autoimmune basis; that is, the fundamental basis of the pathophysiology is a genetically determined immune system status that results in a predilection to autoimmune responses in which individuals produce antibodies against hypocretin. This is an attractive hypothesis but it remains to be established.

There are two independent clusters of symptoms that may require treatment in narcoleptic patients. The first is daytime sleepiness. Given the severity of the sleepiness, it

would be unusual for behavioural interventions to be completely effective. Some patients find that adding periodic, brief daytime naps reduces some of the sleep attacks. Allowing for adequate sleep at night is advised, and occasionally, these patients will demonstrate insomnia, or nightmares, that require the use of a sedative hypnotic medication. The primary treatment for sleepiness, however, consists of the use of either a stimulant medication or a medication that promotes wakefulness. The commonly used stimulants include methylphenidate, dextroamphetamine, and pemoline, in descending order of stimulant potency. Short-acting preparations last around 4 hours and longer-acting preparations extend this effect a few hours. Consequently, these medications are often prescribed at least at morning and around lunchtime. Occasionally, a patient may need a late afternoon dose if he/she anticipates being involved in activities during the evening that require full attention. Often, the development of tolerance to low doses forces escalation to effective levels. Side effects such as nervousness, affective symptoms and nocturnal insomnia require monitoring. An alternate medication is modafinil. This medication often reduces daytime sleep and benefits most patients. Some patients, however, do not obtain full relief of their sleepiness with modafinil and require addition of a stimulant. Modafinil is an interesting addition to the treatment of narcolepsy in that it does not appear to act via the dopamine systems, has very limited potential for abuse and does not appear to induce tolerance.

The second cluster of symptoms that require treatment includes cataplexy, hypnagogic hallucinations and sleep onset paralysis. Of these, the cataplexy is the most significant symptom clinically, as it is associated with considerable limitation in psychosocial function and potential danger to the individual as a result of personal injury from falls. These symptoms are generally effectively managed with the use of antidepressant agents such as clomipramine, the selective serotonin reuptake inhibitors, or venlafaxine. Dosages that relieve cataplexy are generally lower than those used to treat depression. Tolerance to these agents can develop which may require switching to an alternative agent.

Disorders of circadian function

The function of the CTS is to provide a temporal organization of physiological processes and behaviour to promote effective adaptation to the environment. At the behavioural level, this is expressed in regular cycles of sleep and waking and disorders of circadian function are typically characterized by disturbances of sleep and waking and by other behavioural symptoms that reflect both the sleep disturbances and alterations of circadian regulation of waking adaptive behaviour. From the organization of the CTS, we would expect three types of circadian disorder: abnormalities of entrainment, pacemaker function and pacemaker coupling to effector systems (for recent review, see Moore, 1998).

Disorders of entrainment

Blindness (non-24 hour sleep–wake syndrome)

Congenital and acquired blindness provide instances of pure disorders of entrainment. Individuals who are blind typically attempt to adapt their behaviour to that of their community. For a number of years it was believed that the blind accomplished this by entraining their circadian system to the social cues of the environment, but it now appears that many are not able to do so. Blind subjects fall into two categories. The first is composed of individuals with a free-running melatonin rhythm indicating that they were not entrained to the environmental light–dark cycle. These individuals typically maintain 24-hour sleep–wake cycles, however, and when their melatonin rhythm peaks during sleep, they report sleeping well and feeling well. When their melatonin and sleep periods are out of phase, they experience sleep disturbances and other symptoms indicative of disturbed circadian regulation. The second blind group has entrained melatonin rhythms and sleep–wake cycles and reports no symptoms of sleep disturbance or those related to circadian disruption. Some of these individuals show a normal suppression of peak melatonin levels by light even though they are totally blind. The nocturnal suppression of peak melatonin levels is a function of the retinohypothalamic projections so that we must conclude that, in these individuals, the retinal phototransduction mechanisms are intact through those pathways even though all other retinal mechanisms are non-functional. The mirror image of this is individuals who are not blind but exhibit the free-running rhythms and symptoms of the non-24-hour sleep–wake syndrome. Although this remains to be established, we would presume that these individuals lack the specific circadian phototransduction process. There are also blind individuals who are normally entrained but lack light suppression of melatonin. It is assumed that these individuals employ a non-photic entrainment process.

Rapid time zone change syndrome (jet lag)

The jet lag syndrome is a disorder of modern life. Symptoms of rapid time zone change occur in some indi-

viduals with changes of as little as 3 hours but at least a 5-hour change is required for most. The typical symptoms of jet lag include sleep disruption, fatigue, difficulty concentrating, gastrointestinal distress, impaired psychomotor coordination, reduced cognitive skills and alterations of mood. The symptoms remit spontaneously over days with their duration determined by the direction of travel, west to east produces more impairment than east to west, and the number of time zones crossed. Numerous measures have been reported to ameliorate jet lag but the evidence is usually anecdotal. Recent studies done with a placebo control indicate that melatonin is an effective treatment, presumably by acting on the SCN pacemaker. An interesting recent study has reported both cognitive changes and temporal lobe atrophy in individuals with chronic jet lag (Cho, 2001).

Work shift syndrome

Many workers in industrialized countries perform their occupation at unusual hours. This is particularly true of health care workers, police and security guards, truck drivers and some workers in heavy industry. The factors involved in adjusting to shift work are complex and disruption of circadian mechanisms is only one of those involved. The major symptom of work shift disorder is impaired sleep and attendant impairment of function. There have been recent descriptions of the use of bright light and melatonin to treat the circadian abnormalities associated with shift work.

Delayed sleep phase syndrome

This is a syndrome characterized by a persistent inability to fall asleep and arise at conventional clock times. This reflects a delay in the phase of the sleep–wake cycle. Sleep onset is usually delayed to early morning hours with a consequent delay in arising. If individuals attempt to go to bed earlier, they are unable to go to sleep until their usual time and, if they attempt to maintain a normal schedule, they suffer insomnia and daytime fatigue. This syndrome has customarily been viewed as a consequence of choice, or lifestyle, so-called 'night' people. It often begins in the teenage years which, with the other behavioural manifestations of this difficult period, has tended to reinforce this view. While the symptoms clearly represent lifestyle in some individuals, it is also clearly a disorder of entrainment in others in which there appears to be an alteration of normal pacemaker sensitivity to entraining stimuli.

Advanced sleep phase syndrome

This is the mirror image of the delayed sleep phase syndrome. Individuals with the advanced sleep phase syndrome have persistent early onset of sleep, usually around 7–9 pm with a consequent awakening at 3–5 am. Attempts to delay sleep onset are usually met with failure and complaints of an inability to stay awake for social events in the evening, and being alone without companionship in the early morning, are typical. If they try to maintain a normal bedtime, they have difficulty with severe evening fatigue. This syndrome is most often reported in the elderly.

Disorders of pacemaker function and pacemaker–effector coupling

There are two types of disorders associated with pacemaker dysfunction. The first is a loss of circadian function; arrhythmicity similar to that seen in animals with destruction of the pacemaker. The second is an alteration of normal pacemaker output. A diminution of the amplitude of circadian rhythms is characteristic of aging. In this circumstance, however, it is unclear whether the problem is at the level of the pacemaker or reflects a partial inability of effector systems to respond to a normal pacemaker input.

Irregular sleep–wake pattern syndrome

This is a relatively uncommon syndrome in which affected individuals have an irregular distribution of sleep and wake with numerous interruptions. These individuals complain both of their difficult schedule and insomnia and of daytime fatigue, and appear to be arrhythmic. In some instances in which 24-hour recordings have been made, there is no discernible rhythm in core body temperature. This may occur in two situations, with evident hypothalamic pathology such as a tumour compressing the anterior hypothalamus, and spontaneously without evident neuropathology.

Syndrome associated with decreased amplitude

In many elderly individuals, there is increased fragmentation of sleep and less sleep in the deeper stages of slow wave sleep, decreased amplitude of the body temperature rhythm and decreased amplitude of the cortisol and melatonin rhythms as well as the advance in phase described above. These observations suggest that there is a decrease in pacemaker output in aging and that the symptomatic expression of this abnormality is insomnia. It has been reported recently that melatonin therapy, which should improve pacemaker coupling, is significantly better than placebo in treating sleep disturbances in the elderly. It is not possible to state, however, that the sleep disturbances of the elderly do not include problems of pacemaker coupling to output systems. It seems likely that a complex

interaction of decreased pacemaker output and decreased responsiveness of effector systems to pacemaker output are operative in many of the circadian disturbances of the elderly.

Parasomnias

Restless legs syndrome/periodic limb movement disorder

The restless legs syndrome (RLS) and periodic limb movement disorder are related sleep disorders. Restless legs refers to a waking complaint that interferes with sleep onset, whereas periodic limb movements are found during sleep and may interfere with restorative sleep. The restless legs complaint is a dysesthesia described as an uncomfortable restless, or creeping and crawling sensation in the lower legs. This sensation is only relieved with vigorous movement of the legs, often requiring the patient to get out of bed. The disorder affects between 5 and 10% of the population, beginning generally in mid-life. Periodic limb movements during sleep often occur with restless legs syndrome, but may be found in isolation. In this disorder, stereotypic periodic (every 20–40 seconds) limb movements (0.5 to 5 second extensions of the big toe and dorsiflexion of the foot at the ankle are often associated with signs of arousal from sleep, such as K complexes followed by alpha EEG waves. The degree to which PLMS is a disorder that either impairs sleep or that requires any intervention remains unclear, however, since roughly 11% of the normal population without sleep complaints, especially the aged, will demonstrate PLMS on polysomnographic assessment.

The pathophysiology of RLS and PLMS has not been well defined. The effectiveness of dopamine agonists and levodopa in the treatment of RLS-PLMS suggests that abnormal dopaminergic function in the CNS may play a role. The efficacy of opiates in the treatment of the disorder suggests a role for the endogenous opiate system. Associated medical conditions for RLS include uremia, iron deficiency anemia, peripheral neuropathy, fibromyalgia, magnesium deficiency, rheumatoid arthritis and post-traumatic stress disorder. Medications that exacerbate RLS or PLMS include lithium, tricyclic and SSRI medications as well as withdrawal from anticonvulsants, benzodiazepines and barbiturates. Bupropion is one antidepressant that has been associated with a reduction in periodic limb movements, perhaps related to its dopaminergic activity.

The treatment of RLS and PLMS is primarily dopaminergic agonists, or levodopa/carbidopa, administered at bedtime. The relatively short duration of action of these drugs often requires a second dose during the night unless the sustained release preparation is used. Benzodiazepines and traditional sedative/hypnotics consolidate sleep and may reduce arousal secondary to the PLMS. Opiate medications are useful in the treatment of these disorders but, given their abuse potential, they should be employed as a last measure. Less information is available to support the use of other agents such as carbamazepine, clonidine and gabapentin.

NREM parasomnias

Three related sleep disorders, or sleep syndromes, fall into a category of NREM parasomnias: confusional arousals, sleep terrors and sleepwalking. Each is thought to represent a 'disorder or arousal'. As a group, these disorders tend to occur normally in children below the age of 5 when behavioural state regulation is not yet well differentiated. There appears to be a genetic tendency for these disorders as a group. Persistence into adulthood is not the norm, but when they do, they can interfere with psychosocial functioning. They each tend to occur out of a deeper NREM sleep stage (slow wave sleep) early in the night and each is associated with amnesia for the event.

Confusional arousals refer to periods of partial sleep and partial waking behaviour with amnesia for the events on full awakening. The individual will have the appearance of being confused, disoriented with incomplete responsiveness to their surroundings. These episodes may last from a few seconds to a few minutes with return to sleep.

Sleep terrors refer to periods in which the individual seems to be in the midst of a panic-like state with crying out, sitting erect in bed with acute autonomic arousal such as increases in heart rate, respiration and sweating. No recall of the event is noted.

Sleep walking refers to the appearance of motor behaviour during sleep that can lead to an individual getting out of bed and walking around his/her environment. Occasionally the motor behaviour is isolated to the bed, with uncomplicated, brief, automatic behaviours. At other times, the behaviour can be very complex, including walking around the bedroom performing some stereotypic act, or leaving the bedroom and walking around the house. Sleep-related eating episodes are not uncommon. On rare occasions, a sleepwalker may leave his/her immediate home, walk around the neighbourhood or even drive a car. In general, the individual returns to bed voluntarily, either on completion of the episode, or after full awakening from the episode. The individual is often somewhat difficult to arouse and only partially responsive to environmental stimuli. Complete amnesia for the events is most common.

The pathophysiology for all of the confusional arousals is unclear. A strong genetic component is recognized for both sleep terrors and sleepwalking. Aside from this, factors which are associated with increasing the depth of sleep, such as sleep deprivation, or dissociating sleep, such as acute toxic/metabolic changes, or stressing an individual may increase the likelihood that these episodes will occur in genetically predisposed individuals. Presumably, these episodes occur when there is dissociation between the brain mechanisms that regulate cortical activation or behavioural arousal and those that regulate motor behaviour. It remains unclear whether there is an association between these events and psychopathology. Any association may simply be related to the observations that mental disorders are themselves associated with disruptions in sleep continuity, factors that would be expected to increase the frequency of such events in susceptible individuals.

The diagnosis of each of these disorders is generally a clinical one. Reports of parasomnias in the first third of the night with specific features as described above support the diagnoses. Polysomnography can be performed, although it is infrequently helpful given the difficulty of 'capturing' one of the episodes in the sleep laboratory. Attempts to precipitate an episode in the lab by forced arousals from delta sleep may aid in diagnosis. In cases where a seizure disorder may be suspected, one or several daytime diagnostic EEGs and an EEG during sleep may be performed to detect epileptiform activity.

Treatment of these disorders is largely conservative and educational in nature, informing the patient and his/her family about sleep and the generally benign longitudinal course of parasomnic behaviours. At the time of occurrence, the individuals should not be disturbed, but rather the parasomnic events should be allowed to self-terminate. Occasionally, forced arousals during an event can precipitate an unconscious aggressive attack. Minimizing sleep deprivation, stressors and medications or dietary factors that may interfere with sleep integrity (e.g. alcohol, caffeine, antidepressant medications) are recommended. If there is reason to suspect that the behaviours may be interfering with either sleep integrity or with daytime functioning, occasional use of sleep consolidating medications such as the benzodiazepines may be effective in preventing the escalation of these partial arousals into more complex behaviours during sleep. If an underlying mental disorder is present that appears to be interfering with sleep continuity, this can be referred for appropriate intervention, either psychotherapy or pharmacotherapy with non-alerting antidepressant medications. If there is a history of either self- or other- injury during the events, steps should be taken to 'sleepwalker-proof' the bedroom and surrounding environment. This may include the removal of potentially dangerous objects, locking doors and separating bed-partners from the sleepwalker.

Nightmares

The term 'nightmare' implies a vivid dream in which something catastrophic or frightening is happening either to the dreamer or to someone else. Often, this term also implies an awakening from the frightening dream in a fearful state. There is no clear distinction, however, between a nightmare and a dream. Nearly everyone has experienced a nightmare suggesting that this is a normal phenomenon of sleep. In general, the causal occurrence of nightmares does not come to the attention of the medical community and no interventions are required. Nightmares are more common in childhood than in adulthood and more common in girls than in boys. The prevalence of a nightmare disorder is difficult to define, however, given the difficulty in defining a separate disorder from the more common occurrence of having bad dreams.

The pathophysiology of nightmares is unknown. Human brain imaging studies performed during REM sleep consistently reveal selective activation of anterior limbic and paralimbic structures, regions thought to play a significant role in emotional behaviour, although no comparative studies have been performed to differentiate regional cerebral function during REM sleep in healthy subjects vs. nightmare disorder subjects. Elevations in autonomic arousal prior to awakening with a nightmare have been observed. Behavioural studies suggest that individuals with 'thin' interpersonal boundaries, defined as more open, sensitive and vulnerable to intrusions, are more susceptible to suffering from nightmares. Numerous drugs that affect sleep, and REM sleep specifically, such as many antidepressant medications, are known to precipitate nightmares. Alcohol withdrawal is particularly associated with bizarre vivid dreaming. Subjects with post-traumatic stress disorder have recurrent intrusive nightmares related to their traumatic life experience as part of their diagnostic criteria.

Given the diverse etiologies of nightmares, there is no uniform therapy. Identification and removal of precipitating factors including toxic/metabolic or drug induced is often the simplest treatment. There have been no empirical medication trials to determine the efficacy of any medication treatment for nightmare sufferers and clinical experience would suggest that response is highly individual. Psychotherapy may be of some benefit in cases where the nightmare appears to reflect an unsuccessful attempt at some type of emotionally adaptive behaviour to a stressful life situation.

REM sleep behaviour disorder

Clinically, REM sleep behaviour disorder (RBD) refers to a parasomnia in which there are sleep-related behaviours associated with elaborate dream mentation. Depending on the elaborateness of the behaviour and the aggressiveness of the dream, these behaviours can result in accidental self- or other injury. In general, the nature of the dream enactments is out of character for the person's waking behaviour. Often, the presenting complaint comes from the bed-partner who is concerned about the behaviours rather than the actual patient who often is unaware that anything unusual has happened during sleep. The disorder most often occurs in men and is more common in aging.

The pathophysiology of the disorder can best be understood, based on an understanding of the normal physiology of REM sleep. REM sleep occurs periodically throughout the night, alternating with NREM sleep in roughly 90-minute cycles. During REM sleep the brain is in an active behavioural state in which cerebral metabolism and other signs of cortical activation are comparable to those of waking. Two exceptions include the absence of conscious awareness and the near complete immobilization of skeletal musculature via an active inhibition of motor activity by pontine centres in the locus ceruleus region. These exert an excitatory influence on the magnocellular reticular nucleus of the medulla. This nucleus in turn, hyperpolarizes spinal motor neurons. It is inferred that a defect in some aspect of this REM sleep atonia system is disturbed in patients suffering from REM sleep behaviour disorder.

Acute toxic/metabolic RBD has been associated with alcohol and benzodiazepine Withdrawal, or an adverse effect associated with administration of tricyclic antidepressants, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors and clomipramine. Chronic RBD is either idiopathic (estimated to be around 40%) or associated with some form of neurologic insult. These can be from a variety of etiologies including vascular, malignant, infectious and degenerative. The specific pathology in each case, although presumed to have a final common pathway on the REM sleep atonia system is not known.

Diagnosis is suspected based on a clinical report of potentially harmful sleep-related behaviours in which there appears to be an acting out of some dream sequence. Diagnosis is confirmed in a polysomnographic study that shows increased tone, or increased twitching in the chin EMG channel. Videotaping sleep-related behaviours is helpful diagnostically when increased movements are seen during a polysomnographically identified REM sleep period.

The most widely supported treatment for RBD is administration of clonazepam at bedtime beginning with small doses and titrating upwards to achieve clinical benefit. In general, tolerance is not seen and this medication is reported to be helpful in over 90% of cases.

Medical–psychiatric sleep disorders

Sleep disorders associated with psychiatric illness

We turn now to characterizing the sleep disturbances in the major mental disorders, where the vast majority of research has been in the areas of depression and schizophrenia.

Depression

The majority of patients with mood disorders describe difficulty falling asleep, difficulty staying asleep, and difficulty returning to sleep after early morning awakenings. Clinically, they report a paradoxical state of physical daytime fatigue, yet with persistent mental activity that makes it difficult for them to fall asleep at night. Whereas insomnia characterizes the melancholia of middle age and elderly unipolar depression, younger patients and bipolar depressed patients will often describe difficulty getting up in the morning and hypersomnia during the daytime.

An extensive literature describes the changes in electroencephalographic (EEG) sleep in patients with depression. Measures derived from the EEG sleep recordings that have been found to differ between healthy and depressed subjects include measures of sleep continuity, measures of visually scored EEG sleep stages, and automated measures of characteristics of the EEG waveform across the sleep period such as period amplitude or EEG spectral power measures.

The changes in subjective sleep complaints are paralleled by EEG measures of sleep. These include increases in sleep latency and decreases in sleep continuity. In terms of EEG sleep stages or 'sleep architecture', depressed patients often show reduced state 3 and 4 NREM sleep. Several changes in REM sleep have also been noted. These include an increase in the amount of REM sleep, a shortening of the time to onset of the first REM period of the night, a shortened REM latency, and an increase in the frequency of eye movements within a rapid eye movement period. Depressed women appear to have relative preservation of stages 3 and 4 slow wave sleep in relation to depressed men.

Other studies have correlated the severity of psychopathology with sleep abnormalities in depression. Patients

with psychotic depression have particularly severe EEG sleep disturbances and very short REM sleep latencies. Patients with recurrent depression have more severe REM sleep disturbances than patients in their first episode and sleep continuity and REM sleep disturbances are more prominent early in a recurrent depressive episode. EEG sleep findings help to inform our understanding of the neurobiology of longitudinal course and treatment outcome in depression. Although severely reduced REM latencies, phasic REM measures and sleep continuity disturbances generally move toward control values after remission of depression, most sleep measures show high correlations with clinical manifestations across the course of an episode. Reduced REM latency is associated with increased response rates to pharmacotherapy, but not to psychotherapy. Depressed patients with abnormal sleep profiles (reduced REM latency, increased REM density and poor sleep continuity) are significantly less likely to respond to cognitive behaviour therapy and interpersonal therapy than patients with a 'normal' profile. Reduced REM latency and decreased delta EEG activity in the first episode appear to be associated with increased likelihood, or decreased time until recurrence, of depression in patients treated with medications or psychotherapy.

Each of the major neurotransmitter systems which has been shown to modulate the ascending activation of the cortex, i.e. the cholinergic, noradrenergic and serotonergic systems, have been implicated in the pathophysiology of mood disorders. Nearly all effective antidepressant medications show a pronounced inhibition of REM sleep including a prolongation of the first REM cycle and a reduction in the overall percentage of REM sleep except for nefazadone and bupropion which do not suppress REM sleep. Enhanced cholinergic function concurrent with reduced monoaminergic tone in the central nervous system has been proposed as a pharmacologic model for depression. In an exaggerated sense, the state of REM sleep mimics the formulation. REM can be viewed as a cholinergically driven state with reduced firing of noradrenergic and serotonergic neurons. Cholinergic agents such as the muscarinic agonist, arecoline, physostigmine and scopolamine produce exaggerated REM sleep effects in depressed patients in comparison to patients with eating disorders, personality disorders, anxiety disorders, and healthy controls. These studies suggest that there may be a supersensitivity of the cholinergic system driving REM sleep in depressed patients, although an alternative plausible hypothesis is that there may be reduced monoaminergic (5-HT and/or NA) inhibition of the brainstem cholinergic nuclei. Selective serotonin reuptake inhibitors (SSRIs) are known to have prominent REM suppressing activity, most notably early in the night when alterations in REM sleep are most common in depression. A tryptophan-free diet, which depletes central serotonin activity, is noted to decrease REM latency in healthy controls and in depressed patients and ipsaparone, a 5-HT1a agonist, is noted to prolong REM latency in both normal controls and in depressed patients. Anatomically, 5-HT1a receptors have been conceptualized as the limbic receptors given their high densities in the hippocampus, the septum, the amygdala, and cortical paralimbic structures. The action of serotonin in these structures is largely inhibitory. Given the importance of limbic and paralimbic structures in REM sleep modulation, the influence of SSRIs may be mediated by these limbic receptors. Importantly, in the brainstem laterodorsal tegmental nucleus, a cholinergic cell group involved in the generation of REM sleep, bursting cholinergic neurons are inhibited by the action of serotonin on 5-HT1a receptors. The 5-HT1a antagonist pindolol reduces REM sleep in healthy subjects. This has been interpreted to be a consequence of a reduction in midbrain raphe serotonin neuron autoregulation resulting in increased serotonergic input to pontine cholinergic centres which inhibits REM sleep.

Given the selective activation of limbic and paralimbic structures during REM sleep in healthy subjects, the study of the functional neuroanatomy during REM sleep in depressed patients may provide insight into the pathophysiology of depression. In contrast to healthy controls, depressed patients fail to activate anterior paralimbic structures (anterior cingulate and medial prefrontal cortices) from waking to REM sleep and show large activations in the dorsal tectum and activations in the sensorimotor cortex, inferior temporal cortex, uncus, amygdala, and subicular complex during REM sleep. These findings indicate that depressed patients have patterns of brain activation from waking to REM sleep that differ markedly from healthy controls. In the context of models relating forebrain function during REM sleep to attention, motivation, emotion and memory, these results suggest that REM sleep abnormalities in depressed patients are associated with alterations in limbic and paralimbic forebrain function which reflect the basic pathophysiology of depression (Fig. 55.4, see colour plate section).

Functional neuroimaging of sleep in depressed subjects would be expected to provide insight into homeostatic regulation of sleep in mood disorders patients since this is a time in which the build-up of a sleep-dependent process, process S, is discharged and during which growth hormone secretion occurs. Whole brain and regional cerebral glucose metabolism are elevated during the first NREM period of the night for depressed men in relation to

healthy men suggesting a reduction of homeostatic mechanisms secondary to cortical hyperarousal. Other studies have shown that reductions in delta sleep in depressed patients are associated with reductions in afternoon waking relative and global blood flow. This suggests that the elevations in glucose metabolism during NREM sleep in depressed patients are not related to a waking hypermetabolic state. Studies across waking and NREM sleep are needed in order to clarify this notion. Depression symptoms respond to acute sleep deprivation and imaging studies have shown that depressed patients who have high pre-treatment relative glucose metabolic rates in the medial prefrontal cortex are more likely to respond to sleep deprivation. Further, a reduction in relative metabolism in this region was found following sleep deprivation.

Schizophrenia

The predominant current view in biological psychiatry is that schizophrenia is a developmental brain disorder with many of its manifestations the consequence of selective, early onset neuronal degeneration. Early sleep studies sought to test the intriguing hypothesis that aspects of the thought disorder in schizophrenia are a spillover of the dream state into wakefulness. No evidence has accrued to support this view, but subtle alterations in architecture of REM sleep have been reported. These are difficult to interpret, however, as studies examining treatment of naïve schizophrenia patients show no increases in REM sleep and the increases in REM sleep observed in previously treated subjects probably reflect effects of medication withdrawal, and/or changes related to the acute psychotic state.

Slow wave sleep is of particular interest to schizophrenia because of the implication of the prefrontal cortex in this disorder and in the generation of NREM sleep. Several studies have shown a reduction of NREM sleep in schizophrenic patients. NREM sleep deficits have been seen in acute, chronic, and remitted states and in never-medicated, neuroleptic-treated and unmedicated patients. Research since 1990 has focused increasingly on both the positive and negative syndromes of schizophrenia, a conceptual distinction of particular importance to understanding its pathophysiology. In a longitudinal study, alterations of NREM sleep appeared to be stable when polysomnographic studies were repeated at 1 year, but the REM sleep parameters appeared to change. These observations suggest that NREM sleep deficits in schizophrenia might be trait related. Consistent with this view, delta sleep abnormalities have been found to correlate with negative symptoms and with impaired outcome at one and at two years.

In general, it has been difficult to determine a clear abnormality in sleep–wake regulation in schizophrenia.

Alzheimer's disease

Disturbances in sleep commonly accompany Alzheimer's disease. These disturbances are a significant cause of distress for caregivers often leading to institutionalization of these patients. The changes in sleep often parallel the changes in cognitive function in demented patients. Also, daytime agitation has been associated with sleep quality at night. A large-scale community-based study of Alzheimer's disease patients reported that sleeping more than usual and early morning awakenings were the most common sleep disturbances in non-institutionalized patients. Night-time awakenings, however, were more disturbing to caregivers. Night-time awakenings were associated with male gender, and greater memory and functional declines. Three groups of subjects were identified in association with nocturnal awakenings: (i) patients with only daytime inactivity; (ii) patients with fearfulness, fidgeting and occasional sadness; and (iii) patients with multiple behavioural problems including frequent episodes of sadness, fearfulness, inactivity, fidgeting and hallucinations.

In terms of sleep laboratory-based evaluations, sleep continuity disturbances in these patients include decreased sleep efficiencies, increased lighter stage 1 NREM sleep, and an increased frequency of arousals and awakenings. Sleep architecture abnormalities include decreases in stages 3 and 4 NREM sleep and some reports of decreases in REM sleep. Loss of sleep spindling and K complexes have also been noted in dementia. Sleep apnea has been observed in 33 to 53% of patients with probable Alzheimer's disease. It is unclear if there is an increased prevalence of sleep apnea, however, in Alzheimer's patients in relation to age- and gender-matched controls. Nocturnal behavioural disruptions, or 'sun-downing' are reported commonly in the clinical management of Alzheimer's patients, although specific diagnostic criteria for a 'sun-downing' episode have been difficult to define. Despite extensive clinical research in this area, the pathophysiology of sun-downing, including its relationship with brain mechanisms that control sleep/wake and circadian regulation remain unclear. Overall, the literature on sleep in Alzheimer's disease suggests that the primary defect in this disease is the more general neurodegenerative changes that lead to the profound cognitive and functional declines of this disease and that the sleep changes are secondary manifestations of the disorder. If sleep is viewed as generated by core sleep systems that then require a relatively intact neural cortex and subcortical areas for expression of behavioural states, then the sleep changes in Alzheimer's disease are most likely related to end-organ failure, in the cortex, as opposed to pathology in key sleep or circadian systems themselves.

Parkinson's disease

Light, fragmented sleep occurs frequently in Parkinson's disease patients. Sleep problems have been reported in as high as 74–96% of patients. Complaints included frequent awakenings, early awakening, nocturnal cramps, pains, nightmares, vivid dreams, visual hallucinations, vocalizations, somnambulisms, impaired motor function during sleep, myoclonic jerks, excessive daytime sleepiness, REM sleep behaviour disorder, sleep-related violence leading to injury. These changes may result from the disease itself, or to complications from treatment with dopaminergic agents. Additionally, depression is common in Parkinson's disease and the sleep disruption may in part be related to this comorbid disorder.

Sleep architecture abnormalities include increased awakenings, reductions in stages 3 and 4 sleep, REM sleep and sleep spindles. Reductions in REM latency have been observed. Increased muscular activity, contractions and periodic limb movements may prevent slow-wave sleep and foster light fragmented sleep. Disorganized respiration is also found. Recent studies have raised concern about abrupt onset daytime sleep episodes in Parkinson's disease in association with treatment with newer dopamine agonists. Although this requires further analysis, it is unclear whether the sleep episodes are more frequent with dopamine agonist therapy than in the Parkinson's disease population.

In conclusion, sleep disorders are common and carry a substantial morbidity and cost to society. They occur as primary disorders, responses to the environmental demands of modern society, major manifestations of psychiatric diseases and important complications of medical illnesses, including neurological diseases. Understanding the neurobiology of sleep and sleep disorders is critical to the practice of neurology.

Bladder and sexual dysfunction

Oliver J. Wiseman and Clare J. Fowler

Institute of Neurology, Queen Square, London WC1N 3BG, UK

Control of bladder function

The bladder performs only two functions, storage and voiding of urine. Control of these two mutually exclusive activities requires intact central and peripheral neural pathways. Neural programmes for each exist in the dorsal tegmentum of the pons, and suprapontine influences act to switch from one state to the other. The decision as to when to initiate voiding is determined by the perceived state of bladder filling and an assessment of the social circumstances.

As an individual may micturate once every 4 or so hours, and take only one or two minutes to void, the bladder is in storage mode for most of the time. During the storage phase, contraction of the detrusor smooth muscle in the bladder is prevented by inhibiting parasympathetic outflow. Closure of the bladder outlet is maintained by sympathetic influences on the detrusor smooth muscle in the bladder neck region and by contraction of the striated muscle of the urethral sphincter and pelvic floor innervated by the pudendal nerve. Voiding is initiated by a complete relaxation of the urethral sphincter and the reciprocal action of a sustained detrusor contraction, so that urine is effectively expelled.

To effect both storage and voiding, connections between the pons and the sacral spinal cord must be intact as well as the peripheral innervation which arises from the most caudal segments of the sacral cord (reviewed in Chapter 53). From there the peripheral innervation passes through the cauda equina to the sacral plexus and via the pelvic and pudendal nerves to innervate the bladder and sphincter. Thus the innervation needed for control of the bladder is extensive, requiring suprapontine inputs, intact spinal connections between the pons and the sacral cord, as well as intact peripheral nerves. Urinary continence is thus a severe test of neurological integrity.

An excellent review on the control of bladder function is available (de Groat, 1999).

Bladder dysfunction in neurological disease

Cortical lesions

Anterior regions of the frontal cortex are crucial for bladder control. This was shown by a series of patients with disturbed bladder control who had had various frontal lobe disturbances, including intracranial tumours, intracranial aneurysm rupture, penetrating brain injuries or prefrontal lobotomy (Andrew & Nathan, 1964). The typical clinical picture of frontal lobe incontinence is of a patient with normally coordinated micturition who has severe urgency, urge incontinence and frequency, or loss of sensation of impending micturition but who is not demented such that they are aware of and embarrassed by the incontinence. Micturition is normally coordinated, indicating that the disturbance is in the higher control of these processes.

Six cases were described with disturbances of micturition due to aneurysms of anterior communicating or anterior cerebral arteries (Andrew et al., 1966). The authors hypothesize that the disconnection of the frontal or anterior cingulate regions from the septal and hypothalamic areas allows micturition to proceed automatically and involuntarily following brain damage. In an earlier paper Ueki analysed the urinary symptoms of 462 patients being operated upon for brain tumours, 34 cases of frontal lobectomy and 16 cases of bilateral anterior cingulectomy. He concluded that there was a strong positive influence on micturition by an area in the pons and an inhibitory input from the frontal lobe and bilateral paracentral lobules (Ueki, 1960).

Positron emission tomography (PET) studies of male and females voiding have shown that there is significant activity in the right inferior frontal gyrus during voiding that is not present during the withholding phase (Blok et. al., 1997).

It should be noted that, as well as urinary incontinence, urinary retention has also been described in patients with right frontal lobe pathology, with restoration of normal voiding after successful treatment of the lesions.

Head injuries

There are a few reports of bladder dysfunction occurring after minor head injuries. However, serious traumatic head injury is typically followed by a period of detrusor areflexia, followed by detrusor hyperreflexia (McGuire, 1984). In 17 patients in a vegetative state 1–6 months after injury, urodynamics revealed that all patients had detrusor hyperreflexia (Krimchansky et al., 1999).

Cerebrovascular disease

The effects of a stroke on bladder function depend upon the size and site of the disruption caused to cerebral tissue and pathways. During the early stages of injury, a period of detrusor areflexia may occur, resulting in acute urinary retention, but after this initial period most commonly detrusor hyperreflexia develops (Khan et al., 1990; Wein & Barrett, 1988). Urodynamic studies show that voiding is mostly normally coordinated, with the most common cystometric finding being detrusor hyperreflexia. The patient complains of frequency and urgency, and may also have urge incontinence. The presence of urinary incontinence within seven days of a stroke is actually a stronger prognostic indicator of poor survival than a depressed level of consciousness (Wade & Langton-Hewer, 1985).

Epilepsy

Urinary incontinence is a common feature of generalized tonic clonic seizures, and occurs due to relaxation of the external sphincter (Gastaut et al., 1974). However, urinary incontinence and ictal urination are rare during focal seizures (Freeman & Schachter, 1995; Liporace & Sperling, 1997). Symptoms of detrusor overactivity may occur with seizures, manifested by urgency and urge incontinence. Urinary urgency may be seen during typical absence seizures, and urodynamics have revealed detrusor hyperreflexia during such seizures (Gastaut et al., 1964). 'Ictal urinary urge' is a rare symptom during temporal lobe seizures (Baumgartner et al., 2000).

Basal ganglia

Bladder dysfunction may occur for a number of different reasons in patients with parkinsonism.

In idiopathic Parkinson's disease (IPD), bladder symptoms usually occur later, and thus in elderly men bladder overflow obstruction caused by benign prostatic hyperplasia is usually the cause of urinary symptoms. Patients with IPD typically complain of frequency and urgency. They may also suffer from urge incontinence because with poor mobility they may not have time to reach a toilet. The most common urodynamic finding is detrusor hyperreflexia (DH), because in health the basal ganglia have an inhibitory effect on the micturition reflex. Animal studies have supported this, concluding that the D1 receptor is the main inhibitory influence (Yoshimura et al., 1992).

In patients with mild parkinsonism but disproportionately severe urinary symptoms, or where urinary symptoms precede the development of neurological involvement, a diagnosis of multiple system atrophy (MSA) must be considered. A retrospective study of 62 patients diagnosed with MSA showed that bladder symptoms and erectile dysfunction preceded the diagnosis of MSA by 4–5 years, and the onset of neurological symptoms by 2 years. Almost half the male patients had had a transurethral prostatectomy (TURP), from which few benefited (Beck et al., 1994).

That urinary complaints are so severe early on in patients with MSA may be explained by the fact that the disease affects several locations in the central nervous system which are important for bladder control. Both DH and incomplete bladder emptying may be seen in these patients, the former tending to present first, followed by increasing post micturition residuals over time. DH may be explained by neuronal loss in the pontine region, and incomplete bladder emptying by degeneration of the parasympathetic input to the detrusor following neuronal loss in the intermediate grey matter of the sacral cord segments (S_1–S_5). In addition to the hyperreflexia and increasing residuals, these patients also develop sphincteric weakness due to anterior horn cell loss in Onuf's nucleus, exacerbating their incontinence (Kirby et al., 1986).

The reports of poor outcome of patients with Parkinson's disease from prostatic surgery may well have been due to the inclusion of some patients with MSA, and a TURP should be considered only if there is convincing evidence of bladder outflow obstruction in a man with a definite diagnosis of IPD.

Spinal cord

Interruption of the spinal pathways which connect the pontine micturition centre (PMC) with the sacral cord has

severe consequences for micturition, and spinal cord pathology is the most common cause of neurogenic bladder dysfunction. As the innervation of the bladder arises more caudally than that of the lower limbs, unless the lesion is entirely confined to the conus, patients with bladder dysfunction due to spinal cord disease will almost always have neurological signs in their lower limbs.

Patients develop detrusor hyperreflexia due to the emergence of new spinal segmental reflexes, and experimental work in cats suggests C fibres become the major afferents (de Groat, 1998). Patients complain of frequency and urgency due to their small bladder capacity and may also suffer from urge incontinence if DH is severe and/or they have poor mobility. Decreased sacral neural input to the detrusor in these patients can lead to decreased bladder emptying. Residual urine can exacerbate the symptoms due to detrusor hyperreflexia.

Reciprocal activity of the detrusor and external urethral sphincter, which is required for normal voiding, needs intact connections between the sacral spinal cord and the PMC. When these are lost, uncoordinated activity results, with the sphincter contracting during detrusor contraction, a condition known as detrusor sphincter dyssynergia (DSD) (Betts, 1999). Although the voiding process may have been as severely disrupted as the storage process, it is usually symptoms related to the latter that the patient complains of. Symptoms of hesitancy and an interrupted stream may only be elicited on direct questioning. Approximately 75% of patients with MS have bladder dysfunction, a similar percentage to those who have been shown to have spinal cord involvement. Patients most commonly complain of urgency, and several series of urodynamic studies have shown that this is due to DH.

Patients with MS rarely develop upper tract problems, in contrast to patients with spinal cord injury (SCI). The reason for this is unknown, but treatment of these patients must therefore be directed towards symptomatic relief. This can be hard to achieve, as with disease progression DH worsens as does the inability to effect bladder emptying. The deterioration in bladder function occurs against a background of decreasing mobility and possibly cognitive decline, making symptomatic relief and the avoidance of urge incontinence a difficult goal (Fowler, 1997).

Bladder dysfunction also occurs in other non-traumatic forms of spinal cord disease. In transverse myelitis bladder dysfunction may typically be the only remaining neurological remnant of a condition that, during the acute illness, may have required artificial ventilation and caused a quadraparesis (Sakakibara et al., 1996). The reason for this is unknown. Patients with tropical spastic paraparesis, a progressive myelopathy caused by infection with HTLV-1, may have DH as a presenting symptom.

Management of patients with traumatic spinal cord injury (SCI) necessarily has a different focus as, in this group, upper tract damage can occur (Arnold, 1999). Renal failure arises secondary to DH and loss of compliance which causes ureteric reflux, hydonephrosis and subsequent upper tract damage. Thus these patients, who are often young and otherwise fit, need to have their bladder problems managed aggressively. They often have surgical rather than solely medical management.

Spina bifida

Open and closed spina bifida are the commonest causes of neurogenic bladder dysfunction in childhood, and can also cause significant problems in adults (Borzyskowski, 1999).

Patients may develop similar complications from bladder dysfunction to those patients with spinal cord injury, namely DH, ureteric reflux, and subsequent renal failure. However the advent of CISC, anticholinergic medication and newer surgical techniques has decreased the morbidity from urological problems. Even so, the most common reason for hospital admission in these patients remains urological problems. Three types of bladder dysfunction, detailed below, have been identified, and these are classified according to detrusor behaviour (Rickwood et al., 1982). Urethral dysfunction is almost universal across the three groups, being dyssynergic in the first group and static in the other two groups.

The first type is ‘contractile’, where patients exhibit DH with a normal bladder. DSD is commonly seen. The majority of patients have decreased capacity and incomplete bladder emptying and incontinence. The risk of upper tract damage is significant if vesicoureteric reflux is present.

‘Intermediate’ is the commonest type of dysfunction, and also has the highest risk of upper tract damage. Intravesical pressure is continuously raised as bladder wall compliance is reduced. The distal sphincter mechanism is defective, both incompetent and obstructive, and this, combined with poor detrusor function leads to incomplete bladder emptying and incontinence. Surgery is frequently required to protect the upper tracts.

The final type of dysfunction is ‘acontractile’, where the detrusor is atonic. This, together with the incompetent bladder neck and dysfunctional sphincter mechanism leads to overflow and stress incontinence. The upper tracts are relatively safe in this group of patients.

Cauda equina

Sacral sympathetic outflow and somatic efferent and afferent fibres travel in the cauda equina, with damage to it therefore resulting in loss of sensation in the perineal saddle area as well as parasympathetic loss to the bladder, bowel and sexual organs.

Bladder dysfunction is unpredictable. Many patients report a reduced flow, incomplete bladder emptying, and in severe cases retention with overflow incontinence due to urodynamically confirmed detrusor areflexia. However, some have symptoms related to DH which has also been reported on urodynamics. Bladder neck incompetence may make stress incontinence an added problem for these patients.

Urodynamics in patients with tethered spinal cord reveals DH together with incomplete bladder emptying. Surgery to release the cord has been claimed to improve bladder dysfunction, but the operation is usually performed to treat pain or prevent neurological progression.

Peripheral innervation

Diabetic neuropathy

Bladder involvement is common as evidenced by cystometry, but is often asymptomatic. Both bladder afferents and detrusor efferents may be involved, and patients symptoms result from a decreased sensation of bladder filling and increasingly ineffective emptying, resulting in overflow incontinence and chronic low-pressure urinary retention. These patients mostly have signs and symptoms of generalized neuropathy, especially affecting the feet. This is because the peripheral small fibres are affected in a length-dependent manner, such that when the bladder is affected, the longer fibres subserving sensation to the lower limbs have also been affected. Urodynamics confirms decreased sensation of bladder filling, impaired detrusor contractility and incomplete emptying.

Amyloid neuropathy

Urogenital dysfunction may result in patients with both inherited familial polyneuropathy and amyloidosis secondary to benign plasma cell dyscrasia or myeloma. Amyloid deposition in the pelvic autonomic nerves can lead to similar symptoms as seen in patients with urogenital dysfunction secondary to diabetes. By the time pelvic autonomic dysfunction results however, there will typically be symptoms or signs related to somatic sensory involvement.

Immune mediated neuropathies

In severe cases of Guillain–Barré syndrome bladder dysfunction may result, and cystometry has shown delay in the initial sensations of bladder filling and detrusor areflexia, indicating damage to both bladder afferent and detrusor efferent nerves. Not all patients will recover bladder function, and recovery may take some months in those who do.

Pelvic nerve injury

Peripheral innervation of the pelvic organs may become damaged during pelvic surgery, such as anterior resection, radical prostatectomy or radical hysterectomy. Lower urinary tract dysfunction after the latter two is reported at rates between 10 and 60%, and in approximately one-fifth of these, the dysfunction may be permanent (McGuire, 1984). This injury may be the result of simple denervation, or nerve tethering or encasement in scar tissue, direct bladder or urethral trauma, or bladder devasularization.

The basis of the voiding dysfunction in patients with permanent dysfunction following radical pelvic surgery is a failure of detrusor contraction, with obstruction by the residual fixed striated urethral sphincter.

Urinary incontinence that follows a radical prostatectomy is due to damage to the innervation of the striated urethral sphincter.

Retention in women

Urinary retention and dysfunctional voiding in young women without any evidence of neurological disease has posed diagnostic difficulties for urologists and neurologists for some time, and such retention was often referred to as ‘psychogenic’, physicians believing that there was no organic underlying cause. The combination of urinary retention, abnormal sphincter EMG and polycystic ovaries was first described in 1988 (Fowler et al., 1988), and the hypothesis is that in these patients the primary abnormality exists in the striated urethral sphincter, which is overactive and which has impaired ability to relax.

Patients are typically premenopausal (mean age 26 years) and often present, following an operative procedure, in painless urinary retention, with a bladder capacity in excess of 1 litre. On direct questioning of these patients in one study, 78% claimed to have abnormal voiding prior to the onset of complete retention, and of those who had undergone pelvic ultrasonography, 50% were found to have polycystic ovaries (Swinn et al., 2002).

Urethral sphincter EMG of these patients typically reveals abnormal excitatory activity, with decelerating bursts and complex repetitive discharges. Many of these patients have to manage their voiding dysfunction by performing CISC, but this group of patients appears to respond particularly well to sacral neuromodulation (Swinn et al., 2000).

Investigation of bladder dysfunction in neurologic disease

When faced with a patient with bladder dysfunction and known neurological disease, it is important to ensure that the symptoms the patient is experiencing are not due to 'other' pathology, such as a bladder tumour, or bladder outflow obstruction caused, for example, by an enlarged prostate gland. A thorough history together with the investigations detailed below are sufficient in the initial evaluation of these patients.

History

Table 56.1 shows what bladder symptoms might be expected from neurological disease at different levels. Also shown are the other symptoms of pelvic organ dysfunction with a lesion at each level since clustering of symptoms is important in trying to decide if pelvic organ complaints are due to 'ordinary', local pathology or are neurogenic. For example, in a patient with spinal cord disease, bladder and sexual dysfunction are usually present together whereas, if bladder symptoms are due to prostatic outflow obstruction, sexual function is usually preserved. Therefore, when taking the history, attention should focus on identifying whether bladder complaints are isolated or are part of a pelvic organ symptom complex.

Investigations

Urine examination is important. A simple bedside dipstick test will help determine if the patient has a urinary tract infection accounting for, or resulting in, an exacerbation of their bladder symptoms. If positive, the urine should then be sent off for formal microscopy and culture. Dipstick examination may also reveal the presence of hematuria, a finding which, in the absence of an infection, requires full urological assessment. This is to investigate the possibility that local bladder pathology such as a ureteric or bladder stone or transitional cell cancer may be the cause of the patient's symptoms.

'Urodynamic investigations' is a term which includes all investigations of the lower urinary tract function, but it is often incorrectly used as a synonym of cystometry.

Uroflowmetry is the simplest urodynamic investigation. It is non-invasive and involves recording the rate of urine flow during voiding per unit time. A uroflow trace is generated during the test, and parameters of the flow rate calculated, including the maximum flow rate, mean flow rate, flow time and the volume voided. For a flow trace to be meaningful, the volume voided should be over 150 ml. Useful, but limited information may be ascertained from uroflowmetry. A normal flow curve is bell shaped, but may be flattened, with a low maximum flow rate (Q_{max}), in patients with either an element of bladder outflow obstruction, due to an enlarged prostate gland or a urethral stricture, or a hypocontractile detrusor muscle. A normal uroflow trace is shown in Fig. 56.1, with a trace below it showing the curve seen in a patient who has bladder outflow obstruction due to an enlarged prostate.

Ultrasonography is one of the most important investigations in a patient with neurogenic bladder dysfunction, and often this is combined with uroflowmetry. It is used to assess residual urine, with a postmicturition volume of greater than 100 ml being significant. Ultrasonography may also be used to assess upper tract dilatation, which may occur in some patients who have neurogenic bladder dysfunction. While residual urine volume may be measured with relative ease by clinic staff, an upper tract ultrasound needs to be performed by a radiologist.

Often uroflowmetry combined with an ultrasound scan of the bladder to assess residual urine volume is all that is required in patients who have established neurological disease and bladder dysfunction but in others, full cystometry is indicated. Such cases may be in patients with an unusual collection of urological symptoms, or in whom the neurological basis of their disease is unclear. Cystometry requires urethral catheterization with a filling catheter and an intravesical pressure catheter, although single dual lumen catheters are now available, which will provide both functions. A rectal pressure line is also inserted. Subtraction of the measured rectal pressure from the intravesical pressure gives the pressure generated by the smooth muscle of the bladder, the detrusor (Fig. 56.2). During the investigation, the bladder is filled at a controlled rate by an infusion pump, and while the rate of filling is variable, it should be remembered that rapid filling may provoke a rise in detrusor pressure. During the study, recordings are made of the intravesical and intra-abdominal pressures, and the detrusor pressure calculated from this. Once filling is complete, the patient voids with the pressure lines *in situ*, and the pressures are once again recorded, as is the flow rate.

The commonest abnormality shown by cystometry in neurogenic incontinence is detrusor hyperreflexia, which is an involuntary phasic rise in detrusor pressure associated with urgency. If this pressure exceeds urethral pressure, involuntary loss of urine will result (Fig. 56.2). However, bladder outflow obstruction which is indicative of an obstructing prostate or a urethral stricture may also be identified. This may mimic some of the bladder symptoms seen in patients with neurogenic bladder dysfunction which is important, as correct identification may allow treatment of the condition, thus alleviating the patient's symptoms.

Table 56.1. Pelvic organ dysfunction resulting from neurological pathology at different sites

Level of lesion	Neurological causes	Pelvic organ dysfunction
Suprapontine:	Dementia	DH
Cortical	CVA	Fecal incontinence (very rare)
	Tumour	Altered sexuality/sexual apathy
Extrapyramidal	IPD	DH (early in MSA)
	MSA	Incomplete emptying
		Constipation
		MED (early in MSA)
		Note: Signs of Parkinsonism advanced in IPD, minor in MSA
	Note: DH occurs without DSD	
Suprasacral:	Multiple sclerosis	DH
Spinal	Spinal cord injury (trauma)	Incomplete bladder emptying
	Compression (e.g. tumour)	Difficulty with bowel evacuation (in advanced disease), with poor sphincter control
	Transverse myelitis	
	AV malformation	MED, FSD
	Spina bifida[a]	
	Note: DH may occur with DSD	
Infrasacral:	Spina bifida[a]	Various forms of lower urinary tract dysfunction exist (see text)
Conus	Tethered cord	Constipation, soiling
		MED
Cauda equina	Trauma	Detrusor areflexia or DH
	Central disc prolapse	Stress urinary incontinence
	AV malformation	Constipation
	Congenital	Fecal incontinence/difficulty with evacuation
		MED, FSD
		Note also: Saddle sensory impairment and sexual sensory loss
Peripheral	Diabetes mellitus	Detrusor areflexia
innervation	Amyloid polyneuropathy	Diarrhea
	Immune-mediated neuropathy	MED (early)
Innervation	Pelvic surgery	Detrusor areflexia, with external sphincter damage and thus stress incontinence
within pelvis	Childbirth injury	
		MED, sometimes FSD

Note:

[a] Patients with spina bifida may have a combination of suprasacral and infrasacral pathologies.

DH = detrusor hyperreflexia, MED = male erectile dysfunction, FSD = female sexual dysfunction, IPD = idiopathic Parkinson's disease, MSA = multiple system atrophy, DSD = detrusor sphincter dyssynergia.

Neurophysiological investigations

Various neurophysiological investigations of the pelvic floor and the sphincters have been developed and used over the years. Currently, those thought to be useful include anal sphincter EMG to recognize changes of chronic reinnervation in MSA, and the use of urethral sphincter EMG to recognize a primary disorder of sphincter relaxation in young women with isolated urinary retention (Vodusek & Fowler, 1999).

Needle electrode EMG of either the anal or urethral sphincter can be performed to show evidence of sacral segment or root damage in much the same way as EMG is used at somatic sites. However, because motor units in the sphincter fire tonically it is difficult to recognize changes of denervation and most often changes of reinnervation are sought, based on the analysis of individual motor units captured using a trigger and delay line. In general, EMG is held to be the most valuable of the pelvic floor investigations to detect lower motor neuron damage. EMG of the

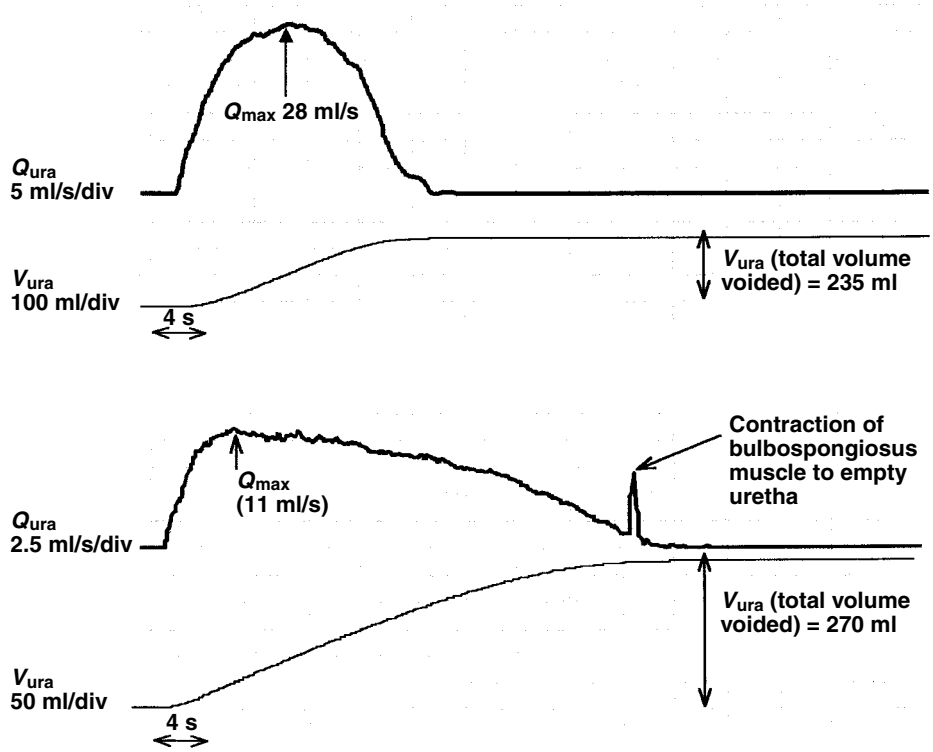

Fig. 56.1. Uroflow traces. The upper trace shows a normal uroflow trace. Note the smooth shape to the uroflow curve. The lower trace shows a flattened curve, as may be seen in a patient with a bladder outflow obstruction. Q_{ura} = urine flow rate (ml/s); Q_{max} = maximum urinary flow rate (ml/s); V_{ura} = volume voided.

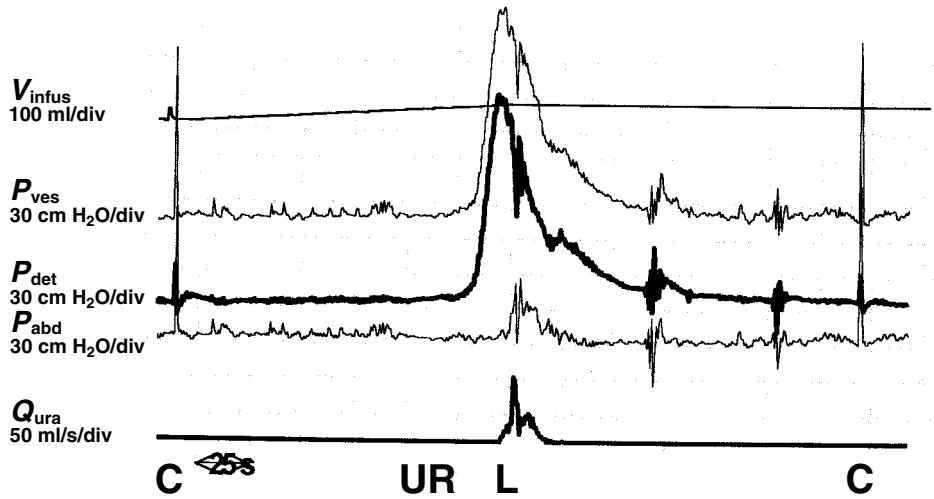

Fig. 56.2. Cystometrogram trace from a patient with MS, demonstrating detrusor hyperreflexia and urge incontinence. After 80 ml had been instilled (V_{infus}), the patient experienced urgency (UR) that was associated with an uninhibitable detrusor contraction (P_{det}) and involuntary leakage of urine occurred (L). The transient rises seen in P_{det} and P_{abd} are due to the patient coughing at intervals to ensure the lines are still in place and recording accurately (C). P_{ves} = intravesical pressure; P_{abd} = intra-abdominal pressure; P_{det} = detrusor pressure; Q_{ura} = urine flow rate.

striated musculature of the pelvic floor can demonstrate changes of denervation and chronic reinnervation in patients with cauda equina lesions as well as those with suspected MSA. Changes of reinnervation in MSA are non-specific and some caution must be exercised in interpreting EMG findings in multiparous women or in patients who have had extensive pelvic surgery. There is some controversy as to the value of the test in distinguishing between MSA and IPD, but extreme prolongation of the mean of ten motor units in a patient with early minor parkinsonism and severe urinary incontinence and erectile dysfunction is strongly indicative of MSA (Palace et al., 1997).

Urethral sphincter EMG may be used to further investigate young women with urinary retention. When a concentric needle electrode is used to record from the striated urethral sphincter in some of these women, abnormal EMG activity may be recorded. This consists of complex repetitive discharges and decelerating bursts (Fowler et al., 1985). A syndrome consisting of this abnormal activity, urinary retention, and polycystic ovaries has been described (Fowler et al., 1988), and the hypothesis is that the primary abnormality lies in the striated sphincter muscle, which is overactive and causes a feedback inhibition of the detrusor muscle, such that these patients are unable to void.

Treatment of bladder dysfunction in neurologic disease

The mainstay of management of neurological bladder dysfunction is a conservative approach consisting of first the treatment of detrusor hyperreflexia, and secondly the management of incomplete emptying.

Treatment of detrusor hyperreflexia (DH)

Oral agents

Most patients with detrusor hyperreflexia respond well to oral anticholinergics (Chapple, 2000), of which the most widely prescribed is oxybutynin (Yarker et al., 1995). It should be commenced at a dose of 2.5 mg twice daily, with the dosage being increased as necessary up to a maximum of 20 mg per day in divided doses. Oxybutinin, however, has the disadvantage of troublesome antimuscarinic side effects, which include a dry mouth, constipation and blurred vision. A dry mouth is the most problematic and common of these reported, even on low doses, and a patient not experiencing this is probably not achieving therapeutic concentrations. A single dose, taken when required, provides adequate treatment for patients who require treatment only occasionally, when for example they know that they will not have toilet access for a while, such as prior to a long car or train journey.

Controlled release oxybutinin is now available as a single daily dose of between 5 and 30 mg. The drug is released over a 24-hour time period, leading to a smoother plasma concentration–time profile, with a significantly reduced incidence of a dry mouth, and comparable efficacy to the immediate release formulation. A multicentre, prospective trial has shown that patients are able to tolerate a higher dose of controlled release oxybutinin than of the conventional preparation, which may lead to a more effective control of symptoms (Anderson et al., 1999).

More recently, tolterodine, a more 'bladder selective' anticholinergic has been introduced, which in clinical studies led to fewer treatment withdrawals compared to oxybutinin. In this study a troublesome dry mouth was reported in 60% of oxybutinin-treated patients, compared to 17% of those taking tolterodine (Appell, 1997). It may be given at a dose of up to 2 mg, twice daily.

Propiverine hydrochloride, at doses of up to 15 mg four times a day, is another effective treatment for DH (Madersbacher et al., 1999). It has both anticholinergic and calcium antagonistic properties, and has been shown to be as effective as oxybutinin in controlling urgency and urge incontinence. The drug is associated with a lower incidence of dry mouth compared to oxybutinin.

Propantheline may be used in some cases when other treatments are unavailable. The addition of a tricyclic antidepressant with antimuscarinic properties such as imipramine, amitriptyline or nortriptyline is sometimes helpful in patients who fail to respond to oxybutynin alone.

Desmopressin, an analogue of ADH, may be used as a nasal spray (Desmospray) or tablets (Desmotabs) to reduce troublesome nocturia in patients not responding to anticholinergics alone (Valiquette et al., 1996). It acts on the kidney, increasing water resorption at the collecting tubule, and thus reducing urine formation. Because of the risk of dilutional hyponatremia, which if it occurs usually does so within the first week or so of starting treatment, it is advisable to check serum sodium levels if the patient experiences any adverse effects. Even though recovery of sodium levels occurs promptly once the medication is stopped, it should be used with caution in patients with compromised renal or cardiovascular function, and avoided in the elderly.

Intravesical agents

There are a number of intravesical agents which have been used to treat detrusor hyperreflexia in patients who do not

respond to oral anticholinergic medication, or who find the side effects of such medication limiting (Fowler, 2000). Two different types of treatment have been used. The first of these blocks cholinergic transmission between the pelvic nerve and detrusor muscle and includes oxybutinin and atropine, while the second group includes agents which act on afferent innervation of the bladder, such as the vanilloids capsaicin and resiniferatoxin.

Oxybutinin acts intravesically by interfering with cholinergic transmission, as well as having a local anesthetic effect. It has been shown to be effective in children and adults with resistant detrusor hyperreflexia, and patients did not report the level of side effects that they experienced with the oral formulation of the drug. Thus for those patients unable to tolerate the oral preparation of the drug, intravesical oxybutinin may be advantageous, but with the normal dose being 5 mg (30 ml of solution) intravesically three times a day, it requires frequent catheterization and is only a realistic option for those patients who are performing clean intermittent self-catheterization already.

Intravesical capsaicin, a member of a group of compounds with a common chemical structure of a vanillyl ring called vanilloids, is a pungent ingredient of the red hot chilli pepper and has been used to treat intractable detrusor hyperreflexia due to spinal cord disease (Fowler et al., 1994). It is a C fibre neurotoxin, affecting those afferent neurons that are responsible for the signals that trigger detrusor activity in patients with DH. It has been shown to increase bladder capacity and reduce the amplitude of hyperreflexic contractions in some patients, with a benefit that lasts for an average of 3–4 months.

Resiniferatoxin is another member of the vanilloid group, and has been demonstrated to be 1000 times more neurotoxic than capsaicin. Initial reports of the use of RTX to deafferent the bladder of patients with detrusor hyperreflexia have been promising (Lazzeri et al., 1998; Silva et al., 2000).

Incomplete bladder emptying or urinary retention

In patients with detrusor hyperreflexia and a significant postmicturition residual, the treatment of incomplete bladder emptying is central, as any treatment to reduce detrusor overactivity is unlikely to be effective in the presence of large residual volumes. In patients with hypo- or acontractile bladders, ensuring bladder emptying is crucial.

Many neurological patients with voiding problems develop their own method of assisting bladder emptying but the best option to deal with significant residual volumes in these patients is clean intermittent self-catheterization (CISC). Patients are often unaware of the extent to which they fail to empty their bladder, and for this reason the measurement of residual volume is the single most important measurement to be made when planning bladder management (Fig. 56.3). A generally accepted figure for significant residual volume is 100 ml, with volumes greater than this requiring drainage.

The patient should be taught CISC by someone experienced in the method and nurse specialist continence advisors are particularly expert. A main requirement for success with this technique is patient motivation; a degree of physical disability may be overcome provided the patient is sufficiently determined. Sometimes impaired visual acuity or other symptoms related to their neurological disease such as spasticity, tremor or rigidity might make it impossible for the patient to perform self-catheterization and in such circumstances it may be performed by a partner if they and the patient are willing, or a care assistant. Most patients are advised initially to perform it at least twice a day.

In spinal cord disease, a combination of intermittent self-catheterization together with an oral anticholinergic manages both aspects of bladder malfunction, namely incomplete emptying and detrusor hyperreflexia. In a patient with a borderline significant residual volume, starting an anticholinergic may have the effect of further impairing bladder emptying. This should be suspected if the anticholinergic has some initial efficacy which then disappears. In any case, however, the residual volume should be checked after initiation of anticholinergic therapy. The management algorithm for the initial treatment of patients with neurogenic incontinence is summarized in Fig. 56.3.

Permanent indwelling catheters/collection devices

Although a combination of anticholinergic medication together with intermittent catheterization is the optimal management for patients with DH and incomplete bladder emptying, there comes a point with worsening neurological disease when the patient is no longer able to perform self-catheterization, or when urge incontinence and frequency are unmanageable. At this stage an indwelling catheter may help greatly with management of bladder symptoms.

Problems with permanent catheterization such as infection, catheter blockage, urinary leakage or expulsion are common. Another major problem may be leakage of urine around the catheter. Bladder stones and recurrent, resistant infections are also more common in patients with a

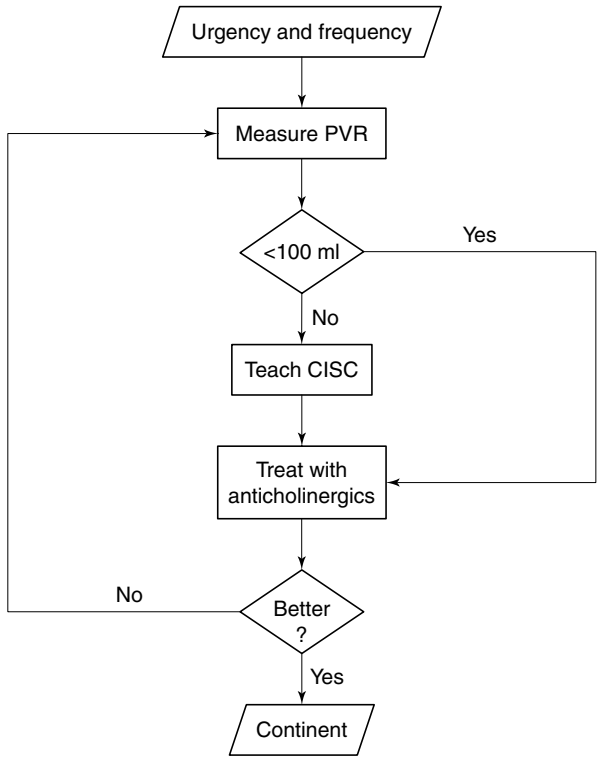

Fig. 56.3. Algorithm for management of detrusor hyperreflexia.

permanent indwelling catheter compared to those who perform CISC.

A preferred alternative to an indwelling urethral catheter is a suprapubic catheter, which can be inserted under local anesthetic. Although by no means a perfect system, a suprapubic catheter is a better alternative to an indwelling urethral catheter and is often the method of choice in managing incontinence in patients for whom other means are no longer effective.

There are some patients in whom medical management is not successful and who then require practical help with their continuing continence problems. The priority in most cases is usually containment of any urine leakage, and the continence advisor is best placed to recommend whether absorbent pads or, in men, an external collecting device may be the best option. A review of these can be found elsewhere (Dasgupta & Haslam, 1999).

Neural stimulation

At present, two different forms of treatment modalities are available. In patients with urge incontinence or voiding dysfunction, neuromodulation of the S3 nerve with an extradural implantable pulse generator (IPG) has been shown to be effective (Shaker & Hassouna, 1998; Swinn et al., 2000). In patients with spinal cord injury, posterior sacral root rhizotomies with implantation of Brindley stimulators on the anterior sacral roots may improve voiding (Brindley et al., 1986; van Kerrebroeck & Debruyne, 1993).

Urological surgery

Various urological procedures can be carried out to treat incontinence (Walsh et al., 1998). Although surgical procedures to deal with urine leakage in an otherwise fit patient are often successful, caution must be exercised before using such measures on those patients with progressive neurological disease. When the bladder symptoms of these patients are becoming unmanageable by using a combination of intermittent catheterization and anticholinergics or even intravesical agents, their neurological disease may be so advanced that urological surgery is not appropriate. However, in some cases, such as those patients with traumatic spinal cord injury, surgery may be the best option for long-term bladder management.

Control of sexual function

Similarities do exist in the neurological control of sexual function in men and women, though that of women is less well understood.

There are two major neurologic pathways of erection, reflexogenic and psychogenic. Reflexogenic erections are the result of direct genital stimulation, with afferent impulses carried in the pudendal nerve to S2–S4, and the efferent arm using the same pathway. Preservation of reflex erections is seen in men with lesions above T11.

Psychogenic erections occur in response to input from higher centres, and require intact long tracts between cortex, spinal cord and autonomic outflow. Somatic sensory afferents deliver information on tactile sexual stimuli which, after synapsing in the sacral spinal cord, pass information centrally leading to awareness of sexual stimulation, and locally to induce the sexual responses dependent upon increased blood flow. Parasympathetic efferents from S2–S4 spinal segments travelling through the pelvic plexus and cavernosal nerves, initiate erection. Blood flow in the penile artery, and the corresponding artery in the clitoris, increases. The smooth muscle of the cavernous sinuses in the penile corpora relax and the sinuses fill with blood. The increased pressure in the corporal bodies reduces venous outflow by compression of the subtunical veins, with the combined reaction resulting in erection. Continued sacral parasympathetic activity maintains this erection.

Seminal emission begins during arousal (Mitsuya et al., 1960) and with continued sensory stimulation, orgasm is triggered with ejaculation resulting from the rhythmic phasic contractions of perineal and pelvic floor muscles. Ejaculation is effected by integrated sympathetic outflow from T11–L2 segments travelling through the sympathetic chain and hypogastric plexus, and along the pelvic and pudendal nerves and somatic efferents travelling through the pudendal nerves. Sympathetic outflow causes smooth muscle contraction in the seminal vesicles, vas deferens and prostate to deliver seminal fluid to the posterior urethra, and bladder neck contraction to prevent retrograde ejaculation. In women parasympathetic activity causes clitoral erection, engorgement of labia, and vaginal lubrication. In the periphery, the main proerectile transmitter is nitric oxide which is colocalized with vasoactive intestinal peptide and acetylcholine (Rajfer et al., 1992). The same mechanisms are thought to be responsible for clitoral erection and nitric oxide synthetase activity has been demonstrated in nerve fibres within the human glans and corpora cavernosa of the clitoris (Burnett et al., 1997).

Orgasmic sympathetic activity results in rhythmic contractions of uterus, fallopian tubes, and paraurethral glands, and the somatic motor activation in rhythmic contractions of pelvic floor muscles (Berard, 1989; Bohlen et al., 1982). Motor innervation of the pelvic floor muscles as well as the ischiocavernosus and bulbocavernosus muscles is conveyed through pudendal nerve branches from below. However, there is also a motor innervation of the pelvic floor muscles directly from the sacral plexus.

Sensory information from the glans and the skin of the penis and clitoris is conveyed through bilateral branches of the pudendal nerve. The afferents from the root of the penis (and from the anterior part of scrotum) join the ilioinguinal nerve.

The role of the cerebral hemispheres, the brainstem, and even of the spinal cord in controlling human sexual behaviour has not been fully elucidated. The forebrain areas regulate initiation and execution of sexual behaviour; the medial preoptic area integrates sensory and hormonal signals, and the amygdala and other nuclei play a role in the execution and reward aspects of sexual function.

Sexual dysfunction in neurological disease

Cortical lesions

Much remains to be discovered about the cortical control of sexual function, and it is thought that cerebral processing determines libido and desire.

Animal experiments have shown that the limbic system is important for sexual responses, and the medial preoptic hypothalamic area has an integrating function. Observations of patients with brain lesions indicate that temporal or frontal disease may cause disturbances in sexuality.

Head injuries

Disability, cognitive impairment and personality change may occur often after a traumatic brain injury, and be accompanied by sexual dysfunction either as a consequence of the cerebral lesion or as a consequence of psychological factors (Elliott & Biever, 1996). In a group of patients with closed head injury admitted for 24 hours or more, an incidence of significant sexual dysfunction in 50% over a 15 years time span was found (O'Carroll et al., 1991). Decreased and increased sexual desire, erectile failure, and retarded ejaculation have been reported (Kreutzer & Zasler, 1989; Meyer, 1955). Lesions of the frontal and temporal lobe seem to result more often in sexual problems than do lesions of the parieto-occipital part of the brain. Hypersexuality, disinhibited and inappropriate sexual behaviour, and changes in sexual preference have been reported with basal frontal and limbic brain injury (Miller et al., 1986).

Cerebrovascular disease

One measure of sexual impairment following stroke is decline in frequency of intercourse. In some studies about 75% of patients who were sexually active before the stroke reported an abrupt and permanent decrease in coital frequency (Boldrini et al., 1991). Furthermore, the majority of men (50–65%) have erectile dysfunction after a stroke (Monga et al., 1986a; Boldrini et al., 1991) and orgasmic dysfunction after stroke is common in men. Whereas 88% of men were able to ejaculate before stroke, only 29% could achieve this afterwards in one study (Bray et al., 1981). However, in another study both erections and ejaculation returned to approximately 60% of men 8 months after the stroke (Boldrini et al., 1991).

Hypersexuality has also been reported after stroke, associated with temporal lobe damage and seizures (Monga et al., 1986b). An overall change in sexual life is reported more frequently by men but changes also occur in women after stroke. In one study 63% of women reported normal vaginal lubrication before, but only 29% did so after the stroke. Similarly only 34% failed to achieve orgasm before stroke, but 77% did so afterwards (Monga et al., 1986a). However, in another study, only one-third of women who

remained sexually active after a stroke suffered a decline in ability to achieve orgasm (Boldrini et al., 1991).

Epilepsy

Sexual dysfunction

It has long been known that epilepsy is associated with sexual problems, more so in men than women. Various types of abnormal behaviour, more commonly hyposexuality, but also hypersexuality, are reported, particularly in temporal lobe epilepsy (Shukla et al., 1979) and basal–medial frontal lobe lesions. Both men and women with epilepsy often suffer from loss of sexual desire, reduced sexual activity, or inhibited sexual arousal; percentages vary in different studies (Morrell et al., 1994; Guldner & Morrell, 1996). It has been suggested that subclinical hypogonadotrophic hypogonadism is the underlying condition, induced by temporal lobe dysfunction (Murialdo et al., 1995).

However, in some men with temporal lobe damage and epilepsy, desire may be preserved with loss of erectile function (Hierons & Saunders, 1966). Apart from inability to maintain an erection, ejaculatory dysfunction, decreased satisfaction with sexual life, and reduced sexual fantasies, dreams and initiatives have all been reported in patients with complex partial epilepsy and a mesiobasal temporal spike focus (Shukla et al., 1979). Loss of nocturnal tumescence has been reported in such patients (Guldner & Morrell, 1996). Surgery for epilepsy rarely restores function (Blumer & Walker, 1967), and antiepileptic drugs including carbamazepine, phenytoin, and phenobarbitone may influence both sexual desire and performance (Isojärvi et al., 1995).

Basal ganglia

Dopaminergic mechanisms are involved in both inducing penile erection and determining libido. The medial preoptic area of the hypothalamus has been shown to regulate sexual drive in animal studies, with D2 receptors being involved. Patients with Parkinson's disease commonly display decreased sexual desire, and sexual dysfunction is also frequent in their partners (Brown et al., 1990).

Erectile dysfunction (ED) is a considerable problem for patients with Parkinson's disease. In one study, 60% of a group of men with IPD were affected compared with 37.5% of an age-matched healthy group (Singer et al., 1992). ED usually affects men with IPD some years after the onset of neurological disease, whereas in men with MSA, ED may be the first symptom. Further adding to their sexual dysfunction, many men with IPD are also unable to ejaculate or to reach orgasm.

Treatment of Parkinson's disease with dopaminergic compounds may result in an apparent increase, or rather a normalization, of sexual desire (Uitii et al., 1989) without corresponding improvement of the movement disorder. Dopaminergic agonists have been shown to induce erection in animal species, and spontaneous erections have been seen in patients treated with L-dopa. Apomorphine, in both subcutaneous and sublingual preparations, has been reported to increase erectile function in some patients (O'Sullivan & Hughes, 1998). There are also reports of hypersexuality in a proportion of patients treated with anti-Parkinsonian medication (Uitti et al., 1989) and this can be of considerable concern to families looking after these patients.

Erectile failure is almost universal among patients with MSA and in a retrospective study of the duration of symptoms in 46 men clinically diagnosed as suffering from MSA, 96% had erectile dysfunction at the time of diagnosis. Erectile dysfunction alone was the first symptom in 37% but was part of the presenting symptom complex in 59% (Beck et al., 1994). The onset of ED usually predated the onset of other neurological symptoms by several years, many of the men having developed ED in their early 50s or late 40s. The reason for the early selective involvement of erectile function in patients with MSA is not known, but preserved erectile function is a clinical feature which suggests a diagnosis of MSA should be reconsidered. There are insufficient clinical grounds for attributing it to part of a general autonomic failure because symptomatic or laboratory-proven autonomic failure occurred much later in most instances (Kirchhof et al., 2000).

Spinal cord

In men, the level and completeness of spinal cord injury determines sexual function. In high spinal cord lesions, while the ability to have psychogenic erections may be lost, reflexogenic erections should be intact. In theory, a lesion below L2 should leave psychogenic erections intact, but in practice the quality of the erection is often insufficient for intercourse. Psychogenic erections are more likely to be preserved if spinal cord damage at any level is incomplete. With lower spinal cord damage, especially if the cauda equina is involved, there may be little or no erectile capacity.

Estimates of the prevalence of ED in MS vary between 35 and 80% (Mattson et al., 1995; Ghezzi et al., 1996), usually in combination with bladder dysfunction as well. Early in the disease process the initial complaint is of trouble sus-

taining erections, and with advancing disease, erectile function may totally cease. Problems with ejaculation are also common in men with MS, affecting approximately 40% of patients (Valleroy & Kraft, 1984) (Minderhoud et al., 1984). One paper (Vas, 1969) reported that all men with complete ED had lost ejaculation, and one-third of those with partial ED also had ejaculatory problems.

In women with MS, sexual dysfunction is a common problem affecting up to 60% of patients. A decrease in lubrication, altered pelvic sensation and inability to reach orgasm are three of the commoner complaints (Shaughnessy et al., 1997), and fatigue, lower limb spasticity and fear of urinary and bowel incontinence may contribute adversely to the situation. A reduction in sexual desire is also commonly reported.

Over 50% of all SCI men have ED (Bors & Comarr, 1960). Reflexogenic, psychogenic, and mixed erections are well described in SCI men, and the percentage of patients achieving such erections varies in different reports (Beretta et al., 1986; Tsuji et al., 1961; Yarkony, 1990). The level of SCI and the completeness of the lesions may have a bearing on the likelihood of ED, although there is much individual variation and an accurate prognosis for future sexual function in the individual may not be possible.

As well as ED, the ability to ejaculate by masturbation or sexual intercourse is impaired in most men with SCI and, consequently, men with SCI rarely father children without medical intervention (Martinez-Arizala & Brackett, 1994). Reduced fertility cannot be attributed completely to ejaculatory dysfunction because semen obtained from SCI men by methods of assisted ejaculation is of poor quality (Brackett et al., 1998; Sønksen et al., 1999). Ejaculation is generally more likely to be preserved among SCI men with incomplete rather than complete lesions.

Although orgasm has been noted to occur in men with SCI, it may differ in quality compared to before the injury (Alexander et al., 1993). Surprisingly, some women with complete SCI may retain their ability to achieve orgasm possibly because of afferents from cervix travelling with the vagus nerve (Whipple & Komisaruk, 1997).

Sympathetic thoracolumbar outflow

Retroperitoneal lymph node dissection may damage the sympathetic thoracolumbar outflow, which leaves the spinal cord at T10–L2 to pass retroperitoneally and enter the pelvic plexus. Loss of this innervation causes disorders of ejaculation, with the result that there is either no emission, or retrograde ejaculation occurs due to the inability of the normally sympathetically innervated bladder neck to contract. However, nerve sparing approaches in retroperitoneal dissection have been developed with considerable success (Donohue et al., 1990).

Spina bifida

As patients with spina bifida now have increased life expectancy and erectile dysfunction is a common problem, it is now recognized as an important quality of life issue (Joyner et al., 1998).

Cauda equina

Erectile dysfunction is commonly seen in men with cauda equina damage (Bors & Comarr, 1960), and sexual dysfunction in women is also a problem with both genders having a severe problem with loss of genital sensation.

Traumatic cauda equina lesions are generally considered with SCI. A complete lesion of the cauda equina will damage the parasympathetic erectile pathways to the penis. However, approximately one-quarter of men may still be able to achieve an erection psychogenically (Bors & Comarr, 1960). This is thought to be mediated by a sympathetic erectile pathway via the hypogastric plexus. Ejaculatory disturbances, penile sensory loss, and pain syndromes have also been described.

Women report loss of lubrication, dyspareunia, diminished sensation, difficulties in achieving orgasm, as well as changes in the qualities of orgasm. The effects on vaginal lubrication and orgasm are related to the level and completeness of the lesion (Berard, 1989). Patients with incomplete SCI retain the ability for psychogenic genital vasocongestion if pinprick sensation is preserved in the T11–12 segments; only reflexogenic responses are obtained in those with complete SCI (Sipski et al., 1995, 1997).

Peripheral innervation

Diabetic neuropathy

Diabetes is the commonest cause of erectile dysfunction, with this as the underlying diagnosis in approximately 25% of patients attending ED clinics. The prevalence of ED in diabetic men is between 30 and 60% (Kolodny et al., 1979; McCulloch et al., 1980) and is higher in patients with longstanding diabetes and in those who have developed some of the other complications of the disease. Neuropathy may not be the only cause, and both microvascular disease and the effect of formation of advanced glycation end products of neurotransmitters involved may play a role. Retrograde ejaculation may occur in patients who have diabetic cystopathy, due to neuropathy

of the sympathetic nerves supplying the bladder neck (Ellenberg, 1966).

Female sexual dysfunction has been studied to a lesser degree, but studies suggest that diabetic women may also be affected by specific disorders of sexual function, which may include decreased lubrication (Tyrer et al., 1983) and inability to reach orgasm, as well as dyspareunia and vaginal fungal infections.

Immune mediated neuropathies

Autonomic involvement may lead to ED in Guillain–Barré syndrome, and Guillain reported this in his original description.

Pelvic nerve injury

The peripheral autonomic nerves to the genital organs may be injured, for example by surgical procedures, leading to ED or ejaculatory problems in men, and loss of lubrication in women. The sympathetic thoracolumbar fibres may be injured by retroperitoneal lymph node dissections. Pelvic plexus and cavernosal nerves may be injured in surgery, such as by abdominoperineal resection of carcinoma, hysterectomy, radical prostatectomy, or sphincterotomy. Surgeons are increasingly aware of these possibilities and have developed 'nerve sparing' operations. In the case of radical prostatectomy, prior to development of nerve sparing techniques almost all patients were impotent post-operation. In one series of patients followed up after nerve sparing radical prostatectomy, erectile dysfunction was reported in almost 60% at 18 months (Stanford et al., 2000). ED has also been reported after injection of sclerosing agents to treat hemorrhoids (Bullock, 1997), and subtrigonal injections to treat a hypersensitive bladder (Bennani, 1994).

Investigation of sexual dysfunction in neurologic disease

In many patients with neurological disease and bladder dysfunction, sexual dysfunction often coexists (See Table 56.1). In some patients investigations are contributory, but in the majority a thorough history and clinical examination are sufficient to attribute the dysfunction to the established neurological disease.

History

In patients with sexual dysfunction secondary to neurological disease there are usually other neurological symptoms. The temporal association of sexual dysfunction with onset or progression of their neurological disease is often strong. Depression which may accompany neurological disease may result in sexual dysfunction as well, as may antidepressant medication or a range of other medications including some diuretics, antihypertensives, H2 antagonists, and a high intake of recreational drugs such as alcohol and marijuana. Normal sexual function with a different partner or during differing sexual activities strongly suggest a psychogenic explanation for erectile dysfunction. It is possible for patients with spinal cord disease to have reflexogenic erections from genital stimulation, but be unable to have psychogenic erections and thus preserved nocturnal and early morning erections need not mean that erectile dysfunction has a psychogenic basis.

Clinical examination

Sexual dysfunction has many different possible neurological causes. However there are also a number of non-neurological causes of which the clinician must be aware. In a neurological patient with sexual dysfunction in whom there are no clues from the history as to the underlying diagnosis, it is necessary to perform a full neurological examination, looking for evidence of neurological disease. Because normal sexual function is highly dependent on the integrity of the spinal cord, examination of the lower limbs should be especially thorough. This should include sensation and vibration perception which, if deficient, may indicate an underlying peripheral neuropathy. In cases of cauda equina injury sensation in the saddle area should be tested, as should anal tone. Erectile dysfunction may occur as the first symptom of multiple system atrophy, and early signs of extrapyramidal or cerebellar dysfunction should therefore be carefully sought.

Inspection of the distribution of body hair may indicate if there is an underlying hormonal basis for erectile dysfunction, as may the finding of gynaecomastia. The patient's leg pulses should always be checked to rule out the possibility of peripheral vascular disease as being the underlying cause of the dysfunction, and the patient's blood pressure checked. It should also be remembered that there are several urological causes of erectile dysfunction.

Investigations

Dipstick examination of the urine may reveal glycosuria, indicating that diabetes may be the underlying cause of sexual dysfunction. Routine laboratory tests should be performed, and these should include serum HbA_1C, also to

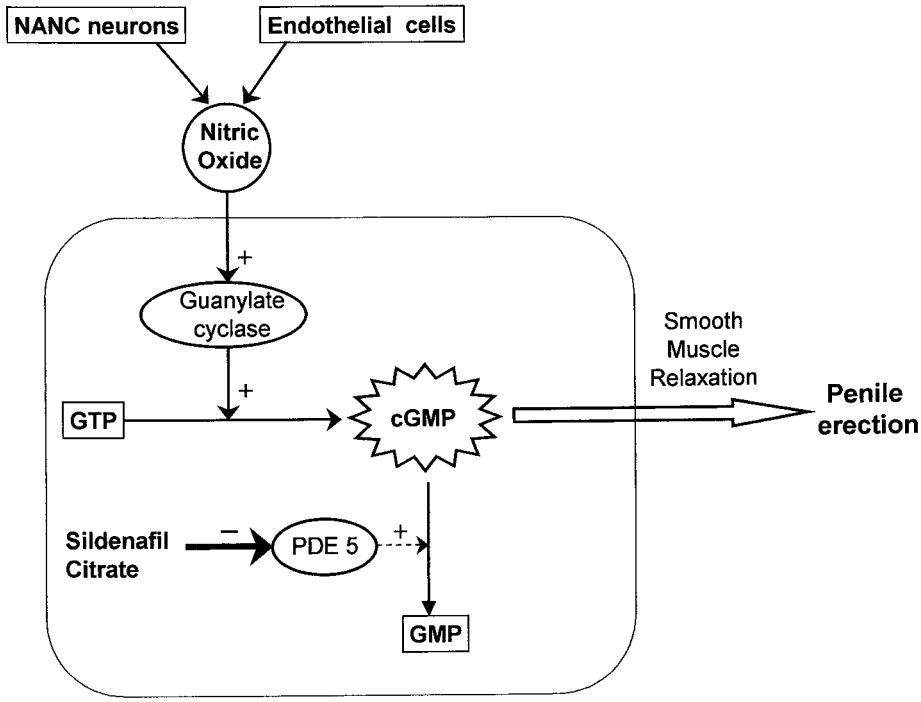

Fig. 56.4. Nitric oxide-cGMP mechanism of corpus cavernosal smooth muscle relaxation and penile erection. Sexual stimulation results in the release of nitric oxide from corporal vascular endothelium and non-adrenergic–non-cholinergic (NANC) neurons. PDE 5 = cGMP-specific phosphodiesterase type 5.

exclude underlying diabetes as a cause, as well as serum testosterone if the history or examination suggest possible hypogonadism. Prolactin should be measured if the serum testosterone is low, or if there is a loss in libido, and LH should be measured if testosterone is low. A hemoglobinopathy screen should be performed in Afro-Caribbean patients, to exclude sickle cell disease, as erectile dysfunction may follow an episode of priapism.

Other investigations, which are really the remit of a urologist with an interest in andrology may include nocturnal penile tumescence monitoring, a Rigiscan which is a home monitoring device capable of continuously monitoring penile circumference and rigidity, or a colour duplex Doppler ultrasound to investigate an underlying vascular cause.

Treatment of sexual dysfunction in neurologic disease

Recent advances in knowledge of the physiology and pharmacology of erection have led to the development of drug treatments by the oral, intracavernous and intraurethral routes. As a last resort, surgical treatment is also possible. Such treatment is available also for neurologically impaired patients.

Oral agents

Since the introduction of sildenafil citrate (Viagra) in 1997, the management of erectile dysfunction has been revolutionized. It is an orally active potent inhibitor of PDE5, thus prolonging the effect of cyclic GMP, increasing the relaxation of smooth muscle in the corpora cavernosa (See Fig. 56.4). In response to sexual stimuli, cavernous nerves and endothelial cells release nitric oxide, which stimulates the formation of cyclic GMP. In turn, this leads to smooth muscle relaxation, and the cGMP is then metabolized by cyclic GMP specific phosphodiesterase type 5 (PDE5). Viagra has been shown to be effective in treating erectile dysfunction of various different etiologies (Goldstein et al., 1998), and has been particularly effective in patients with MS. In one study, 90% of patients reported improvements in erections compared to 24% of those on placebo (Fowler et al., 1999) and had a demonstrable improvement in quality of life (Miller et al., 1999). In addition to MS, it has also been shown to successfully treat ED in men with spinal cord lesions (Guiliano et al., 1999; Schmid et al., 2000). However, the efficacy depended

on sparing of either sacral (S2–S4) or thoracolumbar (T10–L2) spinal segments which, in this study, was shown to be of relevance in mediating psychogenic erections in male SCI patients. Other studies have shown the beneficial effect of sildenafil in patients with spina bifida (Palmer et al., 2000), and Parkinson's Disease (Zesiewicz et al., 2000; Hussain et al., 2000). A note of caution should be sounded, however, in patients with MSA, as profound decreases in blood pressure have been shown following administration of sildenafil in these patients (Hussain et al., 2000).

The use of sildenafil in women with sexual dysfunction secondary to neurological disease is currently an area of research interest. It is believed that the nitric oxide–cGMP pathway which Viagra has been shown to affect so successfully by inhibition of phosphodiesterase type 5 (PDE5) in the male (Fig. 56.4) may be important in the female sexual response, producing clitoral engorgement and vaginal lubrication in the female during sexual stimulation. This may provide a treatment option for women with sexual dysfunction and multiple sclerosis, and trials are currently being undertaken.

Sildenafil is well tolerated with a low side effect profile, which includes headache, flushing and dyspepsia. It is however not suitable for those patients taking nitrates, or patients with severe hepatic disease or hereditary retinal disorders.

Intracavernous injection therapy

Now the most widely used agent for intracavernosal injection therapy is alprostadil, Prostaglandin E1. It is highly effective in treating erectile dysfunction, and produces erections satisfactory for intercourse in 66% of patients self-injecting at home (Godschalk et al., 1994) 94% of the time (Linet & Ogrinc, 1996). It has few contraindications or interactions, is rapidly effective and has high rates of partner satisfaction.

Potential problems with this treatment include the manual dexterity required to give such injections, which is particularly pertinent in a neurological patient population, together with penile pain on injection (Linet & Ogrinc, 1996), and the occurrence of fibrosis, which has reported incidences of up to 20%. There is also a reported incidence of priapism, a urological emergency, of up to 1% (Chew et al., 1997).

Intraurethral therapy

Transurethral therapy with alprostadil (MUSE) has been reported to be effective in the treatment of ED. In a study of over 1500 men with ED of various etiologies, use of MUSE resulted in 65.9% having erections satisfactory for intercourse (Padma-Nathan et al., 1997). However, other reports indicate that this treatment is not very effective, with 63% of men not achieving erections satisfactory for intercourse in one study (Werthman & Rajfer, 1997). Despite this, compared to intracavernosal treatment the risk of priapism is lower, and MUSE may be suitable for patients who have difficulty either in preparing or administering intracavernosal alprostadil. However, it is slower acting than injection therapy, with lower efficacy (Werthman & Rajfer, 1997; Porst, 1997). The reported side effects include mild penile pain and urethral discomfort.

Vacuum devices

A vacuum device consists of an external cylinder which fits over the penis, and then air is pumped out. This results in blood flow into the penis, following which a constriction ring is fitted around the base of the penis to maintain the erection. This type of treatment has a long history; achievement of adequate rigidity for penetration has been reported in 90% of patients with neurogenic ED (Seckin et al., 1996; Denil et al., 1996). The most common complaints are of premature loss of rigidity and difficulty in placing and removing the constriction bands and the most common complications are bruising, petechiae, and skin edema. Severe complications such as penile gangrene, severe erosions, and cellulitis can occur and are associated with prolonged constriction-band wearing (Rivas & Chancellor, 1994).

Penile prostheses

Penile prostheses are semirigid, inflatable or malleable implants that are surgically inserted into the penis to allow an erect state. They are suitable for patients who have an organic basis to their erectile dysfunction who have failed to respond to other treatments. Once placement of a prosthesis is undertaken, other treatments for erectile dysfunction are ruled out. Inflatable prostheses require manual dexterity by the patient or his partner. They allow a flaccid penis when not inflated, which is more practical for everyday life. Most reports in the literature deal with the semirigid type of prosthesis (Evans, 1998). Complications include prosthesis extrusion leading to explantation and prosthesis failure. However this incidence may be higher in neurogenic patients due to the increased risk of erosion because of sensory loss. The biggest disadvantage of this treatment is that it requires an operative procedure, which is invasive and has its own set of potential complications.

Hypothalamic/pituitary function and dysfunction

Roberto Salvatori and Gary S. Wand

Department of Medicine, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

The hypothalamus and pituitary gland are a functional unit forming an interface between the nervous and endocrine systems. The hypothalamic–pituitary axes regulate several endocrine glands (e.g. thyroid, adrenal, and gonad) and many metabolic processes. Abnormalities of the pituitary gland present in three ways. First, a mass within the sella can compress the normal pituitary gland causing varying degrees of hypopituitarism. The spectrum of presentation includes non-specific complaints, slowly progressive constitutional symptoms and acute, life-threatening consequences of hormonal deficiencies. Secondly, an expanding sellar mass can injure continguous structures resulting in visual field abnormalities, diminished acuity, diplopia, headache, and other neurologic symptoms. Thirdly, secretory pituitary adenomas can cause unusual clinical syndromes including acromegaly, Cushing disease, amenorrhea/galactorrhea syndrome or thyroid toxicosis. Sellar abnormalities are also incidentally discovered when radiographic tests are ordered for other reasons. In rare patients, pituitary adenoma is part of the famililal multiple endocrine neoplasia syndrome, Type 1 (MEN 1), which also includes hyperparathyroidism and pancreatic islet cell adenomas.

Hypothalamic disorders (e.g. tumours, infiltrative disease or genetic abnormalities) often affect pituitary function, generally causing panhypopituitarism or monohormonal failure (e.g. Kallman's syndrome causing gonadal failure or growth hormone releasing hormone deficiency causing growth retardation). Less frequently hypothalamic disorders are associated with hyperfunction of the pituitary gland (e.g. precocious puberty).

Normal pituitary function

The pituitary gland receives its blood supply from the superior and inferior hypophysial arteries. The superior hypophysial artery, a branch of the internal carotid artery, forms a capillary plexus surrounding the hypothalamus and infundibulum and drains into the hypophysial–portal system. The hypothalamic releasing and inhibiting factors, which modulate anterior pituitary function, are secreted into this capillary plexus and are carried by the hypophysial–portal circulation to the anterior pituitary, their site of action. Once reaching the anterior pituitary, the hypothalamic releasing and inhibiting factors bind to specific membrane receptors and modulate synthesis, release and sometime posttranslational processing of anterior pituitary hormones. The pituitary gland synthesizes and secretes at least six hormones, and each is under some form of hypothalamic control (Table 57.1). In addition, it is possible for blood to flow retrograde up the infundibulum to the median eminence and thereby provide a route for pituitary hormones to control their own release by positive

Table 57.1. Hypothalamic factors and the pituitary hormones they regulate

Hypothalamic hormones	Anterior pituitary hormones
Growth hormone-releasing hormone (GHRH)	Stimulates growth hormone
Somatostatin	Inhibits growth hormone
Dopamine	Inhibits prolactin
Thyrotropin-releasing hormone (TRH)	Stimulates thyrotropin (TSH)
Corticotropin releasing hormone (CRH)	Stimulates ACTH and other POMC products
Gonadotropin-releasing hormone (GnRH)	Stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH)

and negative feedback mechanisms. The posterior pituitary receives a direct arterial blood supply from the inferior hypophysial artery. This portion of the pituitary does not manufacture hormones but rather is a storage depot for vasopression and oxytocin synthesized in specific hypothalamic nuclei.

Hypothalamic–pituitary–adrenal (HPA) axis

The HPA axis is responsible for generating the glucocorticoid component of the stress response and for stimulating adrenal androgen production. Secretion of ACTH is primarily stimulated by corticotropin-releasing factor (CRH). In response to stress, the hypothalamus secretes CRH, which in turn stimulates the release of ACTH from the pituitary. ACTH is the primary regulator of adrenocortical function and increases cortisol, androgen and to a lesser extent, aldosterone secretion. Cortisol participates in its own regulation through a negative feedback loop inhibiting ACTH at the pituitary level and CRH at the hypothalamus. ACTH secretion has a diurnal cycle, with the highest levels occurring in the early morning before awakening and preceding the early-morning rise in cortisol.

ACTH is 49-amino acid peptide synthesized in the pituitary as part of a larger prohormone, proopiomelanocortin (POMC). POMC is a 265-amino-acid peptide that contains the sequence of ACTH, β-LPH, α-MSH, β-endorphin and other peptides. The endocrine role of ACTH is well understood, but the roles of β-LPH and the other mature peptide derived from POMC precursor are uncertain. The main hypothalamic regulator of ACTH is CRH. This peptide is expressed primarily in the paraventricular nucleus of the hypothalamus. The CRH neurons within the paraventricular nucleus are under regulation by several neurotransmitter systems. Hypothalamic β-endorphin and γ-aminobutyric acid (GABA) inhibit the release of CRH, whereas serotonin and α-adrenergic input stimulates CRH release. Vasopressin (AVP) is co-secreted from paraventricular neurons with CRH and potentiates the action of CRH on ACTH secretion. Angiotensin II, another neuropeptide released during stress, increases ACTH secretion.

Hypothalamic–pituitary–gonadal (HPG) axis

The HPG axis is responsible for maintaining normal gonadal function. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are the main regulators of gonadal steroidogenesis (e.g. estrogen and testosterone). Both hormones are glycoproteins composed of α and β subunits. The β subunits of LH, FSH, TSH, and the placental peptide human chorionic gonadotropin are identical. Immunologic activity for detection of the intact hormone in radioimmunoassys depends on the integrity of the β subunit, whereas biologic activity depends on association of the α and β subunits and appropriate post-translational glycosylation of the subunits.

The decapeptide, gonadotrophin-releasing hormone (GnRH) is the main hypothalamic-stimulating factor for the secretion of LH and FSH. GnRH stimulates the release of both LH and FSH. In turn, LH and FSH stimulate the gonads to produce sex-steroid hormones. Through a sensitive negative feedback loop, estrogen and testosterone participate in their own regulation by inhibiting LH, FSH and GnRH release. The pituitary hormone prolactin (PRL) can also inhibit the release of GnRH accounting for the hypogonadism associated with hypoprolactinemia.

Hypothalamic–pituitary–thyroid (HPT) axis

The HPT axis is responsible for maintaining normal thyroid homeostatis. Thyroid-stimulating hormone (TSH) is a glycoprotein that regulates thyroid gland function. It has a molecular weight of 28 000 and like LH and FSH is composed of two non-covalently linked chains, the α and β subunits. Triiodothyronine (T_3) is the main hormone regulating TSH secretion. Through negative feedback, this thyroid hormone inhibits TSH and hypothalamic thyroid releasing hormone (TRH) synthesis and release. Although some T_3 comes directly from the thyroid, most is derived from the conversion of L-thyroxine (T_4) into T_3 by type II thyroxine 5-deiodinase within the pituitary gland.

The most important peptide regulating TSH is hypothalamic TRH. This simple tripeptide is found throughout the nervous system, but is enriched in TRH-secreting neurons within the median eminence. Like TSH, TRH secretion is inhibited by T3. TRH administration induces a dose-dependent increase in TSH secretion. Although rarely needed, failure of TSH to respond to synthetic TRH is one of the most sensitive clinical tests for hyperthyroidism. TRH can also be used to assess TSH reserve in patients with pituitary disease. In addition to T3 and TRH regulation of TSH, the hypothalamic inhibitory factor, somatostatin, also inhibits TSH secretion.

Somatotroph axis

Somatic growth is regulated by growth hormone (GH), a 21 500 Da protein. Most of the growth promoting effects of GH are mediated through GH-induced release of insulin-like growth factor (IGF-I), a protein made predominantly by the liver but also by other tissues. GH and IGF-I are

required for normal growth and development during childhood. The presence of both factors is necessary for normal adult metabolic processes (e.g. muscle mass, lipid profile, and cognitive function).

Hypothalamic control of GH secretion is mediated by at least two peptides: somatostatin, which inhibits GH and growth hormone-releasing hormone (GHRH), which stimulates GH release. A recently identified third factor, Ghrelin, also stimulates GH secretion (Kojima et al., 1999). The GH inhibiting factor, somatostatin is a 14-amino-acid peptide present in the hypothalamus and distributed widely throughout the human central nervous system. Somatostatin blocks the release of GH induced by exercise, amino acids, and hypoglycemia. Somatostatin is also effective in reducing elevated GH and TSH levels in GH- and TSH secreting pituitary tumours, respectively. In normal humans, dopamine stimulates GH release. In patients with acromegaly (e.g. GH-secreting pituitary tumour), dopamine inhibits GH release. This inhibitory effect of dopaminergic agonists has been exploited in the treatment of acromegaly. Stress, exercise and slow wave sleep induce GH release. In normal individuals, glucose suppresses GH, whereas certain amino acids (e.g. arginine) stimulate GH secretion. In acromegalic patients glucose does not generally suppress GH and often, paradoxically stimulates GH. This difference in GH responses to a carbohydrate load between normals and patients with acromegaly forms the basis for the glucose-GH suppression test, a study employed to diagnosis acromegaly.

Prolactin

Prolactin, a 22 000 Da molecular weight protein, induces breast milk production in the presence of estrogens. In contrast to all other pituitary hormones, prolactin is primarily under inhibitory control by dopamine synthesized within tubero-infundibular neurons of the hypothalamus. In addition, the prohormone for GnRH contains a 56-amino-acid sequence that strongly inhibits the release of prolactin. This peptide is coreleased with GnRH and may serve to reduce prolactin levels.

The rise in prolactin induced by suckling, sleep, stress, and exercise is thought to be mediated through serotonergic input. Endogenous opioids (e.g. endorphin and enkephalins) stimulate prolactin secretion. Moreover, a variety of peptides (e.g. cholecystokinin, vasoactive intestinal polypeptide, neurotensin, and substance P) stimulate prolactin release. However, the physiologic significance of these effects remains uncertain. Estrogen modulates prolactin secretion. It acts on the hypothalamus to regulate dopamine turnover and at the level of the pituitary.

Disorders of the hypothalamic–pituitary unit

Precocious puberty

Precocious puberty results from the activation of the hypothalamic–pituitary–gonadal axis (Lee, 1999). While often observed after the development of a hypothalamic lesion, it can also be idiopathic. Precocious puberty has been described in the setting of various hypothalamic lesions but is most often observed in the presence of hamartomas, teratomas, germinomas and ependymomas. Other types of tumours associated with precocious puberty include optic nerve gliomas, astrocytomas, chorioepitheliomas, and neurofibroma (as part of von Recklinghausen's syndrome). These tumours both synthesize and secrete GnRH or stimulate the hypothalamus to prematurely release GnRH in a pulsatile manner.

Long-acting GnRH analogues are used to treat central precocious puberty because after a brief period of stimulation of LH and FSH, the analogues result in long-term inhibition of LH and FSH (Schally, 1999). GnRH analogues have the advantage of not causing other pituitary dysfunction, and prevent premature closure of the epiphyses (leading to short stature) that can be caused by the gonadal steroids.

McCune–Albright syndrome

The McCune–Albright syndrome is characterized by irregular pigmented areas (e.g. café-au-lait spots) on the trunk and polyostotic fibrous dysplasia of bone (De Sanctis et al., 1999). Precocious puberty and other endocrine hypersecretory syndromes (e.g. acromegaly, hyperthyroidism) can also be manifestations of the disorder. The hypersecretory states seen in McCune–Albright syndrome are the product of a somatic mutation in the Gs alpha gene leading to the constitutive activation of adenylyl cyclase signal transduction. This same mutation also accounts for approximately 30–40% of sporadically occurring GH-secreting pituitary tumours.

Pituitary adenomas

Pituitary adenomas are almost always benign accounting for 90% of sellar lesions and 10% of intracranial neoplasms. Pituitary adenomas are classified as microadenomas if their diameter is less than 1 cm, and macroadenomas if they are 1 cm or larger. This distinction is made because lesions greater than 1 cm often extend out of the sella and injure surrounding structures (e.g. optic chiasm). One can appreciate the potential symptoms (Table 57.2) created by

Table 57.2. Presentations of pituitary tumours

Increased hormone production

GH deficiency
Incidental radiographic detection
Microadenoma
Macroadenoma

an expanding sellar mass by remembering the structures adjacent to the pituitary (Fig. 57.1). As a sellar lesion expands it may induce (i) sign/symptoms of hypopituitarism resulting from compression of the normal pituitary gland; (ii) signs/symptoms secondary to extension of the mass into surrounding structures (e.g. optic chiasm); and (iii) clinical manifestations resulting from excess hormone secretion by the sellar mass. The pituitary gland 'sits' in a cavity, the sella turcica (Turkish saddle). This boney structure surrounds the anterior, ventral (floor) and posterior portions of the pituitary gland. The gland is also attached to hypothalamus by the stalk or infundibulum. However, the pituitary is on the peripheral side of the blood-brain barrier. In the superior direction, the gland is separated from CSF, optic chiasm and hypothalamus by a thin section of dura, the diaphragm sellae. Under normal circumstances, this boundary does not allow CSF to enter the sella turcica. Laterally, the pituitary is separated from both cavernous sinuses by thickened dura. The cavernous sinus contains cranial nerves III, IV, VI and the first two divisions of cranial nerve V. The carotid artery passes through the cavernous sinus and parasympathetic nerves inducing pupillary constriction ride on the surface of the carotids within the cavernous sinus. Below the floor of the sella is the sphenoid sinus.

Similar to any mass within a closed space, the expanding pituitary adenoma usually takes the path of least resistance, which is the superior direction. The lesion may compress the normal pituitary cells and induce various degrees of hypopituitarism (e.g. hypothyroidism, hypogonadism, adrenal insufficiency and GH deficiency). The mass can also stretch the diaphragm sella and induce dull frontal headaches. If the lesion continues to expand in the superior direction, it will compress the optic chiasm causing visual abnormalities. Loss of vision can be the sole presenting symptom of pituitary adenoma. The subtlest visual abnormality is colour desaturation in the superior temporal fields, caused by compression of the medial inferior portion of the optic chiasm. However, some patients describe their vision as dim or foggy, or feel as though they have a veil over their eyes. Many patients have only vague complaints, like loss of depth perception. Some are unaware of their visual loss because peripheral vision is typically affected first. However, they may acknowledge problems with driving, which requires peripheral vision, or may complain that they are bumping into furniture or other people. If the tumour continues to grow, patients may suffer bitemporal hemianopia, optic atrophy, and loss of visual acuity. Papilledema is rare. In a few patients, an expanding tumour impinges on the hypothalamus, disturbing consciousness or temperature regulation, or causing hyperphagia. Tumour obstructing the third ventricle and cerebrospinal fluid flow can lead to hydrocephalus.

Less commonly the tumour will erode through the floor of the sella or into either cavernous sinus. Cavernous sinus invasion can result in injury to cranial nerves III, IV, V, and VI causing diplopia, ophthalmoplegias or facial numbness. Compression of the carotid artery may cause pupillary dilatation by injury to parasympathetic nerves on the surface of the vessel. Lastly, pituitary adenomas may cause a variety of syndromes secondary to excess hormone secretion.

Prolactin-searching and non-functional adenomas are the most common pituitary lesions. Less common are growth hormone-secreting adenomas, mixed prolactin- and growth hormone-secreting adenomas, ACTH secreting adenomas, and gonadotropin-secreting adenomas. Rare adenomas secrete TSH.

Prolactin-secreting adenomas and hyperprolactinemia

Patients with prolactin-secreting pituitary adenomas present with complaints resulting from the hormonal consequences of hyperprolactinemia and/or from tumour expansion (Molitch, 1995). The most common symptom is galactorrhea (non-puerperal lactation). However, this complaint is non-specific, affecting upwards of 20% of all previously pregnant premenopausal women. Most hyperprolactinemica women also have irregular menses. In fact,

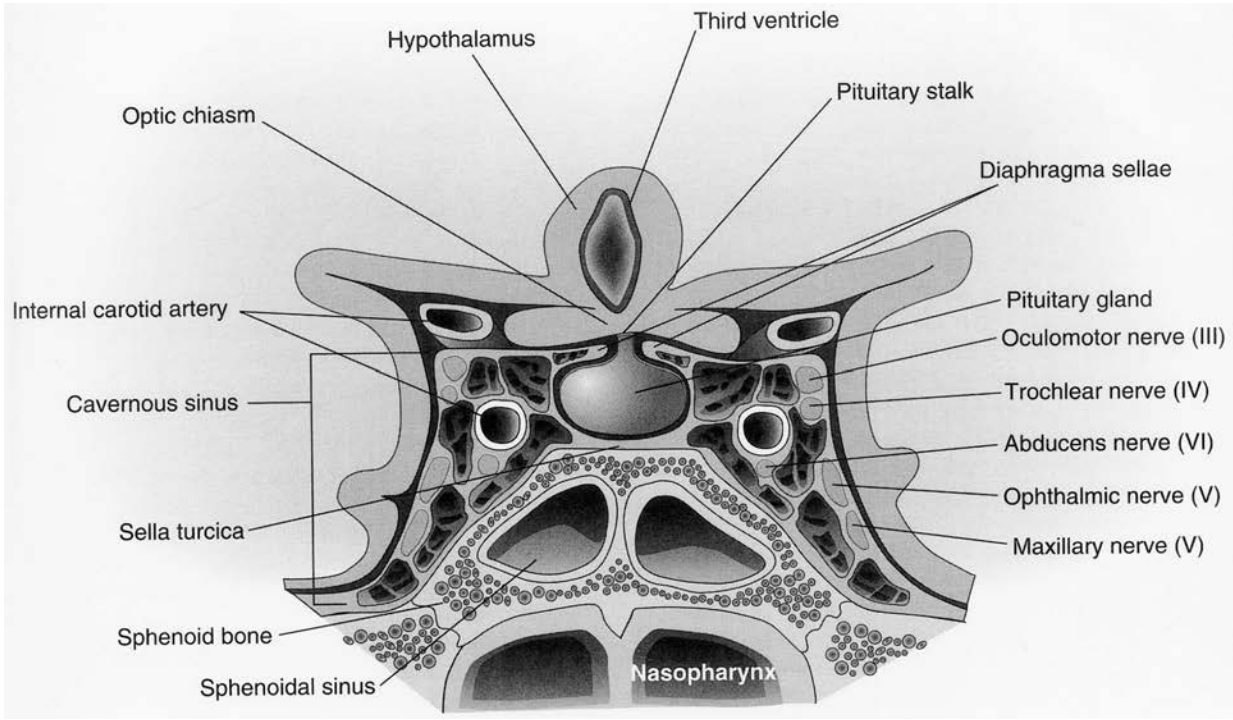

Fig. 57.1. Anatomy of the sellar region. (From Ward, 1996.)

15% of women presenting for evaluation of amenorrhea, 25% with galactorrhea, 35% with infertility and 75% with amenorrhea and galactorrhea have hyperprolactinemia. The prevalence of prolactinoma is approximately 5 cases per 10 000.

While menstrual dysfunction often leads women to seek medical help and permits early detection of prolactin-secreting adenomas, men less frequently complain to physicians about their core symptoms of hyperprolactinemia: impotence and decreased libido. At the time of diagnosis, men's tumours tend to be larger than women's. Hyperprolactinemia suppresses GnRH and therefore plasma LH and FSH levels, resulting in low circulating gonadal steroids causing diminished libido and vasomotor flushing in either sex. Relatively few men present with galactorrhea and gynecomastia.

It is important to consider physiologic and other pathologic causes of hyperprolactinemia and not assume that an elevated prolactin is always associated with prolactinoma (Table 57.3). The most common cause of hyperprolactinemia in women is pregnancy. Other important causes of hyperprolactinemia are (i) sellar or suprasellar lesions that block dopamine transport from hypothalamus to the pituitary (e.g. hypothalamic glioma, craniopharyngioma, and large non-functioning pituitary adenomas); (ii) medications that deplete dopamine synthesis or block the D2-dopamine receptor (e.g. phenothiazines, Reglan^{R}) (iii) kidney failure; and (iv) liver failure. In rare patients, severe primary hypothyroidism causes hyperprolactinemia. In this setting hypothyroidism may mimic a prolactin-secreting pituitary tumour by causing amenorrhea, galactorrhea, and even sellar enlargement due to thyrotropin-secreting cell hypertrophy. A TSH level should be checked in all patients with hyperprolactinemia to exclude primary hypothyroidism. In some patients, hyperprolactinemia is caused by chest wall injury or irritation (e.g. herpes zoster), which activate the neurologic circuitry responsible for elevations in prolactin induced by suckling.

Serum prolactin levels usually distinguish prolactin-secreting macroadenomas from other causes of hyperprolactinemia. Most prolactin-secreting macroadenomas produce serum prolactin levels above 250 ng/ml. Prolactin levels in microadenomas and other hyperprolactinemic disorders are generally lower.

Medical intervention with a dopamine agonist is first line treatment of prolactinoma regardless of size. Cabergoline (Dostinex^{R}) and bromocriptine (Parlodel^{R}) are the most frequently used dopamine agonists in this setting. Dopamine agonists normalize serum prolactin level in more than 90% of patients with microadenomas

Table 57.3. Causes of hyperprolactinemia

Physiologic
Pregnancy
Suckling
Exercise
Sleep
Postprandial
Pathologic
Prolactin-secreting tumours
Lesions interfering with hypothalamic dopaminergic tone
Hypothalamic diseases, e.g. sarcoidosis, tumour

Catecholamine-depleting drugs, e.g. reserpine
Certain other intravenous drugs, e.g. cimetidine, verapamil

and 75% with macroadenomas. In both sexes, unless the tumour has destroyed the gonadotroph cells, both drugs reverse the hypogonadotropic hypogonadism that accompanies hyperprolactinemia. By reversing hypogonadism, medical therapy can halt or partially reverse decreased bone mineralization associated with hyperprolactinemia (Schlechte et al., 1992). In women, estrogen deficiency and galactorrhea production stops. This is accompanied by a return in ovulatory menstrual cycles. In men, normalization in prolactin is accompanied by a return of serum testosterone into the normal range. This is followed by restoration of libido, potency, spermatogenesis and fertility.

Importantly, dopamine agonists significantly shrink more than two-thirds of prolactin-secreting tumours. In most cases the drug needs to be taken indefinitely. The most common side effects are nausea, dizziness, nasal congestion and headache. In most cases, the side effects will abate after several weeks of therapy. In cases where tumours are resistant to dopamine agonists or the patient cannot tolerate medical intervention, transphenoidal surgery should be considered. However, the surgical cure rate is 50% for microadenomas and less than that for macroadenomas. Radiation therapy is efficacious in preventing tumour growth but is not effective in normalizing the serum prolactin level.

Special consideration should be given to women with prolactinomas that become pregnant during medical therapy (Molitch, 1998). Under the influence of high estrogen levels, prolactinomas grow during pregnancy. Upward of 30% of macroadenomas and a small subset of microadenomas will grow to the extent that hypopituitarism or neurological defects occur. For this reason, most endocrinologists maintain macroadenoma patients on bromocriptine during pregnancy. Retrospective studies have strongly suggested that bromocriptine is not teratogenic nor does it induce spontaneous abortion. The safety of cabergoline during pregnancy has not been established at the time of this writing.

Growth hormone-secreting adenomas and acromegaly

Acromegaly is a syndrome caused by GH-secreting pituitary tumours (Klibanski & Zervas, 1991). The prevalence of acromegaly is approximately 7 cases per 100000. Acromegaly is easy to diagnose when the manifestations are severe, but more often, there is a considerable delay between disease onset and diagnosis. This is because GH-induced changes in appearance occur insidiously and these subtle alterations evolve gradually over time. Indeed, family members and physicians often do not notice the gradual change in appearance. It has been estimated that, on average, 8 years separate the time of diagnosis from the onset of the syndrome. It is helpful for physicians to review old photographs of the patient. Unfortunately, by the time most GH secreting tumours are discovered, they are larger than 1 cm (e.g. macroadenoma) and have already caused local compressive effects. Moreover, the larger tumours are more difficult to cure.

Although 99% of acromegaly results from GH-secreting pituitary tumours, if a pituitary tumour is not identified by MRI, the physician must consider other causes. For example, eutopic overproduction of growth hormone-releasing hormone by the hypothalamus or ectopic production of this hormone by a peripheral tumour (e.g. islet cell tumour) can cause excess GH secretion and the syndrome of acromegaly.

Acromegalic patients first develop soft-tissue hypertrophy causing a generalized coarsening of the facial features, thickening of lips, tongue (macroglossia), ear lobes and skin (Table 57.4). Malodorous hyperhidrosis is an early symptom. With time, undiagnosed patients may complain of increasing ring, glove or shoe size resulting from enlargement of hands and feet. They may also develop a

Table 57.4. Common clinical features of acromegaly

Hypertrichosis

deepening voice (hypertrophy of the vocal cords), snoring, sleep apnea, carpal tunnel syndrome and organomegaly. Approximately 40% of growth hormone-secreting tumours also secrete prolactin and therefore patients may complain of breast secretion (galactorrhea). Over time significant boney changes occur resulting in arthritis, enlargement of the mandible (prognathism), wide spacing of the teeth, and hypertrophy of the frontal sinuses (frontal bossing). Metabolic abnormalities can include glucose intolerance, hypertension, hyperphosphatemia and hypercalciuria. If acromegaly begins prior to closure of the epiphyseal growth plates, then excess growth hormone secretion will result in gigantism.

Because GH is secreted in pulses, a single serum growth hormone determination is not an accurate indicator of acromegaly unless markedly elevated. Glucose challenge testing is more reliable. In normal people, 50–100 grams of glucose suppresses GH to undetectable levels; acromegalics typically have either inadequate suppression or a paradoxical rise in GH following a carbohydrate load. Insulin-like growth factor I (IGF-I) synthesized in the liver, is a major mediator of growth hormone action. This protein has a long plasma half-life and is not secreted in a pulsatile manner. Therefore a single elevated plasma IGF-I determination can also be diagnostic, although elevations are found in some normal young adults.

Growth hormone-secreting tumours are usually first treated surgically, by transphenoidal resection through the nasal cavity and sphenoid sinus (Laws & Thapar, 1999). In the hands of an experienced neurosurgeon, approximately 80–90% of microadenomas and 20–50% of macroadenomas are cured. Similar to transphenoidal surgery for any pituitary tumour, fewer than 5% of acromegalics will develop hemorrhage, infection, cerebrospinal fluid leak or injury to the anterior pituitary. However, transient diabetes insipidus occurs in about 25% of patients with permanent diabetes insipidus in fewer than 3%.

Recent studies have established new guidelines for defining cure of this syndrome. These guidelines were revised following reports showing that treated acromegalics still have two- to three-fold higher incidence of mortality compared to the general population unless serum GH levels are 1 μg or less and the IGF-I levels are in the normal range. Patients who still have elevated GH or IGF-I levels after surgery should be given a trial of a somatostatin analogue. Somatostatin analogs (e.g. Octreotide^{R}) normalize growth hormone levels in about two-thirds of patients and occasionally induce tumour shrinkage. Dopamine agonists also have some efficacy. Pegvisomant, a newly developed GH receptor antagonist, is a promising therapy for patients who had unsuccessful surgery (Trainer et al., 2000).

When patients are not cured by medical and surgical therapy, the remaining option is radiation therapy. However, conventional radiation may take 2–5 years to work, it does not cure all patients, and in 30–50% of patients it induces hypopituitarism. Radiotherapy for Acromegaly is often combined with medical treatment. All patients need periodic follow-up of their pituitary function. Ongoing studies are evaluating the efficacy of gamma knife radiation in the treatment of Acromegaly (Jackson & Noren, 1999).

ACTH-secreting adenomas and Cushing disease

Cushing syndrome results from hypercortisolism from any source: ACTH-secreting pituitary adenomas, ectopic production of ACTH by peripheral tumours, autonomies, cortisol secreting adrenal adenomas and autominously administered corticosteroids (Table 57.5). Cushing disease specifically defines hypercortisolism caused by an ACTH-secreting pituitary adenoma. It has a prevalence of approximately 4 cases per 100 000. Cushing disease accounts for approximately 80% of all causes of endogenous Cushing syndrome (Aron & Tyrrell, 1994). The ACTH-secreting pituitary tumour most often afflicts women in their childbearing years. Signs and symptoms include truncal obesity, cervicodorsal fat pad (buffalo hump), moon facies, plethora, purple striae, proximal muscle wasting and weakness, easy bruising, amenorrhea, psychiatric disturbances, and hirsutism (Table 57.6). Many ACTH-secreting pituitary adenomas are less than 0.5 cm in diameter and up to 70% cannot be visualized by MRI.

The diagnosis of Cushing syndrome requires the patient to undergo a low dose dexamethasone suppression test;

Table 57.5. Causes of Cushing's syndrome

Striae
Proximal muscle weakness
Osteoporosis
Easy bruisability
Psychiatric disturbance

the details of which are beyond the scope of this text. Once Cushing syndrome is firmly established, the diagnosis of Cushing disease is made by performing the high dose dexamethasone. Inferior petrosal sinus sampling can be used to diagnosis of Cushing disease, when results from the high dose suppression tests are ambiguous and there is no evidence of a pituitary lesion on MRI.

First-line therapy of Cushing's disease is transphenoidal resection of the tumour, curing upwards of 80% of patients. The remainder can be given a combination of pituitary radiation and 'medical adrenalectomy' with one or more drugs that inhibit adrenal glucocorticoid biosynthesis, for example, Ketoconazole^{R}, metyrapone, aminoglutethimide, Trilostane^{R}, and o,p-DDD. However, none of these agents easily normalizes glucocorticoid secretion, and all have side effects. By 5 years, radiotherapy cures only 50% of adults, but more than 50% of children.

If pituitary surgery, radiotherapy, and medical therapy fail to control hypercortisolism, the last option is bilateral adrenalectomy. This commits patients to lifelong glucocorticoid and mineralocorticoid replacement. About 10% of patients who undergo bilateral adrenalectomy develop Nelson's syndrome, which is a progressive enlargement of the pituitary tumour, hyperpigmentation, and very high plasma ACTH levels unleashed by loss of cortisol-negative feedback. Such tumours can be aggressive and difficult to cure. Tumours causing Nelson's syndrome can be detected radiographically as well as by extremely high ACTH levels. All patients who have undergone bilateral adrenalectomy should be monitored closely.

Gonadotroph-secreting tumours

Many pituitary tumours secrete immunoreactive LH and/or FSH (Snyder, 1995). At the time of diagnosis, most are large and cause local compressive symptoms. Typical patients present with hypogonadism despite their high serum FSH or LH levels, because the hormones produced by the tumour have reduced biological activity. The gonadotroph tumour does not respond to medical therapy and is managed with surgery followed by radiotherapy if a significant tumour remnant remains.

TSH-secreting tumours

The least common pituitary adenomas secrete TSH and usually cause hyperthyroidism (Mindermann & Wilson, 1993). Unlike typical patients with primary hyperthyroidism, for example, from Graves' disease, in whom circulating TSH levels are undetectable, patients with hyperthyroidism from TSH-secreting adenomas have either elevated or inappropriately normal serum TSH levels (inappropriate secretion of thyroid hormone) at the same time that they have high serum T4 and T3 levels. Most TSH-secreting adenomas are managed with surgery; many patients also need antithyroid drugs and radioactive iodine. Somatostatin analogues have been shown to reduce TSH secretion from these tumours.

A cause of inappropriate TSH secretion that is not associated with a pituitary adenoma is the thyroid hormone resistance syndrome, a rare genetic disorder (Refetoff, 1996). When thyroid hormone resistance is more pronounced in the pituitary gland compared to peripheral tissues, patients have an appropriate elevation in TSH and are either euthyroid or hyperthyroid. However, when thyroid hormone resistance exists in the periphery and in the pituitary gland, patients present

with unsuppressed TSH levels and features of hypothyroidism.

Non-functional pituitary tumours

Approximately 40% of pituitary adenomas are classified as non-functional because they produce no clinical syndrome resulting from hormone excess (Shimon & Melmed, 1998). However, the majority of non-functional adenomas do synthesize and secrete hormones, albeit at low levels. These tumours are managed with surgery followed by ratiotherapy if a significant tumour remnant remains. Medical therapy is not effective.

Pituitary incidentalomas

Pituitary adenomas that cause symptoms resulting from mass effect or hormone hypersecretion are uncommon. The prevalence of these lesions is approximately 20 cases per 100 000. However, clinicians are increasingly encountering incidental pituitary adenomas on CT and MRI scanning (Aron & Howell, 2000). The prevalence of pituitary incidentalomas found by CT ranges from 4% to 20%, and the prevalence found by MR imaging is approximately 10% (Katzman et al., 1999).

Given the high incidence of incidentalomas and the low incidence of potentially problematic lesions, an assessment algorithm would be helpful. Unfortunately, the optimal strategy for assessing patients with incidental adenomas has not been established. However, it has been suggested that any patient with an incidentaloma and clinical signs or symptoms suggestive of hormone hypersecretion should undergo appropriate testing as described above. Also, the asymptomatic patient with an incidentally discovered microadenoma should undergo limited hormonal testing. Most neuroendocrinologists would recommend that at least a serum prolactin be obtained. Evaluation of subclinical growth hormone or ACTH excess is not recommended in the absence of any signs or symptoms of these disorders. However, these patients require follow-up and if signs or symptoms of pituitary disease emerge, further evaluation is warranted.

In the presence of an incidentally discovered non-functional macroadenoma, some degree of hypopituitarism is not uncommon. Therefore, hormonal screening is suggested to detect potential deficiency of ACTH, TSH, GH, and gonadotropins. Patients with syndromes of hormonal excess should receive specific therapy as detailed below. These patients require formal visual field testing. Patient with evidence of visual field defects or cranial nerve injury should undergo surgery. For patients with non-functional macroadenomas and no signs of visual abnormalities or hypopituitarism, optimal management is unclear. If the lesion is abutting the optic chiasm, surgery is strongly suggested. If the lesion does not extend into the suprasellar cistern a 'watch and wait' approach is reasonable. However, evidence of tumour growth or hypopituitarism should result in surgical intervention. If there is no evidence of growth of the lesion, the time period between scans can be lengthened.

Empty sella syndrome

The empty sella syndrome is a symmetric enlargement of the sella turcica caused by invagination of the diaphgram sella by CSF, putting pressure on adjacent bone, and compressing the pituitary gland towards the floor of the sella (Vance, 1997). In spite of this pressure, pituitary function is generally normal, although hyperprolactinemia or some degree of hypopituitarism is observed approximately 5% of the time. The empty sella syndrome most often affects obese hypertensive women. It is also seen following pituitary apoplexy and rarely in patients with neurosarcoidosis. MRI of the sella can distinguish it from a pituitary tumour. Empty sella must be distinguished from a Rathke's cleft cyst since the former is never treated surgically whereas enlarging pituitary cysts may require surgical intervention.

Other sellar lesions

In addition to pituitary adenomas, the sellar and suprasellar regions can harbour other types of neoplasm (Albrecht et al., 1995). Craniopharyngiomas are squamous epithelial tumours that arise from the upper part of the pituitary stalk, hypothalamus or third ventricle (Hayward, 1999). They are partly cystic and the cysts often contain a viscous fluid. These lesions have a peak incidence in childhood but can occur any time in life. The craniopharyngioma is treated by surgery, often requiring craniotomy. Other hypothalamic lesions that can alter pituitary function include hamartomas, teratomas, germinomas, ependymomas, gliomas, astrocytomas, chorioepitheliomas and neurofibroma. Metastases from breast and lung cancers, lymphoma, and melanoma are other uncommon hypothalamic and pituitary lesions affecting pituitary function.

Rarely, autoimmune, infiltrative, and infectious diseases involve the pituitary, sometimes mimicking a tumour. Lymphocytic hypophysitis predominantly affects young women in late pregnancy or postpartum, and is thought to have an autoimmune pathogenesis (Beressi et al., 1999).

Infiltrative and infectious processes that can damage the hypothalamus and pituitary include sarcoidosis, Langerhans' histiocytosis, and tuberculosis.

Hypopituitarism

There are numerous causes and various ways patients present with hypopituitarism. Pituitary dysfunction can occur gradually with insidious symptoms or suddenly with a catastrophic event. The most frequent causes of hypopituitarism are listed in Table 57.7. As the posterior pituitary only functions as a storehouse for ADH and oxytocin, the presence of diabetes insipidus usually indicates the involvement of the hypothalamus in the pathological process (Freda & Post, 1999).

Presenting signs and symptoms

Injury to LH- and FSH-secreting cells causes secondary ('central') hypogonadism. In children, this delays or prevents puberty. In adult men, it causes impotence, decreased libido, and infertility. In women, it leads to menstrual irregularities, amenorrhea, infertility, hot flushes, decreased libido, vaginal dryness, and dyspareunia. Deficient prolactin secretion makes women unable to lactate postpartum.

Injury to ACTH-secreting cells causes secondary adrenal insufficiency. Many patients complain of weight loss, anorexia, nausea, weakness, arthralgia, and myalgia. The degree of adrenal insufficiency is often milder than observed in patients with primary adrenal failure, and it is not unusual to observe symptoms only during times of physical stress, when the cortisol requirements are higher (Oelkers, 1996). Decreased adrenal androgen production diminishes women's axillary and pubic hair. Patients with secondary adrenal insufficiency do not have hyperpigmentation, which is a common feature of primary adrenal insufficiency. Further, since ACTH is not the primary regulator of the mineralocorticoid axis, patients with secondary insufficiency do not have extracellular fluid volume depletion and hyperkalemia, which are often seen in primary adrenal insufficiency. Many patients do have hyponatremia; this is caused by impaired renal free water clearance, which is dependent on glucocorticoid action, and by the frequent co-existence of central hypothyroidism. Patients are typically sensitive to infection and other stresses, which can quickly precipitate hypoglycemia, hypotension, circulatory collapse, and death.

The most frequent cause of secondary adrenal insufficiency is long-term exposure to exogenous glucocorticoids, which may last for several months after glucocorticoids are discontinued. Every patient who has been treated with supraphysiological doses of glucocorticoids for 3 weeks or longer needs to be suspected to be adrenal insufficient (Krasner, 1999).

Injury to TSH-secreting cells causes secondary hypothyroidism. Symptoms include fatigue, cold intolerance, dry skin, constipation, weight gain, impaired mentation, and menstrual irregularities in women. These manifestations resemble those of primary hypothyroidism, but are usually less severe.

Growth hormone deficiency impairs skeletal growth if the epiphyses have not fused. Infants with GH deficiency

are prone to hypoglycemia. Growth hormone-deficient adults can lose muscle mass and strength, have reduced bone mineral density, increased adipose mass, hypercholesterolemia and reduced sensation of well being, often associated with emotional lability and feelings of social isolation (Carrol & Christ, 1998). Treatment with recombinant GH at a dose sufficient to normalize IGF-1 has been proven to improve all the above changes (Gibney et al., 1999).

Diagnosis of hypopituitarism

When a patient develops pituitary failure from compression by a sellar mass, the first anterior pituitary hormone to fail is usually GH, followed by LH and FSH, TSH and ACTH. However, especially in the case of radiation-induced-hypopituitarism, this order can be inverted, and it is not unusual to observe isolated deficit of TSH or ACTH.

If a patient is diagnosed with partial or complete hypopituitarism secondary to a pituitary macroadenoma, hormonal function needs to be reassessed after neurosurgical treatment, as it may improve or worsen postoperatively (Webb et al., 1999).

In evaluation of a patient with suspected hypopituitarism, the physician must identify the patient's hormone deficiencies and determine whether they are caused by pituitary failure (secondary, 'central' hormone deficiencies) or target gland dysfunction (primary, 'peripheral' hormone deficiencies). Levels of target gland hormones – T4, cortisol, and estradiol or testosterone – can be low in both primary and secondary endocrine disorders. Distinguishing between peripheral and central failure depends, then, on the level of the pituitary trophic hormone. For example, T4 levels are low in both primary and secondary hypothyroidism, so one must look to the pituitary trophic hormone, TSH. In primary hypothyroidism, diminished negative feedback causes the TSH to be high, while in secondary hypothyroidism, pituitary injury makes the TSH either low or inappropriately normal. Analogous patterns allow the physician to distinguish between primary and secondary adrenal insufficiency and between primary and secondary hypogonadism.

In addition to a careful history and physical examination, evaluation of patients with a possible sellar lesion usually requires a focused hormone assessment, imaging studies, and visual field analysis.

Suspected GH deficiency in children

Growth failure is particularly suspicious when a deflection in growth velocity is observed in a child with previously normal growth curve. Several systemic diseases can also cause growth failure. Therefore, renal failure, malabsorption or hypothyroidism, need to be ruled out before GH secretion is evaluated.

GH deficiency can be isolated or part of multihormonal pituitary failure. Isolated GH deficiency in children manifests itself as growth failure and may be caused by any hypothalamic or pituitary disease. However, structural abnormalities are evident via MRI only in 12.5% of children affected by isolated GH deficiency (Cacciari et al., 1990). Genetic abnormalities (mutations in the GH gene or the GHRH-receptor gene) are present only in a minority of patients, leaving the vast majority classified as idiopathic. The clinical presentation includes growth failure, abdominal fat accumulation and delayed bone age. Several genetic syndromes (such as Turner syndrome, Silver Russel syndrome or Noonan syndrome) also present with short stature, and a careful physical examination in search of dysmorphic characters needs to be performed. Insulin-like growth factor-1 (IGF-1) is produced by the liver under the influence of GH and mediates most of the effects of GH. It circulates as a ternary complex bound to IGF-binding protein 3 (IGF-BP3) and to the acid labile subunit (ALS), whose synthesis is also under control of GH. Therefore, an indirect evidence of GH deficiency may be provided by measurement of serum IGF-1 or IGF-BP3 levels (ALS is not routinely used at the present time). However, confirmation of GH deficiency needs to be obtained via one of the many stimulation tests (insulin-induced hypoglycemia, GHRH, arginine, L-dopa, clonidine or combinations of the above) (Vance & Mauras, 1999). Although the cutoff of normal response is debated, usually a peak value below 7 ng/ml is considered diagnostic of GH deficiency. As each one of these tests has false positives, it is preferable to confirm GH deficiency with two tests before committing a child to a long and expensive injectable therapy.

Suspected GH deficiency in adults

The vast majority of adults with GH deficiency have overt pituitary disease. Among patients with pituitary tumours, those with deficiency in other hormones are very likely to be GH deficient. The likelihood of GH deficiency is close to 100% in a patient with deficit of gonadotropins, TSH and ACTH. Adults with a history of childhood onset isolated GH deficiency need to be retested, as more than 50% have normal GH secretion when retested as adults (Tauber et al., 1997). Serum IGF-1 and IGFBP3 levels are not reliable in diagnosing GH deficiency in adult, particularly in older patients, as a large overlap exists between subjects with normal and abnormal GH secretory reserve. Stimulation tests are often needed: insulin-induced hypoglycemia is the 'gold standard' in adults as well (except for patients

with known or suspected coronary artery disease and in patients with history of seizures). Alternatively, arginine, GHRH or GHRH plus arginine or clonidine can be used. At present, as the long term side effects of GH therapy in adults are not known, it is recommended that only patients with severe GH deficiency (peak GH after insulin <3 ng/ml) be treated (Bengtsson et al., 2000). The usual starting dose is 3–4 mcg/kg/day for males and 4–5 μg/kg/day for females. Side effects are usually dose dependent, limited to edema and arthralgia or myalgia. Absolute contraindications to GH treatment are active malignancy, proliferative or preproliferative diabetic retinopathy and benign intracranial hypertension (Growth Hormone Research Society, 1998).

Suspected secondary adrenal insufficiency

A basal morning cortisol is generally not a useful screening test for adrenal insufficiency, unless the level is above 20 μg/dl (indicating normal HPA axis) or below 3 μg/dl during the morning hours (indicating adrenal insufficiency). Therefore, most patients need to have a dynamic test. The available tests are the ITT, the overnight metyrapone test, the CRF tests and the ACTH tests.

The insulin tolerance test is the gold standard for diagnosing secondary adrenal insufficiency because it assesses the integrity of the entire hypothalamic–pituitary–adrenal (HPA) axis (Abdu et al., 1999). It has the additional advantage of simultaneously testing GH reserve when needed. It is, however, dangerous in patients above 60, or with history of seizures or known or suspected coronary artery disease.

The metyrapone test is an accurate way to diagnose acute secondary adrenal insufficiency as it evaluates both the pituitary and the adrenal cortex. It takes advantage of the ability of metyrapone to reduce serum cortisol by blocking the enzyme 11-beta-hydroxylase, which catalyses the last step in cortisol biosynthesis. Metyrapone (30 mg/kg; maximal dose 3 gm) is given at midnight and a single blood sample is drawn at 8 am the following morning. When cortisol synthesis is inhibited, a normal pituitary responds by secreting more ACTH, thereby raising plasma levels of 11-deoxycortisol, the immediate precursor to cortisol, above 7.5 μg/dl. Patients with secondary adrenal insufficiency have blunted ACTH and 11-deoxycortisol responses. This test needs to be performed with overnight hospitalization because of the theoretical risk of inducing an adrenal crisis (Fiad et al., 1994).

The rapid ACTH stimulation test detects pituitary–adrenal dysfunction only when secondary adrenal insufficiency has been chronic (>6 weeks). Traditionally patients are given 250 μg of synthetic ACTH and one hour later a serum cortisol value >20 μg/dl defines a normal response. Even more sensitive is the low dose of ACTH test where patients receive 1 μg of synthetic ACTH and 30 minutes later a serum cortisol >18.6 μg/dl defines a normal response (Abdu et al., 1999).

The CRF test utilizes the ability of ovine CRF of causing a raise in ACTH and cortisol. It is safe but expensive (CRF costs about $300/vial) and it is not yet well standardized.

Suspected secondary hypothyroidism

The physician should measure the free T4 (by T4 radioimmunoassay or free T4 index) and serum TSH concentrations. In secondary hypothyroidism, the free thyroxine is low, while the serum TSH is low or inappropriately normal. A normal TSH level in a patient with secondary hypothyroidism is explained by the fact that TSH produced in patients with pituitary and hypothalamic diseases is less biologically active than normal. In rare cases a TRH stimulation test (showing reduced TSH response to TRH) may help confirming the diagnosis of central hypothyroidism. As opposed to the treatment of primary hypothyrodism, TSH is not a reliable marker in patients with central hypothyroidism. Appropriateness of L-thyroxine replacement therapy must be assessed clinically and by measuring free T4 levels.

Suspected secondary hypogonadism

The gonadal axis can be evaluated by measuring the LH, FSH, and estradiol or testosterone. Secondary deficiency is marked by LH and FSH levels that are inappropriately low relative to low sex steroid levels. Normal LH and FSH levels in a postmenopausal woman who is not on estrogen replacement, rather than the expected elevations, also suggest hypopituitarism, especially in the initial postmenopausal years (Santoro et al., 1998).

Imaging and visual field testing

Imaging of the sella turcica, preferably by MRI, reveals sellar lesions, defines their size, and occasionally suggests the specific tumour type. For example, a craniopharyngioma can often be predicted by calcification (better detected by CT than MRI) and cystic degeneration as well as by its suprasellar position (Naidich & Russell, 1999). Because many people have clinically irrelevant non-secretory pituitary adenomas ('pituitary incidentalomas', see above), pituitary imaging should be deferred until hormonal or neurologic findings confirm that there is reason to suspect a clinically significant sellar lesion.

If imaging studies show a macroadenoma, the patient should have visual field tests to detect possible optic nerve abnormalities. Although routine physical exam can reveal gross defects in peripheral vision, formal ophthalmologic

evaluation is essential to find subtle abnormalities. Furthermore, visual field test is a sensitive indicator of rapid changes in size of a pituitary mass (such as the growth that may occur after hemorrhage of a macroadenoma or the shrinkage of a macroprolactinoma in response to dopaminergic therapy).

Pituitary apoplexy

About 5–20% of pituitary adenomas hemorrhage spontaneously. About one-third of these hemorrhages are recognizable as pituitary apoplexy, a syndrome of sudden, severe headache, neurologic symptoms and signs, and acute adrenal insufficiency (Randeva et al., 1999). Neurologic problems characteristically include vision loss, diplopia, ptosis, and pupil abnormalities. Within hours, lack of ACTH and cortisol production (present in two-thirds of the cases) may cause nausea, vomiting, and hypotension. If necrotic tissue and blood enter the cerebrospinal fluid, the patient may also develop meningismus, hyperpyrexia, and coma. CSF analysis may show pleiocytosis and increased protein concentration. The diagnosis of pituitary apoplexy is often delayed because 60% of the patients presenting with this syndrome have previously undiagnosed pituitary adenomas. Furthermore, symptomatology often can mimic the symptoms of subarachnoid hemorrhage and meningitis; and differentiating these disorders requires imaging of the sella. Although CT scan of the brain reveals a pituitary mass in about 90% of the cases, MRI is superior in diagnosing pituitary hemorrhage. Treatment requires urgent administration of intravenous glucocorticoids to treat acute adrenal insufficiency. Surgical decompression of the sella is required in the presence of reduced vision (symptom of acute chiasmal compression) and altered level of consciousness (symptom of increased intracranial pressure). Extraocular motor palsies do not constitute indication for surgery, as they revert spontaneously in most cases. Some authors believe that early (within a week) surgical decompression reduces the incidence of long-term hypopituitarism (Arafah et al., 1988) and visual deficit (Bills et al., 1993), but no prospective study is available to support these opinions. Acute pituitary failure is often transient, and patient's hormonal function needs to be re-evaluated weeks after the acute event.

The posterior pituitary

The posterior pituitary is a storehouse for the hormones antidiuretic hormone (ADH) (or vasopressin) and oxytocin produced by neurosecretory cells whose bodies are located in the supraoptic and paraventricular nuclei of the hypothalamus. The axonal processes of these neurons extend into the posterior pituitary where they carry the secretory material, containing the hormones and the associated protein neurophysins. A second secretory pathway releases vasopressin in the portal hypophysial system, where this hormone is believed to play a role in the secretion of ACTH from the anterior pituitary.

The secretion of ADH is mainly regulated by osmotic factors. Osmotic receptors are present in the CNS, and can detect very subtle changes in serum osmolarity. The amount of ADH released is proportional to the increase in plasma osmolarity. Increased osmolarity also stimulates ADH gene expression. ADH causes increase in urinary osmolarity. A 2% increase or decrease in serum osmolarity causes maximal concentration ($>$1000 mmol/kg) or maximal dilution ($<$100 mmol/kg) of the urine, respectively. As the onset of thirst occurs at values of plasma osmolarity similar to those of the threshold of ADH release, in a normal subject with access to water plasma osmolarity is tightly regulated.

ADH release is also regulated by baroreceptors located in the left atrium, aortic arch and carotid sinus. Stimulation of these receptors via ascending neural pathways suppresses ADH release, while reduced activity, as seen in hypovolemia or hypotension, causes increase in ADH release. The threshold for activation is much higher than for osmotically stimulated thirst and ADH secretion. Finally, ADH release is negatively regulated by glucocorticoids and stimulated by opioids, nausea and vomiting.

The effects of ADH on the renal collecting ducts (increase in water permeability) is mediated by a specific V2 receptor which activates water channels called aquaporins (Agre, 2000). ADH has a dual effect: a short-term one, triggering the translocation of aquaporin-containing intracellular vesicles to the plasma membrane, and a long-term one, increasing the number of aquaporin-containing vesicles (Knepper et al., 1997). However, it is the inner medullary-concentrating gradient that determines the degree of urine concentration in the presence of maximal ADH activity.

The effect of oxytocin is to cause contraction of the myoepithelial cells in the lactating mammary gland and to stimulate uterine contraction during parturition and expulsion of the placenta. The only two known stimuli for oxytocin secretion are nipple suckling and vaginal distention.

Diabetes insipidus

Disorders of the posterior pituitary lead to syndromes caused by inadequate (diabetes insipidus) or excessive

(SIADH) secretion of ADH. Diabetes insipidus is a polyuric syndrome of excessive excretion of dilute urine, with secondary polydipsia (Bichet, 1995). Diabetes insipidus can result from either inadequate ADH production ('central' or 'neurogenic' diabetes insipidus) or renal disease impairing responsiveness to ADH ('nephrogenic' diabetes insipidus). Central diabetes insipidus develops when the posterior lobe of the pituitary fails to secrete sufficient amount of ADH. In 10–30% of the cases the disorder is idiopathic; the major known causes are hypothalamic tumours, head trauma, central nervous system infiltrative disorders (e.g. sarcoidosis) or infection (e.g. tuberculosis), and transphenoidal surgery. Primary disease of the pituitary gland is rarely the culprit, because the posterior pituitary is merely a storage site for ADH after its synthesis in the hypothalamus. Thus, diabetes insipidus accompanying anterior pituitary dysfunction suggests underlying hypothalamic disease. Rarely, diabetes insipidus can be caused by very large pituitary tumours, pituitary apoplexy or lymphocytic hypophisitis. Rare familial autosomal dominant forms have been described, caused by mutations in the ADH signal peptide or in the neurophysins.
